From a bibliometric perspective, the structure of this paper is as follows: The Methods section outlines the methodological framework, detailing the data and methods, with a focus on sample data for empirical analysis. The Results section includes several subsections: temporal trends in domestic and international publications, visual comparative analysis of authorship, institutional contributions, and research directions across countries, as well as a keyword clustering analysis that categorizes domestic and international infodemic research. The Discussion section identifies key challenges for the future of information governance and new media development, exploring each in depth. Finally, the Conclusion concludes with a summary and proposes directions for future research.

Methods

Study Overview

This study employed bibliometric methods [13], combined with visualization analysis tools, to systematically map and compare the research landscape of the COVID-19 infodemic at the international and Chinese levels. Bibliometrics is a powerful tool for quantitatively revealing the knowledge structure, evolutionary pathways, and research frontiers within a specific research field [3]. In recent years, this methodology has been widely applied to assess and analyze numerous complex and critical research areas, such as pathways to carbon neutrality [14], the application of artificial intelligence in renewable energy [15], the economic impacts of the COVID-19 pandemic [16], and wastewater treatment for emerging contaminants [17], demonstrating its effectiveness and robustness in mapping interdisciplinary knowledge domains. Therefore, this study utilizes this approach to analyze the equally complex and multidimensional global issue of the infodemic.

Using CiteSpace 5.3, this study systematically searched the Web of Science (WOS) and China National Knowledge Infrastructure (CNKI) core databases, with parameters and outcomes detailed in Table 1. The data visualization timeframe was segmented into 1-year intervals for enhanced clarity.

Table . WOS[a] and CNKI[b] data-related parameter settings.

Related parameter settings	WOS	CNKI
Time limit	2016-2025	
Time slice	1 year	
Retrieval time	Jul 20, 2025	
Node type	The author of the article, the issuing organization, the keywords	
Search method	Subject search	
Retrieve content	“Social media” AND “infodemic”	“infodemic”
Literature resources	Core journal	CSSCI[c]+core journal
Output format	Text format	RefWorks format
Valid data	312	1125

[a]WOS: Web of Science.

[b]CNKI: China National Knowledge Infrastructure.

[c]CSSCI: Chinese Social Sciences Citation Index.

In the WOS database, considering that directly using “misinformation” combined with “social media” yielded limited results, and the term “infodemic” more precisely captures the issue of information overload in the context of COVID-19, we employed a Topic Search with the query: TS=(“infodemic” AND “social media”). In the CNKI database, to comprehensively capture relevant literature, we experimented with multiple search strategies. Both subject searches (Subject=“社交媒体” [social media] AND (Subject=“信息疫情” [infodemic] OR Subject=“错误信息” [misinformation])) and keyword searches (Keyword=“社交媒体” [social media] AND (Keyword=“信息疫情” [infodemic] OR Keyword=“错误信息” [misinformation])) returned limited results. Therefore, we focused on the core theme of “infodemic” and conducted a subject search (Subject=“信息疫情” [infodemic]), as it yielded a larger volume of literature that was highly relevant to our research focus.

XSL•FO
RenderX

The initially retrieved records were screened to ensure relevance and compliance with document type requirements. The inclusion criteria were as follows: document types limited to journal articles (articles or reviews); research content directly related to the infodemic in the context of COVID-19; and language restricted to English (WOS) or Chinese (CNKI). The exclusion criteria were as follows: nonacademic publication types such as news reports, conference abstracts, proceedings, book reviews, notices, and letters; duplicate records; and literature with low relevance to the research topic.

After screening, 312 records from WOS and 1125 records from CNKI were included as the final analytical sample. Complete bibliographic records (including titles, authors, affiliations, abstracts, keywords, and references) were exported in plain text format.

Bibliometrics primarily employs statistical and quantitative techniques to analyze scientific literature. These techniques and their results are summarized in Table 1, referring to the publication timeframe as “time slice.” Publication trends in both domestic and international research are depicted to assess the scope and direction of the field’s evolution. This paper also presents a visual map analysis of author and institution collaborations, offering insights into academic exchange and teamwork patterns. The significance of highly cited works as indicators of scholarly focus is acknowledged [18], allowing us to infer primary academic directions. Current hot topics are identified through cluster analysis of keywords from these highly cited works.

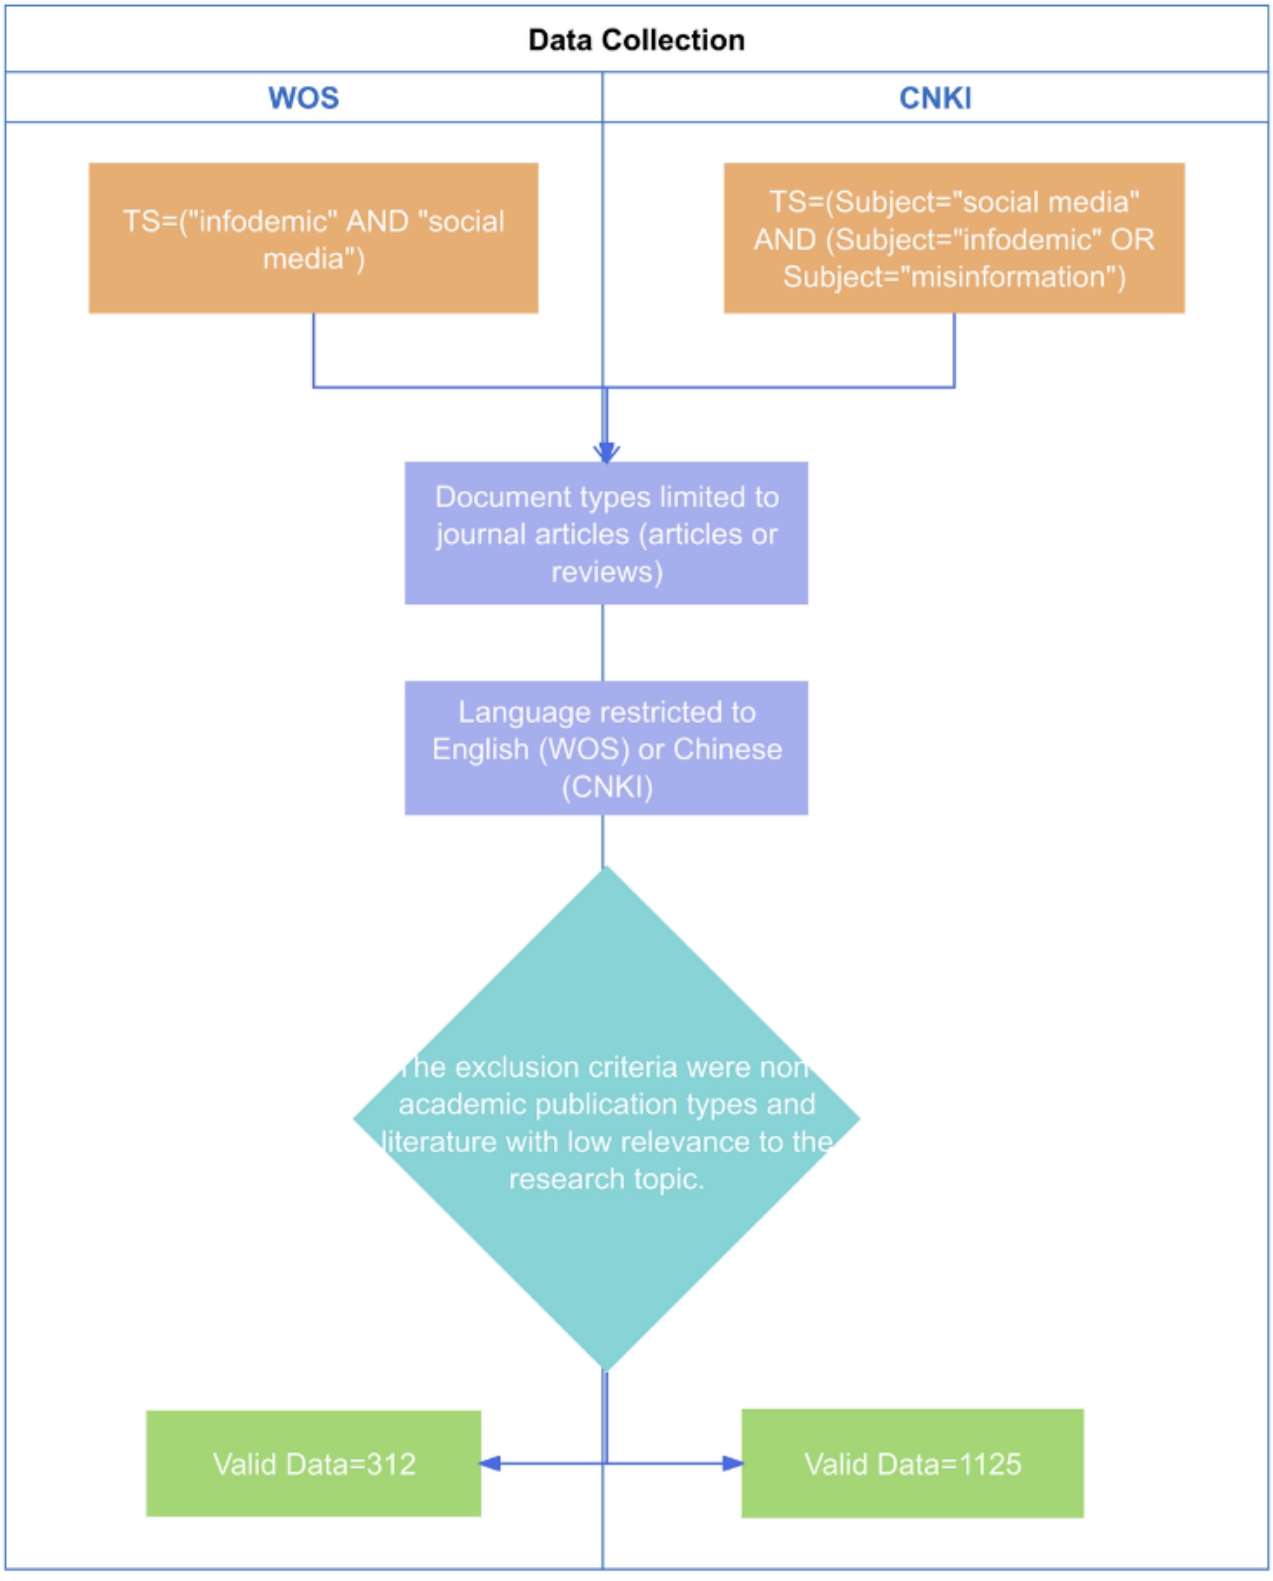
The selection of the WOS Core Collection and the CNKI database was made after careful consideration, aiming to comprehensively cover global research on COVID-19-related infodemics.

WOS, as an internationally recognized premier citation database, indexes high-impact academic literature across multiple disciplines, providing authoritative coverage of international publications.

CNKI, on the other hand, is the most comprehensive and authoritative database for Chinese academic journals, books, dissertations, and conference proceedings, making it indispensable for capturing the substantial body of domestic research on this topic.

Ethical Considerations

Ethical oversight and approval for this study were provided by the School of Urban Construction at Hebei Normal University of Science and Technology, as the university does not have a dedicated ethics committee for humanities and social sciences research. All procedures were conducted in accordance with the Declaration of Helsinki. Participant data were anonymized and stored securely to protect confidentiality. No compensation was provided.



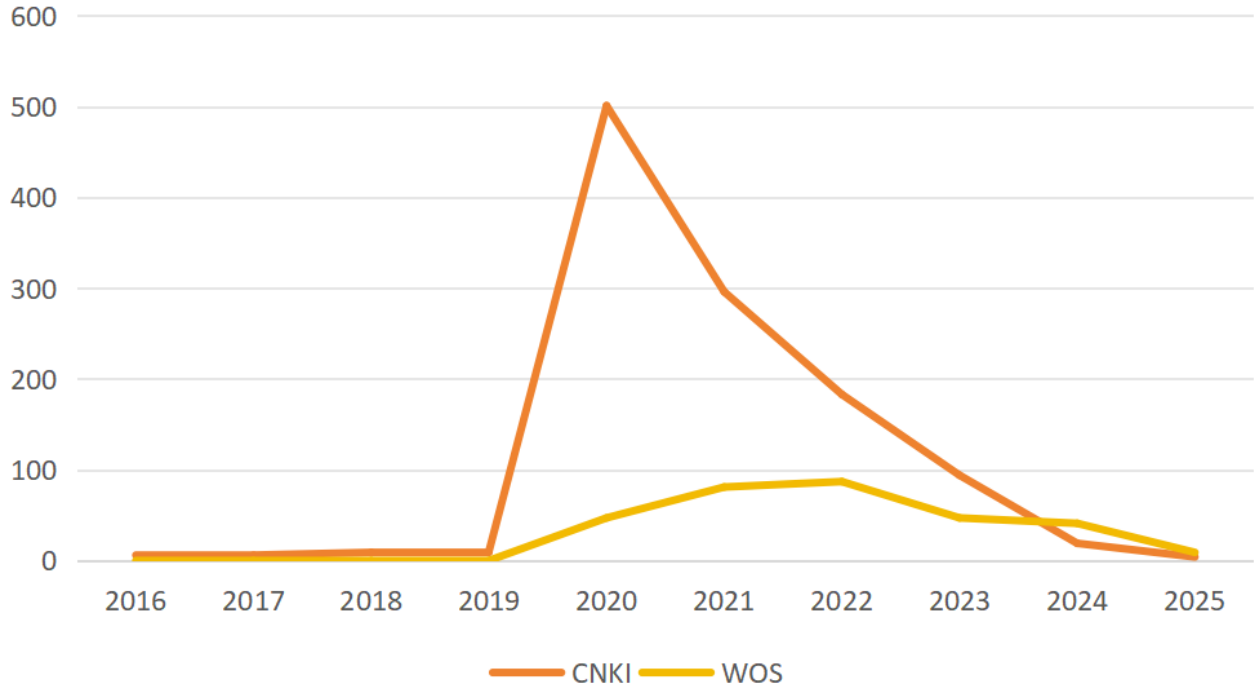
Results

Studies Included

To illustrate the literature identification and screening process, we created a PRISMA-style flow diagram (Figure 1).

XSL•FO
RenderX

Figure 1. Flowchart of literature screening in WOS and CNKI databases. CNKI: China National Knowledge Infrastructure; WOS: Web of Science.



The Time Trend Analysis

The volume of publications over time serves as an intuitive indicator of research activity and interest in a field, aiding in forecasting future research trajectories. Analysis of data up to July 20, 2025, reveals 1125 domestic publications and 312 international publications. Figure 2 illustrates a spike in both domestic and international research during 2020 and 2021, followed by a decline, with international publications surpassing domestic output as of July 2025.

XSL•FO
RenderX

Figure 2. Comparison chart of domestic and international research publications on information epidemics from 2016 to 2025. CNKI: China National Knowledge Infrastructure; WOS: Web of Science.

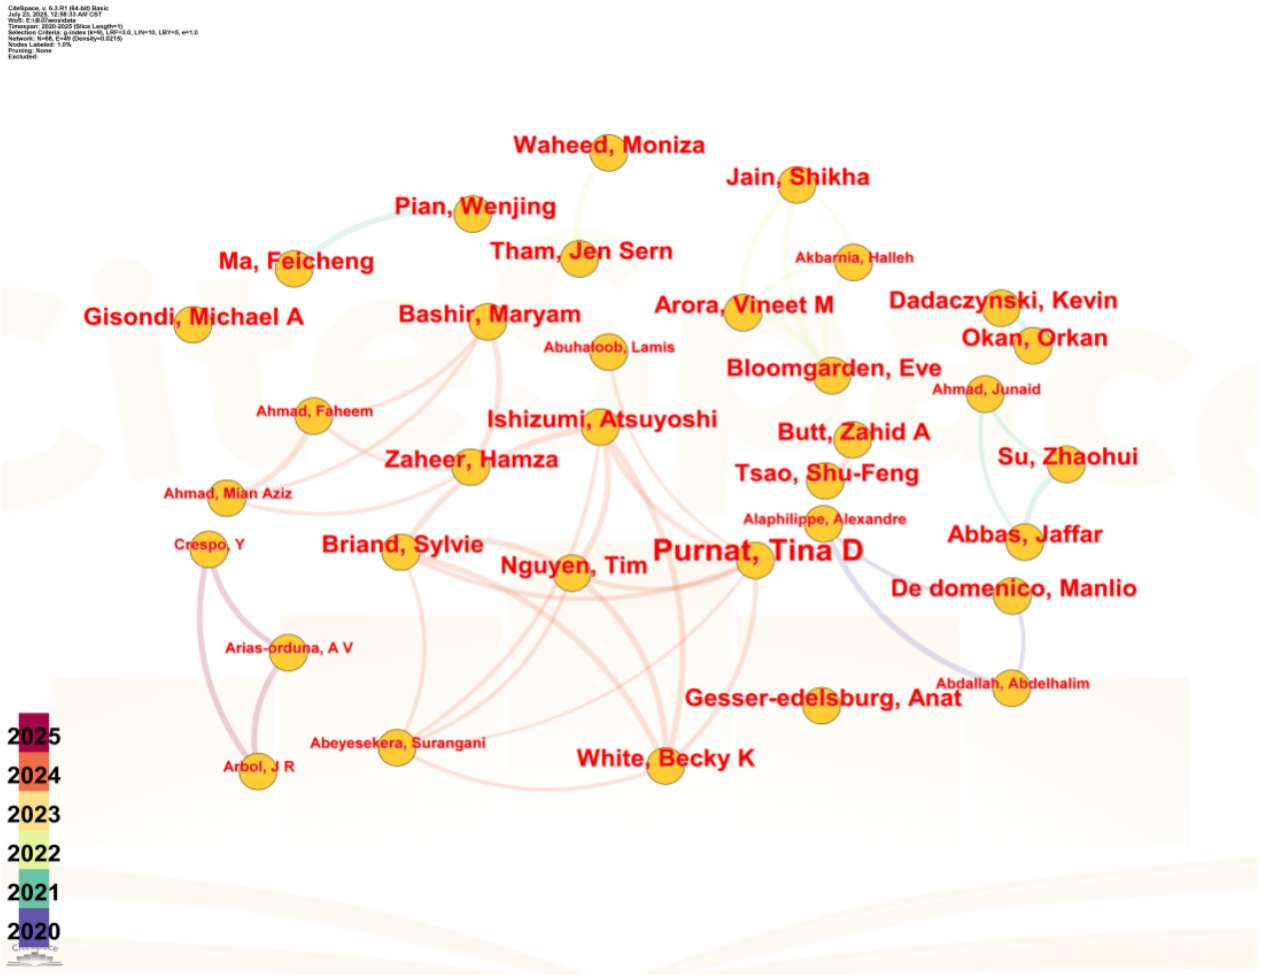
The term "infodemic" emerged in response to the misinformation crisis linked to the pandemic, starting in December 2019 [19]. Initially, this concept received limited academic attention, representing a nascent challenge with unclear societal repercussions [20].

The sustained impacts of infodemics have kept scholarly interest alive internationally, as researchers tackle the complex societal issues they create. This ongoing interest is reflected in the steady volume of international research in 2021, characterized by an interdisciplinary approach focused on developing models for infodemic transmission and algorithms for information management [21]. Such cross-disciplinary synergy and technological innovation likely contributed to the growth of international publications.

In 2020, China experienced a turning point as domestic outbreaks underscored the detrimental effects of infodemics. The urgency to combat misinformation spurred a surge in Chinese research, driven by the need for policy development and effective mitigation strategies, resulting in a significant increase in publications that later tapered off with the successful containment of the epidemic [22].

Analysis of Author Networks

This section analyzes authorship patterns in the field, examining both domestic and international author networks while identifying prolific authors based on their research output. The focus is on authors with multiple publications, exploring themes investigated by collaborative teams through key articles.



Author networks are visually represented by nodes and connections, where each node represents an individual author, and its size indicates the number of publications. Lines between nodes signify collaborative links, with denser lines reflecting more frequent coauthorship. This network analysis provides insights into the level of cooperation and identifies central figures within the research community.

Global Author Analysis

This subsection extends the authorship analysis to the international landscape, employing network visualizations to elucidate the collaborative dynamics among global researchers (Figure 3).

XSL•FO
RenderX

Figure 3. Global author collaboration network for information epidemic research.

The optimized author cooperation network is depicted in Figure 3, generated using CiteSpace software. CiteSpace was developed by Dr. Chaomei Chen, a professor at the College of Computing and Informatics, Drexel University in the United States. The detailed configuration and data information for this part of the CiteSpace analysis are summarized in Table 2, covering key information such as software version and time slice settings. The network consists of 68 nodes (n=68), signifying the involvement of 68 authors, and exhibits a connection density of 0.0215. The sparsity of the connections within the network suggests a low level of collaboration among international authors. Table 3 details articles that have emerged from three distinct collaborative clusters within the network. These articles address a range of topics, including a cross-sectoral information management framework for pandemic response [23], recommendations for social media companies to combat infodemics [24], and novel paradigms for public health communication [25].

Albrecht SS et al [24]	Lessons learned from the dear pandemic, a social media-based science communication project targeting the COVID-19 infodemic	2022	0

Further analysis of international authors' publication patterns reveals that several have published two or more papers on the topic. Notably, De Domenico emerged as the most prolific contributor with 4 publications, while 23 other researchers (representing 34% [23/68] of all authors) produced more than two papers each. In terms of collaborative work, the most-cited single paper received 93 citations, demonstrating substantial academic attention and recognition within this research field. This citation impact strongly reflects the high scholarly value attributed to these studies.

Domestic Author Analysis

Figure 4 shows the optimized author collaboration network diagram, Table 4 shows the articles written by authors, and the detailed data information from this part of the CiteSpace analysis is summarized in Table 5. There are 168 nodes displayed in the graph (n=168), indicating that 168 people are renting the authors, and the connection density is 0.0153. Small nodes and low density indicate that the author has fewer papers and a low level of cooperation. The map shows only two more complex cooperative networks, led by Wang and Chen [26]. Wang's group elaborated expert perspectives on addressing infodemics, informing policymaking and platform information dissemination [27]. Li and colleagues probed characteristics and dissemination of scientific information to devise specific countermeasures [28]. Overall, 51 authors have published 2 or more papers, accounting for 30% (51/168) of the total number of authors analyzed. The highest number of citations for a collaborative paper is 3.

[c]LBY: leading board year.

Identifying core authors is a process that considers both the quantity of output (importance) and the extent of influence (citation counts). The analysis of both domestic and international authors reveals that overall author productivity is modest, with no individuals exhibiting exceptionally high publication rates. Furthermore, the citation rates for the literature are not optimal, suggesting that research into infodemics is still in its formative stages. There is a clear opportunity for researchers to engage in more diverse collaborative efforts, which could significantly enhance the quality and impact of their work.

Core author groups are essential for carrying out in-depth investigations into complex issues, fostering sustained and comprehensive research efforts. Although there are nascent collaborative teams both domestically and internationally, the metrics of importance and influence indicate potential for theoretical expansion and development. This underscores the need for increased interdisciplinary collaboration and more robust research networks to advance the field.

Institution Analysis

This section evaluates the contribution of various institutions to the field by examining the volume of publications and the extent of interinstitutional collaboration. The analysis of the institutional co-occurrence network, represented through nodes and connecting lines, offers insights into the depth of research on the topic and the collaborative intensity among institutions.

Foreign Institution Analysis

The assessment of international institutional engagement is visualized in Figure 5, which illustrates a network comprising 81 entities. The detailed data information of CiteSpace analysis in this section is presented in Table 6, including key parameters such as time span and selection criteria, providing support for the reliability of network analysis. The network exhibits a slightly higher level of connectivity (density=0.0148) compared to domestic institutions, indicating a modest degree of international collaboration. Predominantly universities, these foreign institutions demonstrate greater collaborative activity than their domestic counterparts, though there is still considerable room for deepening these cooperative relationships.

Wuhan University emerges as the most prolific contributor with six published articles, having established collaborative links with Fudan University and Fuzhou University, each on two occasions. Despite these partnerships, the depth of international cooperation, as reflected by the overall network density, remains limited.

Further analysis of the data from institutions publishing international papers reveals that among those publishing four or more international papers, Wuhan University stands out with six papers. Its research focuses on the characteristics, transmission mechanisms, and network information flow regulation strategies of information epidemics. Notably, one of the university's papers has been cited seven times. Through media type analysis, it quantifies the spatial correlation between information epidemics and actual epidemics, finding that mobile media may increase the transmission risk coefficient. Other major institutions include Oxford University, Hong Kong Polytechnic University, Bruno Kessler Foundation, and the University of Pennsylvania, all of which have published four significant research outcomes.

XSL•FO
RenderX

Domestic Institution Analysis

The visualization of domestic institutions indicates 209 contributing entities (n=209), yet the network's density is 0.0028, signifying no discernible connections between them. The modest number of publications from each institution results in smaller nodes and an absence of a visible network, suggesting a nascent stage of institutional collaboration in this research area.

Among domestic institutions, 76 have published two or more papers, primarily universities and research institutions. As the core force in academic research, these institutions continue to explore this emerging social issue; from a geographical perspective, they are widely distributed across China, reflecting the widespread attention of the domestic academic community to this field.

The School of Information Management at Nanjing University has published 10 papers, making it the university with the highest number of published papers in China. The Communication University of China stands out with seven publications, underscoring its significant role in examining information dissemination and governance. One notable publication from this institution delves into media users' characteristics, cognitive assessments, and interactions, providing theoretical insights for governance.

The fact that 133 institutions have contributed only a single paper each highlights a lack of sustained research efforts across most entities. The absence of connectivity within the network (density=0) indicates that research efforts are isolated, with institutions working independently rather than collaboratively. This isolation suggests potential for greater cooperation, which could foster more comprehensive studies and a deeper understanding of the issues at hand.

In conclusion, while the foundations for international institutional cooperation are in place, the impact and breadth of this collaborative effort require enhancement. It is important to recognize the multidisciplinary nature of infodemic research, which intersects with journalism, communication, computer science, public management, and other fields. Sustained and strategic collaboration among institutions is pivotal for in-depth exploration of the topic and for elevating the quality of research outputs. Therefore, there is a clear need to fortify the collaborative ties between research institutions and to facilitate interdisciplinary communication to advance the study of information epidemics effectively.

Highly Cited Literature Analysis

The frequency of citations serves as a barometer for scholarly impact, with highly cited papers often indicative of their influence and prominence within the academic community. An in-depth examination of citations and keywords from these seminal works provides insight into the prevailing research themes and potential future directions.

Foreign Highly Cited Literature Analysis

Table 7 contrasts the domestic citation landscape with the international scene, which demonstrates a broader academic reach. Keywords such as "COVID-19," "social media," "mental health," "depression," "public attention," and "communication content" dominate these papers, reflecting concerns over the spread of misinformation on social media during the pandemic. The synthesis of keywords from these influential international articles reveals focal areas of global concern: the mental health impact of the infodemic [32], the development of infodemic response strategies and various facets of information governance, including thematic communication and evolution [33,34], as well as monitoring and evaluative frameworks [35,36].

XSL•FO
RenderX

Table . Top 5% citation frequency in WOS.[a]

Number	Title	Citation frequency	Keywords
1	Mental health problems and social media exposure during COVID-19 outbreak [6]	595	COVID-19; mental health; social media
2	The COVID-19 social media infodemic [32]	274	epidemiology; computer science; information theory; and computation
3	COVID-19–related infodemic and its impact on public health: a global social media analysis [34]	192	COVID-19; infodemic; impact on public health
4	Mental health, risk factors, and social media use during the COVID-19 epidemic and Cordon Sanitaire among the community and health professionals in Wuhan, China: cross-sectional survey [37]	181	COVID-19; social media; population mental health; depression
5	Coronavirus (COVID-19) "infodemic" and emerging issues through a data lens: the case of China [38]	178	COVID-19; infodemic; humanitarian emergency
6	The impact of social media on panic during the COVID-19 pandemic in Iraqi Kurdistan: online questionnaire study [25]	175	social media; COVID-19; infodemic; mental health
7	COVID-19 infodemic; more retweets for science-based information on coronavirus than for false information [35]	151	communicative content analysis; infodemic; social media analytics
8	Framework for managing the COVID-19 infodemic: methods and results of an online, crowdsourced WHO technical consultation [19]	94	COVID-19; infodemic; knowledge translation; message amplification; misinformation; risk communication
9	Chinese public attention to the COVID-19 epidemic on social media: observational descriptive study [39]	94	public attention; social media; public health emergency
10	Assessing the risks of “infodemics” in response to COVID-19 epidemics [33]	92	COVID-19; infodemic; risk

[a]WOS: Web of Science.

In summary, while the domestic articles are gaining traction, international literature, with its broader citation reach, highlights a global engagement with the intricate challenges posed by the infodemic. This underscores the necessity for a concerted, multidisciplinary approach to understand and mitigate the effects of misinformation, especially in the context of global health crises.

Foreign Highly Cited Literature Analysis

As of the data collection cutoff, domestic literature exhibits a relatively modest citation footprint. However, it is important to acknowledge the potential for a rise in citation frequency for more recent publications. Table 8 lists the three most cited domestic articles, with citation counts of 49, 45, and 35, respectively. A keyword analysis of these leading papers reveals primary research themes among the highly cited domestic literature: infodemic response strategies, information governance mechanisms, and patterns of information dissemination.

Keywords Clustering Analysis

Keyword clustering is a methodological approach that groups semantically related keywords to identify dominant themes within a body of literature. This analytical technique can provide insights into the central topics of research by examining the centrality, frequency, and co-occurrence of keywords. In this section, the software CiteSpace is utilized to conduct a clustering analysis of the literature, with the aim of highlighting distinctions between domestic and international research foci.

Foreign Keywords Clustering Analysis

The data information regarding the keyword clustering analysis of foreign literature in this section is detailed in Table 9. To facilitate a clearer representation, the “Convex Hull: Show/Hide” feature in CiteSpace can be employed to display the clustering outcomes as distinct colored shapes. The modularity value Q and the mean silhouette value S are recognized as key indices for evaluating the quality of clustering. A Q value greater than 0.3 is indicative of a well-defined structure characterized by high internal consistency and relatedness, while an S value approaching 1 suggests an optimal clustering scale. Internationally, the Q value is 0.3842, S value is 0.7323, and the mean of Q and S is 0.5583, as shown in Figure 6. The clustering results for both domestic and international literature denote clear demarcations and appropriate scales, affirming the reliability of the cluster analysis.

Figure 7. Thematic hotspots distribution in China's infodemic research.

Further, to delve into the specifics of the keyword clusters, this section examines the predominant keywords within each cluster. Clusters are assigned serial numbers, with smaller numbers indicating a larger scale and a higher number of keywords. CiteSpace analysis of the CNKI and WOS databases yielded 9 and 8 keyword clusters, respectively. Based on clustering intensity, the top six clusters were identified for further scrutiny. The "Cluster Explorer" function in CiteSpace calculates the intensity of topics, and the high-frequency keywords within each cluster are summarized to capture the essence of the research themes, as indicated in Table 11.

XSL•FO
RenderX

Table . Classification and intensity of foreign and domestic literature themes.

No	WOS[a] topics' high frequency words	Intensity of themes	WOS topics	CNKI[b] topics	Intensity of themes	CNKI topics' high frequency words
0	Social media; Twitter; behavior; attitude; online	0.757	News	Information literacy	0.924	Epidemic prevention and control; emergency management; information technology; integrated media
1	Information; communication; Facebook; impact; knowledge	0.746	Fake news detection	Information spreading	0.978	Social media; opinion leaders; risk communication; response strategies
2	Health; adult; care; virus; support	0.812	Machine learning	Message protection	0.835	COVID-19; mainstream media; information disclosure; personal information
3	Media; misinformation; risk; quality	0.86	Social network	Infodemic	0.858	Information overload; information explosion; political epidemic; public opinion guide
4	Fake news; diffusion; science; anger	0.711	Mortality salience	Major epidemic disease	0.785	Interest measurement; proportionality

[a]WOS: Web of Science.

[b]CNKI: China National Knowledge Infrastructure.

The keywords encapsulate the essence of the articles' content and mirror the research directions. Through the keywords clustering analysis, this study categorizes the research domains of the infodemic both domestically and internationally into six themes: (1) Domestic clusters #1 and #3 and international clusters #0 and #3 are focused on the dissemination of information. (2) Domestic clusters #0 and #4 are primarily concerned with utilizing information for COVID-19 control. (3) Domestic clusters #4 and #5 underscore the importance of information governance. (4) Domestic cluster #2 is dedicated to the protection of information. (5) International clusters #1 and #2 are centered on machine learning and algorithm development. (6) International clusters #4 and #5 highlight the need for clinical attention to mental health issues stemming from the epidemic, advocating for prompt and effective psychological interventions. The subsequent sections will provide a detailed analysis of these identified research directions.

Information Spreading

The rise of the internet and digital technology has transformed information dissemination, necessitating a reevaluation of distribution methods in contemporary society. The interaction between traditional and social media has become central to this transformation, with researchers suggesting that they can complement each other. Integrating new media technologies with professional journalism principles creates a synergistic opportunity for enhancing information spread.

However, the complexity and unpredictability of online communication, along with public engagement with new media, contribute significantly to the proliferation of the "information plague." In this context, it is vital that the social responsibilities of social media platforms are not overshadowed by their technological capabilities.

To effectively regulate information spread, it is crucial to monitor and address the dissemination of false information while understanding its evolving patterns. Research indicates that trends in misinformation often align with the trajectory of the pandemic, with themes developing in tandem. The role of influential figures and institutions in propagating misinformation is significant; for instance, former President Donald Trump played a key role in amplifying COVID-19 vaccine conspiracy theories on Twitter [49,50]. This underscores the need for new methods to regulate and standardize information dissemination.

Furthermore, inadequate evaluation and oversight of information releases have contributed to misinformation spread. Initiatives like WeChat's rumor evaluation system have effectively curbed certain false narratives [21]. These examples demonstrate the potential for systematic approaches to mitigate misinformation risks in the digital age.

XSL•FO
RenderX

Using Information to Control COVID-19

During the COVID-19 pandemic, information has emerged as a critical tool for maintaining social stability and managing public health emergencies. A nation's ability to respond effectively to such crises depends on its governance and strategic information dissemination. Empirical evidence indicates a positive correlation between public trust in information and adherence to preventive measures, highlighting the importance of leveraging information to control the virus's spread.

In response, some scholars have proposed an innovative model for information communication designed to enhance interaction among stakeholders. This model could improve public policy quality and reduce resistance during implementation [23,51], while also boosting public confidence in official agencies and media [52].

Research shows that online information resources are crucial for governments to rapidly assess public health needs and refine health interventions [53]. Practical experiences demonstrate that managing the COVID-19 crisis requires coordinated efforts among diverse stakeholders. Information resources play a pivotal role in bridging departmental gaps, fostering consensus, and establishing comprehensive response mechanisms, thereby expediting epidemic prevention and control. The mainstream media, particularly official outlets, is critical for promptly disseminating accurate information, shaping public opinion, and fostering a unified societal response.

These findings illustrate that information has become an invaluable resource for governmental governance during the pandemic.

While countries have adopted various strategies to combat COVID-19, the universal objective remains effective control guided by humanitarian principles. The government's role is central to navigating public crises, and the misuse of information for political gain undermines global efforts against the epidemic. The politicization of the pandemic, as evidenced by contentious social media discussions on issues like racism, can detract from a unified response. Therefore, adherence to scientific principles, judicious policymaking, and harmonizing government and societal efforts are essential to prevent the politicization of the pandemic response.

Information Governance

The concept of information governance has gained heightened significance following the COVID-19 pandemic, particularly regarding the regulation of information dissemination and the role of social media. Misinformation has demonstrated a lasting and detrimental impact on social trust, often surpassing the effects of the virus itself, which underscores the urgent need for stringent governance by authorities. A key governance strategy is the responsibility of official media to swiftly provide accurate news, thus countering the spread of falsehoods.

At the heart of information governance is oversight. Researchers assert that timely dissemination of factual information can significantly mitigate information asymmetry, necessitating a greater sense of responsibility among information publishers and a reinforced commitment to ethical and legal standards. Misinformation not only incites public panic and erodes societal trust but also challenges the rapidly evolving social media landscape. Addressing these challenges requires targeted legislation to regulate information publication on social media platforms.

The improvement of the institutional framework serves as the cornerstone for the systematic and standardized operation of information governance. Given the complexity and uncertainty in the current information environment, there is an urgent need to establish a regulatory policy and standard system that is structured, clear in terms of responsibilities, and dynamically adjustable. First, it is imperative to strengthen top-level design and formulate forward-looking and inclusive national or regional information governance strategies. Second, targeted and highly operable special regulations should be introduced to provide a solid legal basis for governance practices. Simultaneously, promoting cross-departmental and cross-disciplinary policy coordination is crucial. It is essential to break down information barriers and establish unified standards for information quality assessment, content review norms, and crisis response plans to ensure consistency and effectiveness of governance actions. Lastly, the formulation and promotion of standards are indispensable. It is advisable to encourage the development and adoption of internationally and domestically recognized technical and management standards for information security, privacy protection, data interoperability, etc, providing a unified scale and a basis for mutual trust for the development and application of information governance tools.

The iterative upgrading of technological tools is a key driving force for enhancing the efficiency of information governance. In the face of the explosive growth and complex evolution of information epidemics, it is imperative to fully tap into and integrate the potential of cutting-edge technologies. At the information recognition level, we should deepen the application of artificial intelligence and natural language processing technologies, develop multimodal (text, image, audio, and video) content understanding capabilities, and enhance the efficiency of automated and precise identification of false, misleading, and harmful content in massive amounts of information, with particular attention paid to the analysis of implicit intentions and emotional tendencies at the semantic deep level.

The experience of managing the COVID-19 crisis has underscored the necessity of robust information governance for governments. Recognizing it as a systematic endeavor, establishing a professional intelligence team is essential. Relevant departments must align information science development with practical needs, implement a national security strategy informed by big data analytics, and encourage interdisciplinary collaboration supported by technological advancements. In this process, it is crucial to improve the institutional framework and technical support for information governance. By clarifying the rights and responsibilities of each subject and optimizing regulatory technical tools, we can ensure the authenticity and security of information dissemination, providing a standardized and orderly environment for information exchange among different cultures, countries, and civilizations around the world.

XSL•FO
RenderX

Information Protection

The use of big data technologies for epidemic prevention—such as disease monitoring and population flow management—has become widespread. However, the associated risks of personal information exposure and data breaches necessitate a robust information protection strategy.

To mitigate these vulnerabilities, a new systemic approach to prevent information leakage is essential. The rise of digital technologies calls for a reevaluation of traditional ethics and regulations, particularly in balancing individual rights with societal needs and harmonizing social governance with privacy protection. Research indicates that an institutional framework allowing extensive data collection alongside stringent usage controls (a "wide entry and strict exit" model) can help reconcile public and private interests.

Furthermore, prioritizing the development and implementation of technologies to prevent unauthorized data access is critical. Creating specialized storage platforms for sensitive information will aid in developing standards and protocols for data usage. Additionally, enhancing public awareness of personal information security and clarifying the responsibilities of data collectors are urgent.

In summary, comprehensive protection of personal information relies on sustained engagement from multiple stakeholders. This involves establishing systematic data collection and storage, rigorously assessing data usage, and implementing traceability measures to ensure accountability.

Machine Learning

The divergence in machine learning application between domestic and international research is notable, particularly in the realm of information governance. Global studies extend beyond the technical manipulation of social media, delving into the intricate layers of information management.

Machine learning emerges as a critical tool where traditional information technologies falter, especially in curtailing the proliferation of misinformation [54]. The intersection of big data and machine learning is a breeding ground for innovation, with algorithms spearheading theoretical advancements. Empirical evidence underscores the efficacy of techniques like the Synthetic Minority Over-sampling Technique and Classifier Vote Ensemble in identifying and curbing the spread of false narratives [55].

In the context of Twitter, Latent Dirichlet Allocation models have been instrumental in sifting through data to extract prevalent topics and sentiments, thereby mitigating the adverse effects of negative discourse on COVID-19 management. Elhadad and Gebali [56] have harnessed machine learning to create an integrated information management system on Twitter, bolstering data protection and reducing misinformation. Similarly, Lu [57] developed a health belief model to quantify health information, promoting the dissemination of constructive content to users. Domestic research has conducted algorithm adaptation based on local data characteristics in the application of such technologies, such as optimizing text classification models for Chinese semantic complexity, analyzing short video content for rumor identification during the pandemic, and accurately disseminating health knowledge on mainstream social platforms based on user personas.

Platforms like WhatsApp have been leveraged by entities such as the WHO and governmental bodies to disseminate verified information rapidly across demographics, capturing the pulse of public sentiment [58]. Machine learning's capacity to assimilate societal feedback epitomizes the concept of 'social listening,' refining policy relevance and efficacy based on public input, thus facilitating smoother policy implementation [59]. The Chinese government utilizes a multimodal collaborative governance system, including the China Internet Joint Rumor Refutation Platform, intelligent public opinion monitoring system, etc, combined with a three-tier public opinion response mechanism, to improve the efficiency of information content governance.

Overall, global research is highly convergent in terms of underlying machine learning technologies, but application paradigms vary due to social governance structures and data ecosystems. International research focuses on algorithmic innovation for open platforms, while domestic practices emphasize multisystem collaborative governance. These investigative efforts converge on the objective of harnessing machine learning to streamline information dissemination, with a strong underpinning in computer science, all while aiming to alleviate the detrimental effects of the pandemic and accelerate the practical testing and iterative optimization of these technologies during the pandemic.

Psychological Intervention

The domain of psychological intervention distinguishes itself in the dichotomy of domestic and international research orientations. Prompt psychological interventions have emerged as innovative strategies for supporting COVID-19 patients' mental health. The "infodemic" associated with the pandemic often triggers mental health challenges like anxiety and depression [60]. Evidence indicates that youths with extensive media consumption are particularly susceptible to psychological distress, including anxiety. Moreover, the barrage of negative information prevalent on social media platforms can disrupt public sleep patterns, adversely affecting patient recovery [61].

Research reveals that under similar stressors, psychological resilience tends to be more robust in males. Timely psychological interventions, akin to mental "inoculations," have proven effective in bolstering individuals' resilience to negative information. It has also been observed that psychological responses vary across different stages of an information epidemic; hence, interventions should be tailored to these specific stages to optimize mental health outcomes [62]. This insight advocates for a clinical approach that integrates psychological support with traditional medical treatments, emphasizing the necessity for regulatory bodies to monitor and manage media narratives [63]. These findings underscore the practical importance of research in information dissemination and governance.

Furthermore, machine learning can play a pivotal role in information-based psychological interventions. Enhancing the

XSL•FO
RenderX

credibility and authenticity of online information through machine learning algorithms has the potential to decrease morbidity [64]. A healthy social network platform developed connects patients with medical professionals, leveraging intelligent algorithms to amplify beneficial health information and counteract negative influences. Addressing societal psychological challenges requires a comprehensive approach that merges epidemic management with the establishment of dedicated psychological organizations to undertake community mental health initiatives [65]. Notably, the research on psychological interventions increasingly intersects with the themes of machine learning, information dissemination, and governance.

Discussion

Overview

In light of the pervasive information challenges posed by the global novel coronavirus pneumonia pandemic, this paper posits five critical challenges for the future of information governance and the development of new media. These challenges underscore the need for robust, adaptive frameworks capable of navigating the complexities of information dissemination and management in an era defined by rapid technological advancement and global interconnectedness. This study systematically captures the multiagent interaction characteristics of the information epidemic from multiple perspectives and simultaneously responds to the WHO's call for "interdisciplinary collaboration gaps," combining domestic practical experience to deepen the understanding of governance complexity. The insights garnered from this study not only contribute to academic discourse but also serve as a guiding beacon for policymakers, media professionals, and researchers striving to fortify societal resilience against the pernicious effects of misinformation in the digital age.

Enhancing Collaborative Networks Among Scholars and Institutions

The study's findings highlight a significant gap in knowledge exchange among domestic and international scholars and institutions, hindering effective responses to emerging challenges. The absence of a prominent cohort of authors and institutions in this discourse underscores the need for a more unified and collaborative approach to address the information epidemic. Publication trends indicate a decline in academic output following an initial surge, suggesting that while research on the information epidemic spans six main domains, it remains in an embryonic stage, with considerable potential for further exploration.

To advance the field, scholars must move beyond isolated research practices and engage in active collaboration with peers. Establishing research networks and sustainable communication channels will facilitate a more comprehensive exploration of complex issues, foster the development of authoritative research leaders and teams, and generate practical solutions for societal advancement and governance. Academic institutions need to step out of the theoretical ivory tower and pay attention to real-world issues in practice; enterprises should open up their technological resources to participate in public issue research; and the government needs to build a neutral collaboration platform. This collaboration is not simply a matter of resource accumulation but rather the formation of a governance synergy through complementary knowledge. In particular, in the context of rapid changes in the information ecosystem, a flexible network structure is more adaptable to demand than a fixed mechanism.

Given the interdisciplinary nature of the infodemic, which intersects journalism, communication, computer science, and public governance, there is an urgent need to create cross-disciplinary communication frameworks that transcend temporal and spatial barriers. Research entities should organize regular academic forums to encourage interaction among experts from various fields. Additionally, online platforms can play a crucial role in achieving consensus, shaping actionable and educational methodologies, and enhancing the quality of scholarly contributions.

Fostering Expert Teams for Advanced Media Intelligence

The analysis emphasizes the critical importance of information governance and strategic information utilization in mitigating COVID-19, identifying these as key research areas. Post-pandemic reflections underscore the need to assemble skilled professional teams to effectively manage the information epidemic and enhance information management systems. Despite progress in forming domestic intelligence teams, a significant gap remains between big data analysis and its practical application. The efficiency bottleneck of information governance largely stems from the capability gap among professionals: traditional media practitioners lack the ability to apply technological tools, while technical experts often overlook the social impact of information dissemination. This gap leads to a disconnect between technological innovation and actual governance needs. The rapid evolution of digital technologies necessitates a reevaluation of talent development programs, innovative cross-disciplinary training models, and alignment of educational outcomes with societal needs.

Higher education institutions should restructure their curriculum systems by breaking down disciplinary barriers. For instance, they are well-positioned to cultivate multidisciplinary talent by adopting "journalism+ X" approaches that enhance journalists' skills in data acquisition, processing, analytics, and digital media operations. Educational policymakers should implement a dual-track system that fosters both specialized and technologically proficient professionals. Integrating computer science with social sciences, such as journalism, can enrich curricula and enhance students' practical experience.

For industry professionals, comprehensive vocational training through expert-led workshops, digital courses, and certification programs is essential to equip the workforce with the skills necessary for managing intelligent media technologies and operations.

Simultaneously, news media must uphold their fundamental societal role. Media professionals should remain vigilant to the challenges of the digital landscape and strive to deepen their

XSL•FO
RenderX

humanitarian insights. News content creation must reflect an understanding of diverse cultures and foster global citizenship. With the diversification of communication channels and social platforms, there is an urgent need for a future workforce skilled in advanced media technologies and operational competencies, capable of engaging international audiences while maintaining the humanistic ethos central to journalism.

Refining the Public Emergency Information Management System and Bolstering Personal Data Protection

The core contradiction faced by information management in public emergencies is the balance between efficient information flow and personal privacy protection. Advancing a public emergency information management system requires a dual focus on efficient information gathering and stringent protection of that information. The system must enhance response capabilities to information risks, supported by technological tools, standardized security measures, and privacy protections. Employing machine learning and algorithmic techniques is crucial for data assimilation, processing, and analysis, enabling informed engagement in societal governance. Tools such as health codes and information flow tracking have proven instrumental in managing the COVID-19 crisis.

In the digital age, intelligence analysis has shifted toward a big data-centric approach, emphasizing the need to understand the interactions between online and offline elements within information systems. This involves harmonizing online theoretical advancements with offline practical applications. Additionally, machine learning and algorithms can provide insights into the psychological responses of different social demographics during emergencies, enhancing intelligent management capabilities.

Establishing standardized information protocols is foundational to an effective management system. For example, China's initiative to develop a health information standard framework could serve as a model for creating standardized digital technology protocols, data security measures, and benchmarks across various sectors.

To improve the digital emergency information system, it is essential to address the overcollection of personal data and strengthen personal information protection [66]. Technological advancements should elevate information security protocols, including routine data anonymization, to prevent unauthorized access and the development of encryption and real-time monitoring systems.

At the legislative level, robust laws are critical for information security. Clearly defining the boundaries of information collection, analysis, and use while adhering to ethical and legal principles is vital. Regulatory authorities should implement safety protocols to ensure secure information practices.

From the public's perspective, raising awareness about information security is paramount. Individuals should understand their legal rights and engage with digital services with vigilance and informed caution.

Enhancing Public Information Literacy and Psychological Resilience

The spread of the information epidemic is partly attributed to the public's limited skills in observing, analyzing, and evaluating information. Active public participation in information governance is crucial to addressing this challenge. In an information-overloaded environment, the public is prone to experiencing "information anxiety" and may even reduce their trust in authoritative information. Evidence suggests that areas with lower reliance on social networks and reduced trust in online information have experienced lower mortality rates, indicating that the psychological effects of the information epidemic may be more difficult to manage than the pandemic itself.

To enhance the public's information discernment capabilities, a multifaceted and ongoing approach is essential. Educational initiatives in science can provide timely and factual information about current issues, establishing a robust mechanism for public awareness. This can be achieved through traditional seminars and online platforms, utilizing short videos, social media, and interactive app-based Q&A sessions to create an engaging information dissemination network.

Equally important is the development of critical thinking skills, enhanced information literacy, and a judicious approach to consuming information. These steps are vital for mitigating the negative impacts of the information epidemic on individuals and society.

Enhancing Media Accountability and Directing Public Discourse Positively

An effective information dissemination environment is essential for managing the information epidemic, a concern shared by scholars globally. Strengthening media accountability requires advocating for the rule of law. In response to the evolving digital media landscape, authorities have implemented laws and regulations to support healthy sector growth. Administrative oversight must involve nuanced management, imposing sanctions that align with the impact of misinformation and its divergence from the truth. Timely release of authoritative information is vital for shaping public opinion and countering misinformation with verified facts.

During emergencies, establishing a direct reporting system is crucial for enhancing information dissemination speed. Legislative amendments have improved the transparency of professional institutions, streamlined the information approval process, and facilitated timely information release during crises.

The timely release of authoritative information is crucial for guiding public opinion. State media should create a robust platform for information dissemination, leveraging social media to integrate official and community channels. Furthermore, cultivating a culture of legal and ethical awareness within the media is indispensable. Media professionals must prioritize information refinement and quality throughout the news production cycle, enhancing fact-checking and peer review processes to ensure authenticity and neutrality [67].

XSL•FO
RenderX

Media personnel should strive for accurate and prompt translation services, maintain objectivity, and minimize biases from political, cultural, or commercial influences to prevent the information epidemic from escalating into a political crisis. Additionally, industry professionals must elevate ethical standards, adopt a people-centric approach, and enhance their expertise through in-depth interviews with scientists and similar initiatives to improve public access to scientific information.

Research Limitations

There are several limitations in this study that need to be objectively explained: the research perspective is mainly based on the analysis of domestic information governance practices, and there is insufficient comparison of information governance models under different countries' social systems and cultural traditions, which may limit the cross-contextual applicability of the theoretical framework. The analysis focuses on the construction of macro governance mechanisms, and the exploration of micro-psychological motivations for individual information behavior is not deep enough, making it difficult to fully explain the complex decision-making logic of the public in information selection. The research method focuses on qualitative analysis and framework construction. Although some practical cases are combined, there is a lack of dynamic verification of governance effectiveness through long-term tracking data, and the timeliness of the conclusions needs further observation. These limitations provide directions for improvement in future research, which can be improved through cross-border comparative studies, microbehavioral experiments, and long-term follow-up surveys.

Potential Research Directions

Our research has found that there are differences in research between the East and the West in related fields, which provides many perspectives for future research.

First, a cross-cultural comparative framework can be established to study the different effects of information governance under different political systems; for example, comparing social media platforms in the East and the West to see the similarities and differences in the effectiveness of using algorithmic censorship to suppress misinformation, especially pseudoscientific content with medical terminology. It is also possible to combine useful technologies in international research with governance experience in domestic research to develop a set of methods and tools that combine machine learning and social network analysis. In addition, observe the differences in the roles played by medical practitioners such as doctors and nurses in information dissemination in different countries and develop a set of scientifically based and universally applicable guidelines for professional social media behavior in different countries.

Second, we should pay attention to the changes in the information environment in the later stage of the epidemic. Most of the current research focuses on the period from 2020 to 2021 when the epidemic is serious, but some aspects are ignored: everyone's scientific understanding of the "long-term COVID-19" is constantly updated, but the public's understanding is not up to date, and the gap between them is changing; what long-term impact will the habit of frequent exposure to information during the epidemic have on other public health issues such as vaccination and antibiotic resistance; the structural changes of cross-border information dissemination networks, especially the transformation of the role of overseas accounts in new hot events. This type of long-term tracking research can refer to international long-term tracking methods for mental health and domestic analysis of public opinion fluctuations.

Contribution and Novelty

Systematically carry out comparative bibliometric analysis of Chinese and Western information epidemic research: This research innovatively uses WOS and CNKI databases as samples and systematically compares the differences between China and the West in the information epidemic research of COVID-19 through bibliometric methods (such as CiteSpace visual analysis), filling the gap in the existing research that lacks cross-country and cross-database system comparison.

Clearly revealing the core differences and commonalities between Chinese and Western research: The study found that international research focuses on machine learning, social media analysis, and the impact of information epidemics on mental health, while Chinese research focuses on information governance, public opinion guidance, and information dissemination mechanisms. At the same time, it clarifies the commonalities between the two in the core goal of curbing the spread of misinformation, providing specific entry points for subsequent cross-cultural cooperation.

Pointing out the shortcomings of research cooperation and emphasizing the necessity of global collaboration: Through the analysis of the collaboration network between authors and institutions, the current situation of sparse collaboration between authors and institutions in Chinese and foreign research is revealed. The importance of establishing cross-border and interdisciplinary cooperation mechanisms is emphasized, providing a basis for building a globally unified information epidemic response system.

Provide practical and theoretical guidance for policy formulation and future research: Based on research differences, propose the possibility of integrating technological means and governance experience, provide reference for public health departments to formulate information management strategies, and point out directions for cross-cultural comparison and long-term information ecology tracking for subsequent research.

Conclusions

As the world continues to confront the challenges of COVID-19, the concurrent information epidemic presents a complex issue. This paper provides a comprehensive analysis of five categories of sample data: publication trends, authorship, institutional affiliations, highly cited literature, and keyword topic clusters. Through this analysis, we have examined the evolution of the information epidemic and its multifaceted societal impacts, delineating its contours as perceived by scholars across different nations, institutions, and research orientations. This synthesis highlights research trajectories, differences in domestic and international approaches, and suggests strategies for addressing the information epidemic. Additionally, given the global impact

XSL•FO
RenderX

of infodemics, integrating knowledge from various disciplines and regions is essential for fostering more effective responses.

Abstract

Background: Autism spectrum disorder (ASD) is a prevalent neurodevelopmental condition that can be quite difficult to diagnose due to a lack of objective diagnostic methods in the currently used behavioral assessments. Recent work has shown that children with ASD have a higher incidence of motor control differences. A compilation of studies indicates that between 50% and 88% of the children with ASD have issues with movement control based on standardized motor assessments or parent-reported questionnaires.

Objective: In this study, we assess a variety of deep learning approaches for the classification of ASD, utilizing data collected via inertial measurement unit (IMU) hand tracking during goal-directed arm movements.

Methods: IMU hand tracking data were recorded from 41 school-aged children both with and without an ASD diagnosis to track their arm movements during a reach-to-clean up task. The IMU data were then preprocessed using a moving average and *z* score normalization to prepare the data for deep learning models. We evaluated the effectiveness of different deep learning models using the preprocessed data and a k-fold validation approach, as well as a patient-separated approach.

Results: The best result was achieved with a convolutional autoencoder combined with long short-term memory layers, reaching an accuracy of 90.21% and an F_1-score of 90.02%. Once the convolutional autoencoder+long short-term memory was determined to be the most effective model for this datatype, it was retrained and evaluated with a patient-separated dataset to assess the generalization capability of the model, achieving an accuracy of 91.87% and an F_1-score of 93.66%.

Conclusions: Our deep learning approach demonstrates that our models hold potential for facilitating ASD diagnosis in clinical settings. This work validates that there are significant differences between the physical movements of typically developing children and children with ASD, and these differences can be identified by analyzing hand-eye coordination skills. Additionally, we have validated that small-scale models can still achieve a high accuracy and good generalization when classifying medical data, opening the door for future research into diagnostic models that may not require massive amounts of data.

Introduction

Throughout the world, autism spectrum disorder (ASD) is a prevalent neurodevelopmental condition marked by challenges with communication in social settings, as well as restricted and repetitive behaviors [1,2]. An individual with autism spectrum disorder can have a range of challenges, primarily in social communication and interaction; for example, they may have difficulties understanding and responding to social cues, forming relationships, and effectively communicating with others using verbal and non-verbal languages [3-5]. Additionally, individuals with ASD may engage in repetitive behaviors or have highly specific interests, leading to an inflexibility in daily life activities and hardship when trying to keep up with fluid or dynamic social situations [6]. Behavioral patterns and communication difficulties like these tend to vary widely in presentation and severity, making ASD particularly challenging to diagnose. The most current methodologies for diagnosing ASD predominantly rely on behavioral evaluations and structured interviews conducted by trained clinicians [7,8]. An ASD assessment

XSL•FO
RenderX

typically involves gathering a detailed history, conducting interviews with friends and family members, and sometimes observing an individual's behavior in various social situations. However, despite the expertise of the clinicians involved, diagnosing an individual with ASD is very imprecise, depending heavily on the clinician's subjective interpretation and experience [9]. The subjective nature of this diagnosis can be a problem; if different evaluators can come to different conclusions based on the same observations, then the chance for a missed diagnosis or a misdiagnosis is significant. This subjectivity also means that an ASD diagnosis might not properly reflect the subtleties of an individual, as ASD manifests a very wide spectrum of possible symptoms.

It is also worth noting that diagnosing ASD earlier in life is important; early access to support can significantly improve long-term outcomes and quality of life when addressed before behavioral patterns are solidly set [10]. Unfortunately, diagnosing ASD is much more difficult in young children, for all of the reasons explained before. For example, it is very subjective whether a child is having social communication problems or just being shy. Due to these challenges, there is a significant need for a more objective approach to diagnosing ASD.

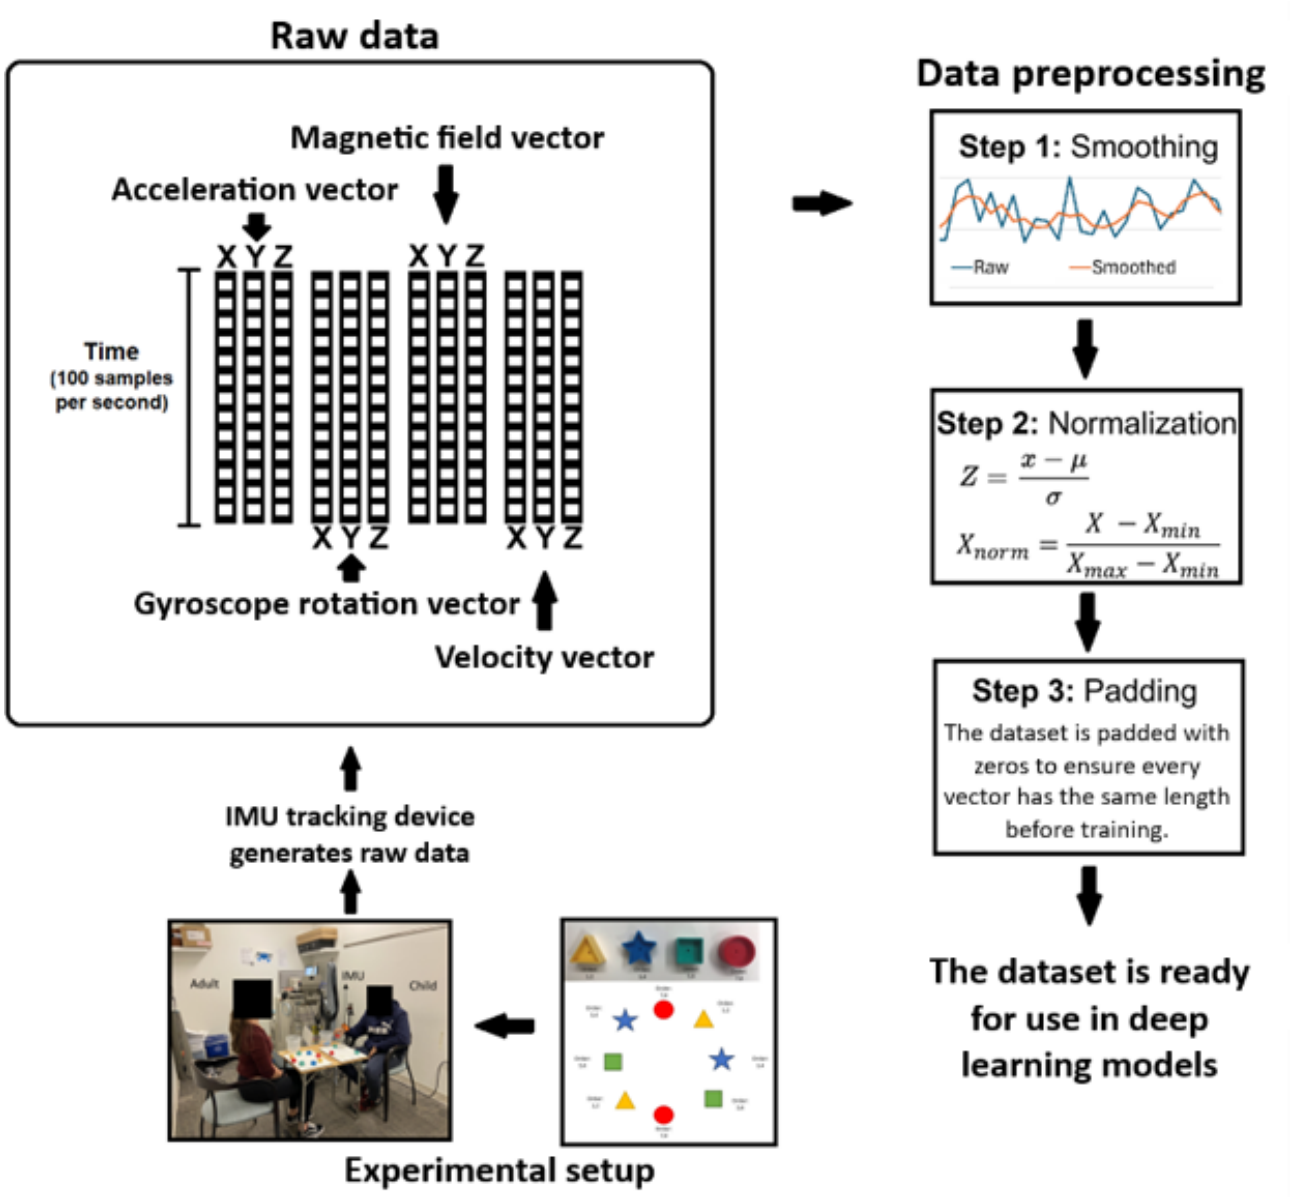
Recently, it has been noted that there is a high incidence of motor control differences in children affected with ASD [11]. A compilation of studies indicates that between 50% and 88% of the children with ASD have issues with movement control based on standardized motor assessments or parent-reported questionnaires [11,12]. These children often exhibit significant differences with posture, hand-eye coordination, fine motor control, and gait. Importantly, these motor abnormalities are highly correlated with their primary social communication problems and manifest earlier or at the same time as any social communication issues [13-16]. This provides clinicians a new avenue for identifying ASD earlier.

In the past, it has been shown that machine learning and deep learning methods have been successful in classifying between children with ASD and typically developing (TD) children based on resting state functional magnetic resonance imaging data [17,18]. One study showed that a combination of a restricted Boltzmann machine and a support vector machine was able to achieve an accuracy of ~80% on a dataset of ~180 patients [18]. Another study using a deep learning model matched these results with a significantly larger dataset, achieving an accuracy of ~80% for a model classifying 871 participants [17]. Many other studies have been conducted attempting the same classification, using different combinations of functional near-infrared spectroscopy, magnetic resonance imaging, functional magnetic resonance imaging, and electroencephalogram data [19]. The average accuracies for these models are around 70% - 85%, with some specific models approaching 90% - 95%. The best functioning models that surpassed 90% accuracy were deep learning autoencoders, as well as multidimensional convolutional neural networks [19].

Despite the promising findings of using neuroimaging data to classify children with ASD, there are certain limitations. For example, neuroimaging is often expensive and difficult for typical families to access. Moreover, some neuroimaging tools are not child-friendly, making their widespread use in toddlers and children challenging. As a result, there is a pressing need for low-cost, child-friendly, objective methods to children's performance. To solve these problems, we decided to use an inertial measurement unit (IMU) device. An IMU device is a very small motion–tracking device, easily strapped on to a participant's wrist like a light-weight watch. These devices are nonintrusive and very discrete, allowing for data collection from sensitive children. Previously, our research group had achieved an accuracy of 78.1% in classifying children with and without ASD using IMU data and a multilayer perceptron model [20]. However, it remains unclear which deep learning methods would produce the best classification results. Therefore, the goal of our study is to evaluate a variety of simple and customizable deep learning models, including long short-term memory (LSTM), multilayer perceptron (MLP), and convolutional neural networks (CNNs), for an automatic classification of children with ASD. Recent studies have highlighted the growing efficacy of deep learning techniques such as these, including LSTM-based models for advancing the predictive accuracy in medical and diagnostic contexts. We will first assess the effectiveness of different types and configurations of deep learning models on this type of IMU data. Once the best models are determined, we will test them for effectiveness on unseen patient data.

Methods

Study Methodology



A total of 41 children, both with and without ASD, participated in this study (mean age [SE]: TD group: 10.3 [0.8], 8 male participants and 7 female participants; ASD group: 10.3 [0.5], 21 male participants and 5 female participants). No significant differences in age or sex were observed between the TD and ASD groups (P=.05). Participants were recruited through fliers, phone calls, and online postings distributed to local schools and community centers, as well as through Simons Powering Autism Research participant research match service [21]. The inclusion criteria of the TD children were (1) age between 6 and 17 years, while the exclusion criteria included (1) having any neurological or developmental diagnosis or delays, (2) having a history of preterm birth or significant birth complications, and (3) having a family history of ASD. For children with ASD, the inclusion criteria were (1) age between 6 and 17 years and (2) having a professionally confirmed diagnosis, while the exclusion criteria were (1) inability to follow 1-step instruction; (2) exhibiting sensory and behavioral challenges that would prevent them from wearing the IMU sensors and completing the reaching-and-placing tasks. These criteria were chosen for a very simple reason: if a child has ASD so severe it prevents them from engaging in the task, such as having issues wearing the hand device or following instructions, it is likely that they would not need this test to diagnose them in the first place. We are attempting to evaluate ASD based on significant differences in hand-eye coordination skills and approaches, so the TD children and the children with ASD were not screened for hand-eye coordination skills to ensure fair results. Our hypothesis is that a deep learning model can evaluate the

XSL•FO
RenderX

harder-to-define edge cases of ASD by identifying key differences in how children with or without ASD interact with a simple hand-eye coordination task.

The hand-eye coordination task itself is simple; while seated across from an adult experimenter, each participating child performed a simple reaching task while wearing a small IMU hand tracking device fastened to the wrist of their right hand. The task itself consisted of a set of blocks arranged in a circle and placed in front of the participant, as shown in Figure 1. Each participant would pick up the blocks in a specific order, specified by the picture instructions, and place each block one at a time into a box next to them until all the blocks had been moved. This task was repeated for a total of roughly 6 trials per child, with each trial taking anywhere from ~10 seconds to ~40 seconds to complete. Once the data collection was complete, the final dataset consisted of 76 trials from TD children and 145 trials from children with ASD.

Figure 1. The experimental setup, consisting of an adult experimenter, a child participant wearing an inertial measurement unit (IMU) device, and a table with a series of blocks setup and a bucket next to the blocks. Also shown is the rough shape of the raw IMU data, as well as the data preprocessing steps performed to prepare the data for use in a model.

Ethical Considerations

All study procedures were carried out in accordance with the Declaration of Helsinki and were approved by the University of Delaware Institutional Review Board. Informed consent from parents and assent from children were obtained prior to participation. Each participant was assigned a unique study ID, and all collected data were subsequently deidentified using these IDs. Families received US $20 as compensation for their participation. Additionally, written permission was obtained from parents and experimenters for the use of their photographs in this publication.

Data Processing and Analysis

The primary outputs of the IMU device are the acceleration vector, the gyroscopic rotation vector, the velocity (Δv) vector, and the magnetic field vector, with each showing a basic representation of the movement in space. Each vector consists

XSL•FO
RenderX

of an x, y, and z component to represent the movement of the IMU device in space, sampled at 100 Hz (Figure 1). The first 3 sets of movement vectors (acceleration, velocity, and rotation) are important for calculating the exact position of the IMU device in 3D space. Then, the magnetic data vector was used because the magnetic data are critical to counteract any drift experienced by the accelerometer and gyroscope. At this point, the raw data consisted of just these 4 vector types, with the final shape of the combined data being an Nx12 array, where the unknown length N is equivalent to the amount of time the participant took to complete the task in seconds, multiplied by 100 due to the sampling rate, as shown in Figure 1.

In order to prepare the data for use in a deep learning model, several preprocessing steps were implemented, as shown in Figure 1. First, a 3-point moving average was applied to each of the x, y, and z components of each vector to slightly smooth out the data without losing any of the features. Small-scale testing showed that a little bit of smoothing is critical to the accuracy of the model; it helps the model look for generalizations between different trials without getting caught up on outliers. Next, the data were normalized by applying a global *z* score, followed by a global min-maxing. A *z* score is an algorithm to normalize a signal of any length based on the mean and SD, and it has been shown to significantly improve model accuracy and generalization capability [22]. By applying the *z* score function globally, it standardizes the data by bringing all values into the same reference frame, relative to their mean and SD. Min-maxing is not strictly necessary after a *z* score, but it has also been found to improve model accuracy [22]. It does this by ensuring that all values fall between 0 and 1, preventing deep learning models from experiencing runaway gradients and thus speeding up convergence during training. Finally, the trials with different lengths were zero-padded to be equal length, producing data in the shape 4000×12. While a few specific types of deep learning can handle data of different lengths during training, most of the model architecture we will be using is too rigid to handle variable length data, requiring a fixed input size.

After determining the best preprocessing steps for the data, a few final concerns need to be addressed. One concern is the variable length of the data; if the ASD class contains many trials that are significantly longer or shorter than the TD trials, the model could just end up classifying based on length rather than any feature characteristics (features) of children with ASD. It is generally expected that roughly 95% of the data in a normal distribution would fall within 2 SDs of the mean, and beyond this, the data might be considered unusual or even an outlier. Checking the dataset, the average length of a trial is roughly 1897 samples, with an SD of 463. The entire set of TD trials falls within 2 SDs of the mean, and only 13 trials of 145 from the children with ASD dataset are outside 2 SDs, all of them longer. This is a fairly normal distribution of data, where roughly 94% of the data are within 2 SDs of the mean. It is not quite normal to have every trial beyond 2 SDs on one side of the distribution curve, but it was decided that none of the data would be excluded as outliers because a slightly longer trial time might be a characteristic of children with ASD. Also, 13 of the 221 trials being significantly longer would not overwhelm the model, meaning that to achieve any real accuracy, it would have to learn other real characteristics of children with ASD from the kinematics data. After this, 1 final issue needed to be considered. The dataset consisted of 76 trials from TD children and 145 trials from children with ASD, meaning 1 possible classification had nearly double the amount of data compared to the other classification. Generally, deep learning models function best with balanced datasets, meaning they need a similar amount of data from all possible classifications; otherwise, they can run into major training issues. To solve this problem, a simple data balancing technique was employed. The smaller TD dataset was doubled, for a final dataset of 152 TD trials and 145 ASD trials. This data balancing method allows us to compare the validation accuracies, which we used to prototype several kinds of models. This allowed us to determine which models work best on this kind of data, and which models do not function at all.

With the data preprocessed, the next step was to prototype and test several deep learning models. Before any specific model methodologies could be compared, it is critical to determine the basic parameters that will ensure all the models are functioning as best as they can. Parameters such as the number of layers, the number of neurons in the layers, the learning rate, the best activation functions, the overall length of time required to train the model, and the video random-access memory (VRAM) requirements of the models were refined after running the tests shown in Table 1. It should be noted that while almost all of the above parameters are critical for ensuring peak functionality of the models, the training time and VRAM measures are simply a limitation of our computing resources for building and testing models. All models were trained with the Adam optimization algorithm and tested using a k-fold cross-validation scheme.

Video random-access memory

The requirements of the models were refined after running the tests shown in Table 1. It should be noted that while almost all of the above parameters are critical for ensuring peak functionality of the models, the training time and VRAM measures are simply a limitation of our computing resources for building and testing models. All models were trained with the Adam optimization algorithm and tested using a k-fold cross-validation scheme.

CNN only, 10 layers	87.14	~4
Transformer, 8 heads, 4 layers	82.73	~20

[a]Several versions of the long short-term memory models, multilayer perceptron models, convolutional neural network models, and transformer models were tested. All of these tests were performed using the balanced dataset mentioned previously. Because of this, these results do not represent the effectiveness of our motor task for diagnosing ASD, only the effectiveness of the models classifying this type of IMU data.

[b]LSTM: long short-term memory.

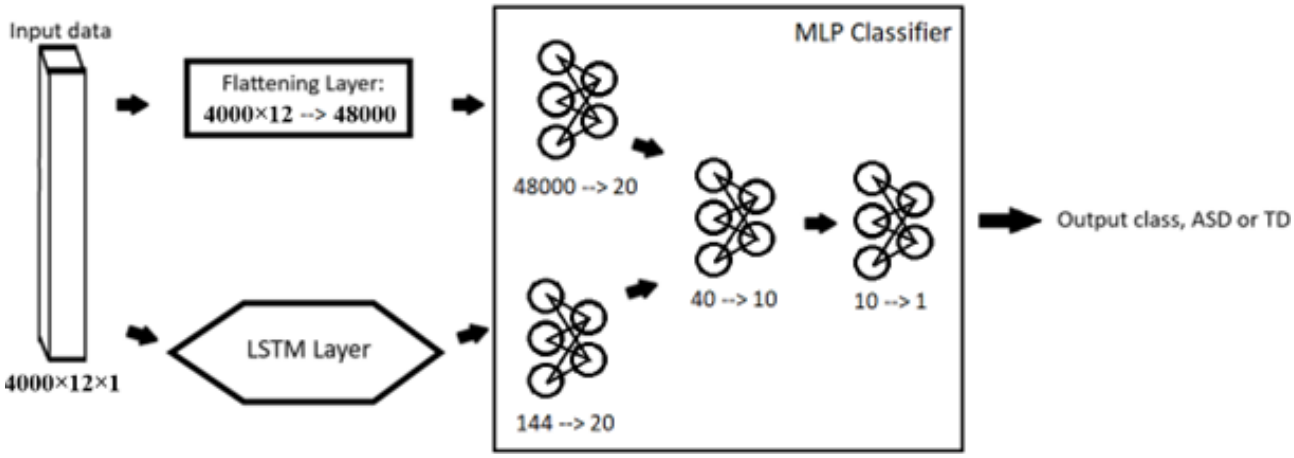
[c]MLP: multilayer perceptron.

[d]CNN: convolutional neural network.

Several key design choices were based on the model prototyping data collected. First, it was decided that any models with LSTM layers attached would use the 1 layer, 6×12 neuron format, as this seemed to provide the best possible LSTM classification, while keeping the runtime and VRAM requirements at a reasonable level. As Table 1 shows, models with significantly more LSTM neurons increase the training time to a matter of days to weeks, which would not be feasible for running many tests on many model permutations.

The second design choice implemented after testing was the use of only 3 layers for all future MLP testing. While adding more MLP layers does not increase the training time like LSTM layers do, having too many layers with too many neurons causes major overfitting problems, leading to the brute force memorization of the training data rather than any real generalizations.

It was also decided that all non-MLP models would have a smaller 3-layer MLP attached to the end as the final classifier. This allows the models a way to concatenate the output from CNN layers with the output from LSTM layers. It also has the side benefit of making all the models directly comparable; by keeping the final classification portion of the models the same, any changes in the features extracted by the LSTM, CNN, and convolutional autoencoder (CNN-AE) model configurations will be apparent. Thus, all models were designed to have 3 MLP layers attached at the end as the final classifier.



Other key design choices informed by the data from Table 1 include limiting the number of CNN layers to 5 to prevent overfitting, using the LeakyReLU activation functions on all layers except for the output layer, using the sigmoid activation function for the output layer, using a learning rate of 1e-4, and training for 200 epochs. Also worth noting is that several transformer type models were tested with no success, likely due to the limited amount of VRAM available for training these models. No further improvements were possible for the transformer type models with our training setup, so this model type was not evaluated any further. Now that the main model parameters have been identified, 6 types of deep learning models were built to test their effectiveness on this task and data type.

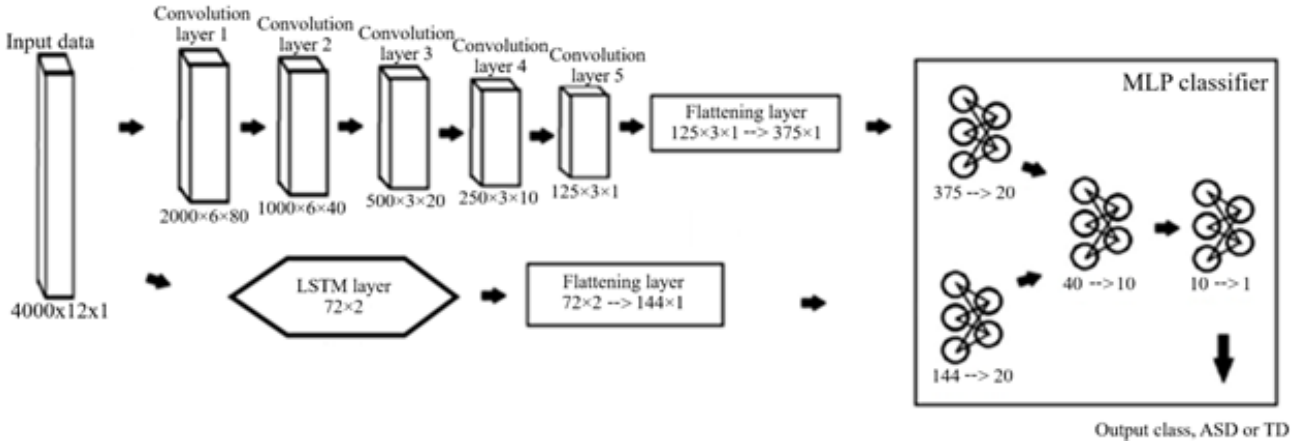
The MLP type models (Figure 2) each had 3 primary linear layers, with a batch normalization layer between each layer. LeakyReLU activate functions were used for the first 2 layers, and the third layer used a sigmoid function for the classification output. Before the first layer, there is a squeeze function to transform the 4000×12 zero-padded data input into a vector of length 48,000, ready for use in the MLP layers. We found that the size of the first layer was quite important; using an output value of much larger than 20 would cause significant overfitting, and using an output much smaller would cause the model training time to increase significantly, by requiring hundreds to thousands more epochs to reach the same level of accuracy. The key difference between the MLP and the MLP+LSTM is the addition of an LSTM layer along with an extra linear layer, as shown in Figure 2. The LSTM layer received the preprocessed input data as a sequence, and the cell state and hidden state were used as its output. Critically, the LSTM layers are able to handle data with differing input sizes, so the zero-padding on the input

XSL•FO
RenderX

data was stripped before being input into the LSTM layers. The output from the LSTM was then fed into a dedicated linear layer to prune the features and produce a separate output of length 20. This 20-point output was then concatenated with the 20-point output produced from the first layer as shown above, and the merged data were then run through the final 2 layers to produce a single classification. Just like the MLP model, the MLP+LSTM used batch normalization between all layers and LeakyReLU for all layers except for the classification, which used the sigmoid function (Textbox 1).

Figure 2. Schematic for the first merged model tested: the merging of a multilayer perceptron (MLP) classifier and a long short-term memory (LSTM) classifier. The MLP-only model takes the same form as this model, minus all of the LSTM-specific layers. ASD: autism spectrum disorder; TD: typically developing.

Textbox 1. Six final model architectures that have been evaluated. There are 3 primary model designs to be tested, the multilayer perceptron (MLP), convolutional neural network (CNN), and convolutional autoencoder (CNN-AE), and a modified version of each of these 3 models using long short-term memory (LSTM) layers. Each type of model was set up with matching layer structures to allow for a more direct comparison of effectiveness.



Deep learning models to be evaluated

- MLP
- CNN
- CNN-AE
- MLP+LSTM
- CNN+LSTM
- CNN-AE+LSTM

The CNN and CNN+LSTM models used a somewhat similar setup to the MLP-only models, with 1 key difference. The CNN model starts with 5 convolutional layers, transforming the input from 4000×12 to 125×3×1, as shown in Figure 3. The first 2 convolutional layers use a window size of 5×5, with the last 3 layers using a window size of 3×3. The optimal sizes of the window in CNN type models can vary greatly from dataset to dataset; however, it has been shown that prime numbers can be very effective in the first 2 layers of a CNN, while the deep layers optimize efficiently when they are small [23]. The stride for each convolution was specifically tuned to slowly compress the featurespace between each convolution, while ensuring that the model does not require too much memory or take too much time to run. The channel count was also tuned for this purpose, while ensuring that the maximum amount of features can be extracted from the data. Each channel functions as a featuremap, a 2D grid that represents all features detected by the convolution window. Importantly, each channel has its own window with optimizable weights. This is why the channel count starts at maximum then slowly decreases layer by layer, to ensure that all possible features can be detected at first, and then refined into the most important set of features from the data. Next, a batch normalization was implemented between each convolutional layer. When tested without batch normalization, these models all take significantly more epochs to train to the same accuracy. This means that adding batch normalization helps these models converge significantly faster. Each convolution also used a LeakyReLU activation function. Afterward, the 125×3×1 vector was squeezed into a linear vector, for use in the final MLP classifier. These layers were set up the same as the MLP model from before, allowing for a direct comparison between the methods. Similarly, the CNN+LSTM model concatenates the results from the convolutional layers and the LSTM layer in this final MLP classifier.

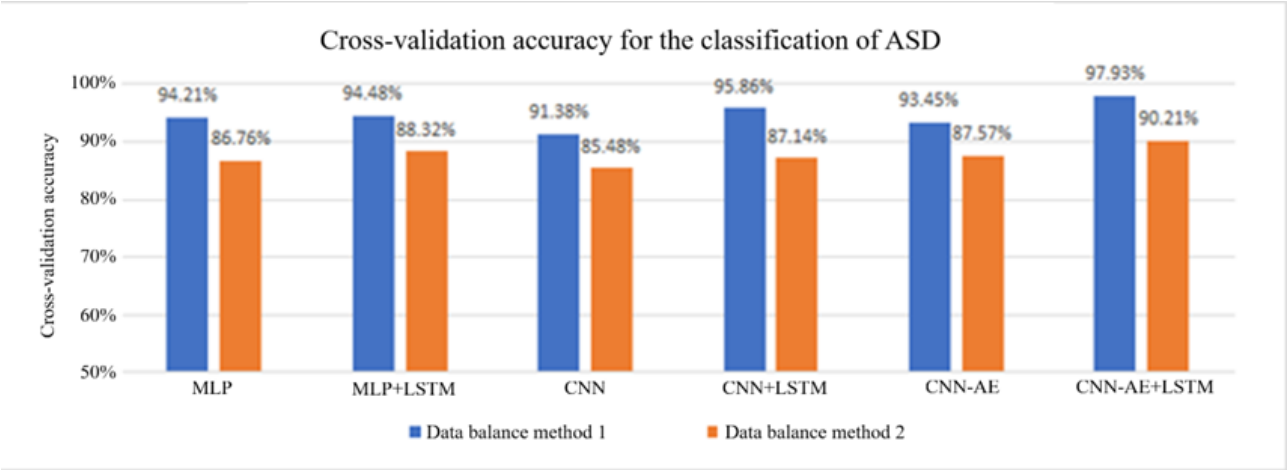
RenderX

Figure 3. Schematic for the merged convolutional neural network with long short-term memory layers (CNN+LSTM) model. The CNN-only model takes the same form as this model, minus all of the LSTM-specific layers. ASD: autism spectrum disorder; TD: typically developing.

The last kind of model we tested was a CNN-AE. This model functions differently from the previous 2 types we have discussed. An MLP model and a CNN model only function to classify the data they are trained on, while an autoencoder can both classify and reconstruct the data it has been trained on. Autoencoder reconstruction works by compressing the input data into a smaller featurespace with an encoder, then rebuilding the original input data back from the compressed featurespace with a decoder. This method of compressing and reconstructing forces the model to identify key signal features fundamental to its composition. In this case, the encoder section has the same convolutional layers as the previous CNN models, compressing the input data from 4000×12 to 125×3×1. The decoder then uses a series of upsampling layers combined with convolutional layers to reconstruct the signal back from 125×3×1 to 4000×12, as shown in Figure 4. Afterward, the model sends the compressed featurespace through linear layers to generate the final classification, using the same layer formatting as all the previous models. Just as with the previous models, the CNN-AE+LSTM model integrates the LSTM data with the featurespace during the same step.

Figure 4. Schematic for the merged convolutional autoencoder with long short-term memory layers (CNN-AE+LSTM) model. The CNN-AE only model takes the same form as this model, minus all of the LSTM-specific layers. ASD: autism spectrum disorder; TD: typically developing.

All of these models were tested using k-fold cross-validation, where k was 10. This means that the data are split up into 10 random subgroups, the model is trained on 9 subgroups and tested on the 10th subgroup, and the resulting accuracy is saved for later. This process is repeated 9 more times, using each unique subgroup as the testing data one time while training on the rest. After all the training is done, all 10 accuracies are averaged to produce the final cross-validation accuracy.



Results

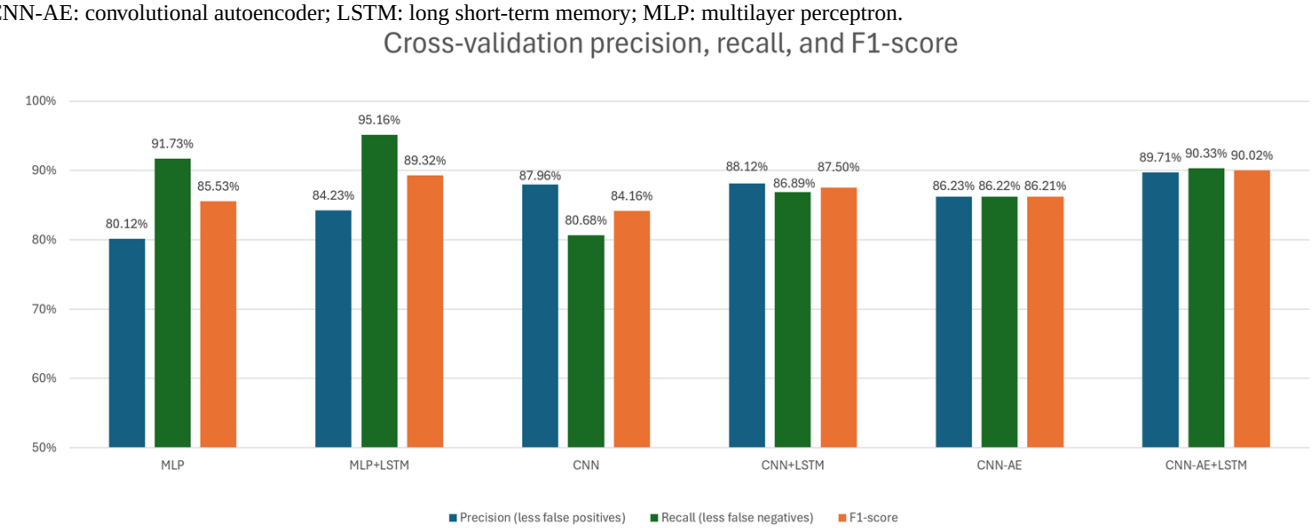
All 6 models were trained and evaluated for accuracy, with several important results. First, we noticed that using LSTM

XSL•FO
RenderX

layers significantly increases the accuracy each model can achieve, as shown below by the blue bars in Figure 5. These data also show that the CNN-AE with added LSTM layers is the best model. Unfortunately, it was at this point that we discovered that these resulting accuracies (labeled in blue in Figure 5) were misleadingly high, due to a fault with the data balancing method. By simply duplicating the TD dataset, the same piece of data could end up in both the training and testing set, due to the random sampling of the data during the standard use of the k-fold cross-validation method. This means that while the model-to-model trend in the data is likely correct, the blue columns in Figure 5 are statistically invalid for drawing conclusions about the effectiveness of the cognitive-motor task.

Figure 5. These are the resulting accuracies from the 2 training sessions for each model. Data balancing method 1 cannot be considered evidence for the effectiveness of the motor task due to the duplication of data in the training and testing sets. Data balancing method 2 is statistically valid and does show the effectiveness of our motor task for distinguishing between children with autism spectrum disorder (ASD) and typically developing (TD) children. CNN: convolutional neural network; CNN-AE: convolutional autoencoder; LSTM: long short-term memory layer; MLP: multilayer perceptron.

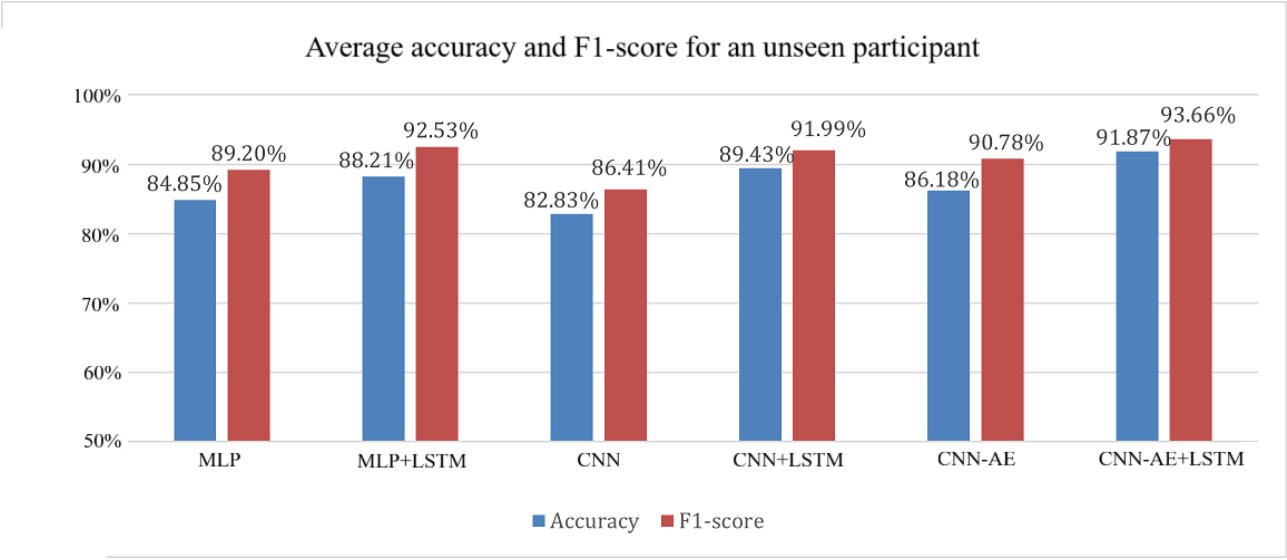
Fortunately, there was a fairly simple way to fix this problem, allowing us to evaluate the effectiveness of our cognitive-motor task. A second data balancing method was implemented, where the larger dataset of ASD trials was split in half, creating one dataset that is 73 ASD trials and 76 TD trials, and another dataset with the remaining 72 ASD and the same 76 TD trials. Each model was evaluated using both datasets, and the cross-validation accuracies were averaged for the final resulting accuracy. This is a statistically useful test for evaluating the effectiveness of the cognitive-motor task, as it ensures that no datapoints from the training set are ever introduced into the testing set. Thus, the accuracy achieved by a model depends on its successful interpretation of the cognitive-motor task. The results from using this second method of data balancing are labeled in orange in Figure 5. These results allow us to assess how well our cognitive task works for the deep learning classification of a participant; clearly, the task is effective, as the average model accuracies range from ~85% to ~90%. Also clearly shown is how the second data balancing method produces the same trend in the data, with the CNN-AE+LSTM once again proving to be the best model.



While accuracy is a great general metric for evaluating the effectiveness of a deep learning model, it is not the only metric that should be considered. For starters, looking at the SD for the models can tell us approximately how reliable a model is, where a low standard deviation means a model is quite stable between k-folds. For our models using data balancing method 2, the average standard deviation was no greater than ~2%. This means our models are stable when they produce these accuracies, which is a good sign for possible future work. Stable models are more likely to generalize successfully when trained with larger datasets. Precision and recall are very useful scores for judging medical artificial intelligence (AI) performance, because these metrics are calculated using false-positive and false-negative results, respectively. When AI is being used as a diagnostic tool, false-positive diagnoses can lead to unnecessary treatment and wastage of time, while false-negative results can lead to a patient missing required care. Both false-positive and false-negative cases are critically important to avoid, so we calculated the F_1-score for each of our models. The F_1-score is a combination of precision and recall that can be considered more important than accuracy for evaluating our diagnostic model in this case. To calculate these scores, the models were run again to generate confusion matrices. The models were run with the second data balancing method described above, where the dataset was split in two, the models run twice, and the results averaged to produce the final scores.

Based on Figure 6, we see that the F_1-scores match closely with the trend shown previously by the accuracies in Figure 5. Adding LSTM layers is once again shown to be vital to increasing the effectiveness of these models when predicting children with ASD. Interestingly, the MLP models score consistently higher recall values with corresponding lower precision values. The higher recall score means that the MLP type models might have less false-negative results overall, ensuring that participants with ASD will not be missed by the model. This does come with the downside of a lower precision, meaning that participants without ASD might be accidentally diagnosed positively more often. The CNN models seem to show the inverse, with higher precision and lower recall, but this might fall within the range of error, due to the random initializations of the weights whenever a new training session is started. Finally, we can see that the autoencoder models achieve a balance between precision and recall, with the LSTM

XSL•FO
RenderX



autoencoder achieving a slightly higher F_1-score of 90.02%, meaning this is a better overall optimization as a result.

Figure 6. These are the precision, recall, and F_1-scores for each model. The number above each set of columns is the F_1-score for each model. All of these scores were calculated using the statistically valid second data balancing method mentioned previously. CNN: convolutional neural network; CNN-AE: convolutional autoencoder; LSTM: long short-term memory; MLP: multilayer perceptron.

Knowing that the CNN-AE+LSTM model functions best for processing timeseries data and that our motor task works is very important information, but it is also critical to evaluate how well the models would predict on a participant they had never seen before. In order to test this, a strict patient-wise training or testing data split was implemented [24]. The methodology used to split the data was simple; one of the 41 participants was selected at random for testing, and their trials were excluded from the training data. The models were trained until the training accuracy was above 95% accuracy, and once this limit was reached, the testing accuracy of the given participant's trials was determined and then saved for later averaging. This was then repeated for each of the 41 participants, and the final resulting accuracy was calculated as the overall average of each saved testing accuracies from each participant. By averaging all possible testing conditions, the patient-wise method allowed us to interpret how well each of the models would work, as a true reflection of how likely a given model will perform correctly on an unseen participant. The precision and recall scores were also averaged in this way, allowing us to calculate the F_1-score. It is important to note that it was not possible to balance the dataset for this particular test, which is reflected in Figure 7 by the worse performance of all non-LSTM models and by the slightly higher F_1-scores relative to accuracy.

Figure 7. These are the resulting accuracies and F_1-scores from the patient-wise classification. Each value is the overall average accuracy achieved on a patient never seen by the model. CNN: convolutional neural network; CNN-AE: convolutional autoencoder; LSTM: long short-term memory; MLP: multilayer perceptron.

The primary result of this patient-wise evaluation is the importance of the LSTM layers. As can be seen in Figure 7, using LSTM layers seems to improve the model accuracy by roughly ~4% for all cases, with a similar effect on the F_1-scores. These results once again confirm that the CNN-AE model is one of the best options for predicting children with ASD.

Discussion

Principal Findings

This study evaluated the effectiveness of various small-scale deep learning approaches for classifying children with and without ASD using IMU hand tracking data. Our results demonstrated that the best performance was achieved with a CNN-AE model combined with LSTM layers, yielding accuracies around 91% and F_1-scores of 90.02% and 93.66%, respectively, using the k-fold and patient-wise evaluation methods. When it comes to the task of scanning sequence movement data for characteristic features of children with ASD, it seems clear that both of the CNN models overfit the data and perform worse than the MLP models, with the CNN-AE+LSTM model continuing to be the best classification option.

Additionally, it is important to understand why these models performed at the level that they did; this understanding could benefit future work involving small-scale models and medical data. Deep learning networks such as these are powerful tools, but they need to be tailored to their specific use cases. Normally, it is unusual to see a CNN model performing significantly worse than the MLP model; however, there could be several reasons for this. One likely reason is the data format: CNN models cannot interpret sequential data in the same way an MLP might be able to. It all comes down to where the optimization happens in each model type. In a CNN-type model, all of primary optimization happens inside the kernels, and a fixed-size filter then scans over an entire signal and looks for a specific set of features that the internal weights are optimized to find. Because these kernels are a fixed size, a single CNN layer can only ever look at a small chunk of the overall data at any given time to look for patterns. All of this to say, a CNN can struggle to capture long-range dependencies and complex patterns in sequence data. The convolutions performed by a CNN are better suited for locating features with short-range dependencies, or in other words, a CNN is better for detecting localized patterns. On the other hand, MLP type models are capable of learning complex, nonlinear relationships between the extracted features and the target variable. This is because every single neuron in an MLP layer is connected to every other neuron with an optimizable weight, meaning the entire input sequence can be evaluated at the same time. This flexibility can sometimes lead to a better performance in learning classifications from intricate, long, and complex patterns. Furthermore, while a CNN-AE model might only have CNN layers for detecting short-range patterns, it has the added bonus of compressing the input sequence into a lower-dimensional latent space, capturing essential features while filtering out noise. This results in a more efficient latent representation of the data, compared to the results of a CNN alone. Effectively, this means that the CNN layers of the autoencoder model will detect and significantly compress all possible information from short-range dependencies, while still preserving the necessary long-range dependencies to allow for accurate reconstruction. This highly compressed version of the input data can seriously mitigate overfitting, which likely explains why the CNN-AE models outperformed the regular MLP and CNN models. It is important to note that we did some experimenting with dropout layers, normally used to mitigate overfitting in simpler model types, but the results were mixed. The models became inconsistent, sometimes performing slightly better, sometimes performing worse. This is likely due to the small size of the dataset; future work with larger datasets should not ignore the possibility that dropouts could increase accuracy even further.

We can also see that despite the feature compression of the CNN-AE model and the ability for an MLP to identify some long-range dependencies, these models still do not perform very well without the addition of LSTM layers. These LSTM layers are critical to improved performance, increasing the accuracy for every type of model. This makes sense, as LSTM layers have a few major advantages for analyzing and learning from sequence type data. LSTM layers are very successful at learning long-range dependencies due to their internal memory, which can hold critical data. This internal memory leverages additive and subtractive gates, known as the input gate and the forget gate, respectively. These gates are mathematical functions that can learn to store useful information in the internal memory while discarding irrelevant information. Also, LSTM layers can handle sequences of different lengths, which is crucial for this project because each trial from each participant is a different length of time, ranging from roughly 10 to 40 seconds. Unlike the CNN and MLP models, which required a fixed input size of 4000×12 (accomplished with zero-padding), all of the LSTM layers were able to utilize that data of different input lengths, and all zero-padding on the data was removed before being input into the LSTM during training and testing. This likely improved accuracy even more because the layers were not forced to handle meaningless data in the form of zeros.

It also seems that the CNN-AE model did somewhat better during the patient-wise test compared to the cross-validation test. This might be explained by the slightly larger amount of training data it had access to; during cross-validation, 10% of the dataset was always excluded for testing, whereas with the patient-wise test, excluding 1 participant is closer to excluding ~1% - 2% of the dataset. This may also explain why the CNN+LSTM model did better during the patient-wise testing, as the larger dataset may have helped the model avoid overfitting. Overall, these are all critical factors to consider in the future when designing a deep learning model that will use medical or cognitive data. Proper fine-tuning of a model can allow for significantly less resource usage and better performance overall.

Comparison to Prior Work

It is also worth noting that in our previous paper [20], we broke down our raw data into a set of useful statistics, such as reaction time, total displacement, average and max velocity, time to peak velocity, and more. We used 1-way ANOVAs to determine that children with ASD had significant differences in reaction time, velocity, acceleration, and total displacement. Compared to TD children, the children with ASD had a slightly longer average reaction time and significantly higher acceleration values, leading to a higher peak velocity. This corresponds to the children with ASD having an increased number of movement subunits (micro-adjustments in path during the reaching motions). Finally, children with ASD had a significantly higher

XSL•FO
RenderX

total displacement during the task. Using this information, we have been able to conclude that the hardest motion patterns for our model to detect were the ones with the most similarity to TD children, with smoother movements and less movement subunits, more consistent accelerations, and a slightly slower peak velocity. Trials where a child with ASD might have really focused and avoided a slower reaction time or finished with a normal total displacement tended to make classification harder. Equally, cases with TD children where they might have been distracted, leading to increased movement jerkiness (increased movement subunits), also caused classification issues. It also seems likely that having each child perform the task multiple times gave the children time to learn and get better at the task, bringing the TD and ASD classes a bit closer together and harder to discriminate between. The consideration of these specific movement features is important for the future design of a physical motor task to better exemplify the differences between ASD and TD goal-based movement.

Limitations

First, an important limitation of this study is the lack of a larger dataset containing a more diverse group of children. With only 41 participants, our model is unlikely to generalize well enough to function as a true diagnostic measure; it does, however, show the need for more robust research. Only one-third of our trials were of TD children; the rest were of individuals with ASD, which we attempted to mitigate by using specialized data balancing techniques to ensure that they would reach a generalization. These models would likely work significantly better if we were able to gather data from more TD children to ensure the true range of neurodivergence is recognized by the model. Increasing the size of the dataset would certainly increase its capability to generalize to new patients and likely reduce the number of false-positive and false-negative results. An even class distribution also eliminates the need for either data augmentation or data balancing methods, which can decrease the complexity of models and reduce the possibility for the introduction of errors and data leakage. Moreover, we did not exclude children with comorbid developmental disorders from the ASD group. While this approach enhances the ecological validity of our findings, it limits our ability to identify movement patterns specific to children with ASD. Future studies that will include participants with varying diagnoses are needed to further explore differences in movement characteristics between children with ASD and those with other developmental conditions.

Second, another limitation of this study was the equipment used to train and test these models. We were limited by run time and VRAM limits when attempting to test more complex networks. It is possible a larger LSTM section attached to the other models could achieve even better results. It might even be possible to build an LSTM-only model that rivals the ones built in this study, but it would require more powerful hardware to prototype a model like this. This is also true of a similarly built transformer classifier, where a transformer built to the limitations of our equipment was unable to perform with significant accuracy, but a much larger transformer might be able to achieve the same or better results. This limitation can also be seen as an advantage, as the small-scale custom models like the CNN-AE developed here require a significantly smaller amount of VRAM. This is a critical consideration as graphics processing unit prices continue to rise; access to powerful AI does not need to be gated by unnecessary costs for larger models that are not significantly more effective than cleverly designed small models.

Third, one final limitation worth considering is the lack of a comprehensive ablation study on these models. We attempted to tackle this problem in Table 1, which represents a fairly rigorous examination of general model hyperparameters such as layer count and neuron count. Unfortunately, this work falls short as it does not specifically validate other choices made such as the use of LeakyRelu activation functions, among other choices. Future work should consider performing an ablation study on these models and the data preprocessing steps to help break down which components and parameters of the models are critical for high accuracy results. Primary targets for the ablation study should be testing the effectiveness of the *z* scoring and min-maxing steps during normalization, as well as altering the number of points used in the moving average. Also worth testing is the number of batch normalization layers; the model may only need 1 or 2 of these layers, rather than the current model setups where every single layer is followed by a normalization. Overall, based on the testing performed during the prototyping phase, we are reasonably confident that the changes mentioned here would have only a minor effect on outcome accuracy.

Future Directions

It is important to consider the context in which models like these might be used to aid the diagnosis of children with ASD. Considering the possible harm of false-positive and false-negative results is a top priority; a false-positive result could lead to unnecessary spending by parents and self-doubt among children diagnosed, while a false negative could lead to a child missing out on critical care during the most important period of their life. For these reasons, a high F_1-score of 90.02% is another critical metric that shows our models are very effective, showing that the CNN-AE+LSTM model can avoid generating false-positive and false-negative results in most scenarios. For future work, there are some other important methods that could mitigate the effects of a false-positive diagnosis. This kind of diagnostic AI should be combined with the same behavioral interviews that children go through now (where the doctor performing the interview should not know the diagnosis provided by AI to avoid bias). In addition, continuing research should focus on using similar models to classify the severity of ASD rather than just producing a diagnosis. This could further limit the problems caused by a false-positive result, allowing doctors to correctly interpret the model results during the many cases when a diagnostic AI does not have a proper yes or no answer for a specific patient. ASD is a spectrum after all, so ensuring our models reflect this is a critical next step to this research. If the primary problems caused by a false-positive result can be mitigated in these ways, it may be possible to train our models to target and remove false-negative results, even at the expense of slightly more false-positive results that need to be caught by doctors during the process. Of course, the ideal goal would be to eliminate all false-positive results along with all false-negative results.

XSL•FO
RenderX

In the future, this research could be continued by collecting a larger dataset from a more diverse group of children with ASD and TD children, which would improve the robustness of the model. Additionally, further analysis could be performed on various kinematic variables, such as submovement stops, an atypical movement characteristic often observed in children with ASD [25,26]. This would aid in developing the most effective motor task for diagnosing children with ASD. Future work should also look at alternative methods of time series data analysis; clever techniques like using the Time Series Feature Extraction Library might be able to provide significant improvements to the LSTM portion of our models. Finally, future studies could explore the use of deep learning approaches to classify children with and without ASD based on additional data such as behavioral data (eg, eye tracking), or even physiological data (eg, heart rate and blood pressure) using small noninvasive recording devices.

Conclusions

This study evaluated the effectiveness of several small-scale deep learning models for classifying children with and without ASD using IMU-based hand tracking data collected during a goal-directed motor task. Across all architectures tested, the CNN-AE+LSTM consistently achieved the highest performance, reaching an F_1-score of 93.66% on unseen participant data. These results support the hypothesis that differences in motor behaviors between TD children and children with ASD can be detected using IMU-based hand tracking.

In contrast to the prevailing trend of retraining large-scale pretrained models, this work demonstrates that compact models with random initializations may also be effective for handling classification tasks involving goal-directed motor behavior.

Abstract

Background: Syndrome differentiation in traditional Chinese medicine (TCM) is an ancient principle that guides disease diagnosis and treatment. Among these, the cold and hot syndromes play a crucial role in identifying the nature of the disease and guiding the treatment of viral pneumonia. However, differentiating between cold and hot syndromes is often considered esoteric. Machine learning offers a promising avenue for clinicians to identify these syndromes more accurately, thereby supporting more informed clinical decision-making in the treatment.

Objective: This study aims to construct a diagnostic model for differentiating cold and hot syndromes in viral pneumonia by integrating TCM and modern medical features using machine learning methods.

Methods: The application of 8 machine learning algorithms (gradient boosting machine [GBM], logistic regression, random forest, extreme gradient boosting [XGB], light gradient boosting machine [LGB], ridge regression, least absolute shrinkage and selection operator, and support vector machine) generated and validated (both internally and externally) a model for differentiating cold and hot syndromes in viral pneumonia, based on clinical data from 1484 patient samples collected at 2 medical centers between 2021 and 2022.

Results: The GBM model, which combines TCM and modern medicine features, outperformed models using only TCM features or only modern medicine features in distinguishing cold and hot syndromes in patients with viral pneumonia. The optimal discrimination model comprised 13 optimal features (temperature, red cell distribution width-SD, creatinine, total bilirubin, globulin, C-reactive protein, unconjugated bilirubin, white blood cell, neutrophil percentage, aspartate transaminase/alanine transaminase, total cholesterol, thrombocytocrit, and age) and the GBM algorithm, achieving an area under the curve (AUC) of 0.7788. Under internal and external testing, the AUCs were 0.7645 and 0.8428, respectively. Moreover, significant differences were observed between the cold and hot syndrome groups in temperature (P=.02), red cell distribution width-SD (P<.001), neutrophil percentage (P=.01), total cholesterol (P=.003), thrombocytocrit (P<.001), and age (P<.001).

Conclusions: This pioneering study integrates the theory of TCM cold and hot syndromes with modern laboratory-based tests through machine learning. The developed model offers a novel approach for differentiating cold and hot syndromes in viral pneumonia, enabling practitioners to identify the syndrome quickly and efficiently, thereby supporting more informed clinical decision-making. Additionally, this research provides new insights into the modernization and scientific interpretation of TCM syndrome differentiation.

Introduction

Traditional Chinese medicine (TCM), a personalized and holistic approach, treats diseases using natural medical products tailored to a patient's TCM syndrome patterns [1], that is, dialectical treatment of TCM. Specifically, TCM syndrome, a concept unique to TCM, is an abstraction of a variety of signs and symptoms. Dialectical treatment is the fundamental principle by which physicians diagnose, understand, and treat diseases. It involves comprehensively collecting patients' clinical signs and symptoms through "inspection, auscultation, olfaction, inquiry, and palpation" to determine the TCM syndrome pattern. Subsequently, corresponding therapies, such as acupuncture, cupping, qigong, massage, and diet, are selected [2] to correct maladjustments and restore the body's self-regulatory ability [3,4]. Guided by this unique principle, TCM has demonstrated remarkable clinical efficacy in treating various acute and chronic diseases, thus attracting increasing attention [5]. Especially in the fight against viral pneumonia, the importance of TCM has been widely recognized [6,7]. Consequently, promptly and accurately understanding the TCM syndrome pattern of a disease can reshape global health and welfare.

In recent years, with the successive outbreaks of SARS, influenza A (H1N1), influenza A (H7N9), COVID-19, and other viruses, viral pneumonia has become a sustained and widespread disease burden in many countries and globally. As with other diseases, the accurate identification of syndrome patterns is a prerequisite for the TCM-based prevention and treatment of viral pneumonia. Numerous studies have reported that the cold and hot syndromes are the pivotal TCM syndrome patterns in cases of viral pneumonia, such as SARS and COVID-19 [8-10]. Cold and hot syndromes, originating from the *Huangdi Neijing*, are 2 key components of the Eight Principle Syndromes—the general principles of dialectical treatment, which include cold and hot, sthenia and asthenia, exterior and interior, and yin and yang—and are used to identify the nature of a disease, reflecting disruptions in body homeostasis [11-13]. Cold syndrome–related expressions include coldness, cold pain, tastelessness, and clear, abundant urine, whereas hot syndrome is mainly characterized by heat, diaphoresis, a flushed face, burning pain, and deep-colored urine. The cold and hot syndrome framework has been widely applied in the diagnosis and treatment of viral pneumonia. Treating cold and hot syndromes within TCM has been shown to significantly alleviate clinical symptoms in patients with viral pneumonia [8,14]. For example, symptomatic treatments with Chinese medicines such as Lianhua Qingwen capsules and Xuanfeibaidu granules can markedly reduce the incidence of severe or critical events and improve clinical recovery [6,7], indicating that the prediction and differentiation of cold and hot syndromes play a vital role in the treatment of viral pneumonia.

Nevertheless, although clinical data and studies have indicated that TCM treatments for the cold and hot syndromes of viral pneumonia are effective, a major challenge remains in distinguishing between these syndromes—similar to the challenges in identifying other TCM syndrome patterns. Specifically, (1) the differentiation of cold and hot syndrome is recondite and lacks a solid scientific foundation in classical TCM theory, and (2) the accuracy of cold and hot syndrome diagnosis in TCM relies heavily on the physicians' skills and years of clinical experience. Subjective factors play a decisive role in TCM diagnosis, which inevitably leads to a lack of standardized criteria and an objective diagnostic basis for cold and hot syndromes. This unique diagnostic model not only supports the open and divergent development of TCM, but also hinders the understanding of cold and hot syndromes in viral pneumonia from a modern biomedical perspective. It further restricts the domestic and international dissemination of TCM syndrome differentiation, making it one of the key bottlenecks in the development of TCM. Therefore, in the process of integrating TCM with modern medicine, it is worth considering how to combine TCM syndrome theory with modern medicine to enhance the scientific rigor and objectivity of cold and hot syndrome differentiation in the treatment of viral pneumonia.

Recently, with the rapid development of machine learning [15-18], artificial intelligence has brought unprecedented challenges and opportunities to the diagnosis of TCM syndrome. Interdisciplinary models combining TCM and artificial intelligence have been proposed to model TCM knowledge, diagnosis, and treatment in clinical practice. Among these, numerous models have been developed to simulate the syndrome differentiation process of human TCM doctors for automatic syndrome diagnosis. For example, Huang et al [19] successfully identified the liver-gallbladder dampness-heat syndrome in patients with breast cancer using a dataset based on the prescriptions of TCM clinical practitioners. Zhuo et al [20] effectively differentiated Qi deficiency blood stasis syndrome and phlegm stasis in channels syndrome in patients with stroke through artificial intelligence–assisted retinal feature analysis. These examples demonstrate that machine learning enables a modern interpretation of the scientific connotation of TCM syndrome differentiation, supporting improved clinical decision-making in disease treatment. However, currently, there is still a lack of machine learning–based differentiation of cold and hot syndromes in viral pneumonia.

Among the machine learning algorithms in artificial intelligence, gradient boosting machine (GBM), logistic regression (LR), random forest (RF), extreme gradient boosting (XGB), and light gradient boosting machine (LGB), among others, have demonstrated promising performance [21-24]. Consequently, this study aimed to compare 8 machine learning methods, namely, GBM, LR, RF, XGB, LGB, ridge regression (RIDGE), least absolute shrinkage and selection operator (LASSO), and support vector machine (SVM), by integrating laboratory test indicators from modern medicine with the TCM cold and hot syndrome, to explore the connection between them and construct

XSL•FO
RenderX

a diagnostic model for differentiating the cold and hot syndromes in viral pneumonia. This approach seeks to provide a new diagnostic method for the clinical differentiation of cold and hot syndromes in viral pneumonia and to offer new perspectives for the scientization, standardization, and objectivity of TCM syndrome differentiation theory in guiding treatment.

Methods

Source of Materials

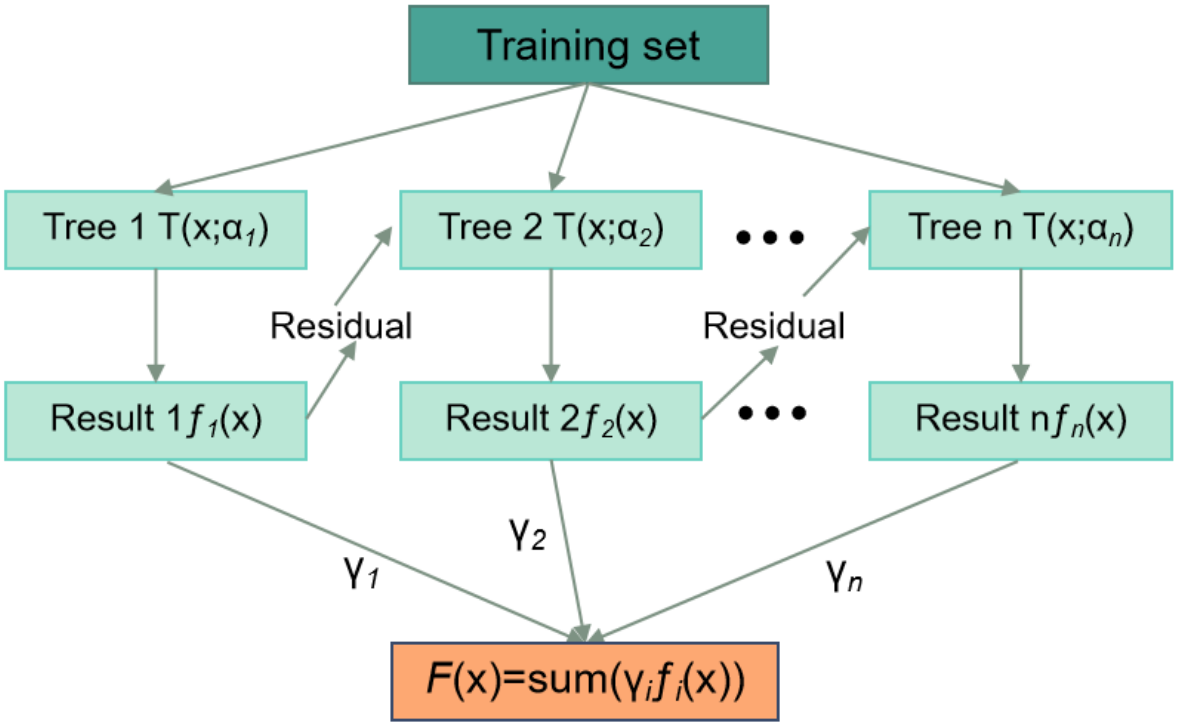
In this study, a retrospective review of case sheets was conducted on samples from 1401 patients diagnosed with viral pneumonia between January 18 and November 6, 2021, at the Second People's Hospital of Lanzhou City in China. Samples were excluded based on the following criteria: (1) the diagnosis was not made using the Eight Principle Syndromes of TCM, and (2) the patient was diagnosed with both cold and hot syndrome patterns simultaneously. A total of 602 samples met the inclusion criteria. Samples with more than 20% (ie, 19/93 features) missing values were further excluded, resulting in 382 samples ultimately included for analysis. These comprised 97 negative samples (cold syndrome) and 285 positive samples (hot syndrome). Additionally, a stratified sampling strategy was applied to split the original dataset into training and internal test cohorts at an 8:2 ratio (details are provided in the "Performance Evaluation and Model Validation" section).

The external test cohort consisted of 83 patients with viral pneumonia diagnosed with either cold or hot syndrome at Lanzhou Heavy Ion Hospital between July and August 2022. This cohort included 36 patients with the hot syndrome and 47 patients with the cold syndrome.

TCM and Modern Medicine Features Collection and Cold and Hot Syndrome Diagnosis

As shown in Multimedia Appendix 1, a total of 93 features related to TCM and modern medicine were collected in this study, including 4 general information items, 19 TCM symptoms, 2 blood gas values, 10 viral pneumonia indicators, 27 biochemical indicators, 30 blood routine indicators, and 1 coagulation indicator. Among these, patients' TCM symptoms were further quantified using a TCM symptom scoring scale for viral pneumonia (Multimedia Appendix 2).

All patients with viral pneumonia were independently diagnosed with either the TCM cold or hot syndrome by 2 TCM chief physicians. If both physicians provided the same diagnosis, the patient was enrolled. In cases of disagreement, a third investigator participated in the discussion to reach a consensus. The diagnostic criteria for syndrome differentiation were based on the textbooks *TCM Diagnostics* [25] and *Guiding Principles of Clinical Research on New Drugs of Traditional Chinese Medicine* [26]. These criteria include the 4 classical diagnostic methods used to determine TCM cold and hot syndrome patterns: inspection, auscultation, inquiry, and palpation, to accurately record the TCM characteristics.



Model Training

In this study, 8 machine learning algorithms (GBM, LR, RF, XGB, LGB, RIDGE, LASSO, and SVM) were used to train a dataset containing all features, and GBM was selected as the final classification model. As shown in Figure 1, GBM operates on the principle of ensemble learning, constructing the final prediction model by iteratively training a series of weak learners, typically decision trees. The core mechanism of GBM lies in its ability to correct the prediction errors of previous decision trees. Each newly generated decision tree is trained to fit the residuals—the differences between the actual values and the predicted values—of the previous model, thereby continuously reducing the overall loss function. Specifically, GBM begins by constructing an initial decision tree based on the training data, and then calculates the prediction error of this tree. A second tree is built to model the residuals, with its predictions aimed at correcting the deficiencies of the first tree. This process continues iteratively until a preset number of iterations is reached or a stopping condition is met. Figure 1 illustrates the structure and decision-making process of multiple decision trees in the GBM model. Each decision tree branches based on input features, and the final prediction is obtained through a weighted sum of the predictions from all individual trees.

The number of top-ranking indexes was gradually increased, and the hyperparameters n_estimators and max_depth were tuned. The final model consisted of 13 top-ranking features, with n_estimators and max_depth set to 797 and 8, respectively. The GBM was implemented using the scikit-learn library (version 0.24.1) in Python (version 3.8.8; Python Foundation).

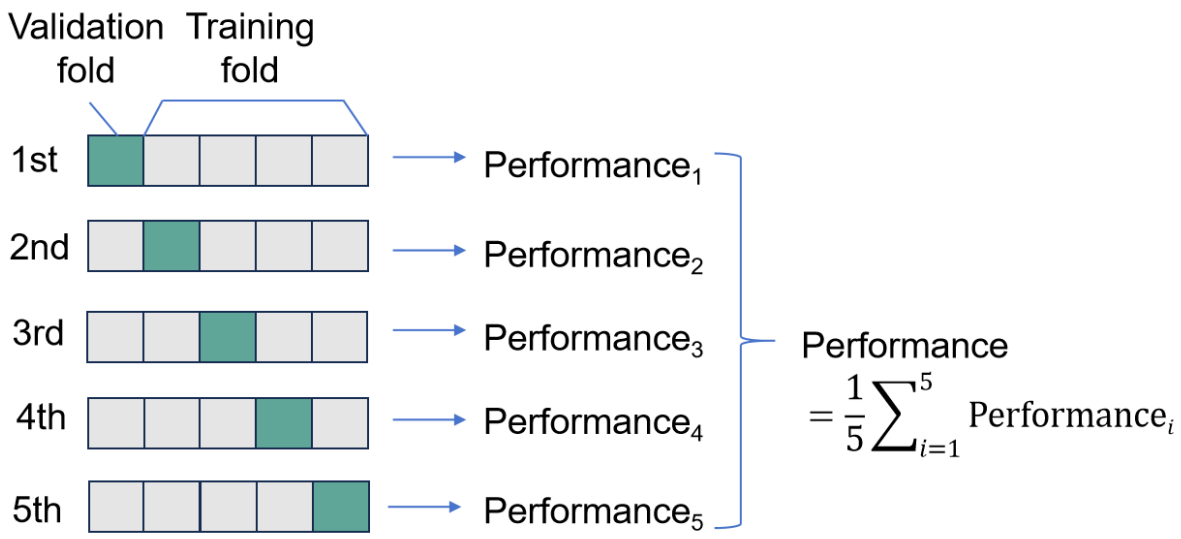
Optimal Feature Ascertainment

"Feature importance," "coef," and "SHAP values" are 3 commonly used methods to assess the relationship between features and machine learning models, and they have received significant attention in recent research [27]. These methods calculate the relevance of each feature to the model's predictions, which are then ranked in descending order to produce a feature importance ranking.

In tree-based models (eg, GBM, RF, XGB, LGB), feature importance is typically evaluated from 2 perspectives: split count and split gain. Split count refers to how often a particular feature is selected as a splitting point during tree construction; a higher count indicates greater importance. By contrast, split gain measures the improvement in the model's objective function (eg, squared error loss) resulting from splitting on a given feature. A larger gain implies a greater contribution to model performance and hence higher importance. Additionally, SHAP (Shapley Additive Explanations) values offer a unified measure of feature importance based on game theory by calculating the marginal contribution of each feature to the model's prediction. SHAP values provide both global and local interpretability of the model. In linear models (eg, RIDGE, LASSO, SVM, and LR), "coef" represents the coefficients assigned to each feature. These coefficients indicate the strength and direction of the linear relationship between each feature and the target variable. SHAP values can complement these coefficients by revealing nonlinear effects and feature interactions that may not be captured by standard linear models.

The insights gained from these methods, especially when combining traditional feature importance metrics with SHAP analysis, can aid researchers in uncovering hidden data patterns and insights, thereby supporting scientific investigations and informing practical applications. Accordingly, these methods are used to rank the feature importance for cold and hot syndromes of viral pneumonia and to ascertain the optimal features.

Performance Evaluation and Model Validation



During the data preprocessing stage, a stratified sampling strategy was adopted to divide the original dataset, ensuring an 8:2 ratio between the training and validation sets. This approach preserved the proportional distribution of each class (cold and hot syndromes) as in the original dataset, thereby avoiding model evaluation bias due to imbalanced category distributions.

Given the relatively small sample size, 5-fold cross-validation was applied to ensure model accuracy and reliability. As illustrated in Figure 2, the dataset was divided into 5 nonoverlapping subsets of equal size. In each round of validation, 1 subset was selected as the validation set (the blue portion in the figure), while the remaining 4 subsets constituted the training set (gray portions). This process was repeated for 5 rounds. In the first round, the first subset was the validation set, and the remaining 4 were used as the training set, resulting in Performance_1. In the second round, the second subset was used for validation, and so on, resulting in Performance_2 through Performance_5. The final model performance was calculated as the average of these 5 evaluation results, with the formula $\text{Performance} = \sum i = 15\text{Performancei}$. This strategy ensured that each sample was used for both training and validation, reduced the variance caused by random sample

XSL•FO
RenderX

division, and improved the robustness and reliability of the model evaluation [28].

Figure 2. The 5-fold cross-validation process diagram.

In addition, a comprehensive evaluation of the model was conducted using commonly used metrics, including sensitivity, specificity (SPE), accuracy (ACC), Matthews correlation coefficient (MCC), and area under the curve (AUC). These metrics are calculated based on the values of true positives (TPs), true negatives (TNs), false positives (FPs), and false negatives (FNs), as defined below:

(1)Sens=TP+FNTP

(2)Spec=TNTN+FP

(3)ACC=TP+TNTP+TN+FP+FN

(4)MCC=TP·TN−FP·FN(TP+FP)(TP+FN)(TN+FP)(TN+FN)

The receiver operating characteristic curve, also known as the sensitivity curve, is a graphical representation of the performance of a classification model across various evaluation thresholds. It plots the true-positive rate against the false-positive rate at different threshold settings. The true-positive rate reflects the proportion of actual positive cases correctly identified by the model, while the false-positive rate represents the proportion of negative cases incorrectly classified as positive. The AUC provides a single summary metric of the classifier's overall performance, with values ranging from 0 to 1. A higher AUC value indicates better classification performance. Therefore, AUC is widely used as a standard metric to evaluate the performance of classification models. The formula for calculating AUC is as follows:

(5)AUC=∫01TPR(FDR) dFDR

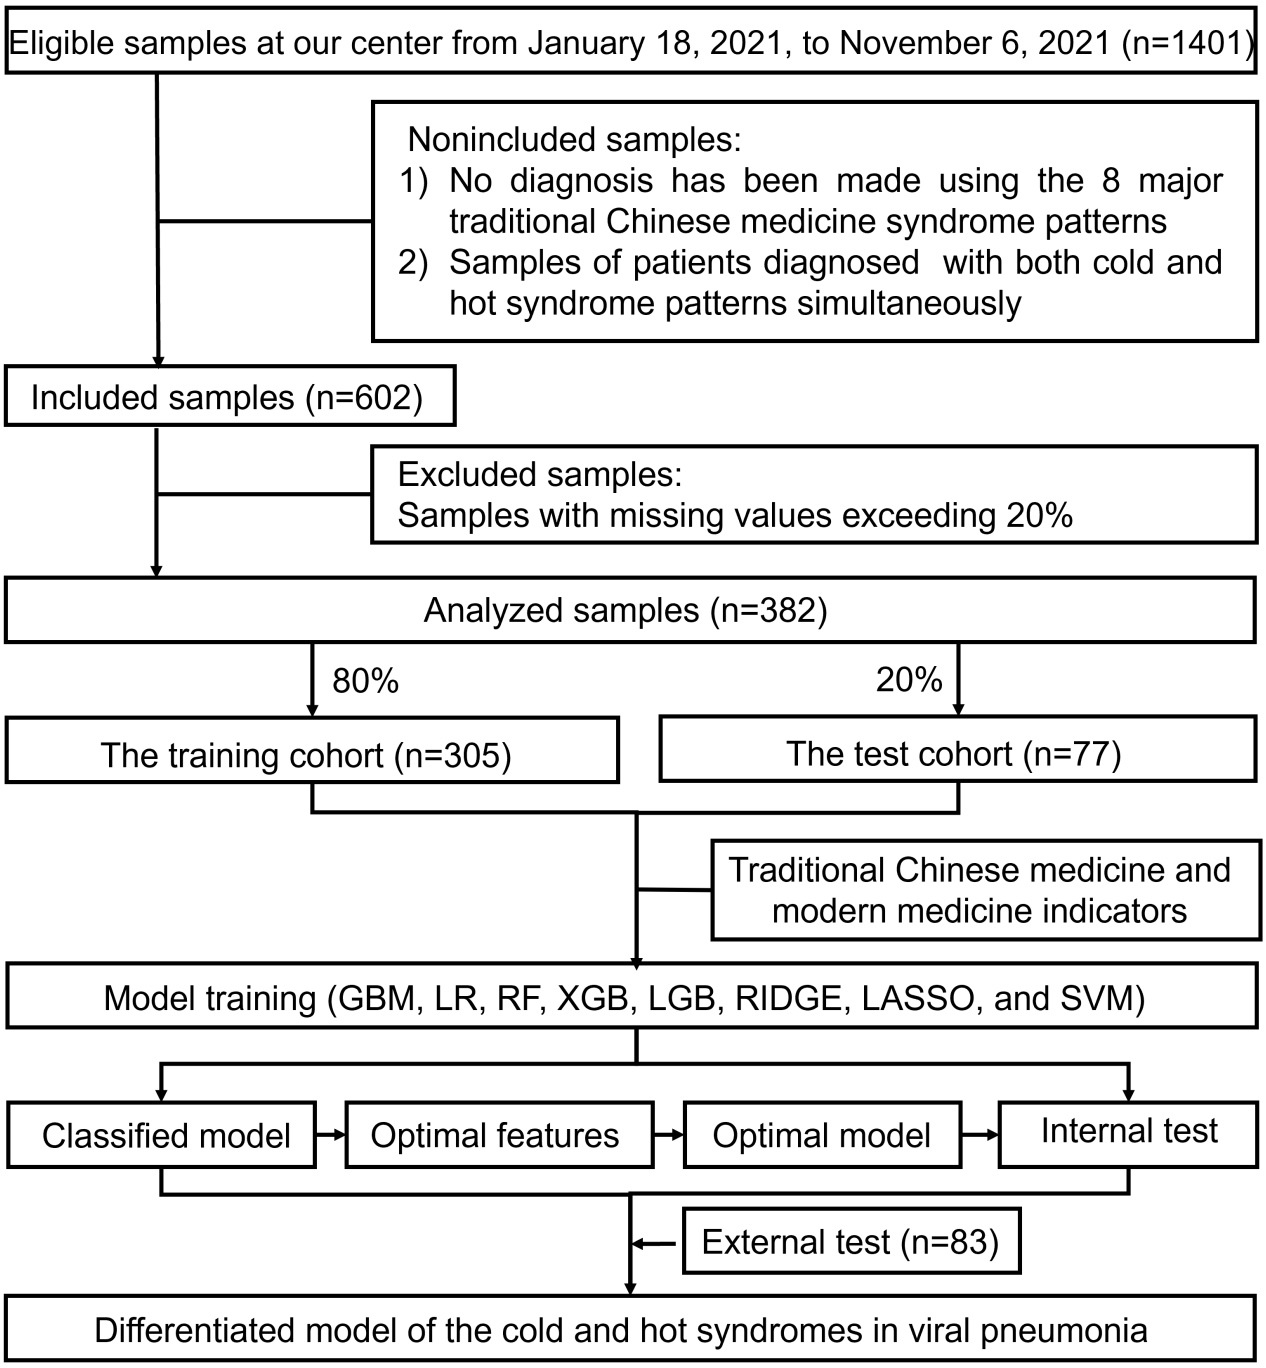
Ethical Considerations

The study was approved by the Medical Ethics Review Committee of the Second People's Hospital of Lanzhou City and Lanzhou Heavy Ion Hospital (approval number 2021-026-01). Informed consent was obtained on an opt-out basis, and all data were anonymized. No financial or material incentives were provided to participants.

Statistical Analysis

All data were analyzed using SPSS version 27.0 (IBM Corp). Categorical variables are presented as counts and percentages, whereas continuous variables are reported as means and SDs or IQRs, as appropriate. Normality was assessed using the Kolmogorov-Smirnov test. Student 2-tailed *t* test was used to compare parametric continuous variables, while the Mann-Whitney *U* test was used for nonparametric variables, the χ^2 test was applied for categorical variables, and the Fisher exact test was used for 2×2 contingency tables. Binomial distribution tests were performed for each feature within the cold syndrome and hot syndrome groups. No correction for multiple comparisons was applied. A 2-sided $P<.05$ was considered statistically significant.

Results



Data Extraction

We included only individual samples from patients with viral pneumonia and excluded those that were not diagnosed using the Eight Principle Syndromes (cold and hot, sthenia and asthenia, exterior and interior, and yin and yang), as well as those simultaneously diagnosed with cold and hot syndrome. A total of 602 eligible samples were retained. Samples with more than 20% (ie, 19/93 features) missing values were further excluded, and the remaining missing values were imputed using the median of each variable. Ultimately, 382 complete samples were included in the final analysis and used to construct the mathematical model. The dataset was split into training and testing sets in an 8:2 ratio. Subsequently, by integrating indicators from TCM and modern medicine and applying 8

XSL•FO
RenderX

machine learning algorithms, we identified the optimal model for differentiating TCM cold-hot syndromes in viral pneumonia through 5-fold cross-validation. The model's performance was further assessed using an external validation cohort. The data processing workflow and model construction process are illustrated in Figure 3.

Figure 3. Research flow for data processing and predictive model construction. After preliminary screening of the collected data, 382 samples of patients with viral pneumonia with TCM cold and hot syndromes were obtained. The dataset was randomly divided into training and test sets in an 8:2 ratio. Traditional Chinese medicine and modern medical indicators were extracted through data processing and statistical analysis. The performance of the 8 machine learning models (gradient boosting machine [GBM], logistic regression [LR], random forest [RF], extreme gradient boosting [XGB], light gradient boosting machine [LGB], ridge regression, least absolute shrinkage and selection operator [LASSO], and support vector machine [SVM]) was evaluated. Based on a comprehensive evaluation of all models, the optimal classification algorithm and feature set were identified. The final model's performance was further assessed using internal and external test cohorts.

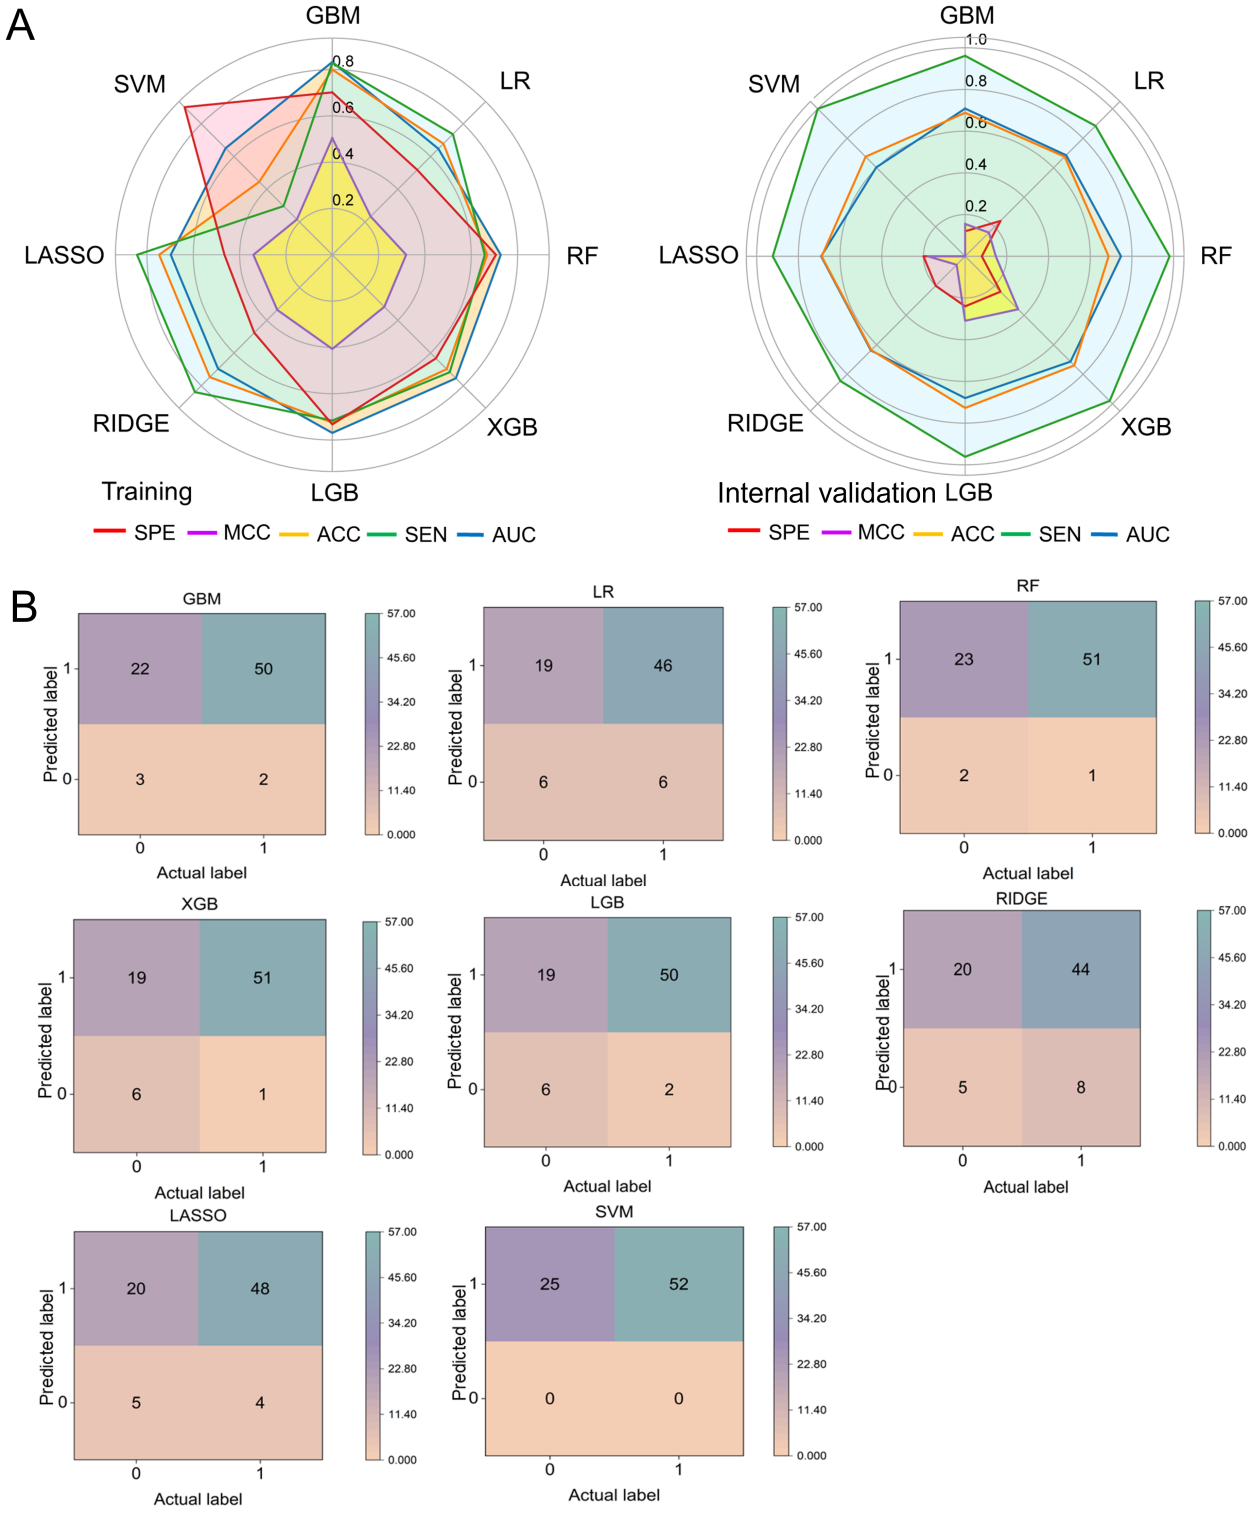
Model Training Based on TCM and Modern Medicine Features

Modern medical indicators based on laboratory testing provide the possibility for intelligent discrimination of TCM syndromes. Therefore, in this study, modern medical indicators were integrated with TCM features for further exploration. A total of 93 features were used to construct the model. The evaluation metrics for models using all 93 features are presented in Table 1 and Figure 4A. We found that GBM and LGB achieved the highest AUC scores of 0.8329 and 0.7693, respectively, indicating their superior overall discriminative performance.

XSL•FO
RenderX

GBM also obtained the highest ACC score of 0.8000, closely followed by RIDGE with a score of 0.7475, suggesting strong overall classification accuracy. LASSO, RIDGE, and GBM achieved the highest sensitivity scores of 0.8430, 0.8388, and 0.8283, respectively, indicating good performance in correctly identifying positive samples and reducing false negatives. SVM, LGB, RF, and GBM achieved the highest specificity scores, suggesting these models had the lowest false-positive rates. Both GBM and LGB also achieved relatively high MCC scores of 0.5043 and 0.4068, respectively, demonstrating their effectiveness in handling imbalanced datasets.

Internal validation showed that GBM, RF, and XGB achieved the highest AUC scores of 0.7085, 0.7477, and 0.7146, respectively. Additionally, we calculated the confusion matrix for each model in the internal validation cohort, as shown in Figure 4B. The sum of correctly predicted cold and hot samples reflects the overall predictive accuracy of each model. GBM, LR, RF, XGB, LGB, RIDGE, LASSO, and SVM correctly predicted 53, 52, 53, 57, 56, 49, 53, and 52 cold and hot samples, respectively. These findings further demonstrate the effectiveness of these models in distinguishing cold and heat patterns in viral pneumonia.



Overall, the results suggest that models incorporating both TCM and modern medicine features exhibit strong predictive performance for differentiating between cold and hot syndromes in viral pneumonia. Among them, the GBM algorithm demonstrated a particularly prominent discriminative capability. Therefore, GBM was selected as the optimal classified model based on the full set of 93 features for subsequent analysis.

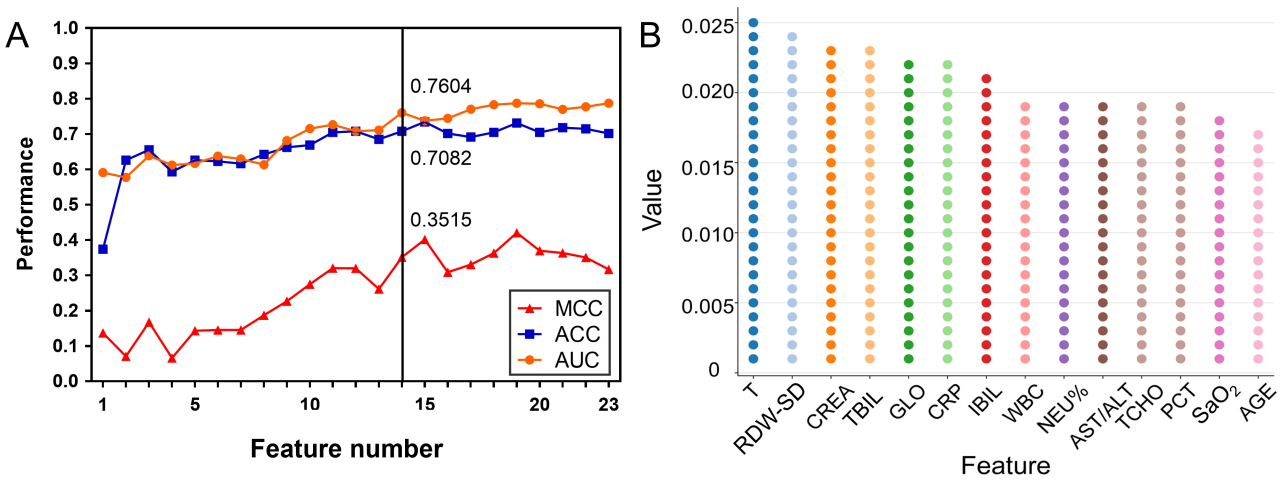
(B) Confusion matrix analysis of the 8 models in the internal validation cohort. ACC: accuracy; AUC: area under the curve; GBM: gradient boosting machine; LASSO: least absolute shrinkage and selection operator; LGB: light gradient boosting machine; LR: logistic regression; MCC: Matthews correlation coefficient; RF: random forest; RIDGE: ridge regression; SEN: sensitivity; SPE: specificity; SVM: support vector machine; XGB: extreme gradient boosting.

Optimal Feature Ascertainment

Based on the optimum classified model (GBM) and the ranking of "feature importance," we identified 23 key features with importance values more than twice the median. These were temperature (T), red cell distribution width-SD (RDW-SD), creatinine (CREA), total bilirubin (TBIL), globulin (GLO), C-reactive protein (CRP), unconjugated bilirubin (IBIL), white blood cell (WBC), neutrophil percentage (NEU%), aspartate transaminase/alanine transaminase (AST/ALT), total cholesterol



XSL•FO
RenderX

(TCHO), thrombocytocrit (PCT), oxygen saturation under load (SaO_2), age, platelets, mean platelet volume, lactate dehydrogenase, mean corpuscular hemoglobin concentration, urea, erythrocyte/red blood cell, Na, ORF1ab gene of novel coronavirus by nose test (nCovORF1ab), and albumin.

Subsequently, to identify the best-performing model with the fewest features, we examined how the number of top-ranked features influenced model performance (AUC, ACC, and MCC) using the GBM algorithm. As shown in Figure 5A and B, as the number of features increases, model performance gradually improves. Notably, at the 14-feature mark, the model achieved strong performance with an AUC of 0.7604, an ACC of 0.7082, and an MCC of 0.3515. To validate the robustness of our feature selection approach, we also used the SHAP feature importance ranking to select the top 14 features and construct a model. This model achieved an AUC of 0.7406, which was slightly lower than that obtained using the feature importance method (0.7604). Therefore, the feature importance method was ultimately retained as the feature selection approach for this study.

Finally, considering both the practicality of indicator testing and the feasibility of the clinical application, this study selected the top 14 features, excluding SaO_2 (under load), as the optimal set for differentiating between cold and hot syndromes in viral pneumonia. These features are temperature (T), RDW-SD, CREA, TBIL, GLO, CRP, IBIL, WBC, NEU%, AST/ALT, TCHO, PCT, and age (AGE), as illustrated in (Multimedia Appendix 3).

Figure 5. Identification of key features based on feature importance analysis and model cross-validation. (A) Effect of the number of selected key features (n=23) on model performance using the gradient boosting machine (GBM) algorithm. (B) Feature importance scores of the top 14 key features identified by the GBM model. ACC: accuracy; AUC: area under the curve; AST/ALT: aspartate transaminase/alanine transaminase; CREA: creatinine; CRP: C-reactive protein; GLO: globulin; IBIL: unconjugated bilirubin; MCC: Matthews correlation coefficient; NEU%: neutrophil percentage; PCT: thrombocytocrit; RDW-SD: red cell distribution width-SD; SaO_2: oxygen saturation under load; T: temperature; TBIL: total bilirubin; TCHO: total cholesterol; WBC: white blood cell.

Performance Evaluation and Optimal Model Establishment

To achieve optimal GBM model performance, we reconstructed the GBM model based on 13 optimizing features. Ultimately, the model was adjusted to threshold=0.99999, n_estimators=797, max_depth=8, min_samples_split=2, and min_samples_leaf=1. Simultaneously, the performance of the model with 13 features was further evaluated using 5-fold cross-validation, and the results suggested that the model performance was outstanding, as the average AUC value reached 0.7788 (Figure 6A). Model verification results showed that the AUC was 0.7645 by the internal test cohort (Figure 6B). Furthermore, the additional external test results showed that the model performance for AUC, ACC, sensitivity, specificity, and MCC is 0.8428, 0.6627, 0.7222, 0.6170, and 0.3369, respectively. These results validated the excellent performance of the model.

Moreover, we found that the temperature in the hot syndrome group was significantly higher than in the cold syndrome group (P=.02). By contrast, RDW-SD (P<.001), NEU% (P=.01), TCHO (P=.003), PCT (P<.001), and AGE (P<.001) were significantly lower in the hot syndrome group compared with the cold syndrome group, as shown in Table 2 and Figure 7. These results align with previous studies, which have reported that temperature, AGE, CREA, and RDW-SD are closely associated with the severity of viral pneumonia [29-33], supporting the validity of our findings.

These results suggest that machine learning algorithms perform well in differentiating between TCM cold and hot syndromes in viral pneumonia. The optimal model was constructed using 13 key features (T, RDW-SD, CREA, TBIL, GLO, CRP, IBIL, WBC, NEU%, AST/ALT, TCHO, PCT, and AGE), combined with the GBM algorithm. Among these, temperature (T), RDW-SD, NEU%, TCHO, PCT, and AGE appear to be the most relevant features for predicting cold and hot syndrome.

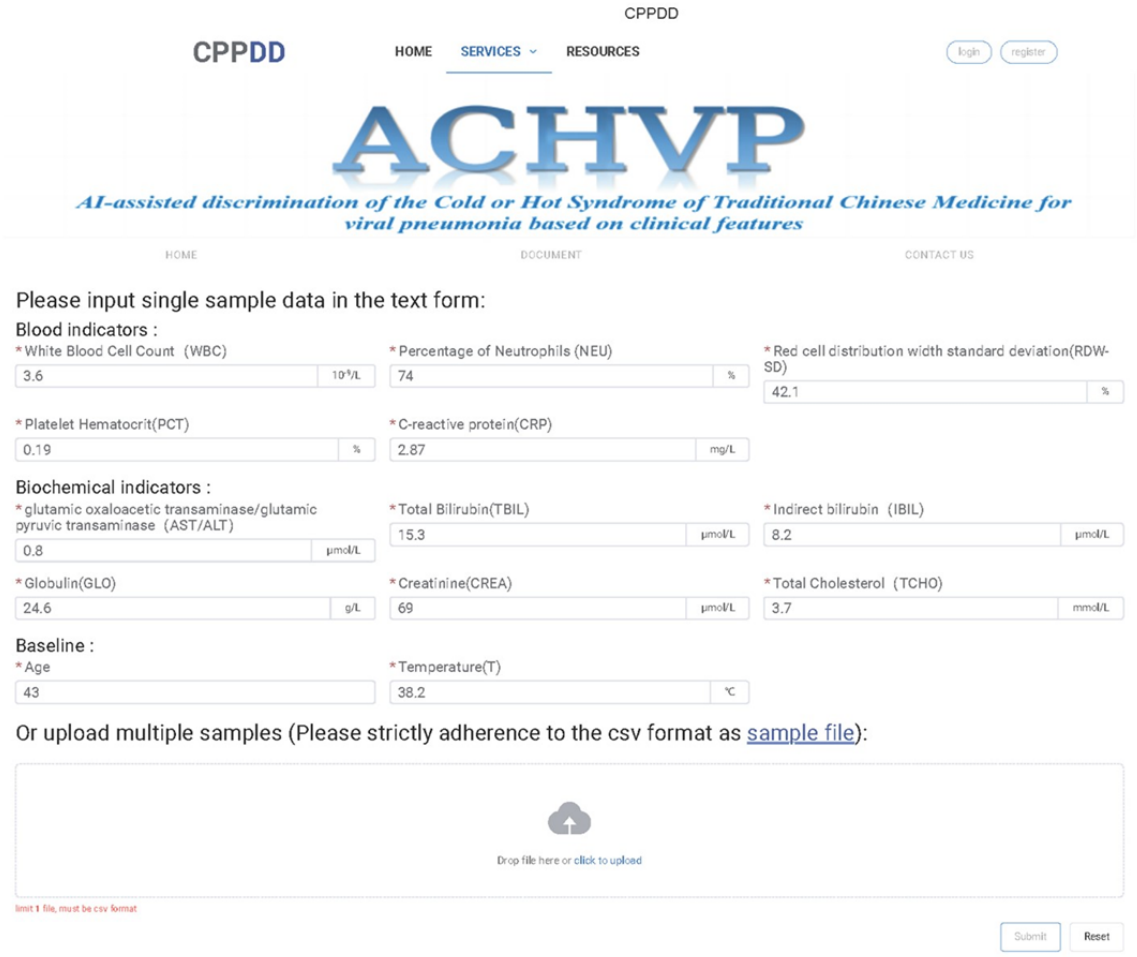
AST/ALT: aspartate transaminase/alanine transaminase; CREA: creatinine; CRP: C-reactive protein; GLO: globulin; IBIL: unconjugated bilirubin; NEU%: neutrophil percentage; ns: not significant; PCT: thrombocytocrit; RDW-SD: red cell distribution width-SD; T: temperature; TBIL: total bilirubin; TCHO: total cholesterol; WBC: white blood cell; *P<.05, **P<.01 versus the cold.



Interactive Web Server

To enhance user experience, an interactive web server named ACHVP was developed in this study, allowing users to test, explore, and experience the proposed method. The platform is designed to be highly convenient and user-friendly—users simply input relevant numerical data into designated textboxes and click the “Submit” button. The system then performs comprehensive data processing and analysis, presenting the predicted syndrome classification results on the output interface. The home page of the web server, developed for identifying cold and hot syndrome patterns in patients with viral pneumonia, is illustrated in Figure 8. The server is deployed in a Linux environment. The backend is developed in Python using the FastAPI framework to ensure efficient data processing and application programming interface management, while the front end is built with JavaScript and the Vue.js framework for a responsive and interactive user interface. Users can access the web server via any standard web browser, such as Google Chrome, Mozilla Firefox, or Safari, using the link specified in [34]. This web-based tool demonstrates significant potential as a practical diagnostic aid, facilitating early detection of cold and hot syndromes in patients with viral pneumonia. It can support TCM practitioners in syndrome differentiation and

Discussion

Principal Findings

Dialectical treatment is a fundamental principle in TCM for diagnosing and treating diseases, with cold and hot syndromes serving as 2 key components for identifying the nature of illness [11,35-38]. In recent years, the study of TCM cold and hot syndrome has become a focal point in disease research. Numerous studies have shown that cold and hot syndromes also exhibit major TCM diagnostic patterns in various viral pulmonary diseases, including COVID-19 and SARS [8,14]. Based on these syndrome classifications, TCM has demonstrated a prominent role in alleviating symptoms, shortening treatment duration, and reducing the progression to severe pneumonia in patients with viral pneumonia [39-43]. For example, formulas such as Hanshiyi for cold syndrome [44] and Jinhua Qinggan Granules for hot syndrome have shown favorable clinical efficacy [45]. Therefore, the rapid, accurate, and specific identification of cold or hold syndrome is essential for the effective application of TCM in the treatment of viral pulmonary diseases. However, the abstract and complex nature of TCM syndrome differentiation poses challenges in accurately distinguishing between cold and hot syndromes in clinical practice. Machine learning offers a promising solution to this challenge by supporting clinicians in syndrome differentiation and facilitating more precise treatment decisions. Consequently, there is an urgent need to integrate TCM theories of cold and hot syndromes with modern laboratory diagnostics and machine learning approaches to advance the modernized differentiation and treatment of viral pneumonia.

In this study, 8 machine learning algorithms were applied to develop and evaluate a model for differentiating TCM cold and hot syndromes in viral pneumonia, using clinical data from 1484 patients across 2 medical centers. Among the models incorporating both TCM and modern medical features, the GBM model demonstrated superior learning capability, achieving an AUC of 0.8329. This indicates that GBM was particularly effective in distinguishing cold and hot syndromes based on a given dataset. The “feature importance” method of the GBM model was subsequently used to rank all features, from which the top 13 features were selected based on the highest AUC value. To validate the model’s effectiveness and generalizability, both internal and external test sets were used, each demonstrating strong discriminatory performance. As a result, the optimal model was constructed using the GBM algorithm and 13 selected features (T, RDW-SD, CREA, TBIL, GLO, CRP, IBIL, WBC, NEU%, AST/ALT, TCHO, PCT, and AGE), achieving an AUC of 0.7788. These findings suggest that

XSL•FO
RenderX

effectively combining modern medical indicators, primarily based on laboratory tests, with TCM features primarily based on clinical observation may offer a viable pathway toward the modernization of TCM syndrome differentiation. This approach provides a foundation for the objectification and standardization of TCM diagnostic practices. Furthermore, the proposed model holds promise as a practical tool to assist clinicians in accurately identifying cold and hot syndromes in viral pneumonia, thereby informing appropriate and individualized treatment strategies.

Comparison With Prior Work

Machine learning, as an advanced artificial intelligence technology, has demonstrated broad potential in the field of "artificial intelligence+TCM diagnoses." For example, Zhang et al [46] proposed a comprehensive model using convolutional neural networks to classify 187 types of TCM diseases. Wen et al [47] also applied deep neural networks to identify tongue image data and determine patients' constitutions, effectively addressing the imbalance problem among constitution categories. However, limited research has focused on identifying TCM cold and hot syndromes in viral pneumonia by integrating both TCM theory and modern medicine through machine learning approaches. Although some scholars have attempted to explore the cold and hot attributes of diseases to guide clinical treatment, most studies have been limited to network analysis, clustering, or laboratory testing, without incorporating artificial intelligence methods. For instance, Li et al's [11] network analysis revealed that the leptin biomarker indicated low levels of energy metabolism in patients with cold syndrome, while the human monocyte chemoattractant protein-1 (CCL2/MCP1) biomarker suggested intensified immune regulation in patients with hot syndrome, based on a study involving patients with chronic superficial gastritis and chronic atrophic gastritis. Wang et al [13] differentiated heat and cold patterns in rheumatoid arthritis through cluster and factor analyses to guide clinical medication. Wu et al [48] investigated TCM cold and hot constitutions using pulse wave parameters such as augmentation index and heart rate variability. Although some individual studies have applied artificial intelligence to differentiate cold and hot properties, most efforts have been limited to identifying the properties of Chinese herbal medicines. For example, Lin et al [49] developed a classification strategy for the cold and hot properties of Chinese herbal medicines using artificial intelligence and biological experiments. Wei et al [50] applied machine learning techniques to intelligently identify the cold-hot nature of Chinese herbal medicines based on the similarity of their volatile oil ingredients. Therefore, this study innovatively constructs a model for differentiating cold and hot syndromes in viral pneumonia using machine learning approaches that integrate TCM and modern medicine, aiming to assist in diagnosis and medication guidance for viral pneumonia in clinical practice.

It is worth noting that in this study, we collected a large number of clinical features, including patients' symptoms, signs, laboratory examination results, and other relevant information, which were essential for training and testing the machine learning models. As shown in Table 3, based on the model training results using only 19 TCM features, we found that the AUC values of GBM, LR, RF, XGB, LGB, RIDGE, LASSO, and SVM were 0.6942, 0.6317, 0.6783, 0.6787, 0.6055, 0.6151, 0.6145, and 0.5874, respectively. Meanwhile, the study also attempted to build models using only 70 laboratory results. The AUC values for GBM, LR, RF, XGB, LGB, RIDGE, LASSO, and SVM were 0.6799, 0.6282, 0.6797, 0.6910, 0.7345, 0.6637, 0.6157, and 0.6618, respectively. Among them, the GBM model constructed using TCM features achieved an AUC of 0.6942, outperforming the GBM model constructed using laboratory features, which had an AUC of 0.6799. Internal validation and the confusion matrix results also demonstrated performance consistent with the training results, as shown in Multimedia Appendix 4. These findings suggest that the models possess auxiliary diagnostic value for differentiating TCM cold and hot syndromes in viral pneumonia.

Based on “feature importance” or “coef,” the 8 models were further used to evaluate the significance of TCM features in distinguishing cold and hot syndromes of viral pneumonia. We found that, according to the significance values, there were 7 common features with importance values equal to or greater than the median in the GBM, RF, XGB, and LGB models, namely, fatigue, sore throat, fever, expectoration, cough, body pain, and diminished sense of smell. Interestingly, sore throat and fever also appeared among the features with importance values equal to or greater than the median in LR, RIDGE, LASSO, and SVM models. Based on this, we believe that fatigue, sore throat, fever, expectoration, cough, body pain, and diminished sense of smell may be the primary distinguishing factors for differentiating between cold and hot syndromes in the TCM diagnosis of viral pneumonia, which aligns with the key symptomatology commonly used by clinical TCM practitioners [51,52]. Therefore, more attention should be given to these features, especially sore throat and fever, in the discrimination of cold and hot syndromes in viral pneumonia, as shown in Multimedia Appendix 5. Unfortunately, the AUC values of these models did not exceed 0.7. We boldly speculate that this might be due to the quantification of TCM features not aligning with modern medical standards. Specifically, TCM features lack precise numerical values and are typically categorized as none, mild, moderate, or severe. Moreover, the identification of TCM features primarily relies on the subjective judgment of TCM practitioners and years of clinical experience, leading to a lack of standardization and objectivity. These factors may introduce noise and reduce the effectiveness of model training. Therefore, it is essential to develop objective indicators for TCM syndrome differentiation, further supporting the original intent of our study. In subsequent experiments, we integrated modern medicine features with TCM indicators and were pleasantly surprised to find that, compared with models trained solely on TCM features, those based on integrated TCM and modern medical features demonstrated superior performance in distinguishing cold and hot syndromes in viral pneumonia across 8 machine learning algorithms. This suggests that modern medical features can enhance the predictive value of TCM features.

In addition, the best model we developed indicated that the identification of cold and hot syndromes in viral pneumonia is

XSL•FO
RenderX

closely related to 13 features: temperature, RDW-SD, CREA, TBIL, GLO, CRP, IBIL, WBC, NEU%, AST/ALT, TCHO, PCT, and AGE. Numerous studies have reported that temperature (T), CRP, and WBC hold statistical significance in distinguishing TCM cold and hot syndromes in rheumatoid arthritis [53]. Furthermore, features such as AGE, NEU%, RDW-SD, and CRP are strongly associated with the severity of viral pneumonia and the development of chronic lung sequelae. For example, a study by Liu et al [33] suggested that AGE and NEU% could serve as predictive factors for the severity of viral pneumonia. Shen et al [31] also reported that RDW-SD is a key indicator for assessing the severity of viral pneumonia. Additionally, CRP and AGE play crucial roles in the diagnosis of viral pneumonia [54,55], which is consistent with the findings of this study.

Limitations

The accuracy of traditional TCM diagnosis of cold and hot syndromes largely depends on the skills and years of clinical experience of the practitioner. Subjective factors play a decisive role in this process. Compared with traditional TCM methods, the model developed in this study offers a more objective approach to differentiating cold and hot syndromes in viral pneumonia. It provides valuable decision support and medication guidance in clinical practice, especially for practitioners with limited TCM experience. This shift toward an objective, data-driven approach helps reduce reliance on subjective judgment, improves diagnostic accuracy, and ensures greater consistency in clinical decision-making. Additionally, the model can serve as a practical tool for TCM practitioners, especially in complex cases where traditional diagnostic methods may fall short.

Of course, this study has some limitations. First, it was a retrospective study, and all patient history data were obtained from the internal electronic medical record systems of the Second People's Hospital of Lanzhou and Lanzhou Heavy Ion Hospital. This may have introduced inaccuracies in the collection and recording of medical history, making it difficult to avoid information bias. Moreover, due to the limited clinical sample size, the conclusions, although statistically sound, require further validation and refinement in real-world applications to enhance the model's accuracy and stability.

In recent years, emerging large language models (LLMs) have demonstrated remarkable capabilities in natural language processing, knowledge integration, and complex reasoning [56]. Given the nature of TCM theory, which often involves complex textual descriptions and implicit knowledge, LLMs could potentially offer new perspectives for model development in this study. These models may better understand and integrate the rich, diverse information contained in TCM literature, clinical records, and expert knowledge, thereby enriching the feature set and enhancing the interpretability of the models. For instance, LLMs could analyze the semantic relationships among TCM symptoms, syndromes, and treatment methods, helping to extract more meaningful features that may be difficult to identify using traditional machine learning approaches. Moreover, LLMs could assist in standardizing and structuring the subjective and qualitative information in TCM, thereby reducing the impact of inconsistent data representation. However, applying LLMs also poses challenges, such as ensuring the reliability of the extracted knowledge, addressing potential biases inherent in pretrained models, and efficiently integrating LLM-derived features with existing laboratory test data. In future work, we plan to collect more data to establish a local database and explore the integration of LLMs with traditional machine learning algorithms. By fully leveraging the advantages of both approaches, we aim to further enhance the performance of the TCM cold and hot syndrome differentiation model and advance the modernization and standardization of TCM diagnosis.

Conclusion

This study aimed to establish a differentiation model for TCM cold and hot syndromes in patients with viral pneumonia using machine learning by exploring correlations between cold/hot syndromes and features from both TCM and modern medicine (such as general information, TCM characteristics, blood gas values, viral pneumonia indicators, biochemical indicators, routine blood test indicators, and coagulation indicators). We found that machine learning algorithms based on integrated TCM and modern medicine features outperformed models that used only TCM or only modern medicine features. Specifically, a model composed of 13 optimal features (T, RDW-SD, CREA, TBIL, GLO, CRP, IBIL, WBC, NEU%, AST/ALT, TCHO, PCT, and AGE) and the GBM algorithm effectively differentiated TCM syndromes. This study is the first to integrate the TCM cold and hot syndrome theory with laboratory-based modern medical tests using machine learning. By establishing the relationship between TCM syndrome theory (cold and hot syndromes) and indicators from both TCM and modern medicine, we aim to provide a new auxiliary diagnostic method for the clinical differentiation of cold and hot syndromes. This can support practitioners in making comprehensive diagnoses and identifying effective Chinese herbal medicine treatments, while also offering new insights for the modernization and scientific interpretation of TCM syndrome differentiation theory to guide treatment.

Abstract

Background: Wearable devices are increasingly used for monitoring health and detecting digital biomarkers related to chronic diseases such as metabolic syndrome (MetS). Although circadian rhythm disturbances are known to contribute to MetS, few studies have explored wearable-derived circadian biomarkers for MetS identification.

Objective: This study aimed to detect and analyze sleep and circadian rhythm biomarkers associated with MetS using step count and heart rate data from wearable devices and to identify the key biomarkers using explainable artificial intelligence (XAI).

Methods: Data were analyzed from 272 participants in the Korean Medicine Daejeon Citizen Cohort, collected between 2020 and 2023, including 88 participants with MetS and 184 without any MetS diagnostic criteria. Participants wore Fitbit Versa or Inspire 2 devices for at least 5 weekdays, providing minute-level heart rate, step count, and sleep data. A total of 26 indicators were derived, including sleep markers (midsleep time and total sleep time) and circadian rhythm markers (midline estimating statistic of rhythm, amplitude, interdaily stability, and relative amplitude). In addition, a novel circadian rhythm marker, continuous wavelet circadian rhythm energy (CCE), was proposed using continuous wavelet transform of heart rate signals. Statistical tests (*t* test and the Wilcoxon rank sum test) and machine learning models—Shapley Additive Explanations, explainable boosting machine, and tabular neural network—were applied to evaluate marker significance and importance.

Results: Circadian rhythm markers, especially heart rate–based indicators, showed stronger associations with MetS than sleep markers. The newly proposed CCE demonstrated the highest importance for MetS identification across all XAI models, with significantly lower values observed in the MetS group (P<.001). Other heart rate–based markers, including relative amplitude and low activity period, were also identified as important contributors. Although sleep markers did not reach statistical significance, some were recognized as secondary predictors in XAI-based analyses. The CCE marker maintained a high predictive value even when adjusting for age, sex, and BMI.

Conclusions: This study identified CCE and relative amplitude of heart rate as key circadian rhythm biomarkers for MetS monitoring, demonstrating their high importance across multiple XAI models. In contrast, traditional sleep markers showed limited significance, suggesting that circadian rhythm analysis may offer additional insights into MetS beyond sleep-related indicators. These findings highlight the potential of wearable-based circadian biomarkers for improving MetS assessment and management.

metabolic syndrome; wearable device; digital biomarker; circadian rhythm; explainable artificial intelligence

Introduction

Metabolic syndrome (MetS) is a multifaceted disorder that includes various metabolic conditions, such as obesity, hypertension, and diabetes. These conditions are becoming increasingly prevalent worldwide, posing significant concerns with profound implications for individual health, societal well-being, and the economy. Metabolic diseases involve complex pathophysiological mechanisms [1,2]. Promoting healthy eating habits, integrating appropriate physical activity, and effectively managing stress can significantly reduce the risk of developing MetS [1,3].

Currently, health management systems using wearable devices are gaining significant attention [4]. These systems offer personalized health care by continuously monitoring and analyzing the health status of an individual in real time. Wearable devices enable regular assessment of health-related indicators, eliminating the need for frequent hospital visits [2]. Achieving this requires the integration of various technologies, including semiconductors, artificial intelligence, and the Internet

RenderX

of Things [5]. Smartwatches and bands are among the most commonly used wearable devices in daily life. Smartwatches are equipped with diverse sensors such as optical heart rate (HR) monitors, electrocardiograms, and inertial sensors, enabling the collection of vital signs such as step count, HR, blood pressure, pulse, and oxygen saturation [5].

Wearable devices can continuously monitor an individual's vital signs in real time. This involves the continuous tracking of important indicators related to MetS, such as HR, blood pressure, and activity levels, aiding in the real-time assessment of an individual's health status and the early detection of anomalies [2,6]. The daily data generated by wearable devices can help identify factors influencing the onset and progression of MetS. Recently, there has been a significant increase in attention to the daily monitoring of sleep and circadian rhythms using wearable devices [7,8]. Circadian rhythms are biochemical, physiological, or behavioral processes that occur in living organisms in approximately 24-hour cycles. Circadian rhythm markers are indicators to assess or measure the circadian rhythm state of a living organism [8,9]. Sleep and circadian rhythm biomarkers derived from activity-based wearable devices are now applied in studies on various conditions, including obesity [7], depression [8,9], cognitive function [10], prematurity [11], and mortality [12]. Common sleep markers include sleep timing (sleep onset and sleep offset), sleep duration (total sleep time), midsleep time, and wake after sleep onset [7,8]. Circadian rhythm markers are assessed using both parametric methods, such as amplitude, acrophase, midline estimating statistic of rhythm (MESOR), and circadian quotient (CQ) via cosinor analysis [8,12], and nonparametric methods, such as interdaily stability (IS), intradaily variability (IV), and relative amplitude (RA) [9-11]. Given the periodic nature of circadian rhythms, energy-based methods have been proposed. For example, singular value decomposition (SVD) has been used to calculate energy values from activity data, suggesting potential markers for cognitive function [10]. Traditional methods for measuring signal energy, such as Fourier transform, discrete cosine transform, and wavelet analysis, have been used in various biosignal analysis studies [13]. In this study, we propose a novel marker called continuous wavelet circadian rhythm energy (CCE) using continuous wavelet transform (CWT) for time-frequency analysis of HR as a circadian rhythm marker.

Previously, circadian rhythm analysis using wrist-worn wearable devices focused on activity-centered markers through actigraphy [9,10,12]. However, recently, the demand for circadian rhythm analysis based on HR and step counts provided by smartwatches and bands has been increasing [7,8]. Wearable devices often underestimate and overestimate the number of steps in free-living environments. Therefore, circadian rhythm markers in this study were obtained by integrating 5 days of continuous data, which addressed inaccuracies in step count measurements by reflecting the overall trends in sleep and activity. In addition, this study can compensate for incorrectly measured step counts by exploring HR-based markers rather than step counts.

The majority of the previous studies detected everyday features obtained from wearable devices and analyzed the features limited to statistical techniques without incorporating artificial intelligence technology [9-12]. Explainable artificial intelligence (XAI) techniques that interpret predictive results are gaining attention in the analysis of biosignals and health care information [5,7]. Specifically, research on circadian rhythm analysis based on wearable devices in relation to MetS is still in its early stages. This area requires multifaceted analysis, including the development of circadian rhythm biomarkers specifically tailored for MetS and the application of XAI for data interpretation.

Therefore, in this study, we detected circadian rhythm markers based on step count and HR to develop a wearable-based circadian rhythm marker for MetS and analyzed circadian rhythm markers important for MetS through artificial intelligence technologies such as Shapley Additive Explanations (SHAP), explainable boosting machine (EBM), and Tabular neural Network models (TabNet). Integration with XAI in marker analysis can make the results more actionable in health care applications due to its transparency and interpretability.

Methods

Recruitment

The Korean Medicine Daejeon Citizen Cohort (KDCC) dataset was used to validate the proposed biomarker. The data from the KDCC, spanning from 2020 to 2023, encompassed demographic, lifestyle, clinical, and biochemical measurements collected from 2000 participants. Anthropometric data, including height, weight, BMI, waist circumference, and hip circumference, were measured under standardized conditions. Height and weight were recorded using a digital stadiometer (BSM370, InBody), and BMI was calculated as weight (kg) divided by the square of height (m^2). Waist circumference was measured at the level of the navel, and hip circumference was measured at the widest part of the hips using a measuring tape (Hoechstmass-Rollvix, Germany).

Systolic blood pressure, diastolic blood pressure, and resting HR were measured using an automatic blood pressure cuff (FT-500R PLUS, Jawon Medical, South Korea). Measurements were taken after at least 5 minutes of rest, with an additional 1-minute interval between repeated readings. The average of 2 measurements was used for analysis. Venous blood samples (22.5 mL) were collected in the morning after overnight fasting. After 30 minutes, blood samples were centrifuged at 3450 rpm for 10 minutes, and all samples were transported within 24 hours to Seoul Clinical Laboratories (Seoul, Korea) for analysis. The biochemical analysis included complete blood count, kidney and liver function tests, lipid profile (triglycerides, high-density lipoprotein, low-density lipoprotein, and total cholesterol), glucose metabolism markers, thyroid function tests, and inflammation markers [14].

Daily data was obtained using Fitbit Versa or Inspire 2 wristbands (Fitbit) [15]. Of the initial 2000 participants enrolled in the KDCC cohort, not all consented to wearable device use. Consequently, 745 participants provided usable Fitbit data. Participants who wore Fitbit for less than 5 consecutive weekdays or had data for more than 6 hours of nonwearing in a 24-hour period were excluded from the 745 participants.

XSL•FO
RenderX

Finally, 500 of the 745 participants were included in the analysis.

MetS was defined as meeting 3 or more of the following criteria, based on a 5-criteria system that uses the criteria described in the modified third national cholesterol education program adult treatment panel by modifying the waist circumference cutoff point for Koreans [15] in Textbox 1.

Textbox 1. Third National Cholesterol Education Program Adult Treatment Panel.

- Waist circumference (≥90 cm for men, ≥85 cm for women)
- Systolic blood pressure (≥130 mm Hg) or diastolic blood pressure (≥85 mm Hg), or current use of antihypertensive medications
- Low high-density lipoprotein cholesterol levels (<40 mg/dL in men and <50 mg/dL in women) or use of medication for lipid abnormalities
- Triglyceride level (≥150 mg/dL) or medication for lipid abnormalities
- Fasting blood glucose level (≥100 mg/dL) or medication for type 2 diabetes

Among 500 participants (158 males and 342 females), 88 participants (44 males and 44 females) met the criteria for MetS, and 184 participants (28 males and 156 females) did not meet any of the 5 criteria and were classified as non-MetS.

Ethical Considerations

This study was conducted following the Declaration of Helsinki and was approved by the institutional review board of Dunsan Korean Medicine Hospital, Daejeon University (approval number DJDSKH-17-BM-12) and the Korea Institute of Oriental Medicine (approval number I-1703/002 - 002). Before participation, all individuals provided written informed consent, including consent for collecting human biological materials. Participants were informed that they could withdraw their consent at any time without any consequences.

Participants received US $36 as compensation for transportation costs. Written consent was obtained from the individuals involved for the publication of potentially identifiable images or data. All included images were reviewed to ensure that personal identities could not be inferred. This study was designed and conducted in compliance with ethical standards for human research, ensuring participant rights, privacy, and safety throughout the study process.

Circadian Rhythm and Sleep Indicator

Wearable data included minute-level HR and step-count records collected from Fitbit devices. In addition, the sleep duration records provided by Fitbit were collected. Notably, the minute-level HR records from the Fitbit devices occasionally had missing values, represented by zeros. Missing values were converted to the nearest HR. Missing data mainly consisted of long periods of nonwearing, such as during charging or showering. Spline interpolation resulted in exaggerated patterns, such as sudden increases or decreases in HR during long periods of nonwearing. Given these considerations, linear interpolation was chosen to minimize distortion and better handle long intervals.

The most commonly used indicators in sleep analysis are midsleep time (MST), total sleep time (TST), and wake after sleep onset [7,8]. MST is used to determine phenotype, such as whether an individual is a morning or evening sleeper. Knowing MST and TST can reveal the amount of sleep and phenotype, but it does not provide information about sleep efficiency. Therefore, the ratio of total sleep time to total time spent in bed for sleep is used. However, it is difficult to estimate sleep efficiency with step count and HR data provided by Fitbit.

Cosinor analysis is frequently used to analyze circadian rhythms based on activity and HR. Cosinor analysis fits sine waves to time series using the least squares method [16]. It is often used in biological time series analysis and can be applied to time series with nonuniform intervals. Cosinor analysis expresses observed time series data as a cosine function, as shown in Equation 1. Y(t) is the observation at time t, M is the mean (MESOR), A is the amplitude, τ is the period, t is the time, and ϕ is the phase. MESOR is the middle value of periodic oscillations and represents the central tendency of the data. The amplitude is the amount of variation in the period and represents how much the data deviates from the mean. The phase is the location of the variation corresponding to a specific time in the period and can mean the time when the peak of the data occurs. Amplitude, acrophase, MESOR, and CQ (amplitude or MESOR) are used as cosinor-related indicators [8,9,12].

$$(1) Yt = M + A\cos(2\pi t\tau + \phi)$$

Nonparametric indicators used in circadian rhythm studies related to daily activity include RA, IV, and IS, which evaluate the stability and variability of individual activity patterns and circadian rhythms [8-10]. RA is an index that evaluates the amplitude of activity in circadian rhythms and is calculated by the difference in activity between the maximum and minimum activity times as shown in Equation 2. M10 means the mean activity during the 10 hours with the highest activity during the day, and L5 means the mean activity during the 5 hours with the lowest activity during the day. The higher the RA, the greater the difference in activity between day and night, indicating a more distinct circadian rhythm.

IV is an index that evaluates the variability of activity patterns within a day, as shown in Equation 3. N is the total number of measured time data, Yt is the activity at time t, and Y- is the mean activity over all times. The numerator of Equation 3 is the sum of the squares of the activity variance between consecutive time periods. The larger the change in activity between time periods during the day, the larger the IV value. The denominator is the total change in activity by time, which expresses the variability for the mean activity during the day.

IS is an index that evaluates how consistently activity levels are maintained at the same time across multiple days. It indicates

XSL•FO
RenderX

how regular and consistent the activity patterns are maintained by the time zone of the day. In Equation 4, N is the total number of measured time data, S is the number of data per day, and x-his the hourly mean. The numerator represents the squared deviations of the hourly means from the overall mean, whereas the denominator reflects the total variance of the entire series. As the ratio of these 2 terms increases, the IS value becomes larger, and activity patterns that recur at identical clock times on successive days yield higher IS values.

(2)RA=M10-L5M10+L5

(3)IV=N∑t=2N(Yt-Yt-1)2(N-1)∑t=1N(Yt-Y-)2

(4)IS=N∑h=1S(x-h-x-)2S∑i=1N(xi-x-)2

Dimension reduction technology is being utilized as a method of analyzing biosignals, which is a method of converting high-dimensional data into low-dimensional data to easily visualize or analyze the data [17,18]. Dimension reduction is mainly used to reduce computational costs, remove noise, and express data more concisely while preserving the features of the data. Principal component analysis, linear discriminant analysis, and SVD are used as dimension reduction methods. In a study that applied dimension reduction technology to circadian rhythm, circadian activity rhythm energy (CARE) was proposed to detect the energy of subsignals with a cycle of less than 24 hours through singular spectrum analysis based on SVD to analyze the circadian rhythm of cognitive function. CARE showed a higher correlation coefficient than RA for melatonin amplitude [10].

The activity and HR obtained from wearable devices have a 24-h periodicity. Wavelet transform (WT) is used as a method to analyze signals that have time periodicity [19]. WT is a powerful tool that can analyze signals in the time and frequency domains simultaneously. WT analyzes frequency information in each time interval by decomposing them into wavelets of various sizes. CWT calculates wavelet changes for all times. Morlet wavelet is a sinusoidal waveform that is attenuated by a Gaussian curve, which is very advantageous in detecting the temporal changes of specific frequency components, allows for high-resolution frequency analysis, and captures continuous and periodic signal components well [14,20]. The CWT for a signal x(t) is obtained by computing the inner product with the Morlet wavelet. In Equations 5 and 6, Wx(a,b) is the CWT coefficient of a given signal x(t), a is a scale factor that controls the frequency variation. A smaller a corresponds to a higher frequency component, and a larger a corresponds to a lower frequency component. b is a shift parameter that controls the variation in time, and the signal is analyzed along the time axis as b changes. ψ*is the complex combination of the Morlet wavelet, t is time, and x(t) represents the signal to be analyzed. ψt is the Morlet wavelet function, ω0 is the center frequency, and i is the imaginary unit. The magnitude (energy) of the CWT coefficients Wx(a,b) represents how strongly the signal x(t) exists at a given scale a and time b. This energy is used to generate a spectrogram, which is a map that shows the intensity of the signal in the time-frequency plane. The center frequency means that the Morlet wavelet is optimized for analyzing signals in a specific frequency band. To obtain circadian rhythm markers for the acquired 5-day HR and step count per min, spectrograms were obtained for each signal, and then the total energy of the center frequency was derived as a marker by adding up all the energy over time for each center frequency. The proposed CWT-based circadian rhythm energy is called CCE.

Feature Selection and XAI

XAI is a methodology used to interpret the results of machine learning models. XAI enabled us to analyze the contribution of the features to the model outcomes. The local interpretable model-agnostic explanation (LIME) and SHAP are commonly used XAI algorithms, particularly for analyzing tabular data. As LIME often focuses on local explanations, it may not effectively explain the global behavior of the models. SHAP is a model-agnostic post hoc algorithm that is gaining attention. SHAP offers special implementations of tree-based models and provides more accurate and efficient explanations [21]. A tree-based model was used to identify MetS. Thus, SHAP was used to analyze the important features. SHAP provides insight into the contribution of each feature to the model outcomes, considering both the positive and negative impacts of wearable-based daily life features on the identification of MetS. XGBoost was used as the SHAP learning model, and the resulting SHAP values were as follows [5]:

(7)∅i(v)=∑S∈N{i}|S|!(n−|S|−1)!n!(v(S∪{i}−v(S))

XGBoost is a boosting model for decision trees that enhances the performance of gradient-boosting machines in terms of their speed. Boosting models iteratively update the parameters of previous classifiers to create a more powerful classifier, thereby increasing the accuracy and reducing the gradient of the loss function [5].

EBM is an interpretable structure of the model itself, unlike SHAP, which explains how each feature contributes to the prediction [22]. EBM is based on a generalized additive model (GAM), and GAM models the relationship between features and target variables as a sum of functions for each feature [23]. EBM can visualize how each feature contributes to the prediction so that users can easily understand the influence of individual features on the results. Equation 8 represents GAM, where β0 is a constant term, and fixi is a function learned for each feature, indicating how each feature contributes to the prediction. g is a link function that adjusts GAM to various settings, such as regression or classification. EBM learns each function fixi of GAM using boosting techniques. Boosting is a method of sequentially learning multiple weak models and correcting errors made by previous models, as shown in equation 9. hmxi is the m-th weak model, αm is the weight of the m-th weak model, and M represents the boosting step. EBM, including GAM and boosting techniques, is shown in Equation 10, and EBM can automatically detect pairwise interactions between each feature that are important for prediction and include them in the model, as shown in Equation 11.

In addition to EBM and XGBoost, TabNet, a deep learning architecture designed for tabular data, was used. TabNet leverages a novel attention mechanism that automatically selects relevant features and effectively learns their interactions [24]. TabNet is particularly well-suited for analyzing complex datasets because it handles missing values and displays the most influential features for prediction, providing interpretability. In TabNet, the method to automatically evaluate the importance of each feature to the model is related to the attention mechanism and Gated Linear Units (GLU). To evaluate the importance of each feature in a given input X, the attention weights Wa are calculated as in Equation 12. Z is the input value of the current layer, A is the learnable weight, and P is the prior-scale term that reflects how frequently the corresponding feature has been selected in earlier steps. Consequently, A becomes a probability vector indicating the importance of each feature. TabNet performs prediction through features selected from each layer, and the set of selected features is defined as in Equation 13. GLU is used in the process of performing prediction using selected features. GLU can emphasize or suppress input features through nonlinear transformation, as shown in Equation 14. Wis a weight matrix, b is a bias, and σ is a sigmoid activation function, which provides a ratio representing the importance of each feature. The output computed through the attention weights and GLU of each layer evaluates the importance of each feature to the final prediction.

(12)A=Sparsemax(P·(WaZ))

(13)Xselected=A·X

(14)GLU(x)=(W1x+b1)·σ(W2x+b2)

The XGBoost parameters used were booster=gbtree and objective=binary logistic. The other parameters were set to the default values in Python (v3.10.9), NumPy (v1.23.5), and scikit-learn (v1.2.2). EBM was implemented using the interpret library version 0.6.4, and TabNet was implemented using pytorch-tabnet version 4.1.0 with max_epochs=2000 and batch_size=32.

Results

Associations of Sleep and Circadian Rhythm Indicators With MetS

Based on HR, step count, and sleep data obtained from wearable devices, bio-digital markers of circadian rhythm for MetS were detected and the significance of the markers was analyzed. For the analysis, continuous wearable data for 5 days during the week of 88 MetS and 184 non-MetS obtained from smart bands on the wrist were used. Demographic and clinical information used to determine MetS are shown in Table 1. The age of the MetS group was 48.94 years, which was 4 years older than that of the non-MetS group. The average BMI of MetS was 27.9. Systolic blood pressure, diastolic blood pressure, triglyceride, high-density lipoprotein, and glucose used to determine MetS all showed statistically significant results ($P<.001$). The *P* value was obtained using an independent *t* test.

XSL•FO
RenderX

Table . Demographic and clinical characteristics of MetS and non-MetS groups. Demographic data (age and sex) and clinical variables, including BMI, waist circumference, blood pressure, lipid profile, and glucose levels, are presented for participants classified into MetS (n=88) and non-MetS (n=184) groups. Statistical significance was tested using *t* tests.

	Non-MetS[a]	MetS	*P* value
Sex, n (%)			
Male	28 (38.9)	44 (61.1)	
Female	156 (78.0)	44 (22.0)	
Age (years), mean (SD)	44.04 (6.48)	48.94 (6.92)	<.001
BMI (kg/m^2), mean (SD)	21.70 (2.08)	27.90 (2.94)	<.001
Waist (cm), mean (SD)			
Male	81.82 (5.28)	96.98 (7.41)	<.001
Female	75.88 (5.11)	90.45 (8.04)	<.001
SBP[b] (mm Hg)	110.32 (8.98)	130.68 (15.42)	<.001
DBP[c] (mm Hg)	67.97 (8.80)	83.07 (11.31)	<.001
Triglyceride (mg/dL)	78.29 (26.62)	210.01 (102.54)	<.001
HDL[d] (mg/dL)	68.17 (14.21)	46.40 (11.35)	<.001
LDL[e] (mg/dL)	123.02 (33.19)	124.13 (35.95)	.74
Total_Cholesterol (mg/dL)	204.94 (35.05)	200.51 (42.11)	.45
Glucose (mg/dL)	82.97 (6.52)	99.89 (20.84)	<.001

[a]MetS: metabolic syndrome.

[b]SBP: systolic blood pressure.

[c]DBP: diastolic blood pressure.

[d]HDL: high-density lipoprotein.

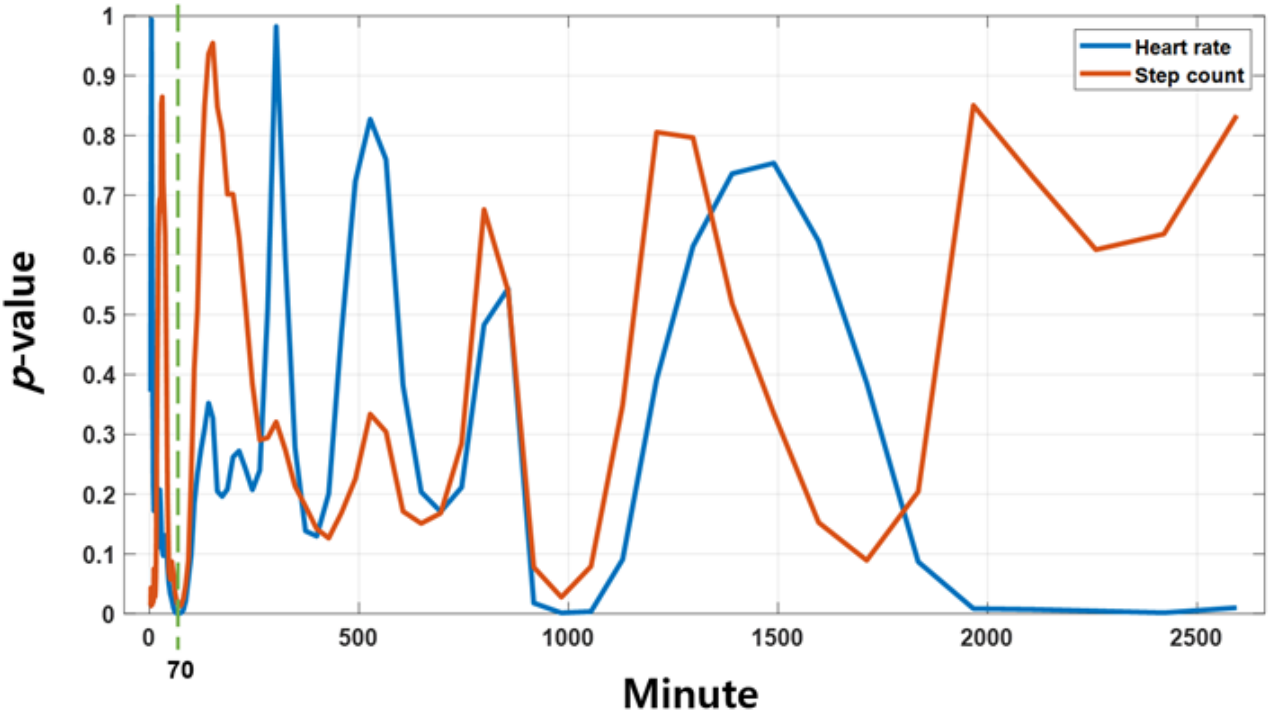
[e]LDL: low-density lipoprotein.

Twenty-six indicators were identified as sleep and circadian rhythm markers. The sleep-related indicators consist of 4 measures: the mean and SD of MST and TST. MESOR, amplitude, acrophase, and CQ for both step count and HR, derived from cosinor analysis, make up 8 indicators. In total, 10 indicators, including L5, M10, RA, IS, and IV for step count and HR, were calculated as nonparametric indicators. In addition, one indicator was based on dimension reduction proposed in a previous study, and 3 indicators using CCE based on HR were introduced in this study.

The statistical significance of MetS in the results obtained by analyzing the energy of the CWT based on the central frequency of the circadian rhythm for step count and HR, in order to detect MetS markers related to the CCE proposed in this study, is shown in Figure 1. The CCE value for step count showed the lowest *P* value at a central frequency of 70 minutes, but it did not reach a value below .001. However, HR exhibited statistical significance below 0.001 at central frequencies of 70 minutes and 1000 minutes. Therefore, the total CCE value was obtained for the central frequencies between 69 and 80 minutes (midfrequency) and between 900 and 1100 minutes (low-frequency). In addition, the ratio of the 2 central frequency ranges (mid_low ratio) was calculated as a single indicator. The energy of HR according to the central frequency reaches its highest at the 1440-minutes circadian cycle and also shows high energy in the 700-minutes range (Figure 2). In the central frequency range of 69 - 80 minutes, the energy of MetS is lower than that of non-MetS, while in the 900 - 1100-min range, the energy of MetS is higher.

XSL•FO
RenderX

Figure 1. Statistical significance of continuous wavelet transform energy derived from step count and heart rate (HR) data across different central frequencies in the identification of metabolic syndrome (MetS). *P* values for each frequency range compare MetS (n=88) and non-MetS (n=184) groups, using HR and step count data recorded from Fitbit devices over 5 weekdays. HR circadian rhythm energy (CCE) showed statistical significance (*P*<.001) at 70 min and 1000 min, whereas step count CCE did not reach this threshold.



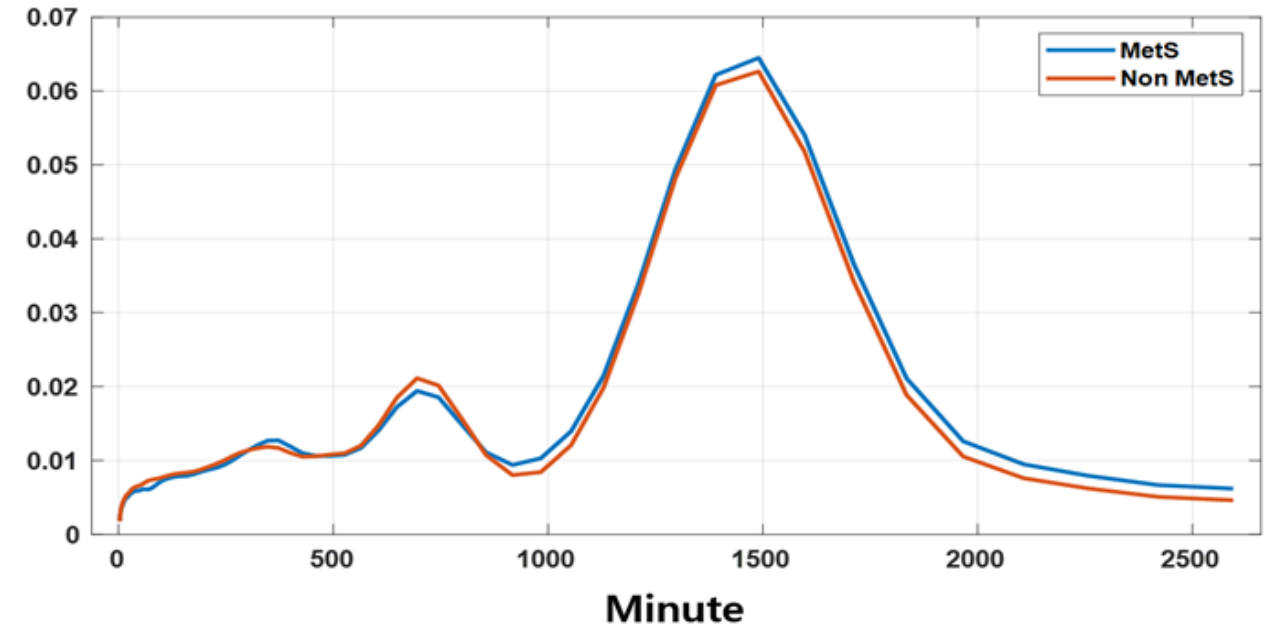


Figure 2. Comparison of heart rate (HR) energy at different central frequencies between metabolic syndrome (MetS) and non-MetS groups based on continuous wavelet transform analysis of wearable data. HR energy peaked at 1440 min (circadian cycle) and 700 min. In the 69 - 80 min range, MetS energy was lower than non-MetS, while in the 900 - 1100 min range, MetS energy was higher.

In Tables 2 and 3, the means, SD, and statistical significance of 26 indicators for MetS and non-MetS can be observed. Statistical significance was assessed using parametric testing (independent *t* test) and nonparametric testing (Wilcoxon rank sum test) [25].

XSL•FO
RenderX

Table . Comparison of sleep, cosinor, and nonparametric circadian rhythm indicators between metabolic syndrome (MetS) and non-MetS groups in Korean adults. Means, SD, and statistical tests (*t* test and Wilcoxon rank-sum test) are reported for each indicator derived from wearable-recorded step count and heart rate data, including sleep duration, midline estimating statistic of rhythm, amplitude, relative amplitude, interdaily stability, and others.

Sleep-related indicators did not show statistical significance for MetS (P<.05). For the Cosinor and non-parametric methods, step count showed statistical significance with Amplitude (MetS was 0.96 smaller, P=.03), L5 (MetS was 0.031 larger, P<.001), RA (MetS was 0.012 smaller, P<.001), and IS (MetS was 0.067 smaller, P<.001). HR showed statistical significance with MESOR (MetS increased by 3.14, P<.001), L5 (MetS increased by 4.36, P<.001), M10 (MetS increased by 2.67, P=.012), RA (MetS decreased by 0.018, P<.001), IS (MetS decreased by 0.054, P=.002), and IV (MetS decreased by 0.04, P=.04). The CARE method based on step count did not show statistical significance for MetS. In this study, the proposed indicators CCE showed statistical significance in midfrequency (MetS decreased by 0.005, P<.001), low-frequency (MetS increased by 0.005, P=.003), and mid_low ratio (MetS decreased by 0.382, P<.001).

XAI-Based Importance Analysis of Sleep and Circadian Rhythm Indicators for MetS

An importance analysis was conducted on the 26 detected sleep and circadian rhythm indicators using SHAP (with XGBoost), EBM, and TabNet. Figure 3 presents the SHAP plot, where the color gradient from red to blue reflects the value of each indicator, with higher values appearing in red. The x-axis represents the contribution direction: positive values indicate a higher contribution to predicting MetS, while negative values correspond to a higher contribution to non-MetS. Indicators positioned higher on the y-axis are considered more important.

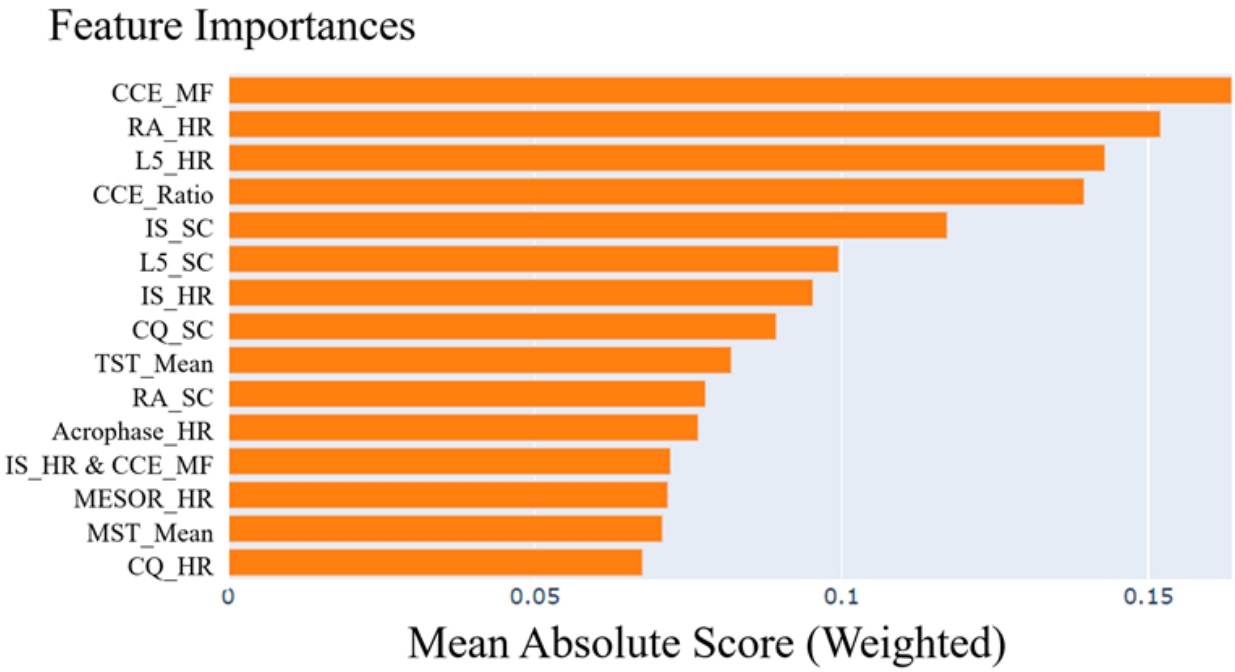

Figure 3. Important indicators identified for metabolic syndrome (MetS) using Shapley Additive Explanations (SHAP). Importance analysis was conducted on 26 sleep and circadian rhythm indicators using SHAP with an extreme gradient boosting (XGBoost) model. The color gradient from red to blue represents the values of each indicator, with higher values in red. The x-axis indicates the contribution direction, where positive values correspond to a higher contribution to predicting MetS, while negative values indicate a higher contribution to non-MetS.

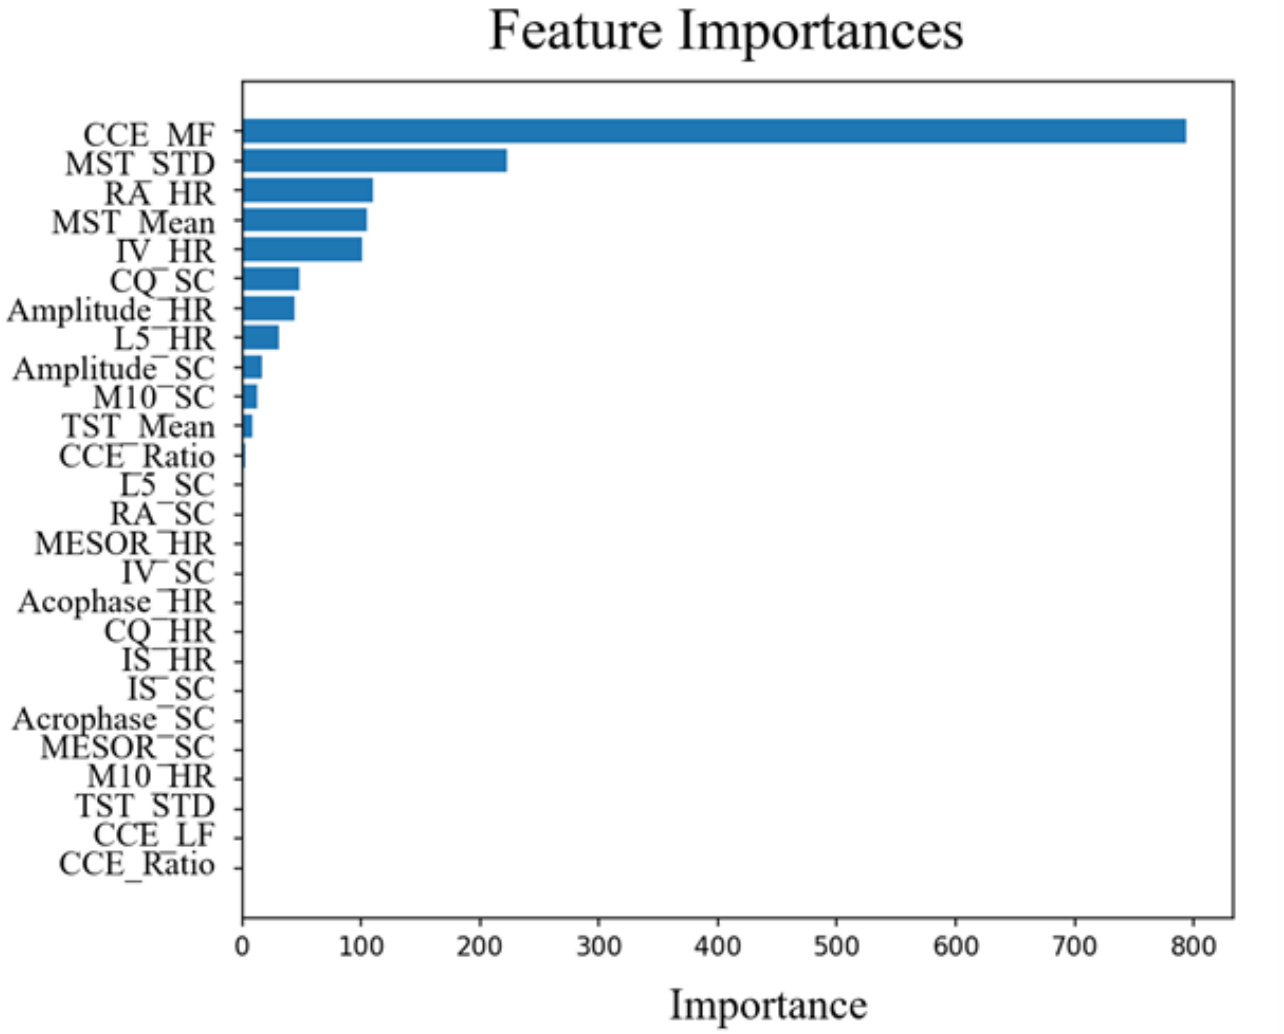
Figures 4 and 5 display the importance values of indicators using EBM and TabNet, respectively. Among the three models, the midfrequency of CCE (CCE_MF), proposed in this study, exhibited the highest importance for identifying MetS-related circadian rhythm patterns. In addition, relative amplitude of HR (RA_HR) consistently ranked among the top 3 indicators across all three methods. These findings highlight the critical role of both CCE_MF and RA_HR in distinguishing between MetS and non-MetS groups.



XSL•FO
RenderX

Figure 4. Important indicators identified for metabolic syndrome (MetS) using explainable boosting machine (EBM). Importance values of 26 sleep and circadian rhythm indicators were analyzed using EBM. The midfrequency of continuous wavelet circadian energy (CCE_MF) exhibited the highest importance for distinguishing MetS.

XSL•FO
RenderX

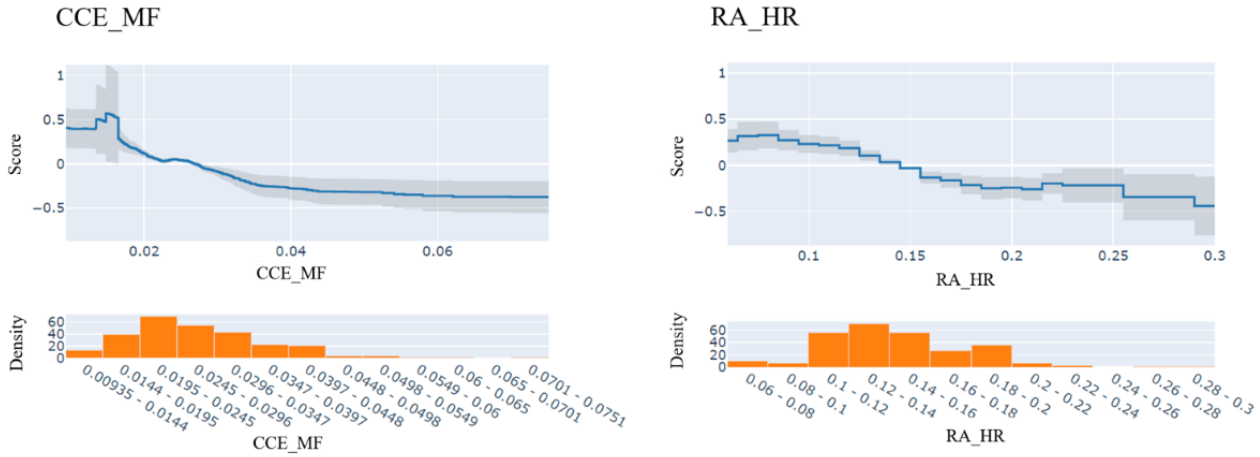


Figure 5. Important indicators identified for metabolic syndrome (MetS) using Tabular Neural Network. Feature importance was analyzed using TabNet, a deep learning model optimized for tabular data. Similar to explainable boosting machine, CCE_MF showed high importance in distinguishing MetS, while RA_HR also remained among the top-ranked indicators.

Apart from CCE_MF and RA_HR, differences in importance rankings were observed between the tree-based models (SHAP and EBM) and the deep learning-based TabNet. In the SHAP plot, both CCE_MF and RA_HR showed a higher contribution to MetS as their values decreased. Figure 6 further visualizes the changes in scores based on CCE_MF and RA_HR using EBM. The average value of CCE_MF was 0.024 for the MetS group and 0.029 for the non-MetS group, with most data points concentrated in the range of 0.0195 - 0.0245. A lower CCE_MF value was associated with a higher contribution to MetS, while non-MetS data were distributed over a broader range from 0.03 to 0.08.

XSL•FO
RenderX

Figure 6. Score changes for CCE_MF and RA_HR identified by explainable boosting machine in metabolic syndrome (MetS) classification. Lower CCE_MF values were associated with a higher MetS risk, with most MetS cases clustered between 0.0195 - 0.0245, while non-MetS values ranged from 0.03 - 0.08. For RA_HR, values above 0.15 increased the likelihood of non-MetS, while those exceeding 0.25 were linked to a reduced probability of MetS. CCE: circadian rhythm energy; CCE_MF: midfrequency of CCE; RA_HR: relative amplitude of heart rate.

Similarly, RA_HR values were distributed between 0.1 and 0.2, with a shift observed in the EBM plot. When RA_HR exceeded 0.15, its contribution to non-MetS increased, while values above 0.25 were associated with a reduction in the probability of MetS.

Among the top 10 indicators, SHAP identified 5 HR-related and 5 SC-related indicators. EBM included 5 HR-related, 4 SC-related, and 1 sleep-related indicator, while TabNet identified 5 HR-related, 3 SC-related, and 2 sleep-related indicators. Across all three methods, HR-related indicators showed a high contribution to MetS. Notably, CCE_MF, RA_HR, and L5_HR consistently appeared as key contributors across all models.

The results presented above are based on the analysis of the entire dataset. To evaluate the robustness of the marker and model, the data were cross-validated 5 times. The proposed CCE_MF marker showed the highest importance in 3 of the 5 results for SHAP and was explained as the second most important marker, after RA_HR, in two results. In the EBM model, CCE_MF showed the highest importance in all five times. In the TabNet model, CCE_MF was selected within the top 10 markers, but the most important marker varied, so the probability was not shown. Therefore, the reliability of the results of the TabNet model was low.

Additionally, an analysis was conducted using SHAP, EBM, and TabNet to evaluate the impact of key demographic variables, including age, sex, and BMI, on the importance of sleep and circadian rhythm variables in the MetS prediction model.

As presented in Table 1, age, sex, and BMI are closely associated with MetS and may influence the assessment of the independent contributions of other variables when included in the model. Therefore, by comparing models that include and exclude these variables, the independent importance of sleep and circadian rhythm markers can be more clearly analyzed. The top 10 indicators in SHAP, EBM, and TabNet, when age, sex, and BMI were included, are as follows: (1) SHAP: BMI, Age, IS_SC, CCE_MF, MST_Mean, Amplitude_HR, RA_HR, M10_HR, M10_SC, and Amplitude_SC; (2) EBM: BMI, Age, Sex, CCE_MF, IS_SC, RA_HR, Age & BMI, CCE_Ratio, CQ_SC and BMI, and L5_HR; and (3) TabNet: BMI, TST_Mean, Sex, L5_SC, CCE_MF, MST_Mean, Age, IS_SC, L5_HR, and Amplitude_HR.

In models that included age, sex, and BMI, these variables significantly impacted prediction, leading to a relative decrease in the importance of some sleep and circadian rhythm markers. However, when age, sex, and BMI were excluded, the proposed CCE_MF consistently ranked among the top 3 most important markers across all methods and was identified as the most significant marker. The results indicate that the CCE_MF marker exerts a strong independent influence on MetS prediction even after accounting for potential confounding factors.

Notably, IS_SC showed a higher contribution than RA_HR and L5_HR, which is a finding worth highlighting. The findings confirm that CCE_MF plays a crucial role in MetS prediction independently of age, sex, and BMI and suggest that IS_SC contributes more significantly than traditional HR-based markers, including RA_HR and L5_HR.

Finally, the comparison between the statistical methods and the XAI-based importance analysis revealed that sleep-related indicators, which did not achieve statistical significance, emerged among the top 10 indicators in the XAI-based analysis. These findings underscore the value of explainable artificial intelligence methods in uncovering hidden patterns that may be missed by traditional statistical approaches.

Discussion

Primary Findings

Currently, studies analyzing circadian rhythm digital markers related to MetS are still in their early stages. Previous research has primarily focused on individual factors such as physical activity levels and sleep patterns, but in-depth analysis of circadian rhythm markers for metabolic diseases using wearable devices has rarely been conducted [26-28]. This study aimed to identify and analyze circadian rhythm indicators related to MetS using data from wearable devices.

XSL•FO
RenderX

In addition to existing circadian rhythm indicators, recent studies are proposing new indicators tailored to each target disease area. Table 4 shows studies focused on wearable-based sleep and circadian rhythm analysis. For instance, Cui proposed CARE as a circadian rhythm marker for cognitive function, comparing it with existing indicators like RA [10]. Similarly, Shim introduced a new marker called CosinorAge, which analyzes the relationship between aging and mortality, in addition to Cosinor-based indices such as MESOR, amplitude, and acrophase [12]. In this study, we proposed a time-frequency analysis-based circadian rhythm indicator called CCE and compared it with indicators used in previous studies. As a marker, CARE analyzes circadian rhythms using an energy-based approach, similar to the CCE marker. However, although CARE proved to be a strong marker for cognitive function, it did not show high significance in MetS.

Table . Previous studies on sleep and circadian rhythm indicator analysis using wrist-worn wearable devices. A summary of studies investigating sleep and circadian rhythm indicators in various health conditions using wearable devices. Each study includes target condition, device type, key indicators analyzed, and methodology used. Indicators include sleep parameters (eg, sleep duration and onset latency), circadian rhythm markers (eg, midline estimating statistic of rhythm, amplitude, and interdaily stability), and novel metrics (eg, circadian activity rhythm energy and midfrequency circadian rhythm energy).

Author	Target	Device	Indicator	Methodology
Kiss et al 2024 [7]	Obesity	Fitbit Charge HR[a] 2	Sleep onset, sleep offset, sleep duration, sleep onset latency, sleep inertia, MST[b], total step count, sleeping HR, and resting HR	Explainable boosting machine
Zhang et al 2024 [8]	Major depressive disorder	Fitbit Charge HR 2 or 3	Sleep duration, sleep onset, sleep offset, sleep variability, daily step, step IV, step IS, L5 onset, M10 onset, HR MESOR[c], HR amplitude, and HR acrophase	Linear mixed-effects models

Existing statistical analysis methods may have limitations in detecting complex temporal patterns or interactions. In contrast, XAI offers clearer insights into hidden data patterns by making the predictions of complex models explainable [29]. Kiss et al [7] analyzed the relationship between sleep and HR indicators and obesity through EBM, while Ravindra et al [11] investigated circadian rhythm indicators for prematurity using novel interpretability algorithms that integrate unsupervised clustering, model error analysis, feature attribution, and automated actigraphy analysis. This highlights the growing importance of using XAI to analyze target diseases and circadian markers. Our study aims to address the limitations of previous research by examining the significance of circadian rhythm indicators related to MetS using XAI models such as SHAP, EBM, and TabNet. Analyzing the contribution and significance of circadian rhythm indicators across various models enhances the development of objective markers that more effectively explain MetS.

XAI-based analysis of circadian rhythm indicators revealed that CCE_MF is the most important marker for identifying circadian patterns related to MetS. A decrease in CCE_MF with a 1-hour cycle correlated with an increased contribution to MetS. The HR variability observed in the 1-hour cycle can be related to exercise, physical activity, eating, digestion, and fluctuations in the autonomic nervous system [30,31]. A low energy level in the 1h cycle indicates minimal amplitude or frequency components, suggesting strong physical activity, low metabolic changes, or an absence of exercise. Our study also noted low step counts in the same cycle. Additionally, the RA_HR consistently ranked high across all models and displayed low values in MetS. A low RA_HR indicates reduced HR variability, which can act as a cardiovascular risk factor. For example, HR variability tends to decrease in conditions such as hypertension, MetS, or heart failure [32].

XAI methods, including SHAP, EBM, and TabNet, enabled us to comprehensively understand the contribution of individual indicators to MetS prediction. While SHAP and EBM, both tree-based models, identified similar HR and sleep-related indicators, TabNet, a deep learning approach, highlighted a different set of significant sleep-related indicators. Notably, some sleep-related indicators that did not achieve statistical significance in traditional analyses emerged among the top indicators in the XAI method. This underscores the limitations of conventional statistical approaches that may overlook essential relationships and interactions among variables. The ability of XAI to uncover these hidden patterns suggests its valuable role in advancing research on MetS and related diseases.

Adding CCE markers to existing markers and comparing the results of MetS prediction can be another method to demonstrate the importance of CCE markers. The results of predicting MetS with sleep and circadian rhythm markers showed that incorporating the CCE marker into the EBM model increased the prediction accuracy from 64.31% to 65.44%, while the RF model showed the highest prediction accuracy, increasing from 68.38% to 69.47%. When sex, age, height, weight, and BMI were included, the accuracy increased from 88.23% to 88.93% in the EBM model, and the highest model showed an increase from 89.70% to 90.43% in XGBoost. All prediction results were validated using five-fold cross-validation. In a previous study on obesity prediction, the prediction accuracy of wearable devices and questionnaires (such as age, sex, race, income, and education level) was 72.6% when the EBM model was used. Although new markers have been proposed in various fields, they have not achieved a high level of prediction, and the proposed CCE model showed an increase in prediction accuracy of 1% but did not significantly improve overall performance. However, the introduction of new markers provides valuable insights by explaining MetS through interpreting circadian rhythms, rather than relying simply on existing known factors such as sex, age, and BMI.

The growing prevalence of wearable devices, such as smart bands and watches, is fostering an environment where individuals' everyday health information can be collected and analyzed in real time. These data could be instrumental in personalized health care, particularly in the early detection and prevention of chronic diseases such as MetS. Keshet provided an overview of wearable and digital devices capable of alerting individuals to specific metabolic outcomes, emphasizing the unique opportunities for creating personalized prevention and treatment strategies for cardiometabolic diseases [2]. This study may contribute to the healthcare landscape by developing wearable data-based circadian rhythm markers, addressing the need for technologies aimed at preventing and treating MetS in everyday life.

Limitations

This study has some limitations. The dataset used was limited in size and was collected from specific regions or population groups, making the generalization challenging. Further research should delve deeper into investigating the stability and generalizability of the model when considering real-world medical applications. Additionally, there was an issue of data imbalance for MetS and metabolic diseases, potentially leading to model bias toward the majority class. Although ensemble methods such as EBM and XGBoost, which are robust to data imbalance, were used [33], random undersampling was performed five times during model training to further address this issue, and the results were analyzed. In particular, the proposed CCE_MF marker emerged as the most important marker in four of the five tests using SHAP and EBM, and as the second most important marker in one test. However, the most important markers are not consistent in the TabNet model, indicating that a larger dataset is needed for deep learning models to achieve more stable and consistent results. Future studies should further explore deep learning models based on larger datasets.

Conclusions

The study analyzed a total of 26 digital biomarkers related to MetS using wearable wrist sensor data, with a particular focus on the newly proposed CCE. The XAI techniques, including SHAP, EBM, and TabNet, were applied to assess the significance and importance of each biomarker. Key findings demonstrated that circadian rhythm markers based on HR, particularly CCE and RA_HR, showed high importance across multiple models, reinforcing their potential as robust biomarkers

for MetS monitoring. The study also highlighted that traditional sleep markers did not exhibit strong statistical significance, suggesting that circadian rhythm analysis could provide additional insights for MetS research.

Abstract

Background: Diseases of the oral cavity, including oral squamous cell carcinoma, pose major challenges to health care worldwide due to their late diagnosis and complicated differentiation of oral tissues. The combination of endoscopic hyperspectral imaging (HSI) and deep learning (DL) models offers a promising approach to the demand for modern, noninvasive tissue diagnostics. This study presents a large-scale in vivo dataset designed to support DL-based segmentation and classification of healthy oral tissues.

Objective: This study aimed to develop a comprehensive, annotated endoscopic HSI dataset of the oral cavity and to demonstrate automated, reliable differentiation of intraoral tissue structures by integrating endoscopic HSI with advanced machine learning methods.

Methods: A total of 226 participants (166 women [73.5%], 60 men [26.5%], aged 24 - 87 years) were examined using an endoscopic HSI system, capturing spectral data in the range of 500 to 1000 nm. Oral structures in red, green, and blue and HSI scans were annotated using RectLabel Pro (by Ryo Kawamura). DeepLabv3 (Google Research) with a ResNet-50 backbone was adapted for endoscopic HSI segmentation. The model was trained for 50 epochs on 70% of the dataset, with 30% for evaluation. Performance metrics (precision, recall, and F_1-score) confirmed its efficacy in distinguishing oral tissue types.

Results: DeepLabv3 (ResNet-101) and U-Net (EfficientNet-B0/ResNet-50) achieved the highest overall F_1-scores of 0.857 and 0.84, respectively, particularly excelling in segmenting the mucosa (0.915), retractor (0.94), tooth (0.90), and palate (0.90). Variability analysis confirmed high spectral diversity across tissue classes, supporting the dataset's complexity and authenticity for realistic clinical conditions.

Conclusions: The presented dataset addresses a key gap in oral health imaging by developing and validating robust DL algorithms for endoscopic HSI data. It enables accurate classification of oral tissue and paves the way for future applications in individualized noninvasive pathological tissue analysis, early cancer detection, and intraoperative diagnostics of oral diseases.

KEYWORDS

hyperspectral Imaging; endoscopic HSI; eHSI; oral mucosa perfusion; ischemia; oral health diagnostics; deep learning; oral squamous cell carcinoma; medical imaging dataset; tissue classification; spectral analysis; oral pathology; artificial intelligence; dentistry; non-invasive diagnostics

Introduction

Oral diseases, including malignant and premalignant lesions, often occur on pre-existing chronic tissue alterations that are difficult to discern through conventional visual examination. This process heavily relies on the clinician's expertise and subjective interpretation, frequently necessitating additional diagnostic measures. Available methods include incisional and

XSL•FO
RenderX

excisional biopsies, brush biopsies, cytological techniques, and optical approaches. Among these, scalpel biopsy remains the gold standard for diagnosing potentially malignant lesions, offering a diagnostic accuracy of up to 88.9% [1]. However, it involves the partial removal of tissue from a suspicious area for histopathological examination, making it invasive, costly, and potentially inadequate for multilocular lesions. Excisional biopsies, while more reliable due to larger sample sizes, bear the risk of incomplete removal of malignancies and overtreatment in cases of benign lesions [2].

In recent years, less invasive methods, such as brush biopsies, tissue autofluorescence, and chemiluminescence (eg, toluidine blue staining) have been introduced as cost-effective alternatives. Meta-analyses report high sensitivities for these techniques, ranging from 30% to 100% for tissue autofluorescence, 77% for toluidine blue staining, and 91% - 100% for brush biopsies [3-5]. However, these methods have not significantly improved the early detection of oral squamous cell carcinoma. The examiner-dependent variability of less invasive methods can, at worst, delay the accurate diagnosis of oral squamous cell carcinoma, one of the most prevalent malignant tumors globally, accounting for 90% - 95% of all malignant oral cavity pathologies [6-8]. Consequently, the surgical scalpel biopsy remains the diagnostic gold standard [9]. Evidence shows that patients undergoing routine clinical evaluations, including visual inspection and digital palpation, achieve significantly higher 5-year survival rates [10,11].

The integration of advanced imaging technologies into clinical diagnostics is revolutionizing oral health care. Among these innovations, hyperspectral imaging (HSI) stands out as a noninvasive, highly sensitive modality that captures detailed spectral information across hundreds of wavelengths beyond the visible light spectrum. By detecting tissue-specific spectral signatures, HSI combines imaging remission spectroscopy with conventional imaging techniques [12]. HSI acquires spatial and spectral information as a 3D hyperspectral cube in a noncontact, noninvasive, and radiation-free manner. This approach provides vast datasets spanning wide wavelength spectra, enabling the immediate extraction of diagnostically relevant information [13-18]. The efficacy of HSI relies on the distinct spectral signatures of tissues, which result from their absorption, reflection, and refraction properties when illuminated. Each tissue type generates a unique light spectrum that HSI systems can capture, offering the potential for detecting pathological changes with high precision and sensitivity [19].

Endoscopic HSI enhances access to the oral cavity and improves illumination, making it particularly valuable in addressing the growing demand for noninvasive diagnostic methods in oral medicine [20-23]. In this context, the combination of endoscopic HSI with deep learning (DL)–based computer vision techniques provides the potential to significantly enhance diagnostic accuracy, allowing for more comprehensive mapping of the oral cavity and accurate distinction between healthy and pathologically altered mucosa. This offers potential opportunities to avoid unnecessary biopsies and to improve patient-centered therapy by determining individual resection margins. The advanced capabilities of endoscopic HSI, while promising, pose challenges in managing its vast and intricate data output. The spectral data acquired by endoscopic HSI, characterized by tissue-specific signatures, surpass the processing abilities of human observers and traditional analytical tools. This complexity necessitates advanced data analysis, where DL plays a pivotal role. Specialized in interpreting multidimensional datasets, DL uses neural networks to process extensive endoscopic HSI data efficiently, identifying subtle patterns and deviations indicative of pathology that might be missed by human assessment or conventional algorithms [24]. The integration of DL into endoscopic HSI enhances the precision, consistency, and speed of data interpretation, significantly accelerating the diagnostic process. This is especially critical in clinical environments, where timely, accurate real-time analysis can profoundly impact patient outcomes [25-28]. However, implementing DL in endoscopic HSI analysis presents challenges, primarily the limited availability of annotated endoscopic HSI datasets reflecting the complexity and diversity of real-world clinical cases. Existing datasets, often derived from controlled laboratory environments, inadequately prepare DL models for the variability of clinical settings, limiting their practical utility. A review by Cui et al [24] highlights this data scarcity as a major barrier to effective DL analysis in medical imaging, emphasizing the need for specialized datasets. In recent years, DL has also shown great promise in various other domains of medical imaging, including tumor classification in magnetic resonance imaging scans [29] and noise reduction in medical images [30-33]. These studies highlight the versatility and effectiveness of neural networks in processing complex medical images. Building on these advances, the present work applies DL and endoscopic HSI to the oral cavity—an area where such integration remains underexplored despite its clinical potential of enhancing current standards to advance precision and efficacy in oral diagnostics.

Methods

Study Cohort

A total of 226 participants, including 166 (73.5%) women and 60 (26.5%) men aged between 24 and 87 years, were included in this prospective, clinical study. Endoscopic HSI data were acquired at the Department of Oral and Maxillofacial Surgery, Facial Plastic Surgery, University Medical Center. The examined participants represented a heterogeneous group of patients from the oral and maxillofacial surgery outpatient clinic. Patients with macroscopic abnormalities of the oral mucosa, premalignant lesions, or tumors were excluded from the study. All participants provided informed consent prior to the procedure and data collection. The individual pictured in Figure 1 has provided permission for their image to be used in this publication. This study was approved by the local ethics committee of Rhineland-Palatinate (registration number 2021 - 16158) and was conducted in accordance with the code of ethics of the World Medical Association (Declaration of Helsinki).

RenderX

Figure 1. Experimental setup for endoscopic hyperspectral measurements of the oral cavity.

HSI and Patient Data Acquisition

The HSI datasets were acquired using a state-of-the-art endoscopic HSI sensor system (TIVITA Mini® camera system, Diaspective Vision GmbH). This system detects 100 wavelengths in the range of 500 - 1000 nm, offering a bandwidth of 5 nm [34]. The device uses the pushbroom principle, enabling chemical component detection based on light absorption and reflection behavior. During operation, light enters the optical system of the spectrometer through the lens, where it is collimated and separated into individual wavelengths using a transmission grating. The separated light then passes through a second optical system before reaching the sensor of the connected complementary metal-oxide-semiconductor camera. The spectrometer directly detects the spatial direction and width of the object being scanned (Y-axis) while the second spatial direction and length of the object (X-axis) are determined through the continuous mechanical movement of the light entry gate within the scanning unit. This process generates a 3D data cube that includes a spectral dimension (λ), capturing complete tissue spectra for each pixel within the wavelength range of 500 - 1000 nm [35].

Standardized measurement protocols were followed during image acquisition, maintaining a consistent distance of 7 - 10 cm to ensure high-quality and distinct image data (Figure 1). Measurements were performed in an examination room under dimmed lighting conditions to ensure uniformity and comparability. A total of 226 participants aged between 24 and 87 years, including 166 (73.5%) women and 60 men (26.5%), were prospectively recruited at the outpatient department of the clinic of Oral and Maxillofacial Surgery, University Medical Center, where all individuals underwent routine clinical evaluation and inspection. Inclusion was limited to individuals without clinically apparent mucosal lesions, premalignant conditions, or malignancies, ensuring a representative sample of nonpathological oral tissue. Informed consent was obtained from all participants prior to data acquisition. The recruitment strategy was designed to capture a broad range of healthy oral tissue presentations to ensure the generalizability of HSI data across different anatomical sites and patient demographics. For each patient, 5 images were taken, including views of the right and left cheeks, the palate, the back of the tongue, and the closed row of teeth. The data were subsequently pseudonymously archived using camera-specific software tools.

Red, Green, and Blue–Imaging and Endoscopic HSI Data Files

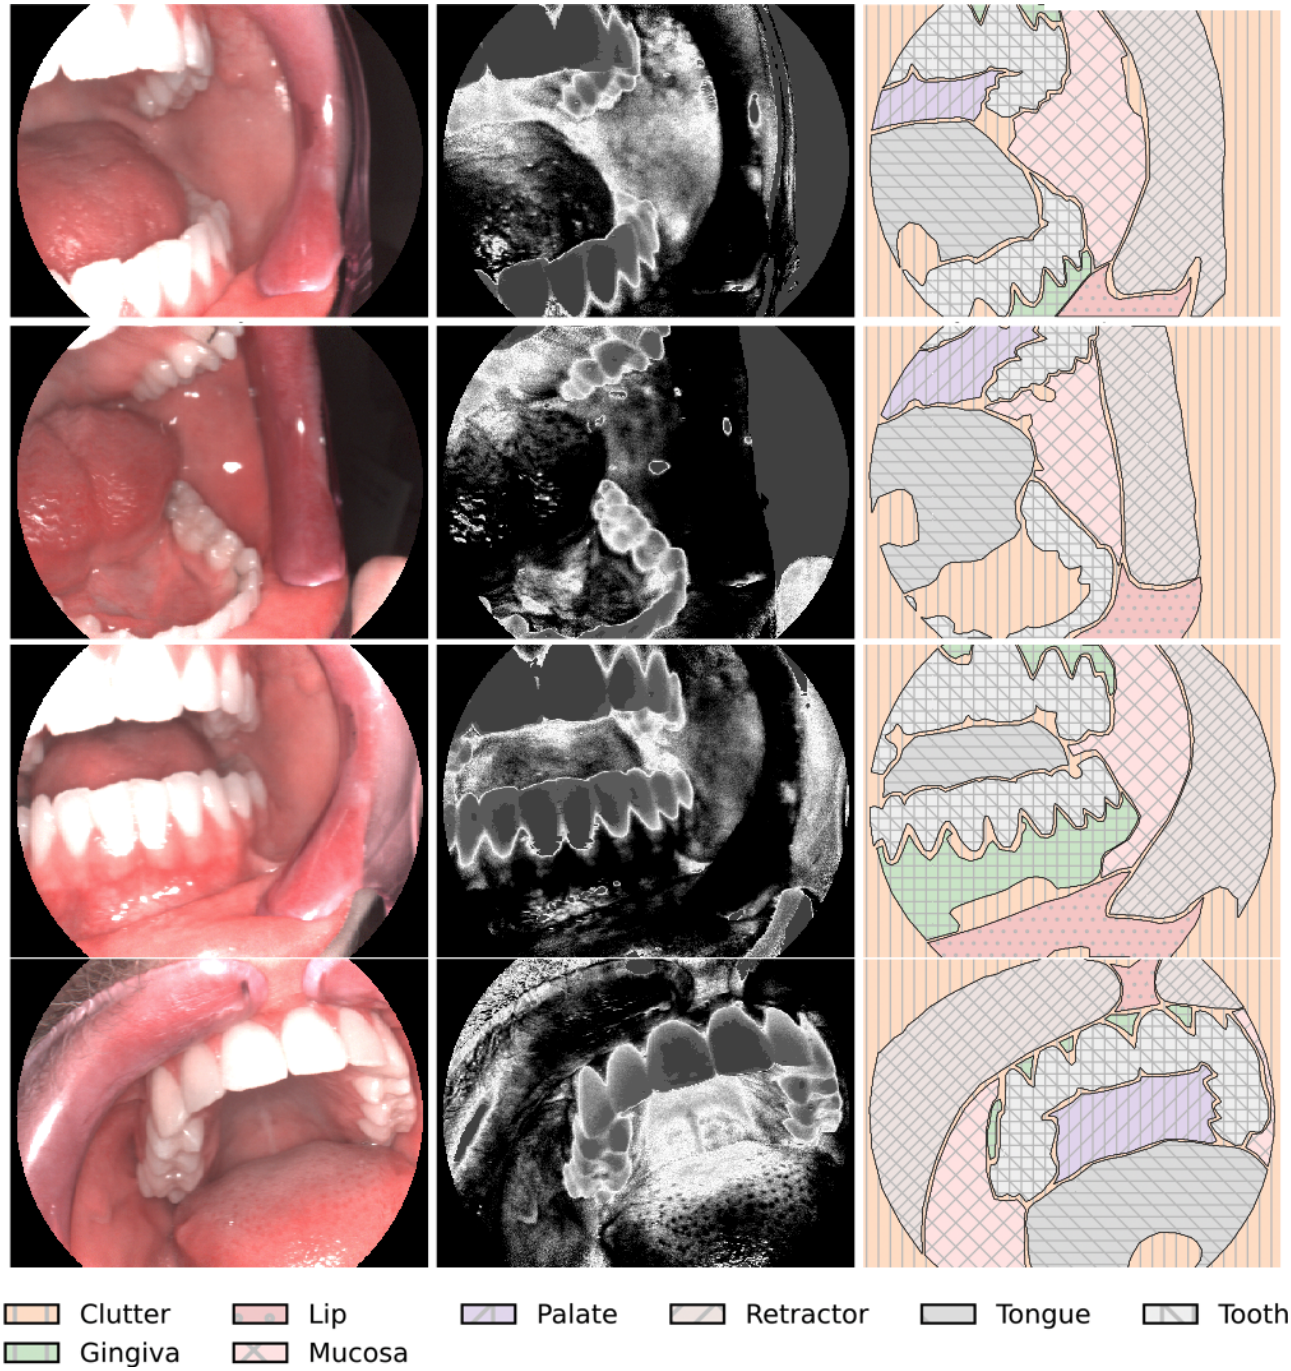
The Comprehensive Oral Health Hyperspectral Dataset (comprehensive, annotated endoscopic HSI dataset of the oral cavity) primarily comprises RGB (red, green, and blue) and endoscopic HSI data with corresponding annotations. These components in the presented dataset are each important to address the fundamental challenges in DL for semantic segmentation [36], providing robust and effective model training. The RGB component offers standard visual spectrum imagery of the oral cavity, serving as a foundational baseline for comparison with more sophisticated imaging modalities like raw and processed endoscopic HSI data.

Annotation Process and Verification

Individual annotations of the oral cavity's anatomical sites were manually performed using an image annotation tool (RectLabel Pro version 2024.06.07, Ryo Kawamura; Tokyo, Japan). To ensure high-quality image data annotation, several key features were implemented. First, detailed annotation guidelines were developed to ensure reproducible results. Comprehensive training sessions and practical exercises for annotators were conducted, followed by feedback rounds to enhance their skills. Each image was annotated by at least 2 independent specialists to minimize subjective errors. Regular quality checks were performed through sample reviews by senior specialists to detect inconsistencies. Continuous feedback was given to annotators, and guidelines were regularly updated based on this feedback. Interannotator analysis of 2 segmentation annotation sets ("original" vs "new"), each assigning a class label (out of 20 possible objects plus background) to every pixel, was carried out additionally for internal quality assurance. Agreement was quantified using metrics that capture both overall and class-specific consistency: (1) Pixel Accuracy, (2) Cohen Kappa (including and excluding background), and (3) Dice Coefficients, which are mathematically equivalent to the F_1-score in the binary case. To ensure a realistic representation of everyday clinical practice, the annotated structures marked for subsequent analysis corresponded to the individual intraoral site and situation, including "clutter (n=752)," "blood (n=3)," "brackets (n=15)," "floor of mouth (n=43)," "gingiva (n=511),"

XSL•FO
RenderX

"implant (n=10)," "lip (n=603)," "mucosa (n=745)," "palate (n=539)," "prosthesis (n=65)," "reflection (n=106)," "retractor (n=702)," "suture (n=2)," "telescopic crown (n=28)," "tongue (n=587)" and "tooth (n=681)," with a number of distinct classes varying from a minimal count of 2 for "suture" to a substantial count of 752 for "clutter".



To minimize diagnostic errors, undersegmentation of anatomical structures was avoided, and experienced clinical experts reviewed each annotation to ensure that all clinically relevant features were thoroughly labeled. This conservative approach occasionally led to small unannotated gaps between each class to prevent the merging of different anatomical sites. The digital annotations in XML format provided a semantic comprehension of the image data, which are essential for the application and training of machine learning and computer vision to differentiate various oral site conditions based on the RGB and endoscopic HSI components (Figure 2).

Preprocessing further involved the conversion of the original hyperspectral data from .DAT format to the NumPy format (.npy) to facilitate interoperability, reproducibility, and ease of use for DL models. Regarding data augmentation, spatial transformations, such as image rotations to enhance model robustness, were used. The addition of noise and blur was intentionally avoided, as these operations could introduce spectral distortions that are not physically plausible in the HSI context.

Given the specific goal of oral structure differentiation, classes with low incidence, such as suture, blood, implant, brackets, telescopic crown, prosthesis, reflection, and floor of mouth were deemed less relevant and excluded from further analysis to prevent skewing the learning process and improve the model's ability to generalize to more common and diagnostically relevant structures. By focusing on higher-incidence classes, such as palate, retractor, mucosa, tongue, tooth, lip, and gingiva, the training process is optimized, enhancing the model's efficiency and effectiveness across diverse oral structures. To achieve representative results for the annotation, an additional interannotator analysis and validation was carried out to detect possible person-dependent deviations.

Dataset Structure

To ensure user-friendly analysis of the hyperspectral dataset and reliable collaboration in the research community, the dataset has been specifically optimized for the Python ecosystem (Python Software Foundation 2023, Python Language Reference, version 3.10) instead of the proprietary software required to load endoscopic HSI data. Regarding scientific computation, Python emerges as the predominant programming language due to its extensive libraries and robust community support. After acknowledging this prevalent preference and recognizing the NPY file format as the most straightforward option for loading data into NumPy, a pivotal library for numerical computations in Python [37], all elements of the comprehensive, annotated endoscopic HSI dataset of the oral cavity (“RGB,” “Annotations,” “HSI_Data_Files”) were archived in the “.npy” format. The NPY format offers several advantages: It is compact and efficient for loading and saving and supports a wide range of data types. This standardization eliminates the complexity and potential incompatibilities associated with proprietary formats. In order to provide high-quality, detailed annotations of the complex intraoral structures, digital annotations were elaborated in XML format. To enhance utility and facilitate integration into researchers’ workflows, a semantic map of the oral cavity was generated directly from the XML datasets for each image. These maps essentially consisted of binary or multiclass masks, delineating the categorization of each pixel based on the detailed

XSL•FO
RenderX

information provided in XML. However, the creation of these maps is an automated process that translates the complex structured information of the XML annotations into a simple but comprehensive format that can easily be integrated into machine learning models to differentiate tissue types based on the values of each pixel corresponding to the specific annotated category. The workflow in short: First, eHSI endoscopic HSI data are loaded, and semantic information is extracted from the XML file. This information is then used to generate a semantic map of the oral cavity, where each pixel value corresponds to a specific annotated category, such as different tissue types or anatomical sites. The resulting semantic map provides comprehensive, pixel-wise annotations of the frame, ready for application in segmentation algorithms.

Statistical Analysis of the Dataset

For an initial assessment of the spectral data, a coefficient of variation (CV) was used as a statistical measure. The CV is a standardized measure for dispersion of a probability distribution or frequency distribution and defines the ratio of the SD to the mean, expressed as percentage. It is particularly useful in the context of HSI, as it allows the comparison of variation between different classes and bands despite the different mean intensities. The formula used for the coefficient of variation is:

$$CV=(\sigma\mu)\times100\%$$

where σ is the SD of the dataset and μ is the mean of the dataset.

Machine Learning and DL Techniques

This study adapted several state-of-the-art models and their performance assessing semantic segmentation in the context of oral health diagnostics. These models included DeepLabv3 [38-40], as well as fully convolutional network (FCN [41]) and pyramid scene parsing network (PSPNet [42]), each tested with ResNet-50 and ResNet-101 [43], backbones. In addition, PSPNet using VGG16 [44] and U-Net [45] models using both EfficientNet-B0 [46] and ResNet-50 backbones were evaluated. Each model was optimized for processing our dataset, which features challenging anatomical structures, enabling a comprehensive analysis of their suitability for handling the variability inherent in endoscopic HSI data for oral health diagnosis. The models were trained over 50 epochs using 70% of the comprehensive, annotated endoscopic HSI dataset of the oral cavity test set, with the remaining 30% reserved for evaluation. This split allowed for a thorough assessment of the models' ability to generalize to unseen data. Each model's performance on endoscopic HSI data was evaluated using Precision, Recall, and the F_1-score, providing a comprehensive measure of their effectiveness in segmenting and classifying the various anatomical structures present in the dataset.

Ethical Considerations

The study was approved by the local ethics committee of Rhineland-Palatinate (registration number: 2021-16158) and was conducted in accordance with the protocol and in compliance with the moral, ethical, and scientific principles governing clinical research as set out in the Declaration of Helsinki of 1975 as revised in 1983. Informed consent was obtained from all participants involved in the study. This study received approval from the Ethics Committee of the Medical Association of Rhineland-Palatinate (reference number 2021-15858). All procedures adhered to institutional and national ethical standards and were conducted in accordance with the Declaration of Helsinki. Participants were provided comprehensive information regarding the study's nature, purpose, procedures, data usage, and the potential publication of anonymized images or data related to their participation. The privacy and confidentiality of all participants were rigorously protected. No identifying information, including names or hospital IDs, has been included in the manuscript. Images containing identifiable features were excluded except for Figure 1, which depicts the corresponding author (PR), who has provided written consent for the use of their image in this publication. No financial or material compensation was offered or provided to the participants in this study.

Results

Variability of the Dataset

A descriptive statistical analysis of the hyperspectral dataset was performed to describe the distribution and variability of the data. Mean values and SD across the spectral bands were analyzed for each class delineated in the hyperspectral images. The objective of the statistical data evaluation was to accurately represent the central tendencies and variabilities of spectral signatures, which are indicative of various anatomical and pathological entities in oral health. Mean values and SDs for all classes across all spectral bands were presented in a consolidated diagram (Figure 3).

The results indicated that the CV for the majority of classes, across most spectral bands, substantially exceeded the commonly recognized threshold of 15%, which is generally considered high. In contrast, a CV below 5% would have denoted homogeneous data, while values between 5% and 15% would have indicated moderate uniformity. The consistently elevated CV values observed across all classes thus underscored significant spectral diversity within each class (Figure 4).

DL Model Performance

The DeepLabv3 model with the ResNet-50 backbone achieved solid overall performance, with an F_1-score of 0.855, performing especially well on the segmentation of mucosa, retractor, and tooth. However, it exhibited moderate performance on gingiva and lip, with F_1-scores of 0.753 and 0.709, respectively. Switching to the deeper ResNet-101 backbone improved the overall performance slightly, with an F_1-score of 0.857, particularly enhancing the model's ability to segment clutter and gingiva (Table 1).

Both FCN-ResNet-50 and FCN-ResNet-101 demonstrated robust segmentation performance, achieving overall F_1-scores of 0.862 and 0.861, respectively (Table 2). They excelled in segmenting retractor (F_1-score=0.942 for both), tooth (F_1-score=0.910), palate (F_1-score=0.890), and mucosa (F_1-score≥0.912). However, lip and gingiva posed challenges for both backbones, reflected by lower F_1-scores around 0.72 and 0.77, respectively. Although switching to the deeper ResNet-101 backbone yielded marginal improvements in certain classes, the overall performance remained comparable between the 2 architectures.

PSPNet models showed slightly lower performance, with the ResNet-50 backbone achieving an F_1-score of 0.837 and the VGG16 backbone scoring 0.808. While these models handled classes, such as retractor and tooth, relatively well, they faced difficulties in the segmentation of gingiva and lip, particularly when using VGG16. The lower overall performance of PSPNet VGG16 compared to ResNet-50 reflects the influence of the backbone on the segmentation outcomes (Table 3).

XSL•FO
RenderX

U-Net (EfficientNet-B0) and U-Net (ResNet-50) both demonstrated robust segmentation performance, attaining overall F_1-scores of 0.867 and 0.840, respectively (Table 4). They excelled particularly at segmenting retractor (F_1-score=0.941 vs 0.927), palate (F_1-score=0.909 vs 0.881), and mucosa (F_1-score=0.920 vs 0.901). Tongue and tooth segmentation also performed well, with F1-scores exceeding 0.85 for both models. However, both networks faced challenges in segmenting lip (F_1-score=0.755 vs 0.695) and gingiva (F_1-score=0.751 vs 0.721), indicating opportunities for further refinement in these classes.

Figure 5 demonstrates that DeepLabv3 (ResNet-101) and U-Net (EfficientNet-B0) outperform other models across most tissue classes, with lower F_1-scores consistently observed for lip and gingiva segmentation.

Figure 5. Spider plot illustrating the per-class F_1-score performance of different deep learning models for oral tissue segmentation.

Interannotator Agreement

The analysis of segmentation annotations revealed an overall pixel accuracy of 80.84%, indicating a high level of interannotator agreement. Cohen Kappa, a more robust measure of interannotator agreement, was 77.56% when including the background class, indicating substantial agreement. When the background was excluded, Kappa increased to 82.91%, highlighting even stronger agreement for the segmentation of foreground structures. Dice coefficients per class ranged from near-zero (in classes with minimal or inconsistent labeling) to 93% in well-defined classes, where the overlap between annotations was nearly perfect. Since the Dice Coefficient measures spatial overlap between segmentation masks, high Dice scores (above 90%) indicate excellent agreement, whereas lower values suggest potential ambiguity or underrepresentation of certain structures.

Discussion

Principal Findings and Comparison With Previous Works

The objective of this study was to establish a digital map of the oral cavity using endoscopic HSI in conjunction with advanced machine learning techniques and therefore to develop a comprehensive endoscopic HSI dataset. This approach aimed to enable reliable and automated differentiation of various tissue types and objects based on the spectral data acquired from the endoscopic HSI system. Despite the continuous interest in faster, minimally invasive diagnostic techniques, methods, such as brush biopsies and in vivo fluorescence procedures have faced challenges in establishing themselves as reliable alternatives due to their comparatively lower sensitivity and specificity [2,4,5,9]. Modern methods, such as endoscopic HSI, represent a state-of-the-art, innovative approach in the field of automated image and tissue classification. In our preliminary ex vivo studies, we have already demonstrated that HSI can differentiate between various tissue types and states based on specific wavelength patterns [20,47]. However, to effectively differentiate between pathological and healthy tissue conditions in vivo, a substantial dataset of hyperspectral signatures from healthy tissues is essential [47].

The study introduces a comprehensive collection of 1,130,751 endoscopic HSI–cubes of healthy oral mucosa, captured in vivo from various angles, creating a representative digital map that includes relevant tissues and objects of the oral cavity. This dataset forms a representative digital endoscopic HSI map, encompassing relevant tissues and structures of the oral cavity. By establishing a robust reference for healthy tissue, this dataset lays the groundwork for advancing HSI-based diagnostics, particularly in the identification of premalignant and malignant mucosal lesions and the precise definition of tumor resection margins.

The findings revealed elevated CV across most classes, indicating substantial spectral diversity in endoscopic HSI data. This high variability poses challenges for threshold-based classification methods, as intraclass variation can lead to class

XSL•FO
RenderX

overlap. However, this diversity also holds valuable information that, when leveraged by advanced computational models, can enhance tissue classification and pathological anomaly detection with high accuracy.

To address this complexity, this study evaluated several state-of-the-art segmentation models, including DeepLabv3, FCN, PSPNet, and U-Net, with different backbones, such as ResNet-50, ResNet-101, VGG16, and EfficientNet-B0. These architectures were chosen for their effectiveness in semantic segmentation, balancing feature extraction capability, computational efficiency, and global context recognition. DeepLabv3 was selected for its ability to handle scale variability and capture fine details while FCN served as a strong baseline due to its foundational role in image segmentation. PSPNet was included for its strong capability in capturing global context, which is crucial for recognizing complex structures in medical imaging. U-Net, widely used in medical imaging, was chosen for its ability to achieve accurate segmentation even with limited data.

The choice of backbones was guided by their specific strengths. ResNet-50 and ResNet-101 were selected for their robust feature extraction, VGG16 for its simplicity and high-resolution detail, and EfficientNet-B0 for its optimized architecture that balances performance and computational efficiency. By incorporating models with varying depths and parameter complexities, this study ensures a comprehensive evaluation of segmentation performance while maintaining a focus on efficient training and inference times. The integration of the DeepLabv3 model with the ResNet-50 as well as with the ResNet-101 backbone offers a robust semantic segmentation approach for endoscopic HSI data interpretation. The primary modification to all the models, including DeepLabv3, FCN, PSPNet, and U-Net (with backbones, such as ResNet-50, ResNet-101, EfficientNet-B0, and VGG16), involved adapting the first convolutional layer to handle the variable number of channels in the dataset. This adjustment was essential to accommodate the multidimensional spectral data of the HSI dataset, as opposed to the standard 3-channel RGB imagery. This modification enables the models to use the unique spectral information in the HSI data cubes beyond the visible spectrum. Despite these adjustments, the deep residual learning architectures of ResNet-50 and ResNet-101 retain their capacity to extract high-level features—an essential aspect of HSI data analysis [43]. These backbones excel at identifying subtle spectral patterns crucial for accurate disease detection and classification. Leveraging atrous convolution and atrous spatial pyramid pooling, the DeepLabv3 model efficiently captures multiscale information [48]. This capability facilitates precise image segmentation, an essential feature for diagnosing oral health conditions with subtle and overlapping visual signatures. Likewise, FCN and PSPNet, with their robust architectures, and U-Net, recognized for its effectiveness in medical imaging, also benefited from the capacity to process and interpret multidimensional spectral data.

The endoscopic HSI procedure implemented in this study achieves results that are comparable to those obtained in preliminary HSI-ex vivo trials conducted by our research group in 2021 [47]. In this study, using a similar approach with a lightweight 6-layer deep neural network containing 10,445 parameters trained over 4000 epochs, tissue samples of fat, muscle, and oral mucosa could be differentiated with an overall class accuracy of over 80%. Similarly, in a study by Ma et al, tissue from various organs, including the kidney, liver, lung, muscle, salivary gland, and spleen, was identified using automated polarized HSI with an accuracy of up to 87% [49]. Furthermore, a deep convolutional neural network established by Poonkuzhali et al [50] could accurately identify brain tissue with an F_1-score precision of 97.3% using HSI in a recent study conducted in 2023. Unlike previous studies that focused on ex vivo tissue samples and organ-specific HSI data [47], the present work introduces the first large-scale in vivo annotated endoscopic HSI dataset of the oral cavity acquired under realistic clinical conditions. While earlier studies demonstrated the technical feasibility of HSI-based tissue differentiation, these approaches often lacked anatomical complexity, semantic annotations, and clinical variability. This study addresses these deficiencies by providing a large annotated in vivo HSI dataset and evaluating multiple DL models especially adapted for HSI data analysis. This provides the basis for clinically applicable segmentation of oral tissues and paves the way for future studies involving pathological lesions.

These findings affirm that HSI, when integrated with appropriate modalities, can serve as a reliable tool for differentiating various tissues in both in vivo and ex vivo setups. In oncological surgery, fast, reliable, and minimally invasive diagnosis of pathological tissue conditions is of paramount importance. Numerous studies in this field have shown that HSI can dependably differentiate between tumor and healthy tissue by analyzing histopathological sections and their spatial-spectral features. Moreover, the combination of HSI and DL has shown superior results compared to the use of RGB images and conventional support-vector-machine approaches [51-56].

In this study, the established DL and neural network approach was able to accurately identify different types of oral mucosa with an overall precision of approximately 91%. DeepLabv3 (ResNet-101) and U-Net (EfficientNet-B0) emerged as the top performers, demonstrating robust segmentation across key anatomical classes. While all models could benefit from further refinement in gingiva and lip segmentation, their consistent accuracy in identifying retractors and teeth underscores the strength of the dataset. While there is no universally accepted threshold for clinical applicability, F_1-scores above 0.85 are generally considered promising in similar biomedical imaging tasks. Scores in this range suggest that the method may already approach a level of accuracy relevant for clinical decision-making, though further validation in real-world settings would be required. Notably, U-Net (EfficientNet-B0) exhibited exceptional segmentation of retractors, mucosa, and teeth, indicating its strong potential for medical image segmentation applications. The results demonstrate the dataset's suitability for training advanced neural networks, particularly in challenging medical segmentation tasks.

Limitations of our study specifically include the acquisition of a higher amount of data, which depended heavily on the individual patient volume of the clinic conducting the study.

RenderX

This represents a major challenge, particularly when aiming to document various oral mucosal lesions and precancerous mucosal conditions. To address the issue of data scarcity, the raw data generated in this study will be made publicly available. This initiative aims to provide other research groups with the opportunity to use and build upon the dataset for further investigations. Furthermore, while the study cohort was intentionally designed to include a broad cross-section of patients from a university-based outpatient clinic, selection bias cannot be fully excluded. As recruitment was confined to a single university clinic, the cohort may not fully reflect the demographic and clinical variability found in primary care or the general population. Other limitations include variable lighting conditions, motion artifacts, and spectral overlaps, as well as overexposure and underexposure. Overexposure can occur due to various factors, such as the variability in patient anatomy, the movement during image capture, or the fluctuation of lighting conditions in an operating room. While overexposed images are typically regarded as artifacts and excluded from datasets, our approach incorporates them, acknowledging that such occurrences are an inherent part of clinical practice. Understanding that these instances present both challenges and opportunities for advanced image processing techniques, we have carefully indexed these overexposed images for further analysis. This approach enhances the resilience and adaptability of the models trained on this dataset, ensuring they perform effectively in real clinical environments. By incorporating overexposed images, the models are better equipped to handle the full spectrum of data variability, including common environmental factors. This combination highlights the substantial potential of endoscopic HSI data to significantly enhance the precision and reliability in detecting and categorizing healthy and pathological oral conditions. This convergence not only paves the way for significant advancements in diagnostic methodologies but also holds the potential to substantially enhance patient care. External validation is currently planned as part of future work, particularly for mucosa segmentation. We intend to validate our model on an ex vivo dataset that includes mucosa samples captured under different acquisition conditions. At this stage, the focus of this study was the initial validation on the internally collected dataset. Corresponding follow-up studies are currently in preparation and will include HSI of pathological tissue conditions, such as oral mucosal lesions and neoplastic changes, to assess the transferability and diagnostic robustness of the proposed models in clinically relevant scenarios. By enabling earlier detection and more precise characterization of oral health conditions, this approach facilitates the development of more effective treatment strategies, ultimately leading to improved patient outcomes and a higher standard of care.

Conclusion

This study presents the first large-scale in vivo annotated dataset of the oral cavity using endoscopic HSI under realistic clinical conditions. By combining hyperspectral datasets and DL-based segmentation, it was possible to demonstrate the feasibility of automated, noninvasive tissue classification across important anatomical intraoral structures. Comparative analysis reveals DeepLabv3 and U-Net as robust architectures for oral tissue classification. The comprehensive dataset consequently provides a sufficient foundation for future work on pathological tissue detection, intraoperative margin assessment in oncology, and early, individualized diagnostics in oral medicine.

Acknowledgments

The results of the present study are part of the doctoral thesis of the co-author and student of the University of Mainz, Katharina Kloster, and as such will be made publicly available as part of the doctorate. It was funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) – Project number 516210826.

Data Availability

All raw data on which this study is based will be made available by the corresponding author upon request. The datasets used and/or analyzed during the current study are available from the corresponding author on reasonable request.

Authors' Contributions

The conceptualization of the study was carried out by DT, JJP, and PR. Methodology development was led by DT, JJP, BP, PR, KK and TK. Validation was performed by DT, JJP, BP, and PR. Formal analysis was conducted by DT, PWK, JJP, BP, PR, and TK. Investigation was carried out by DT, BP, KK and JJP. Resources were provided by DT, JJP, TK and BAN. Data curation was managed by DT, KK, PR and JJP. The original draft was prepared by DT, JJP, PR, SV. Manuscript review and editing were done by DT, JJP, BP, SV, PWK, TK and BAN. Visualization was prepared by DT, JJP and PR. Supervision was conducted by DT, JJP, PR and TK. Project administration was managed by DT, JJP, PR and TK.

Abstract

Background: Machine learning models can reduce the burden on doctors by converting medical records into International Classification of Diseases (ICD) codes in real time, thereby enhancing the efficiency of diagnosis and treatment. However, it faces challenges such as small datasets, diverse writing styles, unstructured records, and the need for semimanual preprocessing. Existing approaches, such as naive Bayes, Word2Vec, and convolutional neural networks, have limitations in handling missing values and understanding the context of medical texts, leading to a high error rate. We developed a fully automated pipeline based on the Key–bidirectional encoder representations from transformers (BERT) approach and large-scale medical records for continued pretraining, which effectively converts long free text into standard ICD codes. By adjusting parameter settings, such as mixed templates and soft verbalizers, the model can adapt flexibly to different requirements, enabling task-specific prompt learning.

Objective: This study aims to propose a prompt learning real-time framework based on pretrained language models that can automatically label long free-text data with ICD-10 codes for cardiovascular diseases without the need for semiautomatic preprocessing.

Methods: We integrated 4 components into our framework: a medical pretrained BERT, a keyword filtration BERT in a functional order, a fine-tuning phase, and task-specific prompt learning utilizing mixed templates and soft verbalizers. This framework was validated on a multicenter medical dataset for the automated ICD coding of 13 common cardiovascular diseases (584,969 records). Its performance was compared against robustly optimized BERT pretraining approach, extreme language network, and various BERT-based fine-tuning pipelines. Additionally, we evaluated the framework's performance under different prompt learning and fine-tuning settings. Furthermore, few-shot learning experiments were conducted to assess the feasibility and efficacy of our framework in scenarios involving small- to mid-sized datasets.

Results: Compared with traditional pretraining and fine-tuning pipelines, our approach achieved a higher micro–F1-score of 0.838 and a macro–area under the receiver operating characteristic curve (macro-AUC) of 0.958, which is 10% higher than other methods. Among different prompt learning setups, the combination of mixed templates and soft verbalizers yielded the best performance. Few-shot experiments showed that performance stabilized and the AUC peaked at 500 shots.

XSL•FO
RenderX

Conclusions: These findings underscore the effectiveness and superior performance of prompt learning and fine-tuning for subtasks within pretrained language models in medical practice. Our real-time ICD coding pipeline efficiently converts detailed medical free text into standardized labels, offering promising applications in clinical decision-making. It can assist doctors unfamiliar with the ICD coding system in organizing medical record information, thereby accelerating the medical process and enhancing the efficiency of diagnosis and treatment.

(JMIR Med Inform 2025;13:e63020) doi:10.2196/63020

Introduction

Background

The *International Classification of Diseases, 10th Revision* (*ICD-10*), is a universally recognized diagnostic categorization system widely used in medical insurance reimbursements, health reporting, mortality assessments, and related fields [1]. The *ICD-10*'s automatic coding mechanism enables rapid and accurate classification and statistical analysis of medical data, offering a scientific foundation for effective hospital administration and decision-making. In addition, the *ICD-10* automatic coding system accelerates disease diagnosis and treatment planning for medical practitioners, thereby improving medical efficacy and quality. Compared with the original *ICD* code, *ICD-10* provides over 14,000 distinct disease codes (in contrast to the thousands in *ICD-9*), enabling more detailed disease classification. This comprehensive system offers clinicians enhanced patient information, supporting the development of more precise treatment plans and care programs, ultimately improving the quality of care and patient satisfaction. Moreover, as an internationally standardized code, *ICD-10* is essential for global public health surveillance, epidemiological research, and international medical cooperation. Consequently, ensuring accurate *ICD* coding remains a critical priority in clinical practice.

In hospital settings, the assignment of *ICD* codes to unstructured clinical narratives in medical records is a manual task performed by skilled medical coders based on the attending physician's clinical diagnosis. Despite its critical importance, this process is often hindered by inefficiencies such as time consumption, susceptibility to errors, and high costs. Additionally, manual coding cannot always ensure the accuracy of *ICD* codes due to the complexity of code assignment, which requires a thorough consideration of the patient's overall health condition, including medical history, coexisting conditions, complications, surgical interventions, and specialized diagnostic procedures [2,3].

Machine Learning Techniques

The need to enhance efficiency and reduce errors has driven the development of various machine learning techniques to automate the medical *ICD* coding process. These techniques can be broadly classified into 4 main categories: rule-based systems [4,5], traditional supervised algorithms [6,7], gate unit–based deep learning approaches [7-9], and pretrained language models (PLMs) [9-19].

First, rule-based systems for automatic *ICD* coding rely on the creation of explicit rules and knowledge bases to map medical records to the appropriate *ICD* codes [4,5]. Although these approaches have been used for decades and have provided a foundation for more advanced techniques, they are limited by their lack of adaptability and scalability.

Second, traditional supervised algorithms, such as gradient-boosted trees, have been utilized for *ICD* coding due to their efficiency in handling large-scale, high-dimensional datasets. These algorithms rely on semistructured preprocessing, which involves organizing and refining semistructured data into a format suitable for analysis [6,7]. For example, Diao et al [6] developed a light gradient boosting machine–based pipeline for automatically coding 168 primary diagnosis *ICD-10* codes from discharge records and procedure texts, achieving an accuracy of 95.2%. Another study integrated long short-term memory networks with attention mechanisms to predict mortality in ICU patients using electronic health records, achieving significantly higher area under the receiver operating characteristic curve (AUC) scores compared with traditional statistical models and stand-alone long short-term memory networks [7].

Third, PLMs are neural network models with fixed architectures trained on large corpora, which can be fine-tuned for specific downstream tasks such as question answering and entity recognition [10-13]. A notable example is bidirectional encoder representations from transformers (BERT), a prominent PLM designed to learn deep bidirectional representations from large-scale unlabeled text data. BERT effectively captures semantic relationships in clinical records and can be easily adapted to various natural language processing (NLP) tasks through task-specific layers [13]. Coutinho and Martins [14] proposed a BERT model with a fine-tuning method for automatic *ICD-10* coding of death certificates based on free-text descriptions and associated documents. Additionally, Yan et al [15] introduced RadBERT, an ensemble model combining BERT-base, Clinical-BERT, the robustly optimized BERT pretraining approach (RoBERTa), and BioMed-RoBERTa adapted for radiology. Liu et al [16] evaluated RadBERT across 3 NLP tasks: abnormal sentence classification, report coding, and report summarization, demonstrating significantly better performance compared with existing transformer language models. Unstructured patient-generated health data can be leveraged to support clinical decision-making, remote monitoring, and self-care, including medication adherence and chronic disease management. By applying named entity recognition and customizable information extraction methods

XSL•FO
RenderX

based on medical ontologies, NLP models can extract a wide range of clinical information from unstructured patient-generated health data, even in low-resource settings with limited patient notes or training data [17]. Textual analysis presents numerous opportunities for future medical applications. It can aid in extracting information from various sources of medical data, such as clinical reports, nursing notes, scientific literature, and user-generated content. Additionally, vector-based representation methods can transform textual data within clinical documents into formats suitable for machine learning and can be applied to sequence modeling tasks, including sentiment analysis [18].

Finally, XLNet is another type of PLM that captures both forward and backward contexts of text [19]. It combines the advantages of autoregressive models and autoencoding models while overcoming their limitations. XLNet utilizes a permutation-based objective function that maximizes the expected likelihood of a text across all possible word orderings. It also incorporates the Transformer-XL (Transformer-Extra-Long) architecture, which enables long-term dependency modeling and improved memory efficiency. XLNet has been shown to outperform BERT and other baseline models on several natural language understanding tasks.

Prompt Engineering Techniques

By contrast, prompt engineering is a technique that involves the careful construction of prompts or inputs for artificial intelligence models to improve their performance on specific tasks. This technique includes selecting appropriate words, phrases, symbols, and formats to guide a large language model in generating high-quality and relevant text. Numerous studies have used prompts for model tuning to bridge the gap between pretraining objectives and downstream tasks, demonstrating that both discrete and continuous prompts can improve performance in few-shot and zero-shot tasks [20,21]. Furthermore, this technique within PLMs has been shown to outperform fine-tuning in various clinical decision-making tasks [22]. It has the advantage of requiring less data and computational resources, making it especially suitable for clinical settings.

There are 2 primary categories of prompting methods: hard prompts and soft prompts [22-25]. Hard prompts involve using an actual text string as the prompt and include methods that automatically search for templates within a discrete space, such as mining-based, paraphrasing-based, and gradient-based approaches [26-28]. The advantages of hard prompts are interpretability, portability, flexibility, and simplicity. However, designing effective prompts for specific tasks requires significant effort and creativity.

Soft prompts, by contrast, are learnable tensors concatenated with the input embeddings and can be optimized for a given dataset. The main advantage of soft prompts is their ability to achieve better performance than hard prompts by adapting to the model and the data. However, they are not human-readable and lack portability across different models.

Prefix tuning and P-tuning are 2 methods of prompt engineering that can enhance performance beyond traditional fine-tuning [22-24]. Prefix tuning is a lightweight approach that keeps the PLM parameters unchanged while optimizing a sequence of task-specific vectors called the prefix [23]. This prefix is added to the input and interacts with the model's hidden states at each layer. Its success depends on how effectively the prefix is initialized, particularly when data are limited. P-tuning is another prompt tuning strategy that performs comparably to fine-tuning across various tasks [24]. It reduces the number of PLM parameters through self-adaptive pruning and tunes a small number of continuous prompts at the beginning of each transformer layer.

The verbalizer is the final layer that defines the answer space and maps it to the target output. Typically, verbalizers are manually created, which can limit their coverage due to personal vocabulary biases [21,29]. To address this, some studies have proposed automatic verbalizer search methods to identify more effective verbalizers, also known as soft verbalizers [20,30-32].

Autonomous ICD Coding in Cardiovascular Disease

Cardiovascular disease (CVD) is currently a leading cause of death worldwide, posing a significant risk of mortality among patients [7]. Automatically labeling patients with CVD is essential for clinical decision-making and resource allocation. However, existing prediction models have limitations, including low accuracy, limited generalizability, and an inability to capture multicenter data. To address these challenges, we propose a prompt learning real-time framework based on PLMs that can automatically label long free-text data with *ICD-10* codes for CVDs without the need for semiautomatic preprocessing.

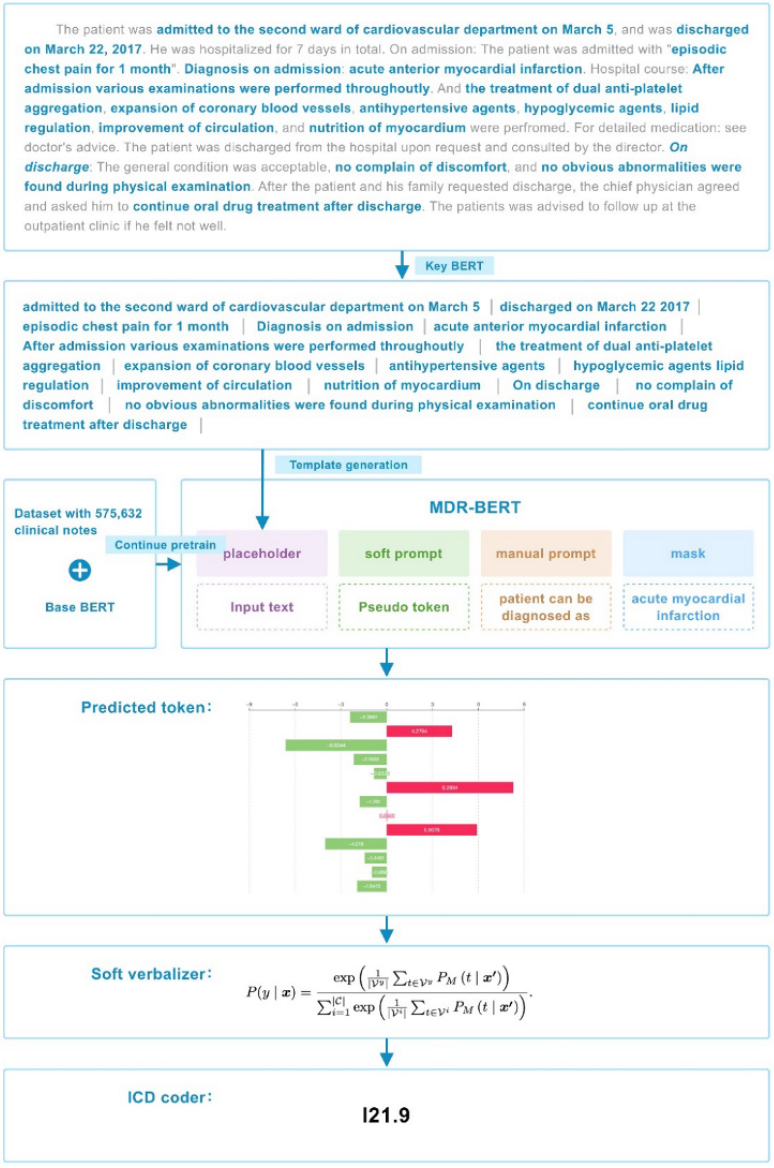
Our framework consists of 4 components: a medically oriented pretrained BERT, a keyword filtration BERT, a fine-tuning phase, and task-specific prompt learning facilitated by mixed templates and soft verbalizers. To validate the efficacy of our framework, we conducted comprehensive evaluations on a Chinese multicenter cardiovascular dataset that includes data from 13,000 patients with CVD. This deliberate choice of dataset ensures the robustness and wide applicability of our framework. We compared our framework with RoBERTa, XLNet, and various BERT-based fine-tuning pipelines to highlight its performance. Additionally, we conducted few-shot experiments to demonstrate its resilience. This work promises to provide valuable insights into enhancing medical knowledge extraction and its effective application, underscoring the need for continued research and development in this promising area. In future work, we plan to implement this fully automated *ICD* coding pipeline across various clinical applications, including clinical decision support systems, cohort studies, and disease early warning and diagnosis systems.

Methods

Ethical Considerations

The study was approved by the Ethics Committee of the Chinese PLA General Hospital (S2023-325-02). Ethical approval included a waiver for obtaining informed consent signatures from participants. The study posed no potential harm to participants and did not involve any compensation for their participation. To protect patient privacy, we used regular

XSL•FO
RenderX



expressions to parse and redact basic identifying information from the medical records. As these records were created using a standardized template, we ensured that the excerpts extracted for this study did not contain patients' names.

Overview

The overall framework of the model is shown in Figure 1. We used a corpus dataset of 575,632 clinical notes to continue training the original BERT model, which we named medical domain refinement-BERT (MDR-BERT), as the PLM for our work. For the classification task, we first applied Key-BERT to filter the discharge summaries. This method extracts keywords and splits long free-text data into shorter sentences.

We then constructed the input template for fine-tuning and prompt learning using 3 components: the soft prompt, the manual prompt, and the mask part. The manual prompt was a handcrafted text prompt containing discrete tokens. The soft prompt was a learnable pseudo-token with a few continuous parameters. The mask part represented the *ICD* coding label. Finally, we used a trainable soft verbalizer to compute and apply the softmax function to the probabilities of the *ICD* classes, producing the output. By designing specific prompts, it is possible to incorporate the knowledge of medical experts into the model, helping it better understand and perform *ICD* coding. These prompts can direct the model to focus on critical sections of the input text, thereby enhancing performance.

Dataset Characteristics

The cardiovascular dataset used in this study was obtained from the Cardiovascular Department of the Chinese PLA General Hospital's Medical Big Data Research Center in Beijing, China, which includes 9 medical centers with data aggregated into a comprehensive medical big data platform. Additionally, the hospital is a key center for the treatment of CVDs, with numerous specialized physicians and detailed medical records, making its data highly practical and representative. To ensure privacy, patient names and addresses were desensitized. The data platform consists of electronic health records aggregated

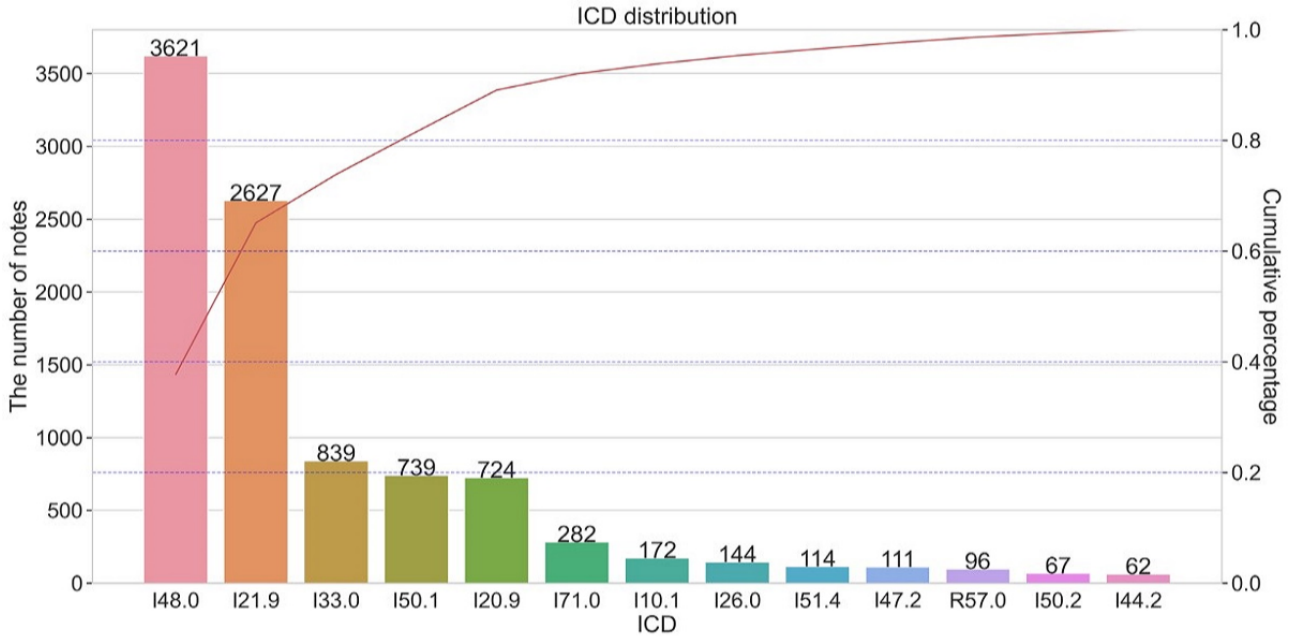
XSL•FO
RenderX

from 8 affiliated medical centers. A total of 584,969 clinical notes with structured *ICD* labels were extracted from admission records and discharge summaries in the Cardiovascular Department. We ensured that each diagnosis included at least 50 cases and adopted a stratified sampling approach to divide each disease category into training, validation, and test sets in a 3:1:1 ratio. The detailed distribution and basic statistical information of the dataset are shown in Figure 2.

Figure 2. Distribution and basic statistical information of the data set. ICD: International Classification of Diseases.

Based on the long-tailed distribution and clinician selection, 13 diseases were chosen for classification. These diseases include atrial fibrillation, acute myocardial infarction, infective endocarditis, acute left heart failure, acute coronary syndrome (ACS), acute aortic dissection, hypertensive emergency, acute pulmonary embolism, acute myocarditis, ventricular tachycardia, cardiogenic shock, acute heart failure, and third-degree atrioventricular block. The corresponding *ICD-10* codes and abbreviations for these diseases are listed in Table 1. Despite the disparity in the number of cases for different diseases, the imbalance inherent in medical data accurately reflects real-world conditions, taking into account the clinical insights of medical professionals. This imbalance represents the varying frequency at which different diseases occur in clinical practice. By preserving the raw data distribution and avoiding artificial balancing, our training approach aligns more closely with real-world medical practice. As a result, this enhances the model's generalization ability and its applicability in practical scenarios.

To ensure task independence and prevent data leakage, all clinical notes were divided into 2 parts: the pretraining corpus dataset and the *ICD* coding dataset. The pretraining corpus consisted of a total of 575,632 notes, while the *ICD* coding dataset included 9337 discharge records. The data were stratified by imbalanced *ICD* labels and randomly split into training, validation, and test sets in a 3:1:1 ratio. The sample sizes were as follows: 5734 in the training set, 1913 in the validation set, and 2007 in the test set. We applied regularization to truncate patients' basic information, as this information could negatively impact the model's fitting.



As shown in Figure 3, the distribution of the 13 *ICD* codes was imbalanced and exhibited a long-tail pattern. The dataset for *ICD* classification contains a total of 4.574×10^7 words, with an average of 490 words per note. The maximum and minimum lengths of the clinical notes are 5243 and 22 words, respectively.

Pretraining

Our study's foundational framework is based on BERT, a multilayer bidirectional transformer encoder known for its conceptual simplicity and empirical effectiveness [33]. This architecture consists of 12 layers, a hidden size dimension of 768, and 12 self-attention heads [13]. BERT's inherent self-attention mechanism provides the versatility to handle various downstream tasks by allowing the interchange of relevant inputs and outputs, making it well-suited for our task involving *ICD* classification through clinical records.

To adapt BERT to the specific requirements of our task, we continued training the PLM using an extensive medical corpus, resulting in MDR-BERT. During the tuning process, we selected a batch size of 32, considering the constraint of a maximum sequence length of 512 tokens. The Adam optimization algorithm was used with a conservative learning rate of 2×10^{-5}. The training was carried out over 15 epochs, an empirically determined figure based on the characteristics of the clinical dataset.

Key-BERT

The Key-BERT method offers a novel self-supervised framework for extracting keywords and keyphrases from textual content using deep learning techniques [34]. This approach leverages the contextual and semantic features provided by bidirectional transformers, with a particular focus on the influential BERT model. The method's architecture is designed for end-to-end training, utilizing a contextually self-annotated corpus that enables the model to develop a nuanced understanding of the complex relationships between words and

XSL•FO
RenderX

their semantic meanings. In the *ICD* coding task, Key-BERT leverages BERT's context-aware capabilities to extract keywords from the document, quickly identify the sections relevant to *ICD* coding, and reduce the risk of miscoding caused by misinterpreting or overlooking critical information in the text.

A distinctive feature of Key-BERT lies in its automated keyword labeling process. This process effectively utilizes contextual insights from bidirectional transformers to construct a carefully curated ground truth dataset. This approach bypasses the labor-intensive task of manual labeling and eliminates the need for domain-specific expertise.

The repository of self-labeled data generated by Key-BERT is partially shared with the NLP community, contributing to a deeper and more comprehensive understanding of keyword extraction techniques across various domains. This collaborative effort enhances the landscape of knowledge and expertise, driving advancements in the field of NLP and semantic information extraction.

To extract keywords using Key-BERT, the contextual feature vector for each word in a sentence is obtained by passing the sentence through the pretrained BERT model. Let $S = [w_1, w_2, ..., w_n]$ be a sentence consisting of n words, where w_i is the ith word in the sentence and E_i is the contextual feature vector of the ith word in the sentence. The sentence embedding vector, denoted as E_s, is obtained by averaging the feature vectors of all the words in the sentence:

$$E_i = \text{BERT_Embedding}(w_i) \quad \textbf{(1)}$$

$$E_s = (E_1 + E_2 + \cdots + E_n)/(n) \quad \textbf{(2)}$$

The cosine similarity metric is used to measure the similarity between the sentence embedding vector and the feature vectors of candidate keywords or keyphrases.

$$\text{Cos_SIM}(E_i, E_s) = (E_i \times E_s)/(||E_i|| \times ||E_s||) \quad \textbf{(3)}$$

The top-scoring keywords or keyphrases are returned as the most relevant to the document. Additionally, key medical terms are directly extracted using the medical diagnostic table, ensuring that essential terminology is accurately identified and applied.

Fine-Tuning and Prompt Learning

To fully leverage the clinical knowledge embedded within the dataset, our fine-tuning approach mirrors the unsupervised task used in the initial pretraining phase, known as masked language modeling (MLM). MLM involves randomly masking a predetermined proportion of input tokens, and the model then attempts to predict these masked tokens based on context. This process, commonly called a Cloze task, helps the model learn contextual relationships effectively.

For the fine-tuning phase in this study, we maintained the MLM framework to align with the pretraining procedure. A consistent masking rate of 15% was applied across the dataset. In addition to the fine-tuning process, we introduced prompt learning during parameter tuning. This approach involved the construction of a template comprising 4 distinct components: the input text, a soft prompt, a manual prompt, and a masking component. The manual prompt included discrete tokens that reflected the downstream task expected by the PLM. By contrast, the soft prompt comprised trainable continuous vectors, which enhanced the model's adaptability.

Formally, automatic *ICD* coding, as a text multiclassification task, can be denoted as (x, y), where x is the set of discharge summaries and y is the *ICD* code set of the 17 chosen discharge diagnoses as labels. Given a clinical record $x \in X$, it can be annotated with *ICD* codes of discharge diagnosis $y^x \in Y$ and a sequence of discrete input tokens $x = (x_0, x_1, ..., x_k)$, where k is the number of tokens in the sequence. Prompt learning can be achieved via modifying the x to a prompt format $x = \text{fp}(x)$, where the template $f_p(\cdot)$ will insert a number of extra embeddings to x along with a masked token, denoted by <[MASK]>. Compared with hard prompts, soft prompts replace some fixed manual components with trainable embeddings (continuous vectors) of the same dimension as the PLM. After that, x is fed into M, to predict the masked token, which is in accordance with the objective of M. The output of M will be a distribution over the fixed vocabulary V of M. The next crucial step is to map tokens in V to y for the downstream task with a mapping , known as verbalization. In a word, there are 2 essential components to be studied, the template of prompt $x' = f_p(x)$ and the mapping of verbalizer .

A mixed template of prompts in this paper is used. For simplicity, the prompt function $x' = f_p(x)$ is denoted as a sequence template:

$$x' = [P_0, P_1, \ldots, P_j], x, [P_{j+1}, P_{j+2}, \ldots, P_t], [\text{MASK}] \quad \textbf{(4)}$$

where P_i refers to the ith token in the template and t is the number of prompt tokens beyond x. P_i does not necessarily meet $P_i \in V$ other than manual hard prompt. As x' is fed to the PLM, the prompt tokens are also mapped to the embedding space, where we can assume that the tokens denoted as <[soft]> in the template can be tuned during training as pseudo-tokens. A simple example of a prompt template for automatic *ICD* coding could be as generated as follows:

$$x' = \text{<x><[soft]>be encoded as <[MASK]>} \quad \textbf{(5)}$$

Once these templates were formulated, the model inputs, along with the established templates, were processed through the trainable MDR-BERT model. Notably, in the final layer of the most advanced pipeline, a soft verbalizer mode was used. This mode manages the mapping process between the predicted tokens and the final *ICD* codes. The innovative feature of the soft verbalizer is its substitution of tokens in the verbalizer with trainable vectors, each tailored to a specific class. Generally, the verbalizer maps the probabilities of infrequent words in the vocabulary to the probabilities of the labels. The set of label words is denoted as V, the label space is Y, and V_y represents the subset of label words for label y. The final estimation of the probability for label y is calculated using equation 5, where g is utilized to convert the probability of label words to the probability of the label:

$$P(y|x_p) = g(P_M([\text{MASK}] = v|X_p)|v \in V_y) \quad \textbf{(6)}$$

XSL•FO
RenderX

This strategy enhances the precision and semantic accuracy of the generated outputs, enabling a more precise alignment between predicted tokens and the definitive *ICD* codes. Consequently, it is unnecessary to manually build an explicit mapping . for the soft verbalizer, as the trainable vectors do not have explainable semantic meaning. A matrix operator can represent the soft verbalizer as  [22-25], where n represents the size of y and m represents the dimension of output embeddings from M. For the verbalizer, θ_i denotes the ith row of  as the trainable vector of the ith class. The soft verbalizer replaces the original decoder head of M by mapping the embeddings of x' from M, denoted as $e(x')$, to the distribution over the classes of y. We denote the resulting mapping from  to the prediction of the embedding of <[MASK]> as , where l is the sequence length of x'. And then, the probability of class y can be calculated as follows:

The loss from the automatic *ICD* coding task can be backpropagated to tune only the embeddings for the prompt template and the verbalizer. The loss function can be expressed as follows:

Ultimately, the model learns to generate and map the most appropriate *ICD* codes to the corresponding discharge record.

The experiments were conducted using the OpenPrompt framework [22-25]. For prompt learning, we utilized the Adafactor optimizer for soft and mixed prompt templates, while the AdamW optimizer was used for the PLMs and soft verbalizers. In conventional fine-tuning, we applied the AdamW optimizer to the MLP heads and PLMs. To expedite the experiments, we used 2 Nvidia TESLA V100 GPUs, each with 16-GB memory, and set the batch size to 32 due to memory constraints.

The model's performance is influenced by variations in hyperparameters. In the comparisons presented, hyperparameters were carefully optimized for each model. To determine the optimal configuration, we used a random search strategy. This approach involves generating multiple random combinations of parameters, evaluating the performance of each combination, and selecting the one that yields the best results. Accuracy and AUC were chosen as the primary optimization objectives during the random search, as they intuitively reflect the model's classification performance. The strategy involved 100 training runs, each using randomly generated hyperparameters from the defined search space. To effectively address model overfitting, we carefully adjusted the dropout rate within a range of 0.1-0.5. After numerous training iterations, we found that the optimal dropout rate for the prompt learning phase is 0.382, while for the prompt tuning phase, it is 0.1563. In the prompt learning phase, a higher dropout rate contributes to improved generalization, serving as an effective safeguard against overfitting. In the subsequent fine-tuning phase, a lower dropout rate is used to ensure the model retains its learned attributes while enabling further performance enhancement. The optimal hyperparameters for the models are detailed in Table 2.

Table 2. The optimal hyperparameters and their search space.

Hyperparameters	Search space	Optimal hyperparameter	
		Prompt learning	Fine-tuning
Learning rate	log.uniform [1*10-5, 3*10-1]	0.0048	0.0121
Batch size	4	4	4
Gradient accumulation steps	range[2,10]	4	3
Dropout	range[0.1,0.5]	0.382	0.1563
Optimizer	[adamw, adafactor]	adamw	adafactor
Prompt learning rate	log.uniform[1*10-5, 3*10-1]	0.3	—[a]
Verbalizer learning rate	log.uniform[1*10-5, 1*10-1]	0.007	—

[a]Not available.

Evaluation Metrics

To thoroughly evaluate and compare the performance of the models, we used a range of metrics, including micro–F_1-score, macro-AUC, and accuracy. The definitions for micro-averaged precision and micro–F_1-score are provided in equations 9-11, while the macro-AUC is defined in equations 12 and 13.

Micro–F_1-score = [2 × (micro-P) × (micro-R)]/[(micro-P) + (micro-R)] **(11)**

where TP_i, FP_i, and FN_i represent true positives (correctly assigned instances), false positives (incorrect assignments by automated methods), and false negatives (correct instances omitted by automated methods), respectively, of code i, and l is the size of the sample space. The micro–F_1-score is the harmonic mean of micro-P and micro-R, and a bigger value of micro–F_1-score indicates a better performance.

XSL•FO
RenderX

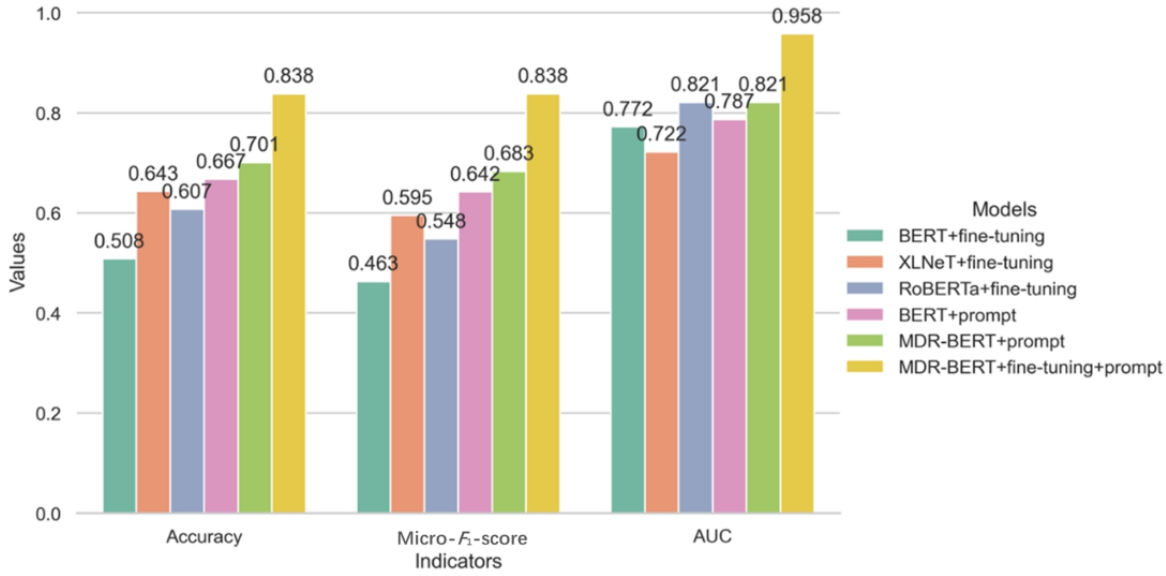
where n is the number of thresholds and K is the number of classes.

Data and Code Availability

Data acquisition requests can be made by contacting the corresponding author (KH). Given the sensitive nature of the hospital data, it cannot be released publicly. However, part of the downstream subtask data is currently undergoing desensitization and approval processes. The source code for this study is publicly available on GitHub [35].

Results

Performance of Different Pipelines



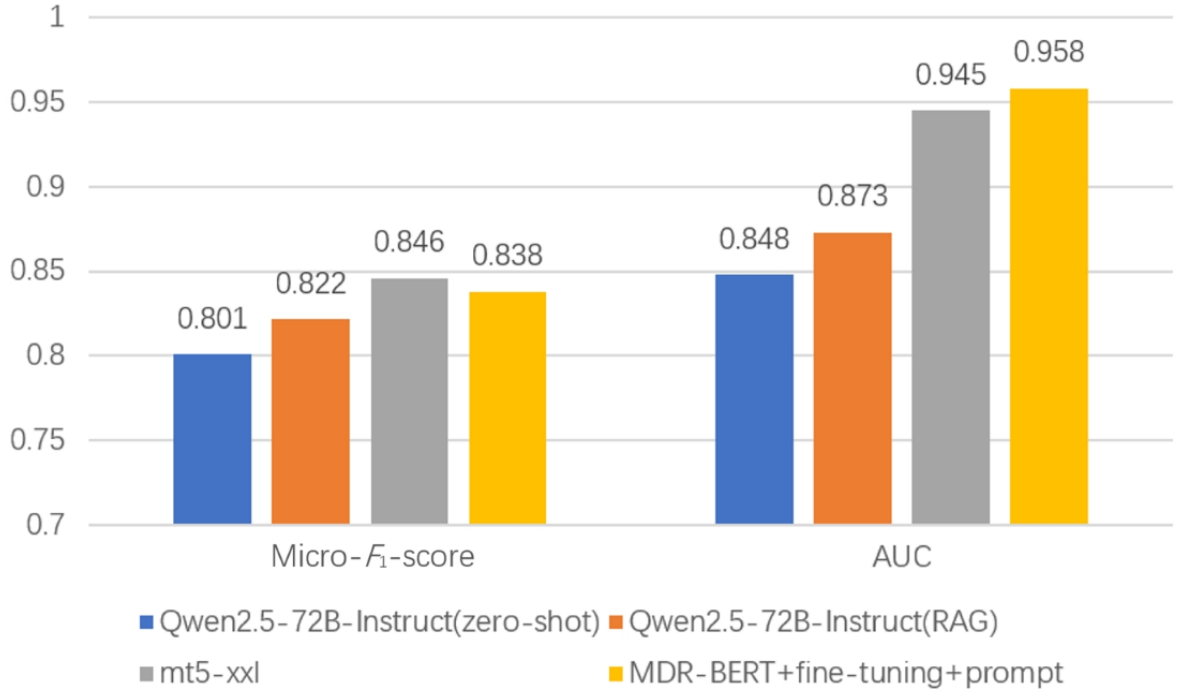
To evaluate the performance of different methods, we implemented 4 state-of-the-art algorithms: BERT [15], XLNet [18], RoBERTa [19,36], and prompt learning [22]. These PLMs were integrated with various algorithms to create 6 main pipelines: BERT with fine-tuning, XLNet with fine-tuning, RoBERTa with fine-tuning, BERT with prompt learning, MDR-BERT with prompt learning, and MDR-BERT with both fine-tuning and prompt learning. MDR-BERT is a PLM developed by further pretraining BERT on our medical corpus.

As shown in Figure 4, MDR-BERT with fine-tuning and prompt learning achieved the highest performance across all evaluation metrics, with a micro–F_1-score of 0.838, a macro-AUC of 0.958, and an accuracy of 0.838. MDR-BERT with prompt learning alone performed slightly worse than the combined fine-tuning and prompt learning approach, but both outperformed the other pipelines by a significant margin. This suggests that continued pretraining on clinical records can significantly enhance the performance of the PLM for the task, while freezing parameters may hinder the adaptation of smaller PLMs to the task.

Among the other pipelines, BERT with prompt learning achieved the highest accuracy (0.67) and the highest micro–F_1-score (0.64), though its macro-AUC (0.79) was slightly lower than that of RoBERTa with fine-tuning. This suggests that prompt learning, as a lightweight tuning approach, can match or even surpass traditional fine-tuning methods, aligning with the findings of Taylor et al [22].

We also conducted a comparison with state-of-the-art methods and selected 2 prominent models: mt5-xxl (11B) and Qwen2.5-72B-Instruct. Among these, mt5-xxl demonstrated the best performance in text classification, while Qwen2.5-72B-Instruct excelled as a large language model. For mt5-xxl, we fine-tuned the model using the training and validation sets from our fine-tuning dataset, setting the "prefix_text" to "Classify the following text:". For Qwen2.5-72B-Instruct, we conducted experiments using both zero-shot and retrieval augmented generation methods. In the zero-shot setting, we used prompts to constrain the diagnostic scope, allowing the model to make inferences based on the input information. For the retrieval augmented generation approach, we first encoded the training set using BGE-M3 (BAAI general embedding multilinguality, multigranularity, and multifunctionality) and stored it in a Faiss vector database. During the testing phase, we retrieved cases and classification results relevant to the input content and concatenated them with the prompt to enhance model performance.

Figure 4. The optimal hyperparameters and their search space. AUC: area under the receiver operating characteristic curve; BERT: bidirectional encoder representations from transformers; MDR: medical domain refinement; RoBERTa: robustly optimized BERT pretraining approach; XLNet: extreme language network.

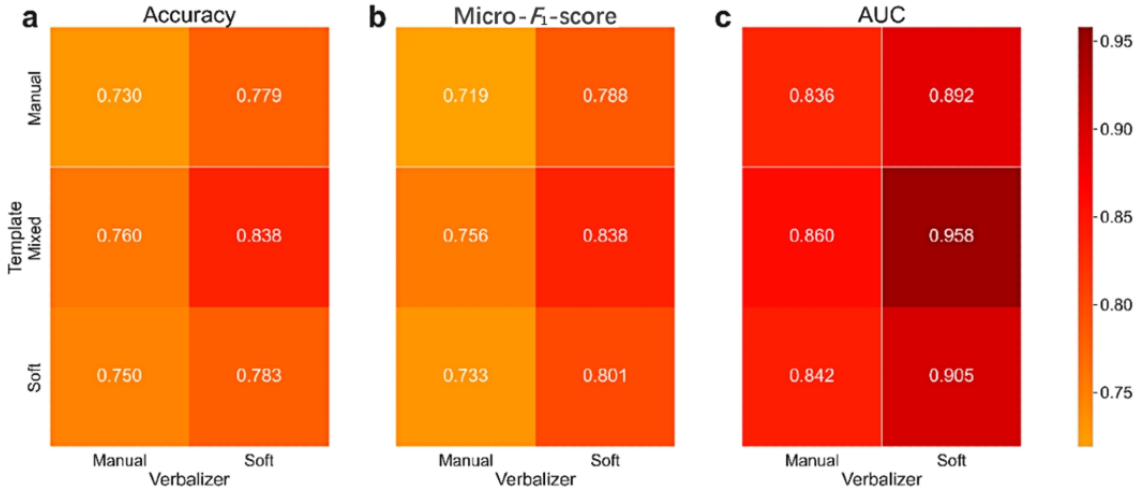


The experimental results indicate that the micro–F_1-score for the mt5-xxl method is 0.846, and the AUC value is 0.945. In comparison, the micro–F_1-score for the Qwen2.5-72B-Instruct method was 0.822, and the AUC value was 0.848. However, the accuracy of both methods does not surpass that of our MDR-BERT model (Figure 5). After a series of strategic

XSL•FO
RenderX

optimizations, our MDR-BERT model achieved results comparable to the fine-tuned mt5-xxl on specific tasks. This is primarily due to the specific structure of the medical records, which can be effectively captured by models with fewer parameters, meaning that overly complex models are not necessary to achieve good performance.

Figure 5. Micro-F_1-score and AUC values for the MDR-BERT model versus the QWEN2.5 and mt5-xxl models. AUC: area under the receiver operating characteristic curve; MDR: medical domain refinement; BERT: bidirectional encoder representations from transformers.



Performance of Different Prompt Learning Modes

We evaluated the performance of MDR-BERT under various settings of prompt learning and fine-tuning, using 3 types of templates (manual, soft, and mixed) and 2 types of verbalizers (manual and soft) as hyperparameters.

For templates, both scripted and self-adaptive patterns performed well independently, and their combination had a cumulative positive effect on performance. For verbalizers, the self-adaptive type outperformed the traditional manual vectors and had a greater impact on overall performance. As shown in Figure 6, the combination of mixed templates and the soft verbalizer achieved the best results.

Figure 6. Comparison among different prompt combinations in verbalizer and template. AUC: area under the receiver operating characteristic curve.

Take the following prompt template as an example:

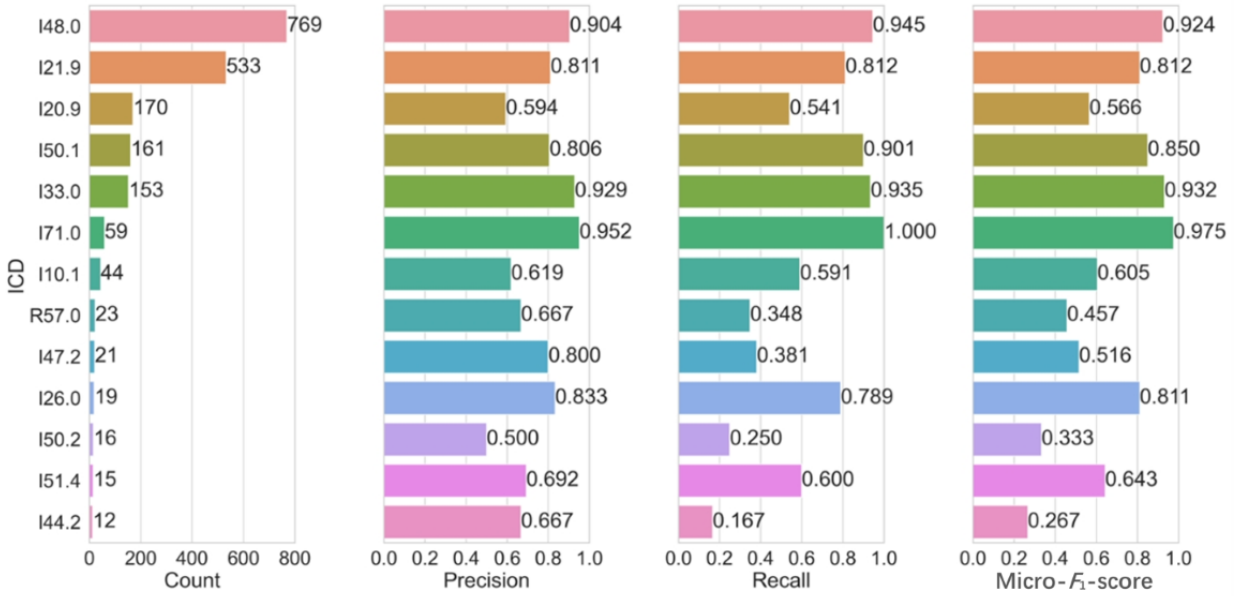
Mixed template: {“placeholder”: “text_a”} patient {“soft”:“ can be diagnosed as ”} {“mask”}.

For the following case:

The patient was discovered to have bradycardia and unconscious disturbance 7 days ago as a result of physical examination. After consultation with the director, lipid-lowering drugs were added. No diarrhea was detected, and no medication was administered at home. Permanent cardiac pacemaker

XSL•FO
RenderX

implantation under local anesthesia was carried out, and after the surgery, cephalosporin for injection was utilized to prevent infection.



The classification result by our model is as follows: "The patient can be diagnosed as {third-degree atrioventricular block}."

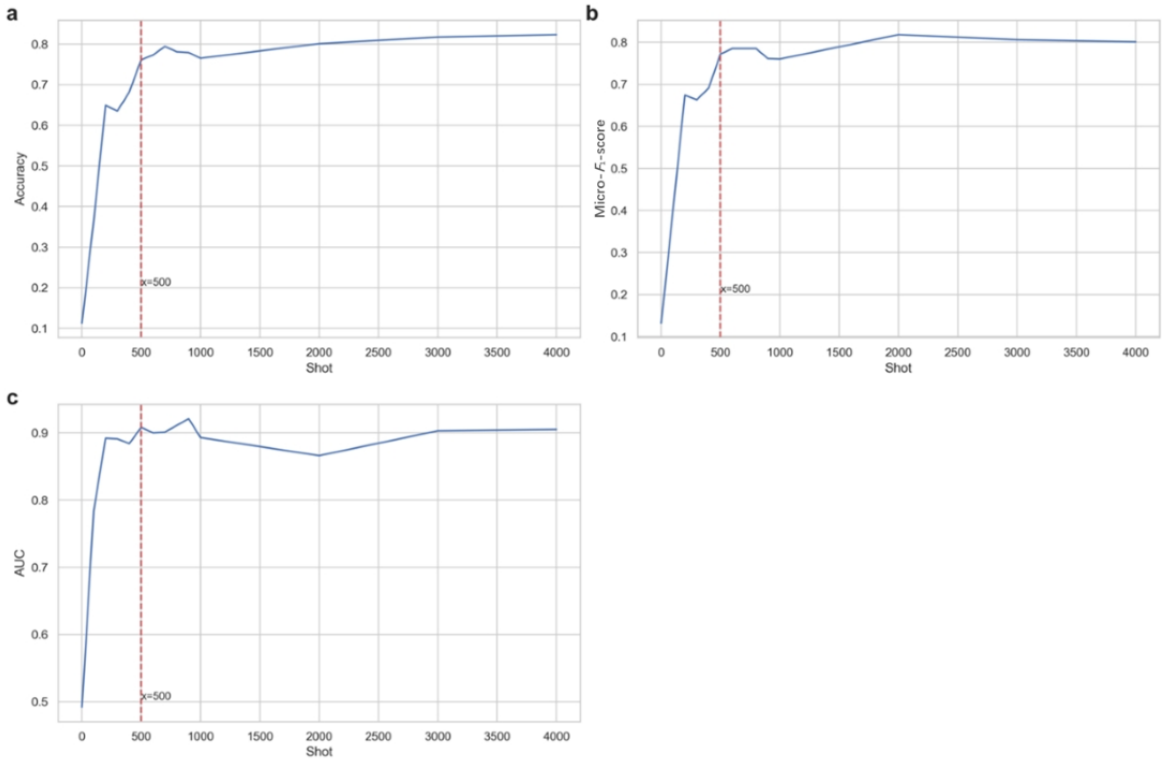
For the mixed template, the patient's bradycardia requires management through the implantation of a permanent pacemaker, indicating that bradycardia is a major medical concern. By applying soft verbalizers, we can guide the correct diagnosis by emphasizing both the reason for the pacemaker implantation and the underlying cause of bradycardia: "The patient can be diagnosed with third-degree atrioventricular block."

Performance of MDR-BERT With Fine-Tuning and Prompt Learning

We evaluated the performance of the MDR-BERT pipeline, incorporating both fine-tuning and prompt learning, for each ICD code using precision, recall, and micro–F_1-score. Figure 7 presents the results for these metrics across the 13 ICD classes.

Figure 7. Precision, recall, and micro-F_1 scores of every ICD code in the MDR-BERT pipeline with fine-tuning and prompt learning. BERT: bidirectional encoder representations from transformers; ICD: International Classification of Diseases; MDR: medical domain refinement.

The pipeline achieved high scores for most *ICD* codes, although the scores varied depending on the data distribution and sample size for each code. We observed a weak positive correlation between sample size and model performance, suggesting that larger samples enhanced the model's learning capability. Conversely, smaller samples tended to have lower micro–F_1-scores, with a trade-off between precision and recall for certain classes. Although our prediction accuracy for ACSs is relatively low, further analysis revealed that in actual clinical settings, ACS was frequently misdiagnosed as cardiac edema (hypertensive emergency) and pulmonary embolism (acute pulmonary embolism). These diseases exhibit similar clinical manifestations and, therefore, require meticulous differential diagnosis to rule out other possibilities. We believe that the overlap of symptoms is a major cause of the difficulty in classifying the model and that inconsistencies in medical histories recorded by physicians further complicate the model's ability to differentiate similar pathologies. Despite these variations, our pipeline demonstrated satisfactory performance across the different *ICD* codes.



Few-Shot Learning

We conducted few-shot experiments to evaluate the performance of the fine-tuned MDR-BERT with the prompt learning pipeline using different sample sizes from the training set. We randomly selected samples ranging from 1 to 4000 and evaluated the models on the test set. Figure 8 shows the accuracy, micro–F_1-score, and macro-AUC scores for each sample size.

The objective of small-sample learning is to develop models that can learn effectively and make accurate predictions with only a small number of samples, such as 500 or fewer. As shown in Figure 8, when the sample size reaches 500, the model's accuracy, AUC score, and other indicators not only achieve relatively high scores but also reach an inflection point and plateau. At this point, the model produces a relatively satisfactory outcome. This indicates that for the task of *ICD* coding using medical records, 500 samples may be sufficient for the model to learn the key features needed to distinguish between different diagnoses. It suggests that the model has captured enough information to make effective predictions. Additionally, the workload involved in annotating 500 medical texts is manageable and feasible. This number strikes a balance between the effort required for data preparation and the performance gains achieved by the model. Given the complexity and specialized nature of medical records, annotating 500 examples provides a comprehensive representation of the dataset while staying within practical limits. This makes it a reasonable and efficient choice for training the model to achieve satisfactory performance in *ICD* coding tasks.

Discussion

Principal Findings

An automated *ICD* coding system for long free-text data is a fundamental platform for clinical research and practice, including clinical trials and pharmacoeconomic management. In this study, we developed a framework based on Key-BERT, a continuously trained and tunable PLM, combined with task-specific prompt learning. We collected a total of 584,969 clinical notes from admission records and discharge summaries in the cardiovascular departments of 8 medical centers.

We used most of the data to continue pretraining a medical corpus and used an independent set of 9337 discharge records with 13 *ICD* codes for CVDs in the *ICD* classification subtask. Although the MDR-BERT model has some limitations, such as restricted generalization capacity and constraints on the length of context it can effectively process, it is important to note that medical texts often have a consistent structure and are generally less dependent on extensive contextual information. Given these characteristics of medical literature, our model is designed to avoid the errors commonly associated with the inherent limitations of BERT's methodology. The structured nature of medical documents enables the MDR-BERT model to function effectively within its designed parameters, mitigating potential issues that could arise from the broader weaknesses of the BERT framework when applied to more contextually complex or varied text types. To remove irrelevant information and limit the input token size, we filtered and truncated all the data for the *ICD* task into keyword-based segments using Key-BERT. The data were then stratified and split into training, validation, and test sets, with the test set used independently for final evaluation.

This study primarily focused on transformer-based algorithms, which have been widely applied and shown superior performance in large-scale medical long free-text tasks [4,11,16,17]. These algorithms can leverage PLMs that capture the semantic and syntactic information of natural language from extensive corpora, leading to significant performance improvements through multicenter datasets.

We compared 6 pipelines for the classification downstream task: BERT with fine-tuning, XLNet with fine-tuning, RoBERTa with fine-tuning, frozen BERT with prompt learning, frozen MDR-BERT with prompt learning, and tunable MDR-BERT with prompt learning. The prompt learning setup included 3 types of templates and 2 types of verbalizers. Among these pipelines, MDR-BERT with fine-tuning and prompt learning achieved the best performance on the test set, attaining a micro–F_1-score of 0.838, a macro-AUC of 0.958, and an accuracy of 0.838.

Compared with the pretraining models of RoBERTa and XLNet, our model achieved superior performance in terms of final accuracy and micro–F_1-score. This improvement was primarily due to the targeted optimization of the methods and the medical data we selected, which substantially enhanced the model's performance. Although RoBERTa and XLNet have larger pretraining corpora compared with BERT, our approach benefited more from using a continuation training corpus built from real electronic health records. This specialized data, tailored to our specific requirements, provided a greater enhancement to the model than more general pretraining data. This is why MDR-BERT performs comparably to, or better than, these alternatives in our settings. The favorable outcome of this pipeline can be attributed to the use of a large-scale

XSL•FO
RenderX

corpus-based PLM and the task-specific enhancements from the combination of fine-tuning and prompt learning [16,20,22-25]. Fine-tuning acts as a model adapter, aligning the model distribution with the task distribution and addressing domain shift and task mismatch issues inherent in PLMs. Prompt learning, with its compact prefix representation and sparse attention mechanism, augments the training data with diverse and natural examples. This augmentation helps mitigate data scarcity and label noise issues in small-sized datasets for downstream tasks.

The combination of fine-tuning and prompt learning acts as a regularization term that balances model complexity with data quality, ultimately enhancing overall performance. This integrated approach highlights the potential of leveraging advanced transformer-based models and customized learning strategies to improve automated medical coding and other clinical tasks.

Among the different prompt learning setups, the mixed template and soft verbalizer achieved the best performance. The soft template method outperformed the manual templates method, which can be attributed to the greater semantic and syntactic information, broader search space, and reduced trial-and-error process associated with the soft template method, making it more effective and less time-consuming [23,24].

The mixed template method is a hybrid approach that combines the advantages of both soft and manual templates. It uses a manual template as a base prompt to provide human-readable instructions and natural language labels, while a soft template serves as an auxiliary prompt to provide tunable embeddings that can adapt to specific downstream tasks. This way, the manual template leverages existing knowledge, while the soft template enhances expressiveness and flexibility.

For the verbalizer, the self-adaptive type had a significantly greater impact on overall performance compared with traditional manual vectors. The soft verbalizer adjusts to the optimal label space for each task and the scale of the pretrained model, rather than being limited by a fixed set of tokens [22,24]. This enhances the accuracy and robustness of the predictions, as well as the diversity and naturalness of the labels. Additionally, by tuning the verbalizer alongside other continuous prompts, it retains the benefits of prompt tuning over fine-tuning, eliminating the need to maintain a separate copy of model parameters for each task during inference.

To explore the influence of sample size on the performance of our pipeline, we conducted few-shot experiments with a range from 1 to 4000 shots. The results showed unsatisfactory evaluation metrics for small-scale shots, but performance improved rapidly and stabilized at around 500 shots. This suggests that for mid-sized language models, such as BERT, the semantic understanding and representation capabilities may not be strong enough. Therefore, tuning the parameters of the PLM with an appropriate sample size is necessary to achieve better performance on specific tasks.

Our research confirms that *ICD* classification tasks can be effectively accomplished by continuously optimizing the BERT model. Although this study used cardiology data for training, our model development strategy is not limited to this specific dataset; substituting the training data with data from other departments would also yield the expected outcomes. Therefore, our model demonstrates remarkable generalization capability. We firmly believe that the model we have developed, combined with the expertise of professional physicians, can effectively address the challenges of *ICD* classification for various diseases.

Limitations

Despite the reasonable performance of our pipeline, this study has certain limitations. First, we trained both the corpus part and the classification task of the framework solely in the cardiovascular department. As a result, the conclusions of this paper may not be generalizable to other medical fields. Second, the *ICD* classification subtask only involved 13 CVD codes, which is not comprehensive enough for clinical practice. Future research could expand to explore the automatic encoding of additional critical heart diseases or even extend to the entire clinical field. This could potentially enhance the applicability and effectiveness of the proposed approach for a broader range of clinical tasks. Third, our model aims to establish an automated analysis system using medical text. However, medical data are inherently multimodal, and modality augmentation can lead to improvements in accuracy. In this context, models such as label alignment for multimodal prompt learning [37] and multimodal equivalent transformer [38] are designed to handle multimodal data, demonstrating the greater potential for future advancements.

Conclusions

We proposed a real-time framework for *ICD* coding from long medical field–related text to *ICD* labels, eliminating the need for semistructured preprocessing. This framework incorporates Key-BERT, a continuously trained and tunable PLM, and task-specific prompt learning with mixed templates and soft verbalizers. We evaluated our model on a multicenter cardiovascular dataset and applied it to predict 13 *ICD* codes for CVDs, achieving high performance. Our model also demonstrated transferability and generalization across different centers.

Furthermore, we conducted few-shot experiments to investigate the impact of data size on model performance. The results showed that while the framework was effective on smaller datasets, a certain sample size was necessary to achieve a relatively stable performance level. This study serves as a benchmark for exploring the feasibility and performance of prompt learning in the subtask of large language models or PLMs. Using a multicenter dataset, the approach demonstrated robust performance across hospitals, highlighting its potential for broad deployment.

Few-shot learning experiments demonstrated feasibility with small-scale datasets, enabling applications for local training on single centers or various single-disease databases. The real-time model identifies *ICD* codes directly, accelerating automated coding compared with semiautomatic approaches that require segment preprocessing. This is particularly impactful for clinical decision support systems that rely on real-time *ICD* coding data.

XSL•FO
RenderX

Overall, the prompt learning paradigm achieved cutting-edge *ICD* assignment accuracy while offering deployability, few-shot learning capacity, and low latency—advantages that are highly beneficial for health care applications. This automated *ICD* coding pipeline could be further implemented in various clinical applications, such as clinical decision support systems, cohort studies, and disease early warning and diagnosis systems.

Abstract

Background: Lateral malleolar avulsion fractures (LMAFs) and subfibular ossicles (SFOs) are distinct entities that both present as small bone fragments near the lateral malleolus in imaging but require different treatment strategies. Clinical and radiological differentiation is challenging, which can impede timely and precise management. Magnetic resonance imaging (MRI) is the diagnostic gold standard for differentiating LMAFs from SFOs, whereas radiological differentiation using computed tomography (CT) alone is challenging in routine practice. Deep convolutional neural networks (DCNNs) have shown promise in musculoskeletal imaging diagnostics, but robust, multicenter evidence in this specific context is lacking.

Objective: This study aims to evaluate several state-of-the-art DCNNs—including the latest You Only Look Once (YOLO) v12 algorithm—for detecting and classifying LMAFs and SFOs in CT images, using MRI-based diagnoses as the gold standard and to compare model performance with radiologists reading CT alone.

Methods: In this retrospective study, 1918 patients (LMAF: n=1253, 65.3%; SFO: n=665, 34.7%) were enrolled from 2 hospitals in China between 2014 and 2024. MRI served as the gold standard and was independently interpreted by 2 senior musculoskeletal radiologists. Only CT images were used for model training, validation, and testing. CT images were manually annotated with bounding boxes. The cohort was randomly split into a training set (n=1092, 56.93%), internal validation set (n=476, 24.82%), and external test set (n=350, 18.25%). Four deep learning models—faster R-CNN, single shot multibox detector (SSD), RetinaNet, and YOLOv12—were trained and evaluated using identical procedures. Model performance was assessed using mean average precision at intersection over union=0.5 (mAP50), area under the receiver operating curve (AUC), accuracy, sensitivity, and specificity. The external test set was also independently interpreted by 2 musculoskeletal radiologists with 7 and 15 years of experience, with results compared with the best-performing model. Saliency maps were generated using Shapley values to enhance interpretability.

Results: Among the evaluated models, YOLOv12 achieved the highest detection and classification performance, with a mAP50 of 92.1% and an AUC of 0.983 on the external test set—significantly outperforming faster R-CNN (mAP50 63.7%; AUC 0.79); SSD (mAP50 63%; AUC 0.63); and RetinaNet (mAP50 67.0%; AUC 0.73)—all $P<.001$. When using CT alone, radiologists performed at a moderate level (accuracy: 75.6% and 69.1%; sensitivity: 75.0% and 65.2%; specificity: 76.0% and 71.1%), whereas YOLOv12 approached MRI-based reference performance (accuracy: 92.0%; sensitivity: 86.7%; specificity: 82.2%). Saliency maps corresponded well with expert-identified regions.

Conclusions: While MRI (read by senior radiologists) is the gold standard for distinguishing LMAFs from SFOs, CT-based differentiation is challenging for radiologists. A CT-only DCNN (YOLOv12) achieved substantially higher performance than

XSL•FO
RenderX

radiologists interpreting CT alone and approached the MRI-based reference standard, highlighting its potential to augment CT-based decision-making where MRI is limited or unavailable.

Introduction

Background

The ankle is the most frequently injured joint in the human body, accounting for nearly 5% of emergency visits and about 40% of sports-related injuries [1,2]. Inversion or blunt trauma often results in ligament sprains, muscle strains, or fractures [2]. Acute lateral malleolar avulsion fractures (LMAFs) occur in about 15% of inversion sprains and, if missed, may lead to nonunion, chronic instability, and pain, necessitating stricter immobilization or surgery compared with simple sprains [3,4]. Small bone fragments near the lateral malleolus may also be subfibular ossicles (SFOs), either as accessory bones (os subfibulae) or as remnants of nonunion avulsion fractures [5,6]. SFO prevalence ranges from 0.2% to 6.7% and they are usually asymptomatic but appear in 10% to 38.5% of chronic ankle instability cases, suggesting a link to chronic dysfunction [7]. Both LMAF and SFO may cause lateral ankle pain and instability, making treatment selection more relevant than etiologic differentiation [8,9]. However, diagnosis is difficult because of overlapping clinical symptoms and ambiguous history or physical findings [10]. Radiography, the first-line imaging, has a missed fracture rate of 14% to 85% owing to small fragments, minimal displacement, suboptimal imaging angles, low quality, insufficient clinical context, and anatomical overlaps [11-15]. Although computed tomography (CT) improves visualization, large-scale validation for LMAF is lacking. While fragment morphology on CT can aid in distinguishing LMAF from SFO [16,17], this is complicated by smooth edges, incomplete separation, or osteophytes [18]. Magnetic resonance imaging (MRI) excels at detecting bone marrow edema and ligament injuries [19] but is limited by thick slices, partial volume effects, contraindications, and poor emergency availability. Thus, reliable and automated imaging-based diagnosis remains a key clinical need.

Deep learning and radiomics have achieved impressive results for the automated detection and classification of musculoskeletal fractures—including those of the ankle [20], femoral neck [21], hip [22], knee [23], spine [24], ribs [25], and scapula [26]—by using various deep convolutional neural network (DCNN) models, such as You Only Look Once (YOLO) and faster region-based convolutional neural network (R-CNN). Despite these advances, most existing studies focus on single-task or single-model frameworks, leaving performance uncertainties for tasks requiring differentiation of closely related lesions. To date, no DCNN-based approaches for automated detection of LMAF and SFO have been reported. With continuous architectural innovation, DCNNs are gaining traction for more complex orthopedic imaging tasks. Early studies focused on normal anatomy identification or simple diagnoses [27], but recent work extended to recognizing and classifying a variety of lesions—including multiple myeloma [28], patellar dislocation [29,30], osteoarthritis [31], bone age assessment [32], bone metastasis [33], and lumbar disk herniation [34]. However, automated detection and classification of LMAF and SFO in CT images remain challenging because of the relatively simple regional anatomy, diverse injury patterns, overlapping structures, and frequent imaging artifacts that even experienced radiologists find difficult. This challenge is more pronounced in primary hospitals lacking experienced musculoskeletal imaging specialists, where misdiagnosis rates are higher. Our study addresses this specific gap and aims to improve diagnostic accuracy and efficiency for this overlooked region using DCNNs.

This Study

Studies using multi-model DCNN comparisons for detection and classification are still scarce. Comparative evaluation of mainstream architectures is valuable for understanding network performance and guiding the selection of optimal solutions for specific clinical tasks. YOLOv12, released by the Ultralytics team in February 2025, introduces substantial optimizations in network structure, feature fusion, and inference speed over its predecessors (eg, YOLOv8 and YOLOv9), achieving a better balance between accuracy and computational efficiency [35]. In this study, 4 advanced DCNN models—faster R-CNN, single shot multibox detector (SSD), RetinaNet, and the latest YOLOv12—were benchmarked for automated detection and classification of LMAF and SFO in multicenter clinical CT datasets. The models' accuracy was quantitatively evaluated using metrics, such as mean average precision (mAP), and their diagnostic performance was compared with that of radiologists to assess clinical utility.

Methods

Ethical Considerations

The authors are accountable for all aspects of the work in ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved. The study was conducted in accordance with the Declaration of Helsinki (as revised in 2013). This study was approved by the Institutional Ethics Committee of the Sir Run Run Hospital, Nanjing Medical University (2025-SRFA-626), and Air Force Medical Center, Air Force Medical University (2025-11-PJ01). The institutional ethics committees waived written informed consent in view of the retrospective nature of the study. All the procedures performed were part of routine care. All images were deidentified before use to protect patient privacy.

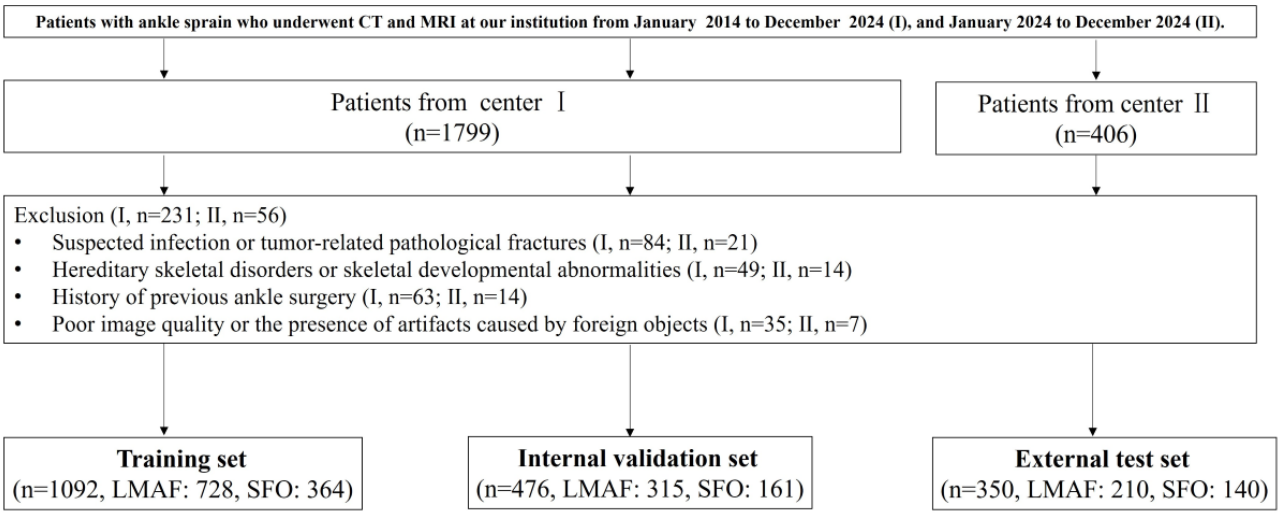
Patient Selection

Our study used medical imaging data from 2 hospitals in China. For the development of the training and internal validation sets, CT and MRI data were collected from patients with ankle sprains treated at Air Force Medical Center, Air Force Medical University, between January 2014 and December 2024 (Textbox 1).

Textbox 1. Inclusion and exclusion criteria for the development of the training and internal validation sets.

Inclusion criteria



- Age ≥18 years with a history of ankle sprain within the past 3 days
- CT images showing a single free bone fragment adjacent to the lateral malleolus (size ≥1 cm)
- Complete raw CT and MRI data, with both examinations performed within a 1-week interval
- Complete clinical information, including sex and age

Exclusion criteria

- Suspected infection- or tumor-related pathological fractures
- Hereditary skeletal disorders or skeletal dysplasia
- Previous ankle surgery
- Low image quality or artifacts

An independent external test set was collected between January 2024 and December 2024 from Sir Run Run Hospital, Nanjing Medical University, using the same inclusion and exclusion criteria (Textbox 1). The detailed case selection process is illustrated in Figure 1. A total of 1918 patients were included in this study, comprising 1253 (65.3%) patients with LMAF and 665 (34.7%) with SFO. Of these, 1568 cases from the Air Force Medical Center were randomly allocated to a training set (n=1092, 56.93%) and an internal validation set (n=476, 24.82%) at a 7:3 ratio. The remaining 350 cases from Sir Run Run Hospital formed an independent external test set. Thus, the final training, internal validation, and external test sets contained 1092 (56.93%), 476 (24.82%), and 350 (18.25%) cases, respectively.

Figure 1. Flowchart summarizing patient selection and allocation to the dataset of our study.

CT and MRI Acquisition Protocol

Patient age and sex were obtained from the clinical record system. Details of CT and MRI acquisition devices and imaging parameters are provided in Multimedia Appendix 1. For CT scanning, patients were positioned supine with toes pointing upward and the ankle in a neutral position. The scan range included the distal tibia and fibula to the talus and surrounding bony structures (including the talus, calcaneus, and navicular). All images were reconstructed using a bone window (window width: 1500; window level: 500) with a slice thickness and interval of 1.0 mm. All image processing and analysis in our study were performed on the bone window of CT images.

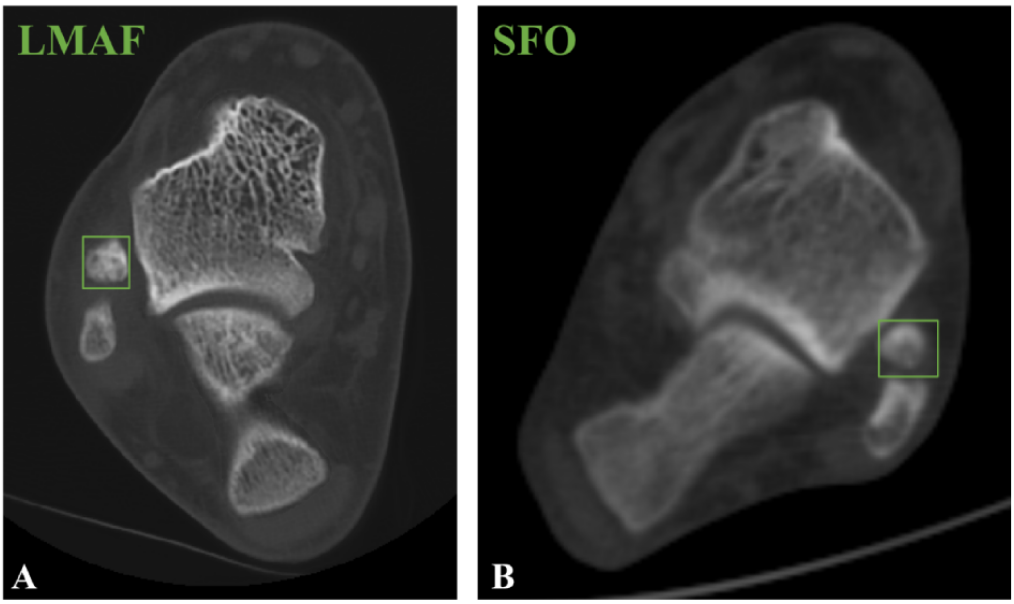
Classification

In this study, the initial differentiation between LMAF and SFO was made on the basis of MRI findings, which served as the reference standard for diagnosis. LMAF was defined as the presence of bone marrow edema in the corresponding region of the distal fibula on MRI, frequently accompanied by soft tissue swelling or evidence of ligamentous injury [36]. In contrast, SFO was characterized by the absence of bone marrow edema and lack of surrounding soft tissue injury, consistent with a chronic, stable ossicle. The interpretation of MRI images was independently performed by 2 senior radiologists, each with more than 20 years of experience in musculoskeletal

XSL•FO
RenderX

imaging. The evaluation criteria included cortical continuity of the distal fibula, the margin and morphology of the bone fragment, and associated soft tissue changes. Any discrepancy between the 2 radiologists' interpretations was resolved through consensus discussion. In cases where consensus could not be reached, a third experienced musculoskeletal radiologist was consulted, and the final diagnosis was established on the basis of a majority opinion.

Evaluation of the Radiologists' Visual Diagnoses Based on CT Images



For the external test set, each case was independently reviewed by radiologist 1 (a deputy chief radiologist with 15 years of musculoskeletal imaging experience) and radiologist 2 (an attending radiologist with 7 years of musculoskeletal imaging experience). Neither radiologist had access to the MRI results or clinical data during image interpretation. All images were evaluated independently by radiologists 1 and 2. Each radiologist recorded their classification of LMAF or SFO independently. For purposes of calculating diagnostic performance metrics, the diagnostic results of each radiologist were compared against the reference standard, which was established by MRI findings. Each radiologist's performance on the external test set was then directly compared with that of the YOLOv12 model to evaluate whether the artificial intelligence (AI) model outperformed human assessment.

Data Preparation

All CT images were acquired in Digital Imaging and Communications in Medicine (DICOM) format to ensure high resolution and rich grayscale information. Data preprocessing, a critical step in our study, included data selection, image format conversion, normalization, and data augmentation to meet the requirements for model development. Metadata, such as scanning parameters, slice thickness, and window width and level, were extracted using specialized tools to ensure data completeness. All images were converted to standardized PNG format while maintaining original resolution, facilitating subsequent size unification. To address grayscale distribution differences resulting from various scanners and settings, histogram equalization and pixel normalization were applied, mapping grayscale values to a fixed range. All images were resized to 640×640 pixels, providing consistent input dimensions for the models. To further increase data volume and enhance model robustness, data augmentation techniques such as random rotation, translation, scaling, and mirroring were used, generating additional training samples without compromising medical image integrity. This approach improved the model's ability to recognize fracture features from various angles and positions. The entire preprocessing pipeline ensured uniform data quality and format, providing high-quality, well-annotated images for training, thereby improving the accuracy and robustness of the detection tasks.

The annotation stage was performed independently by radiologists 1 and 2. Each lesion was labeled with a tight bounding box (Figure 2) using the Visual Geometry Group Image Annotator (VGG Image Annotator, University of Oxford). The fracture regions were manually outlined, and all annotations underwent cross-validation and quality control to ensure that each bounding box accurately represented the clinical lesion. To meet the input requirements of the detection models, we further processed the bounding boxes and cropped the images, ensuring that both the annotated regions and surrounding contextual information were consistently retained. This provided the models with sufficient and high-quality training samples.

Figure 2. The lesions are labeled by drawing a tight bounding box. (A) An example of lateral malleolar avulsion fracture (LMAF). (B) An example of subfibular ossicle (SFO).

LMAF and SFO Detection Networks

In our study, 4 types of state-of-the-art object detection networks for LMAF and SFO detection on CT images were used (Figure 3).

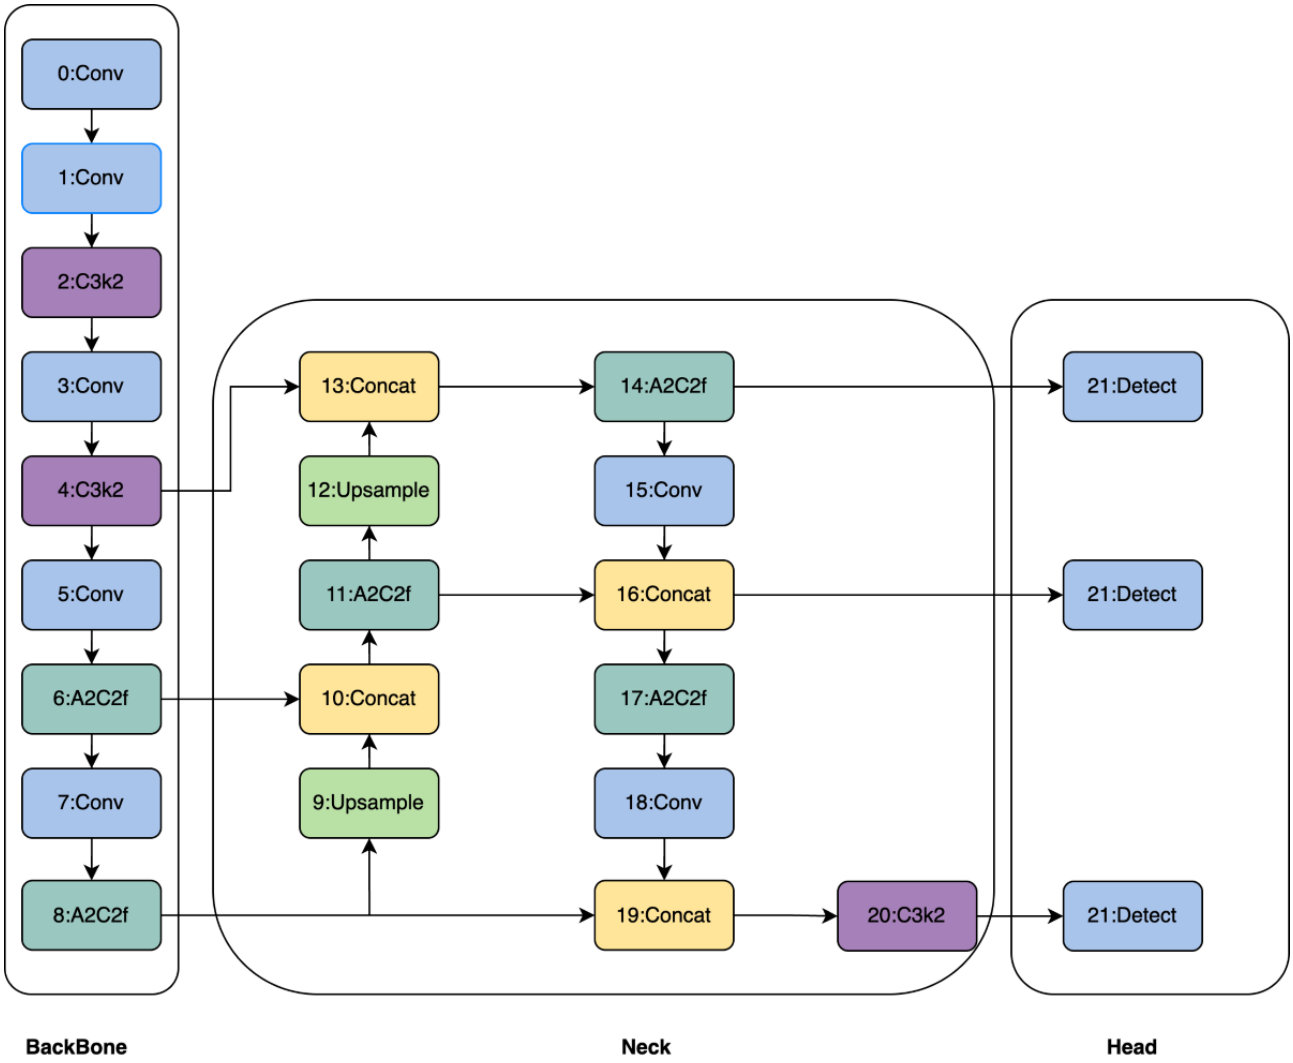

Figure 3. Schematic diagram of deep learning approaches for detection of lateral malleolar avulsion fracture (LMAF) and subfibular ossicle (SFO) on computed tomography (CT) images. R-CNN: region-based convolutional neural network; SSD: single shot multibox detector; YOLO: You Only Look Once.

In this study, we used the YOLOv12 architecture, which was recently introduced on February 19, 2025, as the core detection network for LMAF and SFO identification (Figure 4). YOLOv12 advances previous one-stage detectors through a series of architectural innovations that balance high detection accuracy and efficient inference, which is critical in clinical and real-time applications. YOLOv12 is built upon a fully convolutional network backbone, eliminating fully connected layers to enhance both computational efficiency and spatial information retention. The network starts with a series of stacked convolutional and pooling layers in the front end, enabling progressive extraction of low-level features such as edges, textures, and local structures. This early feature extraction facilitates the precise localization of subtle abnormalities frequently present in medical images. Subsequently, multiple residual blocks capture higher-level semantic features, ensuring a comprehensive representation of features at different scales. YOLOv12 also incorporates a multi-scale feature fusion module, which integrates deep and shallow features via cross-layer connections, enabling precise localization in fine regions, such as fracture sites. In addition, an adaptive anchor box mechanism and multi-scale prediction strategy enable the model to achieve high performance in both classification and localization tasks. Finally, the introduction of a lightweight attention mechanism enhances the model's focus on fracture edges and subtle structural features, improving detection accuracy and robustness while maintaining real-time inference capability.

XSL•FO
RenderX

Figure 4. The model architecture of YOLOv12.

To further boost localization reliability, YOLOv12 uses an adaptive anchor box mechanism. Anchor box sizes are dynamically learned from the training data distributions, optimizing the detection of objects with varying shapes and scales. In addition, a multi-scale prediction head enables simultaneous detection at 3 distinct spatial resolutions, allowing the model to maintain high precision when dealing with objects of different sizes. A notable architectural advancement is the integration of a lightweight attention mechanism based on coordinate attention modules. This enables the network to adaptively recalibrate feature responses, directing more focus toward critical areas—such as fracture boundaries or subtle morphological cues—while suppressing irrelevant background information. This not only improves detection performance, especially for challenging cases, but also preserves the real-time inference speed required in clinical workflows. All experiments were performed using the PyTorch 2.3 framework (Meta Platforms) on an NVIDIA RTX 4090 GPU (NVIDIA Corporation). The above hyperparameter choices were optimized by grid search to maximize the mAP on the validation subset. The main hyperparameter configurations were as follows: input image size: 640×640 pixels; batch size: 32; learning rate: initialized at 0.01 with cosine annealing schedule; optimizer: stochastic gradient descent with momentum 0.937 and weight decay 0.0005; anchor box generation: k-means clustering on the training data set; confidence threshold: 0.01; nonmaximum suppression intersection over union (IoU) threshold: 0.5; attention module: coordinate attention with a reduction ratio of 32; augmentation: mosaic, mix-up, and random affine transformations.

To comprehensively compare the performance of different models in the detection of LMAF and SFO, in addition to YOLOv12, we also implemented 3 other object detection models: faster R-CNN, SSD, and RetinaNet. Faster R-CNN, a representative 2-stage detection model, generates region proposals through a region proposal network, followed by refined classification and bounding box regression, providing a strong benchmark for localization accuracy. The SSD model uses a single-stage detection strategy, enabling high-speed detection while supporting multi-scale object detection. RetinaNet introduces the focal loss function to effectively address class imbalance and enhance the detection of small targets and subtle structures. All models were trained and tested using the same data preprocessing and augmentation strategies to ensure experimental comparability. In addition, specific hyperparameter tuning strategies were designed for each model.

XSL•FO
RenderX

Training Setup

The detection networks were trained for 50 epochs with a batch size of 8. Data augmentation techniques applied during training included rotation (angle range −30° to 30°), width and height translation (horizontal and vertical axes: −20% to 20%), and scaling (range 0% to 20%). The networks were optimized using the AdamW optimizer with β_1=0.9 and β_2=0.999. The initial learning rate was set to 1×10^{3} and reduced to 1×10 if the validation loss plateaued after 25 epochs. All deep learning models were implemented in Python 3 using the PyTorch framework (Meta Platforms) and trained on a workstation equipped with an Intel i9–7900X CPU (Intel Corporation; 3.3 GHz), 128 GB RAM, and 2 NVIDIA TITAN RTX GPU (NVIDIA Corporation). All models were trained and tested under identical computational conditions, using the same data augmentation pipeline and 3 consistent hyperparameters, ensuring an unbiased comparison across models.

Evaluation Metrics and Vision Transformer Shapley Saliency Maps

An end-to-end training architecture was adopted throughout the network design, with joint optimization of module parameters achieved via error backpropagation. To evaluate the detection performance for LMAF and SFO, we used the following metrics: mAP, average precision (AP), precision, recall, and F_1- score. AP was determined by the area under the precision-recall (PR) curve, which was constructed based on the maximum overlap (IoU) between detected and ground-truth bounding boxes. The PR curve is a key tool for assessing the performance of classifiers or object detection models, especially in the context of class imbalance, by visualizing the trade-off between precision and recall across different decision thresholds. Detection time was also measured for a comprehensive performance comparison, aiming to provide multidimensional insights for the clinical application of automated LMAF and SFO detection.

The mAP measures the model's AP across different classes and IoU thresholds, and we calculated the AP at an IoU threshold of 0.5 (ie, mAP50). Please refer to Multimedia Appendix 2 for the calculation method. To further interpret the model's decision process, saliency maps were generated using Shapley techniques [37]. Receiver operating characteristic curves and the AUC were plotted and calculated to assess model performance, and the DeLong test was used to compare AUCs between models. Calibration curves and decision curve analysis were computed and plotted using the *RMS* and *rmda* packages in R software (version 4.0.2), and the Hosmer-Lemeshow test was used to evaluate calibration. For radiologists 1 and 2, diagnostic performance metrics—including sensitivity, specificity, accuracy, and AUC—were calculated for LMAF and SFO diagnosis, and the DeLong test was used to determine whether differences in AUC were significant. A *P* value <.05 was considered statistically significant. The statistical analyses were carried out using our internally developed PixelMedAI platform. This platform was programmed in Python version 3.8 and primarily used libraries, such as PyTorch, NumPy, and SciPy. This approach ensures a robust evaluation of both AI models and human experts, facilitating a comprehensive understanding of the effectiveness of saliency maps in enhancing diagnostic accuracy in clinical settings.

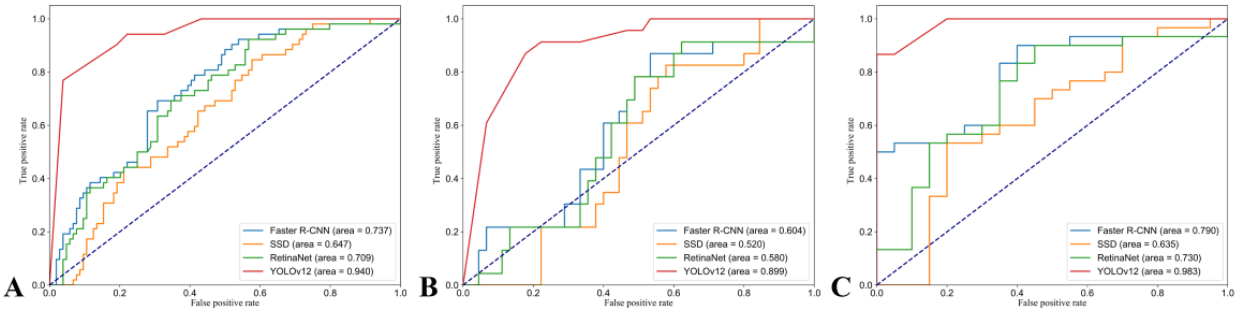
Results

Clinical Features of the Studied Patients

A total of 1918 patients met the inclusion criteria, comprising 1253 (65.3%) cases of LMAF and 665 (34.7%) cases of SFO. The patients ranged in age from 18 to 70 years, with a mean age of 33.52 (SD 12.83) years. There were 1463 male patients (76.3%) and 355 female patients (23.7%). The training set, internal validation set, and external test set included 1092 (56.93%) cases (LMAF: 728, SFO: 364), 476 (24.82%) cases (LMAF: 315, SFO: 161), and 350 (18.25%) cases (LMAF: 210, SFO: 140), respectively. The demographic characteristics of each data set are summarized in Table 1.

Table 1. Baseline characteristics of patients in the training set, internal validation set and external test set.

Characteristics	Training set (n=1092)	Internal validation set (n=476)	External test set (n=350)
Age (years), mean (SD)	31.47 (11.57)	32.19 (11.68)	34.94 (13.03)
Sex, n (%)			
Male	847 (77.6)	364 (76.4)	252 (72)
Female	245 (22.4)	112 (23.6)	98 (28)



Performance of DCNNs

A comparative analysis of the detection performance of the 4 DCNNs models was conducted. Figure 5 and Multimedia Appendix 3 show the PR curves and receiver operating characteristic (ROC) curves for each model, respectively. The mAP values were compared to evaluate the performance of each DCNN in detecting LMAF and SFO on CT images. In the test set, the mAP50 scores for faster R-CNN, SSD, RetinaNet, and YOLOv12 were 63.7%, 63.0%, 67.0%, and 92.1%, respectively. The AUC values for these models were 0.79 (faster R-CNN), 0.63 (SSD), 0.73 (RetinaNet), and 0.98 (YOLOv12). Pairwise comparisons using the DeLong test indicated that the differences were all statistically significant (*P*<.001). These results demonstrate that YOLOv12 achieved the highest performance in LMAF and SFO detection. The calibration curves for the detection performance of the 4 DCNNs on CT images are shown in Multimedia Appendix 4. The calibration curves demonstrated that the predicted probabilities closely matched the actual probabilities for the training, internal validation, and external test sets (Hosmer-Lemeshow test: χ^2=8.2, χ^2=2.6, χ^2=22.7, respectively; *P*=.21, *P*=.46, *P*=.13, respectively). Decision curve

XSL•FO
RenderX

analysis results indicate that YOLOv12 may serve as an effective tool for detecting LMAF and SFO (Multimedia Appendix 5).

Figure 5. Precision and recall curves of the 4 deep convolutional neural networks are displayed in different colors, with the performance of each model shown. YOLOv12 achieved the highest performance, as demonstrated in its precision and recall curve. (A) Training set. (B) Internal validation set. (C) External test set. R-CNN: region-based convolutional neural network; SSD: single shot multibox detector; YOLO: You Only Look Once.

Performance Between the YOLOv12 Model and Radiologists' Readings

Table 2 shows the AUC, sensitivity, specificity, and accuracy of YOLOv12 and radiologists 1 and 2 in detecting LMAF and SFO. The AUCs for YOLOv12, radiologist 1, and radiologist 2 were 0.983, 0.755, and 0.682, respectively. Pairwise comparisons using the DeLong test revealed statistically significant between radiologist 1, radiologist 2, and YOLOv12 (P=.004, P<.001), indicating that YOLOv12 outperformed both radiologists.

Table 2. Comparison of AUC, accuracy, sensitivity, and specificity between the YOLOv12 model and radiologists' readings.

	AUC	Accuracy	Sensitivity	Specificity	*P* value
YOLOv12	0.983	0.920	0.867	0.822	–
Radiologist 1	0.755	0.756	0.750	0.760	.004
Radiologist 2	0.682	0.691	0.652	0.711	<.001

Evaluation of Saliency Maps

Saliency maps generated using the Shapley technique were used to highlight the region's most influential for predicting LMAF (Figure 6) and SFO (Figure 7), with red pixels indicating areas with the greatest impact on the model's predictions. As shown in Figure 6D, YOLOv12 assigned a relatively high probability (0.93) to LMAF, and the saliency map correspondingly highlights the LMAF region. In Figure 7D, YOLOv12 assigned a relatively low probability (0.32) to LMAF, indicating a higher probability for SFO, and the saliency map highlights the SFO region accordingly.

Discussion

Principal Findings

Our study is the first to systematically evaluate and compare multiple mainstream DCNNs for the automatic detection and classification of LMAF and SFO on ankle CT images. Among the models tested, YOLOv12 demonstrated the highest detection accuracy and efficiency, with mAP50 of 92.1% and AUC of 0.98 on the external validation cohort. When compared with radiologists 1 and 2 with different experience levels, YOLOv12 surpassed human performance in accuracy, sensitivity, and specificity, highlighting the powerful potential of deep learning for recognizing subtle and complex anatomical structures. Quantitative analysis further confirmed the model's high reproducibility and stability, effectively addressing limitations of human interpretation, such as inconsistency and time consumption. Most errors were associated with confusing anatomical variations and inaccurate localization of lesion boundaries, but overall, the model met the practical needs for clinical auxiliary diagnosis and provided a solid technical foundation for intelligent diagnosis in orthopedics. In keeping with real-world clinical workflows—where LMAF and SFO may coexist and readers are expected to detect all relevant abnormalities within a single study—our primary evaluation focused on performance in the combined data set.

XSL•FO
RenderX

Comparison to Prior Work

Prior work using object detection networks—such as faster R-CNN, RetinaNet, or earlier YOLO versions (eg, YOLOv3 to YOLOv8)—has achieved promising results for fracture localization in radiographs, but performance often declined in cases involving small, subtle lesions or overlapping anatomical structures [26,38,39]. Furthermore, these studies were typically limited by homogeneous datasets, single-center validation, or a lack of rigorous comparison to clinical radiologist interpretation. Our study addresses these gaps by introducing a comprehensive, multicenter evaluation of several state-of-the-art DCNN architectures, including the newly released YOLOv12 model. Notably, YOLOv12 incorporates advanced multiscale feature fusion and optimized attention mechanisms, resulting in substantial improvements in both detection accuracy and computational efficiency over previous frameworks [40]. Compared with earlier works, our head-to-head benchmarking on large-scale, well-annotated multicenter CT data sets demonstrates that YOLOv12 outperformed established models, such as faster R-CNN, SSD, and RetinaNet in terms of mAP, AUC, sensitivity, and specificity. Moreover, unlike most previous research—which reported model performance in isolation—our study directly compares the diagnostic capability of deep learning models with radiologists of differing clinical experience. YOLOv12 demonstrated superior accuracy (92% vs 75.6% and 69.1%) and AUC (0.98 vs 0.76 and 0.68) over 2 musculoskeletal imaging specialists, underscoring its clinical potential for assisting or augmenting human diagnosis, particularly in settings where radiological expertise may be limited.

Performance Interpretation

In this study, the YOLOv12-based object detection model achieved a mAP of 92.1% at an IoU threshold of 0.5 (mAP50) on the test set, indicating that the model was able to accurately detect 92.1% of actual lesion regions when the IoU threshold was set to 0.5. Specifically, this metric reflects the proportion of predicted bounding boxes whose overlap with the ground-truth annotated lesion regions reached or exceeded 50%. Although this result demonstrates the model's strong performance in localizing lesion targets, some differences remained between the predicted and actual regions in terms of size and shape, mainly because of the relatively lenient IoU threshold. Such discrepancies are common in practical applications; nevertheless, the model is largely capable of accurately capturing key lesion information to meet the requirements of subsequent diagnostic assistance. The automatic detection and classification capabilities of YOLOv12 exhibited high reproducibility and stability, effectively compensating for the limitations of manual interpretation in terms of repeatability and efficiency, thereby providing more reliable technical support for clinical diagnosis. YOLOv12 incorporates advanced attention mechanisms and a multi-branch feature fusion structure, enabling it to efficiently capture object information at different scales and under complex scenarios [41]. Furthermore, its optimized network architecture and lightweight design significantly reduced the number of model parameters and computational load while maintaining high detection performance, balancing inference speed with resource use efficiency. This makes it suitable for edge deployment and large-scale real-time detection tasks in actual applications.

Detection Errors and Challenges

In our study, the first main error observed with the YOLOv12 model was the misclassification of SFO as LMAF, resulting in false positives. This misjudgment was primarily caused by confusion with normal anatomical structures or adjacent soft tissue shadows, as some anatomical variants or features of the fibula could easily be mistaken for pathological findings by the network [42]. These misleading regions also pose a considerable challenge for human readers, reflecting the DCNN's sensitivity to areas with "clear boundaries and interrupted bone continuity" during the learning process [43], which closely mirrors the clinical approach used by physicians. Therefore, many of the model's false positives overlapped with the subtle or ambiguous cases that even experienced clinicians might misinterpret.

The second error type involved correct detection of the presence of abnormal structures, but imprecise localization of the region of interest. In these instances, the model could identify that a loose fragment or abnormal bone structure existed, yet failed to delineate the precise borders or classify the fragment correctly, particularly regarding its exact size, avulsion site, or associated ligament anatomy. Further analysis revealed that while DCNNs are generally adept at capturing the spatial relationship between fractures, joints, and adjacent bone structures, they remain less effective in distinguishing finer anatomical details [44]. Cases with subtle displacement, overlapping structures, or minimal contrast differences contributed to these localization issues. Future improvements could be achieved by integrating detection networks with training datasets that include enhanced annotation of normal anatomical variations, thereby reducing both false-positive and false-negative rates through a more nuanced understanding of the relevant anatomical context [45].

Limitations and Future Directions

Our study still has some limitations. First, when comparing the performance of the YOLOv12 with that of radiologists for automatic detection and classification of LMAF and SFO on CT images, the experimental design required informing the radiologists in advance about the specific lesion types and regions of interest. This likely improved the diagnostic accuracy of the radiologists and resulted in an optimistically biased representation of manual interpretation. In real clinical practice, some lesions are easily missed or misdiagnosed, so this "prompt" provided a considerable advantage to the physicians. Second, this study did not include complex cases with multiple coexisting lesions, which reduced the amount of data available for model training. Future studies should incorporate such complex or multifocal cases to better evaluate the accuracy of DCNNs in clinical scenarios that more closely resemble real-world situations. Third, all imaging data in this study were collected from only 2 medical institutions. Although multiple scanners and extensive data augmentation were used to minimize bias, this may still affect the generalizability of the model to other institutions and populations. To further improve the model's applicability and robustness, future work should involve validation with multicenter, multi-scanner, and multisource

XSL•FO
RenderX

datasets [46]. Fourth, while our design enhances clinical realism, it limits the granularity of class-specific assessment; we did not perform separate training or testing on LMAF-only and SFO-only datasets or report per-class mAP. As our dataset expands, we plan to conduct category-specific experiments and provide detailed per-class detection metrics to further delineate class-dependent performance and error modes.

Conclusions

Our study developed a DCNN-based method for automatic detection and classification of LMAF and SFO in CT images. The results showed that the YOLOv12 network outperformed mainstream models such as faster R-CNN, SSD, and RetinaNet in both detection and classification tasks. In addition, the YOLOv12 model achieved higher classification accuracy than radiologists.

Acknowledgments

This work was supported by Medical Scientific Research Project of the Jiangsu Provincial Health Commission (grant M2024055) and the Medical Imaging Artificial Intelligence Special Research Fund Project, Nanjing Medical Association Radiology Branch (grant 16). We express our gratitude to the editor and anonymous reviewers for their insightful comments and suggestions, which have greatly enhanced the quality of our paper. We also extend our thanks to American Journal Experts for their assistance in editing the language of an earlier draft of this manuscript. We appreciate the guidance and support from the PixelMedAI platform and its developers concerning the code used in this revised manuscript.

Data Availability

The datasets generated or analyzed during this study are not publicly available because of privacy or ethical restrictions but are available from the corresponding author upon reasonable request.

Abstract

Background: Mammography is a key imaging modality for breast cancer screening and diagnosis, with the Breast Imaging Reporting and Data System (BI-RADS) providing standardized risk stratification. However, BI-RADS category 4 lesions pose a diagnostic challenge due to their wide malignancy probability range and substantial overlap between benign and malignant findings. Moreover, current interpretations rely heavily on radiologists' expertise, leading to variability and potential diagnostic errors. Recent advances in large language models (LLMs), such as ChatGPT-4o, Claude 3 Opus, and DeepSeek-R1, offer new possibilities for automated medical report interpretation.

Objective: This study aims to explore the feasibility of LLMs in evaluating the benign or malignant subcategories of BI-RADS category 4 lesions based on free-text mammography reports.

Methods: This retrospective, single-center study included 307 patients (mean age 47.25, 11.39 years) with BI-RADS category 4 mammography reports between May 2021 and March 2024. Three LLMs (ChatGPT-4o, Claude 3 Opus, and DeepSeek-R1) classified BI-RADS 4 subcategories from the reports' text only, whereas radiologists based their classifications on image review. Pathology served as the reference standard, and the reproducibility of LLMs' predictions was assessed. The diagnostic performance of radiologists and LLMs was compared, and the internal reasoning behind LLMs' misclassifications was analyzed.

Results: ChatGPT-4o demonstrated higher reproducibility than DeepSeek-R1 and Claude 3 Opus (Fleiss κ 0.850 vs 0.824 and 0.732, respectively). Although the overall accuracy of LLMs was lower than that of radiologists (senior: 74.5%; junior: 72.0%; DeepSeek-R1: 63.5%; ChatGPT-4o: 62.4%; Claude 3 Opus: 60.8%), their sensitivity was higher (senior: 80.7%; junior: 68.0%; DeepSeek-R1: 84.0%; ChatGPT-4o: 84.7%; Claude 3 Opus: 92.7%), while specificity remained lower (senior: 68.3%; junior: 76.1%; DeepSeek-R1: 43.0%; ChatGPT-4o: 40.1%; Claude 3 Opus: 28.9%). DeepSeek-R1 achieved the best prediction accuracy among LLMs with an area under the receiver operating characteristic curve of 0.64 (95% CI 0.57-0.70), followed by ChatGPT-4o (0.62, 95% CI 0.56-0.69) and Claude 3 Opus (0.61, 95% CI 0.54-0.67). By comparison, junior and senior radiologists achieved higher area under the receiver operating characteristic curves of 0.72 (95% CI 0.66-0.78) and 0.75 (95% CI 0.69-0.80), respectively. DeLong testing confirmed that all three LLMs performed significantly worse than both junior and senior radiologists (all $P<.05$), and no significant difference was observed between the two radiologist groups ($P=.55$). At the subcategory level, ChatGPT-4o yielded an overall F_1-score of 47.6%, DeepSeek-R1 achieved 45.6%, and Claude 3 Opus achieved 36.2%.

Conclusions: LLMs are feasible for distinguishing between benign and malignant lesions in BI-RADS category 4, with good stability and high sensitivity, but relatively insufficient specificity. They show potential in screening and may assist radiologists in reducing missed diagnoses.

KEYWORDS

large language models; BI-RADS; breast; mammography; ChatGPT-4o; Claude 3 Opus; DeepSeek-R1; Breast Imaging Reporting and Data System

Introduction

Breast cancer remains one of the leading causes of cancer-related death among women worldwide. Accurate and efficient diagnosis, along with appropriate clinical management, is critical for improving patient outcomes [1]. The Breast Imaging Reporting and Data System (BI-RADS) provides a standardized framework for assessing the risk of breast lesions. BI-RADS category 4 carries a wide range of malignancy probabilities, from 2% to 95%, with considerable overlap between benign and malignant findings [2]. Consequently, the precise classification and characterization of BI-RADS category 4 lesions remain challenging. Clinical guidelines recommend image-guided biopsy as the next step for BI-RADS 4 lesions, which inevitably leads to unnecessary invasive procedures in patients with benign conditions, increasing both economic and psychological burdens. Moreover, current diagnostic practices rely heavily on radiologists' expertise. The subjectivity in interpretation and potential diagnostic errors may compromise the accuracy of category 4 assessments and subsequently influence patient management and treatment decisions [3].

In recent years, the rapid development of artificial intelligence (AI) has had a profound impact on the field of medical imaging, particularly through the rise of large language models (LLMs), such as the generative pretrained transformer (GPT), which possess outstanding capabilities in understanding human language [4]. ChatGPT, developed by OpenAI, is recognized for its sophisticated natural language processing abilities, leveraging a large-scale neural network trained on diverse textual data to generate coherent and contextually relevant outputs [5,6]. Similarly, Claude 3, created by the AI startup Anthropic, is designed to provide advanced cognitive performance and intelligent task handling. DeepSeek, a more recent entrant in the AI landscape, has attracted considerable attention for its efficient and open-source LLM architecture. It demonstrates forward-thinking design based on a native sparse attention mechanism that significantly improves traditional AI models in both training and inference efficiency, particularly enhancing long-context reasoning while maintaining performance and reducing pretraining costs [7,8]. Notably, DeepSeek is developed by a Chinese team and has been specially optimized for Chinese-language tasks, and multiple studies have already demonstrated its applicability in various medical domains [9-11].

Recent studies have highlighted the promising potential of LLMs in clinical applications, particularly in supporting decision-making processes and improving workflow efficiency across various medical specialties [12-14]. However, most research has primarily focused on converting clinical free text into structured formats, such as standardized summaries or classification labels [15-18]. In parallel, some studies have assessed the diagnostic reasoning or decision support capabilities of LLMs using free-text clinical inputs in controlled scenarios, such as imaging-based risk stratification and patient case assessments [19-23]. To date, only a few studies [24-27] have begun to explore the feasibility of using LLMs to directly generate diagnoses and clinical recommendations from free-text reports, such as those related to thyroid and musculoskeletal disorders. Preliminary investigations have suggested that LLMs have broad potential in assisting physicians with BI-RADS classification [28-30], but these studies have addressed the full spectrum of BI-RADS categories. Currently, no research has specifically focused on the particularly challenging BI-RADS category 4, where there is significant overlap between benign and malignant lesions. To our knowledge, no published studies have examined the use of LLMs to assist in the fine-grained subcategorization within BI-RADS category 4.

This study aims to evaluate the feasibility of using three LLMs (ChatGPT-4o, Claude 3 Opus, and DeepSeek-R1) to predict the specific subcategories of BI-RADS category 4 lesions based on free-text mammography reports and to further analyze the diagnostic reasoning behind their outputs.

Methods

Patients and Data

This study retrospectively collected mammography reports from patients who underwent breast cancer screening or diagnostic evaluation between May 2021 and March 2024. All reports were generated by breast radiologists certified by the institutional board. The reports were written and categorized in free-text format in Chinese. Each report was initially drafted by a junior radiologist (≤5 years of experience) based on imaging findings and subsequently reviewed by a senior radiologist (≥10 years of experience). The final version of each radiology report used as input to the LLMs was based on the senior radiologist's revision, as senior radiologists had the authority to modify initial drafts during review. The final report explicitly assigned BI-RADS category 4 subcategories (4A, 4B, or 4C). The inclusion criteria were as follows: lesions classified as BI-RADS category 4 by the senior radiologist; patients who underwent surgical excision or core needle biopsy within 1 month after mammography and had a definitive pathological diagnosis; and reports containing complete imaging descriptions, including BI-RADS descriptors, impressions, and the final BI-RADS category assigned by the radiologist. The exclusion criteria included (1) a prior diagnosis of breast cancer or a history of breast surgery, radiotherapy, or chemotherapy and (2) follow-up cases after treatment.

Ethical Considerations

The text processed by the LLMs is strictly confined to personal history reports. These reports were stripped of any information that could lead to patient identification, ensuring confidentiality and anonymity. The model's interpretation of the texts focuses

XSL•FO
RenderX

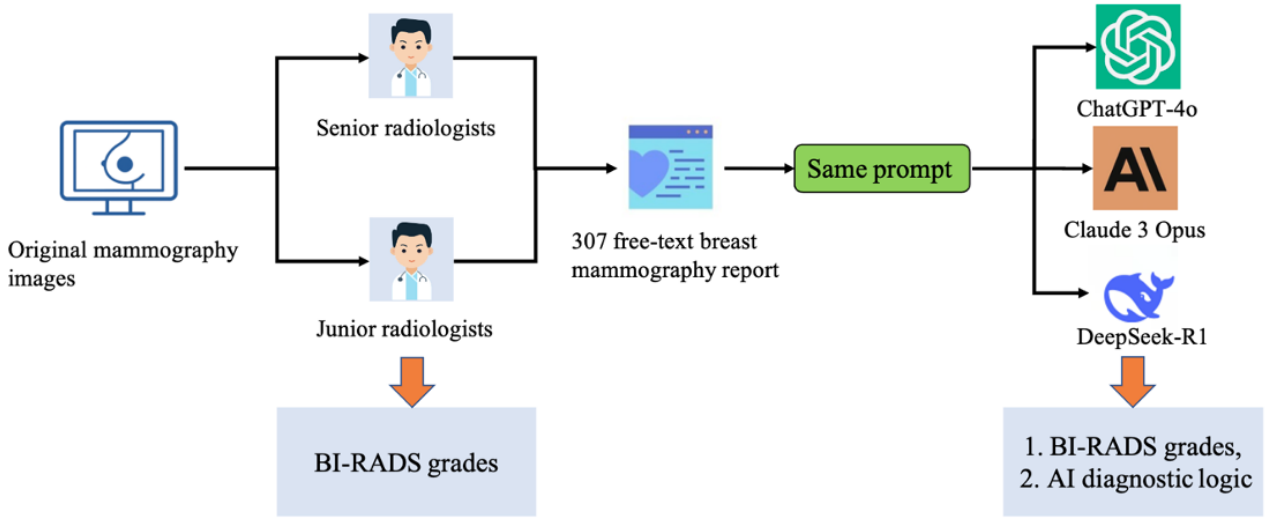
solely on identifying and structuring data relevant to the study without compromising individual privacy.

The study's design and methodology were previously communicated to and reviewed by the hospital's ethics committee. The research received the necessary approval, confirming that it adheres to the ethical standards required for patient data research. The study was granted an exemption from requiring informed consent due to its exclusive use of nonidentifiable data. Formal approval was obtained on June 9, 2025, under the reference number Peking University Shenzhen Hospital (Research) (2025) No.126.

LLMs and Prompt Design

Three LLMs were used in this study: ChatGPT-4o (version May 24, 2024), Claude 3 Opus (version March 4, 2024), and DeepSeek-R1 (version January 20, 2025). All models were called between July 1, 2024, and March 15, 2025, with temperature set to zero and the default max-tokens setting. Each model responded to prompts in a single round.

Each model was instructed to act as an experienced breast radiology expert, providing specific BI-RADS classifications based on the input free-text reports. The following standardized prompt was used:



> *Assume you are a radiologist. Based on the following mammography report, please predict the benign or malignant nature of each nodule and provide a specific BI-RADS classification. Only one BI-RADS category is allowed. If classified as category 4, please clearly specify whether it is 4A, 4B, or 4C, and explain your diagnostic reasoning.*

This prompt was designed to evaluate the model's ability to interpret detailed imaging descriptions, make accurate classifications, and articulate its diagnostic rationale. No fine-tuning was performed on any of the three models, and all prompts were delivered in Chinese. The full Chinese prompt and example outputs from LLMs are provided in Multimedia Appendix 1, and a summary of prompt versions tested during pilot runs and their observed output limitations is presented in Multimedia Appendix 2.

Workflow

The workflow of this study is illustrated in Figure 1. In this study, junior and senior radiologists interpreted the original mammography images to assign BI-RADS subcategories, whereas the LLMs analyzed only the deidentified free-text reports without access to imaging data. All mammography reports were deidentified before model input by removing patient-identifiable information and BI-RADS conclusions to ensure privacy and prevent label leakage. No further structural normalization or terminology unification was performed to preserve the natural language variability present in clinical practice [31]. Each report was analyzed by ChatGPT-4o, Claude 3 Opus, and DeepSeek-R1 using an open-ended prompt. To ensure consistency and reliability, each model was queried three times with the same report. All BI-RADS classification results from LLM outputs were manually extracted by two independent researchers. In cases of disagreement, a third researcher adjudicated the final decision to ensure accuracy and consistency. For each report, the most frequently occurring classification among the three responses was selected as the final result. If the three outputs differed without a clear majority, the case was deemed invalid and excluded from further analysis. This approach was designed to minimize variability and enhance the reliability of LLM-generated outputs. Additionally, we compared the consistency of BI-RADS classifications between LLMs and radiologists, as well as between junior and senior radiologists. To further explore the misclassification mechanisms of the LLMs, we manually reviewed the prediction rationales associated with all misclassified cases. Key imaging features, such as lesion size, calcification, shape, and margin characteristics, were extracted from the explanatory content generated by the LLMs and categorized in reference to the BI-RADS classification criteria. Feature extraction and interpretation were performed independently by two experienced radiologists. Any discrepancies were resolved through consensus discussions to ensure analytical rigor and objectivity.

Statistical Analysis

Categorical variables were presented as frequencies (percentages), and continuous variables were expressed as means (SDs). In this study, lesions classified as BI-RADS 4A or below were considered benign, while those classified as 4B or above were considered malignant, in line with prior studies that have used this binary grouping to reflect increasing malignancy risk across subcategories [32,33]. Pathological diagnosis served as the reference standard only for binary classification (benign vs malignant), and a senior radiologist's subcategory assignment was used as the reference standard for analyses involving BI-RADS 4 subcategories (4A, 4B, 4C). The diagnostic performance of radiologists and LLMs in distinguishing between benign and malignant lesions was assessed using the χ^2 test. Cohen κ coefficient was used to evaluate pairwise agreement between each assessment method, while Fleiss κ was used to assess the consistency of the three repeated outputs from each LLM. A Fleiss κ value less than 0.2 indicated poor agreement, 0.2 to 0.4 fair agreement, 0.4 to 0.6 moderate agreement, 0.6 to 0.8 substantial agreement, and 0.8 to 1.0 almost perfect agreement. Independent samples *t* tests were used to compare the differences in lesion size between benign and malignant groups. Receiver operating characteristic curve analysis was performed to assess diagnostic performance, and the area under the receiver operating characteristic curve (AUC), sensitivity, specificity, accuracy, and F_1-score were calculated. AUC values were compared using the DeLong test. A 2-sided *P* value less than .05 was considered statistically significant. All statistical analyses were performed using SPSS software (version 26.0; IBM Corp).

Results

Patients and Histopathological Subtypes

A total of 307 mammography reports from 307 female patients were included in this study, encompassing 309 breast lesions. The mean age of the patients was 47.25 (SD 11.39) years. Among the lesions, 152 (49.2%) were benign, and 157 (50.8%) were malignant, as determined by histopathological diagnosis. The mean size of benign lesions was 16.2 (SD 11.9) mm, and that of malignant lesions was 17.8 (SD 13.2) mm. The histopathological subtypes of the 309 BI-RADS category 4 lesions are summarized in Table 1.

Table 1. Histopathological findings of 309 Breast Imaging Reporting and Data System (BI-RADS) category 4 breast lesions.

Histopathological subtype	Lesions, n (%)
Benign	
Fibroadenoma	48 (31.6)
Sclerosing lesions/adenosis	42 (27.6)
Intraductal papilloma	11 (7.2)
Inflammatory lesions	10 (6.6)
Cyst/hemangioma	7 (4.6)
Ductal ectasia	7 (4.6)
Benign phyllodes tumor	7 (4.6)
Normal breast tissue	3 (2.0)
Other benign findings	17 (11.2)
Total	152 (49.2)
Malignant	
Invasive ductal carcinoma	121 (77.1)
Ductal carcinoma in situ	28 (17.8)
Malignant phyllodes tumor	4 (2.6)
Invasive lobular carcinoma	2 (1.3)
Other malignant tumors	2 (1.3)
Total	157 (50.8)

Comparison of LLMs and Radiologists in Predicting Malignancy of BI-RADS Category 4 Lesions

If the three responses generated by an LLM were entirely inconsistent, the case was deemed diagnostically invalid. Based on this criterion, ChatGPT-4o had 3 (1.0%) invalid cases, Claude 3 Opus had 10 (3.2%), and DeepSeek-R1 had 5 (1.6%). Comparative analysis of these 18 excluded reports showed no significant differences from the included cases in report length, terminology complexity, and lesion size (all *P*>.05; Multimedia Appendix 3), indicating minimal risk of selection bias. After exclusion, the diagnostic performance of radiologists and LLMs in differentiating benign from malignant BI-RADS category 4 lesions is summarized in Table 2.

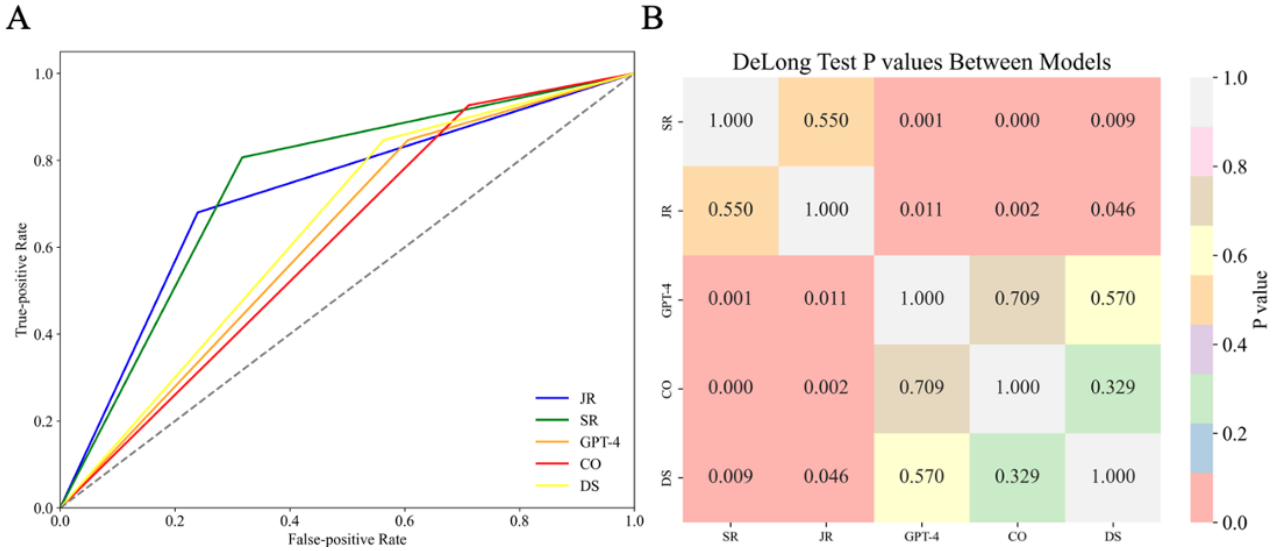
Table 2. Diagnostic performance of large language models and radiologists in assessing the benign or malignant nature of breast lesions.



Evaluator	Sensitivity (%; 95% CI)	Specificity (%; 95% CI)	Accuracy (%; 95% CI)	Positive predictive value (%; 95% CI)	Negative predictive value (%; 95% CI)	AUC[a] (95% CI)	*P* value[b]
Junior radiologist	68.0 (60.2-74.9)	76.1 (68.4-82.3)	71.9 (66.5-76.8)	75.0 (67.1-81.5)	69.2 (61.6-75.9)	0.72 (0.66-0.78)	<.001
Senior radiologist	80.7 (73.6-86.2)	68.3 (60.3-75.4)	74.7 (69.4-79.3)	72.9 (69.4-79.3)	77.0 (68.9-83.5)	0.75 (0.69-0.80)	<.001
ChatGPT-4o	84.7 (78.0-89.6)	40.1 (32.4-48.4)	63.0 (57.3-68.3)	59.9 (53.2-66.3)	71.3 (60.5-80.0)	0.62 (0.56-0.69)	<.001
Claude 3 Opus	92.7 (87.3-95.9)	28.9 (22.1-36.8)	61.6 (55.9-67.0)	57.9 (51.6-64.0)	78.8 (66.0-87.8)	0.61 (0.54-0.67)	<.001
DeepSeek-R1	84.0 (77.3-89.0)	43.0 (35.1-51.2)	64.0 (58.4-69.3)	60.9 (54.1-67.3)	71.8 (61.4-80.2)	0.64 (0.57-0.70)	<.001

[a]AUC: area under the receiver operating characteristic curve.

[b]*P* values represent the test against the null hypothesis of an AUC of 0.5.

DeepSeek-R1 achieved an AUC of 0.64, which was slightly higher than ChatGPT-4o (AUC 0.62) and Claude 3 Opus (AUC 0.61), but all three models underperformed compared to the junior and senior radiologists (AUC 0.72 and 0.75, respectively). The differences in AUCs between each LLM and the junior radiologist (all $P<.05$) as well as the senior radiologist (all $P<.01$) were statistically significant, indicating that both radiologists outperformed the three LLMs. In contrast, no significant differences were observed among ChatGPT-4o, Claude 3 Opus, and DeepSeek-R1, nor between the junior and senior radiologists ($P=.55$), as shown in Figure 2. The results of the DeLong tests are provided in Multimedia Appendix 4.

Figure 2. Receiver operating characteristic curve comparison of the diagnostic performance of large language models and radiologists in distinguishing between benign and malignant breast lesions. CO: Claude 3 Opus; DS: DeepSeek-R1; GPT-4: ChatGPT-4o; JR: junior radiologist; SR: senior radiologist.

Performance of LLMs in BI-RADS 4 Subcategory Assignment

Model performance for BI-RADS 4 subcategory assignment is shown in Table 3. All three LLMs demonstrated variable performance across subcategories. The 4C category consistently achieved the highest F_1-scores for each model, whereas 4B showed the lowest performance overall. ChatGPT-4o and DeepSeek-R1 demonstrated comparable overall F_1-scores (47.6% and 45.6%, respectively), while Claude 3 Opus showed the lowest overall performance (36.2%).

XSL•FO
RenderX

Table 3. Performance of large language models in Breast Imaging Reporting and Data System (BI-RADS) 4 subcategory assignment using the senior radiologist's categorization as the reference standard.

Model and subcategories	Recall (%)	Precision (%)	F_1-score (%)
ChatGPT-4o			
4A	35.2	67.7	46.3
4B	45.1	38.5	41.6
4C	63.1	49.5	55.5
Overall	46.0	54.2	47.6
Claude 3 Opus			
4A	17.6	81.5	28.9
4B	23.2	31.7	26.8
4C	88.1	41.3	56.3
Overall	39.5	55.9	36.2
DeepSeek-R1			
4A	28.0	64.8	39.1
4B	41.5	36.6	38.9
4C	70.2	55.1	61.8
Overall	44.0	54.1	45.6

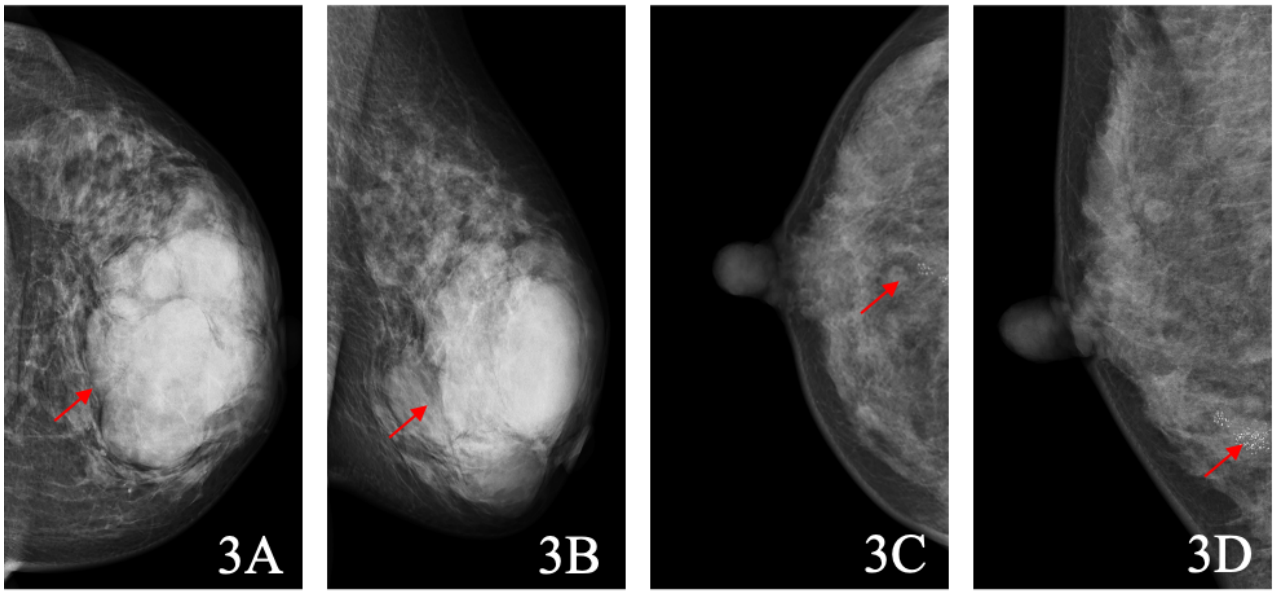
Consistency and Agreement Analysis of LLMs and Radiologists

Each of the three LLMs (ChatGPT-4o, Claude 3 Opus, and DeepSeek-R1) was queried three times per report to evaluate response consistency. The agreement among the three outputs was generally high across all models. As shown in Table 4, ChatGPT-4o demonstrated the highest consistency with a Fleiss κ of 0.850, followed by DeepSeek-R1 at 0.824, and Claude 3-Opus at 0.732. All three models exhibited a high level of internal consistency. The detailed frequency of BI-RADS subcategories for LLMs is presented in Multimedia Appendix 5.

To further quantify agreement across all assessment methods, a pairwise Cohen κ analysis was performed for both malignancy classification and BI-RADS 4 subcategories. The results demonstrated substantial variability in agreement among raters, with consistently higher κ values in malignancy classification (κ range 0.26-0.74) compared to subcategory assignment (κ range 0.09-0.40). Detailed statistical metrics are provided in Multimedia Appendix 6.

Table 4. Response consistency of large language models (LLMs) assessed by Fleiss κ statistics.

LLMs	κ value (SD)	95% CI	*z* value	*P* value
ChatGPT-4o	0.850 (0.023)	0.806-0.895	37.436	<.001
Claude 3 Opus	0.732 (0.017)	0.698-0.766	42.186	<.001
DeepSeek-R1	0.824 (0.023)	0.779-0.868	35.977	<.001



Analysis of Diagnostic Errors by LLMs

To better understand the diagnostic behavior of the LLMs, we performed targeted misclassification analyses for DeepSeek-R1, the model with the best overall performance, and Claude 3 Opus, which showed unusually high sensitivity but low specificity.

DeepSeek-R1 incorrectly classified 86 pathologically benign BI-RADS 4 lesions as malignant. The most common diagnoses were fibroadenoma (n=29, 33.7%), adenosis (n=20, 23.3%), intraductal papilloma (n=7, 8.1%), and inflammatory lesions (n=6, 7.0%). As shown in Table 5, lesion size was the most prominent feature cited in the reasoning text, accounting for approximately 34% of false-positive errors. Misclassified benign lesions were significantly larger than correctly classified benign lesions (mean 17.4, SD 13.9 mm vs mean 11.5, SD 8.6 mm; *P*=.01). Of the 193 extracted features, calcification descriptors constituted a significant proportion (n=49, 25.4%), encompassing both benign and suspicious subtypes. A representative example is illustrated in Figure 3A and B, where a large lobulated mass was upgraded by DeepSeek-R1 but was ultimately confirmed as fibroadenoma. In contrast, DeepSeek-R1 misclassified only 27 (8.7%) malignant cases as benign, primarily invasive ductal carcinoma (n=18, 66.7%) and ductal carcinoma in situ (n=9, 33.3%). Figure 3C and D illustrates a case classified as benign by DeepSeek-R1 but confirmed as ductal carcinoma in situ.

XSL•FO
RenderX

Figure 3. Representative mammographic cases misclassified by DeepSeek-R1. A and C are craniocaudal views; B and D are mediolateral oblique views. (A, B) A 44-year-old woman with type C breast density. A large, well-defined, shallowly lobulated mass (approximately 88 × 68 mm) is visible in the left breast. The radiologist classified the lesion as Breast Imaging Reporting and Data System (BI-RADS) 4A, while DeepSeek-R1 classified it as BI-RADS 4C. Postoperative pathology confirmed fibroadenoma. (C, D) A 37-year-old woman with type C breast density. Clustered calcifications are seen in the lower outer quadrant of the right breast, measuring approximately 16 × 11 mm. The radiologist classified the finding as BI-RADS 4A, while DeepSeek-R1 classified it as BI-RADS 3. Postoperative pathology confirmed ductal carcinoma in situ.

Claude 3 Opus produced 101 false-positive predictions, far more than DeepSeek-R1, which largely explains its markedly reduced specificity. These misclassified benign lesions included fibroadenoma (n=30, 29.7%), adenosis (n=20, 19.8%), papilloma (n=8, 7.9%), and inflammatory changes (n=7, 6.9%). Similar to DeepSeek-R1, lesion size played a major role (Table 5). Misclassified benign lesions were significantly larger than correctly classified benign lesions (mean 16.28, SD 12.64 mm vs mean 13.6, SD 8.2 mm; *P*=.01). Claude 3 Opus misclassified only 10 malignant lesions as benign (invasive ductal carcinoma: n=6), far fewer than DeepSeek-R1.

XSL•FO

Discussion

Principal Results

LLMs have been widely recognized for their potential in medical imaging applications. However, studies evaluating the feasibility of LLM-based diagnostic reasoning against pathology-confirmed gold standards remain limited. In this study, we applied ChatGPT-4o, Claude 3 Opus, and DeepSeek-R1 to the free-text Chinese mammography reports of BI-RADS category 4 lesions, aiming to assess their capability in distinguishing between benign and malignant findings. Our results demonstrated that LLMs provide high diagnostic repeatability, good stability, and reliable outputs, supporting their feasibility in this task. Among the three models, Claude 3 Opus yielded the highest proportion of invalid predictions, while ChatGPT-4o had the lowest, suggesting that ChatGPT-4o offers greater response consistency. ChatGPT-4o also showed the highest intramodel agreement in BI-RADS classification, with minimal variation across repeated outputs. This strong consistency and stability may be attributed to the architecture of its deep learning model and the diversity of its training data, which enable ChatGPT-4o to capture subtle variations in input and deliver highly consistent judgments for the same case across different prompts. DeepSeek-R1 also demonstrated good consistency, although some fluctuations in results were observed. We speculate that this may be due to differences in model architecture and training strategies, indicating that further optimization may be needed for processing complex medical imaging reports.

At the same time, this study preliminarily explored the feasibility of using three LLMs, ChatGPT-4o, Claude 3 Opus, and DeepSeek-R1 to accurately assess the malignancy of BI-RADS category 4 lesions based on free-text Chinese mammography reports, using pathological results as the reference standard. The findings showed that all three models were capable of predicting benign versus malignant outcomes for BI-RADS 4 lesions with high sensitivity: 84.7% for ChatGPT-4o, 92.7% for Claude 3 Opus, and 84.0% for DeepSeek-R1. These values were higher than those of junior (68.0%) and senior (80.7%) radiologists. Sensitivity is considered a critical metric for ensuring early detection of malignancies, particularly in the initial screening phase, where reducing missed diagnoses is essential. Consistent with our results, Pagano et al [34] evaluated five different LLMs and compared their sensitivity in diagnosing hip and knee osteoarthritis. Their findings showed that GPT-4o outperformed the other models, achieving a sensitivity of 92.3%. Similarly, Laohawetwanit et al [35] used GPT-4 to classify histopathological images of colorectal adenomas and reported a high sensitivity of 74% for adenoma detection. In the field of breast imaging, Miaojiao et al [36] evaluated ChatGPT-4 for BI-RADS classification of breast ultrasound nodules and reported a sensitivity of 90.56% in distinguishing malignant lesions, further demonstrating the model's capability in cancer-related diagnostic tasks. In our study, the sensitivity of LLMs for distinguishing benign from malignant BI-RADS 4 lesions reached up to 92.7%, further supporting the potential of LLMs in breast cancer screening. These findings suggest that LLMs could serve as effective high-sensitivity decision support tools to help radiologists, particularly junior physicians, rapidly flag and prioritize high-risk cases in routine breast cancer screening workflows.

This study demonstrates that LLMs exhibit the characteristic of high sensitivity but relatively low specificity in interpreting imaging reports. Previous studies have reported similar findings. Sievert et al [23] showed that, in thyroid nodule risk stratification, ChatGPT achieved a sensitivity of 86.7% to 94.1%, whereas specificity was only 10.7% to 18.2%. Shi et al [37] used GPT-4 to automatically generate biopsy recommendations by integrating prostate reports with clinical data; their results revealed that GPT-4 achieved a sensitivity of 0.84 to 0.90 but a specificity of 0.41 to 0.44 for prostate biopsy triage, indicating an advantage in reducing missed diagnoses but a limitation as a stand-alone diagnostic tool. Yang et al [38] evaluated the ability of ChatGPT to differentiate benign from malignant bone tumors using 1366 imaging reports and further optimized performance through few-shot prompting. In the baseline setting, the model achieved a sensitivity of 0.95 and a specificity of 0.58, again suggesting potential to reduce missed diagnoses but with insufficient specificity. The principal reasons for the low specificity of LLMs may include an overreliance on malignant lexical cues and surface features. When reports contain descriptors such as "microcalcification" or "ill-defined margin," the model tends to upgrade the risk level while inadequately integrating benign evidence. In addition, LLMs possess limited capability to integrate contextual information, especially when only text is provided without imaging, resulting in a lack of multimodal information to support comprehensive judgment [39]. These mechanisms indicate that the optimal clinical role of LLMs is as a screening or triage tool; they can rapidly flag high-risk cases, standardize key findings, and assist radiologists in decision-making, thereby reducing missed diagnoses.

Regrettably, our findings indicate that although DeepSeek-R1, ChatGPT-4o, and Claude 3 Opus are capable of performing benign versus malignant classification for BI-RADS category 4 lesions based on free-text reports, their overall diagnostic performance remains inferior to that of radiologists when benchmarked against pathological results. This observation is consistent with recent literature. Wu et al [26] compared GPT-4, GPT-3.5, and Google Bard in predicting the malignancy of thyroid nodules using pathology as the reference standard. They found that all three LLMs achieved diagnostic performance above 0.8, outperforming junior physicians but still falling short of senior radiologists. Similarly, Liu et al [40] evaluated GPT-4.0 and Bing using ultrasound-based breast imaging reports and demonstrated that GPT-4 outperformed Bing, yet remained inferior to human radiologists. These results suggest that, despite significant advancements, LLMs have not yet fully matched human expertise in medical imaging interpretation. Notably, the diagnostic performance of the LLMs in our study was even lower than that reported by Liu et al [40], which may be due to differences in study populations. While Liu et al [40] included lesions across the full BI-RADS spectrum (categories 2 through 5), our study focused exclusively on BI-RADS category 4, a subset known for its diagnostic ambiguity and overlapping imaging features between benign and malignant lesions. Supporting this, a study by Elezaby et al [41] analyzed data

XSL•FO
RenderX

from the US National Mammography Database between 2008 and 2014, covering 125,447 BI-RADS 4 cases [41]. Among them, 33.3% were subcategorized into 4A, 4B, and 4C, with corresponding positive predictive values of 7.6%, 22.2%, and 69.3%, respectively. This large-scale dataset highlights the intrinsic challenge of accurately characterizing BI-RADS 4 lesions, even for experienced radiologists, and further underscores the difficulty faced by LLMs when attempting to replicate expert-level discrimination within this category.

Interestingly, no significant difference in BI-RADS diagnostic performance was observed between junior and senior radiologists (P=.55), which may be attributable to several factors. First, the BI-RADS system provides highly standardized terminology and structured reporting, offering clear imaging feature descriptions and well-defined categorization rules. This markedly reduces interobserver variability and enables radiologists with different levels of experience to reach comparable diagnostic conclusions. Cozzi et al [28] demonstrated in a multilingual study that even when interpretation was based solely on the "imaging findings" section of reports, interreader agreement remained nearly perfect (Gwet AC1 0.91), underscoring the strong harmonizing effect of the BI-RADS framework on experience-related differences. Second, the sample size and lesion composition of the present study may have influenced the results. The enrolled cases displayed a relatively balanced benign-to-malignant ratio but lacked a large number of highly challenging or borderline lesions, which may have limited the opportunity for differences in reader experience to emerge. Finally, the evaluation criteria themselves, final BI-RADS categories confirmed by pathology or follow-up, with diagnostic performance assessed by DeLong testing, focused on objective diagnostic accuracy rather than subtle variations in descriptive detail. This emphasis on definitive outcomes may have further attenuated measurable differences between radiologists of different seniority.

The relatively low specificity and diagnostic performance of LLMs compared to radiologists have not been thoroughly investigated in previous literature [42]. In this study, using pathology as the reference standard, we attempted to analyze the internal reasoning behind LLM outputs. The diagnostic outcomes of LLMs are influenced by various factors, including the weight distribution of their training datasets and the content of the prompts used. In our case, we used the default versions of ChatGPT-4o, Claude 3 Opus, and DeepSeek-R1 without any additional fine-tuning on domain-specific medical content, which may have contributed to some diagnostic inaccuracies. Regarding prompt design, LLMs primarily rely on extracting and interpreting keywords from BI-RADS mammography reports, such as lesion size, morphology, margins, and calcifications, to make diagnostic decisions. Among these, lesion size emerged as a dominant factor. We observed that lesions with a short-axis diameter greater than 17 mm were often classified as BI-RADS 4B or higher by the models, suggesting a malignant tendency. This aligns with clinical practice, where lesion size is also a critical consideration for radiologists. Our findings are consistent with those of Ong et al [43], who reported that lesion size greater than or equal to 15 mm was an independent predictor of malignancy in contrast-enhanced mammography (adjusted odds ratio 22.5), significantly increasing the likelihood of a malignant diagnosis. Furthermore, prior studies have shown that when the lesion size reaches 17.5 mm, specificity improves to 89.7%, reinforcing the value of size as a key imaging-based risk stratification parameter. Therefore, when using LLMs to assist in further benign versus malignant differentiation of BI-RADS category 4 lesions, caution is warranted for large lesions, as LLMs are more likely to overpredict malignancy. Our data showed a misclassification rate of approximately 34% for benign lesions larger than 17 mm. In addition to lesion size, the handling of the coexistence of benign and suspicious imaging descriptors was also a key reason for false positives. Although LLMs explicitly mentioned typically benign features such as "milk of calcium" during the reasoning process, they struggled to appropriately weigh them against co-occurring, seemingly suspicious features (such as large lesion size, high density, or asymmetry). In a clinical setting, a definitive benign feature should typically be sufficient to de-escalate the risk classification. However, the LLMs failed to assign sufficient weight to this benign evidence to override other findings. Instead, the LLMs appeared to allow the co-occurring suspicious features to dominate the decision-making process, thereby leading to false-positive malignant diagnoses (BI-RADS 4B or 4C). Fibroadenoma and adenosis were the two most common benign lesions misclassified by LLMs, accounting for 34% and 21% of misdiagnosed benign cases, respectively. These lesions were often relatively large, with lobulated or indistinct margins, and sometimes associated with calcifications. As such, these features likely prompted the LLMs to overpredict malignancy. This suggests that one of the main limitations affecting the diagnostic performance of LLMs lies in their tendency to overrely on certain high-risk imaging features. In summary, we believe that the principal limitation of LLMs lies in keyword-triggered escalation. When a mammography report contains malignant-leaning cues, such as spiculated margins, pleomorphic or clustered calcifications, architectural distortion, or indistinct or lobulated borders, or describes a relatively large lesion, the models tend to assign higher BI-RADS categories (4B or 4C). This behavior reflects an overreliance on surface lexical cues and insufficient integration of benign evidence. To mitigate this limitation, future work should refine prompt design to require balanced and explicit extraction of all malignant and benign descriptors, and to discourage upgrades based on any single malignant cue or lesion size alone, which may guide LLMs toward more comprehensive reasoning.

Limitations

This study has several limitations. First, this is a single-center, retrospective analysis based on free-text mammography reports, which may limit the generalizability of the findings and introduce potential selection bias. Future studies should incorporate a more diverse, multicenter dataset with prospective validation to improve external validity. Second, the results are highly dependent on the design of the prompts used to query the LLMs. Only one optimized prompt was applied in this study, and no systematic comparison of different prompt structures was performed. Future research should include multiple prompt designs and iterative optimization, including different language

XSL•FO
RenderX

prompts to assess and enhance the stability and reproducibility of model performance. Third, the LLMs used in this study were not fine-tuned on domain-specific medical data and were evaluated in their default general-purpose form. This lack of domain adaptation may limit their ability to fully capture breast imaging and specific diagnostic patterns and to integrate nuanced clinical knowledge. Future work could include domain-specific fine-tuning, for example, training on large curated radiology report datasets or incorporating expert-reviewed guidelines, to further optimize diagnostic reasoning and improve model performance. Fourth, cases in which the LLMs failed to reach a majority consensus were excluded from analysis. This may introduce selection bias and could result in an overestimation of consistency and diagnostic performance, as the reported metrics reflect only those cases in which the model outputs were sufficiently stable.

Conclusions

In conclusion, this study demonstrated that all three LLMs, ChatGPT-4o, Claude 3 Opus, and DeepSeek-R1 have high sensitivity in predicting BI-RADS category 4 breast benign and malignant lesions with good repeatability and stability but relatively insufficient specificity. The main causes of misclassification by LLMs included larger lesion size (short axis >17 mm) and the presence of specific imaging features described in the reports, such as clustered calcifications, spiculated margins, lobulated contours, and indistinct edges. Fibroadenoma and adenosis were the most common benign lesions misclassified as malignant by the LLMs.

Abstract

Background: Processing data from electronic health records (EHRs) to build research-grade databases is a lengthy and expensive process. Modern arthroplasty practice commonly uses multiple sites of care, including clinics and ambulatory care centers. However, most private data systems prevent obtaining usable insights for clinical practice.

Objective: This study aims to create an automated natural language processing (NLP) pipeline for extracting clinical concepts from EHRs related to orthopedic outpatient visits, hospitalizations, and surgeries in a multicenter, single-surgeon practice. The pipeline was also used to assess therapies and complications after total hip arthroplasty (THA).

Methods: EHRs of 1290 patients undergoing primary THA from January 1, 2012 to December 31, 2019 (operated and followed by the same surgeon) were processed using artificial intelligence (AI)–based models (NLP and machine learning). In addition, 3 independent medical reviewers generated a gold standard using 100 randomly selected EHRs. The algorithm processed the entire database from different EHR systems, generating an aggregated clinical data warehouse. An additional manual control arm was used for data quality control.

Results: The algorithm was as accurate as human reviewers (0.95 vs 0.94; P=.01), achieving a database-wide average F_1-score of 0.92 (SD 0.09; range 0.67 - 0.99), validating its use as an automated data extraction tool. During the first year after direct anterior THA, 92.1% (1188/1290) of our population had a complication-free recovery. In 7.9% (102/1290) of cases where surgery or recovery was not uneventful, lateral femoral cutaneous nerve sensitivity (47/1290, 3.6%), intraoperative fractures (13/1290, 1%), and hematoma (9/1290, 0.7%) were the most common complications.

Conclusions: Algorithm evaluation of this dataset accurately represented key clinical information swiftly, compared with human reviewers. This technology may provide substantial value for future surgeon practice and patient counseling. Furthermore, the low early complication rate of direct anterior THA in this surgeon's hands was supported by the dataset, which included data from all treated patients in a multicenter practice.

Introduction

Total hip arthroplasty (THA) is one of the most effective orthopedic procedures [1]. The number of THAs is projected to rise, along with its impact on health care resources [2]. However, more government funding requires efficient quality control and accountability. Quality monitoring is expected to have a bigger impact on orthopedic practices and on medicine as a whole in the near future. Unfortunately, many surgeons working in nonacademic settings frequently lack the resources and financing needed to properly evaluate the quality of patient care they provide. The broad adoption of electronic health records (EHRs) simplifies access to vast amounts of medical data and facilitates data analysis.

Despite how inefficient and time-consuming manual review is, it remains the gold standard for reviewing medical information. Research has shown that systematic reporting of postoperative orthopedic surgical adverse events is infrequent [3], despite the low complication rates associated with THA. Monitoring the standard of care after THA is still challenging, since evaluating

XSL•FO
RenderX

sufficient records in a timely manner is a complex task. Using natural language processing (NLP) technology, we developed a system that can extract relevant postoperative problems from unstructured EHR data [4]. We questioned whether such an AI-supported approach might be used to provide precise, continuing feedback on the quality of care provided after THA in a high-volume, nonacademic clinical setting. We assumed that a computer algorithm would perform at least as well as a human reviewer, which is considered the industry standard.

The primary goal of this study was, therefore, to design and develop an automated NLP pipeline for extracting clinical concepts from reports on outpatients, hospitalizations, and surgeries from a single surgeon, multicenter practice. Using the pipeline, the secondary goal was to examine and evaluate therapies and complications following THA.

Methods

Ethical Considerations

Patients were invited to participate in the research on the direct anterior approach (DAA) of hip replacement. Informed consent for the use of patient data in this retrospective study was obtained as part of the institutional review board (IRB) protocol (WCG IRB Protocol 20225993). Patients undergoing surgery were provided with a consent form at the time of intake, which was signed before the procedure. Patients who continued to be followed up subsequently signed consent forms that were applicable retrospectively. Data were anonymized before analysis.

Patient Selection

Data from 1290 patients undergoing 1304 primary DAA THAs using a Hana Orthopedic Surgery Table (Mizuho OSI), with the same surgical team and implants. Data was collected from January 1, 2012 to December 31, 2019, and analyzed retrospectively. Exclusion criteria included age under 18 years, failure to provide informed consent, and revision surgery.

Follow-Up Schedule

Patients were followed preoperatively and postoperatively at 2 weeks, 6 weeks, 3 months (on a per-case basis), and 1 year. The algorithm screened EHRs for key sentences, words, and clinical definitions that were compiled by the surgical team.

Adverse Event Classification

A list of 19 complications based on the study of the Hip Society THA Complications Workgroup was compiled [5]. A separate category was added for lower back pain, sciatica, or both. Treatment was categorized as either conservative or interventional.

EHR Data Structure and Documentation Variability

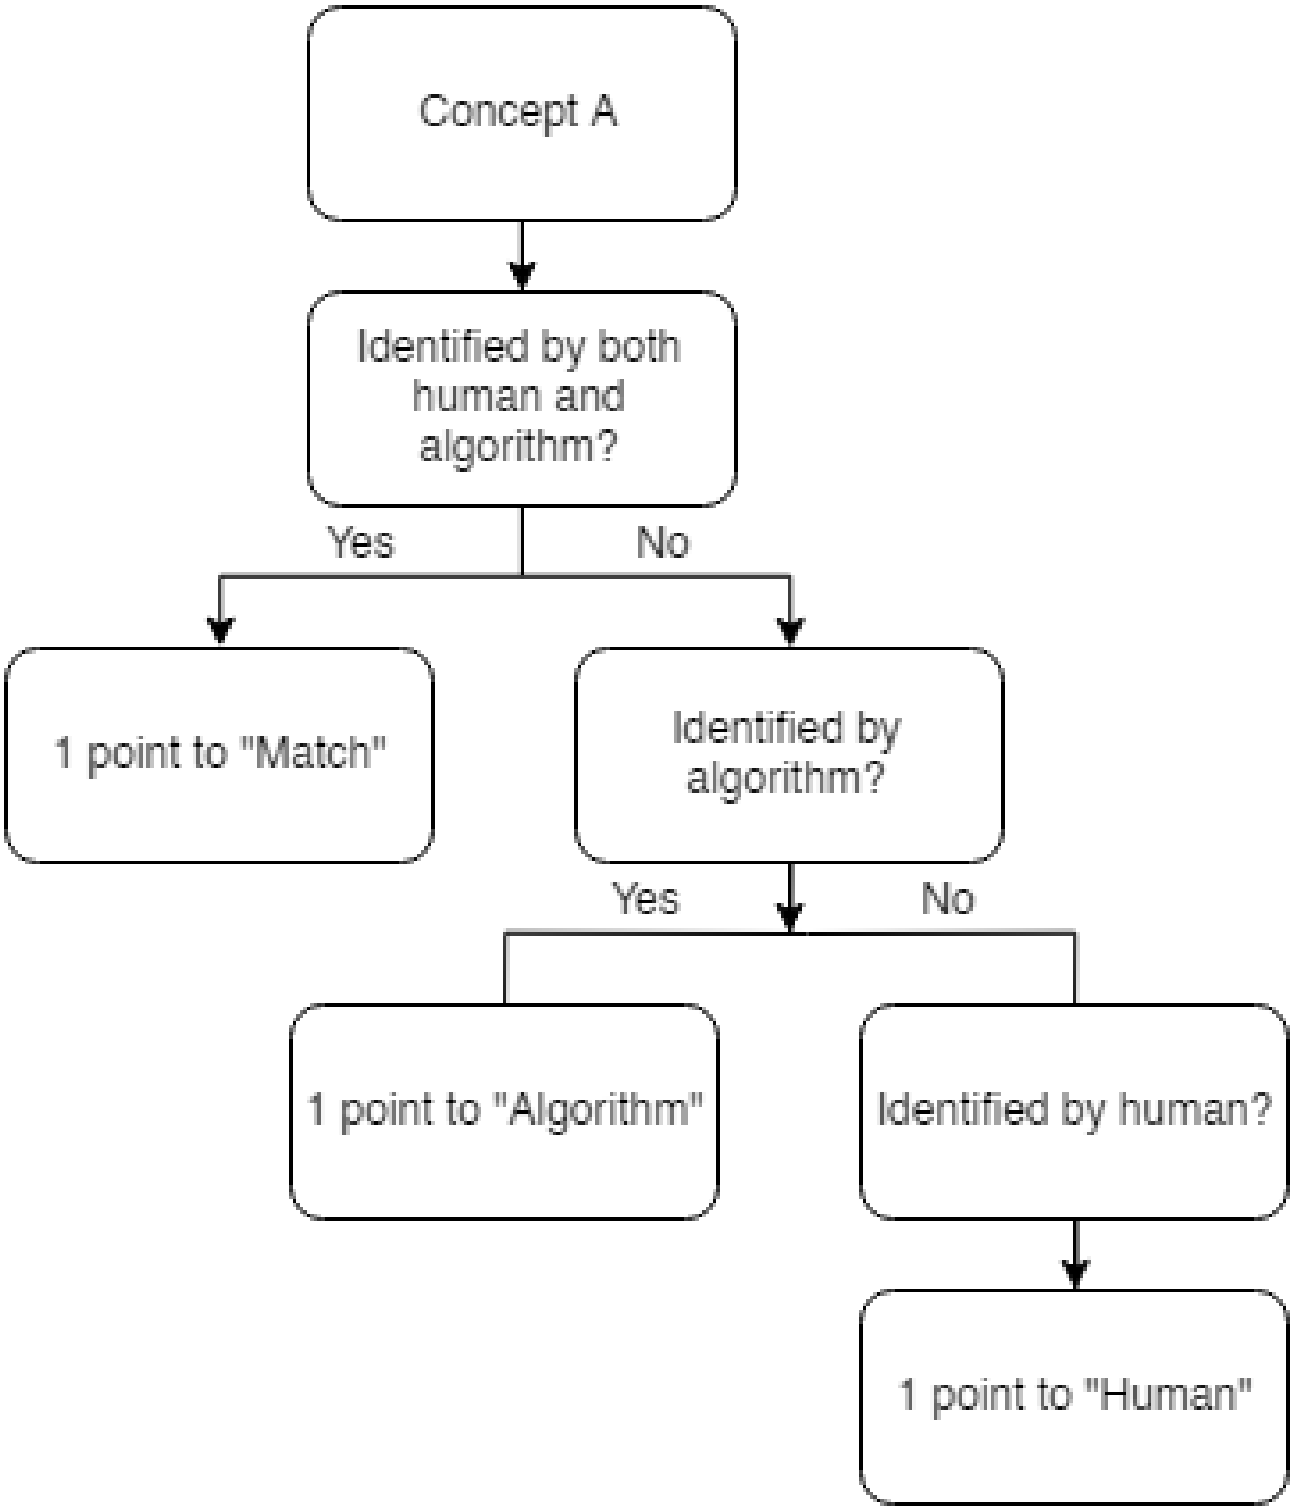
The study used EHR systems that capture all patient interactions across the health system. Documentation varied by note type: operative reports were dictated using a standardized format, with intraoperative complications documented in a dedicated subsection. Radiographic reports, however, were dictated by multiple radiologists without a uniform structure. Complications were often identifiable through multiple associated notes across different document types. Implant records were dictated directly from intraoperative purchasing logs, ensuring high reliability. The NLP algorithm flagged typographical errors in dictated notes that human reviewers overlooked.

Gold Standard Adjudication Process

To ensure consistency in the gold standard corpus used for training the algorithm, all discrepancies among reviewers were resolved through senior adjudication. When ambiguities were identified in a case, they were escalated to the senior author, who conducted a thorough review of the full case file. Final determinations were made based on clinical expertise and consensus, ensuring a standardized and reliable reference dataset.

NLP Pipeline Development and Validation

The NLP pipeline was developed and validated in 3 phases, as described by Van de Meulebroucke et al [4]. First, a training set of 50 EHRs was annotated to generate relevant input, since a sample size of 50 EHRs was previously found sufficient to achieve accuracy over 90% [4]. Second, an independent gold standard was generated through manual review by 3 independent surgeons of a derivation cohort of 100 EHRs. Third, the entire dataset of 1290 patients was manually reviewed to calculate the algorithm's recall, precision, and F_1-score. Patient records were analyzed using standard procedures of each center's EHR system by a manual reviewer.



The pipeline uses a text mining engine based on machine learning and NLP to extract important concepts from EHRs. The NLP pipeline incorporates several preprocessing steps, including language detection, sentence segmentation, and tokenization, to prepare unstructured EHR text for analysis. The core architecture is based on a deep learning model fine-tuned on large-scale clinical datasets and adapted for domain-specific tasks in orthopedics. Named entity recognition identifies relevant medical concepts, relation extraction determines associations between entities, and attribute extraction captures features such as negations and temporal qualifiers. Processed outputs were mapped to Unified Medical Language System (UMLS) Concept Unique Identifiers (CUIs), which includes standard terminologies like the Systematized Nomenclature of Medicine-Clinical Terms (SNOMED-CT). Mapping was performed by a probabilistic entity-linking algorithm that integrates semantic ranking and term preferences, ensuring precise and standardized representation. In addition, the processed data were standardized using the Observational Medical Outcomes Partnership Common Data Model, which harmonizes structured and unstructured data from different EHR systems into a unified format. This approach enables the efficient processing of unstructured clinical text and supports the accurate extraction and mapping of clinical concepts.

Complications and their respective treatment, along with other clinical features, were collected into a database and standardized using UMLS CUIs. The NLP tool mined variables from the full set of source data within EHRs, including, but not limited to, clinical notes, primary care records, radiology reports, laboratory results, discharge summaries, and surgical documentation. The full list of study variables is shown in Multimedia Appendix 1.

XSL•FO
RenderX

To assess accuracy, a scoring system was established such that one point was given to each correct clinical concept, extracted by the algorithm or the human reviewer (Figure 1). Correct clinical concepts referred to those matching the gold standard. Precision, recall, and F_1-score were used as statistical parameters to reflect the performance of the algorithm, as calculated with R (R Foundation for Statistical Computing) statistical programming (Table 1).

Figure 1. Scoring system flowchart for concept identification by human versus algorithm.

XSL•FO
RenderX

Table . Statistical parameters for algorithm performance.

	Definition	Calculation
Accuracy	Percentage (%) of relevant concepts extracted by method A/B.	Number of concepts÷total number of concepts expected to be extracted
Recall or sensitivity	Ratio between all identified concepts and all existing concepts in a given text (0 - 1).	True positives÷(true positives+false negatives)
Precision	Ratio between all adequately identified concepts and all identified concepts (0 - 1).	True positives÷(true positives+false positives)
F_1-score	Harmonic mean of recall and precision (0 - 1).	2×(recall×precision)÷(recall+precision)

Statistical Analysis

For categorical values, the number of patients (n) and relative proportions (%) are shown.

Checks for accuracy, recall, and precision involved measuring model outcomes against a gold standard created by human annotators. The F_1-score assesses the trade-off between precision and recall by calculating their harmonic mean (Table 1).

Results

Performance of the NLP Pipeline

Table 2 compares the accuracy of human reviewers to an algorithm on various aspects of 100 patient records. Overall, the algorithm was slightly more accurate than human reviewers, with an accuracy of 0.952 compared with 0.945 for human reviewers, a difference of 0.007 (P=.01). The most notable differences in accuracy between the algorithm and human reviewers were on the variables of weight (0.24 difference in accuracy), revision (0.06 difference), and offset (0.02 difference), all of which were detected more accurately by the algorithm. The algorithm was less accurate on variables such as cup size, prosthetic loosening, and heterotopic ossification grade, though with small differences in accuracy ranging from −0.06 to 0.04.

In order to further assess the quality of data extracted by the algorithm, we calculated statistical parameters such as recall, precision, and F_1-score of the different variables detected in the study, as defined in Table 1. The results shown in Table 3 reflect that for most variables, the recall and F_1-score are high, indicating that the model is able to correctly identify the presence of the clinical variables in the data. The average values for all the variables show an overall high performance of the model.

Complications and Interventions of DAA THA

The mean age of the patients included in the dataset was 63.5 (SD 9.6) years and 57.4% (740/1290) were women. The complications during the first year after direct anterior THA in these patients are shown in Table 4, as well as the conservative or interventional treatment of these clinical outcomes.

Soft tissue complications were the most common type of complication observed in patients undergoing THA. The most common type of soft tissue complication was sensory deficit (47/1290, 3.6%), followed by hematoma (9/1290, 0.7%) and superficial wound infection (3/1290, 0.2%). No incidents of bleeding, prolonged wound drainage, motor nerve deficit, vascular injury, or sciatica were reported. Regarding mechanical complications, periprosthetic fractures occurred in 1.4% of cases (18/1290; 13 intraoperatively and 5 postoperatively), and instability occurred in 0.5% (7/1290) of cases. Implant fracture, cup-liner dislocation and osteolysis were not reported.

Table 5 shows interventions in the 1-year postoperative period. The most common interventions were intraoperative (cerclage and wiring), which account for 1% (n=13) of cases. Readmission was detected in 0.9% (n=12) of patients. Other interventions such as aspiration, wound debridement, closed reduction, osteosynthesis or cerclage, and revision, each account for less than 1% of cases.

Table . Complications in the 1-year postoperative period (n=1290).

Complication subgroup	Total, n (%)	Conservative treatment, n (%)	Interventional treatment, n (%)
Soft tissue complications: wounds			
Bleeding	0 (0)	0 (0)	0 (0)
Hematoma	9 (0.7)	6 (0.5)	3 (0.2)
Prolonged wound drainage	1 (0.1)	0 (0)	1 (0.1)
Soft tissue complications: infection			
Superficial wound infection	3 (0.2)	3 (0.2)	0 (0)
Deep PJI[a]	3 (0.2)	0 (0)	3 (0.2)
Soft tissue complications: neural deficit			
Motor nerve deficit	0 (0)	0 (0)	0 (0)
Transient sensory deficit (LFCN[b] sensitivity)	47 (3.6)	47 (3.6)	0 (0)
Soft tissue complications: lower back pain			
Lumbago	6 (0.5)	6 (0.5)	0 (0)
Sciatica	1 (0.1)	1 (0.1)	0 (0)

Discussion

Principal Findings

This study reflects the use of AI techniques to streamline and improve data capture from EHRs, in line with the current need for innovative solutions to obtain meaningful information from existing data sources in the field of orthopedics [6]. AI-supported automation, substantiated in the first step by directly comparing it with a manual review of a random sample of patients, showed no statistical differences in accuracy across all compared clinical concepts. Subsequently, application of the algorithm to the entire dataset generated very high F_1-scores, therefore, validating its ability to detect positive results in our cohort with a high degree of precision and recall. This allowed a single-surgeon registry to be populated from existing health data within EHRs in a very short period of time. The NLP pipeline handled documentation variability using named entity recognition, probabilistic entity linking, and attribute extraction, allowing synonym recognition and standardization to SNOMED-CT and UMLS CUIs. This data-driven approach ensured robust identification of complications across different documentation sources. Furthermore, the methodology deployed in this study allows for inclusion of data from different software sources, which can be a limitation of single-surgeon registries that must be populated from diverse clinics or ambulatory care centers. The resulting multicenter, single-surgeon database is comparable in its granularity to single-system registries populated with conventional methods, circumventing the complexity of a system that is becoming increasingly fragmented.

The methodology that was previously described in a smaller cohort of Dutch patients is validated here in a multicenter, US-based practice, screening records in English from 1290 patients over an 8-year period at high accuracy [4]. It also demonstrates its usefulness in the nonacademic setting, compared with previous studies at academic centers [7,8]. Analysis of such a large cohort from a single surgeon permitted categorization of frequent concepts without needing to account for the confounding variables of different techniques and complication rates of multiple surgeons [9].

Our dataset split balances annotation feasibility and model performance, following previous clinical NLP studies. Small, high-quality training sets have been shown to be effective in constrained domains, particularly when leveraging structured reporting patterns [10]. The chosen test set size aligns with established practices in clinical NLP research [11]. Instead of relying solely on predefined training-validation-test ratios, we incorporated post hoc validation on a large dataset to assess generalizability, a common strategy in clinical text mining [12,13].

In addition, clinical insight was also gained regarding the frequency and management of complications over a 1-year period. While the study highlights the effectiveness of NLP tools in single surgeon practices, extensive datasets can greatly benefit from its capabilities. NLP tools offer versatility in both big data settings and smaller subsets, enabling comprehensive analysis across various practice settings and facilitating evaluation of outcomes, for example, relative to regional averages or previously published work.

Ultimately, concept detection and extraction of the pipeline demonstrated accuracy on par with human reviewers at a fraction of the cost and time required for manual chart review. Validation is a necessary step for algorithm use that benefits from physicians' feedback through annotation. This input is necessary to test algorithm performance, to calibrate the algorithm's rates of false positives and false negatives, and to examine if clinical use of algorithms leads to better research insights and health care services [14]. The ease and high degree of fidelity of concept extraction by the algorithm in this study facilitated longitudinal evaluation of clinical complications, and importantly, also precluded the need to manually filter through patient charts, which is time-consuming [15].

Comparison With Previous Work

The representativeness of the methodology in this study is hence reflected by the frequency of the complications, which falls

XSL•FO
RenderX

within the lower range of previously described cohorts [16]. For instance, a frequency of 1% of periprosthetic fractures was detected, which was the most common intraoperative complication in this study, and was found to be 2.1%, 1.6%, and 1.1% in other cohorts [4,9,17]. Other similar comparisons show that revisions were detected in 0.7% (9/1290) of patients in our study vs 2.1% (5/239) and 1.6% (3/187), and prosthetic joint infection, at 0.2% (3/1290) in our study, appeared in 1.3% (3/239) and 1.6% (3/187) of patients in the aforementioned studies [9,17]. In a prospective comparison of DAA to posterior approach THA (43 DAA THAs in total), 2.3% (1/43) had hematoma vs 0.7% (9/1290) in our study, 2.3% (1/43) presented heterotopic ossification vs 0.2% (3/1290) shown here, and neither study detected dislocations [18]. Therefore, the results obtained using the validated, NLP-driven methodology shown here also highlight the quality of practice of the surgeon, for the complications described in this study fall within the lower range of those previously described in the literature [9,16-20].

Limitations

As is the case in real-world evidence studies, there are certain limitations to consider for this study, such as missing values for certain variables. Regarding rare concepts such as bleeding, the scarcity of terms found in the EHRs may hinder algorithm training. The algorithm solely focused on patients undergoing DAA THA, which is the method used by the surgeon, but its validity could be further strengthened by expanding the analyses to other populations. In addition, the quality of records kept at each site determines the quality of algorithm training, highlighting the need for ongoing validation processes as the database expands. Missing structured data were treated as true absences and were not imputed. For unstructured text, missing values could reflect a lack of documentation or true absences. Manual review helped assess whether missing information stemmed from documentation gaps or NLP constraints. While a single-surgeon dataset ensures consistency in surgical technique and documentation style, it may limit generalizability to other surgical practices. However, the inclusion of multisource EHR data and independent validation by multiple reviewers helps mitigate this potential bias.

Conclusions

In this study, the NLP pipeline proved highly effective in improving data capture and enhancing clinical outcomes analysis following DAA THA, overcoming constraints linked to single-surgeon registries, which typically require data aggregation from multiple care sites. It holds significant potential for future orthopedic studies, providing accurate and cost-effective insights. In addition, the dataset supports the low early complication rate of direct anterior THA in this surgeon's multicenter practice.

Conflicts of Interest

NHM declares the following conflicts of interest: royalties from Medenvision and Synthes; speakers bureau or paid presentations for DePuy, Medenvision, and Mizuho/OSI; paid consultancy for Medacta USA and Medenvision; stock or stock options in DEO, Docspera, Ostaudio, OutcomeMD, and Radlink; board member of the Anterior Hip Foundation. Abstract

Background: Data standards are not only key to making data processing efficient but also fundamental to ensuring data interoperability. When clinical trial data are structured according to international standards, they become significantly easier to analyze, reducing the efforts required for data cleaning, preprocessing, and secondary use. A common language and a shared set of expectations facilitate interoperability between systems and devices.

Objective: The main objectives of this study were to identify commonalities and differences in clinical trial metadata, protocols, and data collection systems/items within the VACCELERATE project.

Methods: To assess the degree of interoperability achieved in the project and suggest methodological improvements, interoperable points were identified based on the core outcome areas—immunogenicity, safety, and efficacy (clinical/physiological). These points were emphasized in the development of the master protocol template and were manually compared in the following ways: (1) summaries, objectives, and end points in the protocols of 3 VACCELERATE clinical trials (EU-COVAT-1_AGED, EU-COVAT-2_BOOSTAVAC, and EU-COVPT-1_CoVacc) against the master protocol template; (2) metadata of all 3 clinical trials; and (3) evaluations from a questionnaire survey regarding differences in data management systems and structures that enabled data exchange within the VACCELERATE network.

Results: The noncommonalities identified in the protocols and metadata were attributed to differences in populations, variations in protocol design, and vaccination patterns. The detailed metadata released for all 3 vaccine trials were clearly structured using internal standards, terminology, and the general approach of Clinical Data Acquisition Standards Harmonisation (CDASH) for data collection (eg, on electronic case report forms). VACCELERATE benefited significantly from the selection of the Clinical Trials Centre Cologne as the sole data management provider. With system database development coordinated by a single individual and no need for coordination among different trial units, a high degree of uniformity was achieved automatically. The harmonized

XSL•FO
RenderX

transfer of data to all sites, using well-established methods, enabled quick exchanges and provided a relatively secure means of data transfer.

Conclusions: This study demonstrated that using master protocols can significantly enhance trial operational efficiency and data interoperability, provided that similar infrastructure and data management procedures are adopted across multiple trials. To further improve data interoperability and facilitate interpretation and analysis, shared data should be structured, described, formatted, and stored using widely recognized data and metadata standards.

Introduction

Interoperability is defined as the ability of different information systems, devices, or applications to connect in a coordinated manner within and across organizational boundaries, enabling stakeholders to access, exchange, and cooperatively use data with the goal of optimizing the health of individuals and populations [1].

Interoperability standards provide a common language and set of expectations that enable interoperability between systems and devices. These standards allow clinicians, laboratories, hospitals, pharmacies, and patients to seamlessly share data, regardless of the application or market supplier, thereby improving the coordination and delivery of health care [1].

The health interoperability ecosystem comprises individuals, systems, and processes that aim to share, exchange, and access all forms of health information, including discrete, narrative, and multimedia data. Potential stakeholders in this ecosystem include individuals, patients, providers, hospitals/health systems, researchers, payers, suppliers, and systems, all of whom contribute to the creation, exchange, and use of health information and data. When data are structured according to international standards, they become much easier to analyze, reducing the efforts required for data cleaning and preprocessing. Data standards are not only essential for efficient data processing but are also fundamental to ensuring the interoperability of the data itself [2]. The greater use of data standards is crucial to the success of data sharing. Without such standards, shared data are difficult to interpret with certainty, significantly more time-consuming to process, and therefore more expensive to collect. Standards can be applied to data item definitions and codes, controlled vocabularies for categories, and the structuring and exchange of data. File formats used for storing and transferring data should also be standardized to simplify data processing [3]. Clinical trial datasets should always include metadata describing the characteristics of each data item (eg, type, code, name, and possibly an ontology reference), along with details of the trial's schedule and design. Datasets should be made available for sharing in 1 or more standardized file formats that are compatible with a wide variety of systems [3].

In January 2021, the European Commission launched VACCELERATE—the European Corona Vaccine Trial Accelerator Platform [4] (GA 101037867)—to coordinate phases II and III of COVID-19 vaccine trials across Europe. VACCELERATE aimed to serve as a single-entry point for multicountry vaccine trials in Europe and to address the need for greater inclusion of underrepresented populations in vaccine trials. One of the fundamental objectives of VACCELERATE was to promote the sharing, interoperability, and FAIRness (Findable, Accessible, Interoperable, and Reusable) of data generated through the VACCELERATE network. This included ensuring that data sharing and future reuse were considered by investigators, the scientific community, and study sponsors. The objective of this study was to assess the degree of commonalities and differences among clinical trial metadata, protocols, and data collection systems/items in VACCELERATE consortium projects [5-8]. Additionally, the study aimed to explore the reasons why interoperability was sometimes limited or failed to occur. It also sought to identify areas where interoperability was relatively straightforward and to propose structures and systems that could enhance interoperability in the future, including for data generated outside the trials funded under the VACCELERATE platform [9-11].

EU-COVAT-1_AGED (EudraCT: 2021-004526-29) is a multinational, phase II, randomized, adaptive protocol designed to evaluate the immunogenicity and reactogenicity of different COVID-19 vaccines in adults aged ≥75 years who have already been vaccinated against SARS-CoV-2. It is the first of 3 VACCELERATE phase II COVID-19 vaccine trials and focuses on the immunogenicity and reactogenicity of vaccines in older adults (≥75 years), addressing a critical demographic that is often underrepresented in vaccine studies [9].

EU-COVAT-2_BOOSTAVAC (EudraCT: 2021-004889-35) is an international, multicenter, phase II, randomized, adaptive protocol designed to evaluate the need for, optimal timing of, and immunogenicity of administering a booster messenger RNA (mRNA) vaccination dose against SARS-CoV-2 in the general population (aged 18+ years) already vaccinated against SARS-CoV-2. This trial investigates booster vaccination strategies in the general adult population, providing insights into optimal timing and immunological outcomes for sustaining immunity [9].

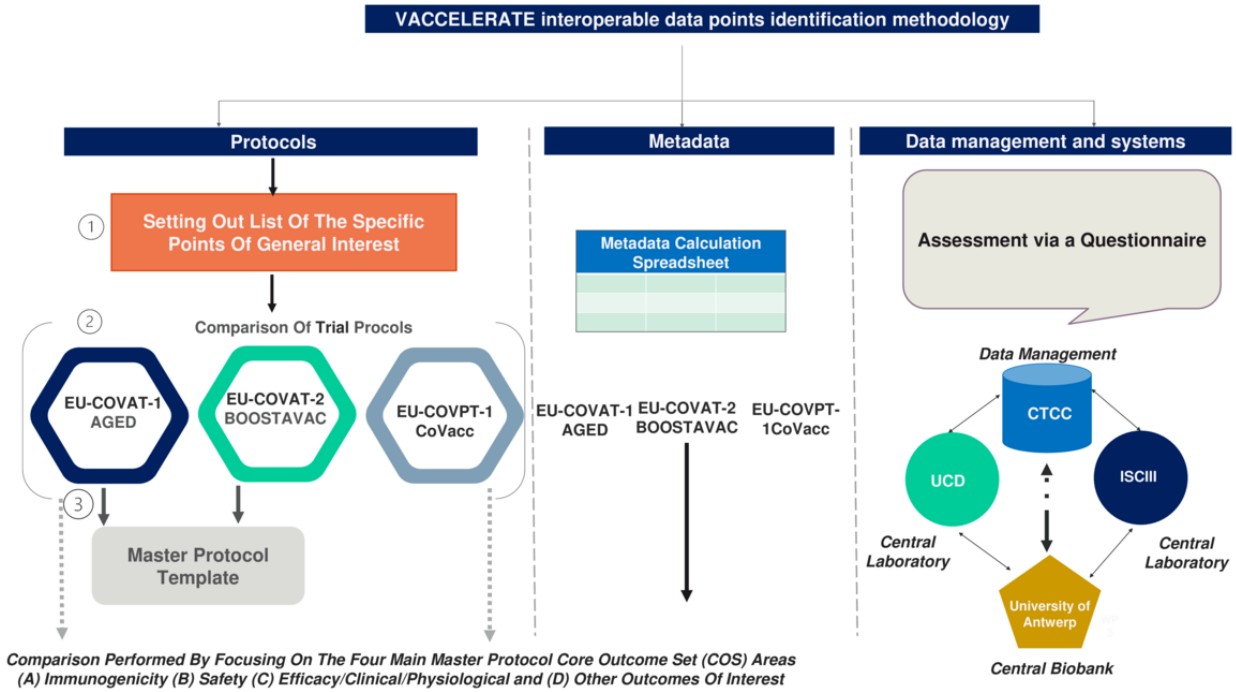
EU-COVPT-1_COVACC (EudraCT: 2021-004526-29) is a phase II, comparative, randomized trial designed to evaluate

XSL•FO
RenderX

the impact of a reduced COVID-19 mRNA vaccination regimen on immunological responses and reactogenicity in pediatric patients with prior SARS-CoV-2 immunity. This trial investigates reduced-dose regimens in pediatric populations, contributing to the understanding of tailored vaccination approaches for children [9].

Together, these trials represent a comprehensive investigation across key demographic groups—older adults, the general population, and children—using adaptive and multinational protocols that address the challenges of rapid vaccine development and deployment during pandemics.

Methods



Overview

The degree of commonality and interoperability among data was assessed across 3 levels: clinical trial protocols, metadata, and data systems and management.

Interoperability Among the VACCELERATE Clinical Trial Protocols and Master Protocol Template

The process began with generating a list of the main points and parameters of general interest (eg, type of trial, randomization, primary and secondary aims, and safety) across the 3 specific clinical trial protocols: EU-COVAT-1_AGED, EU-COVAT-2_BOOSTAVAC, and EU-COVPT-1_COVACC [9,10]. The second step involved comparing the 3 trial protocols to identify interoperable data points based on this list of key parameters. In step 3, the outcomes derived from the adult trial protocols were compared against the VACCELERATE adult master protocol (Figure 1). This comparison focused on 4 core areas of the master protocol template's core outcome set (COS): (1) immunogenicity, (2) safety, (3) efficacy/clinical/physiological, and (4) other outcomes of interest. Differences and similarities among the protocols were identified manually.

Figure 1. Methodology for the identification of the interoperable data points. CTCC: Clinical Trials Centre Cologne; UCD: University College Dublin.

Metadata Interoperability of the VACCELERATE Clinical Trials

All data management (DM) processes, including the design of study databases for all 3 VACCELERATE clinical trials, were carried out by the Clinical Trials Centre Cologne (CTCC). The DM team at the CTCC developed the Study Database Specification (DB Spec) using an Excel (Microsoft Corporation) workbook. This workbook included metadata for defining the study database, case report forms (CRFs), edit checks, and a data dictionary. For each CRF study, the workbook contained an individual worksheet specifying database details such as field names, field response types, and formats. Additionally, the detailed metadata for all 3 vaccine trials were systematically developed using internal standards, terminology, and the general approach of Clinical Data Acquisition Standards Harmonization (CDASH) [12] for data collection, such as on electronic CRFs (eCRFs; Table 1). For instance, questions were categorized into relevant Clinical Data Interchange Standards Consortium (CDISC) [13] domains, along with prefixes for adverse events (AEs), concomitant medications, vital signs, protocol deviation, etc, while standard CDISC suffixes were applied to indicate question types.

[a]CDASH: Clinical Data Acquisition Standards Harmonization.

[b]N/A: not applicable.

Although the databases were generated by a single center and coordinated by the same individual, it was valuable to evaluate the degree of standardization, commonality, and data interoperability among the DB Spec of all 3 trials. To achieve this, a manual comparison of the Excel DB Spec from all 3 VACCELERATE clinical trials was conducted (Figure 1). This comparison focused on the main core areas—immunogenicity, safety, efficacy/clinical/physiological—emphasizing the development of the master protocol template.

The other variables were not considered due to differences in demographic details and treatment approaches among the 3 groups (older adults, adult, and pediatric). Metadata items such as data format, data dictionary name, response type, item text, required field indicator, and review groups were compared for consistency and discrepancies. Once identified, the next step was to analyze the rationale behind the observed consistencies and discrepancies among the metadata items.

Interoperability in Data Management and Systems

Interoperability in DM and systems was assessed through a questionnaire (Multimedia Appendix 1) distributed to the central laboratories: the University College Dublin (UCD) Centre for Experimental Pathogen Host Research (CEPHR, Dublin), Instituto de Salud Carlos III (ISCIII, Madrid), and the central biobank (UZA/UAntwerpen Biobank, Antwerp University Hospital). The questionnaire aimed to gather their experiences working with the VACCELERATE DM systems (Figure 1). UZA/UAntwerpen provided an overview of samples received from local sites (shipment manifest) and transferred to the research laboratories (transport manifest) and the clinical trial center. CEPHR and ISCIII, as research laboratories, performed the specified analyses on samples received from the central biobank. After completing the analyses, the research laboratories sent the results to the CTCC.

The questionnaire was designed to maximize accessibility and ease of use for site staff by categorizing the questions into broad areas while allowing flexibility through free-text response options: (1) laboratory procedures and documentation, (2) sample handling and storage data, (3) data transfer, and (4) general laboratory DM. Based on the information gathered through the questionnaire, a descriptive analysis was conducted to examine how each site handled, stored, and transferred data, as well as how their processes evolved within the VACCELERATE network. Furthermore, the analysis evaluated potential factors and new concepts required to harmonize and standardize the VACCELERATE DM systems.

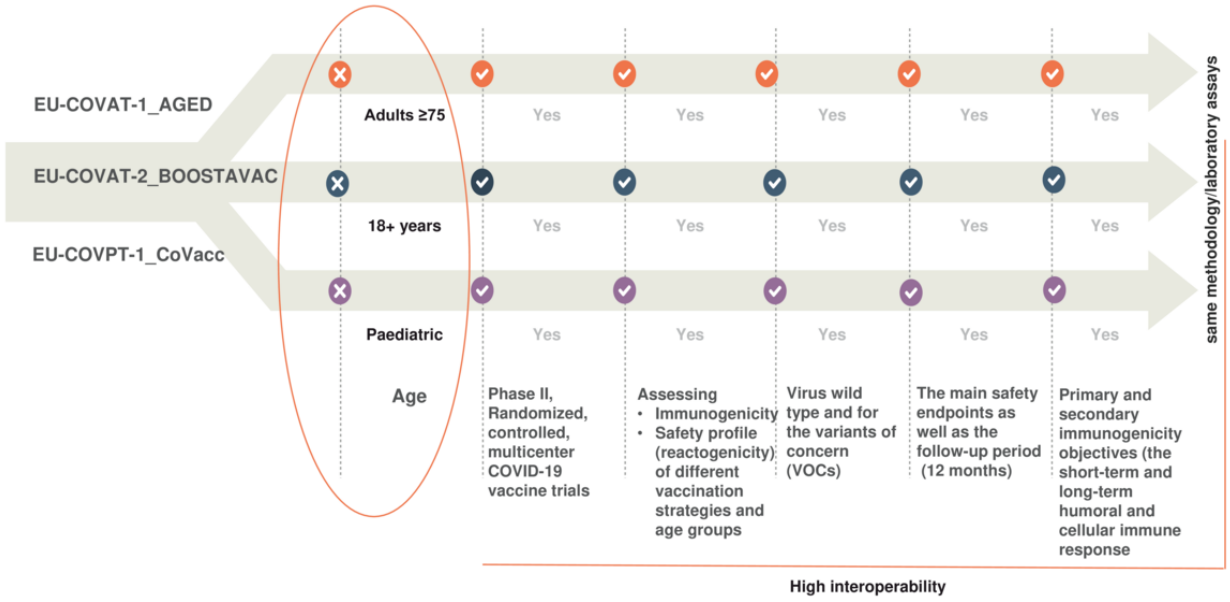
The DM documents—external DM plans, edit check plans, CRF completion requirements, and DB Specs—developed for the clinical trials by the CTCC were reviewed. Guided by the questionnaire, a semistructured interview was conducted with the CTCC data manager.

Ethical Considerations

The 3 VACCELERATE COVID-19 vaccine trials (EU-COVAT-1_AGED, EU-COVAT-2_BOOSTAVAC, and EU-COVPT-1_COVACC) received favorable ethics opinions and approval from the national competent authorities in the participating countries (State Medicines Control Agency, Norwegian Medicines Agency, Spanish Agency of Medicines and Health Products, Health Products Regulatory Authority Ireland, and Paul-Ehrlich-Institut for the EU-COVAT-1 AGED trial; Health Products Regulatory Authority Ireland, Norwegian Medicines Agency, Swedish Medical Products Agency, The Spanish Agency of Medicines and Medical Devices, Federal

XSL•FO
RenderX

Agency for Medicines and Health Products, and Paul-Ehrlich-Institut for the EU-COVAT-2 BOOSTAVAC trial; and Netherlands – Competent Authority, Norwegian Medicines Agency, Swedish Medical Products Agency, Hellenic National Organization for Medicines, and Paul-Ehrlich-Institut for the EU-COVPT-1 COVACC trial). Written informed consent was obtained from all participants before any trial procedures. These trials were conducted in accordance with the International Conference on Harmonization for Good Clinical Practice (ICH-GCP) guidelines and complied with the Declaration of Helsinki at all times. Furthermore, the provisions of the EU General Data Protection Regulation (GDPR) 2016/679 were strictly observed to ensure data protection. All investigational materials and data were pseudonymized in compliance with data protection regulations before undergoing scientific processing.



Results

Interoperability Among the Three Clinical Trial Protocols and Master Protocol

Our harmonization and standardization efforts began with a comparison of the 3 clinical trial protocols against the COS of the master protocol. The COS includes all appropriate measurements necessary to ensure standardization, efficiency, and uniformity in the conduct of clinical trials. Four main COS areas were adopted for phase II and III studies: (1) immunogenicity, (2) safety, (3) efficacy/clinical/physiological, and (4) other outcomes of interest.

The harmonization process resulted in the creation of Tables 2-5, which illustrate the interoperability between the master protocol and the 3 clinical trial protocols based on the COS areas. A summary of the outcomes is presented in Figure 2 (see Table S1 in Multimedia Appendix 2). Humoral and cellular responses to COVID-19 vaccines were assessed in a similar manner across all trials, considering both vaccine and host characteristics (Table 2), although minor adjustments to time points were incorporated into the pediatric protocol.

Figure 2. Interoperability between the 3 specific clinical trial protocols (summary).

XSL•FO
RenderX

Table 2. Core area: immunogenicity (core outcome set).

Objective	Outcome	Method of measurement
To evaluate humoral response to vaccination against wild-type SARS-CoV-2 and variants of interest—(1) short term: 7, 14, and 28 days after randomization and (2) long term: 3, 6, 9, and 12 months after randomization	• Binding antibodies titers (IgAa, IgG, and IgM) against SARS-CoV-2 nucleocapsid, receptor-binding domain, spike 1, and spike 2 viral proteins. • SARS-CoV-2 neutralization	• Immunoassay (enzyme-linked immunosorbent assay, electrochemiluminescence immunoassay, or chemiluminescence immunoassay); expressed as BAU/ml (geometric mean titers). • Neutralizing antibody titers to live wild-type SARS-CoV-2 plaque reduction neutralization test (PRNT50) assay, and pseudovirion-expressing S protein from different variants as measured by NT50 or flow cytometry–based microneutralization assay; expressed as IU/ml
To evaluate the cellular immune response to vaccination against wild-type SARS-CoV-2 and variants of interest—(1) short term: 7, 14, and 28 days after randomization); and (2) long term: 3, 6, 9, and 12 months after randomization)	• Th1b and Th2 immune responses	• Flow cytometry after SARS-CoV-2 S protein peptide stimulation of peripheral blood mononuclear cells and intracellular staining, including CD4+c/CD8+ interferon-gamma, interleukin-2, tumor necrosis factor-alpha, interleukin-4, interleukin-5, interleukin-13, and other Th1/Th2 markers.

[a]Ig: immunoglobulin.

[b]Th: helper T cell.

[c]CD: cluster of differentiation.

The early detection of serious AEs (SAEs) can be vital for the protection of the participants and via the interoperability of safety data, an overall better general view of the patient's clinical data could be achieved, resulting in the reduction of any potential risk of harms or adverse impacts and higher clinical safety. The developing safety profile in the trials is in a sufficiently similar motive and includes all the required information about reporting solicited, unsolicited, serious, and medically attended AEs, as shown in Table 3. By contrast, the definitions of the COVID-19 disease (eg, asymptomatic infection, confirmed and reinfection cases, the severity of signs and symptoms) are not reported in the protocols, even though it is referred to as part of the trial dataset outcomes (Table 4). Finally, the profile of immunophenotyping of immune responses (at the cellular level) and genotypic testing of breakthrough infections (vaccine immunogenicity) were also determined in the protocols, enhancing interoperability among them (Table 5). It should be noted that we did not present herein the comparison of pediatric protocol versus pediatric master protocol because the former is currently under review process.

Table 3. Core clinical area: safety data (core outcome set).

Outcome	Method of measurement
Solicited local and systemic AEs[a] for 7 days after each vaccination.	AEs are collected in a diary and will be entered into the electronic case report form (see all potential adverse reactions in Multimedia Appendix 2).
Unsolicited AEs after each vaccination	AEs are collected during visits upon an open question by the investigator up to the end of the trial.
SAEs[b]	SAEs collected throughout the study (from first vaccination until the end of the study)
Medically attended adverse events	Medically attended adverse events from the day of vaccination until the end of the study.

[a]AE: adverse event.

[b]SAE: serious adverse event.

Several parameters were considered to enable and enhance interoperability across the developed COVID-19 vaccine trials and master protocols (Figures 3 and 4). It is well-known that the lack of standardization in data processing exacerbates inhomogeneity in raw data. This often results in errors and significant time delays, reducing the reusability and interoperability of data within protocols. To address this, the various protocol formats were homogenized by manually identifying discrepancies and commonalities among selected parameters (see Tables S2-S13 in Multimedia Appendix 2). The selection of parameters was based on their relevance to the trials. Parameters present in only 1 protocol were excluded, while efforts were made to promote the consistent use of the same parameters across adult trials.

Concealment (blinding) of treatment group allocation is not anticipated for the current trials, while both adult trials support vaccine booster strategies. All clinical trials assess reactogenicity symptoms and the immunogenicity (efficacy) profile of COVID-19 vaccines (following a fourth dose) to inform potential optimized vaccine strategies. The secondary objectives

XSL•FO
RenderX

include evaluating immune response for up to 12 months (see Tables S2-S4 in Multimedia Appendix 2).

The safety aims and the increase in antibody titer were found to be similar across all trials, as were the primary end points in the adult population protocols, due to the nature of the BOOSTAVAC trial (see Table S5 in Multimedia Appendix 2). By contrast, stratification/subpopulation, inclusion, and exclusion criteria among volunteers are directly influenced by the participants' age and other trial-specific factors (eg, vaccine scheme, gender, immune status; see Table S6 in Multimedia Appendix 2). Additionally, patients' insurance and consent forms are addressed in all protocols, and the sample size calculation was reported based on the specifics of each protocol (see Table S7 in Multimedia Appendix 2).

Table 4. Core clinical area: efficacy/clinical/physiological (core outcome set).

Set of data and definition	Explanation
Confirmed COVID-19 disease	
COVID-19 disease	Molecularly confirmed COVID-19 is defined as a positive SARS-CoV-2 viral RNA result using a PCR[a]-based or other molecular diagnostic test or positive antigen test. (See Multimedia Appendix 2 for the definition of confirmed COVID-19 disease.)
Asymptomatic SARS-CoV-2 infection	
Asymptomatic SARS-CoV-2 infection[b]	The same as above but without symptoms typical for/suspicious of COVID-19
Severity of COVID-19 disease	
Asymptomatic SARS-CoV-2 infection or COVID-19 disease (presence and severity of signs and symptoms of COVID-19 disease)	Signs and symptoms as measured by symptoms of infection with COVID-19[c] at first evaluation and at maximum severity: mild, moderate, and severe COVID-19
Severe COVID-19 disease	
COVID-19 disease fulfilling criteria for intensive care unit admittance	Clinical records
All-cause mortality	
All-cause mortality: (1) at day 30 from randomization and (2) time from randomization	Clinical records
Disease (or infection) duration	
Time to 2019-nCoV RT-PCR[d] negativity (days)	Negativity: 2 consecutive negative results (sampling interval of at least 24 hours) of the 2019-nCoV nucleic acids tests of respiratory pathogens
Length (days) of hospital stay	Discharge standards: (1) normal body temperature for more than 3 days; (2) significant recovery from respiratory symptoms; (3) lung imaging showing obvious absorption and recovery of the acute exudative lesion; and (4) negativity of nucleic acids tests performed twice.
Length of intensive care unit stay	N/A[e]
Reinfection	
Confirmed COVID-19 reinfection	Molecularly confirmed COVID-19 is defined as a positive SARS-CoV-2 viral RNA result using a PCR-based or another molecular diagnostic test or positive antigen test. (See Multimedia Appendix 2 for the definition of confirmed COVID-19 disease.)
Time to reinfection	
Long COVID syndrome	WHO definition[b] [14,15]
Multisystem inflammatory syndrome in children	MIS-C[f] WHO[g] definition

[a]PCR: polymerase chain reaction.

[b]See [15].

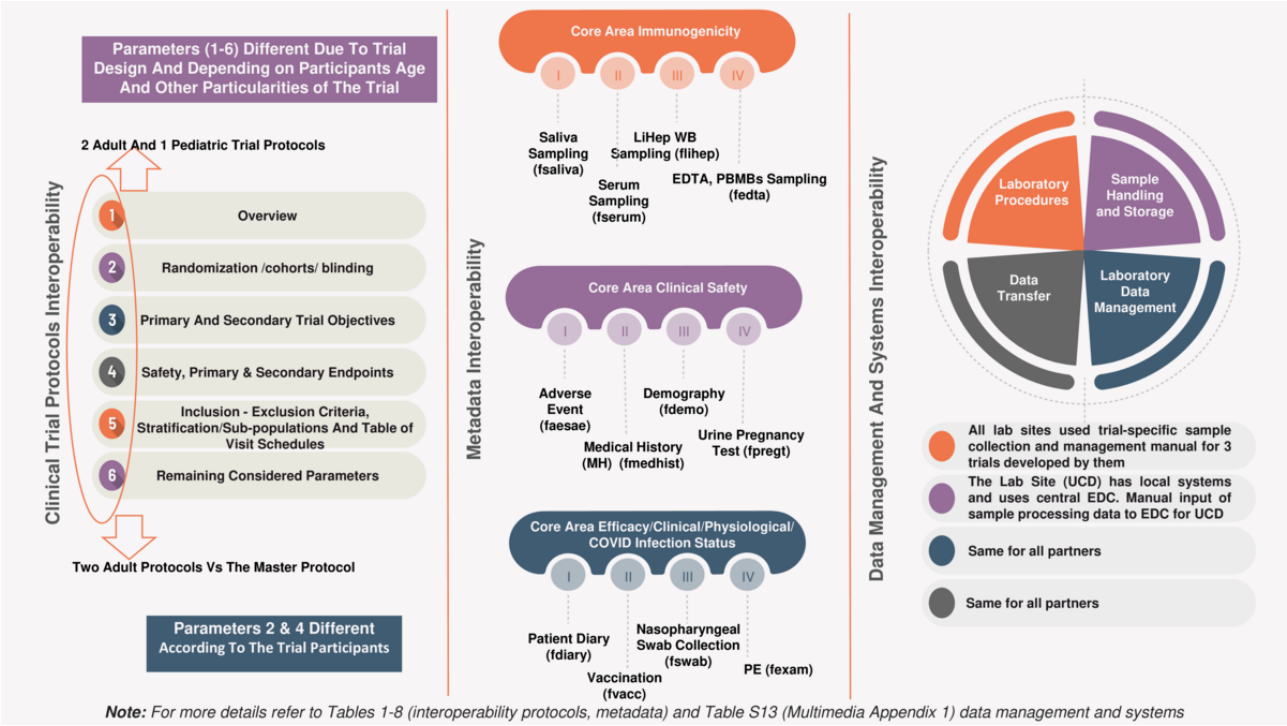
[c]Per case definition for moderate to severe/critical COVID-19.

[d]RT-PCR: reverse transcription polymerase chain reaction.

[e]N/A: not applicable.

[f]MIS-C: multisystem inflammatory syndrome in children associated with COVID-19.

[g]WHO: World Health Organization.



XSL•FO
RenderX

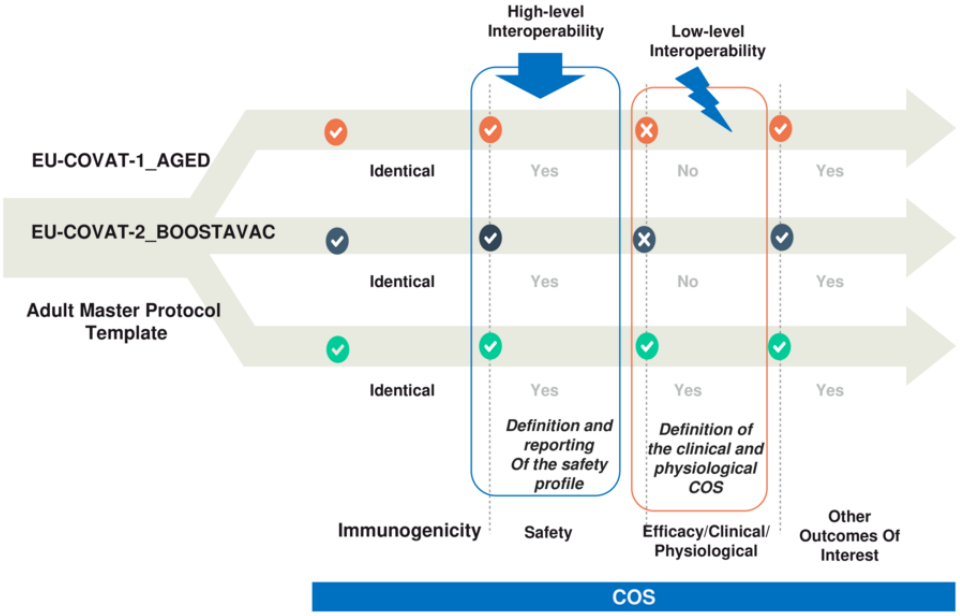
Table 5. Other outcomes of interest.[a]

Set of data	Outcome and methods
Immunophenotyping of immune responses to vaccination	Detailed immunophenotyping of immune responses, including metabolomics, proteomics, and transcriptomics
Genotyping of breakthrough infections	Whole genome sequencing of isolated SARS-CoV-2 viral strains detected in breakthrough infections

[a]Per the CoVacc trial protocol, Participants will be informed that leftover blood samples, remaining after all study-related testing is completed, may be stored indefinitely for potential future research purposes (eg, exploratory immunology). This may include genotypic testing of genetic polymorphisms relevant to vaccine immunogenicity. Participants will have the option to decide whether they permit the future use of any leftover samples. With the participants' informed consent, any remaining cells and plasma will be frozen indefinitely for future analyses related to COVID-19 and other coronavirus-related diseases or vaccine-related responses. If a participant chooses not to allow this, all leftover samples belonging to that participant will be discarded at the end of the trial.

Figure 3. Noncommonality parameters identified in the VACCELERATE projects (protocols, metadata and data management, and systems). EDC: Electronic Data Capture; EDTA: ethylenediaminetetraacetic acid; LiHep: lithium heparin; PBMC: peripheral blood mononuclear cell; PE: physical examination; UCD: University College Dublin; WB: whole blood.

Note: *For more details refer to Tables 1-8 (interoperability protocols, metadata) and Table S13 (Multimedia Appendix 1) data management and systems*



We also conducted a comparison of the 2 adult trials with the master protocol (see Tables S8-S13 in Multimedia Appendix 2). The primary aim of the adult trials is to evaluate the immunogenicity and reactogenicity (safety) of vaccine booster strategies and homologous mRNA vaccination for COVID-19 at different time intervals (see Tables S8 and S9 in Multimedia Appendix 2).

Both the adult and master protocols include the relevant subprotocols, cohorts, and descriptions of the randomization process, while blinding is not anticipated in the adult trials. All protocols support phase II trials and share similar primary objectives. The primary and secondary objectives/end points (including exploratory ones) constitute a nearly identical core dataset. The secondary trial objectives for immunogenicity and reactogenicity focus on the immune response and associated signs and symptoms over up to 12 months (see Tables S9 and S10 in Multimedia Appendix 2).

The reporting periods for unsolicited and solicited AEs, as well as the rates of SAEs, are identical across the adult and master protocols. However, discrepancies in inclusion and exclusion criteria are directly influenced by the trial participants (see Tables S11 and S12 in Multimedia Appendix 2). The treatment duration and follow-up period for the studies are identical in both the adult trials and the master protocol, extending up to 12 months. All clinical trials are conducted in accordance with the ICH-GCP, including the use of appropriate consent forms and patient insurance, based on the allocated treatment group (see Table S13 in Multimedia Appendix 2).

Figure 4. COS interoperability between the vaccine trial and master protocols.

Metadata Interoperability

The points of consistency and discrepancies across the main core areas (eg, immunogenicity, safety, efficacy, clinical, and physiological aspects) among the metadata items of the 3 VACCELERATE clinical trials are presented in Tables 6-8 and Figure 5. The noncommonalities identified within the CRFs were attributed to differences in the 3 populations (aged 75+, adult, and pediatric), variations in protocol design, and differing vaccination patterns (Figures 3 and 5). Additionally, differences in the coding and labeling of variables, as well as in the item groups, were identified. These discrepancies required clarification to enhance interoperability.

Interoperability in Data Management and Systems

VACCELERATE received a significant boost through the selection of the CTCC as the sole DM provider, with system database development coordinated by a single individual. This eliminated the need for coordination across multiple trial units. For the CTCC, the standardized format adopted within the VACCELERATE project utilized a data system featuring an installation of the Anju [16] (formerly OmniComm) TrialMaster clinical database management system, accompanied by metadata.

Data transfer using tried-and-tested methods common to all sites (spreadsheet format) enabled a quick and relatively secure exchange, which proved highly effective. This process was further facilitated by the implementation of the TrialMaster system, which generated templates that could be adapted for use with spreadsheets. The responses received from the laboratories and CTCC are shown in Figures 3 and 6, while the questionnaire results are presented in Table S14 in Multimedia Appendix 2.

Figure 6. Interoperability between the data management and systems. CDASH: Clinical Data Acquisition Standards Harmonization; CTCC: Clinical Trials Centre Cologne; DM: data management; eCRF: electronic case report form; EDC: Electronic Data Capture; FAIR: Findable, Accessible, Interoperable, and Reusable; SOP: standard operating procedure.

Discussion

Principal Findings

To the best of our knowledge, this is the first report to assess the degree of data commonality and interoperability between vaccine clinical trial protocols, the master protocol template, metadata, and data systems and management. In this study, we considered multiple parameters for the first time to enhance and improve interoperability across the developed COVID-19 vaccine clinical trial and master protocols, based on the selected COS areas: (1) immunogenicity, (2) safety, (3) efficacy/clinical/physiological outcomes, and (4) other outcomes of interest. This is significant because the lack of standardization in raw data processing is a well-known issue that exacerbates data inhomogeneity. This often results in errors and significant time delays, reducing the reusability and interoperability of data within protocols. To address this, the various protocol formats were homogenized by manually identifying discrepancies and commonalities among the selected parameters.

The database systems prepared by the CTCC already demonstrate substantial use of CDASH, a key enabler for the implementation of other CDISC standards. CDASH plays a crucial role in supporting the Study Data Tabulation Model (SDTM) [17]. Transforming study data to SDTM could also prove beneficial in the context of data sharing, especially as data interoperability becomes increasingly important. The adoption of CDASH standards [18] within the VACCELERATE DM systems establishes an environment conducive to generating FAIR data throughout the life cycle of the 3 trials. This approach ensures that the data will be available for collaboration and future use.

Pooling the metadata from the VACCELERATE studies would create a valuable metadata resource, independent of the underlying data. This resource could potentially be made accessible (eg, via the VACCELERATE official website and the ECRIN data-sharing repository for COVID-19 trials, EOSC-Life) [19], offering a unique opportunity for other sponsors to design related studies, particularly those utilizing the VACCELERATE infrastructure. The VACCELERATE metadata, as a shared resource, could play a pivotal role in standardizing data items and the controlled terminologies used within categorized questions, thus contributing to greater harmonization and interoperability in future research.

XSL•FO
RenderX

Education and training are critical for the successful implementation of FAIR DM in clinical data. Therefore, additional CDISC training for DM staff could be beneficial, both within VACCELERATE and more broadly, to support the adoption of data standards. Metadata harmonization should be completed before database development.

Although the DM staff at the CTCC are highly experienced and have already implemented international standards, there is a lack of planning for long-term data storage and reuse. This occurred because it was not anticipated during the database setup phase and due to the lack of a long-term data sharing budget, either linked to VACCELERATE itself or allocated to a data-sharing repository. Our report suggests that metadata harmonization planning should begin before database development and be supported by requirements (eg, CDASH) and oversight throughout the entire database setup phase, as well as any subsequent amendments. All subcontractors should be informed and included in this planning process. Furthermore, generating metadata and SDTM data for secondary use can be done under less time pressure compared with other aspects of standards implementation, such as the initial development of eCRFs. Conversely, while the final application of both is likely to occur at the end of the study, this does not mean the work must be confined to that time frame. Transformations can be planned and tested at any stage, using dummy data if necessary, as can the generation of metadata.

VACCELERATE highlights some of the challenges in making data standards a practical reality. At the same time, it provides opportunities to address these challenges, developing methods that can help embed data standards within noncommercial clinical research.

VACCELERATE received a substantial boost from the selection of the CTCC as the sole DM provider, with system database development coordinated by a single individual. This approach eliminated the need for coordination among different trial units, resulting in a high degree of uniformity within the system. The DM systems used in VACCELERATE are relatively new and have the potential to perform well with the limited number of sites currently using them. To effectively test these DM systems, it is necessary to have multiple sites utilizing them, with additional trials planned for later stages of the rollout. While the central Electronic Data Capture (EDC) system (TrialMaster) was used to manage sample processing data, there were concerns from the laboratory sites and the central biobank regarding the time required to enter sample data, resolve errors, and reconcile site datasets with the EDC. Transferring data using tried-and-tested methods common to all sites (spreadsheet format) enabled a harmonized, rapid, and relatively secure exchange. Before a scanning system was adopted, allowing sites to upload processing data directly into the EDC could significantly reduce the time constraints associated with manual data entry.

As only 3 clinical studies were funded under the VACCELERATE project, these results were not applied to any newly registered studies. However, as the objective of the VACCELERATE project has now been extended to other vaccine-preventable infectious diseases with pandemic potential, there will be a broader opportunity in the near future to implement the results presented here. Nevertheless, these trials provide valuable insights and a scalable framework for future vaccine studies, especially in the context of epidemics and pandemic preparedness. The methodology and protocols of these trials address critical questions regarding vaccine immunogenicity, reactogenicity, and optimal dosing strategies across diverse populations, including older adults (≥75 years), the general adult population, and pediatric patients. By using adaptive, multinational protocols, these trials simulate the real-world conditions of pandemic response, where speed, adaptability, and inclusivity are critical.

The methodologies from these trials are highly generalizable and provide a robust blueprint for future vaccine clinical studies within research networks. The inclusion of underrepresented populations, such as older adults and children, ensures that future vaccine trials will generate comprehensive, inclusive data applicable to all demographics. Additionally, the adaptive design of the protocols used in these studies allows for future modifications in response to emerging data and infectious diseases—a critical feature for addressing the dynamic nature of pandemics and evolving infectious threats.

Beyond the outcomes of individual trials, these studies contribute to the establishment and strengthening of international vaccine research networks. The collaborative, multicentric nature of the VACCELERATE network demonstrates the feasibility of harmonized vaccine research across borders, promoting shared protocols, centralized data analysis, and the dissemination of findings. This approach not only accelerates the vaccine development process but also strengthens global preparedness by creating investigator-initiated clinical research infrastructure and expertise that can be rapidly mobilized for emerging epidemics.

Moreover, the lessons learned from these trials can inform the design and implementation of studies for vaccines targeting other infectious diseases with pandemic potential, such as influenza or novel zoonotic pathogens. The emphasis on immunogenicity, dosing strategies, and booster efficacy can be adapted to various pathogens, ensuring that the evidence generated remains both relevant and actionable.

In summary, the VACCELERATE trials serve as a cornerstone for advancing and standardizing vaccine research methodologies. They underscore the importance of inclusivity, adaptability, and international collaboration, setting a precedent for future studies aimed at mitigating the impact of pandemics and safeguarding global public health.

Limitations

This paper presents a novel approach to evaluating the degree of data commonality and interoperability between vaccine clinical trial protocols, the study master protocol template, metadata, and data systems and management. It did not benefit from preexisting methodologies, and its scope may therefore be limited by the specific cases examined. Nonetheless, it is anticipated to provide valuable insights that contribute to the improvement of clinical research data sharing and reuse.

XSL•FO
RenderX

Conclusions

This study demonstrates that using master protocols can significantly enhance trial operational efficiency and data interoperability when similar infrastructure and DM procedures are consistently adopted across multiple trials. To achieve data interoperability while preserving meaning in interpretation and analysis, shared data should be structured, described, formatted, and stored using widely recognized data and metadata standards.

Acknowledgments

The VACCELERATE project has received funding from the European Union's Horizon 2020 Research and Innovation Programme (grant 101037867). For more information, please refer to the official website of the VACCELERATE network [4]. The services of the "BioBank Antwerp," Antwerp, Belgium (ID: BE 71030031000, Biobank Antwerp [BB190007], BBMR-ERIC, Belgian [BIORESOURCE]) are used for the storage of generated samples and aliquots. Special thanks to ECRIN's Communication Officer, Alexandra KUSTER, for proofreading the article.

Generative artificial intelligence is not used by the authors to generate any content (text, tables, and figures) for this manuscript.

Abstract

Background: Despite wide acceptance in medical research, implementation of the FAIR (findability, accessibility, interoperability, and reusability) principles in certain health domains and interoperability across data sources remain a challenge. While clinical trial registries collect metadata about clinical studies, numerous epidemiological and public health studies remain unregistered or lack detailed information about relevant study documents. Making valuable data from these studies available to the research community could improve our understanding of various diseases and their risk factors. The National Research Data Infrastructure for Personal Health Data (NFDI4Health) seeks to optimize data sharing among the clinical, epidemiological, and public health research communities while preserving privacy and ethical regulations.

XSL•FO
RenderX

Objective: We aimed to develop a tailored metadata schema (MDS) to support the standardized publication of health studies' metadata in NFDI4Health services and beyond. This study describes the development, structure, and implementation of this MDS designed to improve the FAIRness of metadata from clinical, epidemiological, and public health research while maintaining compatibility with metadata models of other resources to ease interoperability.

Methods: Based on the models of DataCite, ClinicalTrials.gov, and other data models and international standards, the first MDS version was developed by the NFDI4Health Task Force COVID-19. It was later extended in a modular fashion, combining generic and NFDI4Health use case–specific metadata items relevant to domains of nutritional epidemiology, chronic diseases, and record linkage. Mappings to schemas of clinical trial registries and international and local initiatives were performed to enable interfacing with external resources. The MDS is represented in Microsoft Excel spreadsheets. A transformation into an improved and interactive machine-readable format was completed using the ART-DECOR (Advanced Requirement Tooling-Data Elements, Codes, OIDs, and Rules) tool to facilitate editing, maintenance, and versioning.

Results: The MDS is implemented in NFDI4Health services (eg, the German Central Health Study Hub and the Local Data Hub) to structure and exchange study-related metadata. Its current version (3.3) comprises 220 metadata items in 5 modules. The core and design modules cover generic metadata, including bibliographic information, study design details, and data access information. Domain-specific metadata are included in use case–specific modules, currently comprising nutritional epidemiology, chronic diseases, and record linkage. All modules incorporate mandatory, optional, and conditional items. Mappings to the schemas of clinical trial registries and other resources enable integrating their study metadata in the NFDI4Health services. The current MDS version is available in both Excel and ART-DECOR formats.

Conclusions: With its implementation in the German Central Health Study Hub and the Local Data Hub, the MDS improves the FAIRness of data from clinical, epidemiological, and public health research. Due to its generic nature and interoperability through mappings to other schemas, it is transferable to services from adjacent domains, making it useful for a broader user community.

Introduction

Despite wide acceptance in medical research, implementation of the FAIR (findability, accessibility, interoperability, and reusability) data principles in certain health domains and interoperability across data sources remain a challenge [1]. Clinical trial registries, such as ClinicalTrails.gov [2], the German Clinical Trials Register (DRKS) [3], and the World Health Organization's International Clinical Trials Registry Platform (ICTRP) [4], collect metadata about clinical studies, thus making them searchable and findable [5]. However, they are often not sufficiently detailed and lack further information about relevant study documents (eg, protocols, questionnaires, data dictionaries, etc), which hinders the findability and accessibility of such significant health resources [5]. Moreover, numerous epidemiological and public health studies remain unregistered [1,5], likely due to unfamiliarity with metadata standards and a general lack of a metadata-sharing culture [6,7].

Making valuable data from these studies available to the research community could potentially improve our understanding of essential risk factors associated with various diseases [1]. Several data-sharing initiatives have aimed at promoting the implementation of the FAIR principles. In the field of biobanking, the Minimum Information About Biobank Data Sharing (MIABIS) initiative is dedicated to standardizing metadata describing biobanks, thereby improving their interoperability and enabling the sharing of their valuable data and samples [8]. In cardiology, the joint European Union-Canada project established a cross-border data sharing and multicohort cardiovascular research platform, linking molecular, imaging, functional, and clinical data [9]. In epidemiology, Maelstrom Research provides a comprehensive catalog with search tools to support the discovery of data collected by epidemiological research networks and studies [10,11]. To our knowledge, an overarching search for clinical trials alongside epidemiological and public health studies is not yet available in existing search portals [5].

The National Research Data Infrastructure for Personal Health Data (NFDI4Health) is a nationally funded multipartner German project that seeks to optimize data sharing among the clinical, epidemiological, and public health research communities while preserving protection, privacy, and ethical regulations. This infrastructure for data from various health-related disciplines intends to support health research and facilitate the development of new and personalized preventive interventions and therapies, thereby improving population health [12,13]. With this aim, NFDI4Health develops data management workflows, ensuring that research data are properly organized, documented, and stored throughout its lifecycle. These workflows involve defining metadata standards, data classification systems, and data governance policies that facilitate the findability and accessibility of research data via the central NFDI4Health search portal. Entitled the German Central Health Study Hub (GCHSH) [5,14], the platform allows for the standardized publication of descriptive metadata from clinical, epidemiological, and public health studies. It connects to local data repositories and harvests their relevant metadata via the Local Data Hub (LDH) software

XSL•FO
RenderX

of NFDI4Health [15,16], making such studies and their data findable and accessible through a single-entry point.

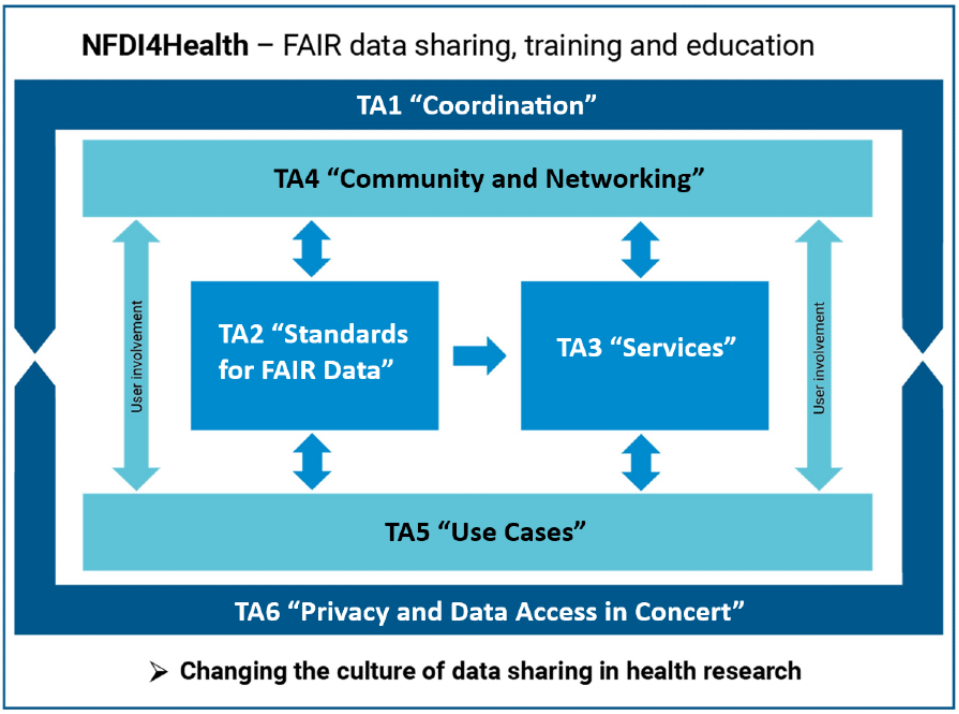
In this paper, we present the development, structure, and implementation of the NFDI4Health metadata schema (MDS), the model underlying the GCHSH and LDH. We also present the ongoing mappings to other schemas, the format currently adopted, and the steps taken toward a machine-readable version. Prospects for further development and extension of the MDS are also discussed.

Methods

Ethical Considerations

As the study presented in this paper did not involve human participants and did not examine human personal data, the approval of an ethics committee was not required.

NFDI4Health Structures and Their Roles in the Development of the MDS



The NFDI4Health project comprises 6 task areas (TAs) [17] as shown in Figure 1, three of which are most relevant for the construction, development, and implementation of the MDS: TA2 “Standards for FAIR data,” TA3 “Services,” and TA5 “Use cases.” MDS development is a crucial part of TA2, as it aims to harmonize and further develop standards for data and their corresponding metadata in clinical trials, public health surveys, and epidemiological cohorts by implementing the FAIR principles. In that sense, TA2 provides the conceptual background for the NFDI4Health services implemented by TA3. Two crucial services that build on the metadata structures of the MDS are the GCHSH [14] and LDH [15,16], in addition to others that NFDI4Health aims to provide to the user community. All NFDI4Health standards and services are developed in close collaboration with domain experts and potential users in TA5 and implemented and tested within the scope of its 5 use cases, namely nutritional epidemiology, chronic diseases, record linkage, clinical trials, and medical imaging radiomics [18]. An additional use case focusing on COVID-19 was introduced during the pandemic, serving as a pilot and addressing the major challenges posed to societies around the world [19].

The MDS team (TA2) develops the metadata model as a conceptual backbone for NFDI4Health services and acts as the interface between NFDI4Health users (TA5) and developers (TA3). It is composed of experts in metadata as well as data interoperability and quality standards from different NFDI4Health coapplicant institutions. The team’s major role is to gather and bundle requirements from the users, model them into the schema, and communicate them to the developers for implementation. The team is also involved in various mapping activities between the MDS and other schemas, aiming to ensure the interoperability of the NFDI4Health metadata and services with other resources and platforms. Further interoperability efforts include representing the MDS using the Health Level 7 Fast Healthcare Interoperability Resources (FHIR) standard as well as value set mappings to concepts from international terminologies [20,21]. The MDS team holds Zoom meetings twice a month to coordinate, review, and discuss potential updates and improvements of the MDS and arrange for meetings with other teams (eg, developers, users, etc) when needed.

In addition to the 3 TAs directly involved in the construction and implementation of the MDS, TA6 “Privacy and data access in concert” provides the legal framework for metadata and data sharing. It helps in identifying relevant metadata items that capture information on data sharing, licensing, and access for studies and data addressed by NFDI4Health. This is especially important for future MDS extensions covering these aspects. TA4 “Community and networking” supports the outreach to the user community at large to demonstrate the usefulness of the MDS and its implementations to researchers and users in Germany and beyond. Finally, TA1 coordinates the whole NFDI4Health project and provides project management support.

XSL•FO

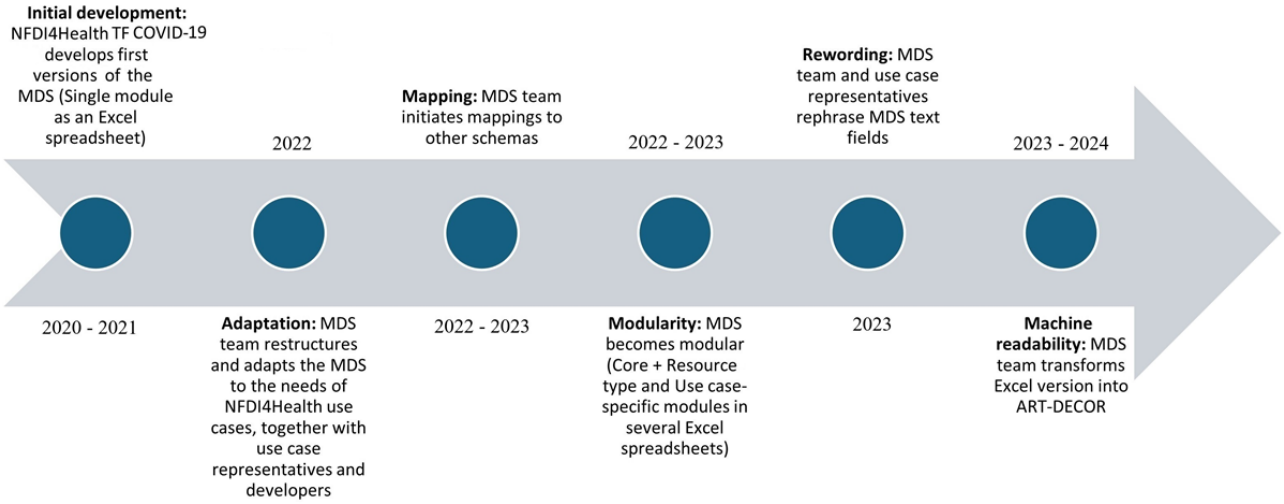
Figure 1. Tasks areas of the NFDI4Health. FAIR: findability, accessibility, interoperability, and reusability; NFDI4Health: National Research Data Infrastructure for Personal Health Data Project.



MDS Development

The MDS is an information model tailored to describe clinical, epidemiological, and public health studies as well as associated documents (eg, study protocols, instruments, etc) or datasets. It improves the FAIRness of these resources by making them searchable and accessible through implementations in metadata repositories tailored to the users' needs, such as the GCHSH [14] and the LDH [15,16]. The MDS was initially developed by the NFDI4Health task force COVID-19 [19], including a single module modeled in Excel and aimed at COVID-19 studies [22]. Many items were primarily adapted from established metadata standards and models, including DataCite [23], ClinicalTrails.gov [2], DRKS [3], Maelstrom [10], MIABIS [24], and the Data Documentation Initiative (DDI) [25].

To ensure broad applicability and ease its implementation across further health domains, the MDS was restructured to meet the needs of other NFDI4Health use cases. It adopted a modular structure, comprising core and use case–specific modules. The extension was carried out by the MDS team in close collaboration with the service developers and use case representatives as domain experts. Mapping activities to other schemas were also initiated to facilitate interoperability. Upon using the GCHSH implementation of the MDS, feedback was received from the German Centers for Health Research, the coverCHILD project [26], among others, and further issues with the MDS were fixed. These included additional structural changes, improvements of item headers and description texts (rewording), and more standardized value sets. Transformation plans were finally executed toward an improved machine-readable version of the MDS in ART-DECOR (Advanced Requirement Tooling-Data Elements, Codes, OIDs, and Rules) [27]. The MDS development process from the year 2020 to 2024 is illustrated in Figure 2.

XSL•FO
RenderX

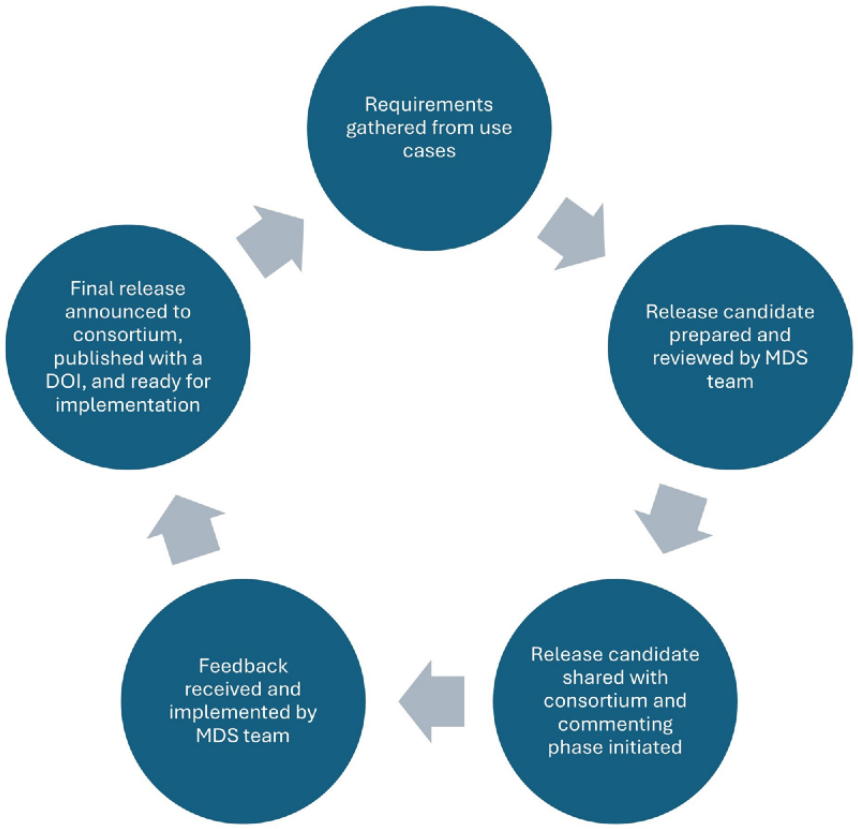


Figure 2. Development process of the MDS. ART-DECOR: Advanced Requirement Tooling-Data Elements, Codes, OIDs, and Rules; MDS: Metadata schema; NFDI4Health: National Research Data Infrastructure for Personal Health Data; TF: task force.

Release Cycle

To adapt to the requirements of the NFDI4Health user community, a new version of the MDS was released every 3 months. During each cycle, use case requirements were gathered and modeled and a release candidate of the MDS was prepared. Upon review by all members of the MDS team, the release candidate was shared with the NFDI4Health community and a commenting phase was initiated. During this phase, feedback could be provided by all members of the NDFI4Health consortium, including users and developers, commonly via a MDS GitHub repository. Feedback was also often provided via email, dedicated meetings, or during workshops. The feedback served as a basis to finalize the new version of the MDS, which was subsequently published with a digital object identifier (DOI) and shared with the GCHSH developers for implementation. The release cycle is shown in Figure 3.

Figure 3. Release cycle of the MDS. DOI: digital object identifier; MDS: metadata schema.

Mappings

For compatibility with existing clinical trial registries, the MDS was mapped to the study-specific models used by ClinicalTrails.gov [2], DRKS [3], and ICTRP [4]. Mappings were performed manually by comparing the MDS to the information present on these search portals, their input masks, as well as their XML exports and documentation, when

XSL•FO
RenderX

available. The objective was to enable the GCHSH, and other services that implement the MDS, to automatically upload the metadata of studies from Germany (ie, studies with at least one participating facility in Germany) registered on these portals, thereby avoiding the need to re-enter their information. Accordingly, all mandatory items of the MDS were compared with individual items in these schemas in search of appropriate matches. Matches were identified by comparing names, definitions, and value sets. When matches were not found or not applicable, a fixed value was assigned to the mandatory field as a workaround for implementation.

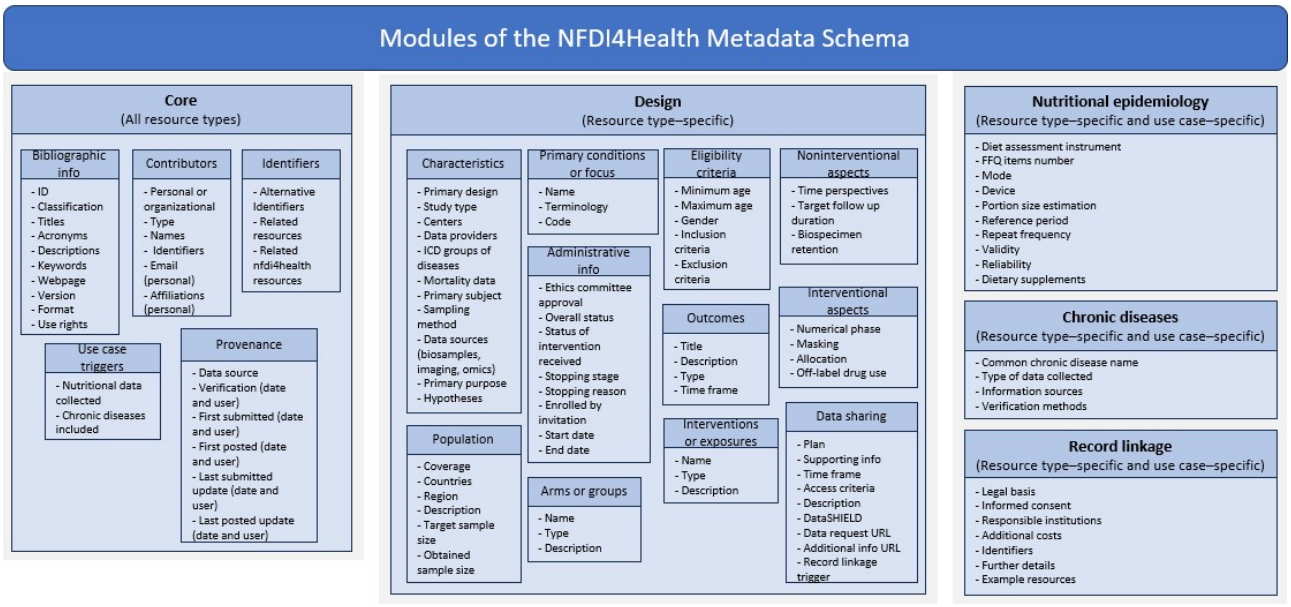
To remain aligned with international and local initiatives, further mappings to the schemas of the European Clinical Research Infrastructure Network (ECRIN) [28,29] and the schema of the German Human Genome-Phenome Archive (GHGA) [30] were performed. These mappings were considered important because ECRIN supports the organization of clinical trials in Europe and GHGA develops one of the most relevant resources in Germany for genomic data from the health domain. The MDS team compared all mandatory items using the same approach described above. It was also agreed with both ECRIN and GHGA teams to prepare their own mapping version in the reverse direction, thereby comparing their mandatory items to the MDS in search of the best matches. The intention was to align both versions, with the goal of allowing the NFDI4Health services to exchange information with ECRIN's metadata repository [31] and GHGA's metadata catalog [32]. In addition, to examine alignment options with the European Rare Disease Registry Infrastructure (ERDRI), a discussion with colleagues from the European Commission's Joint Research Center was initiated, followed by a comparison of the MDS items to the different sections of ERDRI's directory of registries (ERDRI.dor) [33].

Representations

The MDS was initially released as human-readable Microsoft Excel spreadsheets [34]. To develop an improved machine-readable version, a training workshop took place in May 2023 to kick-start a transformation into ART-DECOR [27]. Following the workshop, the Excel version of the MDS was shared with the ART-DECOR team to transform the modules' main information, using their transformation script, into a dedicated ART-DECOR project. The transformed version was afterwards checked by various members of the MDS team. Transformation errors were identified and fixed, and missing information was manually added. In the context of the MDS representation in FHIR, allowed values were mapped to concepts from international terminologies, whenever possible, and integrated into ART-DECOR. MDS values that could not be matched to terminology concepts were placed in a local code system created for NFDI4Health. Besides the ART-DECOR representation, a Simplifier project was also established based on the MDS-to-FHIR mappings, in which different FHIR artifacts were created and published [35]. These, together with details on the terminology mappings, are outside the scope of this study and will be published elsewhere [36].

Rewording

To improve user experience (UX), the GCHSH was tested by external users specialized in UX testing. Recommendations affecting the MDS included rephrasing item display names as well as descriptions and short input help texts based on the guidelines for effective UX writing [37]. Accordingly, dedicated discussions were initiated, involving NFDI4Health users from different domains as well as service developers and members of the MDS team, to examine the GCHSH interface item by item and individually modify and improve the clarity of these texts. Suggested changes were edited directly in a real-time working version of the MDS, which was shared on the NFDI4Health document management system for collaborative review and feedback.



Results

Structure of the Metadata Schema

The most recently released version of the MDS (v3.3) comprises a total of 220 metadata items in 5 dedicated modules. The core module captures information relevant to any type of health resource, while additional modules gather descriptions specific to particular resources, health domains, or use cases. The latter currently include nutritional epidemiology, chronic diseases, and record linkage. In NFDI4Health, the term "resource" or "resource type" is used to refer to health studies, substudies, registries, biobanks, study protocols, data dictionaries, among other types, data collection instruments, or study documents. All modules comprise mandatory and optional items, with conditional cardinalities set when needed. The core and design modules are mostly based on international standards, with 20 of their items representing the mandatory information required for entering or displaying studies on the GCHSH. The 3 use case–specific modules are user-driven, mainly based on the needs of the NFDI4Health user community. Figure 4 provides an overview of the different MDS modules, illustrating their corresponding item groups and subgroups. The complete list of items is available on the web [34].

XSL•FO
RenderX

Figure 4. Overview of the NFDI4Health metadata schema modules. NFDI4Health: National Research Data Infrastructure for Personal Health Data.

Core Module

Based on DataCite, ClinicalTrails.gov, and DRKS, the core module of the MDS comprises 80 generic metadata items descriptive of any type of health resource. These include bibliographic information, such as the resource's title, description, acronyms, keywords, and web page, along with information about the persons and organizations that contributed to the development of the resource. With the use of identifiers, the module provides links to published study results, in addition to relevant resources registered on the NFDI4Health portal or elsewhere. Provenance details about the publication of the resource as well as items to trigger the nutritional epidemiology and chronic diseases modules, where applicable, are also included.

Design Module

For design and data access information, the MDS provides 111 items, representing further characteristics that are specific to certain resource types, namely studies, substudies, and registries. Like the core module, the design module is also based on DataCite, ClinicalTrails.gov, and DRKS, in addition to Maelstrom, MIABIS, and DDI. For studies and substudies, the module distinguishes between interventional and noninterventional study designs and provides dedicated sections for each design type. Information about the study conditions is provided, in addition to a population section including recruitment area and sample size information. An administrative information section includes metadata items about the ethics committee approval, status, and dates of the study, while further sections cover details about the eligibility criteria, outcome measures, and time points. Information about the data sharing plan is also included, with an item to trigger the use case–specific record linkage module, when applicable. Most sections in this module also apply to registries due to several overlapping characteristics.

Nutritional Epidemiology Module

Dedicated to studies and substudies collecting nutritional data, this module provides 15 domain-specific items, mainly related to dietary assessment instruments used in corresponding studies. The modes and devices used to apply an instrument are specified in this module, along with the methods used for portion size estimation. The module also contains items indicating whether the instrument is repeatedly applied, whether it is validated and whether it inquires about dietary supplements.

Chronic Diseases Module

For each chronic disease addressed by the resource, this use case–specific module specifies whether prevalent or incident outcome data were collected and indicates the information sources from which the data were generated. Methods used to verify the outcomes are also described. The module contains 5 items and is only applicable to certain resource types, including study protocols, informed consent forms, case report forms, and patient information sheets, among other study documents.

Record Linkage Module

For resources allowing record linkage, the third dedicated module indicates whether specific legal regulations or permissions are required for conducting record linkage and whether informed consent has been obtained. The module also provides information about responsible institutions that must approve record linkage and whether additional costs are incurred. Identifiers that can be used (eg, date of birth, postal code, insurance number, etc) as well as DOIs of additional related resources specific to record linkage (eg, publications) are also included. The module has 9 items and is only applicable to studies, substudies, and registries.

Preliminary Mapping Results

Based on the mappings of the MDS to the schemas of clinical trial registries, the GCHSH is capable of automatically uploading and displaying study metadata from these portals. With this objective, the 20 mandatory items of the MDS core and design modules were mapped to their counterparts in these schemas

XSL•FO
RenderX

as shown in Table 1, while presetting the NFDI4Health resource type to "Study" and the country to "Germany," as the focus of NFDI4Health is on German studies. The data source and subject items were also preset to "Automatically uploaded" and "Person," respectively. This is considering that these studies would be imported into the GCHSH from clinical trial registries involving only human subjects. Items with value sets (eg, study type) were fixed to selected values such as "Unknown" or "Other," as proper matching values could not be found. Moreover, fixed values, such as "Summary is not provided," were used for string items (eg, description), as corresponding items or their texts were missing. Table 1 also includes mapping metrics, indicating the number of MDS items achieving various matching levels. By October 2024, there were 25595, 659, and 221 studies imported into the GCHSH from ClinicalTrails.gov, DRKS, and ICTRP respectively.

Following a similar approach and with the same objective, several iterations were prepared by the MDS team to map the MDS to version 6 (v6) of the ECRIN schemas [28]. As ECRIN has a study and a data object schema, those iterations were performed twice while considering the same study-specific items in Table 1 in addition to an extra item required for nonstudy resources (Resource.classification.typeGeneral). Table 2 shows mappings of the MDS mandatory items to both ECRIN schemas. Unlike the MDS, which includes only one scientific unabbreviated title for a resource, ECRIN considers several title types (eg, display title, abbreviated title, public title, subtitle, etc). This is also the case for the description item of a data object, which includes multiple types in ECRIN (eg, summary, abstract, table of contents, etc). Further, ECRIN distinguishes between contributors and creators while the MDS includes only contributors; yet, with contributor types matching with both categories in ECRIN. The MDS classifies contributor types into personal and organizational, while ECRIN includes a single list of contribution types, with matches to both groups in the MDS. The resource's subject seems to be missing a direct match in ECRIN, yet could possibly be extracted from multiple items or topic types. Similarly, the data sharing plan does not seem to have a single corresponding item in ECRIN indicating whether data will or will not be shared, or if it is yet to be decided. However, items in ECRIN, such as the data sharing statement, access type, and access details could possibly include this information.

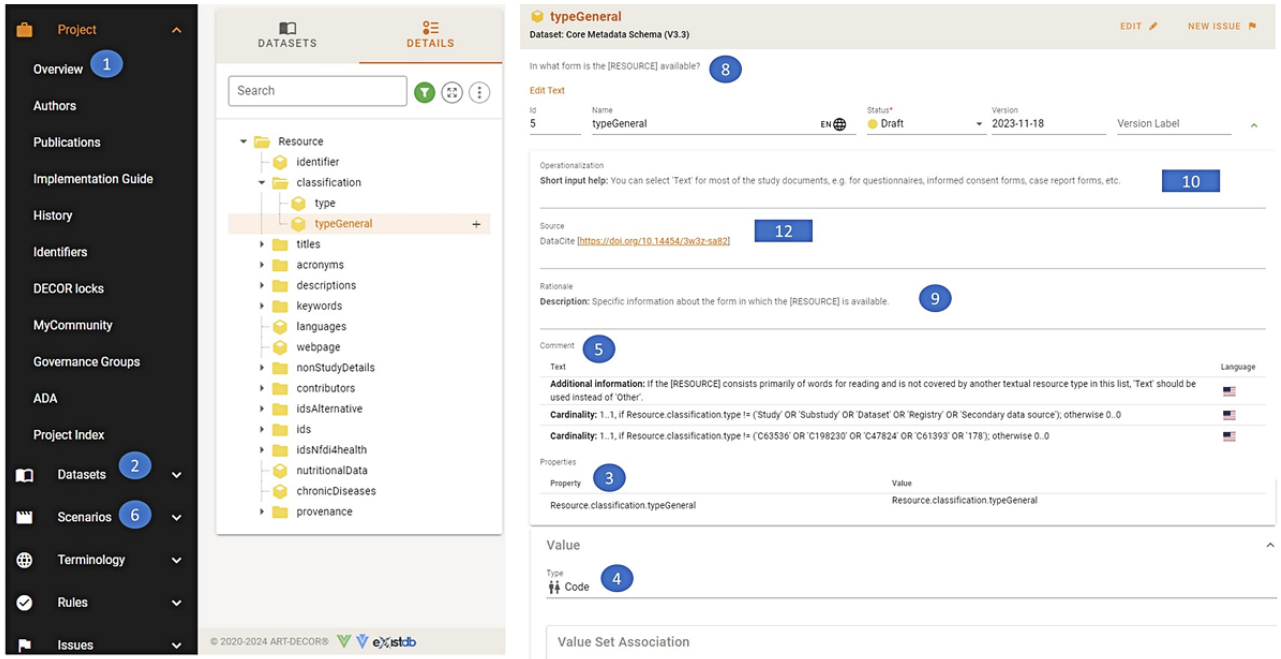
[e]Blank cells indicate that a match could not be found in this iteration.

[f]matched information included in one item in both the MDS and the corresponding matched schema.

[g]matched information included in more than one item in the MDS, the corresponding matched schema, or both.

Although Table 2 presents only the mapping results for the MDS mandatory items, the iterations also included comparisons of optional items and identified a few items in ECRIN that had no corresponding counterparts in the MDS. These include an item defining interstudy relationships, a composite item indicating the type of record keys used within a dataset, an item indicating the amount of deidentification applied to a dataset, and the European Open Science Cloud categorization recommended for data objects. Further mapping iterations have been performed to update the above mappings to ECRIN's most recent version 8. The latest version has been shared with ECRIN colleagues as they were requested to prepare their own mapping version in the reverse direction. Detailed results of these mappings, along with value set comparisons, will be completed and published elsewhere.

Though still in the early stages, single iterations were also conducted by the primary author, mapping the mandatory items of the MDS to GHGA's schema [30] and to the different attributes on the ERDRI.dor portal [33]. At the first glance, some commonalities among study-related items were identified and 9 of the 20 mandatory items of the MDS were preset or matched successfully to items in GHGA, as shown in Table 2. Remaining items could not be matched, as the distinction between interventional and noninterventional study designs in the MDS had no counterpart in GHGA's schema, as well as the specification of the language used for study titles and descriptions. The controlled vocabularies used in GHGA's schema were also not indicated in the version shared with the MDS team, making it challenging to match value set items. This first mapping iteration was shared with GHGA colleagues for review, in preparation of a second iteration. The MDS comparison to the different sections of ERDRI.dor revealed some matches among the registry-specific items as shown in Table 2. These, however, are yet to be shared with Joint Research Center colleagues for further discussion.



Representation and Transformation Into ART-DECOR

The Excel version of the MDS [32] comprises individual spreadsheets for each module. Within each spreadsheet, items are listed in different rows and named according to the camelCase naming convention. Item names, data types, cardinalities, and allowed values are represented in multiple columns. Additional columns contain the information displayed for each item on the GCHSH. These include display names or headers, descriptions, additional descriptive information, input help texts, and input examples. Further spreadsheets include the sources used to build the MDS, value definitions, and documentation of all changes compared with the previous version. The authors of the MDS are also listed in a cover sheet, together with the persons responsible for the version, license details, and version information.

The transformation into ART-DECOR organizes the different modules from the Excel version into separate ART-DECOR datasets, with individual items arranged in a hierarchical tree structure. For each item in a particular dataset, the different Excel columns are represented in corresponding fields, including the item's name, data type, and allowed values or concepts. The value definitions were directly added to the concept description field, thereby providing a structured list of concepts and their definitions. Cardinalities and conditions were initially added as free text in the comment field. However, they were later additionally implemented in different ART-DECOR scenarios toward a more structured version. Besides cardinalities, conformances are also specified in scenarios, indicating mandatory, optional, and conditional items. Figure 5 provides a dataset item view in ART-DECOR, together with a tabular list of Excel spreadsheets and columns and their corresponding representation in ART-DECOR. Terminology mappings are also illustrated under the section "Concepts," listing the MDS item values and their matching terminology concepts. These mappings were taken from the value sets created previously to represent the MDS in FHIR.

XSL•FO
RenderX

Figure 5. Excel to ART-DECOR transformation with a dataset item view. ART-DECOR: Advanced Requirement Tooling-Data Elements, Codes, OIDs, and Rules.

Excel	ART-DECOR
Cover sheet	Project overview page (1)
Module sheets	Datasets (2)
Number columns	Omitted
Item column	Item property field (3)
Data type column	Item value type (4)
Cardinality column	Item comment field (5) + scenarios (6)
Display information columns	Omitted
Allowed values column	Item value concepts (7)
Display name column	Item description field (8)
Description column	Item rationale field (9)
Additional information column	Item comment field (5)
Short input help column	Item operationalization field (10)
Input example column	Item value examples (11)
Source of the property column	Item source field (12)

To navigate the ART-DECOR project, the black menu on the upper left side of Figure 5 provides a list of different pages. The landing or overview page [27] of the project includes a brief description of the MDS, its authors, and copyright and license information. The datasets page enables adding new modules and displays the module hierarchies with all item information. The scenarios page allows for adding and viewing cardinalities and conditions for each dataset, yet in our project, these are also included in comments in the dataset view as shown in Figure 5. The publications page lists published versions of the MDS which have been finalized and can no longer be changed. The project index page allows for exporting the different datasets into various machine-readable formats (eg, XML). Finally, issues to be considered for the next versions of the MDS are raised and discussed on the issues page. Accordingly, the content viewed on these pages changes occasionally as the MDS is updated. Remaining pages on the menu are for technical use and are outside the scope of this paper. Further information on using ART-DECOR can be found in the tool's documentation guide [38].

Rephrasing of Display Texts

With 220 items to be examined, we could only check a few items from the core module by going through the search interface of the GCHSH. This exercise played a great role though in helping users associate the different columns of the Excel spreadsheets with what they usually see on the user interface. Further suggestions were provided via the real-time working version, yet many items were still not covered. This was probably due to the unfamiliarity of the users with the spreadsheets, making it overwhelming and time-consuming to go through the different columns for each item. The MDS team then worked independently on the real-time version and prepared several rewording iterations, covering 302 text changes in line with the UX guidelines [37]. The changes were clearly marked and users were asked to review them, provide their feedback, and agree to final changes in a dedicated meeting. The new texts were implemented in the latest version of the MDS [34].

XSL•FO
RenderX

Implementation

The MDS is implemented in the GCHSH [14,39]. Upon creating an account, users are able to use the platform's input mask or its application programming interfaces to register their resources. Information is requested based on the different sections of the MDS, including general information about the resource, its design characteristics, contributors, administrative information, and related resources. Mandatory and optional items are also indicated. The usage of the service has continuously increased, reaching in October 2024 a total of 626 resources manually registered on the portal, mostly by NFDI4Health users and the coverCHILD project. The majority of these resources were studies (n=243), data dictionaries (n=143), questionnaires (n=78), substudies (n=49), and other data collection instruments (n=35). Remaining resources included datasets (n=19), manuals of operations (SOPs; n=15), other study documents (n=15), registries or secondary data sources (n=9), case report forms (n=5), codebooks (n=5), interview schemes and themes (n=4), data management plans (n=3), other resource types (n=2), and statistical analysis plans (n=1). Based on their experience entering their metadata, users regularly report their issues via GitHub, email communication, or using the platform's feedback button. Further development of the platform is performed interactively based on the received feedback. The platform is freely accessible to external users, thereby enriching its content and facilitating the collection of additional feedback to further improve user experience.

To facilitate sharing metadata by data holding organizations (DHOs), that is, the universities, research institutes, and data integration centers involved in conducting the studies, the MDS is also implemented by LDHs at 12 DHOs throughout Germany. Being the main local connector of the federated concept to the central services of NFDI4Health, the LDH ensures that local data are structured, linked, and easily shared among DHOs, while enabling them to automatically submit their metadata to the GCHSH [15,16]. The LDH also ensures adherence to the FAIR principles, allowing the discoverability of stored information, controlling data access, facilitating data exchange, and making data available for further use. The LDH software is currently rolled out in additional locations throughout Germany and internationally. Further applications of the MDS are promoted by the NFDI4Health FAIRsharing collection [40] of standards for health research data, incorporating standards used in the MDS development and promoting international interoperability.

Discussion

Principal Findings

This paper presented a MDS designed to capture and harmonize information from clinical, epidemiological, and public health studies, enhancing the findability and accessibility of their valuable data. The MDS is based on attributes from ClinicalTrails.gov [2], DRKS [3], Maelstrom [10], MIABIS [24], and DDI [25], in addition to the research needs derived from the NFDI4Health user community. Moreover, properties for assigning DOIs have been adopted from DataCite [23], thereby allowing the MDS to capture metadata about study documents (eg, questionnaires, data dictionaries, and electronic case report forms) and to enable persistent access to published resources. The MDS has the distinct ability to represent the hierarchical relation between different resources, including studies with complex designs and their associated documents. For instance, it can keep track of multiple studies in which a survey instrument is used or indicate that one study is part of another. The MDS also captures metadata essential for users to identify studies within specific health domains, such as studies collecting dietary intake or chronic disease information. It remains generic in its capacity to handle a broad range of resources such as datasets, registries, and data dictionaries, among others [5,41].

Limitations and Challenges

Mapping Efforts and Updates

Due to the generic nature of the targeted schemas, mappings only focused on the core and design modules of the MDS. To illustrate the challenges of importing information into the GCHSH, only mappings of the MDS mandatory items were presented, with the use of fixed values when needed. Mappings were performed manually by comparing the various items of the mapped schemas in an Excel spreadsheet. Despite various efforts by several members of the MDS team, it remains challenging to keep clinical trial registry mappings up to date with newer versions of the MDS. This is mainly due to the absence of structured schemas for these portals, making it difficult for the MDS team members to agree on a common mapping approach or tool to identify matching items. As a result, the mappings presented in this paper are based on older versions of the MDS and need to be revised. Detailed updated mappings, also containing optional items and value sets of the MDS, will be published elsewhere.

As ECRIN's study and data object schemas are based on ClinicalTrails.gov and DataCite respectively, identifying commonalities with the MDS was expected. However, despite their well-structured and detailed schemas, mapping the MDS to their items was still challenging due to their strict distinction between studies and data objects. The abundance of composite attributes and value sets in their schemas also often led us to recognize that some items in ECRIN could be represented by multiple items in the MDS and vice versa. For instance, the study titles item in ECRIN comprises text, type, language, and comment attributes, with the title type having multiple categories. The title item in the MDS only includes text and language and is defined as the scientific unabbreviated title of the study. This could be matched with multiple title type categories in ECRIN, including trial registry title, public title, protocol title, and other scientific title. Similarly, the study features item in ECRIN has categorized feature type and feature value attributes. Each feature type, together with its corresponding feature values, could be matched with a different group of items in the MDS (eg, masking, allocation, study type, primary purpose, etc). Matching items conditionally on certain titles or feature types presented a challenge to both the MDS and development teams. This became even more challenging when matching value sets, due to the presence of user-defined values in the MDS which lacked standardized sources or

XSL•FO
RenderX

definitions. It was, therefore, suggested that a better approach could be to agree on a minimal common data model, thus allowing both platforms to exchange data while saving mapping efforts. The feasibility of this approach, however, is yet to be assessed.

Though still in the early stages, our initial mapping attempt to the GHGA schema also had its challenges. This was mainly due to the strict classification of studies in the MDS by design (ie, interventional vs noninterventional) as well as its support of multiple languages for study titles and descriptions. It was not clear whether such a classification existed in the GHGA schema and if more than one language could be used to provide study descriptions. Further, due to technical issues accessing their public version, we could not identify which controlled vocabularies were used in their schema for codable items, thus limiting value set mappings.

Similarly, mapping to the ERDRI.dor schema is still at an early stage. As ERDRI.dor is a platform for registering European rare disease registries, it is not surprising that some commonalities with our MDS registry-specific items could be detected. Yet, due to the lack of a structured schema, these commonalities could only be observed by examining the different sections of the ERDRI.dor platform. For accurate mappings, further discussions, particularly with ERDRI's metadata team, remain needed.

Excel Versus ART-DECOR Representation

With over 200 items incorporated in the latest MDS releases, it became cumbersome for the MDS team to maintain and frequently update the Excel version and document all changes in a trackable manner. It also became difficult for the users to follow the frequent updates and provide their feedback. Following several discussions about alternative representation formats, the ART-DECOR open-source tool was selected. Due to its user-friendly interface, the tool enables efficient use by experts with or without a technical background, thus allowing NFDI4Health users, developers, and members of the MDS team to work collaboratively on the MDS developments. The tool's major advantage over Excel is that it represents the modeled data elements in a hierarchical structure, thereby illustrating the relations between the various items in an accessible manner. Unlike Excel, the tool also offers diagram views of all modules as well as exports to various machine-readable formats such as XML, JavaScript Object Notation, and FHIR R4. This in turn facilitates the transformations needed for the GCHSH development and representing the model in Simplifier and keeping the FHIR profiling up to date.

Despite these numerous advantages and the continued support from the ART-DECOR team, the transformation from Excel to ART-DECOR faced several obstacles. Though scenarios allowed us to set cardinalities, conformances, and textual and structured conditions, setting cross-module structured cardinality conditions (ie, conditions involving items from different modules) was not permitted. This left us only with the option of using textual conditions in scenarios for better machine readability while keeping the comment field in the datasets for better clarity and human readability.

Another issue we experienced during the transformation was the representation of the mappings to other schemas. Currently, the tool does not offer a structured way for this purpose. This once again left us only with the possibility of adding mappings as free text in the comment field. As this would still require multiple efforts when newer versions of the mapped schemas are released, we skipped representing the mappings in this version and decided to start a discussion with the ART-DECOR team about introducing a new mapping feature to the tool. Many user-defined values in the MDS could not be mapped to terminology concepts and we could not trace them back to determine why they were included and whether there was a need to keep them. This is because the specific sources for each value were not documented in earlier versions of the MDS during development. Placing them in a local code system was agreed upon as a temporary solution until finding proper matches, requesting their introduction to appropriate terminologies, or deciding to remove them from the MDS altogether.

Conclusions and Future Work

This paper presented the development, structure, and representations of the NFDI4Health MDS. The MDS aims to improve the representation of data from clinical, epidemiological, and public health studies, thereby enhancing their FAIRness. With its generic nature and modular structure, it is also transferable to adjacent research fields. The MDS was developed in close collaboration with the NDFI4Health use case experts, thereby ensuring that the needs of the greater user community are met. In addition to its core and design modules, the MDS currently provides 3 use case–specific modules. These cover the domains of nutritional epidemiology, chronic diseases, and record linkage. Two additional modules for clinical trials and imaging radiomics data will soon be implemented. The latest version of the MDS (v3.3) was released in Excel format and transformed into ART-DECOR. Yet, toward better machine readability, future versions will only be released in ART-DECOR.

The MDS is implemented in the GCHSH and several NFDI4Health LDHs. This allows users to register their metadata either centrally in the GCHSH or locally in a LDH instance of their own institution for automatic integration into the GCHSH. For better interoperability with other study portals, the MDS has been mapped to the schemas of clinical trial registries, thereby allowing the automatic upload of their metadata to the GCHSH. To ensure alignment with international and local initiatives, mappings to the ECRIN schemas, ERDRI, and the GHGA schema are ongoing. Mapping of the MDS to the health-related extension of the DCAT-AP metadata standard (HealthDCAT-AP) is also planned, thereby preparing the NFDI4Health services for interoperability with the emerging European Health Data Space.

Having focused on the core and design modules so far, mappings need to extend to the use case–specific modules and strategies need to be defined for handling user-defined items and values in the MDS, as well as items with no counterparts in either of the mapped schemas. To facilitate these activities, mapping goals and standardized mapping approaches need to be agreed

XSL•FO
RenderX

upon in NFDI4Health, thus defining common procedures for matching items, limiting mapping efforts, and optimizing the results of mapping activities performed by different members of the MDS team. In addition, identifying tools that support manual mapping activities could help extend and automize mappings to other data models. To facilitate alignment with international initiatives, the MDS also needs to increase its focus on terminology-based value sets and adopt to a larger extent existing terminologies and FHIR resources, when applicable. For these reasons, the MDS remains in development and is constantly expanded based on the needs of the user community.

Acknowledgments

HA, AS, SAIK, CNV, MG, COS, DW, AAZ, JD, ML, and VC developed and modeled the MDS and MG coordinated its development. FJ, MBS, IP, and UN designed the nutritional epidemiology module. CS, KN, TO, and TP designed the chronic diseases module. TI and MP designed the record linkage module. HA, AS, SAIK, and AAZ performed the mappings. HA and CNV completed the ART-DECOR transformation. All authors provided feedback and helped in the development and testing of the MDS. HA drafted the manuscript and all authors critically reviewed and approved it.

We greatly appreciate the funding from the Deutsche Forschungsgemeinschaft through project numbers 442326535 (NFDI4Health) and 451265285 (NFDI4Health task force COVID-19), as well as from the Klaus Tschira Foundation.

We acknowledge the feedback on the metadata schema from all partners in the NFDI4Health consortium as well as the German Centers for Health Research and the coverCHILD project. We also acknowledge collaborations with the ECRIN, GHGA, ERDRI, and ART-DECOR teams.

Abstract

Background: The adoption of common data models (CDMs) has transformed pharmacoepidemiologic research by enabling standardized data formatting and shared analytical tools across institutions. These models facilitate large-scale, multicenter studies and support timely real-world evidence generation. However, no comprehensive global evaluation of CDM applications in pharmacoepidemiology has been conducted.

Objective: This study aimed to conduct a systematic review and bibliometric analysis to map the landscape of CDM usage in pharmacoepidemiology, including publication trends, institutional authors and collaborations, and citation impacts.

Methods: In total, 5 English databases (PubMed, Web of Science, Embase, Scopus, and Virtual Health Library) and 4 Chinese databases (CNKI, Wan-Fang Data, VIP, and SinoMed) were searched for studies applying CDMs in pharmacoepidemiology from database inception to January 2024. Two reviewers independently screened studies and extracted information about basic publication details, methodological details, and exposure and outcome information. The studies were categorized into 2 groups according to their Total Citations per Year (TCpY), and a comparative analysis was conducted to examine the differences in characteristics between the 2 groups.

Results: A total of 308 studies published between 1997 and 2024 were included, involving 1580 authors across 32 countries and 140 journals. The United States led in both publication volume and citation counts, followed by South Korea. Among the 10 most cited studies, 7 used the Vaccine Safety Datalink, 2 used Sentinel, and one used Observational Medical Outcomes Partnership. Studies were stratified by TCpY to reduce citation bias from publication timing. Comparative analysis showed that high-TCpY studies were significantly more associated with multicenter collaboration (P=.008), United States-based institutions (P=.04), and vaccine-related research (P=.009). These studies commonly featured larger sample sizes, cross-regional data, and enhanced generalizability. International collaborations primarily occurred among North America, Europe, and East Asia, with limited involvement from limited-income countries.

Conclusions: This study presents the first bibliometric overview of CDM-based pharmacoepidemiologic research. The consistent output from United States institutions and increasing engagement from South Korea underscore their central roles in this field. High-TCpY studies tend to be multicenter, collaborative, and vaccine-focused, reflecting structural factors linked to research visibility and influence. Stratified citation analysis supports the value of real-world data integration and international cooperation in producing impactful studies. The dominance of limited-income countries in collaboration networks highlights a need for broader inclusion of underrepresented regions. These findings can help researchers identify key contributors, guide partner selection, and target appropriate journals. As CDM-based methods continue to expand, fostering diverse and collaborative research efforts will be crucial for advancing pharmacoepidemiologic knowledge globally.

common data model; pharmacoepidemiology; bibliometric analysis; systematic review

Introduction

Pharmacoepidemiology applies epidemiological principles and methods to study the effects of drugs, vaccines, and devices, focusing on adverse event monitoring, health economic evaluation, and quality of life assessment [1]. Ongoing pharmacoepidemiologic research aims to ensure drug safety, standardize postmarket surveillance methods, and provide scientific evidence for intervention decisions [1]. To achieve these objectives, especially in postmarketing contexts, robust real-world evidence is essential. However, many current studies are limited by small sample sizes and insufficient population representativeness, making it difficult to detect rare or long-term adverse events [2]. To address these limitations, conducting multicenter pharmacoepidemiologic evaluations has proven to be more reflective of actual clinical settings, enhancing statistical power, improving detection efficiency, and enabling early identification of vaccine safety concerns [3,4]. However, multicenter studies also face challenges related to data heterogeneity, personally identifiable information leakage, lack of standardized protocols for data integration, and terminological harmonization difficulties [5,6].

Common data model (CDM) is a standardized data model designed to facilitate the exchange, integration, sharing, or storage of data from multiple sources [7]. Its development has provided a practical and scalable solution for enabling multicenter studies by harmonizing heterogeneous data sources across institutions and regions. Currently, various CDMs are widely used, including the Observational Medical Outcomes Partnership (OMOP) developed by the Observational Health Data Sciences and Informatics [8], PCORnet [9], and Fast Healthcare Interoperability Resources [10]. Other CDMs, such as the Vaccine Safety Datalink (VSD) [11] and Sentinel [12], are specifically designed for active vaccine safety monitoring. Each CDM emphasizes distinct aspects, with differing methodologies and application areas tailored to specific research needs [13].

Currently, CDMs are widely applied to generate new evidence in clinical practice and drug selection. Some studies leverage real-world data to produce scalable evidence, aiding in the understanding of population diversity as well as the similarities and differences in clinical characteristics and treatment pathways across regions [14,15]. In addition, certain studies based on the OMOP have introduced a large-scale, comprehensive approach to evaluate the effectiveness and safety of various drugs across the world, offering strong evidence to support clinical drug selection [16,17]. Despite the growing application of CDMs in pharmacoepidemiology, no study has systematically reviewed the global landscape of CDM use in this field across all major models and contexts. Previous reviews have often focused on a single CDM or specific application scenarios [6].

In recent years, bibliometrics has advanced rapidly and is widely used to explore the characteristics of academic publications in specific research fields, including influential countries, journals, institutions, and authors, as well as trends in frequently cited references and keywords [18,19]. Since Garfield's seminal work in 1955 on identifying the most cited scientific papers in the Institute for Scientific Information Web of Knowledge (now known as Web of Science) database [20,21], numerous scholars have conducted bibliometric analysis comparing highly cited and less cited papers [22-24]. Building on previous studies that highlighted key features of highly cited papers, this study uses bibliometric analysis to systematically characterize publication patterns, collaboration networks, and thematic trends in CDM-based pharmacoepidemiologic research.

This study aimed to fill that gap by systematically reviewing and visually analyzing global literature on CDM-based pharmacoepidemiology. By grouping studies by citation impact, we sought to identify the characteristics of highly cited studies and offer references for future research design, collaboration strategy, and infrastructure development. Our findings aim to inform researchers and policy makers on emerging trends, methodological priorities, and opportunities to enhance the global reach and inclusiveness of CDM-enabled pharmacoepidemiologic studies. The statement of significance is provided inTable 1.

XSL•FO
RenderX

Table . Statement of significance.

Content	Statement
Problem or issue	There is a critical challenge in integrating heterogeneous, multicenter, real-world data for pharmacoepidemiologic research, which hampers the detection of rare and long-term adverse events and limits the standardization of postmarket surveillance.
What is already known	Previous studies have demonstrated that CDMs[a] facilitate data standardization and enhance multicenter collaborations in pharmacoepidemiology. However, the global adoption, comparative impact, and evolution of these models remain insufficiently explored.
What this paper adds	This paper provides a comprehensive bibliometric analysis of the application of CDMs in pharmacoepidemiology, revealing publication trends, key contributors, and emerging research themes across different countries. It also identifies significant differences between high and low citation groups, underscoring the pivotal role of multi-center research and CDM-based methodologies.
Who would benefit from the new knowledge in this paper?	Researchers, policymakers, and healthcare practitioners involved in pharmacoepidemiologic studies and health informatics will benefit, as the findings offer insights into effective collaboration, selection of appropriate research models, and strategic dissemination for enhancing drug and vaccine safety monitoring.

[a]CDM: common data models.

Methods

Overview

This study was conducted according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta Analyses) guidelines (the PRISMA checklist is provided in Checklist 1) to identify studies that applied CDM in pharmacoepidemiologic research [25].

Search Strategy

Five English databases: PubMed, Web of Science, Embase, Scopus, and Virtual Health Library, and 4 Chinese databases: China National Knowledge Infrastructure, Wan-Fang Data, VIP Database, and SinoMed were searched from the inception to January 22, 2024. In preliminary searches, the names of currently used CDMs worldwide were identified and used as search terms in both their full and abbreviated forms, in both English and Chinese, including terms like “common data model,” “Observational Health Data Sciences and Informatics,” “Observational Medical Outcomes Partnership,” and “Clinical Data Interchange Standards Consortium,” among others. Logical operators such as “OR” truncation symbols, and subject term matching were applied based on the search rules and syntax of each platform to form search strategies. All search terms were listed in Multimedia Appendix 1.

Eligibility Criteria

The inclusion criteria were as follows: (1) studies using CDMs (any CDM identified in the preliminary search, with inclusion based on the use of any single model) to address issues in the drug, vaccine, or medical device fields; (2) the study scope included safety, efficacy, usage, and economic evaluations for drugs, vaccines, and medical devices; and (3) drugs, vaccines, or devices must be the primary exposure, research focus, or outcomes of the study.

The exclusion criteria were as follows: (1) studies that did not apply CDMs, or where the CDM was incomplete; (2) studies that did not include drugs, vaccines, or devices as primary exposure or influence factors, or as main research content or outcomes; (3) editorial materials, including letters, editorials, comments, responses, editorial opinions, advertisements, and unpublished studies; (4) duplicate publications; and (5) studies in languages other than Chinese or English.

Data Extraction

Two reviewers independently screened studies and extracted information about basic publication details, methodological details, and exposure and outcome information. Basic information from the literature was extracted using Excel, including study title, authors, publication year, country, sample size, number of centers, type of CDMs, use of subgroup analysis, whether sensitivity or subgroup analysis was conducted, study exposure, study outcomes, and whether adherence to reporting guidelines. English studies were exported in BibTeX format and merged into a single XLSX file. Some English studies that could not be imported directly into the Bibliometrix package and all of the Chinese studies were exported in XLSX format. These files were modified into compatible tables based on the Bibliometrix data frame structure for analysis.

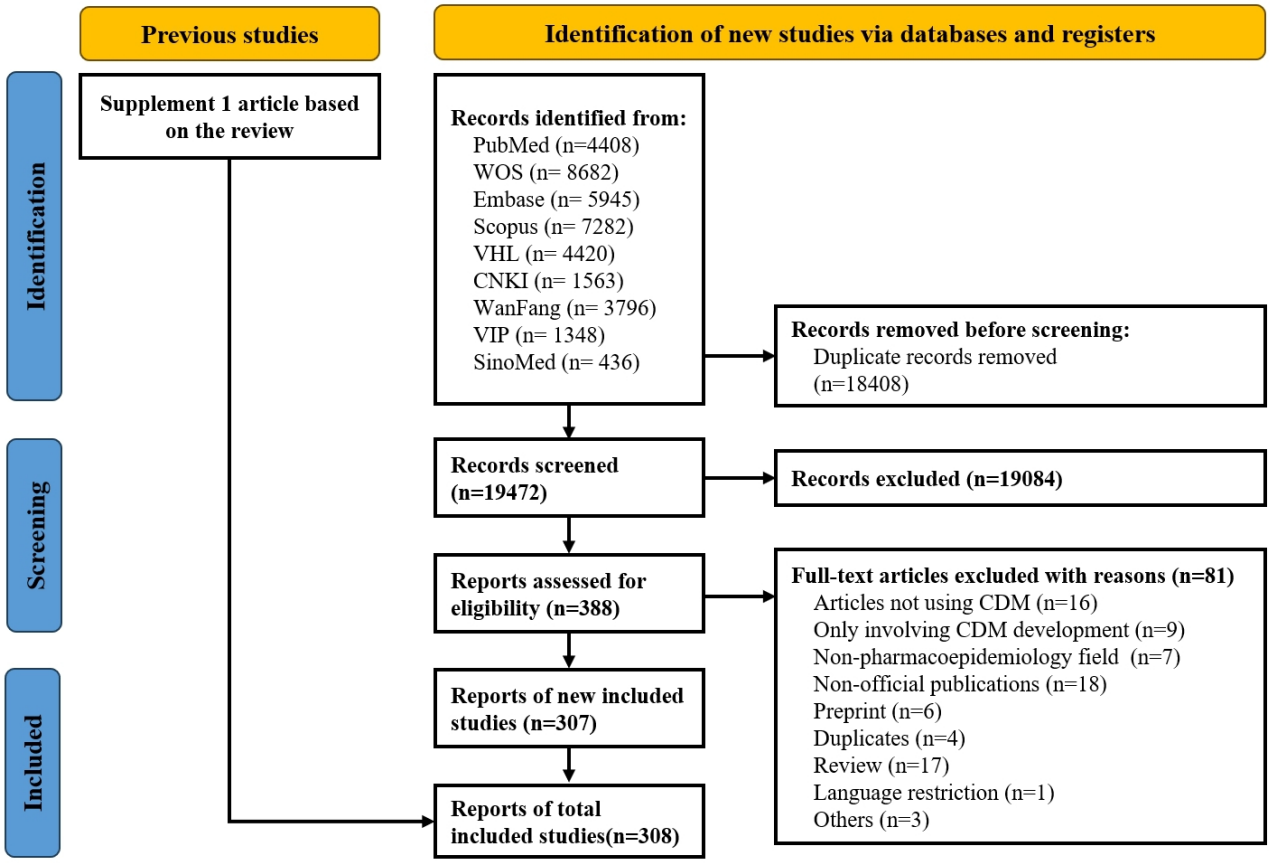
Statistical Analysis

Statistical analysis was conducted using R (version 4.4.0; R Core Team). The bibliometrix package was used to generate standard bibliometric indicators, including annual publication trends, total and average citation counts, and H-index values, as well as to construct coauthorship and keyword co-occurrence networks. To ensure consistency and data quality, all bibliographic records were cleaned and standardized before analysis. This process included deduplication, harmonization of author names and affiliations, normalization of journal titles, and manual review of keywords [26]. Total citation, Total

XSL•FO
RenderX

Citations per Year (TCpY), and the H-index were used as standard metrics for academic influence of studies and authors. The total citation of all studies published in a specific journal was used to represent the journal's overall citation count [27]. TCpY was defined as the average number of citations a study has received per year since its publication, calculated as follows:

$$TCpY = \frac{\text{Total Citations}}{\text{Years since Publication}}$$



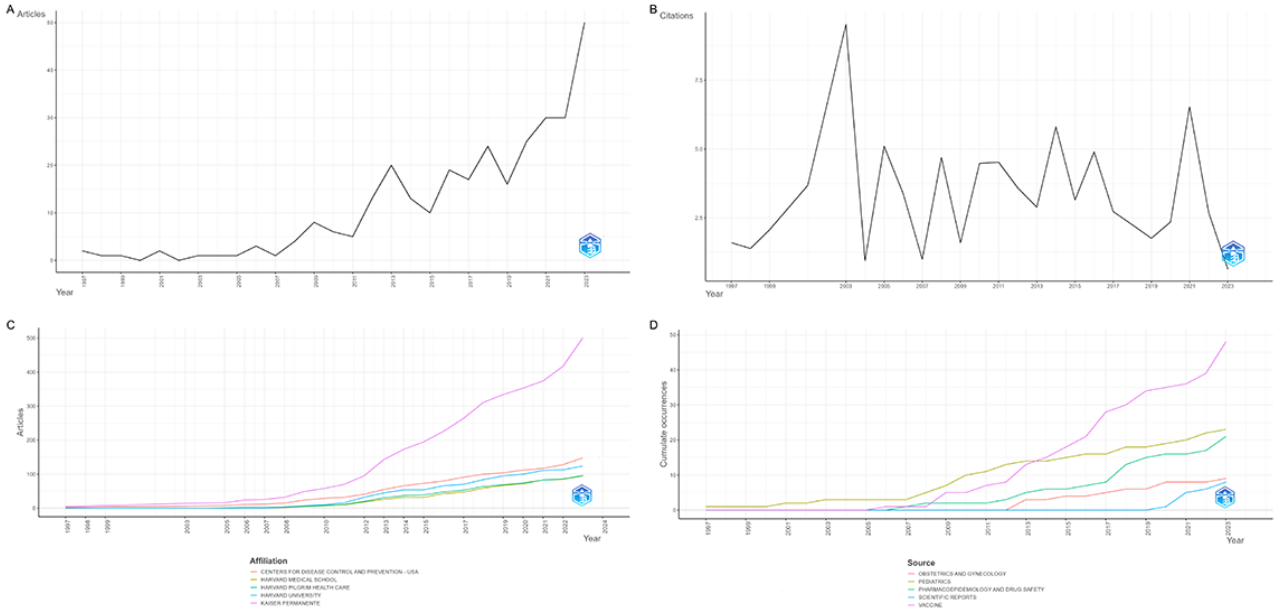
The H-Index is defined as *h* if an author has *h* publications, each of which has been cited at least *h* times [28]. Citation analysis was conducted on 285 studies which could get citations from the Web of Science Core Collection (WoSCC). Analysis of these 285 studies was conducted using R version 4.4.0. The *t* test was used to compare means under the assumption of normal distribution, while the Wilcoxon test served data that did not meet normality assumptions. Chi-square or Fisher exact tests were used for categorical variables. A 2-tailed *P* value of <.05 was considered to indicate statistical significance. To visualize interdisciplinary citation relationships, we conducted a dual-map overlay analysis using CiteSpace (version 6.4.1; Chaomei Chen, Drexel University). This method enables the mapping of citation trajectories between disciplines, highlighting the knowledge flow from citing to cited journals. The map was constructed using WoSCC data, with parameters set to the default configuration for dual-map overlays.

Results

Study Selection

A total of 37,880 studies were identified, of which 308 met the inclusion criteria, comprising 307 in English and 1 in Chinese (Figure 1). The publications originated from 32 countries, involving 1580 authors and published across 140 journals. In total, 590 keywords were identified, covering 12 types of CDMs: OMOP (76 studies), VSD (163 studies), PCORnet (14 studies), PEDSnet (4 studies), Sentinel (19 studies), Mini-Sentinel (14 studies), ConcePTION (3 studies), K-CDM (3 studies), Asian Pharmacoepidemiology Network (1 study), Cancer Research Network's Virtual Data Warehouse (1 study), Intensive Care Unit Medications (1 study), Health Maintenance Organization Research Network (1 study), along with 1 study that modified an existing CDM and 11 studies that created new CDMs. The research topics were categorized as follows: vaccines (173/308, 56.17%), drugs (132/308, 42.85%), and medical devices (3/308, 0.97%).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of the included studies.



Temporal Distribution of Publications

The volume of publications in this field has shown a continuous upward trend. The earliest identified study dates back to 1997. From 1997 to 2007, the volume of studies remained low with minimal growth, maintaining fewer than 5 studies per year. Between 2008 and 2016, the number of studies began to increase, albeit with some fluctuation. Following 2019, study volume exhibited steady growth, reaching a peak of 49 studies in 2023 (Figure 2A).

General trends of included studies in CDM-based pharmacoepidemiologic research through 2024. **(A)** Temporal distribution of publications in pharmacoepidemiologic research based on CDM through 2024. **(B)** Average annual citation frequency in CDM-based pharmacoepidemiologic research through 2024. **(C)** Temporal distribution of publications for the top 5 most productive institutions in CDM-based pharmacoepidemiologic research through 2024. **(D)** Annual publication trends across top 5 journals in CDM-based pharmacoepidemiologic research through 2024. CDM: Common Data Model.

Citation Information of the Studies

Among the 308 studies, the total citation count was 8666, with an average citation frequency of 28 per study and a median of 13.00 (IQR 3.00 - 30.00) citations. The citation distribution by publication year was shown in Figure 2B, with peaks in 2003 and 2021.

The top 10 most cited studies originated entirely from the United States, comprising 7 studies on VSD, 2 on Mini-Sentinel, and one using OMOP. Regarding the focus of exposure, 8 studies investigated vaccines, while 2 examined drugs. Safety outcomes were predominant, accounting for 90% (9/10) of the research endpoints. Multimedia Appendix 2 provides detailed information on the top 10 most cited studies.

The citation analysis was conducted on 285 studies according to citations from the WoSCC. We compared key characteristics between the 285 WoSCC-indexed studies and the 23 non-WoSCC studies. As shown in Multimedia Appendix 3, there were no statistically significant differences between the 2 groups. The included studies were divided into 2 groups based on total citation counts, and their basic characteristics were compared (Table 2). The median citation count for the low citation group was 4.00 (IQR 1.00 - 8.00), while for the high-citation group it was 35.00 (IQR 20.00 - 64.00). Compared to the low-citation group, studies in the high-citation group generally had larger sample sizes (P=.049), involved more research centers (P<.001), and predominantly originated from the United States (P<.001). Regarding exposure, studies in the high-citation group were more likely to focus on vaccines than those in the low-citation group (72.34%, 102/141 vs 40.97%, 59/144; P<.001). A comparison between studies with vaccine as the exposure and those with drug indicated that high-citation studies were more frequently focused on vaccines (P<.001). Studies with high citation counts also tended to use the VSD. Differences were observed in research direction, with a higher proportion of safety studies in the high-citation group compared to the low-citation group (75.18%, 106/141 vs 64.58%, 93/144).

[a]CDM: Common Data Model.

[b]OMOP: Observational Medical Outcomes Partnership.

[c]VSD: Vaccine Safety Datalink.

We further divided the included studies into 2 groups based on TCpY to compare their characteristics (Table 3). The median annual citation for the low TCpY group was 1.00 (IQR 0.50 - 1.50), while for the high TCpY group it was 4.00 (IQR 2.75 - 6.28). Compared to the low TCpY group, studies in the high TCpY group generally involved a greater number of research centers (*P*=.008) and were predominantly conducted in the United States (*P*=.045). Regarding exposure, studies in the high TCpY group were more likely to focus on vaccines than those in the low TCpY group (63.70%, 93/146 vs 48.92%, 68/139; *P*=.003). A comparison between studies with vaccine as the exposure and those with drug indicated that high TCpY studies were more frequently focused on vaccines (*P*=.009). The proportion of the high TCpY group using reporting guidelines was higher, although the difference was not statistically significant (6.16%, 9/146 vs 5.04%, 7/139; *P*=.88).

[a]CDM: Common Data Model.

[b]OMOP: Observational Medical Outcomes Partnership.

[c]VSD: Vaccine Safety Datalink.

Analysis of Authors and Institutions

Among the top 10 productive authors, Dr Nicola P Klein, director of the Vaccine Study Center at Kaiser Permanente Northern California, held the highest rank with 69 publications. Her work has an H-index of 29, and all publications were based on VSD. The second-ranked author, Dr Matthew F Daley, a senior clinical researcher at Kaiser Permanente Colorado, has 53 publications. The third position is held by Dr Allison L Naleway from Kaiser Permanente Northwest Center for Health Research, with a total of 48 publications. All of the top 10 authors are from the United States, with five affiliated with different Kaiser Permanente institutions. The publications by these 5 authors are all based on VSD (Multimedia Appendix 4).

The top 10 most productive institutions are listed in Multimedia Appendix 5, and the temporal trends of the top 5 are visualized in Figure 2C. Among these, eight institutions are based in the United States, and two are located in South Korea. Kaiser Permanente is the institution with the highest publication volume and the most rapid growth, with all publications based on VSD. South Korea's Hallym University and Seoul National University began publishing around 2020, primarily utilizing OMOP and K-CDM in their studies.

Analysis of Journals

The top 10 productive journals were listed in Table 4. Vaccine ranks first, with 49 publications, accounting for 16.0% (49/308) of the total publications in this field. Among these, studies were based on the following CDM: VSD (46/49, 93.90%), ConcePTION (2/49, 4.10%), and Sentinel (1/49, 2.00%). Pediatrics ranks second, with 24 publications, representing 7.79% (24/308) of the total. The CDMs used in these studies include VSD (21/24, 87.50%), PEDSnet (1/24, 4.17%), PEDSnet + OMOP (1/24, 4.17%), and PCORnet (1/24, 4.17%). *Pharmacoepidemiology and Drug Safety* published 22 studies, accounting for 7.20% (22/308) of the total publications. The CDM used in these studies included VSD (9/22, 40.91%), Sentinel (5/22, 22.73%), Mini-Sentinel (2/22, 9.09%), OMOP (2/22, 9.09%), Asian Pharmacoepidemiology Network (1/22, 4.55%), and newly created CDMs (3/22, 13.64%).

XSL•FO
RenderX

Table . Top 10 journals with most studies in pharmacoepidemiologic research based on CDMs[a] through 2024.

Rank	Journal title	Country	Counts, n	IF[b] (2023)	JCR[c] (2023)	H-index	Total citations, n
1	*Vaccine*	United Kingdom	49	4.5	Q3	19	1207
2	*Pediatrics*	United States	24	6.2	Q2	18	1167
3	*Pharmacoepidemiology and Drug Safety*	United Kingdom	22	2.4	Q3	10	310
4	*Obstetrics and Gynecology*	United States	9	5.7	Q2	8	322
5	*Scientific Reports*	United Kingdom	8	3.8	Q3	4	38
6	*JAMA-Journal of the American Medical Association*	United States	7	63.1	Q1	7	925
7	*Jama Network Open*	United States	6	10.5	Q1	5	147
8	*American Journal of Epidemiology*	United States	6	5.0	Q2	4	187
9	*Drug Safety*	New Zealand	5	4.0	Q2	3	62
10	*Academic Pediatrics*	United States	4	3.0	Q3	4	34

[a]CDM: Common Data Model.

[b]IF: impact factor.

[c]JCR: journal citation reports.

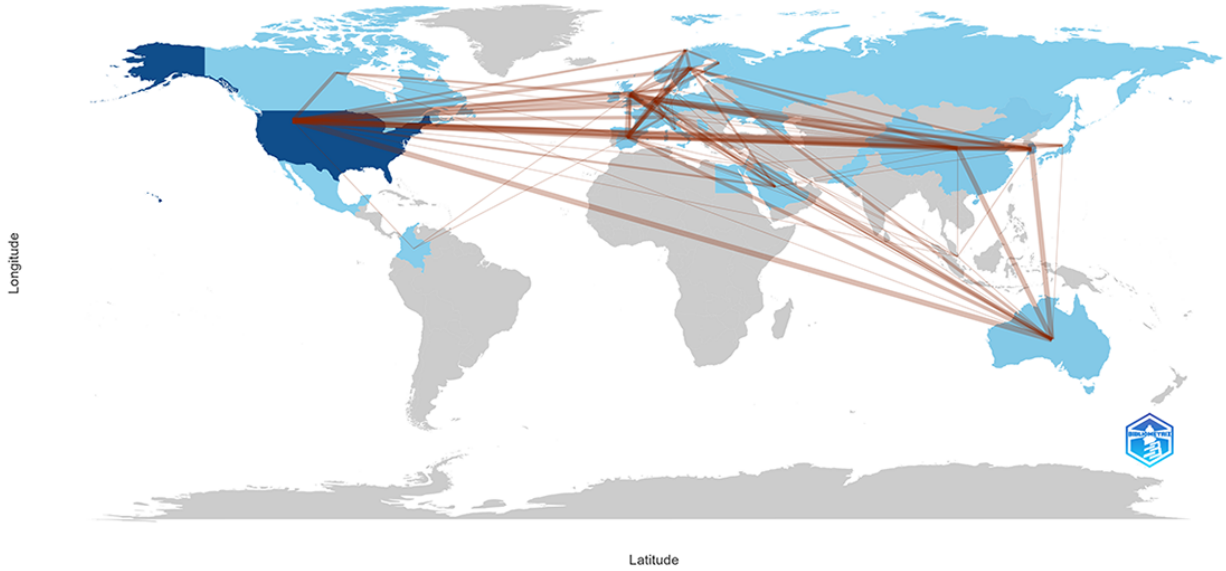
As illustrated in Figure 2D, the number of pharmacoepidemiologic research studies based on CDMs in *Vaccine* shows notable variability, with marked increases in 2016 and 2022. In contrast, publication volume in *Pediatrics* and *JAMA Network Open* has remained relatively stable within this field.

Analysis of Countries and Regions

The top 10 data source countries were listed in Table 5. An analysis of the 308 pharmacoepidemiology publications based on CDMs reveals that the leading countries in research output are the United States with 286 (92.86%) studies, South Korea with 53 (17.21%) studies, the United Kingdom with 11 (3.57%) studies.

Table . Top 10 data source countries in pharmacoepidemiologic research based on CDMs[a] through 2024.

Rank	Country	Counts, n	Average citation counts per study	Average TCpY[b] counts per study
1	United States	286	34.53	4.13
2	South Korea	53	9.26	2.15
3	United Kingdom	11	16.36	3.85
4	France	9	19.56	4.52
5	China	9	15.67	2.73
6	Spain	8	25.75	6.78
7	Germany	7	23.43	6.31
8	Japan	7	23.14	4.52
9	Netherlands	7	15.86	4.20
10	Denmark	6	10.83	1.86



[a]CDM: Common Data Model.

[b]TCpY: Total Citations per Year. Data from multiple countries were counted separately for each contributing country.

XSL•FO
RenderX

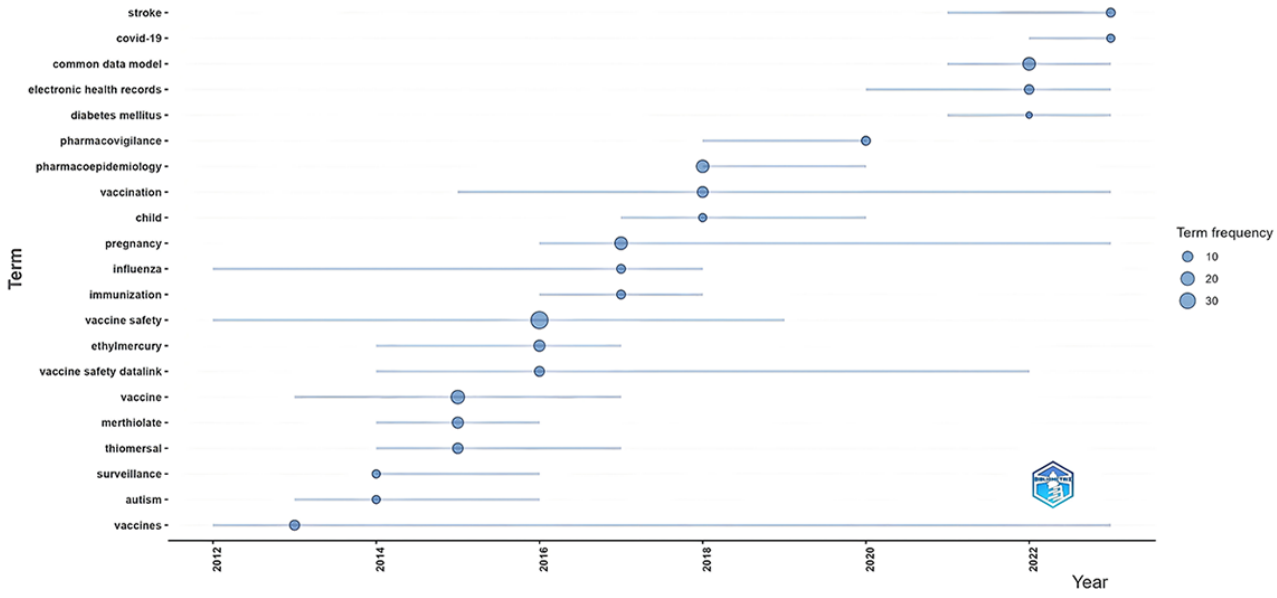
As illustrated in Figure 3, international collaboration is strong among the United States, Europe, Australia, and East Asia. The United States acts as a central hub for multinational collaborations, with substantial partnerships involving China, the United Kingdom, Spain, South Korea, and Australia. South Korea is also actively engaged in various international projects, maintaining particularly close connections with the United States and the United Kingdom.

Figure 3. Global collaboration patterns among countries conducting CDM-based pharmacoepidemiologic research. CDM: Common Data Model; The thickness of the lines represents the strength of collaboration.

Analysis of Keywords

The included publications encompass a total of 590 keywords. Figure 4 illustrates the temporal trends of popular research topics in CDMs based on pharmacoepidemiology. Since 2012, topics such as vaccine safety, immunization, and influenza have remained consistently active. Starting in 2020, research on COVID-19, stroke, and diabetes has increased significantly, with extensive use of electronic health record (EHR) data.

Figure 4. Trends in research topics over time in pharmacoepidemiologic research based on CDM through 2024. Dot: Represents the appearance of a specific topic or keyword. Dot size: Indicates the influence or research volume of the topic. Horizontal line: the duration or active period of the topic. CDM: Common Data Model.



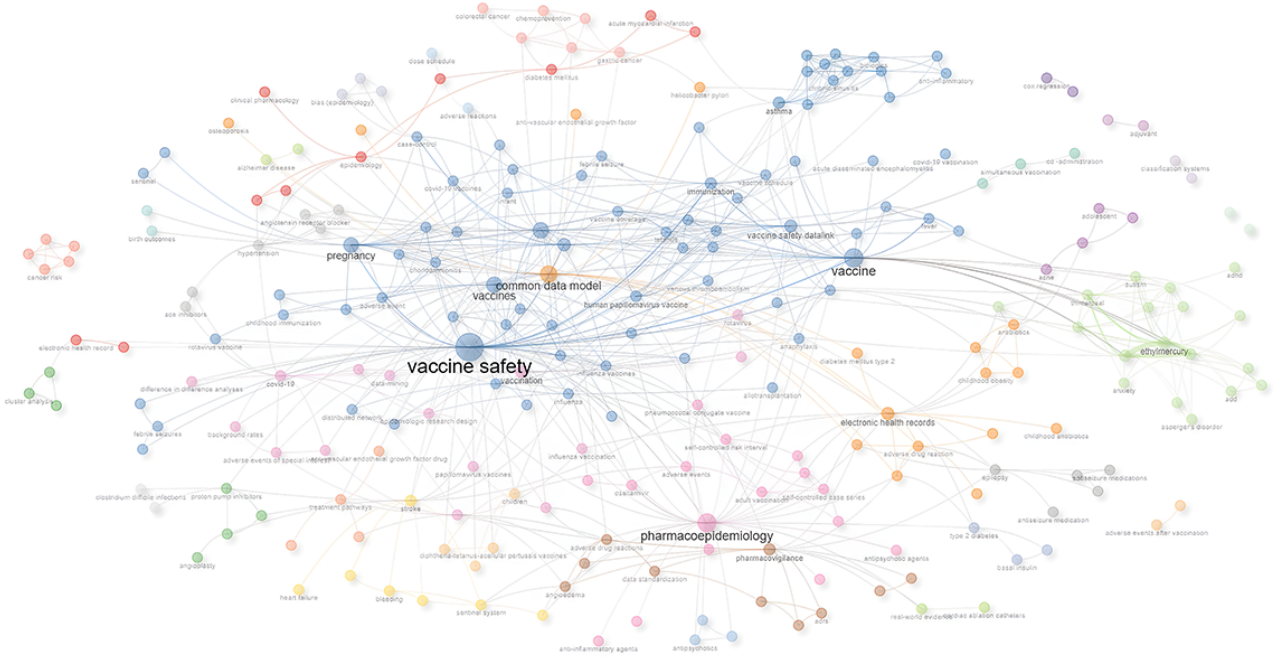


Figure 5 illustrates the trends in research topics. The nodes of the same color within a cluster represent closely related co-occurrences, with node size and link width varying based on the degree and strength of co-occurrence. “Vaccine safety” and “pharmacoepidemiology” occupy central positions in the network, showing strong connections with numerous surrounding topics. “Common data model” serves as another key topic, closely linked to “electronic health records” and “observational research.” The nodes in different colors indicate topic clusters, with the blue cluster primarily focusing on vaccine-related research, the orange cluster on drug monitoring

XSL•FO
RenderX

and adverse reactions, and the brown cluster on drug regulation and risk assessment.

Figure 5. Network map of keywords in pharmacoepidemiologic research based on CDM. CDM: Common Data Model.

The dual-map overlay analysis illustrated the interdisciplinary citation structure of CDM-based pharmacoepidemiologic research. Most publications were clustered in the "Medicine, Medical, Clinical" domains and predominantly cited journals from the fields of "Health, Nursing, Medicine" and "Molecular Biology, Genetics," suggesting strong disciplinary integration (Multimedia Appendix 6).

Discussion

Principal Findings

This study used bibliometric methods to analyze research trends in the application of CDMs in the field of pharmacoepidemiology, while also exploring research hot spots among highly cited studies in this field. The findings revealed that highly cited studies were predominantly originated from the United States, reflecting the central role of the United States researchers and institutions in this field, while South Korea's influence has been rising rapidly in recent years. Included studies were often multicenter, interorganizational collaborations, leveraging extensive sample sizes and cross-regional data coverage to enhance the generalizability and scientific value of research outcomes, thereby increasing citation frequency [29]. Vaccine-related studies were a primary focus, highlighting the significance of the CDM in public health, particularly in supporting real-time assessment of drugs and vaccines and adverse event monitoring during global health crises by integrating data across regions and organizations [30]. Our findings provide essential guidance for researchers embarking on studies in this field, assisting in the identification of potential collaborators, influential studies, and exemplary work for reference, as well as in the selection of suitable journals for publication. It enhances the efficiency of establishing research networks and supports the effective dissemination and academic impact of new studies.

Characteristics of Highly Cited Studies

The most cited publications globally have provided critical insights into adverse events associated with various vaccines, drug safety, and drug usage [14,30-33]. One particularly influential study, titled "Surveillance for Adverse Events After COVID-19 mRNA Vaccination," monitored severe adverse events related to COVID-19 vaccines and has emerged as the most cited and impactful publication in this field [30]. This highlights the rapid response and proactive surveillance capabilities of CDM during public health emergencies, enabling timely evaluation of new vaccines.

We conducted a comparative analysis between globally highly cited studies and less cited ones. To mitigate the advantage of earlier publications due to absolute citation counts, we also grouped studies based on TCpY. The findings indicate that studies in the high-citation group tend to involve more institutions. Cross-institutional collaboration and data sharing provide significant practical guidance for research and policy-making. Multicenter studies, with larger participant numbers from diverse regions, enhance statistical power and ensure that findings are more generalizable for broader populations. Such studies allow researchers to capture a wider range of variables and cases, thus providing a robust data foundation for investigating rare diseases, uncommon adverse events, or smaller subpopulations [29,34,35].

Vaccine studies are more frequently highly cited compared to drug research, due to factors related to their public health impact and resource allocation. First, the high citation rates of vaccine research are closely tied to its critical role in public health. Global public health crises, such as the COVID-19 pandemic, have further elevated the priority of vaccine research, increasing

XSL•FO
RenderX

its visibility and citation rates, as such studies are essential for policy-making and health interventions [36,37]. In addition, vaccine development often involves substantial public funding and data-sharing efforts, enabling wider access and greater citation of vaccine-related findings. In contrast, drug research is typically driven by pharmaceutical companies, with more restricted data availability and limited openness, which can constrain its citation impact [38].

Key Contributors and Institutional Insights

The analysis of authors and institutions highlights the contributions of key researchers to the application of CDMs in pharmacoepidemiology. Core authors such as Nicola P Klein and Matthew F Daley demonstrate their extensive expertise and consistent productivity in this field. Among the top 10 most prolific authors, 5 are affiliated with different regions of Kaiser Permanente, a leading health care provider and nonprofit health plan in the United States since its establishment in 1945, currently serving members across 8 states and the District of Columbia [39]. In South Korea, Hallym University and Seoul National University have conducted multiple studies in this domain around 2020, using OMOP and K-CDM. Between 2016 and 2018, the Ministry of Food and Drug Safety and the Korea Institute of Drug Safety and Risk Management converted EHR of over 9 million patients into CDM, reflecting Korea's progress in integrating and sharing cross-cohort data resources [40]. Subsequently, Korea developed the K-CDM specifically for pharmacovigilance systems, leveraging multi-center EHRs to monitor adverse drug reactions [41,42].

Global Landscape and Collaborative Trends

The majority of studies in the high-citation group originated from the United States, which is the birthplace of several CDMs. As early as 2001, the United States established the VSD to track adverse events across multiple regions and populations [43]. Subsequently, the OMOP was released in 2007, the Sentinel was launched by the FDA in 2008, and the PCORnet initiative began in 2014, positioning the United States at the forefront of CDM development and usage worldwide [43]. Moreover, the United States excels in drug and vaccine surveillance through the VSD and Sentinel systems. VSD provides real-time updates and comprehensive vaccine data, while Sentinel builds on VSD with tools enabling direct, standardized analyses, streamlining research processes [11].

In addition, the United States is the primary contributor in terms of publication volume and frequency, followed by South Korea. These countries have made significant contributions to advancing knowledge in this field. Notably, co-occurrence analysis highlights active participation from other countries in collaborative networks, with strong connections observed among North America, Europe, and East Asia. However, we observed that most international collaborations occur primarily among limited-income countries, with limited participation from other nations, particularly in limited-income countries. Given that CDMs are designed to harmonize data from multiple databases and facilitate standardized analyses [44], future research should focus on fostering broader and more impactful international collaborations from countries at different levels of development. Furthermore, the analysis of institutional productivity provides practical insights that may directly benefit researchers seeking potential collaborators. Our results highlight that Kaiser Permanente and CDC in the United States, both major users of VSD, represent key contributors to CDM-based vaccine research in the United States. Meanwhile, institutions such as Hallym University and Seoul National University in South Korea have emerged as important centers of CDM implementation, primarily using OMOP and K-CDM. Recognizing these leading institutions and their methodological preferences may facilitate strategic planning of future collaborative studies, enabling researchers to align their research agendas, optimize resource allocation, and ultimately enhance the global impact of CDM-based pharmacoepidemiologic research.

Implications for Future Research and Practice

To foster more equitable global participation, particularly from low- and middle-income countries, future efforts should prioritize improving access to CDM infrastructure. This includes the provision of open-source tools, standardized implementation workflows, and multilingual technical documentation. In parallel, the establishment of dedicated funding mechanisms and long-term capacity-building programs—such as technical training and data transformation support—will be essential to enable meaningful international collaboration. These strategies aim to bridge existing disparities and promote a more inclusive and diverse global CDM research ecosystem.

Furthermore, the findings of this study offer practical implications for clinical decision-making and real-world health policy. By identifying highly cited, multicenter studies—many of which focus on vaccine safety and effectiveness—this analysis highlights how CDM-based research can rapidly generate actionable evidence during public health emergencies. The global collaborative networks and methodological practices identified in this study may serve as a reference for designing future pharmacoepidemiologic studies that directly inform clinical guidelines, pharmacovigilance strategies, and regulatory decision-making. Strengthening the application of CDMs in such contexts can ultimately improve patient safety, treatment optimization, and health system responsiveness.

Strengths and Limitations

This study has some strengths. To our knowledge, this bibliometric study is the first of its kind in the field of application of CDMs in pharmacoepidemiology, to summarize the publication characteristics. Using the systematic review, we screened studies that met the inclusion criteria, ensuring the reliability of the selected studies. Furthermore, we imposed no restrictions on publication date or on the types of CDMs, which allowed us to include studies globally. This approach enables comparisons across different periods, countries, and types of CDMs. It must be acknowledged that our research has several modest limitations. First, the most significant limitation of our study lies in the inherent biases of citation analysis. These include the tendency for earlier publications to accumulate higher citation counts, journal and author self-citations, incomplete citation data, and omissions, all of which may affect citation rates [23,45,46]. To mitigate such biases, we attempted to use TCpY as an alternative metric. Second, we selected WoSCC based on previous studies [18,36], as it allows

XSL•FO
RenderX

standardized citation-based analysis. However, WoSCC does not index all eligible studies. Among the 308 included studies, 285 were found in WoSCC and therefore included in citation-related analyses. The remaining 23 studies lacked citation data and were excluded from this component. To evaluate whether their exclusion introduced selection bias, we compared key characteristics between the 2 groups. As shown in Multimedia Appendix 3, no statistically significant differences were found. Therefore, the potential bias introduced by excluding non-WoSCC studies is likely minimal. Third, we included only English and Chinese studies, which means that studies published in other languages were excluded. This may lead to the omission of some research. However, we searched the Virtual Health Library to ensure that literature published in Latin America was also covered to the greatest extent possible. Fourth, the use of the bibliometrix R package, while powerful for large-scale bibliometric analysis, may introduce methodological limitations. For example, its analytical outputs rely on the quality and structure of the input data and specific co-occurrence or clustering algorithms [26]. To minimize these effects, we carefully cleaned and standardized the dataset and interpreted the results in combination with manual validation and descriptive statistics. In addition, the release dates of different CDMs vary, with earlier CDMs having accumulated a higher publication volume and citations compared to those released more recently.

Conclusions

This bibliometric analysis provides a comprehensive overview of the application of CDMs in pharmacoepidemiology. The findings indicate a significant increase in publications over time, with the United States leading in both publication volume and citation counts. Notably, high-citation studies often involve multicenter studies, particularly focusing on vaccine, underscoring the importance of collaborative research efforts. These insights emphasize the critical role of CDMs in facilitating large-scale, collaborative pharmacoepidemiologic research, as well as provide researchers with insights for selecting collaborators and choosing journals for publication. To enhance global equity and clinical relevance, further efforts should support infrastructure accessibility, international cooperation, and the integration of CDM-based evidence into public health and regulatory decision-making.

Abstract

Background: The benefits of smart contracts (SCs) for sustainable health care are a relatively recent topic that has gathered attention given its relationship with trust and the advantages of decentralization, immutability, and traceability introduced in health care. Nevertheless, more studies need to explore the role of SCs in this sector based on the frameworks propounded in the literature that reflect business logic that has been customized, automatized, and prioritized, as well as system trust. This study addressed this lacuna.

Objective: This study aimed to provide a comprehensive understanding of SCs in health care based on reviewing the frameworks propounded in the literature.

Methods: A structured literature review was performed based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) principles. One database—Web of Science (WoS)—was selected to avoid bias generated by database differences and data wrangling. A quantitative assessment of the studies based on machine learning and data reduction methodologies was complemented with a qualitative, in-depth, detailed review of the frameworks propounded in the literature.

Results: A total of 70 studies, which constituted 18.7% (70/374) of the studies on this subject, met the selection criteria and were analyzed. A multiple correspondence analysis—with 74.44% of the inertia—produced 3 factors describing the advances in the topic. Two of them referred to the leading roles of SCs: (1) health care process enhancement and (2) assurance of patients' privacy protection. The first role included 6 themes, and the second one included 3 themes. The third factor encompassed the technical features that improve system efficiency. The in-depth review of these 3 factors and the identification of stakeholders allowed us to characterize the system trust in health care SCs. We assessed the risk of coverage bias, and good percentages of overlap were obtained—66% (49/74) of PubMed articles were also in WoS, and 88.3% (181/205) of WoS articles also appeared in Scopus.

Conclusions: This comprehensive review allows us to understand the relevance of SCs and the potentiality of their use in patient-centric health care that considers more than technical aspects. It also provides insights for further research based on specific stakeholders, locations, and behaviors.

Introduction

Background

New technologies have disrupted health care and imply exposure to complex scenarios. The Internet of Medical Things (IoMT) is increasingly receiving attention from practitioners and scholars to provide more alternatives for monitoring patients' conditions; allowing access to private medical data; and obtaining secure and flawless tools to protect data from attacks that can access or steal essential information or, in some cases, produce a patient fatality [1-3]. In this new technological

XSL•FO
RenderX

landscape, recent studies have highlighted that blockchain technology with smart contracts (SCs) provides the most reliable data security, cryptographic capacities, and decentralized storage and can lead to a low-cost ecosystem and sustainability in the medical setting [4,5].

The health care value chain is another research area where SCs have consistently shown effectiveness in avoiding counterfeiting and ensuring product security and safety. Implementing SCs on value chains can guarantee data provenance, eliminate unnecessary intermediaries, and provide an immutable history of transactions considering all the internal and external stakeholders. Although electronic health records (EHRs) are the most sensitive information in the SC environment, all the sensor devices are essential to provide a robust framework [6]. A health care value chain faces different challenges and aims to monitor diseases by considering real-time patient status updates. Furthermore, some visible barriers include data interoperability and communication among applications, medical devices or machines, and institutions. This increases complexity and continuously impacts costs and efficiency [7]. However, acquiring the logic of the value chain and adapting cutting-edge technologies to specific needs can save millions of lives and enhance quality of life for others.

There are different approaches to analyzing literature data. A classic methodology considers a small number of research studies to synthesize the different perspectives and angles of the topic and provide future avenues of research. In addition, there are various frameworks, such as systematic or structured reviews. Thus, a bibliometric framework considers an extensive quantity of literature by using statistical software. Multiple objectives are pursued, such as recognizing intellectual models and new trends. Our study aimed to provide a bibliometric analysis of SCs on the health care value chain and, thus, obtain a fundamental knowledge of the intellectual, social, and conceptual structure and other clustering techniques. This review's analysis was primarily interdisciplinary, seeking to discover barriers and possible gaps in the SC domain.

Motivation

Trust reduces complexity [8,9], manages uncertainty by compensation [8], and is an element of social capital [10]. Trust involves the truster and trustee as actors and expectations about actions in the future that could entail some risk for the trustee [11]. Trust applied to new technologies implies the transition from personal trust to system trust [8,11,12].

The literature refers to trust as a requirement of sustainable and human-centered technology [13]. Technologies, through trust, also look to fulfill social interests and be responsive. This affirmation is essential when technologies—including blockchain and SCs—are introduced in fields such as health care [11].

A blockchain is a distributed ledger [14] formed by chronologically ordered blocks [15,16]. It consists of multiple nodes connected peer to peer [15] and without a hierarchy among them [15]. Each block has an identification linked to the previous one via a reference or hash [14,15]. There is a genesis block, which is the first block of the chain, and any subsequent block also has the hash that allows for the identification of the previous one [15]. Blocks have a block header—that usually includes the hash of the last block, a time stamp, and a nonce [16]—and a payload or data with transactions [15,16]. The blockchain holds a consensus algorithm [14] that adds information to the chain [16]. Blocks are accepted or refused based on this algorithm [15]. In doing so, miners, who are a particular type of node, solve a challenge (ie, a mathematical puzzle) to verify the block and receive a reward [16] (ie, "gas"). Information cannot be modified once a block has been added to the chain. SCs are codes stored in a blockchain [17] containing transactions executed without intermediaries [14]. Thus, technologies such as blockchains and SCs promise transactions that do not require trust among parties—called trust-free, trustless [18], or trustless trust [11]—and distribute trust among the system—called distributed trust [11]. It is relevant to point out that their origins are independent despite the extensive joint use of blockchains and SCs. SCs were propounded as a transaction protocol [19], whereas blockchains uses cryptography to allow for the exchange between participants worldwide without the necessity of a central authority [20]. Blockchains and SCs look for trust development, where trust lies in the system design [18].

SCs strengthen the capabilities of a blockchain [21], aiming to (1) implement customizable business logic [22] through different functionalities [23] and (2) automatize the execution of preassigned transactions [3,24-26]. One of the most essential characteristics of SCs is that transactions are automatically executed [27]. For this, the interposition of a third party is not required [27]. This characteristic improves efficiency, accountability [28], and trust building [28,29]. SCs are transparently auditable [30] owing to their immutability. The decentralization of these systems also improves their resilience. Centralized systems represent a unique vertex of failure, a limitation that is overcome by SCs [31] deployed in blockchains [32]. Thus, SCs are especially relevant in health care as system trust generators [26,29].

Contribution and Related Works

This study fills a gap and responds to a request in the literature. Even though SCs are relevant in health care, a sufficient assessment is necessary. Some studies characterize SCs but do not refer to health care. It is the case of the proposal by Alzhrani et al [32], which presented a characterization of some SCs in real-world systems based on a blockchain's taxonomy. Nevertheless, this study does not focus on health care, and only 11 SCs were selected to exemplify its taxonomy. Other studies have focused on the health care sector but had a limited scope [14,33] and have not provided an in-depth characterization of SCs. Vargas and da Silva [14] assessed 3 case studies or frameworks related to SCs in the IoMT. Sookhak et al [33] limited their study to entering patient data into EHRs.

Several theoretical studies or literature reviews regarding blockchains in health care have considered or mentioned SCs in the health care domain. Nevertheless, they need to focus on providing in-depth information about the role and features of SCs. The closest one is the review by Marbouh et al [1], who inquired about the advantages of blockchains in improving

XSL•FO
RenderX

patient safety. The challenges and opportunities of this technology were the starting point of the aforementioned study, which referred to the uses of blockchains in health care. It introduced SCs and some uses of blockchains. Still, these contracts were not the study's primary goal, and it did not offer a systematic survey of the literature based on propounded frameworks.

Furthermore, Villarreal et al [29] studied blockchains in health care management systems and classified the architectural mechanisms in the literature. This study acknowledged SCs' relevance and problems in health care, but they were not systematized and referred to one specific telemedicine case. Similarly, in the study by Arbabi et al [34], the authors surveyed studies on blockchains in health care. They acknowledged the relevance of SCs but did not review their attributes in depth and suggested further assessment of the role of SCs.

Similarly, Khatri et al [35] systematically analyzed the broad topic of health care and blockchain integration and selected 50 publications for an in-depth analysis. In their study, the authors mentioned SCs; nevertheless, they did not propound specific functionalities or roles of SCs or link them with the authors' proposal about blockchains. Finally, McBee and Wilcox [36] studied the application of blockchains in medical imaging. Nonetheless, the literature has barely mentioned SCs to specify the origin of the name "blockchain 2.0" and its relationship with artificial intelligence (AI) [37].

Finally, Arbabi et al [34] suggested further research on SCs in health care. The authors mentioned that the potential of SCs in health care requires an in-depth assessment. In addition, Hawlitschek et al [38] propounded the development of additional research on the design of trusted interfaces. Thus, our study aimed to fill a gap in the literature—detailed in Table 1—and be responsive to its suggestions [34,38], focusing on an extensive review of SC frameworks in health care as elements that enhance trust and shift the traditional concept of trust among people to system trust, providing a characterization of it.

Table 1. Gaps in the literature.

Study	Health care sector	Focused on SCs[a]	Included different topics (extensive review)	Review based on propounded frameworks	The roles or characteristics of SCs were developed

Research Goals

Our study aimed to provide a holistic understanding of SCs in health care. We focused on developing a structured literature review of the state-of-the-art scientific landscape of new technological advances, tendencies, and bibliometric analysis to help provide a comprehensive understanding and up-to-date overview of the recent research and outline new perspectives and future research directions.

These contributions allow this research to fill a gap in understanding and respond to the suggestions by Arbabi et al [34] and Hawlitschek et al [38]. We adopted a systematic literature review approach because it allows for the replication of this study. A quantitative bibliometric analysis followed by an in-depth qualitative review of the studies enabled us to provide a detailed standpoint of the topic.

Methods

We used the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) principles [37] for our systematic literature review [39]. Multimedia Appendix 1 contains the PRISMA checklist. The Web of Science (WoS) database provided the data, which were retrieved on July 4, 2023. The selection of databases for literature reviews is a topic under discussion [40], and there is no unique response. Some studies have used several databases, whereas others have been restricted to 1. Among the latter, several systematic reviews have selected WoS as their search database [39,41], including some in health care [42,43] and digital health [44]. The propounded reasons were the reputation and reliability of this source [45] and its extended use [39].

We chose to use only 1 database, WoS, because the joint use of several databases could introduce bias in our study. First, the search engines need to be unified and standardized. If we compare 2 of the most well-established databases of academic literature, WoS and Scopus [46], and one of the most relevant specialized databases in medical topics, PubMed [47], we could highlight some differences. For example, PubMed, Scopus, and WoS have the search option All Fields; nevertheless, this option encompasses different meanings for each database as they have other fields that are difficult to integrate [48] (ie, PubMed has

XSL•FO
RenderX

the field Pharmacological Action that is absent from WoS; WoS has the search fields Keyword Plus and Author Keyword, whereas PubMed has the search field Word-Term, MeSH Term, and Other Terms; Scopus includes a field named References, which is absent in the other 2 databases; and WoS has the search field Topic encompassing Title, Abstract, Keyword Plus, and Author Keyword, whereas Scopus has the search field Article, Title, Abstract, Keyword. Even though they could seem the same, they are not because WoS includes KeywordPlus, which responds to a proprietary algorithm, and Scopus's Keyword field includes both Author Keywords and Index Terms [controlled vocabulary]). Something similar happens with other well-known databases such as EBSCOhost (ie, EBSCOhost consists of a field named All Text, which is absent in WoS and other databases). The literature has highlighted the discrepancies among WoS, Scopus, and PubMed regarding different topics [49,50], such as document type [51,52], funding information [53], and subject classification [54].

The combination of information obtained from ≥2 databases also generates an additional source of bias caused by data wrangling [55]. Each database provides its search results in its format (ie, WoS uses commas [,] in some fields such as Keywords, whereas Scopus uses semicolons [;]). The different files require to be combined to assess them as one sample. This procedure could be performed manually or using an informatic tool; nevertheless, the data are always altered. For example, the order of the fields is different, and thus, we would have had to uniformize the data and the fields.

In addition to the possible bias caused by combining multiple databases as our main decision criteria to select only WoS, there is also the concern regarding coverage and overlap with other databases as different databases have unequal scopes and coverage policies [56].

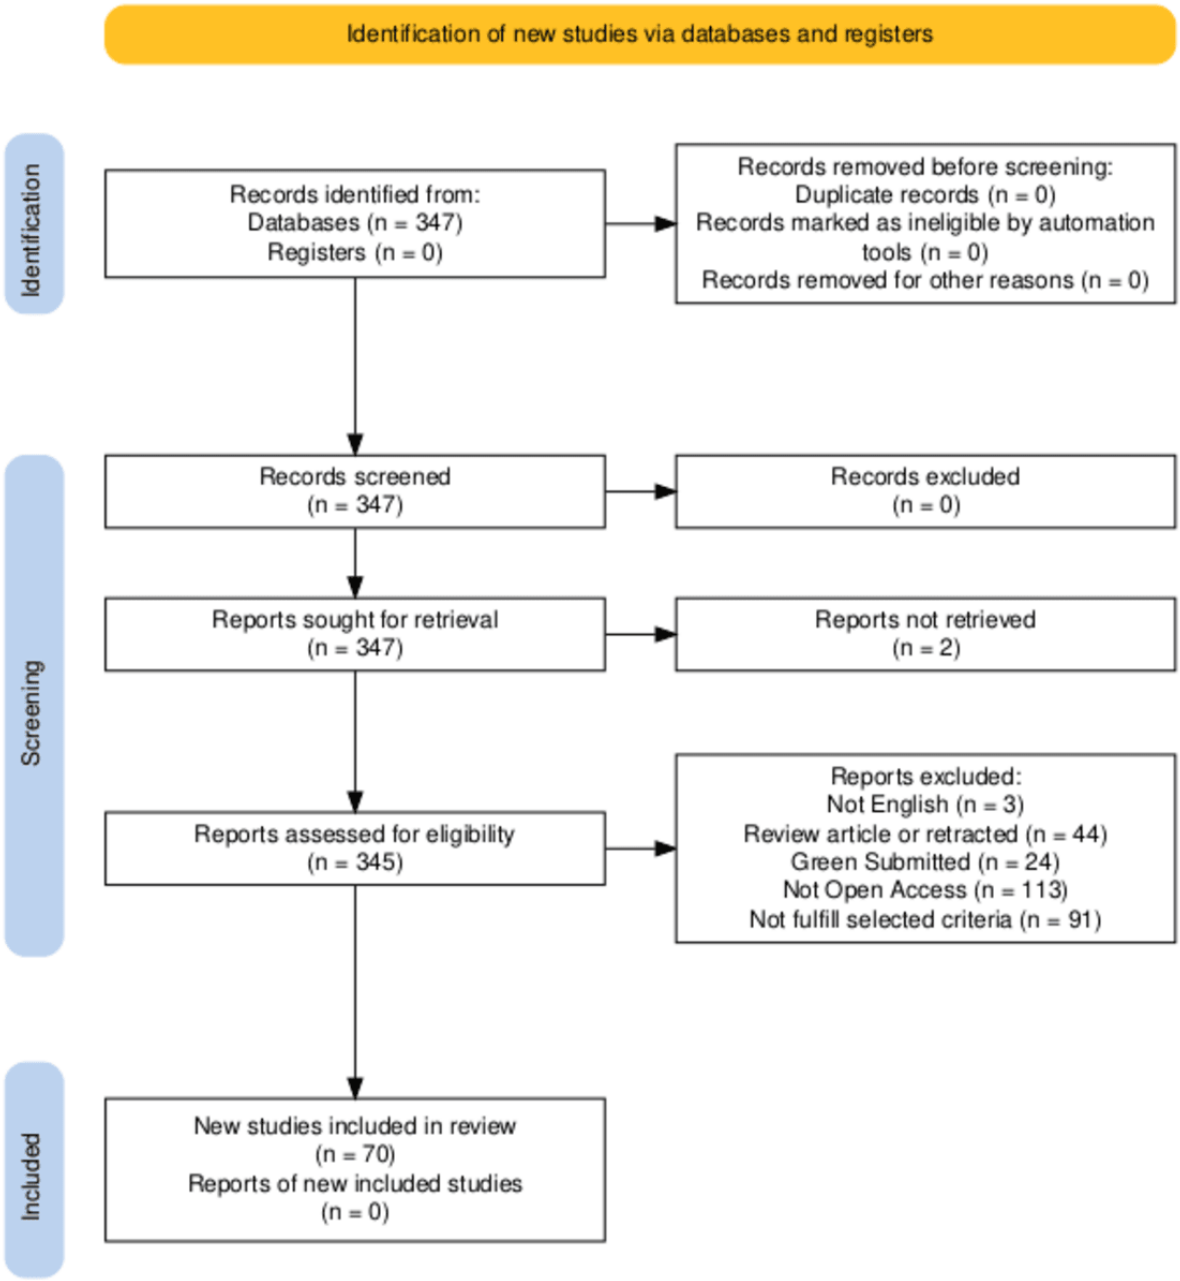
There are several studies on different databases' coverage, but they are inconclusive regarding which database could be considered the most suitable for all cases. Some databases, including Scopus, could generally encompass a higher number of articles than WoS [57,58]; nevertheless, when specific topics are searched for, the coverage could be very similar [59], and some authors have also remarked that WoS coverage depth is better [47]. WoS is a multidisciplinary database with more articles than PubMed [57], but PubMed specializes in medicine and biomedical sciences [47,49]. On the basis of the novelty of the topic under study and its relationship with other disciplines, such as engineering, using a multidisciplinary database with a broader scope was considered the most suitable option. In addition, WoS has also essential coverage in medicine, similarly to Scopus. As an example, the evaluation of the content of Scopus and WoS in the context of Norway's scientific and scholarly publications concludes that both databases are highly and similarly comprehensive in medicine and health—with 89% of scientific publications and 87% of scholarly publications in Scopus and WoS, respectively—and natural sciences and technology—with 85% of scientific publications and 84% of scholarly publications in Scopus and WoS, respectively [60]. In addition, WoS has high levels of overlap with Scopus [58,59] and PubMed [57], which means that WoS shares an essential number of publications that are the same as those in each of the other databases (Scopus and PubMed).

Therefore, the most suitable option was to use only 1 database, WoS, for our study to avoid possible bias caused by the differences in the structures of different databases and data wrangling. In addition, WoS is a well-known and esteemed database with comprehensive coverage of the topic under study, presenting a high level of overlap with other multidisciplinary and specialized databases.

Furthermore, peer review is relevant to avoid selection bias [61]. Both authors participated in the different stages of the identification and screening process and discussed and agreed on the search terms, procedure, and screening and selection criteria before executing this process. Following previous studies [62], one of the authors (CDP) conducted a detailed review of the titles and abstracts and, when necessary, the complete texts to apply the selection criteria in the screening stage. The senior researcher (CAM) then shared and peer reviewed the results. Both authors discussed doubts and discrepancies until they reached an agreement.

Exact searches were used to identify articles to reduce the risk of bias. The terms used to refer SCs included 6 variations encompassing singular and plural for the word with and without a hyphen and the joint form, similarly to the study by Dwivedi et al [63]. The search was exact for each variation, and brackets were used. Adopting this approach did not leave the interpretation of term combinations to the subjective judgment of the researchers. The use of loose or approximate phrases was allowed for "health care." For the term "health care," we used an open search with a wildcard in the middle and at the end of the word ("health care*" or "health*care"). The search was Boolean. The query included the connectors OR for the same concepts and AND between different ideas considering the sense of the search and the rules of precedence of these operators in the WoS database. The query was as follows: ("smart contract" or "smart contracts" or "smart legal contract," or "smart-contract" or "smart-contracts" or "smart legal contracts") and (Health care* or health*care) (All Fields).

Results



Overview

The search produced 374 results. The exclusion criteria were based on language (only English), type of source (review article, retraction, editorial material, and retracted publications were excluded), and availability (green submitted publications were excluded, and only open access publications were included). All these restrictions were established based on WoS filters. Finally, 163 publications were assessed. The selection encompassed the following criteria. Only those publications that (1) had the health care industry as their focus, (2) included a framework (framework, system, model, prototype, or similar), and (3) incorporated details about the roles of SCs and identified SCs were included in the study. In addition, the texts of the studies by Subramanian et al [64] and Elgendy et al [65] could not be accessed. A list of the 163 papers and their assessment results based on the aforementioned criteria can be reviewed in

XSL•FO
RenderX

Multimedia Appendix 2. A final sample of 70 publications was selected to be reviewed. Figure 1, which was made using the template propounded by the PRISMA organization, details the selection process [66].

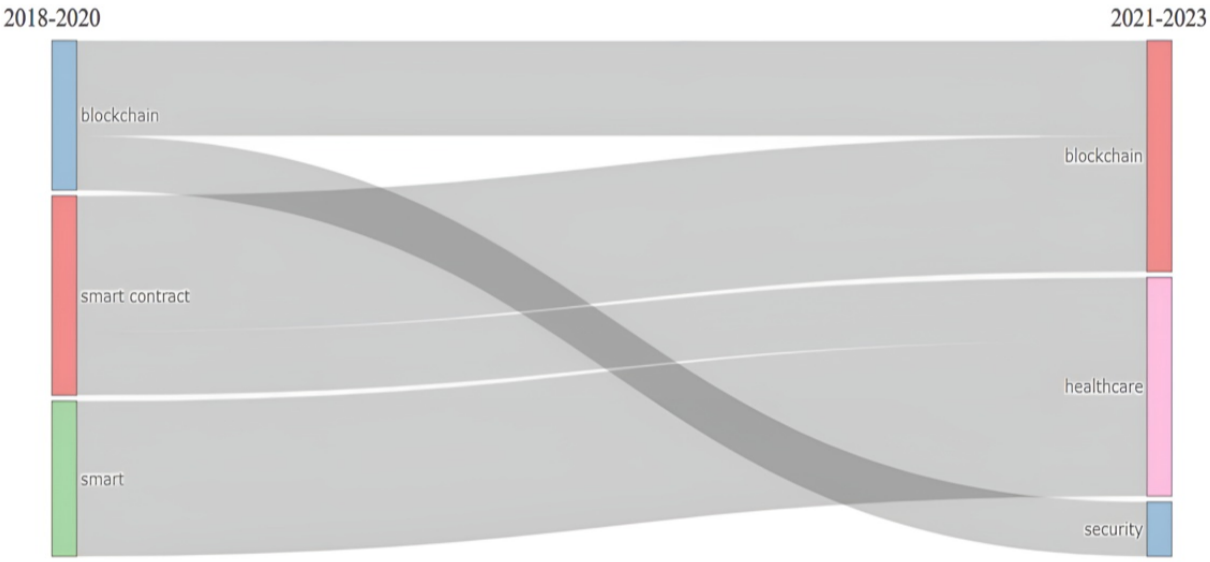
Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) framework for literature assessment.

Bibliometric Assessment

We assessed the selected studies to find the main trends. The biblioshiny app and the *bibliometrix* tool (K-Synth Srl) was used in this process [67]. First, the data were screened. A total of 7% (5/70) of the studies had incomplete information about the authors' keywords. Some techniques such as multiple correspondence analysis [68] and network analysis [50] are sensible to missing data [69]. Keeping these studies could have biased the results.

Consequently, we decided to withdraw 7% (5/70) of the articles [70-74]. Thus, we included 65 articles in the bibliometric assessment. The aforementioned 7% (5/70) of the articles were withdrawn only for these purposes; they were read in depth for reporting in the literature review section. In addition, the terms "smart contract," "smart legal contract," "smart contracts," and "smart legal contracts" were signaled as synonyms where required.

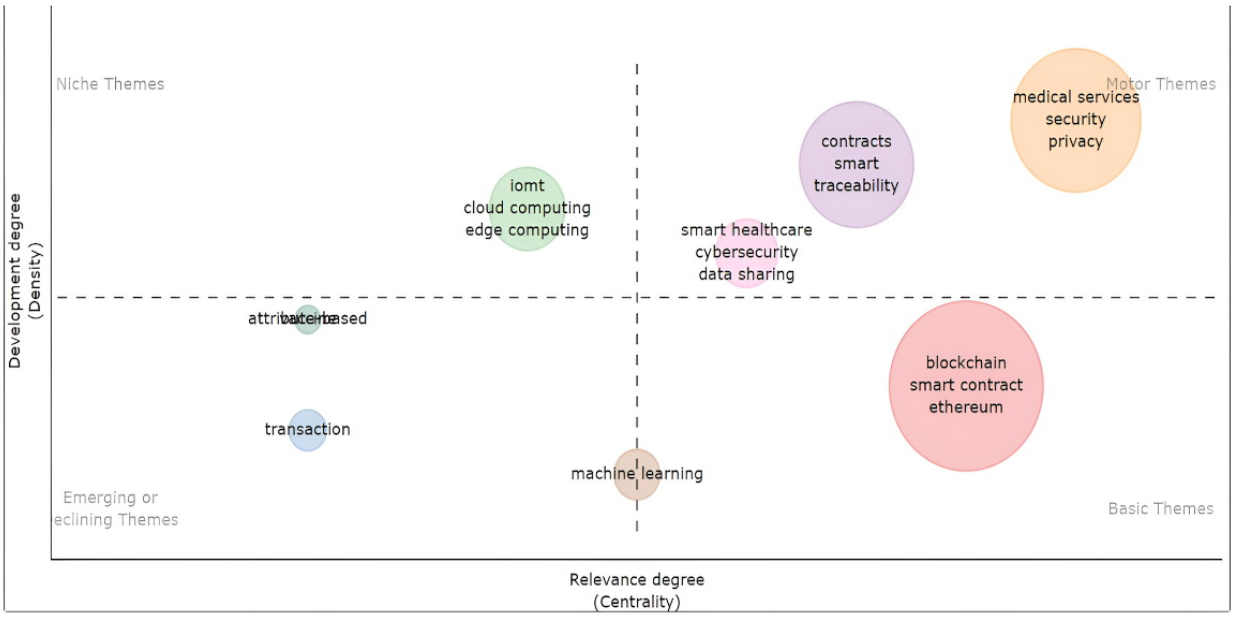
The studies were published in 34 journals, and one of the journals, *IEEE Access*, published 29% (19/65) of the studies. The countries with the most citations were the United States, the United Arab Emirates, South Korea, and Egypt with >100 citations per country. Table 2 summarizes the descriptive information.



XSL•FO
RenderX

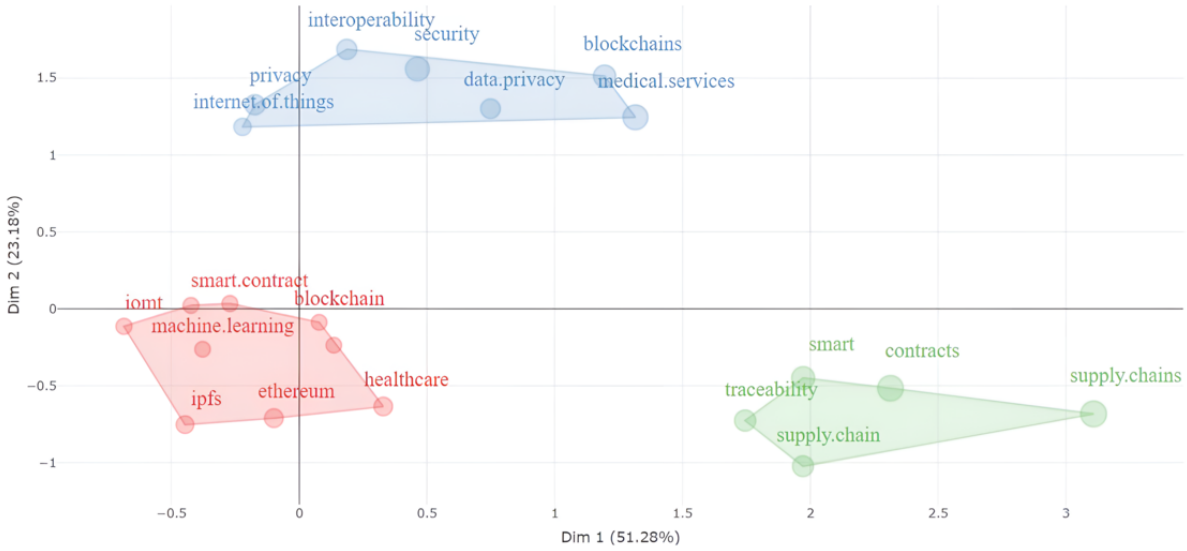
Table 2. Descriptive information.

Topic	Values
Sources (eg, journals and books), N	34
Documents, N	65
Annual growth rate (%)	67.03
Document age (y), mean (SD)	2.52 (1.16)
Authors, N	246
Single-authored documents (n=65), n (%)	2 (3)
International coauthorship, n (%)	32 (49)



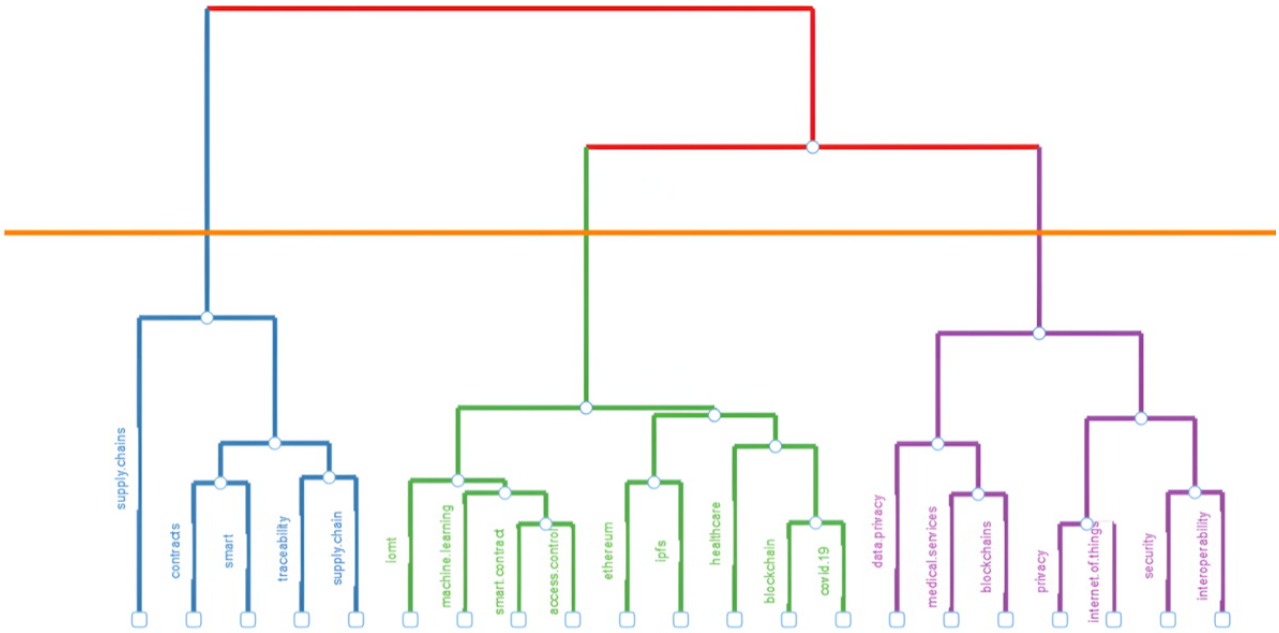
The historical evolution of this topic encompasses 6 years, from 2018 to 2023. The oldest study in our group was the one by Dagher et al [75], published in 2018. Although this theme is relatively new, its historical evolution (Figure 2) reflects the relevance of COVID-19. The literature has propounded that this disease was one of the most important in recent years [76,77]. Until 2020, a total of 3 topics represented the field. After 2020, a new independent concept, *security*, emerged, and the term *health care* acquired relevance. In addition, the map of subjects organizes them into 4 groups given their significance and development (Figure 3). It shows that security, privacy, medical services, traceability, innovative health care, cybersecurity, and data sharing are the most developed and relevant topics, known as motor subjects. The IoMT constitutes a niche theme and developed topic. Cloud and edge computing are also niche themes. On the other hand, machine learning has a low level of development, which could be explained by its novelty and a medium level of relevance. This situation could reflect the first attempts to use SCs and machine learning together in the same framework.

Figure 2. Historical evolution of the topic.



XSL•FO
RenderX

Figure 3. Map of subjects. IoMT: Internet of Medical Things.



We obtained the conceptual map and keyword cluster [67] through factor analysis, a data reduction technique. Multiple correspondence analysis was used. This technique depicts the words on a map based on a similarity measure [67]. The study yielded 3 factors in 2 dimensions (Figures 4 and 5), representing 74.44% of the variability or inertia (dimension 1: 51.28%; dimension 2: 23.18%). The factorial analysis tree supported the existence of 3 dimensions under the cutting line (Figure 5). The first factor represents the concern for the technical aspects of the topic. In this factor, Ethereum and InterPlanetary File System (IPFS) had the highest contributions (Ethereum: 3.083%; IPFS: 2.054%; together: 5.137%). The second factor concerns data privacy and security. Security, privacy, and data privacy represented the highest contributions to this factor (security: 8.191%; privacy: 4.498%; data privacy: 4.026%; together: 16.715%). Finally, the third factor is concerned with the processes themselves. Supply chain and supply chains had the highest contributions (supply chain: 5.135%; supply chains: 10.066%; together: 15.2%).

Literature Review

Overview

The literature review encompassed the in-depth reading of the 70 selected articles. The factors related to processes and patients' privacy provided an initial approach to comprehending the role of SCs in health care. A detailed review of frameworks also permitted learning of SCs' technological characteristics, which are linked to the third factor in the quantitative stage. In addition, and following the motivation of this study, the assessment of the authors' proposals also allowed for propounding the building elements of system trust in health care SCs.

Roles of SCs in Health Care

Overview

SCs in health care encompassed 2 main kinds of business logic, depicted in Table 3: process improvement and protecting patient privacy rights. The first business logic, process improvement, included six themes: (1) the medicine and medical equipment supply chain [3,22-24,31,78-83], (2) insurance claim attention [26,84], (3) vaccination passports and certificates [72,76,77,85], (4) clinical research [86,87], (5) emergency attention process [88,89], and (6) regulatory compliance [90,91]. The second business logic, protecting patient privacy rights, incorporated three themes: (1) patient consent management [17,71]; (2) authentication, authorization, and access [21,27,73-75,92-114]; and (3) telemedicine and eHealth care [70,74,102,115-126]. This classification aims to understand the business logic reflected in SCs based on the main goal or goals pursued in developing the framework and the most relevant stakeholders.

Table 3. Roles of smart contracts in health care.

Roles and themes	References
Role 1: process improvement	
Medicine and medical equipment supply chain	[3,22-24,31,78-83]
Insurance claim attention	[26,84]
Vaccination passports and certificates	[72,76,77,85]
Clinical research	[86,87]
Emergency attention process	[88,89]
Regulatory compliance	[90,91]
Role 2: protecting patient privacy rights	
Patient consent management	[17,71]

Telemedicine and eHealth care	[70,74,102,115-126]

XSL•FO
RenderX

Role 1: Improving Health Care Processes

The studies that adopted this perspective used SCs as a lever to face problems related to processes, and their frameworks presented solutions to generate accountability and efficiency as their primary challenge. The topics encompassed in this group were medicines and medical equipment supply chain, insurance claim attention, telemedicine and eHealth, vaccination passports and certificates, clinical research, emergency attention processes, and regulatory compliance.

Medicine and medical equipment supply chains constituted the primary category of this group. The use of SCs in health supply chains [3,22,24,31,78-82] aimed to solve problems related to efficiency. These problems could be associated with tracing the supply chain stages, reducing overproduction and underconsumption, automating procurement contracts, or verifying the route of resealable returned drugs. Some studies had the specific mission of correcting malpractice, as exemplified by cases of counterfeit medicines and medical equipment [78,80,82].

Immutability, decentralization, transparency, and automatized execution of blockchains are valuable features that could solve these problems. Musamih et al [79] aimed to track all controlled drugs. SCs were required to follow all actions; thus, the actors in the supply chain would be individually accountable for their participation in the process because their activities could be tracked back. The framework included 7 actors: the controlled drug regulator, manufacturer, distributor, hospital and pharmacy, nurse station, and patient. The drug manufacturer controls the process. In total, 3 SCs were propounded in this framework: registration, production, and consumption.

One particularity of these frameworks is that several included the participation of specific government regulators, such as the Food and Drug Administration in the United States [22,31,81] and the Central Drugs Standard Control Organization in India [80], or nonspecific ones [3,79] that interact with private stakeholders. It is relevant to mention that SCs look to generate relationships without the necessity of trust among participants. Trust goes from the interpersonal level to the system level. In this case, government agencies that participate in blockchains could interact with their counterparts without the need to trust them, and vice versa.

As was previously stated, some frameworks depicted the extraordinary complexities of their stakeholders. As an example, Munasinghe and Halgamuge [82] propounded a framework that tried to uncover counterfeited COVID-19 vaccines. The authors realized that there was an international move of vaccines and then a nationwide distribution. This framework considered the ingredient provider, the vaccine manufacturer, the external company (vaccine supply), consolidation (government), the primary distribution, hospitals, clinics, pharmacies, and zone distributions as stakeholders. On the basis of these characteristics, the authors propounded 4 SCs.

Similarly, the study by Omar et al [24] depicted a particular negotiation structure of transactions. The authors applied SCs to procurement contracts negotiated by group purchasing organizations. In this context, several health providers negotiate procurement contracts with manufacturers. These health providers must pay a membership fee to the group, but they achieve better prices or loyalty rebates under this form of negotiation. The group negotiates prices with the manufacturer and determines the distributor for the entire group. This framework encompassed 5 SCs that represent the joint negotiation, the individual interests (rebates), and health care providers' actions (purchase placement).

The frameworks related to the health supply chain could also use additional technologies in the solution, but these are the exceptions. For example, Abbas et al [78] suggested combining blockchain and machine learning techniques in the same framework. This framework sought more efficient supply chain management and provided final consumer recommendations. SCs improved the supply chain. Recommendations were propounded based on machine learning outputs. In these solutions, SCs include functionalities related to registration and production, consumption, and waste assessment.

Insurance claim frameworks include SCs to facilitate the attention of these claims, reduce [24] fraudulent activities [26,64], or improve efficiency [84]. These contracts could include government entities as stakeholders [26], health insurance providers [84], claimants, patients, and health care providers or hospitals. The process automatized by SCs includes claim submission and attention and could also encompass billing and payment processes. Unlike in supply chain studies, patients have a relevant participation in these frameworks.

SCs could also enhance the processes related to vaccination passports and vaccination certificates. These vaccination records can (1) certify the status of vaccination required to do other activities, such as traveling; (2) provide information related to possible causes of the symptoms of a patient to physicians [72]; and (3) be used in sanitary emergencies [76,77,85]. In the first and second cases, the stakeholders are mainly patients and hospitals or clinics—where the patient was vaccinated and where they request later attention based on specific symptoms—and the primary function of the propounded technology is recording and providing access to the data. The third case, referring to vaccination records in emergencies such as the COVID-19 pandemic, involves more complex frameworks, including generating certificates and providing access to them to several stakeholders. These frameworks also consider the international movement of people and countries' requirements regarding vaccination [77,85]. Stakeholders include hospitals, vaccination centers, and governmental entities—ministries of health and foreign affairs [77,85].

Clinical research can use SCs for sharing and aggregating health care–related data because SCs provide secure storage and querying while protecting privacy in managing the data [86]. Both features are particularly relevant for research because they could promote collaboration among entities and data aggregation. Increasing the amount of data could also improve the generalization of studies [86]. Hospitals, as stakeholders, could act together to develop research activities [87]. For example, Kuo and Pham [87] introduced a framework allowing different hospitals to assess data during the COVID-19 pandemic. This inquiry encompassed 13 hospitals that acted as

XSL•FO
RenderX

a federation, which means that these institutions were required to share information and obtain, in some cases, a global aggregate.

The provision of attention to patients in an emergency context can also benefit from this technology [88,89]. For example, Ksibi et al [88] suggested using SCs to manage processes related to an emergency caused by a car crash. This framework allowed emergency vehicles to improve communication with the cars involved in the accident and with hospital emergency services. Peyvandi et al [89] established a framework that supported the prediction of diagnoses—or computer-aided diagnosis—in an emergency. Machine learning technology was used to forecast a diagnosis, whereas SCs preserved patients' privacy and granted access to the data. The stakeholders are emergency units that attend hospital emergency services.

Regulatory compliance could be enhanced using SCs [90,91], detecting and flagging privacy regulation violations. SCs allow patients to select their data privacy preferences, record events, and verify compliance with regulations. Regulatory compliance could also be enhanced using edge computing [90]. In these appraisals, the stakeholders are patients, health care providers—including hospitals—and clinical researchers. Governmental agencies are not included as the perspective of these frameworks is not enforcement but private compliance.

It is pertinent to note that these frameworks mentioned the United States [22,31,81] and India [80] through their regulators. They also referenced other regions such as Southeast Asia [85]. The studies were also concerned with complying with the regulations of the European Union [91] and the United States [90]. In addition, institutions located in the United Kingdom [87] and the United States [78,86] provided datasets used to test proposals.

Role 2: Improving Patient Privacy Protection

A new paradigm has influenced patient data management: patient centrality [15,92-94]. Patients are acknowledged as owners and managers of their health data [92]. Moreover, Jadav et al [115] have also alluded to a new reality in this field characterized by machine-centric interaction [92], where technology—especially the IoMT—provides different solutions for the health care sector. Both new complementary paradigms, patient centrality and machine-centric interactions, guide data management.

Data fragmentation [17], data breaches [86,116], compliance with regulations [115], cross-organizational coordination [95], and interoperability [96] are some challenges that the frameworks deal with. The stakeholders are patients and health facilities—including hospitals, clinics, physicians, laboratories, and researchers. Hospitals and clinics could act independently or as a consortium. Moreover, the blockchain could also act as a federation. Hashim et al [96] highlighted the problems that arise from the interoperability of independent blockchains and proposed a solution based on 3 SCs (search, global, and local). It is also relevant to mention that one study applied its framework in an animal health care service [97].

This role includes three main topics: (1) patient consent management; (2) authentication, authorization, and access; and (3) eHealth care. The patient centrality paradigm is reflected in patient consent management, which includes the possibility of patients defining viewer authorizations. For example, El Majdoubi et al [71] propounded a framework in which patients could manage their health data privacy preferences. A privacy agreement and enforcement were automatically settled if patients' preferences coincided with provider policies and privacy law. A privacy offer was published; this privacy offer could become a privacy agreement if it was accepted. After that, the system tracked the execution of this agreement. Thus, compliance with legal requirements and the stakeholders' preferences was ensured. In addition, this framework encompassed 3 levels of privacy. The first one, or P0, included data that could be viewed only by patients. The second one, or P1, referred to data that health care providers could also access. Finally, the third one, or P2, contained publicly available data [76].

Authentication, authorization, and access are central topics in patient privacy protection. SCs in these frameworks deploy different functions. They manage patients' consent, transfer and share data, search for patients, administer registration (add new users, view users, delete users, and create accounts), actualize data (add and update information), request access permission, restrict access, store data, provide search functions, and establish viewership criteria. The complexity of SC functions depends on the framework scope. The main stakeholders are hospitals and patients, as well as insurance companies and governmental agencies [98].

In addition, some frameworks use additional protocols or technologies to protect patient data privacy better. Saidi et al [99] used the self-sovereign identity (SSI) model. SSI aims to prove the identity in a digital environment, and a verifiable credential and a decentralized identifier underpin it. SSI has given rise to the SSI-based access control that allows for separate authentication, which is decentralized, and authorization, which is centralized. The SC—policy decision SC—provides efficiency and security to role assignments. In addition, this framework introduced an adaptive access control policy for emergencies. Other authors used ciphertext-policy attribute-based encryption (CP-ABE) [27,100] and attribute-based access control [95]. CP-ABE [81] and attribute-based access control determine access based on attributes; nevertheless, the first one, CP-ABE, offers a higher degree of granularity and is related to data encryption [100]. Biometric technology [20] such as fingerprints was also included in access control [21]. The use of ring signature and stealth address [20,87] to improve security was also considered [101]. Ring signature can hide the sender's identity, keeping the transaction safe because the receiver has the elements to verify the transaction authenticity [101]. Meanwhile, a stealth address maintains the anonymity of the sender's address, creating a 1-time address [101].

eHealth care and telemedicine represent a particular case, where SCs are mainly recommended for granting patient data access in a secure environment. Commonly, these frameworks are mentioned together in telemedicine, the IoMT, and eHealth [70,90,117], including wearable sensors, smart devices [118], and ambient intelligence [119]. Telemedicine faces several

XSL•FO
RenderX

challenges, including interoperability, incorrect diagnosis, and unfavorable perceptions. These perceptions are grounded on the fact that they are not the same as physical environments [120]. In telemedicine, the frameworks use SCs to generate secure transactions and automate participant communication [120]. In doing so, the frameworks could encompass laboratory test results [90], payment, and drug delivery, among other things [102,118,120]. The stakeholders include the usual ones—patients, hospitals, physicians, insurers, medical research organizations, and laboratories—and special ones, such as a telemedicine center [120] or diagnostic center [102] and federated hospital clouds [90]. Javed et al [2] referred to the health care regulator in their framework and gave the regulator control of the blockchain.

Telemedicine and eHealth care are concerned with malicious nodes and use additional technologies to deal with this problem or detect health abnormalities. Puri et al [70] suggested using SCs and AI to identify malicious nodes and security breaches. Similarly, Jadav et al [115] recommended including AI, specifically recurrent neural networks, to ensure data integrity. Neural networks train data to detect attacks and review data before storing them. Baiju et al [121] relied on machine learning (logistic regression) to anticipate abnormalities in the stored data. Dhasarathan et al [116] adopted a supervised machine learning approach to monitor risk factors in data transmission. In addition, Masud et al [119] suggested a framework that uses biometrics, among other technologies. The use of edge computing [122] and fog-cloud computers was also suggested [74,123,124].

In addition, Shaikh et al [125] suggested a framework that aimed to transform medical data into wisdom. In this framework, data collected from patients were cleaned and transformed into information, which was evaluated and converted into knowledge. Finally, metadata were extracted and converted into wisdom that could be used in medical research. The stakeholders were patients, physicians, data analysts, and knowledge managers. SCs provided registration advantages, data privacy customization, and exchange policies in this proposal. Abou-Nassar et al [126] were also concerned about the knowledge management and interoperability of IoMT devices related to semantic differences. The authors proposed an ontology model to achieve a higher level of trust.

It is relevant to mention that, without prejudice to their generalization capability, several studies obtained their testing dataset from institutions in the United States [17,89,94,100,101,103,115] and South Korea [127]. Some studies dealt with regulatory privacy concerns in the United States (Health Insurance Portability and Accountability Act; HIPAA [21,75]) and Europe (General Data Protection Regulation [95]). Finally, 2 frameworks were tailored for specific countries: the United Arab Emirates [98] and Italy [104].

Technical Characteristics That Provide Efficiency to Frameworks That Incorporate SCs in Health Care

The frameworks that propound the use of SCs face an essential challenge regarding their efficiency, requiring specific technical strategies to optimize their use [128]. The literature [28] mentioned limited data storage and inefficient execution as problems of SCs [129]. One of the strategies used to solve data storage problems is in-chain and off-chain data storage. Only the most relevant information is kept in the chain; additional information is sent to another source. IPFS is the preferred solution for maintaining data off the chain. This system optimizes resources because access to the data requires only the hash generated when the data are stored [105].

Some frameworks had an essential level of complexity and were required to preserve a critical quantity of data. Doing it in the blockchain could turn the system into an inefficient one. For example, Debe et al [22] propounded a framework for tracking resalable returned drugs that included several stakeholders and SCs. The medicines were produced by manufacturers in lots. These manufacturers were also required to share images of the package. Storing these images in the blockchain would be costly and inefficient. Thus, they were stored off the chain in the IPFS. Rai [80] suggested a similar solution, which also proposed keeping a lot of drug images in the IPFS.

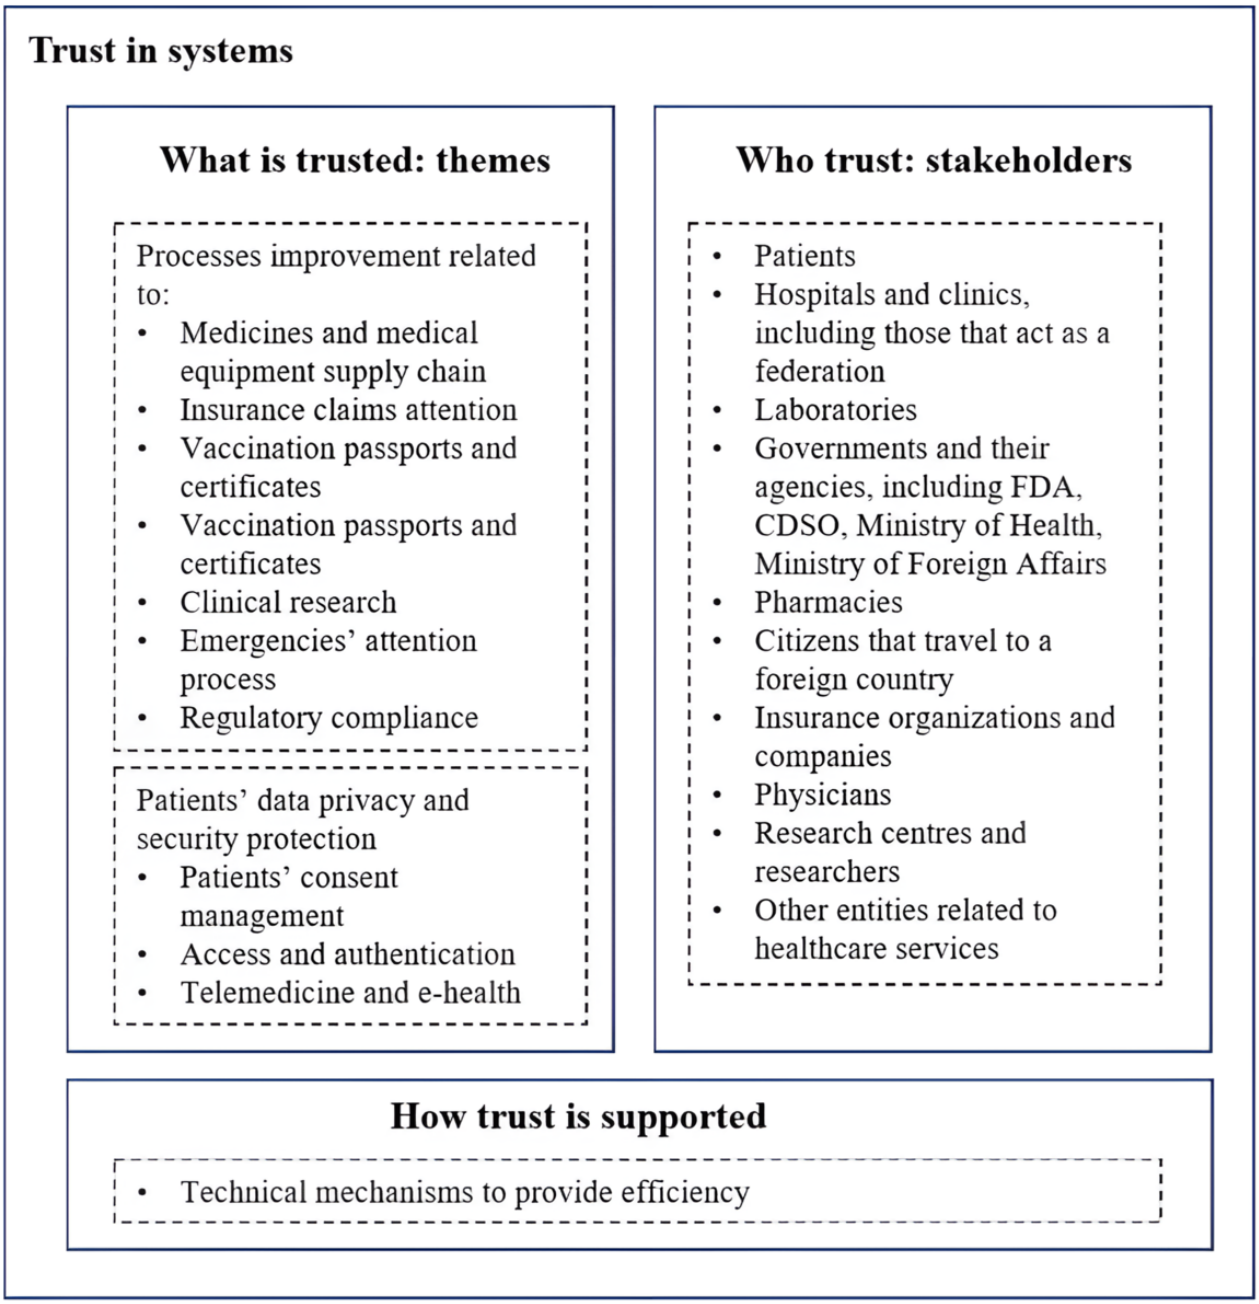
The IPFS was also used in frameworks focused on patient data privacy and security. For example, Azbeg et al [105] propounded that only hash data should be stored in the chain. The IPFS preserved additional data as the off-chain storage, and Hussien et al [100] introduced a procedure to encrypt medical data before their storage in the IPFS, extending the CP-ABE and comprising searchable symmetric encryption [86].

Another strategy proposed to optimize resources was the specialization of SCs. SCs contain functions deployed when they are called. Under this strategy, the different parts that the framework requires are organized in several specialized SCs that could be individually deployed when needed, optimizing the resources. The quantity of SCs and the functions included in each could vary, and they are related to the complexity of the objectives that the framework aims to achieve. Frameworks based on 1 SC were the exception (ie, the study by Peyvandi et al [89], who proposed a single SC for patient data sharing).

In addition, the specialization of nodes was also propounded [78,97]. For example, Abbas et al [78] established a framework to manage medicine supply chain management and a recommendation system to avoid counterfeit drugs. This framework leveraged the attributes of SCs using machine learning. The SCs had an execution rate that was lower than desirable. The solution was to deploy them only on specified nodes, and only some of them—called endorsers—could validate the transactions. This solution enhanced the efficiency of the system.

The frameworks' efficiency and optimization are reflected in their cost analysis. The Ethereum platform provides the cost of gas or ether for function deployment. This cost can be converted to a specific national currency. Gas is relevant because it incentivizes miners to work [24] and protects them from distributed denial of service attacks [82]. Omar et al [24] and Chen et al [72] reported the cost based on a low average and fast execution in this platform converted to US dollars. The Hyperledger Fabric platform does not include ether; nevertheless, a computational cost can be calculated and compared. Munasinghe and Halgamuge [82], for example,

XSL•FO
RenderX



calculated and compared the cost of their framework developed in Hyperledger Fabric based on previous inquiries.

It is relevant to mention that the frameworks used extended cryptography mechanisms of blockchains, such as hash functions, digital signatures, public-private keys, and Merkle trees. Ethereum and Hyperledger Fabric were the preferred platforms. The frameworks used the features and facilities provided for these platforms (ie, the programming language Solidity in Ethereum). The different types of blockchain were represented in the frameworks. There were private blockchains (ie, the study by Omar et al [23]), public blockchains (ie, the study by Debe et al [22]), and consortiums (ie, the study by Mackey et al [26]). A detailed review of this specific topic can be found in the study by Sookhak et al [33]. Ganache, Truffle, and MetaMask were frequently used [26,31]. The SCs were commonly tested in Remix IDE [24,31].

Characterization of System Trust in Health Care SCs

SCs imply a transition from trust in people to trust in systems [8,11,12] where people interact without needing to trust each other or a central authority. On the basis of the previously exposed findings, we characterized system trust in health care SCs. The object of trust, or what is trusted, is represented by the 2 roles identified and the subjects they encompass. The stakeholders that interact without the necessity of a central authority are the subjects that are trusting and represent whom they trust. Finally, the technical strategies that these frameworks adopt support the trust in this system. Figure 6 summarizes these elements.

Coverage Bias Assessment

Overview

This study used a single database, WoS, to avoid bias caused by the differences in database structure and data wrangling considering that the literature supports WoS's acceptable coverage and overlap with other databases. Nevertheless, assessing possible bias caused by the difference in coverage among different databases was considered relevant. Thus, subsequently, in our study, a comparison of coverage and overlap between WoS and other databases was conducted. The selected databases were (1) a multidisciplinary one of extended use, Scopus; and (2) a specialized one, PubMed.

The procedure had 2 stages. The first conducted a comparison between WoS and Scopus and between WoS and PubMed regarding their coverage and overlap. In this stage, the queries were evaluated to make them as similar as possible. The raw results on WoS were compared to identify the overlap between studies in both WoS and Scopus or both WoS and PubMed.

The second stage asked whether the articles published in Scopus or PubMed but not in WoS could provide relevant additional information to our literature review. Thus, we selected those studies that were only in Scopus or PubMed and were published until June 2023. They were then evaluated based on the 3 selection criteria of our research. For such purposes, the titles and abstracts and, in case of doubt, the full texts were reviewed by one of the researchers. The results were then discussed between the researchers, and the doubts and discrepancies were resolved. Third, the selected studies were read and compared with the literature review results. The searches for comparison purposes in PubMed, Scopus, and WoS were conducted on June 5, 2024.

Coverage Bias Between Multidisciplinary Databases: WoS and Scopus

The starting point of the comparison between WoS and Scopus was to select the most suitable field in both databases to conduct the search as All Fields was not adequate. The fields Topic in WoS and Article, Title, Abstract, Keyword in Scopus were close enough to our purposes. In addition, the difference between a search of All Fields and Topic was only 8 articles. Restrictions regarding language (only English), access, and type of article were included. The queries were as follows: Refine results for (“smart contract” or “smart-contract” or “smart contracts” or “smart legal contract” or “smart-contracts” or “smart legal contracts”) (Topic) AND (Healthcare* or health*care) (Topic) and English (Languages) and Review Article or Retracted Publication or Retraction or Editorial Material (Exclude – Document Types) and Green Submitted (Exclude – Open Access) and All Open Access (Open Access) for WoS and (TITLE-ABS-KEY (“smart contract” OR “smart-contract” OR “smart contracts” OR “smart legal contract” OR “smart-contracts” OR “smart legal contracts”) AND TITLE-ABS-KEY ((healthcare* OR health*care))) AND (LIMIT-TO (LANGUAGE, “English”)) AND (LIMIT-TO (OA, “all”)) AND (LIMIT-TO (DOCTYPE, “ar”)) for Scopus.

These searches produced 205 and 270 documents for WoS and Scopus, respectively. The results were then compared based on the digital object identifiers to obtain the level of overlap between both databases. The databases shared 181 documents, which represents an 88.3% (181/205) coincidence for WoS and a 67% (181/270) coincidence for Scopus. Notably, these percentages are higher than those obtained in other systematic reviews that also used WoS as their search engine. Maia et al [130] obtained a 61.4% (167/272) and 56.1% (213/380) overlap for the WoS and Scopus results, respectively.

Despite the high level of overlap, the next question was whether Scopus's additional documents could provide relevant qualitative information for our study. Thus, in the second stage, we selected the Scopus documents published before July 2023 because we conducted the search for our review on July 4, 2023, and 71 papers were obtained. We then applied the selection criteria used in our study. Finally, a list of 15 articles was retrieved and reviewed in depth. Most of them referred to data exchange and EHRs and could be included in the second role of SCs related to privacy and security [65,131-140]. The additional ones could be included in the first role of SCs related to process improvement [141-144].

Coverage Bias Between Multidisciplinary and Specialized Databases: WoS and PubMed

A procedure similar to the previously detailed one was performed between WoS and PubMed. PubMed used the field Title/Abstract. Filters for language—only English—and text availability—free full text—were then applied. The WoS query was the one previously detailed, and the PubMed query was as follows: ((“smart contract”[Title/Abstract] OR “smart-contract”[Title/Abstract] OR “smart contracts”[Title/Abstract] OR “smart legal contract”[Title/Abstract] OR “smart-contracts”[Title/Abstract] OR “smart legal contracts”[Title/Abstract])) AND ((Healthcare*[Title/Abstract] OR health*care[Title/Abstract])).

These searches produced 77 and 205 documents for PubMed and WoS, respectively. A total of 4 PubMed documents did not have a digital object identifier and were not considered in the comparison with the remaining 74 papers. A total of 49 of those documents were also included in WoS, which represents a 66% (49/74) overlap with PubMed. On the basis of previous studies [130], this percentage can be considered satisfactory.

The second step started with selecting PubMed documents published until June 2023. The result was 11 documents. The 3 selection criteria were applied to those documents, and only 9% (1/11) fulfilled them [145]. This study [145] dealt with privacy preservation and can be included in the second role of SCs.

Discussion

Principal Findings

This study aimed to provide an extensive understanding of SCs in health care through a comprehensive review of their roles and characteristics based on the frameworks developed in the literature. In doing so, this study fills a gap in the literature [34].

XSL•FO
RenderX

SCs are code or short programs whose output is a transaction [15] that is produced automatically when certain previously established conditions are met. These programs reflect the business logic [15] and provide flexibility (requirements can be introduced) and efficiency (their execution does not need additional enforcement) to a blockchain. The extensive review of frameworks offered insights into the business logic that was prioritized.

A quantitative bibliometric assessment highlighted the topic's novelty and importance, including subjects with high relevance and development. In addition, 3 factors were identified. These factors guided the in-depth review of each framework. Two roles of SCs were found—(1) process improvement, which encompassed 6 topics; and (2) patient data privacy enhancement, which encompassed 3 topics—and technical strategies and features that provide efficiency were found. These results provide more detailed information than previous inquiries, which have mentioned only this technology's use for medical devices, prescription tracking, remote patient monitoring, counterfeit drugs, EHRs, and incident report systems [1]. In addition, several stakeholders were identified.

This study acknowledged the relevance of technical topics. Previous studies have provided taxonomies based on technological features that consider the blockchain type, ledger type, consensus, identification, authentication and authorization, and EHR storage and features [33]. This study provided a new perspective based on the features selected by the literature that provide efficiency to systems.

The studies on trust and health care had different scopes. Some authors focused on trust in the system [146,147]. Others considered trust among various actors in this system, such as physicians and patients [25]. Independently of the orientation, the main proposal was that trust is relevant for accomplishing health care goals. The quantitative and qualitative review findings characterized system trust in health care SCs, which considered systems [146,147] and actors [25], through what is trusted, who trusts, and how trust is supported.

Finally, this study revealed different levels of impact on the concerns of multiple health care stakeholders. Individuals' rights—such as privacy [17,71], mobility [72,76,77,85], or health [88,89]—can be better protected. Physicians and researchers can use enhanced access to traceable and secure data when required [21,105]. SCs offer traceability, immutability, transparency, decentralization, automatization, and security to the different suppliers related to health care—such as hospitals, clinics, laboratories, research centers, and pharmacies—for their processes [16]. Governments can also obtain benefits from SCs. SCs facilitate private compliance with governmental regulations [90,91], preventing crime such as counterfeit drugs. In addition, SCs can facilitate the coordination of processes that require governmental intervention [22,31,81]. This study highlights new technologies, such as consensus and cryptographic methods, to address data security and privacy concerns. Second, this study details the different efforts to make potential solutions scalable and provide them to policyholders. Finally, this study shows the complexity of the health care systems, which is crucial for understanding the definition of multiple agreements among various involved stakeholders.

Strengths and Limitations of This Review

The strength of this review lies in its systematicity and comprehensiveness. This review evaluated studies that included SCs in health care in their frameworks. We applied several procedures to reduce the risk of selection bias. The criteria used in the selection process tried to avoid researchers' subjectivity, provide transparency, and allow for the review's replicability [148]. The PRISMA principles were followed, a peer review procedure was contemplated, 1 database was selected, and its coverage and overlap with 2 databases—a specialized and a multidisciplinary one—was assessed. Moreover, quantitative bibliometric techniques were guided by and complemented with an in-depth and detailed literature review.

Even so, the selection of articles had 2 significant limitations. First, the different academic databases needed to be unified or standardized. Indeed, we had to decide between possible bias caused by the differences between databases and data wrangling or selecting 1 database and assessing its coverage and overlap. Our decision was the latter, but we acknowledge that it entails a limitation. Second, our study included only open access documents because they were relevant to guarantee the review of this study and ensure our research's transparency.

Conclusions and Further Research

Overview

The theme of SCs in health care is not only novel but also relevant. SCs reflect the business logic into the blockchain. Using SCs is advisable to enhance access to health records with advanced tiers of security and privacy. They can also solve other problems requiring security and traceability, such as counterfeit drugs. SCs provide benefits to several stakeholders, both individual (ie, patients, researchers, and physicians) and institutional (ie, hospitals, clinics, and governments), who interact in the context of the themes that SCs cover without the need to know each other or having a central authority or intermediaries, supported by the technical mechanisms that provide efficiency to the processes. SCs have limitations, such as data storage and use of resources [129], but techniques have emerged to deal with these issues [28].

The literature review provided some topics that could be considered in further research regarding specific stakeholders, locations, behaviors, and issues.

Specific Stakeholders

Although the relevance of children's health data sharing is essential, there is a lack of studies that have dealt with the particular characteristics of this topic. The concept of patient centrality can be challenging in cases involving children and teenagers with limited control over their information. Moreover, no study has analyzed the characteristics of health care privacy protection for minors. The closest one is the study by Dagher et al [75], which acknowledged possible special conditions of the owner, such as the existence of a parent or guardian [84].

XSL•FO
RenderX

Specific Locations

SCs' advantages can help solve problems related to low- and middle-income countries. Nevertheless, only some studies focused on solving the particular necessities of low- and middle-income countries using SCs. Abbas et al [78] referred to counterfeit drugs as an extended problem in countries with weak economies, and Rai [80] designed their framework for the specific case of drug traceability in India.

Specific Behaviors

Hawlitschek et al [38] highlighted the relevance of considering fundamental interactions among people and systems. The authors named these interactions behavioral layers. It is necessary to decode these real-world behaviors so that they can be modeled into systems. This affirmation has an extended application to the SC because it oversees the deployment of business logic in the chain. Nevertheless, evidence must be provided regarding how these real-world behaviors are deciphered and converted into systems.

Specific Topics

First, the internet is a system requirement [88] and is considered an element that provides ease and simplicity [75,88,106] to SCs. Nevertheless, only a few aspects are known about the proper relationship between the quality of internet connectivity and the possible expansion of the use of SCs. Second, the cost of transactions is an existing health care problem [20]. SCs allow for the automation and optimization of these transactions and save costs [74,123]. Indeed, some studies provided a cost analysis based on the computational cost (gas cost) [75] and indicated the execution cost in a specific currency [24,79,91]; a qualitative cost comparison between a blockchain-based solution and a traditional one was made [85], and the execution cost based on workflow was also assessed [123]. Nevertheless, contrary to other industries [149-151], there is a lack of studies evaluating cost as a factor in the adoption of SCs in health care.

Abstract

Background: The Observational Medical Outcome Partners-Common Data Model (OMOP-CDM) is an international standard for harmonizing electronic medical record (EMR) data. However, since it does not standardize unstructured data, such as medical imaging, using this data in multi-institutional collaborative research becomes challenging. To overcome this limitation, extensions such as the Radiology Common Data Model (R-CDM) have emerged to include and standardize these data types.

Objective: This work aims to demonstrate that by standardizing optical coherence tomography (OCT) data into an R-CDM format, multi-institutional collaborative studies analyzing changes in retinal thickness in patients with long-standing chronic diseases can be performed efficiently.

Methods: We standardized OCT images collected from two tertiary hospitals for research purposes using the R-CDM. As a proof of concept, we conducted a comparative analysis of retinal thickness between patients who have chronic diseases and those who have not. Patients diagnosed or treated for retinal and choroidal diseases, which could affect retinal thickness, were excluded from the analysis. Using the existing OMOP-CDM at each institution, we extracted cohorts of patients with chronic diseases and control groups, performing large-scale 1:2 propensity score matching (PSM). Subsequently, we linked the OMOP-CDM and R-CDM to extract the OCT image data of these cohorts and analyzed central macular thickness (CMT) and retinal nerve fiber layer (RNFL) thickness using a linear mixed model.

Results: OCT data of 261,874 images from Ajou University Medical Center (AUMC) and 475,626 images from Seoul National University Bundang Hospital (SNUBH) were standardized in the R-CDM format. The R-CDM databases established at each institution were linked with the OMOP-CDM database. Following 1:2 PSM, the type 2 diabetes mellitus (T2DM) cohort included 957 patients, and the control cohort had 1603 patients. During the follow-up period, significant reductions in CMT were observed in the T2DM cohorts at AUMC (P=.04) and SNUBH (P=.007), without significant changes in RNFL thickness (AUMC: P=.56; SNUBH: P=.39). Notably, a significant reduction in CMT during the follow-up was observed only at AUMC in the hypertension cohort, compared to the control group (P=.04); no other significant differences in retinal thickness were found in the remaining analyses.

Conclusions: The significance of our study lies in demonstrating the efficiency of multi-institutional collaborative research that simultaneously uses clinical data and medical imaging data by leveraging the OMOP-CDM for standardizing EMR data and the R-CDM for standardizing medical imaging data.

Introduction

The Observational Medical Outcomes Partnership-Common Data Model (OMOP-CDM) is an internationally standardized model designed to harmonize medical data across various health care institutions [1]. Its primary goal is to facilitate efficient, large-scale, multi-institutional collaborative research. Currently, a federated database developed collaboratively by researchers from over 80 countries contains data from 12% of the global population [2].

The OMOP-CDM is a model that standardizes structured clinical data such as diagnoses, prescriptions, and procedures. However, unstructured data, such as genomic and imaging data, often fall outside the standardization scope of the current OMOP-CDM, presenting challenges for use in multi-institutional collaborative research. To address this limitation, extended models based on the OMOP-CDM are being actively developed [3,4]. One such model used in this study, known as the Radiology Common Data Model (R-CDM), standardizes imaging data, enabling the efficient integration of multi-institutional imaging and clinical data to enhance research capabilities [5].

Optical coherence tomography (OCT) captures detailed images of the eye's internal structure, including parameters such as retinal thickness. Studies using OCT data have explored relationships between retinal thickness and various factors including age, hypertension, type 2 diabetes mellitus (T2DM), and vitamin D deficiency [6-8]. However, these investigations have generally been limited by their confinement to single medical institutions with small patient cohorts, due to the simultaneous requirement for clinical and imaging data. To address these constraints, this study aims to standardize multi-institutional OCT data using the R-CDM, thereby facilitating research that integrates clinical and imaging data across multiple institutions.

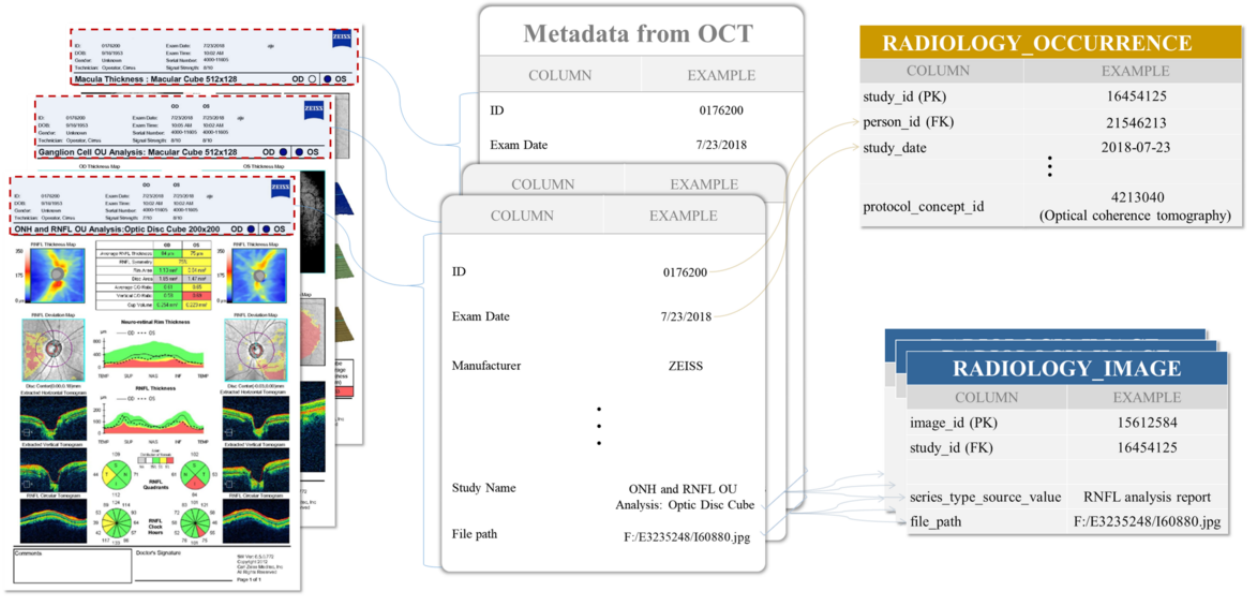
Methods

Data Sources

This study used clinical and imaging data from two of the leading tertiary hospitals in South Korea: Ajou University Medical Center (AUMC) and Seoul National University Bundang Hospital (SNUBH). For clinical data, standardized OMOP-CDM databases were used. The AUMC OMOP-CDM database included standardized electronic medical record (EMR) data spanning from 1994 to February 2023, with records from 2,752,765 patients. The SNUBH OMOP-CDM database contained standardized EMR data from April 2003 to 2021, covering 2,017,421 patients. For imaging data, we had authorization to use selected OCT data collected with specific medical devices. OCT data were typically stored on the OCT device itself and were not automatically integrated into the EMR or picture archiving communication systems. To use these data for research purposes, the stored images had to be manually collected and converted into a usable format. Due to these limitations, OCT data were collected from all devices available at the participating institutions. Rather than selectively choosing specific devices or time periods, an inclusive approach was adopted to address potential selection bias. As a result, AUMC provided access to OCT data captured with Zeiss medical devices from 2013 to April 2022, while SNUBH granted access to OCT data obtained with Heidelberg medical devices from July 2006 to August 2019, for research purposes. This study was conducted per the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) guidelines to ensure transparency [9].

Ethical Considerations

We obtained ethical approval from the Institutional Review Board of AUMC (approval number: AJOUIRB-DB-2024 - 341) and SNUBH (approval number: SNUBH-EX-2024 - 123). This study was conducted with an exemption for informed consent, as there were no direct benefits or risks to participants arising from their involvement in the study. All data were anonymized to ensure participant confidentiality and privacy. No identifying information was retained during the data analysis process.



Constructing an R-CDM–Standardized OCT Database

Although the clinical data in this study had been standardized according to the OMOP-CDM and were ready for immediate application in multi-institutional research, the OCT imaging data still needed to be standardized to the R-CDM format to be efficiently used in research. The R-CDM standardized medical data through two distinct tables: the radiology occurrence table and the radiology image table. The radiology occurrence table cataloged each imaging event, detailing which patient used which company's equipment, the type of imaging performed, and the date on which it was performed. The radiology image table organized information about each image, including the type, file path, and resolution. These tables were interconnected through a "study_id" that served as the primary key, allowing researchers to uniformly extract specific types of image data from imaging events.

Consequently, a process was necessary to extract metadata within the OCT data using optical character recognition (OCR) techniques and load it into the R-CDM format. For OCT data captured using Zeiss medical devices at AUMC, the sections of OCT images documenting retinal thickness were cropped, and data extraction was performed using the Python Tesseract package. OCT data from SNUBH, taken with Heidelberg medical devices, were processed using a proprietary OCR machine learning model [10]. Only high-quality OCT scans (signal strength ≥7) were used in this study. Figure 1 illustrates the process of standardizing OCT imaging data into the R-CDM format.

Study Design With the OMOP-CDM

In this study, we performed retinal thickness comparisons between cohorts of adult patients (aged ≥18 years) with and without chronic diseases, all of whom had undergone OCT. Among the chronic diseases, we focused on T2DM and hypertension. To ensure the comprehensive inclusion of all patients with these conditions, we used the highest-level SNOMED (Systematized Nomenclature of Medicine) hierarchy codes for enrollment. First, a T2DM cohort composed of patients diagnosed with T2DM and a control cohort of patients who were neither diagnosed with nor treated for T2DM were established. Eligibility for the T2DM cohort required a T2DM diagnosis and the administration of T2DM medications within 3 months of diagnosis, with the diagnosis date set as the index date. Patients who discontinued T2DM medications for more than 90 days were considered lost to follow-up. The control cohort included adult patients who were neither diagnosed with nor treated for T2DM, and the OCT imaging date was the index date in this cohort. Patients who had not been observed in the 90 days that preceded their respective index dates were excluded from the study. Additionally, patients with any recorded diagnosis or treatment for retinal or choroidal diseases that could affect the retinal thickness were also excluded (Figure 2). Second, an additional cohort of patients diagnosed with hypertension and a control group of patients who were neither diagnosed with nor treated for hypertension, who also had records of undergoing OCT imaging, were established in Figure E1 in Multimedia Appendix 1. Patients who discontinued hypertension medications for more than 90 days were considered lost to follow-up.

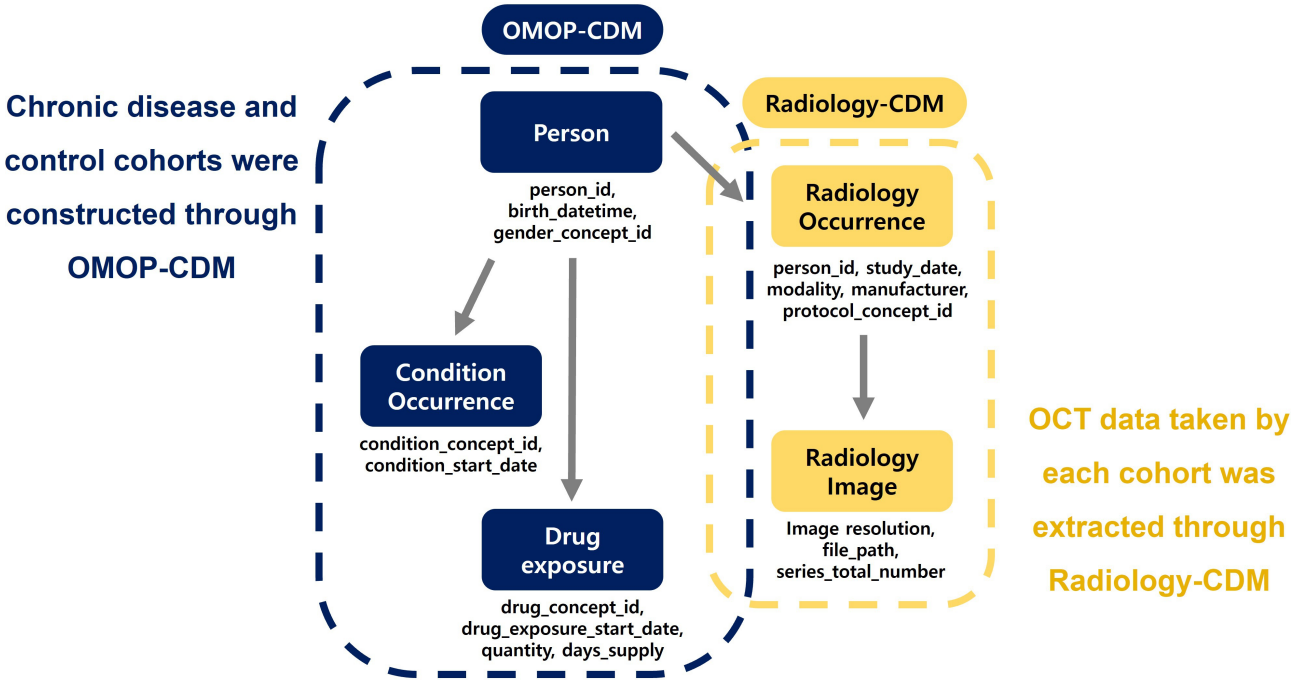
Figure 2. Cohort definitions for T2DM and control groups. (**A**) Patients with T2DM, excluding those diagnosed or treated for choroidal or retinal disorders, who have undergone OCT imaging. (**B**) Patients without T2DM or any choroidal or retinal disorders, who have undergone OCT imaging. OCT: optical coherence tomography. T2DM: type 2 diabetes mellitus.

Statistical Analysis 1: Large-Scale Propensity Score Matching for Characteristics Between Chronic Disease Cohort and Control Cohort

The propensity score matching (PSM) method was used to adjust for potential biases arising from confounding variables between the cohorts of patients with chronic diseases and the control cohorts. Propensity scores were estimated through a logistic regression model, and matching was performed using a nearest-neighbor approach within a 0.2-SD caliper on the logit scale, as recommended by Austin [11]. The balance of covariates was assessed using the absolute standardized mean difference (aSMD), with covariates including age categorized into 5-year bands, sex, and all condition diagnoses recorded in the year preceding the index date. Various matching ratios (1:1, 1:2, and 1:4) were explored for the sensitivity analysis.



Interworking of the R-CDM and OMOP-CDM

During the standardization of OCT imaging data to the R-CDM, patient numbers used in the hospital were pseudonymized and replaced with research patient IDs for use in the OMOP-CDM database. This transformation not only eliminated the risk of personal information leakage when conducting research with imaging data but also ensured seamless integration between the OMOP-CDM and R-CDM. Following these processes, R-CDM-based OCT databases were established in both institutions.

By linking the OMOP-CDM and R-CDM, an environment was established that enabled the extraction of specific medical imaging data from designated patient cohorts. The hypertensive, diabetic, and control cohorts were easily constructed using ATLAS, an open-source software provided by the Observational Health Data Sciences and Informatics (OHDSI) group, which manages OMOP-CDM development [12]. Once these cohorts were established, the OCT imaging data collected from each cohort were uniformly extracted using the R-CDM (Figure 3). In this study, all OCT data taken after the index date of each patient cohort were used for analyses.

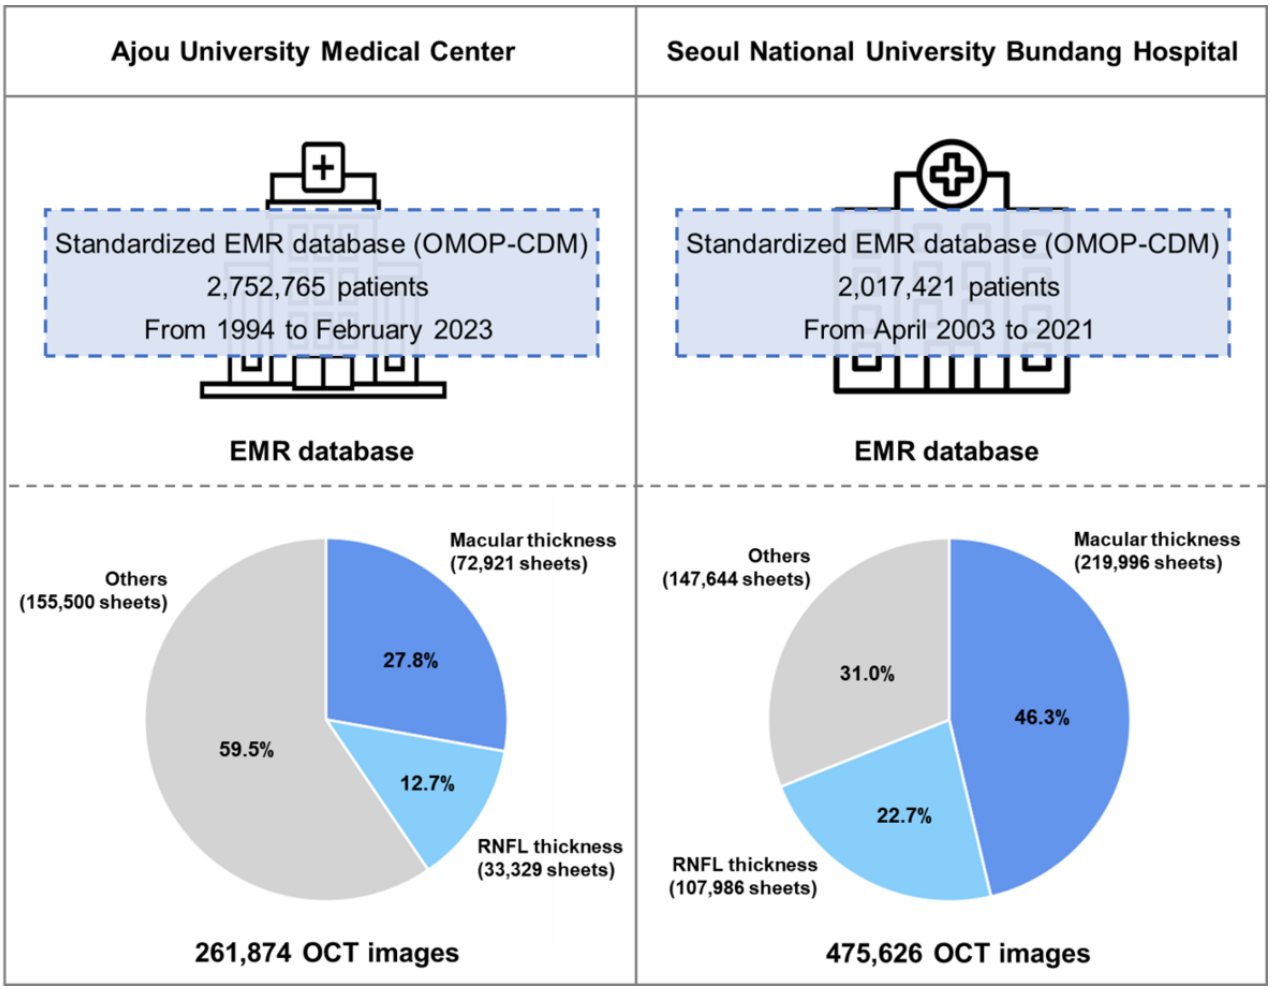
Figure 3. Schematic illustration of the integration between the OMOP-CDM and Radiology-CDM for extracting optical coherence tomography data from chronic disease and control cohorts. CDM: Common Data Model; OMOP-CDM: Observational Medical Outcome Partners-Common Data Model.

Extracting Retinal Thickness Values From OCT Data Using OCR Techniques

While the R-CDM database included information that was useful for describing and categorizing images, it lacked the pixel data from each image. Therefore, to extract recorded retinal thickness values from OCT data via the R-CDM, an additional OCR technology was required. The same OCR techniques previously used to extract metadata from OCT images for the R-CDM transformation were used. However, retinal thickness data within the OCT imaging data captured using Zeiss equipment at AUMC were recorded at inconsistent locations and centered on backgrounds of various colors, significantly reducing OCR accuracy. Initially, the process involved cropping the segments containing information and performing OCR using the Tesseract package (Python), consistent with the existing methods. Thereafter, all extracted data were manually reviewed by a single researcher. Through this method, retinal nerve fiber layer (RNFL) thickness and central macular thickness (CMT) were successfully extracted from OCT imaging data of chronic disease cohorts and control cohorts from the two institutions.

Statistical Analysis 2: Retinal Thickness Analysis Using Mixed-Effects Regression Analysis

We used the mixed-effects regression analysis to examine the CMT and RNFL thickness across the chronic disease and control cohorts. This analysis was crucial for determining if the differences in retinal thickness between the two groups were statistically significant at multiple time points and whether the changes in retinal thickness over time were significant. Furthermore, the model was specifically designed to adjust for confounding factors that could influence the retinal thickness, allowing for the independent analysis of the effects of the treatment duration on the former. Additionally, the model accommodated data from repeated measurements taken from the same individuals. The model we designed for this study was adjusted for age and sex and incorporated patient study ID as a random effect for repeated measures.



Results

Composition of R-CDM–Standardized OCT Data

In this study, we used CDM databases from two medical institutions along with an R-CDM–standardized OCT database. The OCT data from AUMC and SNUBH, standardized in the R-CDM format, consisted of data from 261,874 and 475,626 patients, respectively. The specific composition of the data is presented in Figure 4. For our analysis, a total of 292,917 OCT images of the macular thickness and 141,314 OCT images of the RNFL thickness were used.

Study Population

Figure 5 illustrates the patient selection process across two tertiary hospitals in South Korea, using the AUMC and SNUBH databases. Within the T2DM cohort, from a total of 53,413 patients with diabetes and 1391 individuals who had undergone OCT imaging and were not diagnosed with or treated for any retinal diseases were selected. In the control cohort, out of 116,637 patients who underwent OCT imaging, 25,442 with no history of diabetes or retinal disorders were chosen. Following 1:2 PSM, 957 patients from the T2DM cohort and 1,603 from the control cohort were matched. After PSM, the median age group for the T2DM and control cohorts was 60 - 64 years. Additionally, females accounted for 44.6% (427/957) and 43.9% (703/1603) of patients in the T2DM and control cohorts, respectively.

Table 1 presents the baseline characteristics, including patient demographics and comorbidities, along with aSMDs before and after PSM at AUMC. Before PSM, higher prevalences of chronic conditions such as chronic liver disease, hyperlipidemia, and obesity, as well as cardiovascular diseases including coronary arteriosclerosis and peripheral vascular disease were observed in the T2DM group (all aSMDs>0.1). After matching, age, sex, and comorbidities were well-matched (all aSMDs<0.1). This trend was consistent with findings at SNUBH, as detailed in Multimedia Appendix 1. Additionally, the baseline characteristics before and after 1:1 and 1:4 PSM for the T2DM and control cohorts and the results for the hypertension versus control cohort are outlined in Tables E1 and E2 in Multimedia Appendix 1.

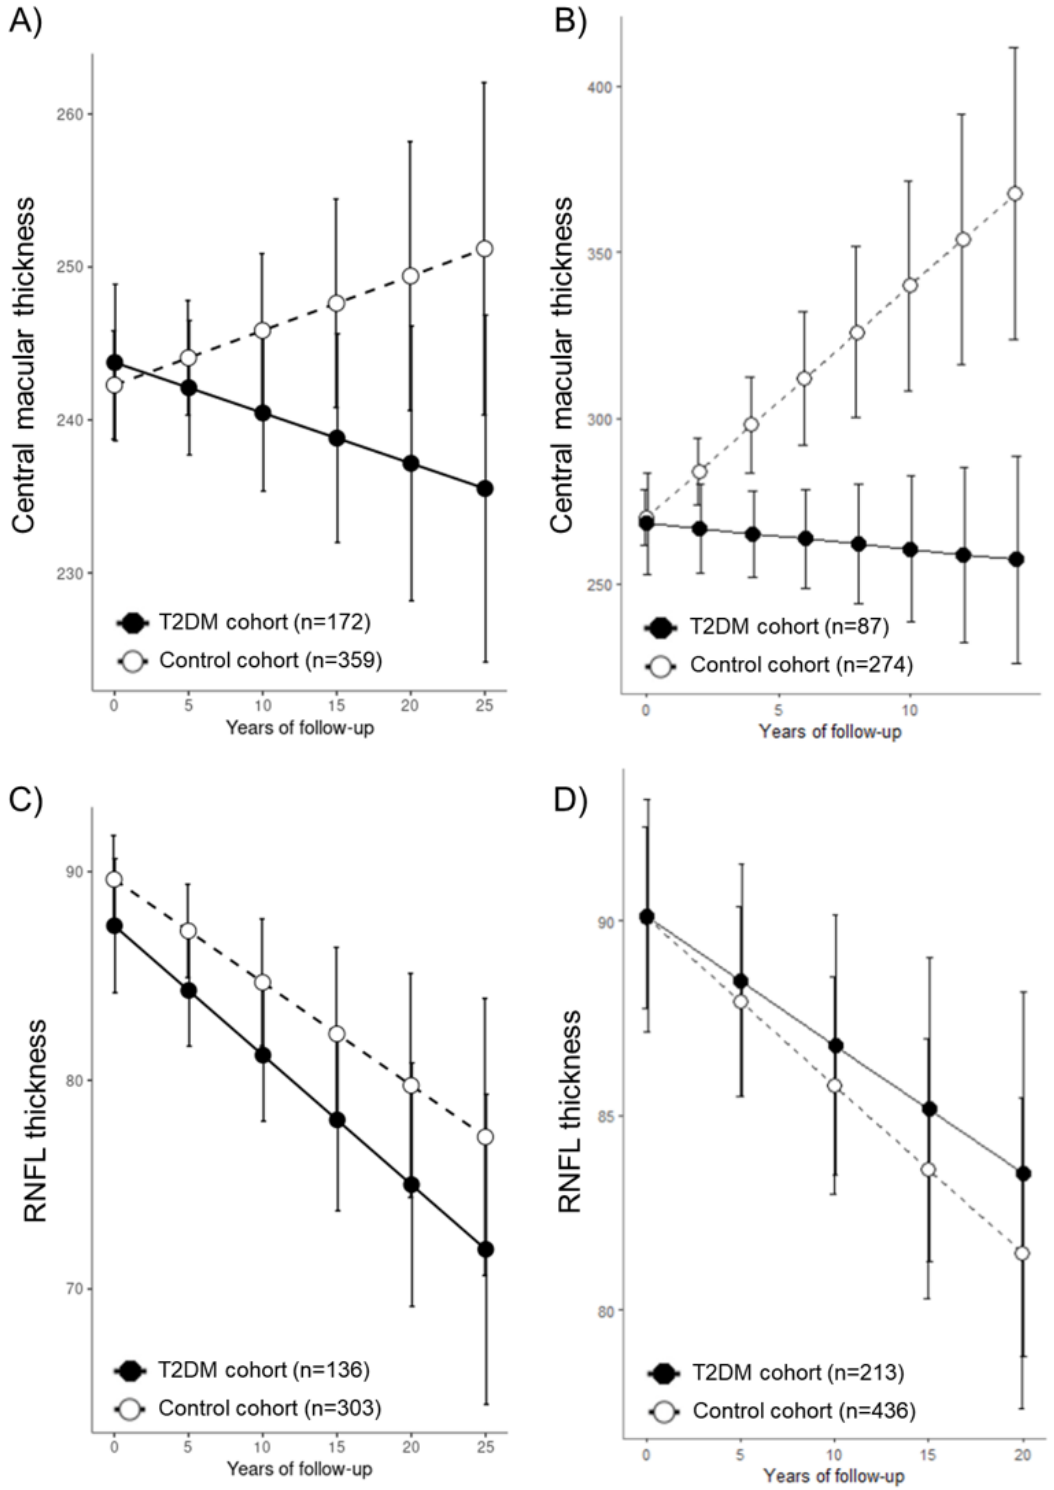
[c]aSMD: absolute standardized mean difference.

Clinical Outcomes



The median follow-up period was 807 (IQR 215-2523) days (4105 person-years) in the T2DM cohort and 966 (IQR 265-2946) days (4641 person-years) in the control cohort. In a longitudinal study using a mixed-effects regression, we investigated differences in retinal thickness between the T2DM and control cohorts (Figure 6). Throughout the follow-up period at both AUMC and SNUBH, the CMT significantly decreased in the T2DM cohort compared with the control cohort (P=.04 and P=.007, respectively; detailed in Tables E3-4 and E4-4 in Multimedia Appendix 1). Initially, there were no significant differences in CMT between the T2DM and control cohorts. However, significant reductions in CMT in the T2DM cohort, compared with the control group, began from the 15th year of follow-up at AUMC and the 5th year at SNUBH (Tables E3-5 and E4-5 in Multimedia Appendix 1). Conversely, the RNFL thickness analysis revealed no significant changes in the T2DM and control cohorts during the follow-up period, and there were no significant differences between them at any time point. These findings were consistent across both institutions.

For retinal thickness comparisons between the hypertension and control cohorts during the follow-up period, a decreasing trend in CMT in the hypertension cohort compared with the control cohort was observed only at AUMC (P=.04), while no such trend was noted at SNUBH (P=.56), as detailed in Tables E3-4 and E4-4 in Multimedia Appendix 1. Additionally, the analysis of RNFL thickness showed no significant differences between the cohorts.

For the sensitivity analysis, chronic disease and control cohorts were matched in 1:1 and 1:4 ratios to analyze the CMT and RNFL thickness, with results detailed in Tables E3 and E4 and Figures E4 and E5 in Multimedia Appendix 1. The analysis of CMT between the T2DM and control cohorts revealed that, except for one outcome (1:1 at SNUBH; P=.24), all other results were consistent with the main findings, showing a significant decrease in CMT in the T2DM cohort throughout the follow-up duration. Additionally, while results at AUMC indicated a marginally significant decrease in CMT in the hypertension cohort compared with the control cohort during the follow-up period (all P<0.1), no significant differences were observed at SNUBH.

Discussion

Principal Results

In this study, OCT imaging data collected from two tertiary hospitals for research purposes were standardized into the R-CDM format. We developed an environment that integrates this standardized OCT database with the previously established OMOP-CDM database at each medical institution, allowing for the systematic extraction of specific imaging data types captured by patient cohorts built with the OMOP-CDM. As a proof of concept, we assessed the changes in retinal thickness in patients with chronic diseases over an extended period. Notably, we observed a significant reduction in the CMT among patients

XSL•FO
RenderX

who had been receiving long-term treatment for T2DM at both institutions. This research is believed to be the first global study to simultaneously use OCT data and clinical data, demonstrating that the application of the R-CDM can significantly enhance the efficiency of multicenter collaborative research that integrates clinical and imaging data.

The R-CDM used in this study for OCT data standardization represents the first model to standardize medical imaging data based on the OMOP-CDM. It is available as an open-source software program on the official OHDSI GitHub site and was published in a 2022 paper [5] that elaborates on the structural design and terminology system of the R-CDM, and as a proof of concept, it standardizes 90 million sets of medical imaging data collected for research purposes from AUMC. Both domestically and internationally, there have been instances in which the R-CDM has been used to standardize imaging data and facilitate research with these standardized datasets. For instance, Wonkwang University Hospital established an R-CDM database of standardized abdominal computed tomography (CT) data for 123 patients with cirrhosis and 123 control patients, using these data to develop a predictive model for cirrhosis [13]. Additionally, the paper introduced a web-based management system enabling researchers to search for and download standardized R-CDM datasets, enhancing the accessibility and utility of the R-CDM. Furthermore, a study by Lee et al [14] used clinical data, magnetic resonance imaging (MRI) data, and clinical notes simultaneously to develop a multimodal deep learning model predicting treatment-resistant depression, using AUMC's R-CDM database to extract MRI data that was suitable for study conditions. Additionally, within the European Health Data & Evidence Network project, the R-CDM was used to standardize brain CT and MRI data. This standardization successfully integrated quantitative data extracted from brain imaging studies by Icobrain's AI model [15]. Therefore, the R-CDM supports global researchers in efficiently leveraging their medical imaging data for advanced studies.

In addition to the R-CDM used in this study, various other efforts exist to standardize medical imaging data. Rubin et al [16] proposed common data elements, which standardize radiologic reports using a uniform terminology and structure. Although common data elements effectively standardize data produced in radiology, they encounter difficulties when integrating with standardized clinical databases like the OMOP-CDM. Furthermore, there are two additional efforts to standardize medical imaging data based on the OMOP-CDM. The first is the medical imaging common data model (MI-CDM) developed by the Foundation of Research and Technology Hellas [17], and the second is the MI-CDM codeveloped by Yonsei University and Johns Hopkins University [18]. Both MI-CDM models not only facilitate the extraction of necessary data by standardizing medical imaging data, but they also design tables to accommodate features from images, thereby enhancing the efficiency of the use of these features in research. While the structures of the models differ slightly from each other, the majority of their architectures are considerably similar, and their standardization methods and principles are consistent. Researchers can select the model that best suits their immediate needs and later convert it to another model format with simple modifications to the database if needed. The multiple cases of the R-CDM and the development of enhanced models demonstrate the demand among researchers to use medical imaging data more efficiently.

In this study, we observed a significant reduction in CMT in patients receiving long-term treatment for T2DM compared to the control group, with an annual decrease of −0.69 µm (95% CI −1.34 to −0.03; *P*=.04) at AUMC and −7.78 µm (95% CI −11.84 to −3.71; *P*<.007) at SNUBH. In contrast, RNFL thickness showed no significant difference in annual changes between the two groups (AUMC: −0.13 µm, 95% CI −0.55 to 0.30, *P*=.56; SNUBH: 0.10 µm, 95% CI −0.13 to 0.32, *P*=.39). This finding highlights the subtle but measurable structural changes that occur in the macula as a result of prolonged exposure to diabetes. However, there was no significant difference in the rate of RNFL changes over time between the two groups. These results are consistent with findings reported by Oshitari et al [19], where the CMT in patients with diabetes without diabetic retinopathy was significantly thinner compared to the control group (mean 210.7, SD 28.6 µm vs mean 195.6, SD 23.3 µm; *P*=.02). Similarly, while RNFL thickness in the group without diabetic retinopathy was thinner than the control group (mean 104.4, SD 10.9 µm vs mean 100.4, SD 13.7 µm) the difference was not statistically significant. A study conducted at the Jamaica Plain Veteran's Affairs Medical Center further supports these findings, reporting a significant decrease in macular thickness associated with a longer duration of diabetes in the group without diabetic retinopathy. They observed a significant negative correlation between retinal thickness and diabetes duration (central foveal thickness: *r*=−0.30, *P*=.003; total foveal thickness: *r*=−0.26, *P*=.012; total macular thickness: *r*=−0.26, *P*=.013) [20]. The observed reduction in macular thickness, which was significantly correlated with the duration of diabetes, is likely attributed to retinal neurodegeneration, an early event in the pathogenesis of diabetic retinopathy that precedes and contributes to diabetic microangiopathy [21].

Retinal thickness comparisons between the hypertension group and the control group revealed that only at AUMC did patients with long-term hypertension exhibit a reduction in CMT (−0.81 µm/y, 95% CI −1.57 to −0.06; *P*=.04). These findings align with prior studies conducted at Izmir Military Hospital and Samsung Medical Center, which also reported decreased macular thickness in patients with hypertension compared to control patients [22,23]. The Izmir Military Hospital reported a significantly thinner mean macular thickness in the hypertension group compared to the control group (mean 254.97, SD 21.81 µm vs mean 262.11, SD 21.05 µm; *P*=.037). Similarly, a study from Samsung Medical Center reported a significant reduction in percent thickness in patients with hypertension compared to control patients, with changes of –1.6% (95% CI −2.59% to −0.6%; *P*=.02) in the composite inner macula and −2.26% (95% CI: −3.32% to −1.19%; *P*<.01) in the composite outer macula.

Conversely, other studies have reported significantly thinner CMT and RNFL in patients with hypertension, highlighting the association between systemic hypertension and retinal microvascular abnormalities, such as retinal arteriolar narrowing and ischemic retinal disorders. These findings underscore the importance of prompt and effective management of systemic

XSL•FO
RenderX

hypertension [7,24-27]. Notably, our study excluded all patients diagnosed with retinal or choroidal disorders by leveraging SNOMED codes and used large-scale PSM with thousands of covariates to control for baseline differences between groups. While these methodological approaches may account for some discrepancies with earlier studies, further large-scale research is needed to provide more conclusive evidence.

Large-scale PSM methodology, which was actively used and validated by the OHDSI community, meticulously matched baseline characteristics between the patient and control groups. This approach incorporated more covariates than reported in previous studies [28]. Additionally, while the existing literature indicates that the macular thickness is significantly higher in males than in females [29,30] and decreases with age [6,31], our study used a linear mixed model to comprehensively adjust for variables that significantly affect this parameter. Moreover, to generate more robust evidence, we conducted analyses with the same settings across multiple institutions. However, to date, most studies exploring the association between chronic diseases and retinal thickness using OCT data have been conducted at single institutions. This is primarily due to the diverse data storage formats across medical facilities, making cross-institutional research exceedingly labor-intensive. Furthermore, as our study requires both clinical and imaging data, the workload for data preprocessing increases exponentially. By leveraging the OMOP-CDM and the associated R-CDM system, we demonstrated a significant reduction in inefficiency. We anticipate that future research will achieve greater scalability and generate more generalized and impactful findings through multi-institutional analyses using the R-CDM.

Limitations

Nevertheless, this study has the following limitations. First, while the R-CDM significantly enhances the use of medical imaging data, we encountered persistent inefficiencies due to stringent governance requirements for research approval. Although we had unrestricted access to OMOP-CDM standardized EMR databases from two institutions, the acquisition of imaging data for research purposes remained time-consuming and labor-intensive. This underscores the necessity for a more comprehensive R-CDM that standardizes all medical imaging data across multiple institutions, which is our ultimate objective. We anticipate that as the R-CDM gains widespread acceptance comparable to the OMOP-CDM, more health care institutions will adopt it for standardizing all of their medical imaging data, thereby facilitating more efficient multicenter studies incorporating imaging data. Second, due to the inherent characteristics of OCT medical devices that do not automatically integrate with the EMR or the picture archiving communication system, this study was limited to using data from OCT devices specifically approved for research purposes at each institution. Nevertheless, by securing all OCT data from specific periods and specific equipment, we minimized potential biases in data acquisition. In future investigations, we aim to incorporate all available OCT data from both institutions to enhance the robustness and generalizability of our findings. Third, despite using data from two major tertiary hospitals in Korea, the final cohort for retinal thickness analysis comprised fewer than 2000 patients. While our cohort definition and large-scale PSM technique ensured balanced comparisons, it resulted in the exclusion of a substantial number of patients. To address these limitations, we propose conducting large-scale collaborative studies involving multiple medical centers, which would ensure a sufficiently large sample size for more conclusive research.

Conclusion

OCT imaging data were standardized into the R-CDM format from two tertiary hospitals in South Korea, and changes in the retinal thickness in patients with chronic diseases were analyzed as a proof of concept. To maximize the use of available data, mixed-effects regression analyses were conducted, revealing that patients with long-standing T2DM exhibited a significant reduction in CMT over time compared with those without the condition. The construction of R-CDM databases across multiple institutions and its integration with the OMOP-CDM has established a robust foundation for conducting efficient multi-institutional collaborative research using both clinical and imaging data, marking a significant step forward in the domain of multidisciplinary research collaborations.

Acknowledgments

This research was supported by the Korea Health Technology R&D Project and the MD-PhD/Medical Scientist Training Program through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (grant number: HR16C0001). Additional support was provided by a grant from the Project for Infectious Disease Medical Safety, funded by the Ministry of Health & Welfare, Republic of Korea (grant number: HG22C0024). Further funding was received from the Korea Environment Industry & Technology Institute (KEITI) through the Core Technology Development Project for Environmental Diseases Prevention and Management, funded by the Korea Ministry of Environment (MOE; grant number: 2022003310001). The funders had no role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Data Availability

The datasets generated during and/or analyzed during this study are available on reasonable request once a proposal is approved, coupled with a signed data access agreement and in collaboration with the study group.

Abstract

Background: Adverse drug events (ADEs) lead to more than 2 million emergency department visits in Canada annually, resulting in significant patient harm and more than CAD $1 billion in health care costs (in 2018, the average exchange rate for 1 CAD was 0.7711 USD; 1 billion CAD would have been approximately 771.1 million USD). Effective documentation and sharing of ADE information through electronic medical records (EMRs) are essential to inform subsequent care and improve safety when culprit medications can be replaced and reexposures avoided. Yet, current systems often lack standardized comprehensive ADE value sets.

Objective: This study aimed to develop a SNOMED CT value set for symptoms and diagnoses to standardize ADE documentation and improve ADE data integration into EMRs.

Methods: We used ADE data from ActionADE, a prospective reporting system implemented in 9 hospitals in British Columbia. We extract 5792 reports that yielded 827 unique ADE symptom and diagnosis terms based on Medical Dictionary for Regulatory Activities preferred terms. Two independent mappers used both automated and manual mapping approaches to match these terms to SNOMED CT concepts. Two clinical experts conducted validation, followed by a quality assurance review by a separate clinical team. Discrepancies were resolved through consensus discussions. Interrater reliability was assessed using Cohen κ.

Results: The automated mapping process identified 63.1% (522/827) semantically equivalent matches from SNOMED CT's Clinical Finding hierarchy. Two mappers manually reviewed the automatically mapped terms and identified appropriate target concepts for the unmapped terms. After the manual mapping process, 95.3% (788/827) of the source terms were successfully mapped to SNOMED CT concepts, with 4.7% (39/827) remaining unmapped. Interrater reliability between the mappers was strong (κ=0.87, 95% CI 0.85 - 0.89). The validation phase identified and removed 1 irrelevant term, resulting in 98.4% (813/826) terms mapped, with 1.6% (13/826) unmapped, and a high interrater reliability (κ=0.88, 95% CI 0.80 - 0.95). During quality assurance, 6 terms were flagged for concerns regarding clinical relevance or safety risks and were resolved through discussions. The final value set comprised 813 SNOMED CT concepts, with 95.7% (778/813) of terms classified as semantically equivalent and 4.3% (35/813) as semantically similar. Thirteen additional terms remained unmapped and will be reviewed as new SNOMED CT codes are added.

Conclusions: This study developed a SNOMED CT–based value set to document symptoms and diagnoses for ADEs observed in adults in EMRs. Adopting this value set can improve the consistency, accuracy, and interoperability of ADE documentation in EMRs, helping to reduce repeat ADEs and enhance patient safety. Ongoing refinement and improved clinical usability are essential for its widespread adoption. Future research should assess the impact of integrating this value set into EMRs on ADE reporting, pharmacovigilance, and patient safety outcomes.

Introduction

Every year, more than 2 million Canadians visit an emergency department due to adverse drug events (ADEs)—unintended and harmful events related to medication use [1,2]. These events lead to more than 700,000 hospital admissions and exceed CAD $1 billion in health care costs across Canada annually (in 2018, the average exchange rate for 1 CAD was 0.7711 USD. 1 billion CAD would have been approximately 771.1 million USD) [2,3]. Critically, 75% of these events are preventable [4,5]. A common cause of preventable ADEs is the represcription or redispensing of the same or a similar class of medication that previously caused harm, which may or may not be warranted [6,7]. Addressing unintentional repeat ADEs is essential to enhancing patient safety and aligns with the World Health Organization's public health priorities [8].

Unintentional repeat ADEs may occur because health systems lack effective mechanisms to communicate and integrate ADE information into clinical workflows [9]. For example, community pharmacists lack access to hospitals' electronic medical records (EMRs) and do not receive discharge summaries or consultation notes, leaving them unaware of ADEs diagnosed in hospital where safer alternatives may exist and where reexposure should be avoided [10,11]. This communication gap presents a critical opportunity to reduce repeat ADEs through improved data-sharing practices [12].

The widespread adoption of EMRs offers an opportunity to enhance the documentation and sharing of ADE information among health care providers [13-15]. However, for this information to be effectively shared across clinical disciplines and care settings and follow the patients along their care trajectory, it must be recorded, stored, and shared in a standardized form. Currently, most EMRs include allergy modules for documenting symptoms and diagnoses related to ADEs. Allergies constitute a small percentage of clinically significant ADEs, and many are subsequently refuted [16]. Current EMR modules often rely on nonstandardized adverse reaction code sets provided by third-party vendors, with varying quantity, quality, and data standards. This hinders the uniform documentation, extraction, and sharing of ADE data [17]. Inconsistent and nonstandardized ADE documentation can lead to underreporting and miscommunication, contributing to adverse patient outcomes and posing challenges for population-level pharmacovigilance efforts. Studies have shown that ADEs are responsible for 6%-27% of adult patients' hospital or acute medical unit admissions, with a substantial portion being preventable through accurate tracking and effective communication [18,19].

Adopting standardized value sets can bridge these discrepancies and improve the reliability of clinical documentation [17]. This standardization is particularly important in reducing unwarranted clinical variation, ultimately leading to more consistent and evidence-based care [20]. A value set is a collection of coded values from 1 or more terminologies that is intended for use in a particular context [21]. Selecting terminologies with broad applicability across a range of clinical areas can help create robust and effective value sets.

While several terminology standards are available to document symptoms and diagnoses of ADEs, not all are ideal for use in EMRs due to limitations in granularity, hierarchical design, and semantic expressivity. For example, the Medical Dictionary for Regulatory Activities (MedDRA) and the *International Classification of Diseases, Tenth Revision* (*ICD-10*) have limitations that impede effective data capture and integration within EMRs. Although MedDRA is designed for pharmacovigilance, its terms are categorized at high level without distinguishing specific conditions, limiting its clinical use. Its hierarchical structure is broad and fixed, limiting its flexibility to support detailed data retrieval and analysis [22,23]. Bodenreider [24] has discussed its limitations when used in isolation and the potential benefits of combining it with SNOMED CT for improved signal detection and ADE reporting. Similarly, *ICD-10* is primarily designed for billing and statistical reporting. Its broad disease categories can fail to capture the nuances of complex clinical relationships, such as disease severity, laterality, or specific symptoms, lacking the clinical granularity needed for detailed ADE documentation within patient records. These limitations impact real-time decision-making [25-27].

In contrast, SNOMED CT (Clinical Terms) is specifically developed to support detailed clinical documentation and interoperability across various health care settings. It offers more than 300,000 active concepts that cover a broad range of clinical areas, allowing for precise and consistent recording of patient information [28-30]. SNOMED CT key strengths lie in its granularity, polyhierarchy, and semantic expressivity. making it a preferred choice as the basis of clinical documentation within EMRs across multiple jurisdictions [31]. Alecu et al [32] demonstrated that SNOMED CT's hierarchical structure is particularly useful for grouping ADE terms, which can aid in clinical decision-making and data analysis. However, if left unconstrained, its vast size and complexity can be overwhelming for end users. Therefore, SNOMED International recommends the development of subsets or value sets that cater to specific clinical use cases, such as ADEs.

There are currently no internationally published SNOMED CT value sets designed to streamline and standardize clinical documentation of ADE symptoms and diagnoses. This study aimed to fill this gap by developing a SNOMED CT–based value set to document and code symptoms and diagnoses of ADEs in EMRs. By doing so, we can enhance the reliability and consistency of ADE documentation and improve patient safety.

RenderX

Methods

Setting

We used ADE data from ActionADE, an ADE reporting system. ActionADE is a web-based application designed to address repeat ADEs, which occur in 32.5% (421/1296) of emergency department cases. Repeat ADEs often occur because health systems lack effective means of communicating and integrating ADE information into clinical workflows [10]. A systematic review, participatory design process and pilot testing, involving software developers and end users, was completed to optimize the system to integrate ADE information into clinical workflows [11,33]. ActionADE allows providers to document and communicate ADE information bidirectionally through its integration with the provincial drug-dispensing database (PharmaNet) to providers in other health settings. Preliminary results showed that ActionADE prevents culprit or same-class medication redispensations in 33% of patients who present to a community pharmacy with a culprit or same class medication prescription [34].

ActionADE contains patient's ADE information entered by clinicians across acute care hospitals serving adult populations within the Vancouver Coastal Health Authority, British Columbia, since 2021 [25]. Between May 1, 2021, and May 1, 2024, ActionADE captured 5900 ADE reports. After excluding 108 reports with missing symptom and diagnosis information, we extracted source terms from a final sample of 5792 reports.

Data Extract and Processing

Each of the 5792 reports contained up to 3 ADE symptoms and diagnoses, which we extracted into an Excel file. After removing duplicates, we identified 881 unique terms. ActionADE uses MedDRA preferred terms for documenting ADE symptoms and diagnoses, based on its usability, and as recommended for reporting to Health Canada's pharmacovigilance database [35]. Since data entry into ActionADE is restricted to the use of MedDRA preferred terms, data are already standardized and free from potential data entry errors. We linked the 881 terms to MedDRA numeric codes, resulting in 879 coded terms and 2 uncoded terms. Upon review, we removed the 2 uncoded terms as they were noncurrent. Additional adjustments, such as removing irrelevant terms and duplicate entries, updating display names, and merging terms with different spelling but the same codes, resulted in a final source code set of 827 terms.

Mapping Approach

Our mapping approach was informed by the SNOMED CT-AU mapping guide [36] and enhanced by additional resources [36-38]. It consisted of the following steps: (1) define purpose and scope of the map, (2) identify personnel, (3) define mapping rules, (4) select mapping tool, (5) map source to target (automated and manual), (6) validation, and (7) quality assurance and creation of the value set.

Define Purpose and Scope of the Map

Defining the purpose and scope of the map helps ensure that the mapping aligns with the intended use of the terminology and covers the necessary range of source and target codes with the appropriate granularity [30,36]. The purpose of this mapping is to standardize the documentation of symptoms and diagnoses of ADEs within EMR. This involves mapping ADE symptoms and diagnoses documented in MedDRA preferred terms to corresponding SNOMED CT concepts within the clinical finding hierarchy.

Identify Personnel

The mapping team should be composed of individuals with extensive knowledge in health terminology standards and clinical practice to ensure the effective management and accuracy of the mapping process. In this study, the mapping process was designed and overseen by a mapping manager with specialized graduate training in health terminology standards. Execution was led by 2 mapping team members (Y-L AC and AL), both research pharmacists with extensive experience in clinical applications and practice. The team also included 2 clinical map advisors (CH and KB): an emergency physician and health services researcher specializing in drug safety and health IT, and a clinical pharmacist with extensive research and clinical practice experience in this area. Additionally, a technical advisor (LB), who is an expert in health informatics and SNOMED CT, provided essential technical oversight and support.

Define Mapping Rules

This unidirectional mapping from MedDRA to SNOMED CT involved matching each MedDRA preferred term to a semantically equivalent SNOMED CT concept (ie, they mean the same thing), ensuring accuracy in the representation of clinical data.

Select Mapping Tool

We used Snap2SNOMED, a mapping tool provided by SNOMED International, to conduct the mapping [39]. Snap2SNOMED is an online platform designed for creating and maintaining simple maps from other code systems to SNOMED CT. It allows teams of users to author and review a map. It has a built-in search engine that allows users to browse SNOMED CT concepts while mapping. Users can import their own code sets and export maps in various formats, such as CSV, TSV, and XLSX. Snap2SNOMED allowed us to import our source term file, use the MedDRA-SNOMED CT cross map, and automate much of the mapping process, which was then reviewed and refined by the team.

Map Source to Target

We used a dual mapping process where 2 mappers independently identified and documented semantically equivalent SNOMED CT concepts for each source term. If an exact match was unavailable, the mappers documented up to 3 semantically similar concepts, marking them as inexact, broader, or narrower matches. For example, "heart attack" is a semantically equivalent match to "22298006 | Myocardial infarction" as both represent the exact same clinical condition. A narrower match occurs when "heart attack" is mapped to "57054005 | Acute myocardial infarction (disorder)," which represents a specific type of myocardial infarction. When selecting a target code, the mappers reviewed the concept's fully specified name (FSN) and its parent and child concepts within the hierarchy to ensure

XSL•FO
RenderX

semantic accuracy. The mapping process involved two key strategies:

1. Automated mapping: We first used the MedDRA-SNOMED CT cross map to identify appropriate target concepts. This cross map was developed by SNOMED International in collaboration with the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use. This map supports interoperability between terminologies by linking commonly used pharmacovigilance terms from MedDRA to SNOMED CT. The cross map released on April 30, 2024, includes 6779 MedDRA lower-level terms and 3594 SNOMED CT FSNs [5]. While ActionADE relies on MedDRA preferred terms, each preferred term is associated with a single lower-level term, so this did not impact our mapping process [22].
   The mapping manager imported the source code set and the cross map into Snap2SNOMED. The map was constrained to the Canadian Edition (version: 20240531) and the SNOMED CT clinical finding hierarchy. The software automatically mapped the source terms to SNOMED CT concepts within the cross map. Then, it generated a table with each row representing a single source term, displaying its corresponding source code, source display, target code, and target display. For matched terms, the relationship type was default as "EQUIVALENT," with the status marked as "DRAFT."
2. Manual mapping: For each automatically mapped term, the mappers independently reviewed and edited the suggested target terms and relationship types, updating the status to "MAPPED" upon completion.
   For source terms that were unmatched in the automated mapping, the mappers used Snap2SNOMED's built-in search function to identify target terms. By entering the source term in the search box, the software provided a list of suggested target concepts. The mappers reviewed the suggested terms and their attributes, selected the most appropriate candidate concept, assigned it to the source code with a relationship type (equivalent, broader, narrower, and inexact), and marked the status as "MAPPED" or "NO MAP" if no suitable match was found. For the source terms that lacked semantically equivalent matches, the mappers were asked to suggest up to 3 broader, narrower, or inexact alternatives (see Snap2SNOMED screenshots in Multimedia Appendix 1).

The mapping manager then exported and compared the maps from both mappers. A mapping was considered complete when both mappers independently identified the same SNOMED CT concept as the target. Any discrepancies were discussed and resolved through a virtual meeting moderated by the mapper manager. If consensus could not be reached, the issues were documented and adjudicated by the clinical advisors [36].

Validation

Two validators (CH and KB) independently evaluated the initial map using Snap2SNOMED. For each row, they reviewed the mapped terms and marked the status as either "ACCEPTED" or "REJECTED," recording the rationale for any rejections in the notes section. A map was considered correct only when both reviewers agreed on the target SNOMED CT concept (Multimedia Appendix 1). The mapping manager then exported and compared the results from both validators, consolidating a list of discrepancies. A virtual meeting was held to discuss and resolve these discrepancies. If consensus could not be reached, the issues were escalated to an additional reviewer and, if necessary, further to the technical advisor.

Quality Assurance and Creation of the Value Set

Quality assurance was performed by clinical experts who were not involved in the initial mapping and validation process [30,38]. A quality review team, consisting of 2 pharmacists (SB and CS) and a physician (KG-K), evaluated the final map for mapping appropriateness, safety risk, and clinical relevance. Each reviewer reviewed all the terms included in the validated map and flag terms with concerns by adding a note on the Snap2SNOMED platform.

As a final step, the reviewers completed a survey to assess clinical relevance of the validated map. The survey included two questions: (1) Does the current map capture the majority of ADE symptoms and diagnoses commonly encounter in your clinical practice? If not, which key terms are missing? (2) Are there any terms in the map that seem clinically irrelevant to your practice, or do you have suggestions for alternative terms that should be considered in future iterations? Terms flagged by 2 or more reviewers were discussed by the entire team to reach a consensus. This feedback was then used to finalize the value set.

Ethical Considerations

This study is exempt from ethical review according to The University of British Columbia Research Ethics Board policies (sections 4.3.2. and 4.3.3) [40] and TCPS 2 Article 2.3 [41]. The ActionADE dataset used for developing the MedDRA-SNOMED CT map was collected under prior ethical approval, with informed consent obtained from participants allowing for secondary research use. All data were deidentified. Individuals involved in the mapping and validation participated voluntarily, were informed of the study purpose, and provided implied consent. No personal identifiers were collected or shared, no compensation was provided, and the activities posed minimal risk; therefore, ethics review was not required.

Statistical Analysis

We used descriptive statistics to calculate the number and percentage of source terms that matched a corresponding SNOMED CT concept by relationship type in the initial map and validated map. The agreement between mappers was evaluated by checking whether their first selected SNOMED CT concept for each source term matched (first match). Interrater reliability across 2 mapping reviewers and 2 validators was calculated using Cohen κ statistics via the R package "irr" (University of Zurich) [42].

XSL•FO
RenderX

Results

Map Source Terms to SNOMED CT Concepts

The automated mapping identified 63.1% (522/827) semantically equivalent matches and 36.9% (305/827) unmatched terms. After manual mapping, mapper 1 identified 91.1% (753/827) semantically equivalent matches, 5.7% (47/827) semantically similar matches, and 3.2% (27/827) no match terms. Mapper 2 identified 85.0% (703/827) semantically equivalent matches, 8.0% (66/827) semantically similar matches, and 7.0% (58/827) no match terms (Table 1). All automatically mapped terms were accepted by both mappers.

For the source terms that lacked semantically equivalent matches, the mappers were asked to suggest up to 3 broader, narrower, or inexact alternatives. Mapper 1 suggested 57 target terms for 47 source terms without equivalent matches, averaging 1.2 suggestions per term. Mapper 2 proposed 66 target terms for 66 source terms, averaging 1.0 suggestion per term. A detailed breakdown of the semantically similar terms suggested by the mappers is shown in Table 2. The interrater reliability between the 2 mappers, measured by Cohen κ, was 0.87 (95% CI 0.85 - 0.89), indicating strong agreement [43].

We identified 139 terms with discrepancies between the mappers. These were all resolved through consensus discussions. Based on these results, we created an initial map that included 827 source terms, of which 95.3% (788/827) were successfully mapped to a SNOMED CT concept, while 4.7% (39/827) remained unmapped. Among the mapped terms, 96.8% (763/788) were semantically equivalent, 1.5% (12/788) were broader, 0.8% (6/788) were narrower, and 0.9% (7/788) were inexact matches.

Table . Mapping results across all source terms.

Category	Mapper 1	Mapper 2
Semantic equivalent match	753	703
Semantic similar match	47	66
No match	27	58
Total	827	827

Table . Breakdown of semantically similar terms suggested by mappers.

Category	Mapper 1	Mapper 2
Semantically broader than the source term	23	12
Semantically narrower than the source term	24	25
Semantically inexact to the source term	10	29
Total	57[a]	66[b]

[a]Mapper 1 suggested 57 target terms to describe 47 source terms without a semantically equivalent match, resulting in an average of 1.2 target terms per source term.

[b]Mapper 2 suggested 66 target terms to describe 66 source terms without a semantically equivalent match, resulting in an average of 1.00 target terms per source term.

Validation

Validation by 2 clinical experts resulted in 92.3% (763/827) of terms being accepted as semantically equivalent matches, 3.0% (25/827) were semantically similar, and 4.7% (39/827) were unmatched. A detailed breakdown of the semantically similar terms identified by the validators is shown in Table 3. The agreement between the 2 validators was strong, with a Cohen κ of 0.88 (95% CI 0.80 - 0.95) [43]. All automatically mapped terms were accepted by both validators.

We identified 42 terms where discrepancies arose between the validators, which were resolved through consensus discussions. One source term (ie, “endotracheal intubation”) was deemed irrelevant as it represents a clinical procedure rather than an ADE symptom or diagnosis and was therefore removed. A key point during the discussions for the remaining terms was the user-friendliness of the mapped terms. Validators noted that in some cases, semantically similar terms were preferred over semantically equivalent ones for ease of use. For instance, the term “sunburn” had an equivalent match with |403194002| “Solar erythema (disorder),” but the validators flagged this term as non–user-friendly due to lack of clinical use, recommending that “sunburn” to be added as a synonym in the Canada English language reference set. Table 4 shows a list of terms, like these, that were flagged by the map validators due to clinical usability issues.

The validated map included 826 source terms, with 98.4% (813/826) mapped to a target SNOMED CT concept, and 1.6% (13/826) remaining unmapped. Of the mapped terms, 95.7% (778/813) were semantically equivalent, 2.5% (20/813) were broader, 1.0% (8/813) were narrower, and 0.9% (7/813) were inexact matches.

XSL•FO
RenderX

Table . Breakdown of semantically similar terms suggested by validators.

Category	Validator 1[a]	Validator 2[b]
Semantically broader than the source term	12	13
Semantically narrower than the source term	6	8
Semantically inexact to the source term	7	9
Total	25	30

[a]Validator 1 suggested 25 target terms to describe 25 source terms without a semantically equivalent match, resulting in an average of 1.0 target term per source term.

[b]Validator 2 suggested 30 target terms to describe 25 source terms without a semantically equivalent match, resulting in an average of 1.2 target terms per source term.

Table . A list of mapped terms flagged by validators due to clinical usability issues.

Source code	Source display	Target code	Target display	Relationship type	Summary of validator comments
10029147	Nephrogenic diabetes insipidus	111395007	Arginine vasopressin resistance (disorder)	Equivalent	Non–user-friendly. Recommend adding this as a synonym in the Canada English language reference set.
10042496	Sunburn	403194002	Solar erythema (disorder)	Equivalent	Non–user-friendly. Recommend adding “sunburn” as a synonym in the Canada English language reference set.
10066371	Tendon pain	21545007	Tenalgia (finding)	Broader	Non–user-friendly. Recommend adding “Tendon pain” as a synonym in the Canada English language reference set.
10073183	Hyponatremic seizure	230358007	Hyponatremic encephalopathy (disorder)	Equivalent	Non–user-friendly. Recommend adding “Hyponatremic seizure”. as a synonym in the Canada English language reference set.
10080061	Euglycemic diabetic ketoacidosis	420422005	Ketoacidosis due to diabetes mellitus (disorder)	Broader	Mapped to a broader term, but recommend creating a subtype of this for “Euglycemic diabetic ketoacidosis.”

Quality Review and Create Final Value Set

The quality review team flagged 6 terms for further discussion due to potential safety risks or clinical relevance issues (Table 5). The project team reached a consensus on all flagged terms. One term was removed for being irrelevant to ADE documentation, while 5 were left unmapped, with recommendations for requesting new SNOMED CT codes to be added to the SNOMED CT Canadian edition. Similar to the validators’ feedback, 2 quality reviewers flagged the term “solar erythema (disorder)” for lacking clinical usability, with recommendations that the term “Sunburn” be used as the preferred term in the ADE clinical context.

The quality reviewers agreed that the final map included most major ADE symptoms and diagnosis terms commonly encountered in clinical practice, and no additional source terms were suggested (Multimedia Appendix 2). Based on this feedback, we created the ADE value set, consisting of 813 SNOMED CT concepts (Multimedia Appendix 3). There are 13 source terms awaiting new SNOMED CT concepts, which could be added to the value set in a later phase (Table 6).

XSL•FO
RenderX

Table . A list of terms flagged by quality reviewers for potential safety risks and issues related to clinical relevance.

Source code	Source display	Target code	Target display	Relationship type	Summary of quality reviewer comments
10005140	Bleeding time prolonged	165563002	Coagulation/bleeding tests abnormal (finding)	Broader	"Prolonged bleeding time" is more accurate. The term "bleeding time" is commonly used by both clinicians and in lay language, making it a reasonable match.
10028128	Mucositis management	N/A[a]	N/A	Unmapped	The "management" term does not seem to fit under ADE[b] diagnosis and symptoms. If included, it should be simplified to "mucositis." They also suggest using consistent terminology with other coding, and "inflammatory disease of mucous membrane" could be an appropriate replacement for "mucositis."
10071048	Seizure-like phenomena	1208961006	Nonmotor epileptic seizure (finding)	Inexact	Both terms are not ideal. "Seizure-like phenomena" is not equivalent to "nonmotor epileptic seizure," with one noting that it is too vague and the other highlighting its potential relevance as a distinct term.
10080061	Euglycemic diabetic ketoacidosis	420422005	Ketoacidosis due to diabetes mellitus (disorder)	Broader	Both "Ketoacidosis due to diabetes mellitus" and "Euglycemic DKA[c]" should be available.

[a]N/A: not applicable.

[b]ADE: adverse drug event.

[c]DKA: diabetic ketoacidosis.

Table . A list of source terms pending new target SNOMED CT codes.

Source code	Source display
10005140	Bleeding time prolonged
10028299	Muscle discomfort
10031118	Oropharyngeal swelling
10048868	Parkinsonian crisis
10061132	Drug level above therapeutic
10061642	Antibiotic level above therapeutic
10062015	Immunosuppressant drug level increased
10067360	Tongue necrosis
10067969	Cholestatic liver Injury
10079741	Sedation complication
10000489	Acidosis hyperchloremic
10071048	Seizure-like phenomena
10080061	Euglycemic diabetic ketoacidosis

Discussion

Principal Results

This project aimed to develop a standardized SNOMED CT–based value set for the documentation of ADE symptoms and diagnoses, addressing a critical gap in the integration of ADE reporting into EMRs. Our findings demonstrate the feasibility of creating a targeted yet comprehensive value set, which can enhance the consistency, accuracy, and interoperability of ADE documentation across health care systems.

The mapping of 826 unique ADE-related terms to SNOMED CT concepts was largely successful, with 98.3% of terms being mapped in the final value set. This high level of success reflects the comprehensiveness of the SNOMED CT framework and the effectiveness of our systematic mapping process. Strong agreement between mappers and between validators supports the reliability of the mapping. Moreover, the iterative process of consensus building for resolving discrepancies between mappers and validators underscores the importance of expert input in ensuring the clinical appropriateness of mapped terms.

A major challenge encountered was ensuring semantic equivalence while maintaining clinical usability. While semantic equivalence is critical for accurate mapping, as SNOMED CT serves as the reference terminology, achieving clinical usability requires careful management of interface terminology. This can involve using SNOMED CT's dialect-specific language reference sets, also known as the preferred term (eg, en-CA or specialized ADE-context dialects), or establishing one-to-one association between value set entries and interface terms.

In SNOMED CT, the FSN provides an unambiguous and stable description of a concept but is not always clinician-friendly or commonly used [44]. In contrast, the preferred term is the most clinically appropriate and widely used synonym in a given dialect [45]. Therefore, interface terminology should default to the concept's preferred synonym in the give dialect, not the FSN. For example, the source term "gout" maps to the equivalent concept 90560007, with an FSN of inflammatory disorder due to increased blood urate level—a term less familiar in practice. The preferred term in the Canada English reference set, gout, is more user-friendly and should be displayed in clinical interfaces. While display codes can help improve terms usability, clinical reviewers noted that this work-around solution does not resolve the underlying issue of terms lacking clinical usability.

Validators and quality reviewers also flagged terms where the preferred terms in the Canada English language reference set, while semantically equivalent to SNOMED CT concepts, were still not intuitive for clinical documentation. For example, the source term "sunburn" has a preferred term as "solar erythema." Reviewers noted that they had never before heard of or used this term clinically, ever. This highlights the importance of considering both semantic equivalency and clinical usability when developing standardized terminologies for real-world application and minimize barriers for users [35].

Future research should prioritize understanding the clinical usability of standardized terminologies and developing interface terminology that users can understand and apply. While SNOMED CT provides a robust framework for clinical documentation, more work is needed to ensure that mapped terms are intuitive and align with the language clinicians commonly use in practice. It is critical that an effective approach is adopted to supporting interface terms that will enable value sets to be clinically useful. Without suitable interface terms, clinicians may struggle to recognize or apply relevant concepts within clinical systems, limiting the practical use of mapped value sets.

Clinical Implications of the ADE Value Set

The adoption of this value set for ADE documentation holds significant implications for clinical practice. By standardizing the terminology used in EMRs, health care providers can improve the accuracy of ADE reporting, leading to better

XSL•FO
RenderX

communication across care teams and potentially reducing the risk of medication-related harm. The use of standardized terminology can facilitate data sharing across health care institutions and enhance pharmacovigilance efforts at the population level, improving patient safety, if the code set can be used and understood by clinicians. Moreover, the standardized terminology provided by this value set could enhance the performance of text-mining algorithms designed to identify ADEs in EMRs [46]. However, the success of this value set depends not only on its development but also on its integration into EMR systems and clinical workflow. A key challenge lies in the willingness of EMR vendors to incorporate value sets, such as importing standardized value sets external to the Cerner system.

To ensure the successful adoption of the SNOMED CT–based ADE value set, provincial or federal governments may need to engage with EMR vendors. Governments could explore ways to encourage or mandate vendors to engage with clinical users to support the integration of locally relevant value sets, either through regulatory frameworks or through financial incentives. Without such support, the clinical benefits of standardized ADE documentation may be difficult to achieve.

In addition, the success of the value set relies on its integration into clinical workflows. Ensuring that the terminology is not only accurate but also practical and intuitive for day-to-day use will be critical. Ongoing collaboration between technical experts, clinical users, and policy makers will be essential to make certain that the value aligns with current clinical documentation practices and meets the needs of health care providers. Additionally, it is crucial to regularly update the terms to reflect the modern language and evolving practices in health care. As medical terminology changes and evolves, ensuring that value sets remain current will maintain their relevance and improve their usability in real-world clinical settings. By addressing these challenges, the value set has the potential to significantly improve the quality and consistency of ADE reporting, ultimately enhancing patient care.

Ineffective communication of ADE information across health care settings can lead to repeat ADEs, partly because different EMR systems use varied terminology standards. Recognized as a Canadian national standard and widely adopted in clinical areas including e-prescribing [47], our SNOMED CT value set adds values by standardizing ADE documentation in EMRs and enabling seamless ADE data exchange between hospital and community settings. This will allow clinicians to have timely access to patient's ADE data at the point of care, preventing unintentional represcription or redispensation of culprit drugs, thereby reducing the incidence of repeat ADEs.

Limitations

It is important to note that our study extracted source terms from a single ADE reporting system—ActionADE—which captures ADEs from patients presenting predominantly in emergency departments across 9 hospitals within a specific geographic region during a specific time period. As a result, the symptoms and diagnoses captured in this context may not fully represent ADEs occurring in other health care settings, such as inpatient wards, community care, or long-term care facilities, where different patient populations and clinical presentations are more common. For example, ADEs in long-term care settings may involve different drug classes and clinical manifestations than those seen in emergency departments. Similarly, pediatric ADEs were underrepresented in our sample, as none of the included hospitals were dedicated pediatric centers. Finally, as new drugs are developed and use of existing drugs is expanded to new clinical indications, new ADEs may emerge over time. Future work will need to expand the scope of this project by exploring and refining the value set to ensure its applicability across a diverse range of clinical environments, patient populations, and over time.

We acknowledge that using MedDRA's broad, high-level terms as our source may limit the potential granularity of our resulting SNOMED CT value set. While our approach may not have enhanced granularity of the resulting value set, the benefits of SNOMED CT's superior semantic framework, logical definition, and hierarchical structure, along with its increasing adoption as a Canadian national standard, justify its use in creating an initial ADE value set. Future research should explore the impact of using more granular source terminologies on the resulting SNOMED CT value set.

Another limitation is the potential variability in how individual reviewers interpreted ADE-related terms, which may have been influenced by their clinical background, experience, or familiarity with SNOMED CT concepts. While mapping should be grounded in semantic equivalence to ensure technical accuracy, variability may have occurred when terms had multiple valid mappings depending on the clinical context. These discrepancies highlight the need for better education on the importance of mapping based on meaning and semantics only, and tooling needs to provide better support for the incorporation of interface terms into terminology service using additional synonyms and a context-based language reference set.

Additionally, due to vendor limitations, we were unable to test the value set in the context where it will be used to ensure that it meets the needs of relevant stakeholders. Further studies are required to evaluate the impact of adopting standardized ADE value sets on clinical outcomes. Research examining how the integration of a SNOMED CT–based value set in EMRs affects the quality of ADE reporting, patient safety, and pharmacovigilance on a larger scale will be crucial to demonstrate the real-world benefits of this approach.

Conclusions

The development of a SNOMED CT–based value set for the documentation of ADE symptoms and diagnoses represents an important step toward improving the standardization of clinical documentation and enhancing patient safety. While the mapping process was largely successful, ongoing efforts to refine and expand the value set, improve user-friendliness, and evaluate its impact on clinical practice will be critical for ensuring its long-term adoption and use. By integrating this value set into clinical workflows and continuing to address gaps in terminology, health care systems can enhance the quality and interoperability of ADE documentation, contributing to better patient care.

Acknowledgments

The ActionADE platform is funded by the Canadian Institutes of Health Research, with support from the Ministry of Health British Columbia, Vancouver Coastal Health, the Lower Mainland Consolidated Pharmacies, and the BC SUPPORT Unit. CMH was supported by the Michael Smith Foundation for Health Research Health Professional-Investigator award during the study period. EYL was supported by the CIHR REDI Early Career Transition Award. The funder has no role in the design, conduct, analysis, interpretation of data, or the drafting of scientific manuscripts.

Data Availability

The MedDRA–SNOMED CT map and the SNOMED CT–based value set generated in this study are included in the supplementary information files in Multimedia Appendices 2 and 3.

Authors' Contributions

All authors contributed to the study's conception and design. EYL drafted the study protocol; oversaw and coordinated the mapping, validation, and quality review process; and wrote the first draft of the manuscript. LB provided technical guidance on the study methodology, oversaw the quality of the protocol execution, and contributed to the refinement of the data analysis. EYL, CMH, KB, Y-LAC, and AL participated in the mapping or the validation process and contributed to the refinement of the data analysis. SB, KG-K, and CS participated in the quality review process and contributed to the refinement of the data analysis. All authors contributed to the interpretation of the findings and commented on previous manuscript versions. All authors read and approved the submitted manuscript and have agreed to be personally accountable for their contribution.

Abstract

Background: As the importance of person-generated health data (PGHD) in health care and research has increased, efforts have been made to standardize survey-based PGHD to improve its usability and interoperability. Standardization efforts such as the Patient-Reported Outcomes Measurement Information System (PROMIS) and the National Institutes of Health (NIH) Common Data Elements (CDE) repository provide effective tools for managing and unifying health survey questions. However, previous methods using ontology-mediated annotation are not only labor-intensive and difficult to scale but also challenging for identifying semantic redundancies in survey questions, especially across multiple languages.

Objective: The goal of this work was to compute the semantic similarity among publicly available health survey questions to facilitate the standardization of survey-based PGHD.

Methods: We compiled various health survey questions authored in both English and Korean from the NIH CDE repository, PROMIS, Korean public health agencies, and academic publications. Questions were drawn from various health lifelog domains. A randomized question pairing scheme was used to generate a semantic text similarity dataset consisting of 1758 question pairs. The similarity scores between each question pair were assigned by 2 human experts. The tagged dataset was then used to build 4 classifiers featuring bag-of-words, sentence-bidirectional encoder representations from transformers (SBERT) with bidirectional encoder representations from transformers (BERT)–based embeddings, SBERT with language-agnostic BERT sentence embedding (LaBSE), and GPT-4o. The algorithms were evaluated using traditional contingency statistics.

Results: Among the 3 algorithms, SBERT-LaBSE demonstrated the highest performance in assessing the question similarity across both languages, achieving area under the receiver operating characteristic and precision-recall curves of >0.99. Additionally, SBERT-LaBSE proved effective in identifying cross-lingual semantic similarities. The SBERT-LaBSE algorithm excelled at aligning semantically equivalent sentences across both languages but encountered challenges in capturing subtle nuances and maintaining computational efficiency. Future research should focus on testing with larger multilingual datasets and on calibrating and normalizing scores across the health lifelog domains to improve consistency.

Conclusions: This study introduces the SBERT-LaBSE algorithm for calculating the semantic similarity across 2 languages, showing that it outperforms BERT-based models, the GPT-4o model, and the bag-of-words approach, highlighting its potential in improving the semantic interoperability of survey-based PGHD across language barriers.

Introduction

Person-generated health data (PGHD) is becoming increasingly important in managing individual health. PGHD encompass health-related information that individuals create and collect outside traditional clinical environments, helping them monitor and manage their well-being [1,2]. Examples of PGHD include biometric data from wearable devices and self-reported information such as patient-reported outcomes. Since PGHD has the potential for continuously capturing health insights beyond health care settings, there is growing interest in leveraging PGHD to support clinical care [3-5]. In parallel, PGHD is increasingly explored as a resource for patient-centered outcomes research [6,7]. However, there are several challenges

XSL•FO
RenderX

in the effective use of PGHD, including developing robust data management systems, ensuring data security, deploying it seamlessly into clinical workflows, and maintaining high data quality [5,7,8].

Standardizing survey-based PGHD is a critical step in enabling its broader use [9]. An important aspect of standardization is to identify redundancies in the form of semantic equivalencies. These redundancies may arise because the clarity, tone, tense, directness, and formality of the language can be phrased differently for the same purposeful inquiry depending upon the author. For example, emotional symptoms may be captured by questions such as “Do you feel like withdrawing from family or friends?” or “I don’t really want to talk to people around me.” This variation makes identifying semantically equivalent questions—and thus standardizing survey-based PGHD—a complex task. Efforts such as the Patient-Reported Outcomes Measurement Information System (PROMIS) and the National Institutes of Health (NIH) Common Data Elements (CDE) repository aim to provide standardized health survey questions. PROMIS, a consensus-based item bank designed for managing patient-reported outcomes, offers standardized measures that are applicable across various diseases and clinical settings [10-12]. These measures have helped health care providers across various clinical settings, including pain management [13], orthopedics [14], and primary care [15]; in cancer care [16]; in managing patient symptoms; in tailoring treatments; and in improving communication between patients and clinicians. The NIH CDE repository, through metadata tagging, also plays a key role in standardizing data elements, including health surveys [17,18]. Both PROMIS and the CDE repository are essential for enhancing the interoperability of health data.

In practice, the deployment of PGHD acquisition applications requires that survey questions be drawn from these established standardized resources. Data collected using questions outside of these resources still require additional efforts to achieve standardization. Although previous studies have explored ontology-mediated methods to identify semantically equivalent health questions [10,11], annotating each question with ontology concepts is labor-intensive and lacks scalability as such knowledge sources expand. As a complementary approach, deep learning and transformer-based methods have been applied to semantic textual similarity (STS) tasks in clinical texts, including radiology and pathology reports [19], clinical notes [20-22], and medical question-answer pairs [23]. A range of models has been explored, such as convolutional neural networks [19]; transformer-based architectures such as bidirectional encoder representations from transformers (BERT), robustly optimized BERT approach, and XLNet [20-22]; and the Siamese network [23]. Despite their promising performance, most of these models have been limited to single-language settings—predominantly English [20-22] or Chinese [19,23]. Consequently, cross-lingual STS remains underexplored, highlighting the need for standardization efforts that promote semantic interoperability across languages.

To address these challenges, we developed Standardized PGHD Utilization Resources and Tools (SPURT), which supports the standardization and reuse of survey-based PGHD by identifying semantically equivalent questions and facilitating the storage, retrieval, and sharing of these data. Unlike PROMIS and the NIH CDE repository, SPURT annotates and stores health survey questions in both English and Korean while also detecting semantically redundant questions. This ensures the use of consistent question formats whenever possible. Technically, assessing semantic similarity between texts is well-established and widely applied for managing text resources [24]. However, SPURT faces 2 unique challenges in its assigned task. First, it must effectively assess semantic similarities within or between 2 different languages—English and Korean. Although multilingual embeddings can be used to address this challenge [25,26], they often perform less effectively for low-resource languages such as Korean compared to high-resource languages such as English [27]. One common solution is to translate low-resource languages into high-resource ones before embedding, but this approach risks losing or distorting the original meaning [28,29]. Second, it must ensure computational efficiency for real-time semantic comparisons between questions. Calculating semantic similarity by using large language models such as BERT is computationally expensive, with a time complexity of O (N!). For example, computing the similarity of approximately 10,000 sentence pairs can take around 65 hours using a V100 graphics processing unit [30]. Given that SPURT is designed to be a real-time, reactive data processing tool, achieving reasonable response times is crucial for its functionality.

This study presents the development of a novel algorithm for detecting redundant questions, addressing the challenges outlined above. The algorithm utilizes sentence-BERT (SBERT), a variant of BERT designed for efficient sentence-level semantic similarity calculations [30] along with language-agnostic BERT sentence embedding (LaBSE) [31] to enhance multilingual capability. Sentence-BERT is a model specifically designed for calculating STS between sentences, and LaBSE is an embedding that supports efficient cross-lingual STS by mapping multilingual sentences into a shared embedding space. The SBERT-LaBSE algorithm integrates the strengths of both models and facilitates the identification of semantically equivalent questions across languages.

Methods

Corpus Description: The STS Dataset

An STS dataset contains text pairs along with predefined similarity scores that quantify their semantic closeness [32-36]. This study shows an STS dataset that fine-tunes pretrained language models and evaluates our algorithms’ performance in determining the semantic similarity between health-related questions.

We collected English and Korean questions from self-reported questionnaires covering 5 health lifelog domains, that is, diet, physical activity, living environment, stress management, and sleep. English questions (n=1222) were sourced from the NIH CDE repository, PROMIS, and academic publications, while Korean questions (n=963) were gathered from web-based resources provided by public health agencies and hospitals in Korea [17,37-40].

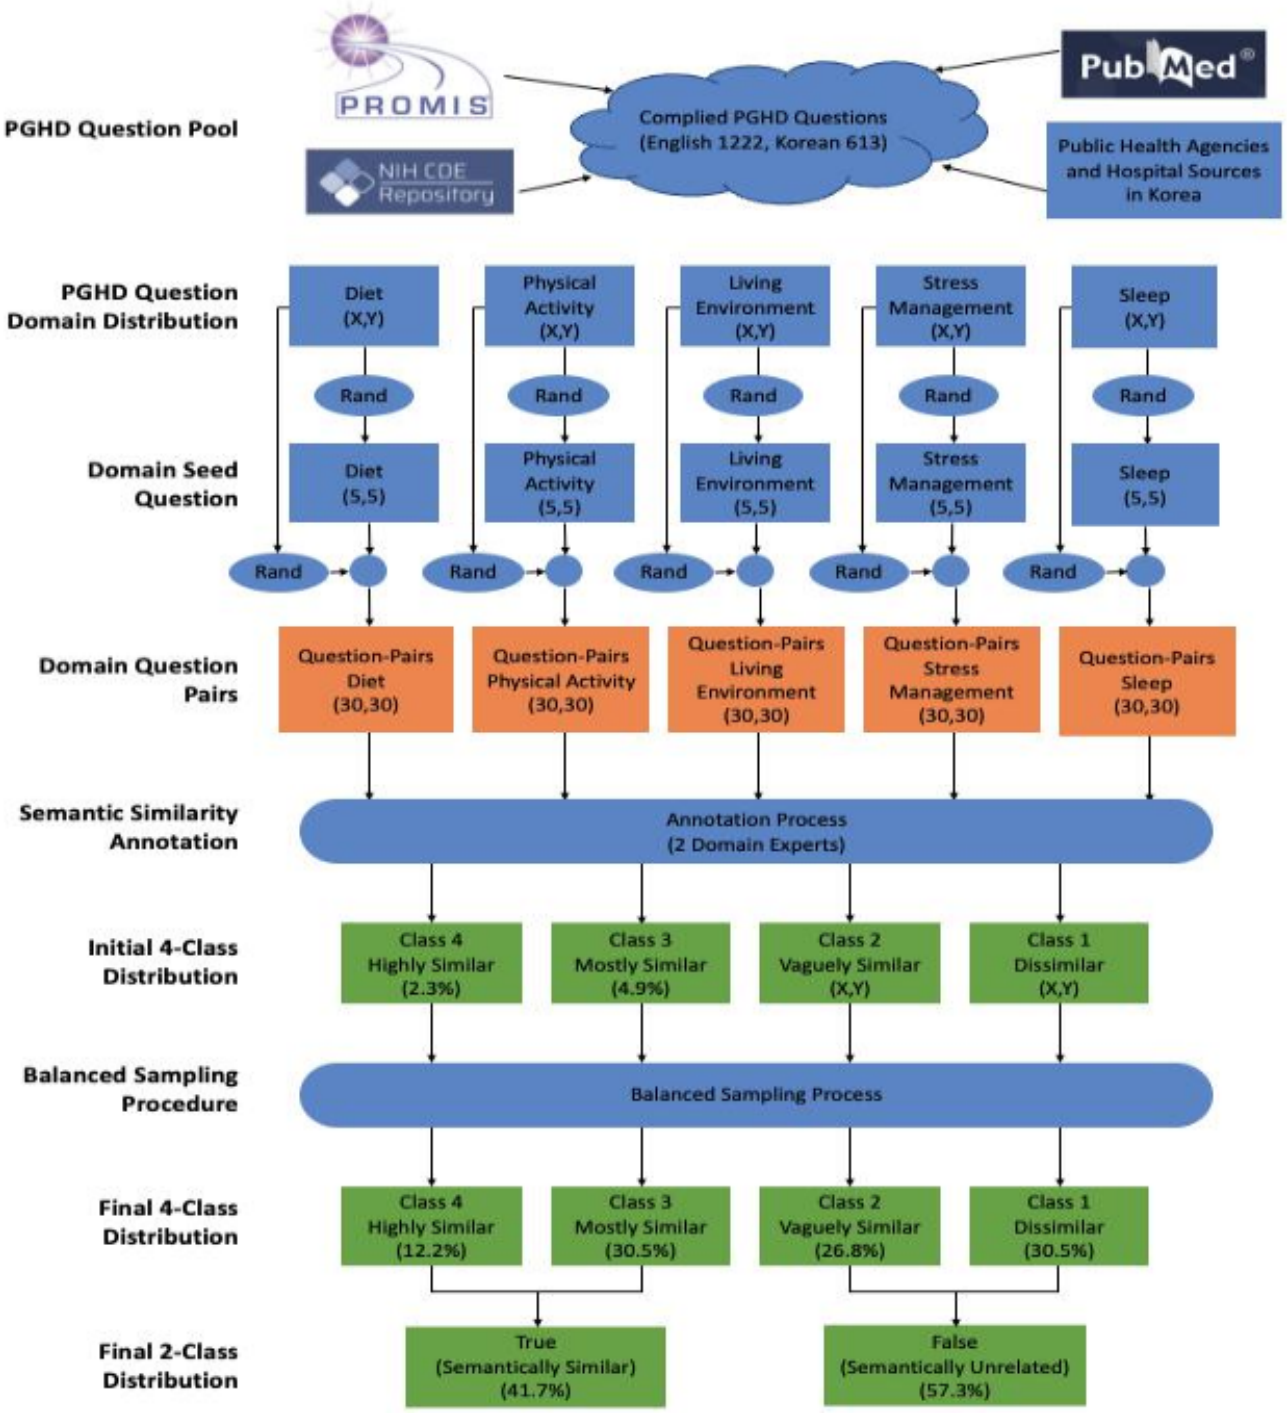
XSL•FO
RenderX

To build the STS dataset, we began by randomly selecting 5 seed questions from each of the 5 health lifelog domains in Korean, resulting in 25 seed questions. For each question, correspondingly similar questions for Korean were identified, resulting in 25 similar seed questions for each language. This correspondence of seed questions was performed to minimize the effects of semantic complexity on algorithm performance. We then randomly selected 30 comparison questions for each seed question, which yielded a total of 1500 question pairs (750 in each language).

The gold standard for semantic similarity between the question pairs was determined by 2 researchers with nursing backgrounds who independently scored the similarity of each question pair, following a standardized scoring protocol (Table 1). The agreement between the researchers, as measured by Cohen κ, varied by the health lifelog domains: 0.91 for diet, 0.72 for living environment, 0.83 for physical activity, 0.86 for sleep, and 1.0 for stress management, with an average Cohen κ of 0.86 across all the health lifelog domains.

Table . Scoring protocol for semantic similarity. The seed question was "In the past month, have you ever had chest pain when you were not performing any physical activity?"

Score	Scoring protocol	Examples
4	Minor differences in word choice from the seed question but takes the same form of response	In the past month, have you had chest pain when you were not doing physical activity?
3	Share the same key topic, although some details may be added, altered, or omitted from the seed question	Do you feel pain in your chest when you do physical activity?
2	The key topics are similar but more specific or general than that of the seed question	Has your doctor ever said that you have a heart condition and that you should only perform physical activity recommended by a doctor?
1	Does not share the core topic from the seed question or belongs to a completely different health lifelog domain	Have you done general conditioning exercises in the past 4 weeks?



Upon completion of this annotation process, we observed that the initial distribution of the similarity scores was imbalanced—skewed heavily toward lower similarity scores. Only 2.3% (7/300) of the pairs received a score of 4, and 4.9% (15/300) received a score of 3. To address this imbalance, we supplemented the dataset with an additional 117 English and 142 Korean question pairs from other sources, chosen to increase the frequency of semantically similar (ie, higher scores) samples in the evaluation STS dataset. These additions brought the final evaluation set to 820 question pairs (410 in each language) with the following distribution: 12.2% (99/810), 30.5% (247/810), 26.8% (217/810), and 30.5% (247/810) for scores 4, 3, 2, and 1, respectively.

Using a similar procedure as described above, we compiled a second English STS dataset for fine-tuning our pretrained language models. This fine-tuning dataset included 938 annotated English question pairs. The fine-tuning set had a distribution of 6.2% (58/938) scoring 4, 14% (131/938) scoring 3, 23.5% (220/938) scoring 2, and 56.4% (529/938) scoring 1.

In total, the STS dataset consisted of 1758 question pairs, broken down into 820 for evaluation testing (410 English and 410 Korean) and 938 in English for classifier model refinement (see Multimedia Appendix 1). The process of constructing the STS dataset is illustrated in Figure 1.

Semantic Similarity Calculation Algorithms

Overview

We developed 4 classifiers to compare their performance capability for distinguishing the binary task of semantic similarity between STS question pairs. These were (1) the bag-of-words (BoW) model, (2) SBERT with BERT-based embeddings (SBERT-BERT), (3) LaBSE, and (4) the GPT-4o model (GPT-4o). Among these, the SBERT-BERT algorithm was included to serve as a translation-dependent baseline, enabling comparison with multilingual models such as SBERT-BERT and GPT-4o. Model fine-tuning and algorithm development were performed using Python (version 3.11).

BoW Classifier

The BoW algorithm, a traditional language model that represents sentences by their word frequency, serves as the baseline [41]. The BoW model's vocabulary was derived from the STS dataset, comprising 1349 unique word forms after stop-word removal and lemmatization. Each sentence was represented as a 1349D vector based on the vocabulary. Cosine similarity was used to calculate the semantic distance of the question pairs. For Korean questions, translation to English was performed using the Google

XSL•FO
RenderX

Translator application programming interface prior to similarity calculation [42].

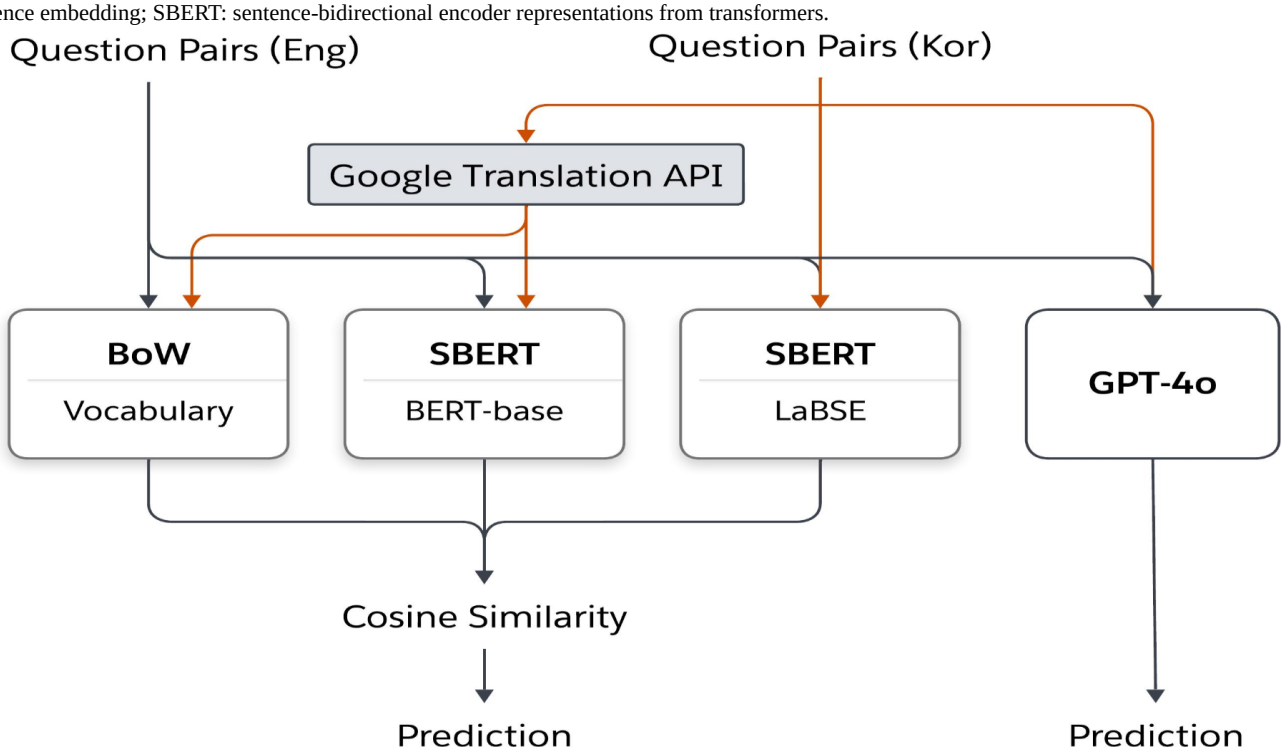
The SBERT-BERT Algorithm

The SBERT-BERT large language model was derived from the pretrained BERT-based model, which has 12 layers, a 768D hidden layer, 12 attention heads, and 110 million parameters [30]. SBERT-BERT supports only English. We fine-tuned the pretrained SBERT-BERT model to optimize its performance for identifying semantic equivalency among health questions by using the 938 English question pairs described above. The fine-tuning was performed with a batch size of 32, 8 epochs, and a learning rate of 2e-5, which were deemed optimal after testing various configurations. The AdamW optimizer was used for model optimization [43]. The fine-tuned SBERT-BERT algorithm was then evaluated using the test STS dataset of 410 English question pairs and 410 Korean question pairs. As previously stated, the Korean questions were translated into English using the Google Translator application programming interface to execute the evaluation.

The SBERT-LaBSE Algorithm

The SBERT-LaBSE algorithm differs from SBERT-BERT in that it supports multiple languages within a single embedding space [31]. The pretrained SBERT-LaBSE model was derived from the LaBSE model, which also consists of 12 layers, a 768D hidden layer, 12 attention heads, and 110 million parameters [31]. Fine-tuning was performed in the same manner as for SBERT-BERT. Unlike the other models, SBERT-LaBSE can assess the semantic similarity of English and Korean questions without requiring translation.

The GPT-4o Algorithm



The GPT-4o model, a state-of-the-art large language model, is designed to understand and generate text in multiple languages, including English and Korean [44]. Unlike the SBERT-BERT and SBERT-LaBSE, which rely on fixed embeddings for similarity calculation, the GPT-4o operates as a generative model that dynamically evaluates semantic similarity based on contextual understanding. However, in this study, we utilized GPT-4o in a deterministic manner to predict the score of sentence pairs. Each sentence pair was presented with a specific instruction asking to evaluate the score on a scale from 1 to 4 (Multimedia Appendix 2). Fine-tuning of the GPT-4o model was conducted using the fine-tuning application programming interface from the OpenAI platform [45].

Performance Evaluation

The performance of the similarity calculation algorithms was evaluated as a binary classification problem to simplify interpretation. The 4-point ordinal similarity scores from the STS dataset were converted into binary labels, where scores of 3 and 4 were categorized as similar and scores of 1 and 2 as dissimilar.

Optimal thresholds for predicting similarity were determined for the continuous similarity scores, which ranged from –1 to 1. Precision, recall, and F_1-scores were calculated to assess algorithm performance, and the area under the curve for both the receiver operating characteristic and precision-recall curves were examined. The processes used by the 3 algorithms to calculate similarity are illustrated in Figure 2.

Ethical Considerations

This study does not involve human participants, intervention, or identifiable private information. The analysis was based on publicly available and nonidentifiable health survey questions from open repositories and published sources. As such, it does not fall under the scope of human subject research as defined by the Seoul National University institutional review board. According to Article 2 and Article 8, Paragraph 2 of the Seoul National University institutional review board regulations (regulation 27, effective September 11, 2023), studies that do not involve human participants or human-derived materials are exempt from institutional review board review. Therefore, this study was not submitted for ethical review. No informed consent, compensation, or privacy protection measures were applicable, as no human participants were involved, and no personal data were collected or analyzed.

Results

The performance of the 3 models for classifying similar versus dissimilar question pairs when aggregating the 5 health lifelog domains is summarized in Table 2 and Figure 3. In the zero-shot trials (ie, without the model refining stage), there were minimal differences in performance among the 3 algorithms for both English and Korean questions. All algorithms exhibited higher recall than precision in both languages. After fine-tuning, the SBERT-BERT algorithm showed substantial improvement, particularly for English questions, in which the F_1-score increased from 0.65 to 0.96. For Korean questions, the improvement was moderate, with the F_1-score progressing from 0.68 to 0.73. In contrast, SBERT-LaBSE demonstrated significant improvements for both languages post fine-tuning. For English questions, the F_1-scores increased from 0.66 to 0.98, while for Korean, the F_1-scores increased from 0.68 to 0.98. Fine tuning for both SBERT-BERT and SBERT-LaBSE models resulted in noticeable balanced performance between recall and precision. Similarly, GPT-4o exhibited improved performance following fine-tuning, with its F_1-scores increasing from 0.69 to 0.79 for the English questions and from 0.67 to 0.79 for the Korean questions. However, the degree of improvement was smaller than that observed in SBERT models.

Table . Performance metrics for the 3 algorithms, combining the health lifelog domains.

Performance metrics	BoW[a]	GPT-4o pre-trained	GPT-4o fine-tuned	SBERT[b] with pretrained		SBERT with fine-tuned

Figure 3. Receiver operating characteristic and precision-recall curves for pretrained and fine-tuned embeddings on English and Korean questions, combining the health lifelog domains. AUC: area under the curve; BERT: bidirectional encoder representations from transformers; BoW: bag-of-words; Eng: English; Kor: Korean; LaBSE: language-agnostic bidirectional encoder representations from transformers sentence embedding; PR: precision-recall; ROC: receiver operating characteristic; SBERT: sentence-bidirectional encoder representations from transformers.

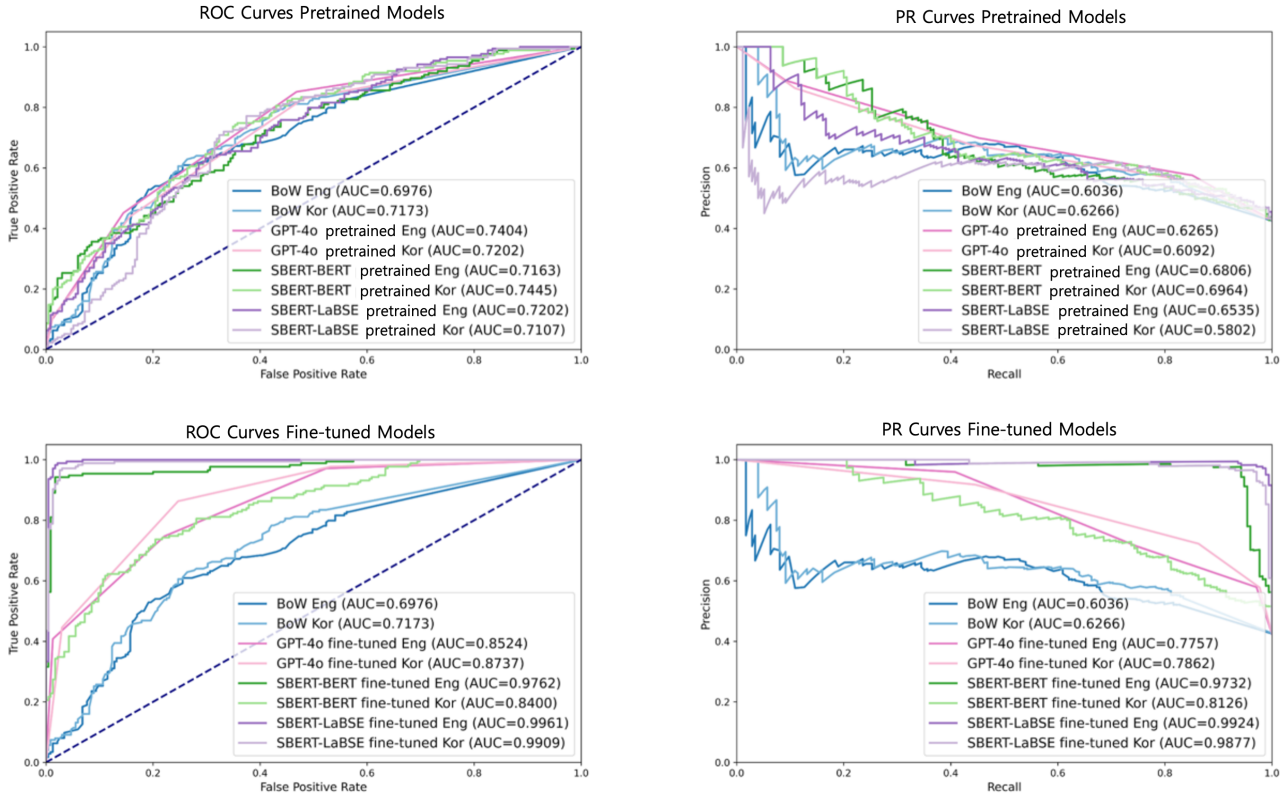

Table 3 presents the performance of the 2 SBERT algorithms across the 5 health lifelog domains. For all the health lifelog domains, the fine-tuned SBERT-BERT and SBERT-LaBSE algorithms demonstrated high performance on English questions, with receiver operating characteristic and precision-recall area under the curve values exceeding 0.95 and approaching 0.99. However, the SBERT-BERT algorithm struggled with the English-translated Korean questions, particularly in the physical activity domain. In contrast, the SBERT-LaBSE algorithm consistently delivered strong performance across all the health lifelog domains even for Korean questions.

Table 4 presents the optimal cutoff values for the 3 algorithms. The pretrained SBERT-BERT and SBERT-LaBSE models showed considerable variation in the cutoff values across the 5 health lifelog domains. However, after fine-tuning, these variations decreased, indicating that fine-tuning helped stabilize the algorithms. Despite this improvement, the SBERT-LaBSE algorithm still exhibited more variability in the cutoff values across the health lifelog domains compared to SBERT-BERT, suggesting that further calibration may be required for SBERT-LaBSE. Multimedia Appendix 3 provides example question pairs from each health lifelog domain, along with the similarity scores assigned by human reviewers and predicted by the 3 algorithms.

Table . Optimal cutoff for algorithms on bag-of-words and pretrained and fine-tuned SBERT-BERT and SBERT–LaBSE in each health lifelog domain.

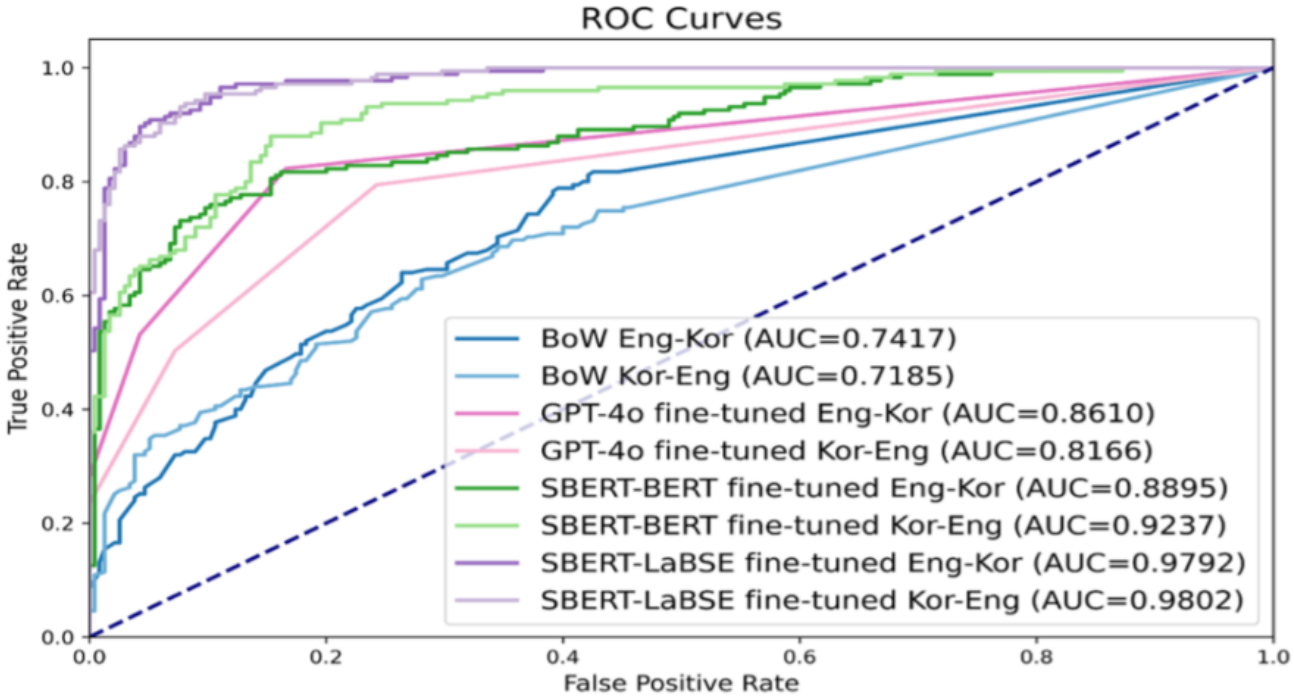
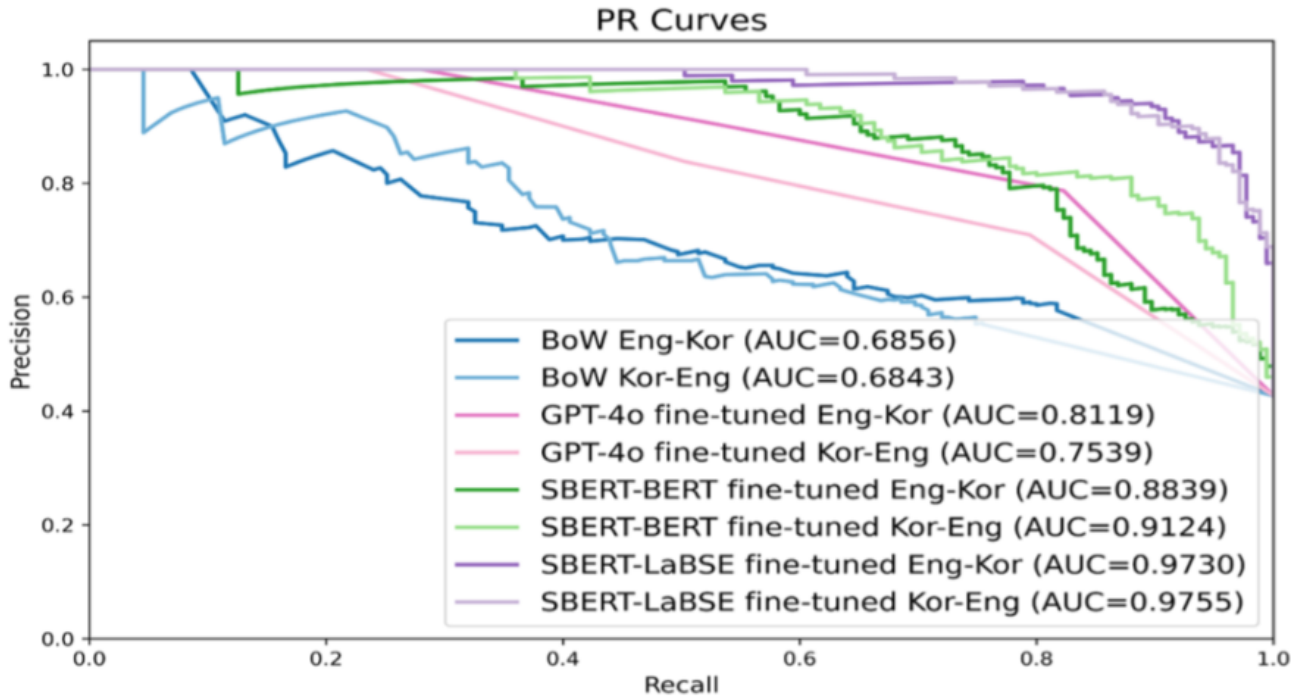
[a]SBERT: sentence-bidirectional encoder representations from transformers.



[b]BERT: bidirectional encoder representations from transformers.



[c]LaBSE: language-agnostic bidirectional encoder representations from transformers sentence embedding.

Figure 4 illustrates that SBERT-LaBSE effectively determined semantic similarities between the 2 languages, with slightly better performance in identifying the semantic similarities of English questions relative to the Korean seed questions. The complete results of the cross-language semantic similarity analysis are provided in Multimedia Appendix 4.

AUC: area under the curve; BERT: bidirectional encoder representations from transformers; BoW: bag-of-words; Eng: English; Kor: Korean; LaBSE: language-agnostic bidirectional encoder representations from transformers sentence embedding; PR: precision-recall; ROC: receiver operating characteristic; SBERT: sentence-bidirectional encoder representations from transformers.

Discussion

Principal Findings

This study demonstrates the utility of large language models for determining semantic similarities among health questions to facilitate the standardization of survey-based health data. Our results indicate that the fine-tuned SBERT algorithms were significantly more effective than the traditional BoW approach in identifying semantic similarities for both English and Korean questions. Furthermore, the SBERT-LaBSE algorithm demonstrated superior performance particularly for Korean questions, suggesting that it is a more effective method than the SBERT-BERT algorithm, which relies on English translation, for assessing semantic similarity in non-English texts. Notably, the SBERT-LaBSE algorithm outperformed the GPT-4o algorithm, particularly in Korean. Although it is possible that the full potential of the GPT-4o algorithm was not realized, the

XSL•FO
RenderX

results clearly show that for the specific task examined in this study, the fine-tuned SBERT algorithms achieved better performance than GPT-4o, with significantly lower computational costs [46].

The SBERT-LaBSE algorithm's success with Korean questions can be attributed to its structural design and the limitations of language translation. Structurally, LaBSE aligns semantically equivalent words or sentences from different languages into a unified embedding space, preserving semantic consistency across languages. This allows for more accurate semantic similarity assessments. In contrast, the SBERT-BERT algorithm's lower performance with Korean questions may be due to meaning loss or distortion during translation, which disrupts semantic comparisons between languages [28,29]. Although previous studies have noted that LaBSE may struggle with subtle, sentence-level nuances, limiting its performance in fine-grained similarity tasks [47], our study shows that the SBERT-LaBSE algorithm effectively captured the meanings in both English and Korean sentences, outperforming the SBERT-BERT model. However, this finding should be validated with a larger and more diverse dataset that includes a broader range of syntactic features.

Limitations

When implemented in the SPURT system with 1835 questions in the comparison space, the SBERT-LaBSE algorithm evaluated the similarity of a new question in just 0.03 seconds. This was achieved on a Naver Cloud Platform server with 8GB RAM and no graphics processing unit [48]. Despite its impressive performance, LaBSE's 440 million parameters—4 times that of BERT base—make it a resource-intensive option, potentially increasing costs for complex tasks. This resource demand may limit its applicability on resource-constrained devices such as mobile platforms [49]. To address these limitations, future work will explore techniques such as distillation [50] and the use of small language models [51], with the goal of reducing model size while maintaining performance.

This study has some limitations. First, the cutoff values for the similarity scores were not uniformly calibrated across the 5 health lifelog domains, leading to inconsistencies in how similarity scores were interpreted. For example, the SBERT-LaBSE algorithm assigned a similarity score of 0.7 to the dietary question pair "I've binge eaten" and "Do you ever overeat?" and identified them as similar. However, the algorithm correctly identified the human living environment questions, that is, "Have you moved in the past 5 years?" and "In the last 5 years, the number of people in this community has?" as dissimilar while assigning the same similarity score of 0.7 to the pair. These inconsistencies may impact the accurate interpretation of similarity scores, highlighting the need for future work to focus on calibrating and normalizing scores across the health lifelog domains to ensure greater consistency. Second, our evaluation was conducted on a small set of English and Korean question pairs. Future studies should explore the feasibility of applying the SBERT-LaBSE algorithm to a broader range of sentence types from diverse domains. Additionally, by incorporating texts from more diverse languages, future research can investigate the algorithm's potential to overcome language barriers and facilitate semantic interoperability.

Comparison With Prior Work

Previous methods that relied on metadata tagging [17,18] and ontology-mediated annotation [10,11] were effective in providing structured mappings between concepts, facilitating interoperability. However, they struggled with comparing the meanings of survey questions composed in multiple languages and addressing semantically redundant questions. This study leverages fine-tuned large language models such as SBERT-BERT and SBERT-LaBSE to assess semantic similarity. In particular, the fine-tuned SBERT-LaBSE algorithm demonstrates the potential to enhance semantic interoperability by capturing semantic similarities across multiple languages with high performance.

Conclusion

This study highlights the potential of large language models in identifying semantic redundancy in survey-based PGHD collections. Specifically, the SBERT-LaBSE algorithm excelled in classifying semantic similarity across diverse question formats in 2 languages. Our findings demonstrate that SBERT-LaBSE outperforms the traditional BERT-based algorithm, the GPT-4o algorithm, and the conventional BoW approach in both languages, highlighting its capacity to improve semantic interoperability of PGHD across language barriers.

Acknowledgments

We are thankful to our colleagues Eunyeong Lim and Jeongha Kim for their help with the semantic textual similarity dataset preparation. This study was supported in part by a grant from the National Research Foundation of Korea (grant 2022R1A2C201136011).

Abstract

Background: Pathology reports contain critical information necessary for the management of cancer patient care. Efforts to structure pathology cancer reports by the College of American Pathologists and the International Collaboration on Cancer Reporting (ICCR) have been successful in standardizing pathology reports. Likewise, standards development organizations have advanced methods to improve data computability and exchange, by enabling interoperability of pathology cancer reports.

Objective: This study aimed to provide a tractable method to render pathology cancer reports computable and interoperable using published cancer reporting protocols, SNOMED Clinical Terms (SNOMED CT) and Health Level 7 (HL7) Fast Healthcare Interoperability Resources (FHIR).

Methods: The ICCR colorectal cancer (CRC) reporting dataset (version 1.0) was evaluated by terminologists and pathologists. SNOMED CT concepts were bound to the data elements. The dataset was then converted into a FHIR structured data capture (SDC) questionnaire using the United States National Library of Medicine tooling and rendered into a FHIR-conformant message for data exchange.

Results: The ICCR CRC dataset contained 216 data elements; 207 data elements were bound to SNOMED CT and incorporated into a FHIR SDC construct. The 9 uncoded data elements were ambiguous and could not be reliably encoded. The resultant FHIR SDC form fully represented the ICCR CRC dataset and rendered these data in an R4 JSON format for data exchange.

Conclusions: This study demonstrates a tractable and extensible approach to making cancer pathology reports fully computable and interoperable that can be broadly adopted. ICCR datasets are supported internationally and supported by multiple national pathology societies. These datasets can be fully represented using SNOMED CT to render data elements computable and semantically faithful to their intended meaning. The use of the FHIR SDC construct enables widespread and standardized data exchange of clinical information. While challenges remain, including FHIR adoption and the need to maintain current clinical content and standard terminology, this approach provides a clear pathway toward implementation.

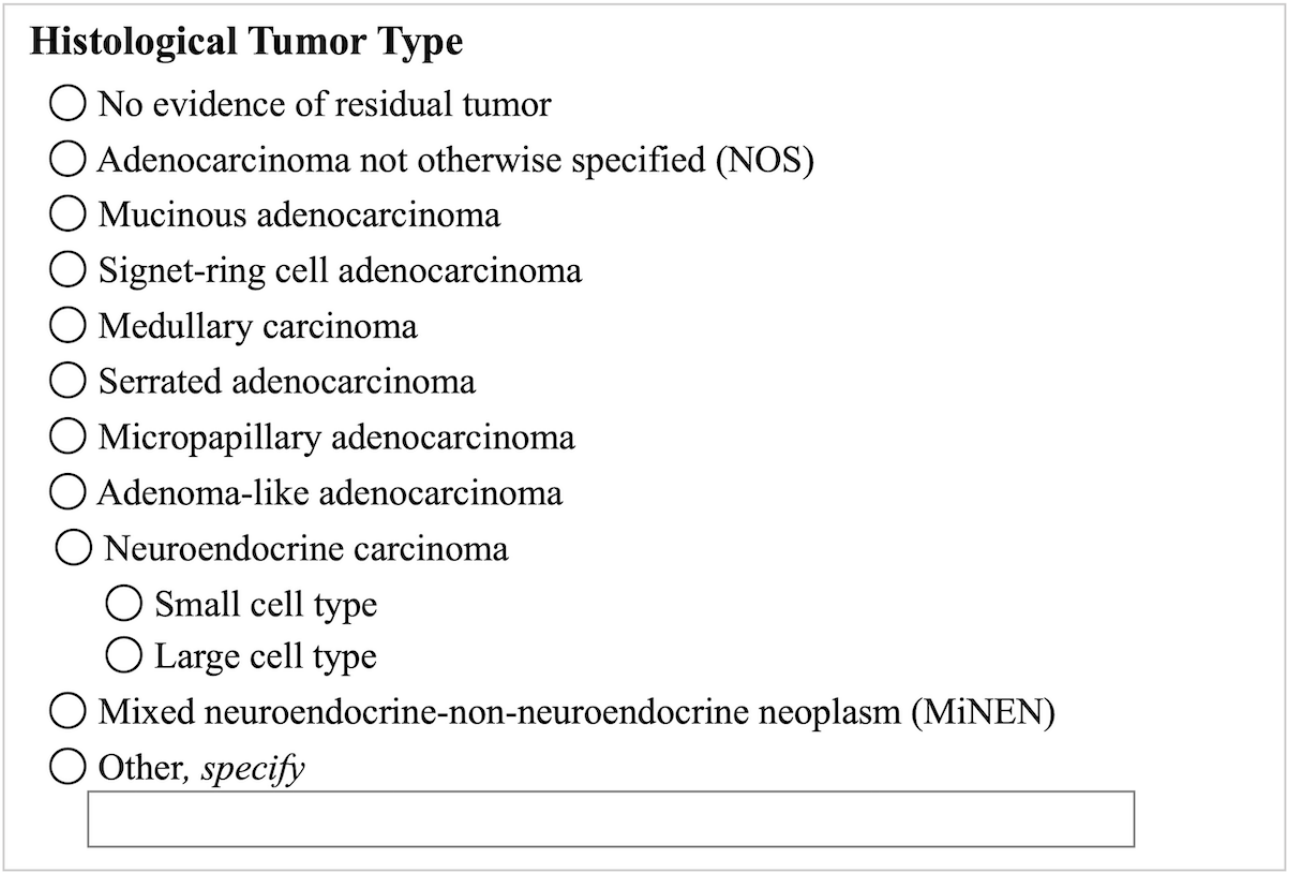
KEYWORDS

semantic interoperability; syntactic interoperability; synoptic pathology report; SNOMED clinical terms; fast healthcare interoperability resources; structured data capture

Introduction

Pathology assessment of tissue specimens is the standard for cancer diagnosis and prognosis, and structured synoptic reporting for cancer pathology reports has been shown to improve report quality [1-8], ease of use [9,10], and patient outcomes [8,11]. However, rendering pathology cancer synoptic reports as computable, electronically interoperable, and exchangeable has been elusive [12]. Developments in computable terminologies and data exchange methods,

XSL•FO
RenderX



specifically SNOMED Clinical Terms (SNOMED CT) and Fast Healthcare Interoperability Resources (FHIR) [13,14], provide a pathway toward achieving computable and interoperable pathology cancer reports. This paper demonstrates the use of SNOMED CT and FHIR to produce a fully computable, electronic pathology cancer report for international use.

Cancer Synoptic Reporting

Multiple national and international bodies of pathology, including the College of American Pathologists (CAP) [15], the International Collaboration on Cancer Reporting (ICCR) [16], the Royal College of Pathologists (RCPath) [17], and the Dutch Nationwide Pathology Database (Palga) [18], develop and publish cancer pathology reporting protocols based on prevailing medical knowledge. These protocols are referred to as synoptic reporting protocols or datasets and prescribe specific data elements that are to be collected and reported. Data include the primary site of tumor, histologic type, histologic grade, anatomic structures invaded directly or metastatically by the tumor, lymph nodes involvement, and, in some protocols, prognostic or predictive immunohistochemistry stains. Protocol guidelines define core and noncore information for inclusion in the report. Core data elements are essential for the cancer's clinical management, staging, or prognosis for the patient, and for the development of an appropriate treatment plan. Noncore elements represent desirable information that may improve patient care based on emerging science. The benefits of synoptic cancer pathology reporting are abundant, and this reporting approach has been broadly deployed [19]. However, the benefits of structured synoptic reports are not fully realized as the information is not structured in a computable and readily exchangeable format.

In practice, pathology cancer reporting protocols are structured into a series of categories to be assessed by the pathologist. Each category contains a limited number of predetermined assessments or observations. For example, the pathologist is required to assess and report the histologic type of the neoplasm. As shown in Figure 1 for colorectal cancer (CRC), the histologic type of the neoplasm should be selected from the constrained list of the most frequent CRC histologic types. A fill-in option is available for rare morphologies.

Figure 1. Synoptic pathology reporting template: –histologic tumor type of colorectal cancer.

Interoperability

At the most basic level, synoptic reports are complex "check sheets" on which pathologists select the appropriate observation for each category (see Figure 1). In a digital environment, check sheets are rendered graphically. Upon completion of the graphical user interface (GUI), corresponding text is created, stored, and often distributed as a PDF or other rich text format. While users easily understand the text, it is not represented with computable terminologies. Thus, the report is reduced to a textual document and not readily available for computation, secondary use, or electronic data exchange. The evolution of pathology cancer reporting from free-text reports to structured reports ensures that pathology reports are easily understood by users and can be computable using controlled medical terminology [8,20]. Recent developments in SNOMED CT content specific for use in pathology cancer reporting provide

XSL•FO
RenderX

the avenue to achieve the goal of semantic, computable representation of pathology cancer reports [21].

In addition to standardized terminologies, interoperability of pathology cancer data requires an information model and a data exchange structure. The cancer synoptic reporting formats provided by the CAP, ICCR, RCPath, and Palga ensure a common information model to which standard terminology, specifically SNOMED CT, is bound. FHIR builds on modern web standards technologies to provide meaningful options for data exchange in a variety of health care contexts and provides a scalable data exchange protocol for pathology cancer report data exchange. This review provides a tangible example of using the pathology cancer synoptic structure, SNOMED CT, and FHIR to represent and allow for the exchange of a pathology report. This approach is consistent with international data exchange and interoperability objectives and shows promise for widespread use.

Methods

Resource Selection

Dataset

The ICCR CRC dataset (version 1.0) [22] was selected to demonstrate the tractability and plausibility of a standardized, interoperable cancer pathology report for broad, international application. The ICCR is a collaboration of pathologists from multiple international professional and academic colleges and societies of pathology [23]. The ICCR publishes pathology cancer reporting guidelines and datasets that are internationally free for use and have been adopted by several nations as the basis for pathology cancer reporting. The colorectal dataset was selected as an example, as this form of cancer occurs across the globe.

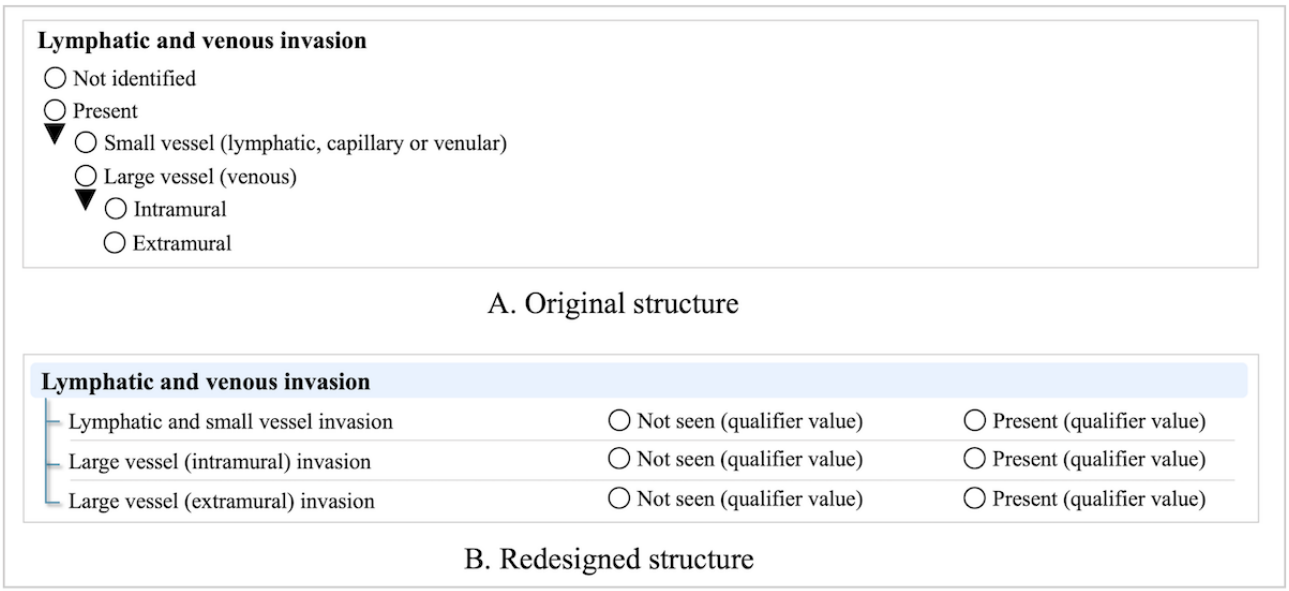
Terminology

SNOMED CT was used as the base terminology standard for this project. It is widely recognized as the most comprehensive clinical terminology worldwide. The SNOMED CT concept model allows for extensive terminology expression to support explicit concept definition, and the use of description logic enables concept inferences and enhanced data navigation [24]. The recent development of SNOMED content specific to cancer pathology reporting became available in SNOMED CT in late 2023. This content was developed by an international group of pathologists, data scientists, and registrars and was specifically developed for the cancer synoptic reporting use case.

Data Structure

In addition to terminology, common information models facilitate data exchange between health care systems by providing structure and syntax for data. FHIR is a data exchange structure with international appeal and serves as a standard for achieving syntactic interoperability in health care [24,25]. Due to the widespread interest in FHIR, this syntactic model was employed in this project, notably the Structure Data Capture (SDC) questionnaire. SDC was developed as part of an initiative sponsored by the US Assistant Secretary for Technology Policy from 2013 - 2016 [26]. During this project, the XML version maintained by Integrating the Healthcare Enterprise (IHE) and a FHIR version of SDC were used [27]. The CAP uses the IHE SDC to represent its cancer checklists. The United States National Library of Medicine form builder tool (version 9.7.2) [28] was used to develop an FHIR-compliant cancer synoptic report questionnaire.

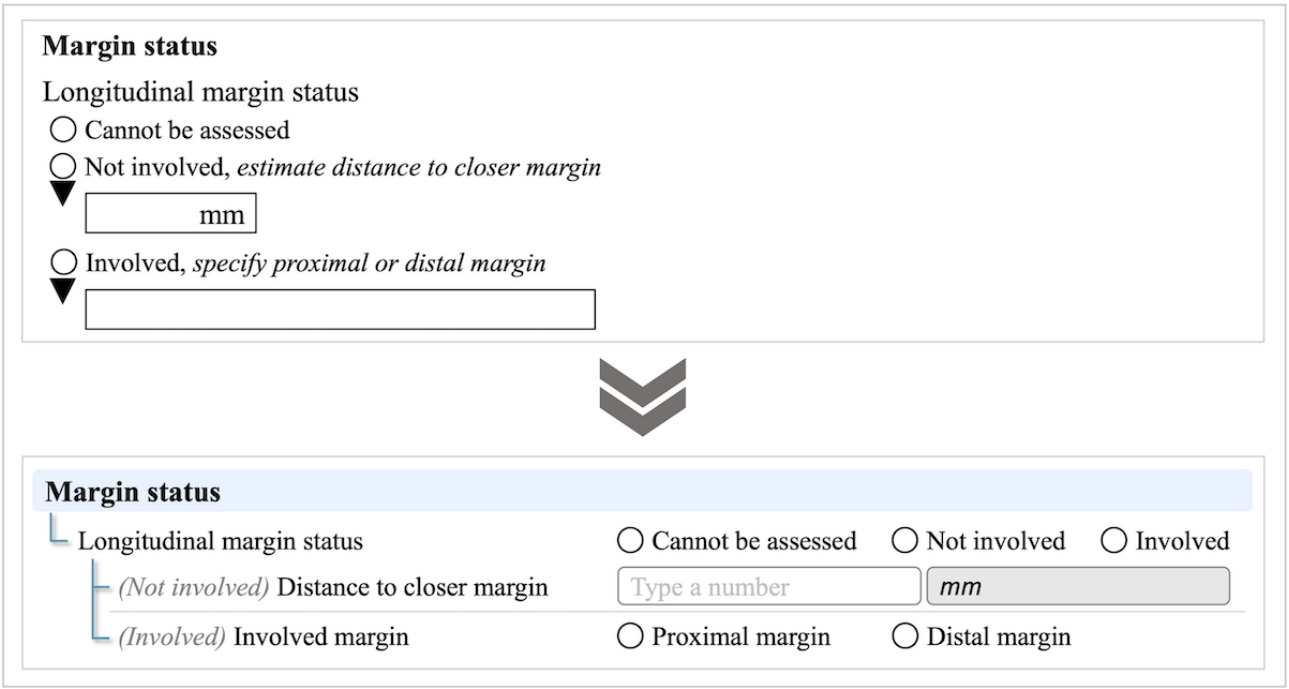
Interoperable Cancer Reporting Template Development



Evaluation of Data Elements and Structure

To develop an SDC of the ICCR CRC dataset, each category of information to be assessed by the pathologist and set of potential observations (ie, constrained value set) was evaluated.

Categories of observations are often “nested” or grouped into logical subcategories when represented in reporting protocols. Such categories can be semantically different, and reporting of subcategories can be contingent upon assessments of predicate subcategories. This condition requires the ability to selectively (ie, logically) solicit observations based on prerequisite information and to associate the semantically correct SNOMED CT concepts for each subcategory of observations. For example, the overarching category of lymphovascular invasion nests three separate semantics into a single category. The observation to be made is the presence or absence of direct invasion in particular lymphovascular spaces: specifically small vessels (ie, venule, arteriole, or lymph vessel), large extramural blood vessel (ie, vessels in pericolic tissue), or large intramural vessels (ie, vessels in the colonic submucosa or colonic muscularis propria). To accommodate these categories and accurately represent each category’s semantic meaning, the overarching lymphovascular category was reconstructed into separate questions (ie, subcategories; see Figure 2).



XSL•FO
RenderX

Figure 2. Reconstruction (separate question): lymphatic and venous invasion.

The ICCR datasets and those of the CAP are published with observation value sets that consist of the list of expected or plausible assessments. These lists do not represent all possible assessments, which would be unwieldy, if not impossible, to represent in a dataset. Therefore, a free-text option is made available for most categories of assessments. Nevertheless, where possible, we converted free-text fields into structured data entry. For example, we changed the data type from free text to an answer list for assessments of involved surgical margins based on ICCR supporting notes. Free-text data types require human intervention, consume significant time, and are prone to error. Automatically identifying the specific data within free-text fields is not feasible. To minimize human intervention, we specified which margin was involved by carcinoma, as shown in Figure 3. In the original CRC dataset, pathologists were required to describe the surgical margin if the longitudinal margin was involved by carcinoma. We changed this data element into two answers: proximal margin and distal margin.

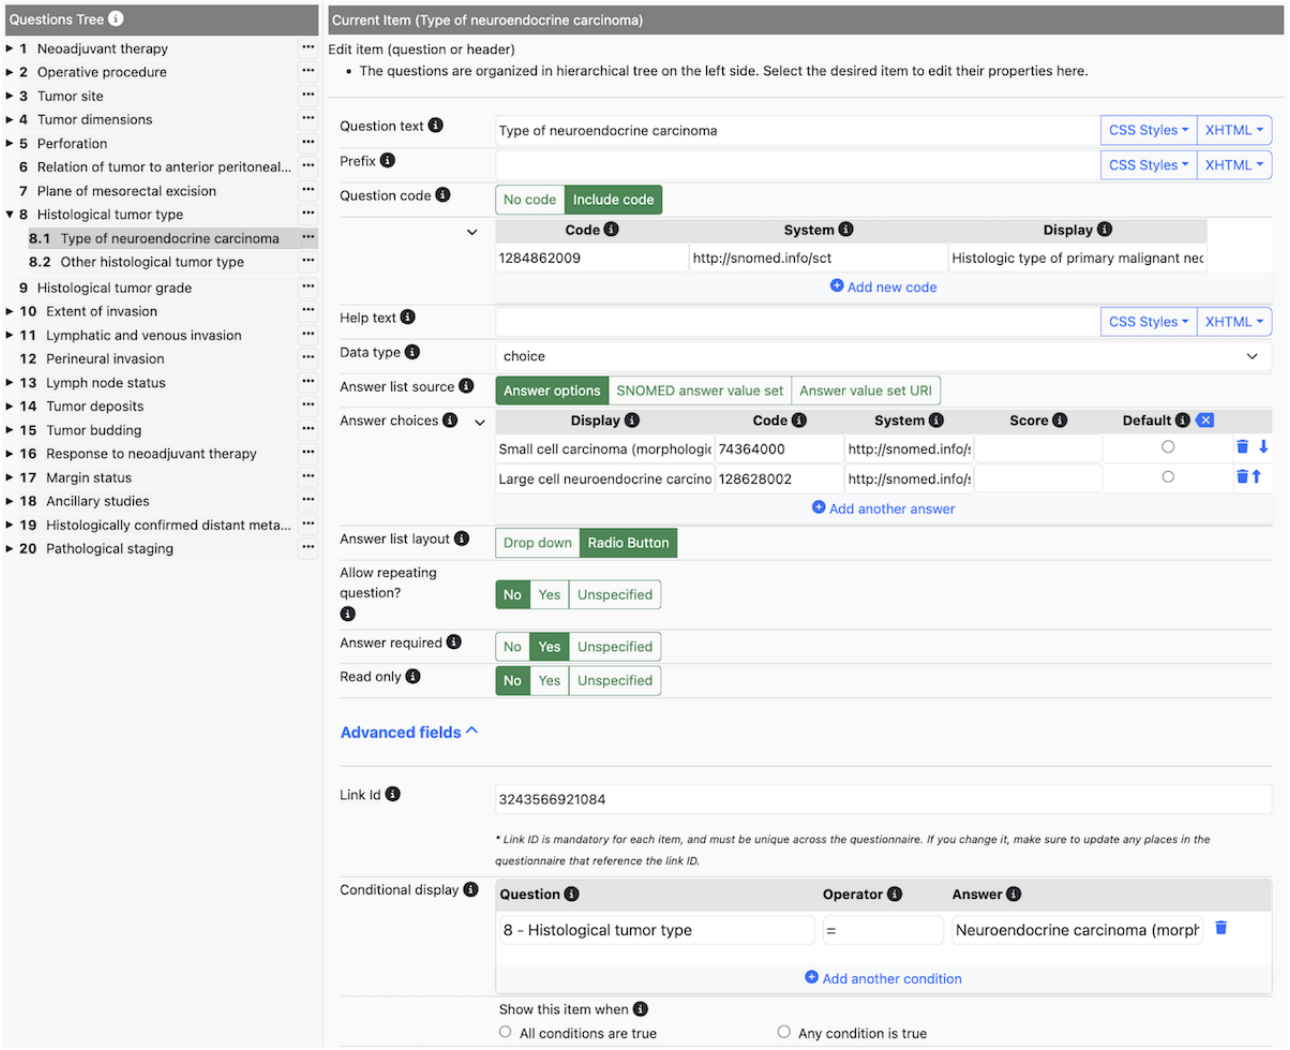
Figure 3. Reconstruction (data type convert): margin status.

Terminology Binding

After reconstruction, SNOMED CT concepts from the latest version of SNOMED International (version 2025-02-01) were associated (ie, bound) with each data element. Following the synoptic style, (ie. question and answer pair structure), the context for any recorded observation is represented in the observable entity concept; we referred to it as the observable entity approach. Table 1 shows an example of SNOMED CT terminology using this observable entity approach for histologic type of CRC malignant neoplasm.

XSL•FO
RenderX

Table . Example of terminology binding - Histological tumor type.



Element value	SNOMED ID and fully specified name
Question	
Histological tumor type	1284862009 |Histologic type of primary malignant neoplasm of cecum and/or colon and/or rectum (observable entity)|
Answer	
No evidence of residual tumor	41647002 |No evidence of (contextual qualifier) (qualifier value)|
Adenocarcinoma	1187332001 |Adenocarcinoma (morphologic abnormality)|
Mucinous adenocarcinoma	72495009 |Mucinous adenocarcinoma (morphologic abnormality)|
Signet-ring cell adenocarcinoma	87737001 |Signet ring cell carcinoma (morphologic abnormality)|
Medullary carcinoma	32913002 |Medullary carcinoma (morphologic abnormality)|
Serrated adenocarcinoma	450948005 |Serrated adenocarcinoma (morphologic abnormality)|
Micropapillary adenocarcinoma	450895005 |Micropapillary carcinoma (morphologic abnormality)|
Adenoma-like adenocarcinoma	28558000 |Villous adenocarcinoma (morphologic abnormality)|
Neuroendocrine carcinoma	1286767006 |Neuroendocrine carcinoma (morphologic abnormality)|
Small cell type	74364000 |Small cell carcinoma (morphologic abnormality)|
Large cell type	128628002 |Large cell neuroendocrine carcinoma (morphologic abnormality)|
Mixed neuroendocrine-non-neuroendocrine neoplasm (MiNEN)	785766008 |Mixed neuroendocrine-non neuroendocrine neoplasm (morphologic abnormality)|
Other	74964007 |Other (qualifier value)|
Other, specify	This response is not codable data.

Building an SDC

The NLM form builder tool was then used to represent the category for assessment and the value sets of responses in an FHIR-compatible SDC (see Figure 4). Natural language consistent with the ICCR template was used for the user interface (ie, question text). At the same time, the data layer and semantic meaning of the recorded observations made in the SDC were represented using a reference to SNOMED CT. Most data elements were qualitative values, but several assessments to be made by the pathologist required discrete or numerical entries. In these situations, the NLM SDC data element was configured to solicit and accept a numerical entry. These included categories of assessments pertinent to tumor dimensions (size) and numbers of lymph nodes examined and involved.

XSL•FO
RenderX

Figure 4. The National Library of Medicine (NLM) form builder (version 9.7.2).

Ethical Considerations

This study did not involve human participants and therefore was not subject to institutional ethical review.

Results

Targeted Elements and Reconstruction

The CRC dataset contains a total of 25 categories (ie, items to be assessed by the pathologist), comprising 19 core categories and 6 noncore categories. After evaluating the value of data elements, all data elements from core categories and some noncore categories were selected as target items. Following reconstruction based on meaning, the standardized CRC dataset from ICCR was converted into 45 questions and 171 answers.

Building Results

Table 2 summarizes the SNOMED CT concepts used for binding. Of the 216 data elements in the ICCR CRC protocol, 207/216 (95.8%) were able to be bound to SNOMED CT concepts. All questions bound with SNOMED CT concepts used the semantic tag (observable entity). For answers, concepts with the semantic tags (qualifier value), (body structure), (morphologic abnormality), (procedure), and (tumor staging) were used accordingly. Answer values are not necessarily unique to the question, and SNOMED CT answer concepts represent answer or observation values across several question categories. For example, ‘52101004 |Present (qualifier value)|’ or ‘47492008 |Not seen (qualifier value)|’ are used in several observation categories. The observable entity concept representing the question or category is unique and carries all necessary context by which to interpret the answer or observation. Thus, the same SNOMED CT concepts may be used for multiple answers and still maintain the semantic integrity of the data. Further details are provided in Multimedia Appendix 1 which includes data elements and the corresponding bounded SNOMED CT concepts.

XSL•FO
RenderX

Table . Summary of the binding results.

Binding status	Semantic tag	Values, n
Question		
Not bound	__[a]	3
Bound	Observable entity	42
Answer		
Not bound	__[a]	6
Bound	Body structure	15
Bound	Morphologic abnormality	13
Bound	Procedure	12
Bound	Qualifier value	122
Bound	Tumor staging	3

[a]Not applicable.

Table 3 includes unbound data elements and reasons why they are not bound. Among the 9 unbound elements, 2 data elements were added during the construction of the SDC without specific meaning, serving only as part of the logical structure. Of the remaining 7 unbound items, the first, related to 'Circumferential margin–Involved by primary tumor or other' is ambiguous and cannot be encoded accurately. Likewise, reference to 'Ancillary study for neuroendocrine markers' is not precisely defined by ICCR and cannot be reliably encoded. Finally, changes by the American Joint Committee on Cancer and Union for International Cancer Control regarding tumor, node, metastasis (TNM) descriptor representation require additions to SNOMED CT content and will be bound once a new concept is authored.

Table . Unbound data elements with their corresponding reasons and solutions.

Type of data elements		Unbound elements	Comment
Question	Answer		
Tumor dimension	Can be assessed	Answer	This item was added during creating the SDC[a].
Tumor budding	Can be assessed	Answer	This item was added during creating the SDC.
Circumferential margin–Involved by	By primary tumor By other	Question and answer	The meaning of the elements is unclear.
Ancillary studies for neuroendocrine markers	Not applicable Neuroendocrine markers	Question and answer	It is difficult to predict what will be recorded here.
TNM[b] descriptor	m–multiple primary tumors r–recurrent y–post-therapy	Question	Authoring a new concept is requested.

[a]SDC: structured data capture.

[b]TNM: tumor, node, metastasis.

FHIR Questionnaire

Discussion

Principal Results

This study describes the creation of a structured CRC ICCR pathology cancer reporting dataset bound with standardized terminology for international use, in a manner compliant with the Health Level 7 (HL7) FHIR standard for syntactic and semantic interoperability. Cancer protocols developed by CAP, ICCR, and other institutions follow a synoptic style. SNOMED terminology development for synoptic use follows this model, and newly authored concepts were used in this study. The observable entity approach is necessary to maintain the encoded question and answer data element pair for data integrity. As a result, the implementation and data storage of synoptic reports must accommodate this pairing. The NLM SDC precisely accommodates synoptic style and retains the question-answer binding, as reflected in Figure 2. Interoperation on a syntactic level, known as syntactic interoperability, is a mainstay of interoperability [29] and facilitates data transmission between information systems. The standards to achieve this are HL7 version 2 (HL7 v2) and FHIR. Electronic synoptic reporting is supported using either version. However, we focused on the FHIR representation to demonstrate the feasibility of using its architecture for pathology reporting, as it leverages open web

XSL•FO
RenderX

technologies and represents the future direction of international health data exchange [14].

The primary purpose of the NLM form builder is to create SDC-based questionnaires. The form builder is very user-friendly and supports features such as conditional display, data type and value restrictions, cardinality of responses, valid observation values, and default values. In short, using SDC-based questionnaires facilitates usability while ensuring that well-structured and high-quality data are collected.

Much of this paper addresses data collection, data quality, and data representation. The primary purpose of FHIR is data exchange. HL7 message creation and formatting is a function of the NLM SDC form builder tool. The form builder produces a FHIR Release 3 Standard for Trial Use and Release 4 compliant FHIR message capable of transmission in FHIR format as well as devolution into a compliant HL7 v2 format. Thus, using the approach described in this work, a FHIR-capable method for pathology cancer reporting data exchange is created.

Challenges

While the findings of this project are promising, it is necessary to consider operational challenges.

Version Control

Cancer reporting guidelines evolve over time. In some instances, new SNOMED CT content will be necessary. Therefore, a process for protocol (dataset) version control and terminology binding review must be developed. The ICCR is responsible for maintaining clinical content, and SNOMED International is responsible for terminology content. The organizations have agreed to ongoing collaborations to ensure alignment of terminology with clinical content.

Implementation Complexity

Using the ‘observable entity approach’ implemented in cancer synoptic reporting can be more complex than other approaches. In the observable entity approach, the question, or tumor characteristic to be observed, is represented by a SNOMED CT observable entity concept. Observations made and recorded by the pathologist use a variety of SNOMED CT concepts based on the tumor feature benign recorded. The observable entity concept contains full contexts and definitions to unambiguously understand the pathologist’s recorded measurement, which is represented by more generalizable concepts such as histological types, grades, and presence of various other tumor characteristics. As a result, the observable entity concept and corresponding observation concepts must be stored in tandem. This is consistent with other laboratory data types. This approach was deliberate. Existing SNOMED CT concept definitions do not support the development of fully defined clinical finding concepts in which multiple observations are contained within a single concept. Furthermore, developing such an approach would result in an unmanageable, combinatorial explosion of SNOMED CT concepts; for example, colorectal adenocarcinoma, lung adenocarcinoma, endometrium adenocarcinoma, and all possible ‘body site’ x ‘histology type’ combinations. Software developers and clinical information system vendors will need to consider this design feature when developing future applications.

Future Studies

Although an approach for interoperable synoptic pathology cancer reporting using international standards is presented in this paper, such a system has to our knowledge not yet been implemented. Interoperability, the intended objective of SNOMED CT and FHIR cannot be realized unless the system is fully tested when implemented in the real-world settings. Ultimately, FHIR may offer an improved methodology for storing SNOMED CT coded data and would enhance the exchange and sharing of pathology data. As part of implementation, there will be opportunities to test how FHIR can improve data storage, analytics, and other secondary data use cases. Future activity in this realm should include using FHIR SDC Data Extraction guidance to convert data collected using the ICCR datasets into more readily usable FHIR resources. When a FHIR Questionnaire, such as those authored as part of the methodology of this paper, is rendered in a GUI, the system produces a FHIR Questionnaire Response. Converting the data from the FHIR Questionnaire Response resource to Observations and other applicable resources would enhance the semantic interoperability and ensure that the data can be queried from FHIR-based systems. Further promotion of the benefits of adopting FHIR and incentives for both technology vendors and healthcare providers would improve adoption, as evidenced by the adoption of the standard incentivized by the 21st Century Cures Act in the United States [19], which encouraged significant FHIR adoption across the country.

Conclusions

The findings of this paper demonstrate that syntactic and semantic interoperability for cancer synoptic reporting is possible using existing international standards. The current international release of SNOMED CT contains the necessary concepts required for synoptic pathology cancer reporting for all solid tumors. Along with FHIR SDC tooling from the United States NLM, we demonstrate the plausibility of FHIR-based encoded pathology cancer reporting on a global scale.

Abstract

Background: Clinical research studies rely on schedules of activities (SoAs) to define what data must be collected and when. Traditionally presented in tabular form within study protocols, SoAs are critical for ensuring data quality, regulatory compliance, and correct study execution. Recent efforts, such as the Health Level 7 Vulcan SoA Implementation Guide, have introduced Fast Healthcare Interoperability Resources (FHIR) as a standard for representing SoAs digitally. However, current approaches primarily handle simple schedules and do not adequately capture complex requirements such as conditional branching, repeat cycles, or unscheduled events—features essential for many study designs, particularly in oncology.

Objective: This study aimed to extend SoA representation methods to address these limitations. Specific objectives were to (1) develop methods for defining multiple SoA paths within a single model, (2) specify conditional scheduling requirements, (3) design a human-readable syntax for study specifications, (4) reflect these requirements as FHIR definitional resources, and (5) test bidirectional conversion between graph-based SoA models and FHIR representations.

Methods: Building on previous work, SoAs were modeled using directed graphs in which nodes represented interactions (eg, visits) or activities, and edges defined transitions. Attributes were added to capture timing, conditional rules, and repeatability. Graph-based models were translated into FHIR PlanDefinitions and related resources (ActivityDefinition, ResearchStudy, and ResearchSubject). Extensions to PlanDefinition were developed (soaTimePoint and soaTransition) to store graph-specific attributes. Proof-of-concept models were implemented and tested using Python, NetworkX, pandas, and FHIR Shorthand, with validation conducted through FHIR servers to ensure structural equivalence and information retention.

Results: The graph-based approach successfully modeled multiple paths, unscheduled events, and conditional rules within a single SoA. Edge attributes such as transitionDelay and transitionRule enabled accurate timing calculations and runtime evaluation of permitted paths. Conditional scheduling was expressed using a parameterized syntax interpretable by logic engines. More than 25 study protocols of varying complexity were tested; all could be represented without information loss. The proposed FHIR extensions allowed PlanDefinition resources to fully capture SoA graphs rather than limited tabular forms. Round-trip testing confirmed that the graph models and FHIR resources could be converted without loss of fidelity. The approach also highlighted inconsistencies in some protocol specifications, suggesting its utility for protocol quality assurance.

Conclusions: This study demonstrates that graph-based modeling, combined with targeted FHIR PlanDefinition extensions, enables an accurate and comprehensive representation of clinical study SoAs, including complex scheduling features that are not supported by current standards. These methods improve interoperability, reduce reliance on manual interpretation, and provide a basis for the automated integration of study protocols with electronic health records. While further tooling (eg, FHIRPath and clinical quality language) is needed for operational deployment, this approach offers a more precise and extensible solution for digital protocol implementation.

KEYWORDS

Fast Healthcare Interoperability Resources; FHIR; Health Level 7; HL7; graph methods; clinical trials; schedule of activities; interoperability; electronic health records

Introduction

Background

Healthcare interoperability standards such as the Fast Healthcare Interoperability Resources (FHIR) [1] are providing new methodological approaches for the collection, collation, and confirmation of clinical research data for both observational studies and trials supporting product regulatory submissions [2-4]. To be successful, clinical research studies require that (1) the correct data are available to answer the research question and (2) these data are collected at the correct times. These are detailed in the study protocol, where the schedule of activities (SoAs), usually in the form of a square table, provides the key data and scheduling requirements. Various recent projects are underway to explore methods for digitizing all or parts of study protocols with FHIR as a key interoperability component (International Council for Harmonization M11, CDISC Unified Study Definitions Model, and Vulcan Utilizing the Digital Protocol) [5,6].

In a previous paper [7], a graph-based minimum viable set of characteristic attributes needed to define a study's SoA was developed, along with commentary on the range of "variations on the theme" encountered in different clinical study types and therapeutic areas. Operational use cases that depend on the SoA were also considered. The resulting graph representations of an SoA were converted to FHIR PlanDefinitions compliant with the Health Level 7 (HL7) Vulcan clinical study SoA Implementation Guide (IG) [8].

While the current Vulcan SoA IG can model a wide variety of clinical study SoAs, it is recognized that it is principally limited to defining relatively simple SoAs. It works well to convert SoA tables to FHIR resources; however, it does not have methods to define schedules that repeat (cycle), an essential part of most oncology studies. Similarly, it does not offer methods for conditional switching or to select different permitted (multiple) study paths. It may be coerced in some cases to manage specific situations, but this is not ideal when these "fixes" are key scheduling requirements. This can mean that a Vulcan SoA IG–compliant SoA will specify only part of the total scheduling options that a specific study requires. Subsequent use by consuming applications, such as electronic health record (EHR) systems, may or will require additional tooling to implement all study scheduling variations and control.

Considering previous work, this study investigated (1) what attributes or modifications to a graph model are needed to cover the extended use cases outlined earlier and (2) develop a FHIR PlanDefinition representation that can communicate these requirements. Additional tooling—such as FHIRPath expressions, clinical quality language, or system-specific methods (eg, EHR)—will be required to fully implement the FHIR PlanDefinition into the operational workflow of a clinical system.

This Study

The primary objectives of this study were to (1) develop methods for defining multiple SoA paths within a single graph, (2) develop methods for defining SoA conditional scheduling requirements, (3) develop a human-understandable syntax to support specific study specification, (4) reflect these requirements as FHIR definitional resources, and (5) test and confirm converting the graph representations to FHIR and vice versa

Methods

Graphical SoA Definition

Overview

The adopted methodological approach was to (1) build on previous work to investigate and develop the necessary attributes required to meet the objectives described earlier and (2) develop and test FHIR resource options to accurately describe and exchange these requirements.

Table 1 shows part of an SoA as might be presented in a protocol, and Figure 1 [7] shows a graphical representation of the primary schedule elements. The minimum set of characteristic attributes required to reflect it in this form is shown in Table 2 (refer to the study by Richardson [7] for more details). Two SoA graph node types are used in this model: "interactions," modeling study events, visits, or other direct or indirect contacts with research participants and "activities," defining the tasks required to be undertaken to meet the study objectives. These have a simple and easily understood correspondence with the tabular forms found in protocols. These were used to convert the SoAs into Vulcan SoA IG–compliant FHIR resources [7].

Table 2. Schedule of activities graph characteristic attributes[a].

Attribute	Minimal required attribute	Notes or example
Nodes		
nodeID	Yes	Universally unique identifier
Type	Yes	"Interaction" or "activity"
Subtype	No	For example, clinic visit and telephone call
Name	Yes	Protocol name of interaction or activity
Description	No	Description of interaction or activity
plannedTiming	Yes	Schedule timing (D1 etc)
referenceTimepoint	Yes	Schedule t(zero)
plannedWindow	No	Schedule timing permitted variance
plannedDuration	No	Duration of interaction or activity (eg, 24 h)
Edges		
edgeID	Yes	Universally unique identifier
transitionType	No	Timing relationship between nodes

[a]Adapted from the study by Richardson [7].

Multiple SoA Paths

Standard graph methods were used to develop and test the attributes necessary to model and define the routing objectives (use cases) established earlier. The primary considerations were to (1) accurately reflect different study scheduling options using property graph methods and (2) ensure that the resulting models had a user-friendly correspondence to standard clinical trial scheduling concepts. Only methods using directed graphs were considered.

Conditional Scheduling

Methods to accurately model the conditional scheduling requirements within a single SoA graph initially used path analysis to identify the set of adjacency matrices required for each scenario. These were then used to develop a specification syntax that could define any specific conditional requirement, which, with appropriate tooling, can be implemented such that any subgraph can be extracted from the primary specification. Consideration was given to ensure that (1) permitted routes, such as those required by schedules with different treatment arms, could be defined and (2) the method could support controlling individual schedules dynamically (eg, as individual research participants were reviewed during their visits)

FHIR PlanDefinition

The Vulcan SoA IG [8] was used as the starting point for reviewing and evaluating methods to reflect the approaches mentioned earlier as FHIR resources. The primary resources used were *PlanDefinition*, *ActivityDefinition*, and the associated resources that are required to configure a complete description for a specific study (ie, *ReseachStudy, ResearchSubject*, etc). The main *PlanDefinition* elements investigated were *action.condition*, *action.relatedAction*, *action.timing*, and the 5 *action.<xxx>Behaviors*. All work was undertaken using version FHIR Release #5 (version 5.0.0) resources [1].

Model Testing and Proof of Concept

Graph database methods were used to develop and test the specification methods. Proof-of-concept example graphs were built using the Python generalized programming language [9], the NetworkX graph and network libraries [10], and the pandas data analysis library [11].

FHIR resource examples were generated using the Python fhir.resources library [12,13] and HL7 FHIR Shorthand definitions [13]. The yED graph editor (yWorks GmbH) was used to create the visual graph presentations and as an editor to create specific test examples [14]. The accuracy of the FHIR resources versus the graph model was confirmed by visual and programmed comparisons of the resulting definitions. The FHIR resources generated from each proof-of-concept example were confirmed as valid FHIR resources by loading them to publicly available FHIR end points, recovering the specifications using FHIR searches, and confirming that the full original specifications could be recovered without information loss.

SoA Example

Examples and illustrative figures used in this paper are based on the SoA graph shown in Figure 1.

Ethical Considerations

The study does not include human participants, use of medical records, or patient information.

Results

Multiple SoA Paths

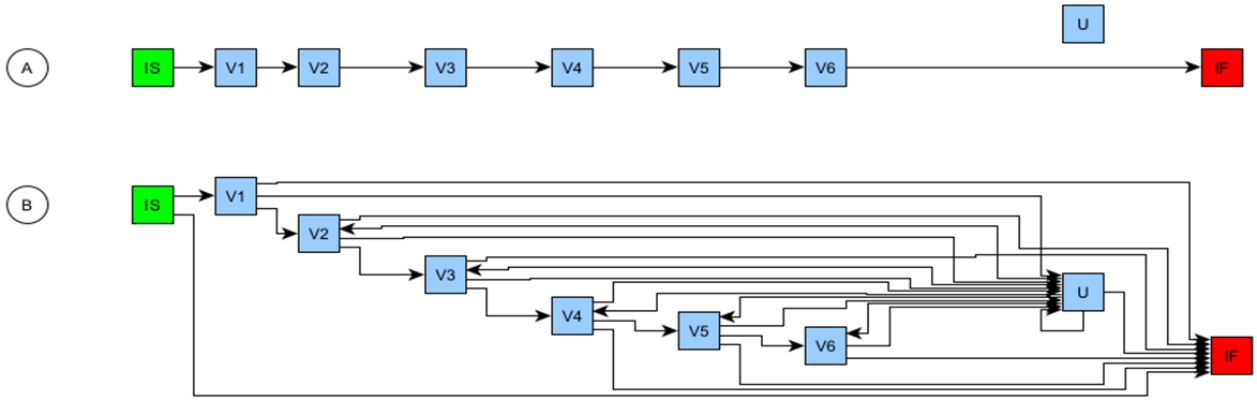
Figure 2 illustrates the general problem that arises even with a simple study design when considering how to define all protocol-defined permitted paths. Figure 2A shows how the scheduled visits of Table 1 might be presented as a directed graph. However, the "unscheduled" visit "floats" independently

XSL•FO
RenderX

as it is to be used on an "as required" basis over the period of the planned visits.

Defining all permitted paths (ie, extending Figure 2A to add all protocol-implied paths) is shown in Figure 2B and is easily achieved simply by adding appropriate visit-visit edges. Similarly, all potential activity sequencing options can be defined using the same method (Figure 3).

Figure 2. The schedule of activities directed graph representations of the visit schedule described in Table 1. (A) Protocol explicitly defined schedule with "floating" unscheduled visit (U). (B) Expanded version with all implied permitted paths defined. Two important implied paths are now present: routes for a participant to leave the study at any point (eg, V1>IF), and routes to and from U, if required. IS: instantiation start; IF: instantiation finish.



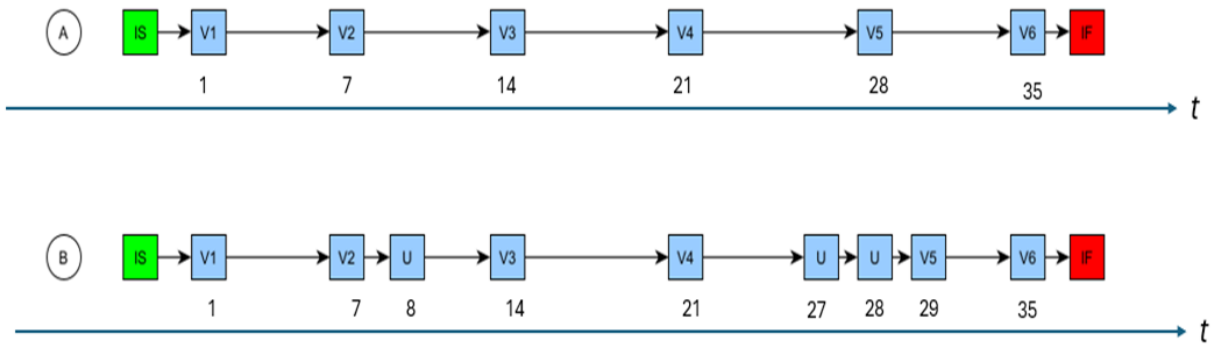


Figure 3. The schedule of activities directed graph representation of visit V1 activities from Figure 1, showing the protocol specified order (left to right) with the added requirements for those cases where (A) the inclusion criteria are not met, or (B) exclusion criteria are present. These paths formally define how to finish the visit "early." The resulting visualizations, although busy, remain user-friendly from a review or quality control perspective. AS: activity start; AF: activity finish.

No additional node or edge attributes beyond those listed in Table 2 are required to define all permitted paths. However, ensuring that the timing calculations for any path are computable cannot be achieved using the planned timings alone. Here, the problem is that the scheduled planned timings are node (visit) attributes, but calculating the timings for any path requires a summation of the transitions along whichever path is selected (Figure 4).

Figure 4. (A) Timing calculation attributes per protocol schedule, together with the relative day on which the visit occurred. (B) The same schedule but with 3 unscheduled visits. The first unscheduled visit (U; day D8) has no effect on the planned schedule, whereas the second (D27) and third (D28) U caused V5 to occur on D29 rather than on D28. In this case, the relative day of the visits cannot be determined from the planned timings alone. IS: instantiation start; IF: instantiation finish.

Unscheduled visits may necessitate rescheduling of scheduled events. The addition of a *transitionDelay* edge attribute (Table 3; defined as the time to wait before transitioning to the next node) was found to provide the necessary timing information. It also provides the basis for a key timing consistency check.

plannedTiming (V_n)*=sum(transitionDelay) from referenceTimepoint to* V_n

XSL•FO
RenderX

Table 3. Edge attributes required for path timing calculations.

Edge attribute	Minimal required attribute	Notes or example
transitionDelay	Yes	"Wait" time before moving from source to target nodes (ie, V1>V2 7d)
transitionWindow	No	Permitted transitionDelay variance
transitionType	No (default)	start-to-start, default; start-to-finish; finish-to-start; and finish-to-finish

Conditional Scheduling Attributes

Figures 2B and 3 also illustrate that there are many cases where specific conditions require different (but permitted) routes to be followed. Some cases are generic and are present in any study (eg, participant's right to withdraw at any time), some are protocol-specific (eg, if the participant is male, a pregnancy test is not required), and some complex, as illustrated in Figure 2B for managing all "unscheduled" path options (eg, an "unscheduled" visit following V_n cannot return to early visits, only being able to proceed to the next planned visit).

To accurately carry all conditional scheduling requirements within a single SoA graph, it was found that 3 things were required as follows:

1. A method to specify (and therefore recognize) a graph within the graph.
2. A syntax to define how to select a subgraph and restrict access to identified paths in the graph.
3. A method that can be implemented as a dynamic graph (ie, as the graph changes over time).

Both graph node attributes and edge attributes in the model here could be used to hold conditional scheduling information. Adding conditions to the nodes (eg, [visit] *repeatAllowed: true/false*) was found to satisfy some standard requirements (eg, can a visit be repeated? *V2: repeatAllowed: false*, and *Unscheduled: repeatAllowed: true*), but the other requirements were very poorly satisfied (particularly regarding what routes are available following an unscheduled visit). Adding the following edge attribute was found to accurately and easily model all the SoA tested use cases:

- Attribute: transitionRule
- Minimal required: yes
- Explanation: rule specifications that can be resolved to True (path can be selected) or False (path unavailable)

This approach was also user-friendly, as only the conditions on each edge (transition) were needed to ensure the use of any specific path (ie, by answering the question "under what conditions can this path be selected or is not available?" and this can also include multiple conditions).

Conditional Scheduling Syntax

A parameterized specification syntax was developed to hold the edge attribute conditions that can be consumed as inputs to a truth table engine that would resolve all edge conditions to the single "true" or "false" as described above. Simple *{"function": "inputs"}* pairs were used to specify the "true" or "false" state at runtime for that condition (eg, *{"consentObtained": true}*) or any combination of conditions.

The following examples show how several commonly required SoA conditional requirements can be defined using this approach.

Dynamic Graph Specification

The primary use case here is the definition of permitted paths through the study, including, but not limited to, the primary path. For example, in Figure 2B, paths exist to and from "unscheduled" to all "visits" permitting return to the primary schedule. However, "unscheduled" visits cannot return to a previously visited "visit" (discussed earlier). Two rules are required for this case: one to confirm the existence of previously visited visits, and one to ensure that all "future" visits have not yet been visited. The following example shows the rules required on edge U>V3 in Figure 2B, which will ensure that only this path is available at runtime:

{'interactions_exist': ['IS', 'V1','V2']}, {'interactions_not_exist': ['V3', 'V4', 'V5', 'V6", 'IF']}

(ie, If visits instantiation start [IS], V1, and V2 have occurred and visits V3, V4, V5, V6, and instantiation finish [IF] have not occurred, moving from unscheduled visit [U] to V3 is allowed).

Similar rule pairs, when applied to all U>V_n edges, can then ensure that only "forward" paths are available for selection.

Conditional Activity Selection

Restricting, adding, or skipping activities dependent upon participant conditions is a very common feature of SoAs, with the details often provided as footnotes to SoA tables. Examples include requiring pregnancy testing if the participant is female (and conversely not requiring this if the participant is male) and not proceeding with further tasks if inclusion criteria cannot be met (Figure 3). Example rules for these cases are simple to define, but consideration of all edge options is usually required, as follows:

On edge to "exclusion criteria" {"if_criteria_met":true}

On edge to "AF" {"if_criteria_met":false}

Conditional Repeats

An important feature of many SoAs is the requirement to repeat activities (eg, blood pressure measurements) or to repeat visit blocks. This last use case is particularly important in the case of many oncology studies where repeating treatment cycles is an inherent part of the study design and will have some limit on the number of cycles and the requirement to exit the study if too many cycles are proving necessary. Typical edge rules for controlling repeat or cycle situations include the following:

XSL•FO
RenderX

Repeat blood pressure measurement 3x. On edge to "self": {"maxRepeats":4}

Limit the number of cycles to a max of 5.On edge to start of cycle: {"n_cycles": "<6"}

Subject States, Milestones, and Events

Often, the requirement to select different SoA paths is dependent upon states, milestones, or events, as, for instance, defined by the FHIR ResearchSubject resource [1]. This can be illustrated by the following examples:

To enter an off-label extension study.

On edge to Open Label Extension schedule: {"continue_to_OLE": true}

If an adverse event occurs.

On edge to adverse event activity: {"record_AE": true}

Multiple Conditions

The syntax also permits any number of conditions to be defined easily within a single SoA graph for any given edge to obtain a sample for genetic testing. This can be illustrated by the following example:

{"studyPhase":"onStudy"},
{"sampleObtained":"true"},
{"geneticTestingConsent":"true"},

The runtime assessment of each condition then serves as the input to a logic engine that determines the final true or false state.

Undefined SoA Graphs: Implied Edges

Undefined SoA paths can also be recognized using this approach. An undefined path is defined here as one that may occur but is not recognized formally within the SoA graph. A good example of this is the right to withdraw from a study at any time or skip an activity. Formally recognizing every point where these conditions may occur and providing a defined path may add too much complexity to the graph, and it may be unreasonable to model it. However, placing a general requirement on all transitions (edges) of *{"withdrawn": false}* will permit proceeding through the schedule until *{"withdrawn": false}* == "false" (ie, withdraw is now "true"). Using suitable runtime coding, the "undefined" transition can be applied to the specific participants' SoA graph instance.

FHIR SoA PlanDefinition Review

The primary objective of this study was to identify methods that enable SoAs to be more fully defined using FHIR resources. The SoA graph review identified the necessary additional requirements needed to satisfactorily model SoA specifications, such as those shown in Figure 1. To successfully define these specifications using FHIR resources, they must meet the following requirements:

1. Represent all SoA-identified paths
2. Recognize and "respond" to conditional cases
3. Allow consuming applications to be able to "walk" any permitted path

The Vulcan SoA IG [8] was used as the starting point for developing a more comprehensive SoA FHIR model with the goal of extending or modifying it to be able to manage the complex designs, conditions, and "variations on the theme" as discussed earlier.

FHIR PlanDefinition SoAGraph Definition

From the graph attributes model developed earlier, it follows that for the *PlanDefinitions* to fully specify all SoA requirements, it needs to hold a definition of the SoA graph, and not the SoA table. Reviewing the use of the *PlanDefinition.action* and *PlanDefinition.action.action* elements, the basic graph node and edge relationship can be defined. Specifically, with nodes (visits) mapped to *PlanDefinition.actions* and edges(transitions) mapped to *PlanDefinition.action.actions*, all the relationships defined, for example, in Figure 1, can be specified within a single *PlanDefinition.*

PlanDefinition.action in its standard form does not support those elements (attributes) to hold all the necessary SoA specification details. These have been added using 2 extensions, that is, *soaTimePoint* and *soaTransition* (Figure 5 [7]) to hold the graph information, which in turn then forms the basis for an *soaPlanDefinition* profile (Multimedia Appendix 1).

XSL•FO
RenderX

Figure 5. Fast Healthcare Interoperability Resources extensions (as FHIR shorthand) used to associate the soaGraph node and edge attributes with PlanDefinition.action (SOATimePoint) and PlanDefinition.action.action (SOATransition), respectively.

```
Extension: SOATimePoint

* extension[soaTransitionDelay].value[x] only Duration  // wait time between states
* extension[soaTransitionRange].value[x] only Range // transition permitted window
```

FHIR PlanDefinition SoAGraph Condition and Selection Definition

Conditional SoA requirements can now be specified using the *PlanDefinition.action* element *condition* (applied to *PlanDefinition.action.action*), with each edge having all or any true or false conditions for that transition. When combined with *PlanDefinition.groupingBehaviour* and *PlanDefinition.selectionBehaviour*, path selection can be restricted to 1 path only, with only those transitions that are permitted being available for selection. Figure 6 shows the FHIR Shorthand specification for node V2 in Figure 2 and Multimedia Appendix 2.

XSL•FO
RenderX

Figure 6. FHIR shorthand annotated version of PlanDefinition definition of visit V2 (.action) and its associated soaGraph transitions: V2>V3, V2>IF (instantiation finish; withdrawal), V2>U (unscheduled visit; .action.action). V2 attributes are defined using the ...action.soaPlannedTimepoint extension. The selection behavior is defined by ...action.groupingBehaviour and ...action.selectionBehaviour. For each path from V2, the conditions that must be met for that path to be available for selection are given in ...action.action.condition(s). V2, V3, U, and IF are the schedule of activities time points in Figure 2.

```

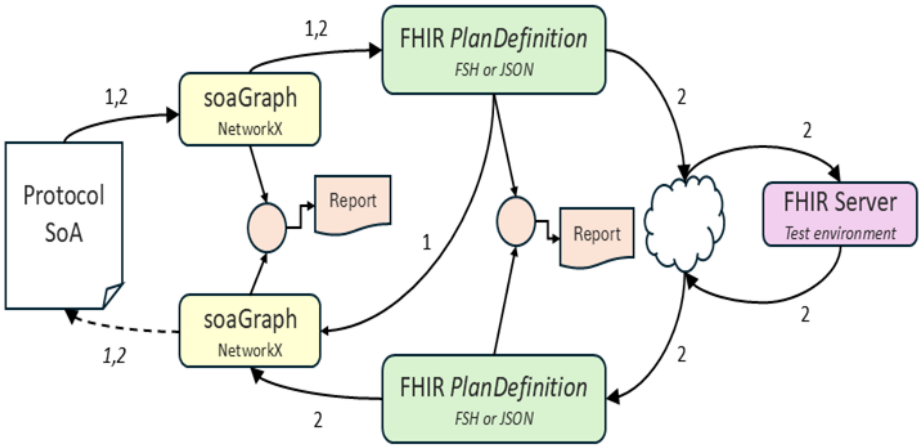
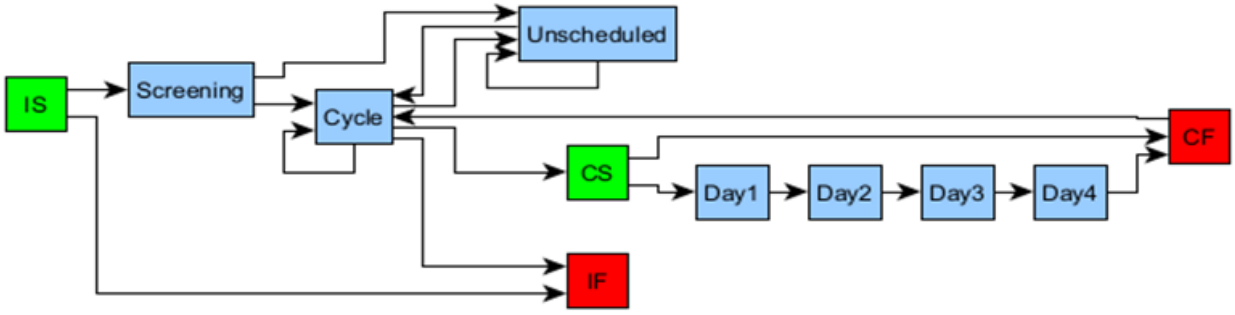
```



To operationalize the FHIR PlanDefinition within the workflow of a clinical system, such as an EHR, additional tooling is required. The illustrative syntax presented in the examples—for instance, *expression = "{'interactions_not_exist': ['V3', 'V4', 'V5', 'V6', 'IF']}"*—serves to demonstrate the underlying logic but is not directly executable within an FHIR environment. In practice, these expressions must be translated into an FHIR-compatible solution, typically by leveraging FHIRPath, clinical quality language, or system-specific functionality. Such translation ensures that the abstract representations in the PlanDefinition can be implemented as concrete, machine-interpretable instructions within the clinical system's workflow.

Proof of Concept

All the interim and final products, methods, and results described earlier were validated using the testing schedule shown in Figure 7. Once interim inconsistencies were reviewed and resolved, no SoA information loss was present after recovering an soaGraph from a FHIR *PlanDefinition* (Figure 7; test cycle 1) or after loading and recovery from test FHIR servers (test cycle 2).



XSL•FO
RenderX

Figure 7. Proof-of-concept testing overview. The numbers highlight the 2 principal testing cycles used. Recovered products were compared with the original for reviewing structural equivalence and information loss throughout the development process. FHIR: Fast Healthcare Interoperability Resources; FSH: FHIR Shorthand; SoA: schedule of activities.

More than 25 studies, ranging from relatively simple designs, as shown in Figure 1, to complex studies incorporating cycles and multiple SoAs (not shown), were used to test and validate the approach. All tests could be accurately defined, with the most frequent finding during this exercise being that it highlighted inconsistencies in the protocol specifications themselves. It also lends itself to defining SoAs more succinctly and potentially more accurately. Figure 8 is a template for studies that includes cycles and shows that each required visit (interaction) is only defined once. With appropriate edge (transition) attributes and conditions, this can be modified to define many specific study scenarios.

Figure 8. Template soaGraph for studies with cycles. Using appropriate edge attributes and conditions, it can be modified for various study designs. The green and red nodes are included to delineate the graph instantiation and the start and finish of the treatment cycle. CS: cycle start: CF: cycle finish; IF: instantiation finish; IS: instantiation start.

Discussion

Overview

The HL7 FHIR standard is becoming, if not already, the de facto healthcare interoperability standard [2,15-18]. The primary source of many clinical trial data is EHRs, and studies usually require manual transcription of these data into electronic data capture systems. For both quality and volume reasons, this is often not optimal and has led to efforts to obtain data directly from electronic data capture systems (direct data capture) [19-22].

This study's protocol and the SoA provide the primary definitional source for a study's required research data and details of other operational requirements. The value of definitional FHIR resources to support clinical research and similar initiatives has been recognized in the Specialized Definitional Artifacts category [1].

The *PlanDefinition* resource is the primary resource for defining "a predefined group of actions to be taken in particular circumstances." The Vulcan SoA IG [23] has developed a set of profiles using this resource to define SoAs. As mentioned earlier, this model does not include methods to define either conditional scheduling, certain study designs (notably cycles), or the scheduling of expected but not planned events (particularly "unscheduled visits"). This work has re-evaluated how *PlanDefinition* might be modified, revised, or extended to model these situations.

Principal Findings

Using a systematic review of the relationships and attributes required to define the SoA characteristics discussed earlier, a graph-based method has been developed that can manage all these cases. Subsequently, by associating *PlanDefinition.action* and *PlanDefinition.action.action* directly with graph nodes and edges, respectively, SoAs with all scheduling variations, conditional paths, and methods to manage planned but unscheduled events can be defined within a single

XSL•FO
RenderX

PlanDefinition. Recognizing that an SoA "activity" has both timing and task elements (ie, is "X" in tabular SoAs), the model formally disassociates the scheduling information from the task or activity definitions, which can then be linked using the *PlanDefinition.action.relatedAction.targetId* element. This approach also enables SoA activities as described in study protocols (or not described) to be fully traceable in the SoA schedule, but specified fully using other appropriate FHIR definitional resources (eg, *ActivityDefinition* and *ObservationDefinition*)

Comparison With Prior Work

Earlier work based on using both graph methods for SoA definition [23,24] and FHIR for interoperability [25-27] has shown the value of this approach for communicating sponsor protocol requirements systematically for implementation in EHRs and similar systems [4,21,22,28-31]. The work here has re-evaluated the approach to specifying SoAs as FHIR *PlanDefinitions* to find solutions to several key required SoA characteristics not addressed previously. The model described here uses a radically different conceptual approach, redefining several *PlanDefinition* elements to be able to hold a graph representation of an SoA. The current method can successfully represent a wider range of SoA concepts than before and can also specify a large range of other SoA use cases that are key to many protocol designs (not shown). Because here all SoA requirements can be accurately specified within a single *PlanDefinition*, this should simplify the implementation by consuming applications. It is also clear that, with modification or the use of standard *PlanDefinition* elements, it can support other important SoA use cases not directly considered here (eg, protocol amendments with SoA consequences)

Limitations

The methods in this study were developed using FHIR Release #5 (version 5.0.0) [1] and are not necessarily compatible with earlier FHIR versions.

Conclusions

The methods described in this study offer an alternative approach to defining clinical study SoAs using FHIR definitional resources compared to previously published articles and may offer advantages with regard to some key requirements not addressed by other proposed approaches.

Abstract

Enhancing clinical reasoning and reducing diagnostic errors are essential in medical practice; OpenAI-o1, with advanced reasoning capabilities, performed better than GPT-4 on 15 Japanese National Medical Licensing Examination questions (accuracy: 100% vs 80%; contraindicated option detection: 87% vs 73%), though findings are preliminary due to the small sample size.

(JMIR Med Inform 2025;13:e68527) doi:10.2196/68527

KEYWORDS

natural language processing; artificial intelligence; clinical reasoning; medical errors; large language model

Introduction

Diagnostic errors account for more than 8% of adverse medical events and up to 30% of malpractice claims [1]. Enhancing clinical reasoning could mitigate this [2], improving patient outcomes and potentially lowering legal liabilities. In September 2024, OpenAI introduced OpenAI-o1, a large language model (LLM) trained with reinforcement learning to enhance its complex "reasoning" [3,4]. Key enhancements include advanced attention mechanisms, refined training data and curation, and enhanced fine-tuning protocols [3,5]. However, it remains uncertain whether OpenAI-o1 can improve clinical reasoning and reduce diagnostic errors.

In the Japanese National Medical Licensing Examination (JNMLE), candidates must not only achieve high overall accuracy but also avoid selecting contraindicated options—errors that can lead to failure even if most answers are correct. Although prior studies indicate that ChatGPT-4 performs well on the JNMLE, it sometimes chooses contraindicated options [6]. We posited that OpenAI-o1 would exhibit superior reasoning compared to GPT-4 and hypothesized that it would more proficiently avoid contraindicated options.

Methods

On October 10, 2024, we used 15 text-based JNMLE questions (from 2019 to 2024) that included contraindicated options (Multimedia Appendix 1). Questions with images were excluded due to OpenAI-o1's inability to process visual data. We administered the questions to both GPT-4 and OpenAI-o1, with each model evaluated under the supervision of designated examiners (MO and TM).

The examination comprised 3 steps: (1) Japanese examination—select correct answers, (2) Japanese examination—identify contraindicated options, and (3) English examination—repeat steps 1 and 2 with translated questions. Translation used an automated system and was reviewed by bilingual clinical expert YY.

The responses from both models were recorded, and the results were evaluated based on the numbers of correct answers and correctly identified contraindicated options in both languages.

Results

As shown in Multimedia Appendix 1, among the 15 questions, GPT-4 correctly answered 12 (80%) and identified 11 contraindicated options (73%) in Japanese. In English, GPT-4 correctly answered 13 questions (87%) and identified 11 contraindicated options (73%). OpenAI-o1 correctly answered 15 questions (100%) and identified 13 contraindicated options in Japanese (87%). Both GPT-4 and OpenAI-o1 had consistently equal or better performance in English than Japanese, especially for contraindicated options.

Discussion

OpenAI-o1 had higher accuracy than GPT-4 and was better able to select contraindicated options on the JNMLE, particularly in

XSL•FO
RenderX

English. However, this difference was minimal—only 1 of 15 questions showed improvement in English—indicating that language had little overall impact.

In medicine, avoiding contraindicated actions is crucial. While correct answers reflect basic medical knowledge, recognizing what should not be done requires advanced critical thinking and reasoning. Errors can lead to patient harm, lawsuits, or even license revocation. Here, OpenAI-o1 outperformed GPT-4 in identifying contraindicated actions. OpenAI-o1's enhancements [3,5] and our finding of its superior reasoning ability suggest the importance of using LLMs with robust reasoning capabilities for medical licensing examinations and, by extension, in clinical practice, to safeguard patient safety and uphold high standards of care.

Our study is limited, first, by using only 15 questions, so these findings should be interpreted as preliminary and hypothesis-generating. Second, we used the models' default settings without fine-tuning, prompt engineering, or chain-of-thought modifications, capturing their performance at only a specific time point. Third, we obtained a single response per query, which may not reflect the full variability of LLM outputs. Fourth, continuous model updates limit exact reproducibility. Fifth, only 2 of 15 questions showed discrepancies, limiting our ability to analyze performance trends across question types (eg, clinical scenarios, complexity, and format). Sixth, we focused on comparing OpenAI-o1 and GPT-4 and excluded human performance benchmarks (eg, from medical students) due to the study's rapid initiation in October 2024, immediately following the release of OpenAI-o1. Given GPT-4's extensive dataset training and OpenAI-o1's enhanced reasoning capabilities, our primary objective was to promptly assess their differences in a medical context; frequent updates to LLMs and the time required for ethics approval and participant recruitment precluded human comparisons. Future research should integrate such comparisons. Lastly, we did not statistically evaluate the significance of the observed performance differences, further limiting our findings' interpretability. The "black box" nature of both OpenAI-o1 and GPT-4 also limits interpretability; future research should use methods like attention analysis and causal reasoning tests and compare these models with open-source alternatives (eg, DeepSeek, Qwen) to enhance reproducibility and transparency.

The improved reasoning abilities of OpenAI-o1 may hold promise for real-world clinical applications. However, these findings are preliminary, and further research is needed to determine whether integrating such models into decision-support systems can contribute to reducing errors and enhancing patient care.

Abstract

Background: Digital communication between nurses and medicine interns plays a crucial role in patient care. However, excessive messaging may contribute to alert fatigue, potentially affecting workflow efficiency and clinical decision-making. Although prior research has examined general messaging behaviors among clinicians, few studies have specifically analyzed messaging patterns between nurses and interns, who serve as primary points of contact in inpatient care.

Objectives: This study aims to quantitatively characterize messaging patterns between the primary nurse and primary provider (ie, medicine intern) of hospitalized patients at an academic medical center in order to identify communication burdens and potential inefficiencies. By identifying trends in message volume, timing, and response rates, we seek to inform strategies to optimize communication workflows and mitigate alert fatigue.

Methods: At a large academic hospital (Tufts Medical Center, Boston, MA), we analyzed secure messaging transactions between internal medicine interns and nurses across three medical-surgical units over 6 months. Transaction metadata, time stamps, and unique message tokens were extracted. Data processing was performed using Python, Microsoft Excel, and R. Message volume, interaction frequencies, and response times were analyzed using measures of central tendency and statistical tests of significance.

Results: A total of 61,057 unique messages were exchanged between interns and nurses, with interns exchanging 2.5 times more messages per day with nurses than vice versa (P<.001). Messaging volume exhibited diurnal variation, indicating periods of increased communication burden. Interns read messages from nurses within a median of 35 (range: 0 - 3589) seconds, whereas nurses read messages from interns within a median of 26 (range: 0 - 3584) seconds (P<.001). The longest message response delays occurred at 4 AM, whereas the shortest occurred at 8 AM.

Conclusions: Interns experience a significantly higher messaging burden than nurses, with distinct peaks in message volume during morning rounds and overnight shifts. These findings suggest a need for interventions such as optimized digital communication protocols to reduce nonessential messaging and alert fatigue. Future research should explore the effectiveness of these interventions in enhancing workflow efficiency and the development of both in-person and digital interventions to optimize communication workflows and mitigate alert fatigue.

Introduction

As health care organizations implement secure messaging software to modernize communication among clinicians and address the shortcomings of pagers, a growing body of literature has described patterns in secure messaging transactions [1,2]. Small et al [3,4] describe an uneven burden of secure messaging on medicine providers, while qualitative analysis reveals clinicians' concerns with alert fatigue from digital communication. Alert fatigue is a phenomenon in health care

XSL•FO
RenderX

settings where providers experience a high frequency of clinical notifications, leading to desensitization of safety alerts, increased distractions, missed alerts, or cognitive overload. Such desensitization can significantly contribute to clinician burnout and affect patient care [5,6]. To our knowledge, few studies have examined the specific communication patterns between nurses and medicine interns on secure messaging platforms. Existing research provides general insights into messaging behaviors but lacks in-depth analysis of how messaging patterns between these specific groups—who often serve as the first point of contact in inpatient care—differ in terms of volume or timing [7,8].

Our institution (Tufts Medical Center, Boston, MA) implemented TigerConnect, a clinical communication and collaboration platform, in April 2022, and in turn, disabled the secure chat feature in the electronic medical record "Epic." Although TigerConnect has yielded efficiencies to clinical workflows, such as consult requests, operating room throughput, closure of radiology alerts, and emergency responses, alert fatigue from messages was cited as a reason for decreased job satisfaction on end-of-year house staff surveys. This study aims to characterize the messaging patterns between nurses and medicine interns to inform interventions to mitigate alert fatigue among two groups of clinicians with exceptionally high rates of burnout [9].

Methods

Study Setting and Data Collection

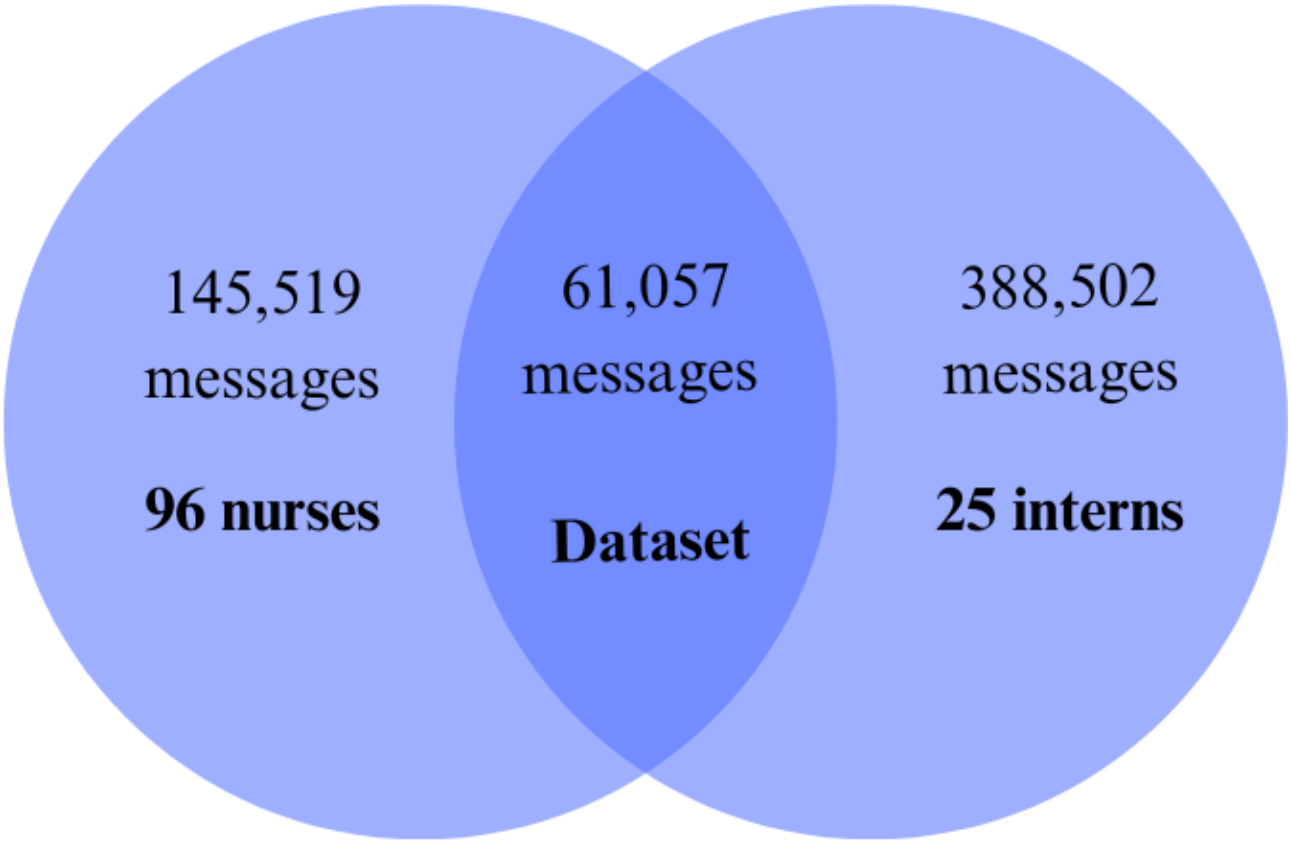
Our study was conducted at Tufts Medical Center, a 415-bed tertiary care academic institution in Boston, MA. We focused on TigerConnect transactions between 25 internal medicine interns and 96 nurses from three medical-surgical inpatient units, excluding the intensive care unit and emergency department, across 5 months from June 2022 through December 2022. We also collected transaction metadata, time stamps, and unique message tokens.

Data Analysis

We compiled the data using Python and Microsoft Excel. A dataset of messages exchanged between the interns and nurses was cleaned and analyzed using R, specifically using the *dpylr* package. We defined an "active" intern or nurse as someone who sent or received a message during a given period. Interaction frequencies were summarized using measures of central tendency. The time lag between message delivery and reading was calculated by subtracting the delivery time stamp from the read time stamp, with messages read over an hour later excluded to avoid skewing caused by outliers. Average interactions were compared using a 2-sided Welch *t*-test. This test was chosen due to unequal variances between the two groups. Median comparisons of time delays were compared using the Mann-Whitney test with an α of .05.

Ethical Considerations

The Tufts Health Sciences Campus institutional review board reviewed this study and determined that it did not constitute human subjects research; thus, it was exempt from institutional review board approval. Data from this study presents only metadata from message transactions between 25 interns and 96 nurses, including time stamps, delivery confirmations, and read receipts. To protect privacy, individual interns and nurses were deidentified, and transactions were aggregated, as the analysis focused on overall trends rather than individual messaging behavior. Individual interns and nurses were deidentified by replacing the names of individual interns with an "intern" label and replacing the names of individual nurses with a "nurse" label. Furthermore, the actual content of any messages was not accessed, in accordance with institutional policy and the scope of this study.



Results

Message Volume and Patterns

A total of 145,519 (sent and received) nurse messages and 388,502 intern messages were collected over the study period, with 61,057 unique messages exchanged between interns and nurses (Figure 1). An active intern exchanged on average 39.8 messages (range: 26.8 - 50.6) with nurses per day, while an active nurse exchanged on average 15.3 messages (range: 2.3 - 37.2) with interns per day ($P<.001$). Each intern covers up to 9 patients, whereas each nurse covers typically up to 4 patients. On average, the total number of messages exchanged over a day peaked at 11 AM. (Figure 2A). Typically, 13 interns work from 7AM to 6PM and 2 interns work from 6PM to 7AM. On average, the number of messages per active intern peaked at 10 PM. (Figure 2B).

Figure 1. Message transactions between 96 nurses and 25 interns over a 5-month period, showing the total number of messages exchanged with nurses, with interns, and specifically between nurses and interns.

XSL•FO
RenderX

Figure 2. (A) Hourly distribution of total message volumes exchanged between nurses and interns by hour of the day. (B) Hourly distribution of message volumes per active intern by hour of the day.

Message Response Times

On average, interns read messages from nurses within a median of 35 seconds (range: 0 - 3589), whereas nurses read messages from interns within a median of 26 seconds (range: 0 - 3584) (P<.001). The daily nadir and peak of delivered-to-read delays occurred at 4 AM and 8 AM, respectively.

Discussion

Principal Results

Similar to Small et al [3], we found a significantly disproportionate message burden between interns and nurses. On average, interns exchanged 2.5 times more messages per day with nurses than nurses exchanged with interns (Figure 1). This difference is reasonable, as interns care for twice as many patients as nurses. Our study also highlights diurnal variation in message volume (Figure 2). The highest volume of messages occurred mid-morning, when interns would participate in rounds and nurses would administer morning medications. During this period, critical questions and information needs to be communicated, and the inability to communicate in person likely led to increased message volume. The overnight peak in messages per active intern was likely driven by the night-time interns' lack of proximity to nurses, making in-person communication more difficult, as well as the reduced number of interns on duty at night (2 night-time interns vs 13 day-time interns).

The mid-morning peak of total messages suggests the need for interventions to reduce nonessential messages during specified time windows—for example, "quiet hours" sponsored by hospital leadership. Previous studies have demonstrated that

XSL•FO
RenderX

cooperative programs focusing on decreasing nonurgent pages can lead to a significant reduction in their number and increase uninterrupted time at night and during educational periods, thereby improving residents' work environment [10,11]. However, success depends on adherence and the ability to balance minimizing disruptions with ensuring timely responses to critical issues [10,11]. The overnight peak in messages suggests the need for investigating the effect of more proactive in-person check-ins between interns and nurses. While structured face-to-face communication—particularly during rounds—enhances team cohesion, reduces cognitive load, and fosters psychological safety, its impact outside of rounds remains sparsely investigated [12,13].

Future studies should involve implementing and evaluating the long-term effectiveness of such interventions across diverse hospital settings with different communication avenues (secure messaging, vs paging, etc), exploring how they influence provider well-being and workflow efficiency. Additionally, research should examine strategies to optimize these interventions, such as integrating quiet hours with structured escalation protocols, and assessing the feasibility of brief but frequent in-person check-ins outside of rounds.

Due to institutional policies restricting access to message content, a breakdown of message types (eg, consults, diet change requests) could not be analyzed. However, by categorizing messages based on content, one could use natural language processing to help identify specific communication patterns that contribute to alert fatigue and guide specific interventions, such as streamlining nonurgent alerts or improving response workflows. Future studies should explore the possibility of using deidentified message content to develop a more nuanced understanding of secure messaging dynamics.

While this study was conducted at a single institution—Tufts Medical Center, the messaging patterns observed between interns and nurses are likely reflective of broader trends in academic medical centers with similar communication infrastructures and staffing structures. Many academic hospitals use secure messaging platforms like TigerConnect and face similar challenges related to alert fatigue, communication breakdowns, and clinician burnout. Thus, the findings from this study can offer valuable insights for other institutions seeking to optimize clinical communication, reduce unnecessary messaging, and implement interventions that support clinician well-being.

Limitations

The study is limited by its observational nature and setting in a single institution, which may limit the generalizability of its findings. Causal conclusions could not be drawn because patterns were only observed without testing for direct effects. Other factors, such as workload, staffing levels, and communication protocols, were not analyzed and could have influenced message patterns. Future studies should include these factors to better understand messaging behavior. Institutional policies restricting message access prevented analysis of message types (eg, consults, diet change requests).

Conclusions

This study quantitatively characterizes messaging patterns between nurses and medicine interns at a large academic hospital in Boston, MA, revealing an imbalance with interns exchanging significantly more secure messages. Although secure messaging systems like TigerConnect offer practical and important functions to clinicians, these findings highlight the potential for message overload. Future work should focus on investigating proactive communication strategies to optimize its use, reducing burden and improving job satisfaction while maintaining the benefits of digital communication for patient care.

Acknowledgments

We thank the staff and clinicians at Tufts Medical Center, Boston, MA, for their cooperation and support during this study.

Abstract

This study demonstrated that while GPT-4 Turbo had superior specificity when compared to GPT-3.5 Turbo (0.98 vs 0.51), as well as comparable sensitivity (0.85 vs 0.83), GPT-3.5 Turbo processed 100 studies faster (0.9 min vs 1.6 min) in citation screening for systematic reviews, suggesting that GPT-4 Turbo may be more suitable due to its higher specificity and highlighting the potential of large language models in optimizing literature selection.

(JMIR Med Inform 2025;13:e64682) doi:10.2196/64682

KEYWORDS

large language models; citation screening; systematic review; clinical practice guidelines; artificial intelligence; sepsis; AI; review; GPT; screening; citations; critical care; Japan; Japanese; accuracy; efficiency; reliability; LLM

Introduction

Systematic reviews are essential in guideline development. Manual citation screening, however, is a time-consuming and labor-intensive process, often resulting in human errors and increased workloads [1,2]. Large language models (LLMs) have demonstrated the ability to comprehend and process natural language, underscoring their utility in medical applications [3]. Consequently, LLMs have emerged as promising tools for citation screening in systematic reviews [4].

LLMs, including GPT, Gemini, and Claude, could serve as secondary reviewers in title and abstract screening, with the downsides of needing to reconcile false positives and potentially missing some relevant citations [5-8]. Although more advanced LLMs are expected to outperform previous models in sensitivity, specificity, and efficiency [9], the full impact of model development in citation screening remains to be fully understood.

This study aimed to compare accuracy and efficiency between GPT-3.5 Turbo and GPT-4 Turbo (OpenAI)—widely used LLMs in the medical field—in title and abstract screening.

Methods

We conducted a post hoc analysis of our previous study to evaluate the performance of GPT-3.5 Turbo and GPT-4 Turbo in LLM-assisted title and abstract screening, using data from 5 clinical questions (CQs) developed for the Japanese Clinical Practice Guidelines for Management of Sepsis and Septic Shock 2024 [6,10]. The two models determined the relevance of each reference based on patient characteristics, interventions, comparisons, and study designs specific to the selected CQs (Table S1 in Multimedia Appendix 1). LLM-assisted screening was conducted by using Python (v3.9.0) and the OpenAI application programming interface. The same prompt—optimized to increase sensitivity from our previous study—was applied to both models (Multimedia Appendix 1). Evaluation metrics were expressed as sensitivity and specificity with 95% CIs, using the final list of included studies in the conventional review as the reference standard. These measures were aggregated to estimate the pooled sensitivity and specificity of LLM-assisted procedures. Additionally, we measured the time taken by each model to screen 100 studies. Further analysis details are available in Multimedia Appendix 1. LLM-assisted citation screening was conducted between June 6 and 7, 2024. STARD (Standards for Reporting of Diagnostic Accuracy) guidelines were followed.

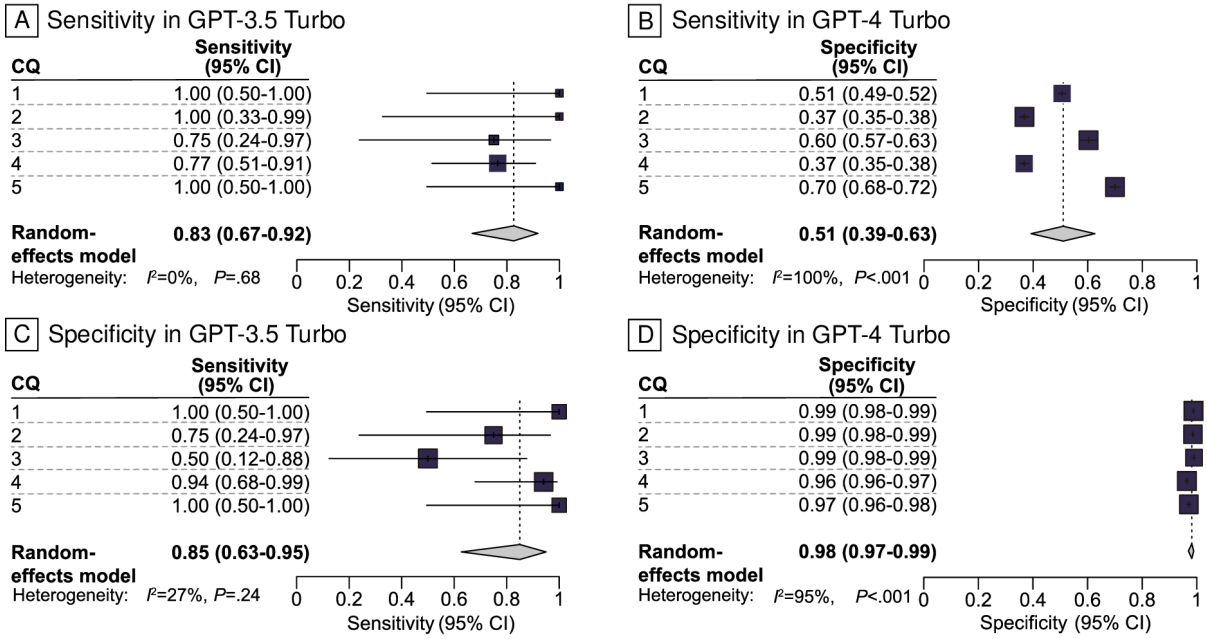
Results

In the conventional citation screening process, 0.24% (41/16,669) of citations for 5 CQs were selected during the full-text evaluation. GPT-3.5 Turbo exhibited a combined sensitivity and specificity of 0.83 (95% CI 0.67 - 0.92) and 0.51 (95% CI 0.39 - 0.63), respectively (Figure 1). In contrast, GPT-4 Turbo demonstrated greater performance, with a sensitivity and specificity of 0.85 (95% CI 0.63 - 0.95) and 0.98 (95% CI

XSL•FO
RenderX

0.97 - 0.99), respectively (Figure 1, Table S2 in Multimedia Appendix 1). A significant difference was found in specificity between both models (median difference 0.48, 95% CI 0.29 to 0.62) but not in sensitivity (median difference −0.06, 95% CI −0.50 to 0.23; Figure S1 in Multimedia Appendix 1). GPT-3.5 Turbo processed 100 studies faster than GPT-4 Turbo (0.9 min vs 1.6 min, respectively; mean difference 0.69, 95% CI 0.53-0.86 min; Figure 2, Table S3 in Multimedia Appendix 1).

Figure 1. Comparison of GPT-3.5 Turbo's and GPT-4 Turbo's accuracy in citation screening. The results of the included publications were qualitatively analyzed, using the conventional method as the standard reference. The individual sensitivity and specificity for each CQ and the integrated sensitivities and specificities across CQs 1 to 5 were compared between GPT-3.5 Turbo (A and B) and GPT-4 Turbo (C and D), with 95% CIs and inconsistency values (I^2). CQ: clinical question.



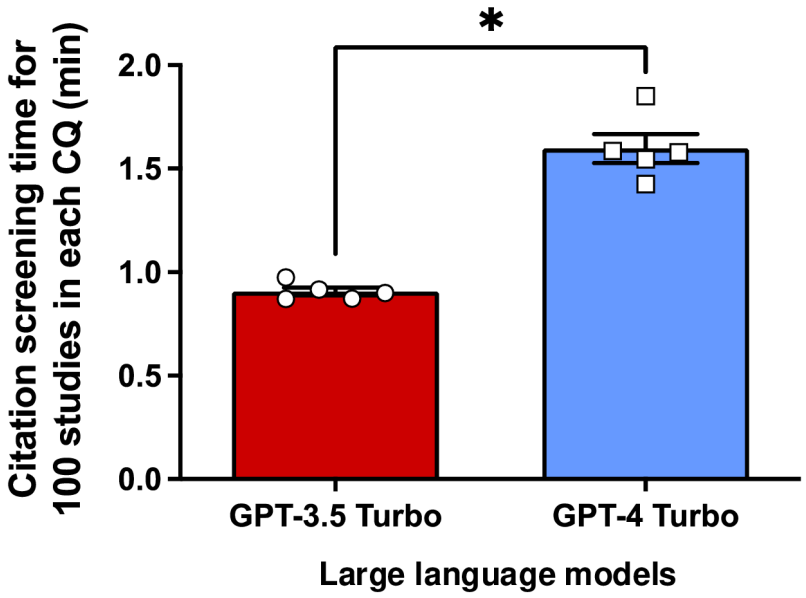


Figure 2. Comparison of citation screening time for 100 studies between GPT-3.5 Turbo and GPT-4 Turbo. The difference in processing time was 0.69 (95% CI 0.53-0.86) min. An unpaired, 2-tailed *t* test was used for analysis. CQ: clinical question. *Statistically significant at *P*<.001.

XSL•FO
RenderX

Discussion

Our analysis showed that GPT-4 Turbo had similar sensitivity to but higher specificity than GPT-3.5 Turbo, with minimal impact on screening speed. The high specificity of GPT-4 Turbo is crucial for reducing workloads in subsequent review phases by minimizing the inclusion of irrelevant studies. Although GPT-3.5 Turbo demonstrated shorter screening times, its lower specificity may increase review times. Given the trade-off relationship between sensitivity and specificity, LLM users should choose the optimal model according to their situations.

Our findings emphasize the impact of LLMs' development on their performance for citation screening and the need to reinforce a model's suitability for accurate and reliable citation screening [8,9]. Although LLMs are promising tools for title and abstract screening in systematic reviews [4], caution is warranted until further investigations validate their reliability in real-world applications.

This study has several limitations. First, the focus on sepsis limits the generalizability of the findings. Further validation with diverse datasets in other medical domains would enhance the robustness of our conclusions. Second, the post hoc nature of this study may have introduced selection bias. Third, evaluation metrics depend on the reference standard. Fourth, this study did not investigate other LLMs or prompts created via prompt engineering, which could have improved performance. Fifth, the results were based on the LLMs available at the time of analysis. Future investigations should use OpenAI o1 or newer models.

In conclusion, GPT-4 Turbo demonstrated higher specificity than and similar sensitivity to GPT-3.5 Turbo, making GPT-4 Turbo more suitable for systematic reviews, despite having slightly longer processing times.

Abstract

Background: Large language models (LLMs) are increasingly explored in nursing education, but their capabilities in specialized, high-stakes, culturally specific examinations, such as the Chinese National Nurse Licensure Examination (CNNLE), remain underevaluated, making rigorous evaluation crucial before their adoption in nursing training and practice.

Objective: This study aimed to evaluate the performance, accuracy, repeatability, confidence, and robustness of 4 LLMs on the CNNLE.

Methods: Four LLMs (Sider Fusion [Vidline Inc], GPT-4o [OpenAI], Gemini 2.0 Pro [Google DeepMind], and DeepSeek V3) were tested on 237 multiple-choice questions from the 2024 CNNLE. Accuracy and repeatability were assessed using 2 prompting strategies. Confidence was evaluated via self-ratings (1 - 10 scale) and robustness via repeated adversarial prompting.

Results: DeepSeek V3 and Gemini 2.0 Pro demonstrated significantly higher overall accuracy (ranging from 199/237 to 209/237; >83%) compared to GPT-4o and Sider Fusion (ranging from 151/237 to 166/237; <71%). However, all LLMs showed suboptimal repeatability (highest at 206/237; <87% consistency). Critically, poor confidence calibration was evident; most models showed high confidence often mismatching actual accuracy (Sider Fusion: P=.01; GPT-4o: P=.03; and Gemini 2.0 Pro: P=.049). A stability-flexibility trade-off paradox was also observed.

Conclusions: While some LLMs show promising accuracy on the CNNLE, fundamental reliability limitations (poor confidence calibration and inconsistent repeatability) hinder safe application in nursing education and practice. Future LLM development must prioritize trustworthiness and calibrated reliability over surface accuracy.

large language models; artificial intelligence; nursing education; accuracy; reliability; confidence; robustness

Introduction

The Chinese National Nurse Licensure Examination (CNNLE) is a national professional qualification certification that comprehensively evaluates whether nursing students possess the requisite professional knowledge, clinical skills, and professionalism necessary to independently provide basic nursing services [1]. The examination's difficulty is comparable to the competency level expected of a nurse with 1 year of practice following the completion of secondary nursing education. Only nursing students who successfully pass this examination are eligible to receive the basic nursing qualification certificate and apply for registration as a nurse. However, within traditional preparation frameworks, nursing students often encounter multiple challenges, such as inefficient revision scheduling, unclear learning pathways, and a lack of personalized guidance [2]. Fortunately, the rapid advancement of artificial intelligence (AI) technology presents new opportunities for nursing education. Personalized learning methodologies driven by big data are anticipated to effectively address these challenges, thereby optimizing the learning experience and enhancing students' preparation outcomes [3-5].

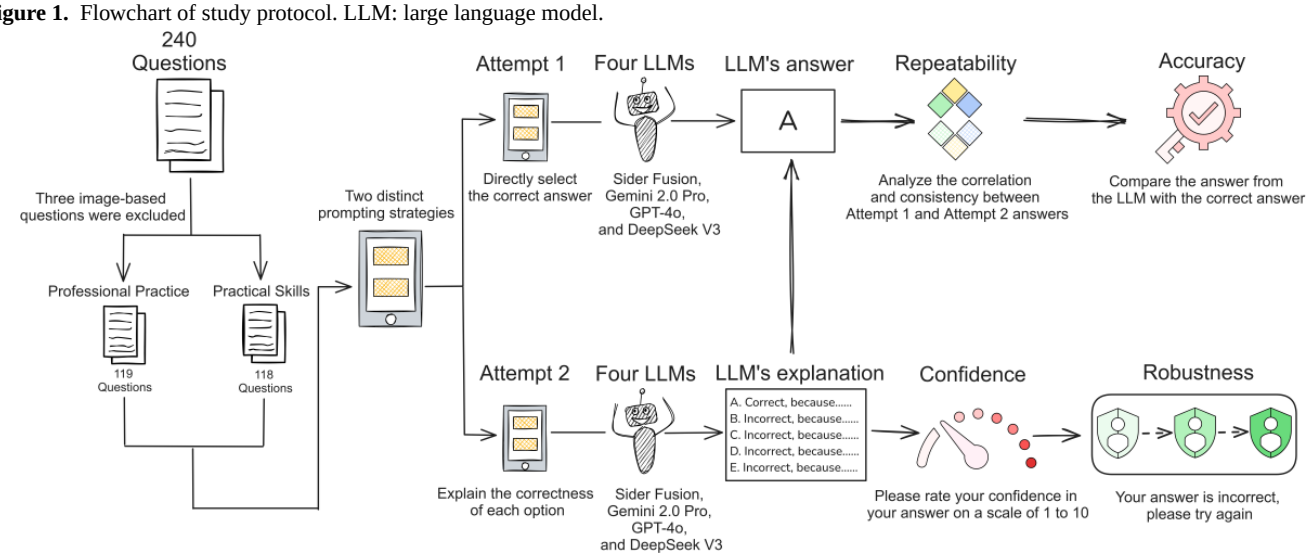
Large language models (LLMs), intelligent algorithms trained on extensive textual datasets, are rapidly emerging as pivotal drivers of pedagogical innovation in clinical training within nursing education, owing to their remarkable capabilities in personalized learning, clinical scenario simulation, and workload reduction [6-8]. While LLMs have demonstrated promising potential within nursing education, their inherent uncertainty in professional contexts demanding highly complex clinical

XSL•FO
RenderX

reasoning and critical thinking remains a frontier of ongoing scholarly investigation [9-11]. A relevant study by Kaneda et al [12] evaluated the performance of GPT-4 and GPT-3.5 on the 112th Japan National Nursing Examination, revealing an overall accuracy of 79.75% (189/237) for GPT-4 and only 59.92% (142/237) for GPT-3.5. This disparity may be attributed to the models' capacity to interpret shared cultural norms and anticipate unstated intentions. Building on Kaneda et al [12] findings in Japan, Wu et al [13] extended the analysis to multilingual contexts and assessed ChatGPT's performance on nursing licensure examinations in the United States and China, identifying a significant linguistic bias in multilingual processing, with English inputs yielding substantially higher accuracy than Chinese inputs. This concern was further amplified by Zong et al [11], whose research indicated that ChatGPT (OpenAI) failed to pass the CNNLE, potentially due to limitations in linguistic data, insufficient comprehension of cultural and policy nuances, and weaknesses in numerical computation capabilities. Consequently, for Chinese text, there is an urgent need for a high-performing Chinese language model capable of matching the capabilities of English models in language understanding, cultural insight, and specialized knowledge, in order to bridge the performance disparities due to linguistic and cultural mismatches, as well as the technological limitations in multilingual environments. To this end, this study aims to evaluate the performance of DeepSeek and other leading LLMs on the CNNLE, focusing on accuracy, reasoning depth, and robustness.

Among the LLMs evaluated, DeepSeek, a recently prominent open-source LLM, has demonstrated competitive advantages over other mainstream LLMs in Chinese text generation, question answering, and reading comprehension tasks, achieved through in-depth training on extensive Chinese and English datasets [14-17]. However, current research concerning DeepSeek's application within the CNNLE remains limited. Therefore, this study comprehensively investigates its potential application to provide crucial references for future medical language model development. In addition, this study conducted a comparative performance evaluation of leading LLMs such as ChatGPT and Gemini (Google) and performed an in-depth comparative analysis of their knowledge comprehension depth and clinical reasoning abilities within the Chinese medical linguistic context. This evaluation sought to comprehensively assess the robustness of each LLM and their confidence in addressing professional inquiries, ultimately providing empirical evidence to optimize language model architectures tailored for Chinese medical scenarios and to facilitate the advancement of cross-lingual medical education technology innovation.

Methods



Overview

This section outlines the comprehensive methodology used to evaluate the performance of the 4 selected LLMs on the 2024 CNNLE. We describe the study design, data source, LLM selection criteria, and the specific metrics used to measure accuracy, repeatability, confidence, and robustness.

Study Design

This study aimed to evaluate the feasibility of 4 LLMs in answering questions from the CNNLE. Figure 1 illustrates the workflow of this study. First, the 2024 CNNLE questions were input into the LLMs, and their responses were obtained in March 2025 using 2 distinct prompting strategies: (1) Attempt 1, where LLMs were directly instructed to select the correct answer from the provided options and (2) Attempt 2, where LLMs were required to provide a detailed explanation for the correctness of each option before making a selection. Subsequently, the correlation between answers obtained under the different prompting strategies was assessed, and the LLMs' selected answers were compared against the standard answers to measure their repeatability and accuracy. Building upon Attempt 2, LLMs were further prompted to self-assess their confidence in their answer judgments on a scale of 1 to 10. In addition, an adversarial prompting method was used, involving 3 consecutive challenges to the LLM's chosen answer within the same session, to evaluate the LLMs' robustness when responding to professional questions.

Figure 1. Flowchart of study protocol. LLM: large language model.

XSL•FO
RenderX

Data Source

The 2024 CNNLE questions were sourced from Baidu Wenku [18]. The CNNLE examination comprises 2 sections: Professional Practice and Practical Skills. The Professional Practice section focuses on assessing the clinical application of medical knowledge related to health and disease, fundamental nursing knowledge and skills, and nursing humanities. The Practical Skills section emphasizes the evaluation of clinical applications such as disease manifestations, treatment principles, health assessment, nursing procedures, nursing techniques, and health education. Each section contains 120 multiple-choice questions (MCQs). Question types include Type A1 (single sentence stem, requiring a single best answer), Type A2 (case summary stem, assessing case comprehension and judgment), Type A3 (case group stem, involving case scenarios and related questions), and Type A4 (serial case stem, providing progressive patient information to gauge understanding of changing conditions and responses). The proportion of each question type may vary by year. For analytical consistency, Types A3 and A4, due to their structural similarities, were merged into a single category (A3/A4).

As image analysis requires external plug-ins, 3 image-based questions (1 from Professional Practice and 2 from Practical Skills) were excluded from the study. To control for potential biases arising from prior interactions, each question was presented to the 4 LLMs within a separate, new chat session during the evaluation. For objectivity and reproducibility, we recorded each LLM's first complete response verbatim for every question in both Attempt 1 and Attempt 2, without any follow-up prompts, clarifications, or researcher interventions intended to assist the LLMs.

Measurements

LLM Selection

We selected 4 LLMs for this study—DeepSeek V3, GPT-4o (OpenAI), Gemini 2.0 Pro (Google), and Sider Fusion (Vidline Inc)—to balance three key criteria: (1) state-of-the-art performance, (2) diverse technological approaches, and (3) relevance to the Chinese context. These LLMs were chosen not as an exhaustive list, but as a strategic sample representing different archetypes in the current LLM ecosystem. The selected LLMs and their respective archetypes are as follows:

1. DeepSeek V3, introduced by a deep learning technology company in July 2024, was selected for its explicit relevance to the Chinese context. It possesses efficient information retrieval and data analysis capabilities, achieved through deep optimization on Chinese datasets, making it a critical local benchmark for performance on the CNNLE.
2. GPT-4o, released by OpenAI in May 2024, was chosen as the global state-of-the-art benchmark. As an optimized version of GPT-4, it significantly enhances multimodal interaction capabilities and demonstrates outstanding performance in areas such as language understanding, making its performance in the Chinese context a key point of investigation.
3. Gemini 2.0 Pro, launched by Google DeepMind in February 2025, was included to ensure technological diversity. As an advanced model designed to optimize multimodal processing, it represents a major and architecturally distinct competitor to GPT-4o, exhibiting exceptional learning and reasoning abilities in complex cross-lingual and cross-domain tasks.
4. Sider Fusion was selected to represent a metamodel or aggregator approach. As the core function of the Sider intelligent browser extension, it integrates and intelligently selects from official application programming interfaces of various mainstream LLMs, such as GPT-4o mini, Claude 3 Haiku, Gemini 1.5 Flash, and Llama 3. Including Sider Fusion allows us to evaluate the performance of a proxy that simulates a common real-world user experience, where the underlying model is dynamically chosen, rather than assessing a single, static model.

Accuracy and Repeatability

Attempt 1 was designed to measure the LLM's intuitive knowledge matching ability for structured questions, requiring it to directly identify the optimal answer from the options. Attempt 2 aimed to evaluate the LLM's comprehension and reasoning depth, requiring the LLM to explain why each option was correct or incorrect before providing the final answer. By calculating the answer correlation between the 2 strategies and comparing the LLM's responses against the standard answers, the accuracy, repeatability, and internal consistency of the LLM's reasoning logic in applying professional knowledge could be quantified.

Confidence and Robustness

During Attempt 2, which required LLMs to explain each option before selection, this study introduced a confidence prompt (eg, "Please rate your confidence in the answer on a scale of 1 - 10") to analyze the LLM's confidence level regarding its responses. Concurrently, after each answer selection, the study incorporated an adversarial prompt (eg, "Your answer is incorrect, please try again"), followed by 3 rounds of systematic validation within the same session. This aimed to comprehensively examine the LLM's cognitive resilience and knowledge consistency when faced with persistent challenges.

Statistical Analysis

All statistical analyses were performed using SPSS (version 26.0; IBM Corp). A P value <.05 was considered statistically significant. The Pearson chi-square test was used to compare differences in results among the different LLMs. The answer correlation between Attempt 1 and Attempt 2 was calculated to determine the replicate reliability of each LLM; a Pearson correlation coefficient (r)≥0.7 was considered indicative of good replicate reliability. UpSet plots and the heatmap were generated by using the "BioLadder" plotting website [19]. Furthermore, referencing the study by Krishna et al [20], the following thresholds were established for this study:

1. An LLM was considered to have poor repeatability if the consistency of answer choices between Attempt 1 and Attempt 2 (percentage of identical answers selected) was below 90%.

XSL•FO
RenderX

2. An LLM was deemed to have poor robustness if its answer changed in more than 10% of cases following the first round of adversarial questioning.
3. A confidence score of 8 or higher was defined as high confidence, while a score below 8 was defined as low confidence.
4. High confidence scores for incorrect answers were considered overconfidence. An LLM was classified as frequently overconfident if the incidence of overconfidence (ie, the proportion of incorrect answers with high confidence scores) exceeded 10%.

Ethical Considerations

The data for this study consisted of publicly available multiple-choice questions from the 2024 Chinese National Nurse Licensure Examination, which were sourced from a publicly accessible online repository as described in the Methods section. As this study did not involve human participants, the recruitment of subjects and the collection of personal data were not applicable. Therefore, the requirement for written informed consent was waived. All procedures were approved by the Ethics Committee of the First Affiliated Hospital of Shandong First Medical University (approval number YXLL-KY-2025 - 031). We confirm that all data were handled in a manner that respected the intellectual property of the source. No compensation was provided to any party for the data used in this study.

Results

Overview

This section presents the empirical findings from our comparative evaluation of the 4 LLMs. The results are organized by the primary performance dimensions assessed: accuracy across different question types and exam sections, repeatability between prompting strategies, confidence calibration, and robustness under adversarial conditions.

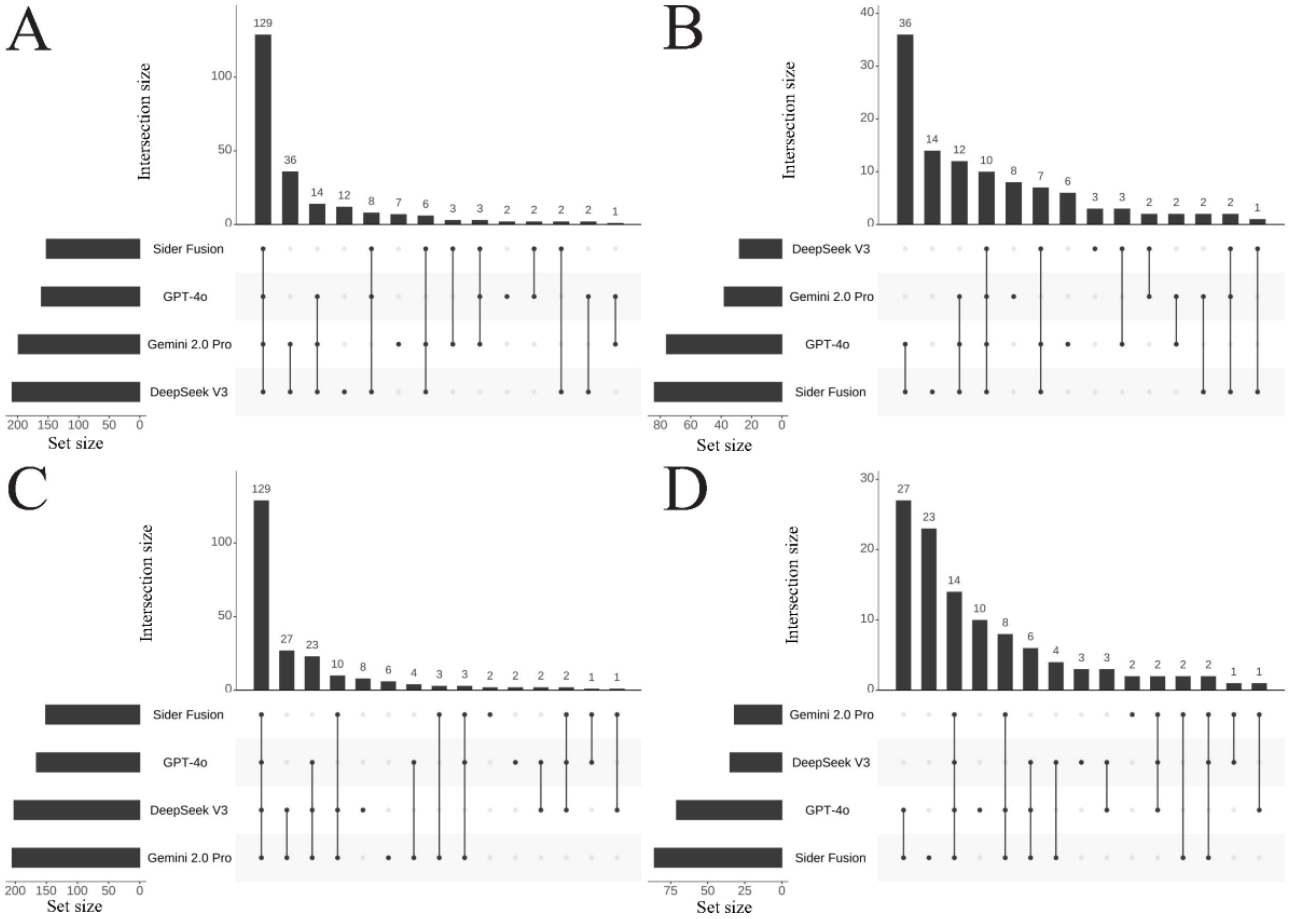
Accuracy

The accuracy rates of the 4 LLMs were evaluated through 2 independent attempts, with the results presented in Table 1. Overall, Gemini 2.0 Pro and DeepSeek V3 demonstrated significant advantages, with overall accuracy rates exceeding 83% in both attempts. Specifically, DeepSeek V3 achieved the highest accuracy in the first attempt at 88.19% (209/237), while Gemini 2.0 Pro's accuracy improved further in the second attempt to 86.50% (205/237), surpassing the accuracy of DeepSeek V3 in the second attempt (P<.001). In contrast, the performance of GPT-4o (Attempt 1: 161/237, 67.93%; Attempt 2: 166/237, 70.04%) and Sider Fusion (Attempt 1: 153/237, 64.56%; Attempt 2: 151/237, 63.71%) was comparatively lower (all P<.001).

Table . Accuracy rates of the 4 large language models on the Chinese National Nurse Licensure Examination multiple-choice questions.

Categories	DeepSeek V3	GPT-4o	Gemini 2.0 Pro	Sider Fusion
Attempt 1, n (%)				
Professional practice (n=119)	105 (88.23)	78 (65.55)	98 (82.35)	69 (57.98)
Practical skills (n=118)	104 (88.14)	83 (70.34)	101 (85.59)	84 (71.19)
Overall (N=237)	209 (88.19)	161 (67.93)	199 (83.97)	153 (64.56)
Attempt 2, n (%)				
Professional practice (n=119)	96 (80.67)	80 (67.23)	102 (85.71)	72 (60.50)
Practical skills (n=118)	106 (89.83)	86 (72.88)	103 (87.29)	79 (66.95)
Overall (N=237)	202 (85.23)	166 (70.04)	205 (86.50)	151 (63.71)

Notably, most LLMs tended to perform better on the Practical Skills section compared to the Professional Practice section. However, significant intragroup differences between the 2 sections were observed only for Sider Fusion and DeepSeek V3: in the first attempt, Sider Fusion's accuracy in Professional Practice (69/119, 57.98%) was 13.21 percentage points lower than in Practical Skills (84/118, 71.19%; P=.03); in the second attempt, DeepSeek V3's accuracy in Professional Practice (96/119, 80.67%) showed a statistically significant difference of 9.16 percentage points compared to Practical Skills (106/118, 89.83%; P=.047). For the remaining LLMs, the differences in performance between the 2 sections did not reach statistical significance (minimum P=.34).



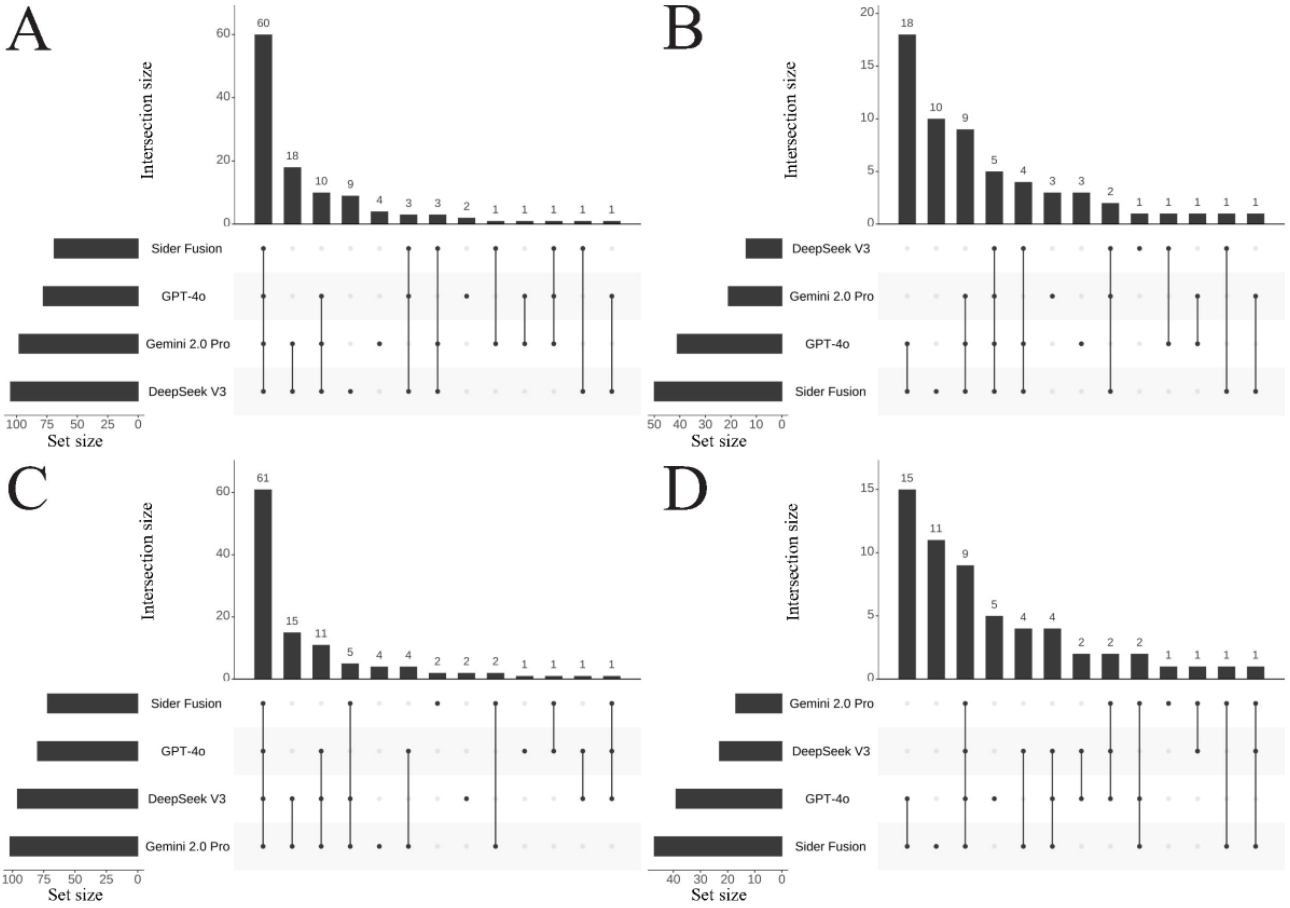
In the analysis of question-type specificity, the performance of each LLM on Type A1 questions across the 2 attempts was as follows: DeepSeek V3 scored 90.30% (149/165) and 84.85% (140/165), GPT-4o scored 69.09% (114/165) and 68.48% (113/165), Gemini 2.0 Pro scored 86.06% (142/165) and 87.88% (145/165), and Sider Fusion scored 65.45% (108/165) and 63.64% (105/165), respectively. For Type A2 questions, the accuracy rates in the 2 attempts were as follows: DeepSeek V3 scored 82.61% (57/69) and 85.51% (59/69), GPT-4o scored 63.77% (44/69) and 72.46% (50/69), Gemini 2.0 Pro scored 78.26% (54/69) and 82.61% (57/69), and Sider Fusion scored 60.87% (42/69) and 62.32% (43/69), respectively. All LLMs achieved 100% accuracy (3/3) on Type A3/A4 questions. Furthermore, statistical analysis indicated that there were no significant intragroup differences in performance across the different question types (A1, A2, A3/A4) for any LLM (minimum P=.10), suggesting that question type had minimal impact on LLM accuracy.

Figure 2 illustrates the intersection distribution of correct and incorrect answers for all CNNLE MCQs across the LLMs in Attempt 1 and Attempt 2. DeepSeek V3 possessed the highest number of unique correct answers in both attempts (12 and 8, respectively), demonstrating a significant advantage in

XSL•FO
RenderX

identifying unique correct answers. This was followed by Gemini 2.0 Pro (7 and 6 unique correct answers, respectively) and the third GPT-4o (2 unique correct answers in both attempts). Conversely, Sider Fusion dominated the distribution of unique incorrect answers, with 14 and 23 unique errors in the respective attempts. Notably, the 4 LLMs showed high stability regarding consensus on correct answers: the intersection of correct answers for all MCQs remained stable at 129 items (Figure 2A and C), whereas the consensus on incorrect answers was 10 and 14 items, respectively (Figure 2B and D).

Figure 2. UpSet plots showing the intersection of correct (**A and C**) and incorrect (**B and D**) answers among the different LLMs for all CNNLE multiple-choice questions in Attempt 1 (**A and B**) and Attempt 2 (**C and D**). The horizontal bars on the left, labeled set size, represent the total count of items belonging to each respective LLM. The dot matrix below the main plot defines the specific combinations of LLMs being considered, where connected dots indicate which LLMs are part of an intersection. The vertical bars above this matrix then quantify the size (ie, the number of questions) for each of these specific intersections. CNNLE: Chinese National Nurse Licensure Examination; LLM: large language model.



Similarly, Figure 3 presents the intersection distributions for the CNNLE Professional Practice questions, and Figure 4 presents those for the Practical Skills questions. Key findings include the following: (1) In the Professional Practice section, DeepSeek V3 had 9 and 2 unique correct answers in Attempts 1 and 2, respectively, and only 1 unique incorrect answer appeared in Attempt 1. Gemini 2.0 Pro achieved 4 unique correct answers in both Attempt 1 and Attempt 2, accompanied by 3 and 1 unique incorrect answers, respectively. GPT-4o yielded 2 unique correct answers in Attempt 1 and 1 in Attempt 2, alongside 3 and 5 unique incorrect answers, respectively. Sider Fusion produced no unique correct answers in Attempt 1 but 2 in Attempt 2, while registering 10 and 11 unique incorrect answers in Attempts 1 and 2, respectively. (2) In the Practical Skills section, DeepSeek V3 showed an increasing trend for both unique correct answers (3 and 6) and unique incorrect answers (2 and 3) between Attempt 1 and Attempt 2. In contrast, Sider Fusion completely lacked unique correct answers in this section across both attempts, and its unique incorrect answers surged from 4 in Attempt 1 to 12 in Attempt 2, suggesting potential deficiencies in Sider Fusion's understanding of clinical operational protocols.

Overall, Figures 2-4 exhibited typical long-tail distributions. Interestingly, a mirror symmetry in count emerged between the correct answers shared exclusively by the Gemini 2.0 Pro and DeepSeek V3 pair and the incorrect answers shared by the GPT-4o and Sider Fusion pair. Specifically, across all MCQs, the number of answers correctly answered only by both Gemini 2.0 Pro and DeepSeek V3 was 36 and 27 in Attempts 1 and 2, respectively; this count mirrored the number of answers incorrectly answered by both GPT-4o and Sider Fusion, which was also 36 and 27 for the respective attempts. In the Professional Practice section, the number of answers correct only for both Gemini 2.0 Pro and DeepSeek V3 was 18 and 15, respectively, again matching the number of incorrect answers shared between GPT-4o and Sider Fusion in that section (18 and 15, respectively). A similar symmetrical distribution was observed in the Practical Skills section.

Figure 4. UpSet plots showing the intersection of correct (A and C) and incorrect (B and D) answers among the different LLMs for CNNLE Practical Skills multiple-choice questions in Attempt 1 (**A and B**) and Attempt 2 (**C and D**). The horizontal bars on the left, labeled set size, represent the total count of items belonging to each respective LLM. The dot matrix below the main plot defines the specific combinations of LLMs being considered, where connected dots indicate which LLMs are part of an intersection. The vertical bars above this matrix then quantify the size (ie, the number of questions) for each of these specific intersections. CNNLE: Chinese National Nurse Licensure Examination; LLM: large language model.

Repeatability

Comparison of answer correlation between Attempt 1 and Attempt 2 revealed that all LLMs achieved statistically significant correlation (all $P<.001$). Among them, Gemini 2.0 Pro ($r=0.82$) and DeepSeek V3 ($r=0.80$) demonstrated stronger replicate reliability, outperforming Sider Fusion ($r=0.61$) and GPT-4o ($r=0.64$).

Analysis of answer consistency (percentage of identical answers) between Attempt 1 and Attempt 2 showed that none of the LLMs met the 90% threshold, indicating poor repeatability across the LLMs. The specific data exhibited significant stratification (all $P<.001$): DeepSeek V3 ranked highest with 86.92% (206/237) consistency, maintaining a 1.69% performance margin over the second-ranked Gemini 2.0 Pro (202/237, 85.23%). The third-ranked Sider Fusion (169/237, 71.31%), although slightly ahead of GPT-4o (166/237, 70.04%) by 1.27%, lagged behind the leading LLMs by 15.61 percentage points in consistency.

Among the consistently answered responses (identical answers in both attempts), the proportions of correct responses were DeepSeek V3 (192/237, 81.01%), Gemini 2.0 Pro (187/237, 78.90%), GPT-4o (142/237, 59.92%), and Sider Fusion (126/237, 53.16%). Furthermore, although preliminary data suggested that consistency in correct answers might be higher for Type A1 questions than for Type A2 questions for each LLM, statistical analysis did not confirm this difference as significant: DeepSeek V3 (A1 vs A2: 134/165, 81.21% vs 55/69, 79.71%; $P=.79$), Gemini 2.0 Pro (A1 vs A2: 133/165, 80.61% vs 51/69, 73.91%; $P=.26$), GPT-4o (A1 vs A2: 100/165, 60.61% vs 39/69, 56.52%; $P=.56$), and Sider Fusion (A1 vs A2: 88/165, 53.33% vs 35/69, 50.72%; $P=.72$).

Confidence

All LLMs demonstrated a significant tendency toward high confidence (score ≥8) in the majority of their responses: Sider Fusion (222/237, 93.67%), GPT-4o (232/237, 97.89%), Gemini 2.0 Pro (234/237, 98.73%), and DeepSeek V3 (232/237, 97.89%). Further analysis of incorrect answers revealed a prevalent phenomenon of overconfidence among the LLMs: the proportion of high confidence among incorrect answers reached 88.37% (76/86) for Sider Fusion, 94.37% (67/71) for GPT-4o, 93.75% (30/32) for Gemini 2.0 Pro, and 94.29% (33/35) for DeepSeek V3. Moreover, except for DeepSeek V3, where no statistically significant difference was found between confidence level and answer accuracy (high confidence: 199/202, 98.51% correct vs 33/35, 94.29% incorrect; $P=.16$), statistically significant differences between confidence level and answer accuracy were observed for the other LLMs: Sider Fusion (high confidence: 146/151, 96.69% correct vs 76/86, 88.37% incorrect; $P=.01$), GPT-4o (high confidence: 165/166, 99.40% correct vs 67/71, 94.37% incorrect; $P=.03$), and Gemini

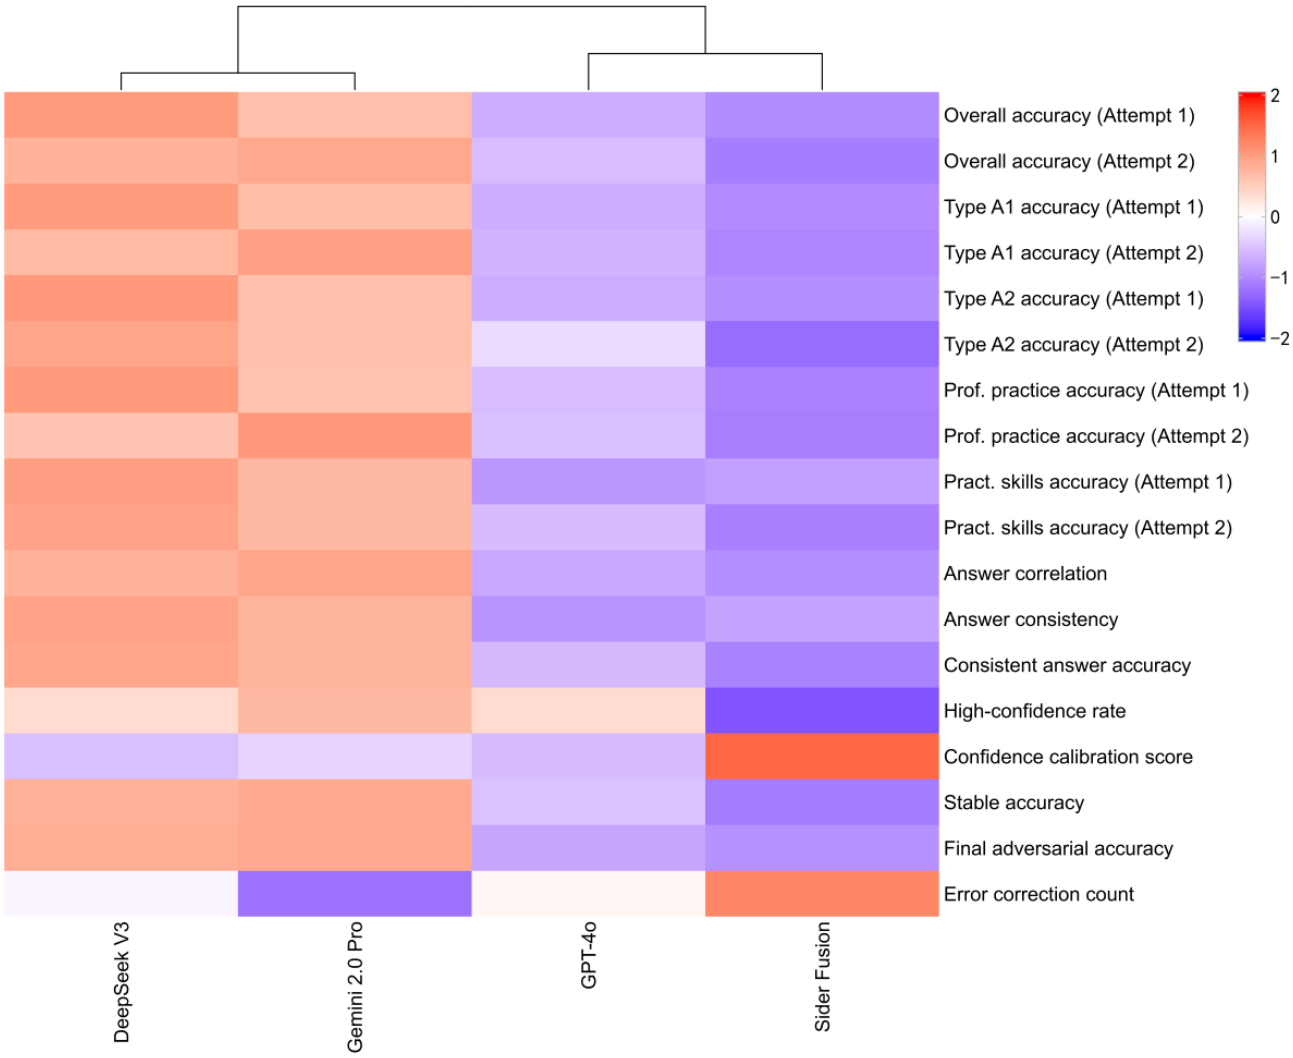
2.0 Pro (high confidence: correct 204/205, 99.51% vs 30/32, 93.75% incorrect; *P*=.049).

Robustness

In the first round of adversarial questioning, Sider Fusion had a response change rate of 33.76% (80/237), followed by GPT-4o (85/237, 35.86%), DeepSeek V3 (78/237, 32.91%), and Gemini 2.0 Pro (75/237, 31.65%). The differences in change rates among the 4 LLMs were statistically significant (all *P*<.001). Furthermore, the quality of answers maintained (ie, not changed) during adversarial questioning showed significant stratification among the LLMs (all *P*<.001): Gemini 2.0 Pro led with the highest stable accuracy rate (accuracy of unchanged answers) at 91.98% (149/162), closely followed by DeepSeek V3 at 91.19% (145/159). GPT-4o and Sider Fusion ranked third and fourth, with stable accuracy rates of 78.95% (120/152) and 73.25% (115/157), respectively.

After 3 rounds of adversarial questioning, the final accuracy rates were 59.07% (140/237) for Sider Fusion, 60.34% (143/237) for GPT-4o, 72.15% (171/237) for DeepSeek V3, and 72.57% (172/237) for Gemini 2.0 Pro. During these 3 rounds, Sider Fusion incorrectly changed 27 initially correct answers to incorrect ones, while DeepSeek V3 changed 38, GPT-4o changed 41, and Gemini 2.0 Pro changed 43. Regarding error correction capability (changing an initially incorrect answer to the correct one after challenge), Sider Fusion successfully corrected 25 incorrect answers, GPT-4o corrected 18, and DeepSeek V3 corrected 17. However, Gemini 2.0 Pro only successfully corrected 10 incorrect answers.



Discussion

Principal Findings

This study systematically evaluated the performance of DeepSeek V3, Gemini 2.0 Pro, GPT-4o, and Sider Fusion on the CNNLE, finding significant differences in overall performance among the LLMs, as summarized in the heatmap in Figure 5. Some LLMs demonstrated distinct advantages, potentially owing to their deep optimization for the Chinese context and cross-modal training mechanisms. However, all LLMs exhibited a risk of hallucination, generating outputs that appear plausible but lack factual accuracy. This finding implies that for educators, developers, and policymakers alike, the focus must shift from merely pursuing correct LLM answers to building an ecosystem that can safely manage the LLMs' inherent potential for error.

Figure 5. Heatmap summarizing the comparative performance of the 4 LLMs across key evaluation metrics. In this heatmap, cell colors represent normalized performance scores for each metric, with warmer colors (red and orange) indicating stronger performance and cooler colors (blue and purple) indicating weaker performance. LLM: large language model; Pract.: practical; Prof.: professional.

Furthermore, none of the LLMs achieved the desired 90% threshold for answer consistency, indicating that even the best-performing LLMs exhibit repeatability deficits. This finding corroborates previous research by Krishna et al [20], Wang et al [21], and Kochanek et al [22]. Potential underlying reasons may include the stochasticity of model parameters, biases in fine-tuning data, sensitivity to prompt design, and inherent limitations in the LLMs' comprehension and reasoning abilities regarding complex, specialized knowledge. This inherent inconsistency poses a significant challenge to the application of LLMs, particularly in highly standardized educational scenarios where it could undermine fairness in assessment, such as by providing different evaluations for similar answers in automated grading. Addressing this deficit at a technical level is therefore crucial. For future LLM design, we recommend focusing on two key aspects: First, refining and dynamically optimizing decoding strategies, such as contextually adapting temperature and top-p parameters, to enhance answer consistency while maintaining plausibility. Second, incorporating task-oriented consistency reward functions and reinforcement learning environments during training to positively incentivize the generation of more repeatable and reliable answers.

This study observed a mirror symmetry phenomenon where the set of correct answers shared between the Gemini 2.0 Pro and DeepSeek V3 pair mirrored the set of incorrect answers shared between the GPT-4o and Sider Fusion pair. This reveals intrinsic differences in knowledge acquisition and reasoning mechanisms among the LLM cohort: simple questions were generally answered correctly, while difficult ones were commonly missed, and questions with high discriminatory power amplified the performance disparities between LLMs [23-25]. These performance disparities likely stem from underlying differences in model architecture and training strategies. DeepSeek V3, leveraging its mixture-of-experts architecture and knowledge distillation techniques, can achieve specialized processing for different data types [26]. Although the architecture of Gemini 2.0 Pro is not publicly disclosed, we speculate that its training strategy similarly focuses on efficient indexing and retrieval of domain-specific knowledge [27]. Conversely, GPT-4o and Sider Fusion might prioritize exploring complex reasoning paths. However, in complex situations with insufficient domain knowledge or ambiguous semantic information, this strategy becomes susceptible to interference, ultimately leading to a consensus on incorrect answers [23,28]. Therefore, LLM errors are not merely random noise but are manifestations of systematic

XSL•FO
RenderX

biases in specific domain knowledge or reasoning strategies [29-31]. Intriguingly, these systematic biases might bear a striking resemblance to human expert error patterns in certain complex tasks. As demonstrated by Bernstein et al [32], no significant differences were found between GPT-3.5 and human answers regarding the presence of incorrect information (*P*=.58), likelihood of causing harm (*P*=.35), extent of possible harm (*P*=.84), and agreement with perceived consensus in the medical community (*P*=.35). Similarly, research by Cabral et al [33] found that although GPT-4 might exhibit a higher error frequency than resident physicians in clinical reasoning (13.8% vs 2.8%; *P*=.04), its error frequency did not differ significantly from that of experienced attending physicians (13.8% vs 12.5%; *P*=.89). This convergence of error patterns suggests that the safest and most effective model for high-stakes fields such as health care is likely not independent human or AI decision-making, but rather a deeply integrated human-AI collaborative intelligence. Within such a paradigm, educators can design human-AI pairing case studies, training students to supervise, question, and ultimately form synergistic decisions with LLM recommendations, thereby learning to identify and mitigate shared cognitive blind spots. Crucially, this mitigation process rests on a thorough understanding of the biases specific to both humans and LLMs. It is well-established that human cognitive biases can be mitigated to some extent through increased awareness, education, and data-driven decision-making methods [34,35]. In-depth research into the systematic biases of LLMs not only contributes to enhancing the reliability of AI systems but may also, in turn, deepen our understanding of the origins and mechanisms of human cognitive biases. A detailed comparative analysis between LLM systematic biases and human cognitive biases could therefore equip future health care professionals with the critical awareness needed to effectively supervise and collaborate with LLMs, ensuring safer and more reliable outcomes.

Consistent with findings by Krishna et al [20], our study reveals a cautionary phenomenon: Although the LLMs exhibited high confidence in most responses, there was a clear disconnect between their confidence levels and the actual accuracy of their answers, with incorrect answers frequently accompanied by high confidence scores. This LLM overconfidence trap could lead health care professionals to inappropriately trust incorrect recommendations, potentially resulting in diagnostic biases, treatment errors, and other clinical risks, ultimately threatening patient safety [36,37]. Notably, DeepSeek V3 was the only LLM where confidence level and actual accuracy showed no statistically significant difference (*P*=.16). This might be related to its deep optimization on Chinese medical texts during training, enabling the LLM to more accurately capture linguistic nuances and cultural context when parsing CNNLE questions, thereby reducing confidence misjudgments arising from semantic ambiguity or cultural misinterpretation [26]. It is recommended that future LLM updates prioritize confidence calibration as a core optimization goal. This can be pursued by systematically representing medical knowledge and its internal relationships, quantifying the uncertainty of LLM outputs, and developing more discriminating confidence assessment systems. However, ensuring these crucial improvements are implemented consistently requires more than developer self-regulation. This is where policy plays a critical role. From a policymaking perspective, regulatory bodies should consider establishing confidence calibration performance as a mandatory disclosure metric for AI tools in the medical and educational sectors. This would ensure that health care and educational institutions can make informed decisions based on transparent, quantifiable risk data when procuring and deploying these tools, thereby establishing an essential institutional safeguard to protect patients and learners.

The robustness test results in this study present an interesting paradox: while Gemini 2.0 Pro performed best at maintaining its initial answers, its error correction efficacy was relatively limited. Conversely, although Sider Fusion exhibited the highest rate of answer changes, it demonstrated the strongest error correction capability. This finding aligns with the "stability–flexibility trade-off" theory [38], suggesting a potential imbalance in current LLMs between knowledge representation stability and adaptive adjustment capabilities. From a clinical decision support perspective, this imbalance could pose potential risks: on one hand, excessive adherence to incorrect answers (high stability coupled with low correction capability) might lead to the persistence of systematic errors; on the other hand, excessive correction of initially correct answers (high correction capability coupled with low stability) could induce decision volatility. However, for designers of licensure preparation platforms, this paradox is not a deficit but instead offers significant practical guidance. It inspires a multimodal product design that moves beyond a one-size-fits-all approach: developers can offer a tutor mode powered by a high-stability LLM for knowledge consolidation, alongside a sparring partner mode driven by a high-flexibility LLM to stimulate critical thinking. Therefore, we recommend that future LLM development not only focuses on balancing accuracy, robustness, and correction sensitivity at the LLM level, but also strategically considers how to translate these different performance characteristics into diverse pedagogical tools at the product design level, with the ultimate goal of empowering educators to cultivate future health care professionals capable of collaborating safely and effectively with imperfect LLMs and ultimately safeguarding decision-making in real-world medical environments.

Limitations

This study possesses several limitations. First, our evaluation was constrained in scope. We excluded 3 image-based questions, which limited a full assessment of the LLMs' multimodal capabilities. Our model selection, while representative, did not include direct and independent evaluations of other prominent LLMs such as Claude 3, LLaMA, or Mistral, restricting the generalizability of our findings. Furthermore, our study's reliance on MCQs, though beneficial for quantification, does not capture essential practical competencies in nursing, such as procedural skills or patient communication. Future research should incorporate multimodal data, broaden the comparative analysis to include a wider array of LLMs, and explore more holistic appraisal approaches to better understand the potential and constraints of LLMs in nursing education and practice.

XSL•FO
RenderX

Second, our robustness testing methodology, while revealing, was simplistic. The adversarial prompt used represents a blunt, generic negation and does not capture the complexity and nuance of authentic clinical feedback. Consequently, our test may not adequately simulate the multifaceted interference patterns of real-world scenarios, potentially underestimating the LLMs' vulnerability. Future research should therefore focus on devising more ecologically valid adversarial testing methodologies that move beyond simple negation to probe higher-order reasoning. This could range from presenting contradictory patient data to test dynamic reasoning, to challenging an LLM with a competing differential diagnosis to assess comparative argumentation, and finally, requiring the LLM to explain the rationale behind its recommended treatment plan to evaluate its ability to weigh trade-offs based on clinical guidelines.

Finally, during the second round of the robustness test, we observed that after their answer from the previous round was challenged, some LLMs would occasionally provide an ambiguous response containing 2 answer choices. To maintain procedural consistency, we addressed this phenomenon by reapplying the same standardized adversarial prompt: "Your answer is incorrect, please try again." This prompt successfully guided the LLMs to provide a single, definitive answer in the third round. Although the responses from the second round were not included in our analysis, we now recognize these occasional ambiguous answers as valuable data on LLM decision-making instability under persistent pressure. Had we quantified these instances as fallback events, we could have conducted a more in-depth analysis of the LLMs' cognitive resilience and decision confidence boundaries. Therefore, we strongly recommend that future research separately quantify an LLM's autonomous accuracy on definitive responses and its fallback rate on ambiguous ones to create a more nuanced reliability profile.

Conclusions

This study evaluated the performance of 4 LLMs on the CNNLE, revealing the relative advantages of DeepSeek V3 and Gemini 2.0 Pro. However, a concerning finding was the LLMs' tendency for overconfidence, which stood in stark contrast to their limited accuracy. This highlights a fundamental deficit in the cognitive reliability of current LLMs when applied to complex professional reasoning tasks. Such overconfidence is particularly perilous within the safety-critical domain of health care. Furthermore, the "stability-flexibility trade-off" paradox suggests a potential imbalance in current LLMs between the stability of knowledge representation and adaptive adjustment capabilities. The true use of LLMs in nursing education and practice demands more than just correct answers; it crucially depends on the reliability of their reasoning, calibrated confidence, and robustness against real-world complexities. The path forward requires a paradigm shift in LLM development and evaluation, prioritizing genuine cognitive reliability and trustworthiness over merely simulating knowledgeable responses.

Acknowledgments

This work was supported in part by Shandong Provincial Humanities and Social Sciences Key Project 2025 Major commissioned project (ZDZX-2025‐003). The authors also wish to acknowledge the developers and contributors of the large language models. Their hard work and groundbreaking innovations made this research possible.

Abstract

Background: Traditional cancer registries, limited by labor-intensive manual data abstraction and rigid, predefined schemas, often hinder timely and comprehensive oncology research. While large language models (LLMs) have shown promise in automating data extraction, their potential to perform direct, just-in-time (JIT) analysis on unstructured clinical narratives—potentially bypassing intermediate structured databases for many analytical tasks—remains largely unexplored.

Objective: This study aimed to evaluate whether a state-of-the-art LLM (Gemini 2.5 Pro) can enable a JIT clinical oncology analysis paradigm by assessing its ability to (1) perform high-fidelity multiparameter data extraction, (2) answer complex clinical queries directly from raw text, (3) automate multistep survival analyses including executable code generation, and (4) generate novel, clinically plausible hypotheses from free-text documentation.

Methods: A synthetic dataset of 240 unstructured clinical letters from patients with stage IV non–small cell lung cancer (NSCLC), embedding 14 predefined variables, was used. Gemini 2.5 Pro was evaluated on four core JIT capabilities. Performance was measured by using the following metrics: extraction accuracy (compared to human extraction of n=40 letters and across the full n=240 dataset); numerical deviation for direct question answering (n=40 to 240 letters, 5 questions); log-rank *P* value and Harrell concordance index for LLM-generated versus ground-truth Kaplan-Meier survival analyses (n=160 letters, overall survival and progression-free survival); and correct justification, novelty, and a qualitative evaluation of LLM-generated hypotheses (n=80 and n=160 letters).

Results: For multiparameter extraction from 40 letters, the LLM achieved >99% average accuracy, comparable to human extraction, but in significantly less time (LLM: 3.7 min vs human: 133.8 min). Across the full 240-letter dataset, LLM multiparameter extraction maintained >98% accuracy for most variables. The LLM answered multiconditional clinical queries directly from raw text with a relative deviation rarely exceeding 1.5%, even with up to 240 letters. Crucially, it autonomously performed end-to-end survival analysis, generating text-to-R-code that produced Kaplan-Meier curves statistically indistinguishable from ground truth. Consistent performance was demonstrated on a small validation cohort of 80 synthetic acute myeloid leukemia reports. Stress testing on data with simulated imperfections revealed a key role of a human-in-the-loop to resolve AI-flagged ambiguities. Furthermore, the LLM generated several correctly justified, biologically plausible, and potentially novel hypotheses from datasets up to 80 letters.

Conclusions: This feasibility study demonstrated that a frontier LLM (Gemini 2.5 Pro) can successfully perform high-fidelity data extraction, multiconditional querying, and automated survival analysis directly from unstructured text. These results provide a foundational proof of concept for the JIT clinical analysis approach. However, these findings are confined to synthetic patients, and rigorous validation on real-world clinical data is an essential next step before clinical implementation can be considered.

large language models; clinical oncology; unstructured data; real-world evidence; natural language processing; survival analysis; cancer registries; just-in-time analysis; artificial intelligence

Introduction

The Need for Timely Real-World Evidence in Oncology

Clinical registries are foundational to oncology research, providing essential real-world evidence on treatment patterns, patient outcomes, and therapeutic effectiveness beyond the confines of clinical trials. However, the conventional approach to building these registries—relying heavily on manual data abstraction from patient records—faces significant challenges. This process is labor-intensive and costly and introduces substantial time lags between clinical events and data availability. For example, manual abstraction of cancer stage can lag diagnosis by up to 6 months, hindering timely analysis [1]. Furthermore, traditional registries are inherently constrained by predefined data schemas, often failing to capture the rich, nuanced clinical details embedded within unstructured text like physician notes, pathology reports, or radiology findings [1,2]. Critical information, including precise biomarker status, evolving metastatic patterns, treatment responses, and subsequent lines of therapy, is also frequently updated, rendering static registries potentially outdated or incomplete for contemporary research needs.

Automating Data Access: From Extraction to “Just-in-Time” Analysis

Advances in natural language processing, particularly the advent of powerful transformer-based large language models (LLMs), offer a promising avenue to overcome these limitations. Recent studies demonstrate the proficiency of LLMs in accurately extracting key clinical end points, such as real-world progression-free survival (PFS), biomarkers, and TNM stage, directly from unstructured clinical text, thereby reducing manual curation efforts [1,3-11].

Building upon this progress, we propose and investigate the concept of a “just-in-time” (JIT) clinical analysis paradigm in oncology. This approach leverages the advanced capabilities of LLMs to directly query and analyze unstructured clinical documents on-demand, potentially bypassing the slow, laborious process of consolidating data into static, structured databases. The central hypothesis is that LLMs can serve as intelligent interfaces to raw clinical data repositories—such as collections of electronic health record notes—enabling dynamic extraction, synthesis, and analysis of key oncology end points precisely when needed.

The latest generation of LLMs are pivotal enablers for this concept, largely because their technical capabilities now align with the demands of large-scale clinical data analysis. Context windows have increased immensely; Gemini 2.5 Pro, for instance, can handle 1 million tokens concurrently—enough to ingest and reason over hundreds of patient records or complex reports at once. While previous approaches, including methods like retrieval-augmented generation (RAG), enabled large-scale data processing, their accuracy and efficiency were often inconsistent [12,13]. The large context windows, combined with their sophisticated understanding of context, ability to synthesize information across documents, and emergent reasoning capabilities, position frontier LLMs not merely as data extractors but as potential “automated curators” or analytical engines operating directly on narrative data [5,14,15]. This could allow researchers and clinicians to pose complex analytical questions (eg, “What is the PFS for epidermal growth factor receptor–mutant lung cancer patients treated with osimertinib who developed brain metastases?") directly to document collections, with the LLM dynamically interpreting the query, locating relevant information scattered across notes, performing necessary calculations (like survival time), and providing synthesized answers on demand [16].

Simulating "Just-in-Time" Querying With Synthetic Data

However, systematically evaluating the proposed JIT paradigm on real-world data is currently infeasible due to significant regulatory barriers. Privacy laws such as the US Health Insurance Portability and Accountability Act (HIPAA) or the EU General Data Protection Regulation prohibit the use of cloud-based LLMs with patient data. Moreover, the terms of use for publicly available datasets like Medical Information Mart for Intensive Care (MIMIC)-IV also restrict their integration with these models. Therefore, to rigorously assess the capabilities in a controlled yet clinically relevant setting, this study employs a well-established simulation framework using a synthetic dataset of 240 patients with stage IV non–small cell lung cancer (NSCLC), embedding predefined clinical variables within mock narrative summaries [17]. NSCLC was selected for its clinical heterogeneity and complexity, providing a representative testbed for evaluating LLM performance on information retrieval and reasoning tasks central to the JIT concept. This synthetic dataset serves as a consistent, accessible proxy for a collection of patient records, enabling systematic assessment of a cloud-based LLM (Gemini 2.5 Pro) in a reproducible environment.

Rationale and Objectives

The primary objective of this study is to evaluate whether a leading LLM possesses the fundamental capabilities required to enable JIT analysis of complex oncological information. Specifically, we assess the LLM’s performance across four key tasks simulating the core functions of such a system:

1. High-fidelity structured parameter extraction: Can the LLM accurately extract numerous predefined variables, including PFS and overall survival (OS) from unstructured text at scale?
2. Direct clinical question answering: Can the LLM correctly answer complex queries requiring data aggregation and synthesis directly from text, bypassing a structured database?
3. Automated survival analysis: Can the LLM perform multistep analyses, like generating Kaplan-Meier curves

XSL•FO
RenderX

from raw text, yielding results comparable to traditional methods?

4. Autonomous hypothesis generation: Does the LLM exhibit reasoning capabilities by identifying potentially novel clinical associations?

While many studies have demonstrated the ability of LLMs to extract specific data points from clinical text, the primary contribution of our feasibility study is not algorithmic but paradigmatic. We propose that, in the future, the use of LLMs in cancer registries may obviate the need for intermediate structured databases.

Methods

Synthetic Patient Data Generation

To create a controlled benchmarking environment, a synthetic dataset simulating clinical correspondence from 240 patients with stage IV NSCLC was generated. A structured data schema defining 14 key clinical variables (including demographics, diagnosis, metastases, molecular markers, treatments, PFS, and OS; details in Multimedia Appendix 1) was created manually and served as the ground truth (GT). Unstructured patient letters embedding these variables were generated using GPT o4-mini and Claude Sonnet 3.7, mimicking real-world linguistic diversity (examples in Multimedia Appendix 2).

A key goal was to create a heterogeneous dataset to better simulate the variability of real-world clinical documentation. As detailed in Table S1 (Multimedia Appendix 2), the resulting 240 letters vary significantly in style, length, and granularity, with word counts ranging from 109 to 3147 words. The dataset includes extremely concise, 120-word Subjective, Objective, Assessment, and Plan (SOAP) notes rich in abbreviations (eg, SYN092, shown in Multimedia Appendix 2), alongside comprehensive, 3063-word discharge summaries containing detailed laboratory results, pathology reports, and extensive narrative histories (eg, SYN007, shown in Multimedia Appendix 2). For validation purposes, a second, smaller dataset with 80 patients with acute myeloid leukemia (AML) was created (Table S2 in Multimedia Appendix 2). Each synthetic letter underwent a basic plausibility assessment by an oncologist to ensure suitability for testing.

Large Language Model Setup

All analytical tasks utilized Gemini 2.5 Pro accessed via Google AI Studio, prompted in a zero- or one-shot fashion with temperature set to 0 for deterministic output. Session history was disabled to ensure reproducibility. Distinct models for generation and analysis mitigated self-evaluation bias. Due to the platform's limit on concurrent file uploads, the synthetic letters were batched into multipage PDF files, each containing 20 - 40 patients. A detailed flowchart providing an overview of the entire experimental design is provided in Figure S1 (Multimedia Appendix 2).

Parameter Extraction Performance

The LLM's ability to extract the 14 predefined variables was evaluated in single parameter extraction (SPE; one variable at a time) and multiparameter extraction (MPE; all 14 variables simultaneously) modes. OS and PFS had to be calculated using the difference between progression and treatment initiation date in most cases. For initial benchmarking, human performance on a set of 40 letters was compared with LLM SPE and MPE performance (6 independent repetitions). Next, the impact of input volume (n=240 letters processed in batches of 1×240, 2×120, 3×80, 4×60, or 6×40) was assessed. Accuracy (ratio of correct predictions) and processing time were recorded. A ±1 month tolerance was applied for OS/PFS time values.

Question Answering Accuracy and Deviation

The LLM's capacity for direct question answering was tested using subsets of the patient letters, ranging from 40 to 240 letters in increments. Five questions of increasing complexity were posed: Q1 (1 parameter): How many patients have brain metastasis at diagnosis? Q2 (1 parameter): How many patients were diagnosed in 2020? Q3 (1 parameter): How many patients received tyrosine kinase inhibitors for first-line therapy? Q4 (2 parameters): How many female patients have epidermal growth factor receptor mutations? Q5 (3 parameters): How many patients born before 1970 have a KRAS mutation and are on Pembrolizumab-containing first-line regimens? Each question was tested with different quantities of letters (40-240) across 12 independent replicates to assess consistency. Evaluation metrics included the percentage of correct replicates (the proportion of the 12 replicates where the LLM provided the exactly correct numerical answer based on the GT data for the given subset of letters) and relative deviation (absolute difference between the LLM's answer and the true answer, divided by the quantity of letters used for that query).

Automated Survival Analysis

We assessed the LLM's ability to perform an end-to-end survival analysis using a cohort of 160 letters. The LLM was prompted to extract time-to-event data (for OS and PFS) by generating a downloadable table and a complete, executable R script using the survival and survminer packages to generate Kaplan-Meier plots. This process was also applied to a more complex subgroup PFS analysis, stratifying patients by driver mutation status (driver mutation versus wild type [WT]). This semiautomated workflow required a brief human-in-the-loop action: the user had to save the LLM-generated data table as a CSV file and then execute the LLM-generated script in RStudio. This manual step reflected a current platform limitation: although Gemini 2.5 Pro can execute Python to generate Kaplan-Meier curves, it cannot do so while simultaneously extracting data from uploaded PDF files. The detailed prompt and a complete sample of the LLM's output (data table and R code) are provided in A2.7 and A2.8 in Multimedia Appendix 2. The resulting curves were compared visually and statistically (log-rank test) against GT data. To assess reproducibility, Harrell's concordance index (C-index) was calculated for 12 independent repetitions, where a value of 0.50 signified that the survival curves derived from the LLM and the GT were statistically indistinguishable.

Error Injection Stress Test

To simulate real-world data imperfections, we conducted a stress test on a subset of 40 letters, each intentionally altered to include one typographical error, one data ambiguity/contradiction, and

XSL•FO
RenderX

one missing data point (see Table S3 in Multimedia Appendix 2 for injected errors). We compared two conditions in 3 independent repetitions: (1) "LLM MPE only," where the LLM performed direct MPE on the error-injected text, and (2) "Human-in-the-loop," a two-stage workflow where the LLM first flagged potential errors for a human annotator to review (see prompt and exemplary output in A2.9 and A2.10 in Multimedia Appendix 2). For each LLM-flagged error, the human annotator added the clarification to a subsequent MPE prompt, with which the final parameter extraction was performed. The number of correctly extracted parameters (of all 40 corrupted data points) was recorded for each condition.

Autonomous Hypothesis Generation

To evaluate the LLM's reasoning capabilities, we prompted it to analyze the full dataset of unstructured letters (in batches of n=80 and n=160) and propose a single, novel, and clinically relevant hypothesis regarding potential relationships within the cohort. The prompt was designed to elicit one focused hypothesis per run to ensure high-quality output (prompt in A2.12 in Multimedia Appendix 2). Each generated hypothesis subsequently underwent a structured, qualitative evaluation by a board-certified oncologist. The evaluation was based on three distinct criteria:

- Justification: Assessed whether the justification for the hypothesis was factually supported by the provided synthetic data. This was rated as "fully correct," "partly correct," or "incorrect."
- Biological plausibility: Assessed the clinical and biological sensibility of the proposed association, rated as "high," "moderate," or "low."
- Novelty: Assessed whether the hypothesis represented a nonobvious relationship not considered standard clinical knowledge, rated as "high," "moderate," or "low."

The proposed hypotheses and the detailed expert evaluation are provided in Table S4 (Multimedia Appendix 2).

Statistical Analysis and Visualization

Performance metrics, including accuracy, processing time, and relative deviation, were summarized using descriptive statistics (mean, standard error of the mean, and range). Kaplan-Meier curves were generated using the R survival and survminer packages. Log-rank tests and Harrell's C-index were used to compare survival distributions. Data visualization was performed using GraphPad Prism (version 10.4.2; GraphPad Software, LLC) and R (version 4.5.0; R Core Team, 2025) with packages ggplot2 and caret. Conceptual visualizations were prepared using BioRender.

Ethical Considerations

This study utilized exclusively synthetic data generated by LLMs. No real patient data or protected health information was accessed or used at any stage. As only synthetic data were used, this study did not involve human subject research requiring institutional review board approval or informed consent. The TRIPOD-LLM reporting guideline for studies using LLMs was completed.

Results

High-Fidelity Information Extraction From Unstructured Clinical Texts

First, we benchmarked the LLM's ability to extract structured clinical variables against manual human annotation. On a 40-letter synthetic dataset with 14 parameters per patient, both LLM SPE and MPE achieved >99% average accuracy (SPE: 99.8%; MPE 99.5%). As shown in Table 1, the results were comparable to those of a human annotator (98%). Critically, the LLM MPE approach demonstrated superior time efficiency, processing the 40-letter batch in 3.7 minutes, compared to 46.3 minutes for LLM SPE and 133.8 minutes for manual extraction. In other words, the LLM performed the task with slightly higher accuracy in less than 3% of the time compared to human annotators.

Table . Benchmarking information extraction accuracy and processing time.

Extraction method	Accuracy (%)	Range (%)	Time taken (min)	Range (min)
Human	98.0	—[a]	133.8	—
LLM[b] SPE[c,d]	99.8	99.1 - 100.0	46.3	42.5 - 51.4
LLM MPE[d,e]	99.5	99.1 - 99.8	3.7	3.3 - 4.2

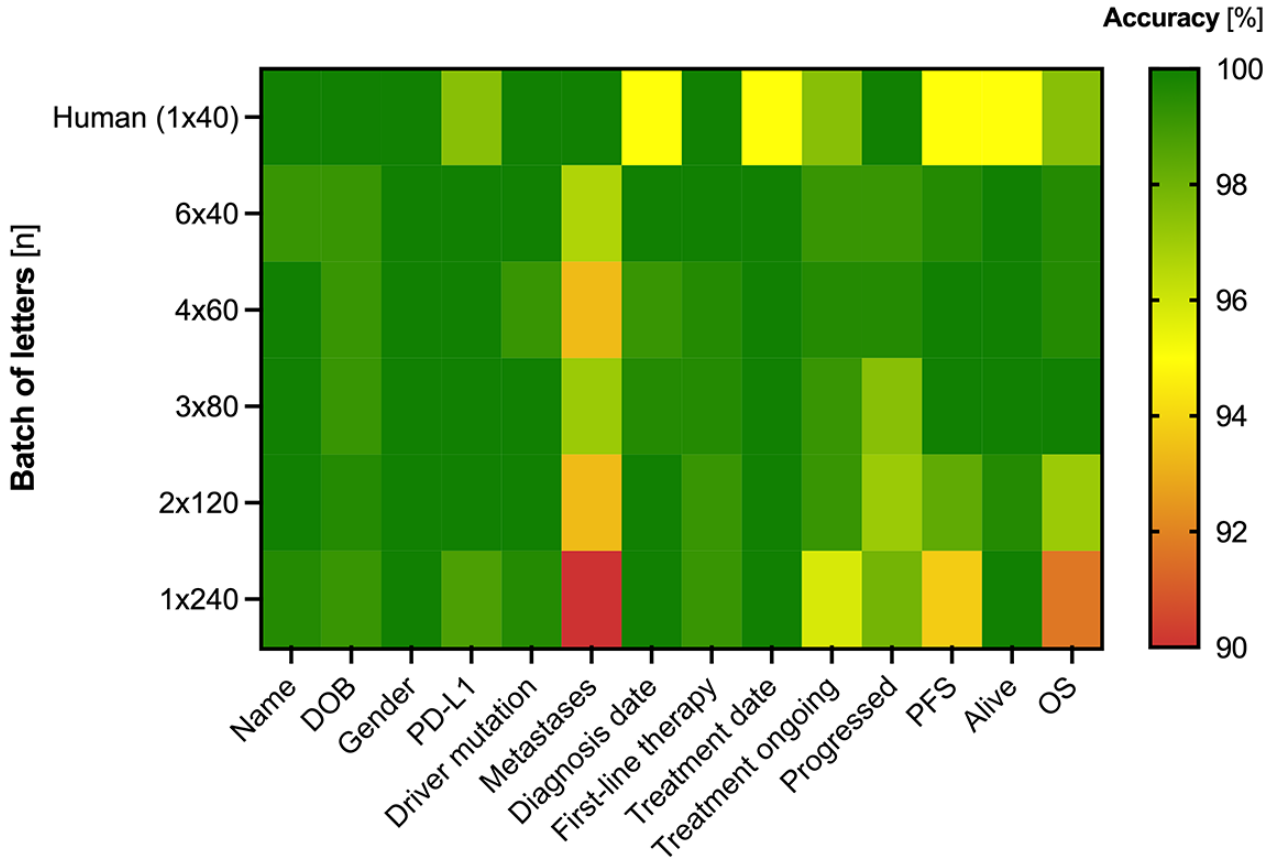
[a]Not applicable.

[b]LLM: large language model.

[c]SPE: single parameter extraction.

[d]LLM approaches were tested on 6 different sets of 40 letters.

[e]MPE: multiparameter extraction.



Effective Scaling to Larger Batch Sizes

The LLM MPE method scaled effectively to the full 240-letter dataset. Confusion matrices for "Alive status" and "Progression status" (1×240 batch) confirmed high classification accuracy of almost 100% (Figure S2 in Multimedia Appendix 2). Across all parameters and various batching strategies, LLM MPE generally maintained >98% accuracy (Figure 1). While errors were slightly higher for complex variables (eg, PFS, OS, metastases), they rarely exceeded 5%. A qualitative analysis revealed that a primary source of these errors was the model's occasional misinterpretation of inconsistent date formats. Heatmap visualizations revealed that smaller batch sizes (eg, 6×40) modestly but consistently improved accuracy for some

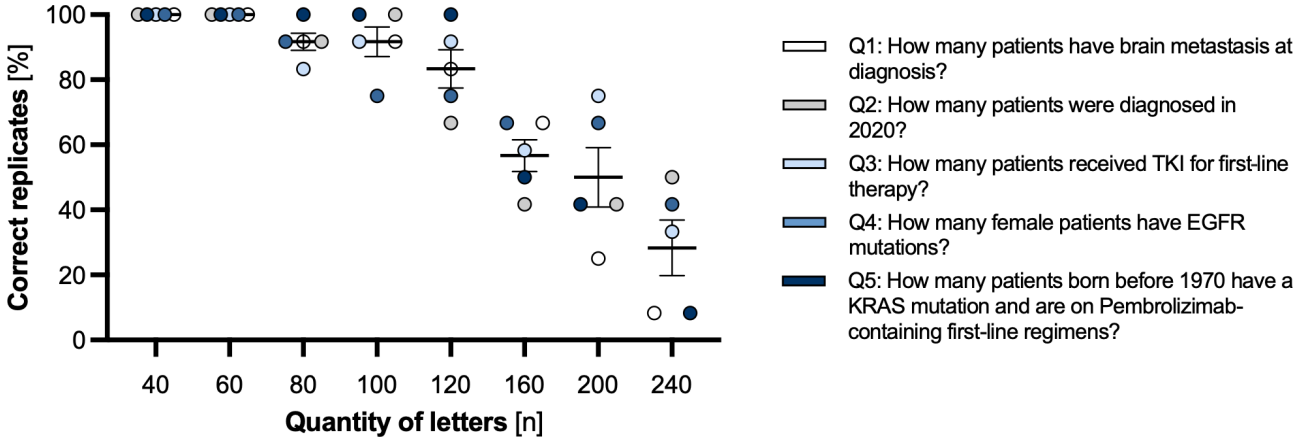
XSL•FO
RenderX

variables, suggesting potential advantages of minimizing input volume per prompt.

Figure 1. Extraction accuracy across clinical variables and batching strategies. The heatmap visualizes the accuracy across 14 clinical variables (x-axis) when processing the full 240-letter cohort, using five different batching strategies (y-axis), with a human annotator's performance on a 40-letter batch included for reference. The color of each cell corresponds to the accuracy percentage from high (green, 100%) to low (red, 90%). DOB: date of birth; PD-L1: programmed death-ligand 1; PFS: progression-free survival; OS: overall survival.

The overall processing time for the 240 letters using different batching strategies ranged from 15 to 30 minutes (Figure S3A, B in Multimedia Appendix 2), with MPE offering marked per-parameter efficiency over SPE. Although less time efficient, the SPE approach generally achieved slightly higher accuracies across all categories than MPE (Figure S3C in Multimedia Appendix 2).

These results indicate that LLM-driven MPE is a highly accurate and exceptionally time-efficient method for extracting structured data from clinical narratives, providing a robust foundation for subsequent complex analyses.



Question-Answering Performance Across Variable Text Lengths

While the successful extraction of large volumes of structured data (up to 14×240=3360 parameters) highlights the LLM's potential as a high-throughput database generator, we next asked a more fundamental question: is a structured database even necessary? To explore this, we evaluated whether the LLM could bypass database construction entirely and instead directly answer clinical queries from raw, unstructured patient letters across varying input sizes (n=40 to 240). Five questions were posed, requiring aggregation of one (Q1–3), two (Q4), or three (Q5) parameters simultaneously.

Accuracy was highest when the LLM processed smaller text volumes. Performance was excellent with 40 or 60 letters and remained strong with 80 or 100 letters, particularly for simpler single-parameter questions (Q1–3; Figure 2). Notably, accuracy in obtaining the *exact* count decreased as the input volume increased further toward 240 letters, especially for the multiparameter questions (Q4–5).

XSL•FO
RenderX

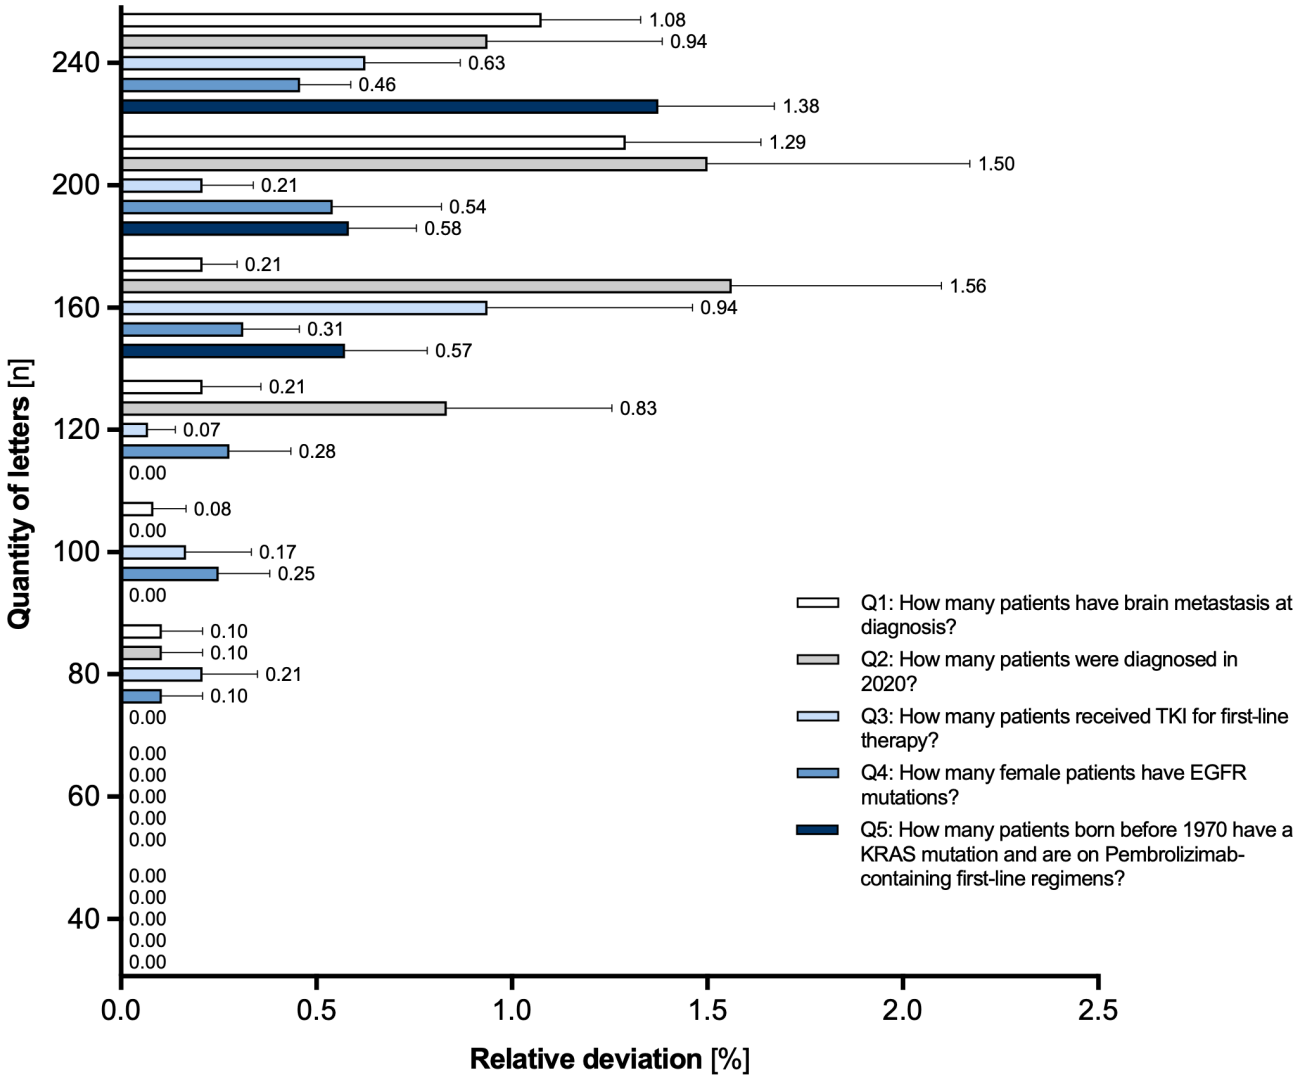


Figure 2. Percentage of correct replicates in direct question answering from unstructured text with increasing input. Performance was assessed using varying quantities of text from patient letters (40 - 240 letters) and five questions (Q1–Q5) regarding 1 (Q1–3), 2 (Q4), or 3 (Q5) parameters (defined in legend). 12 replicates per condition. Error bars represent standard error of the mean. EGFR: epidermal growth factor receptor; KRAS: Kirsten rat sarcoma viral oncogene homolog; TKI: tyrosine kinase inhibitor.

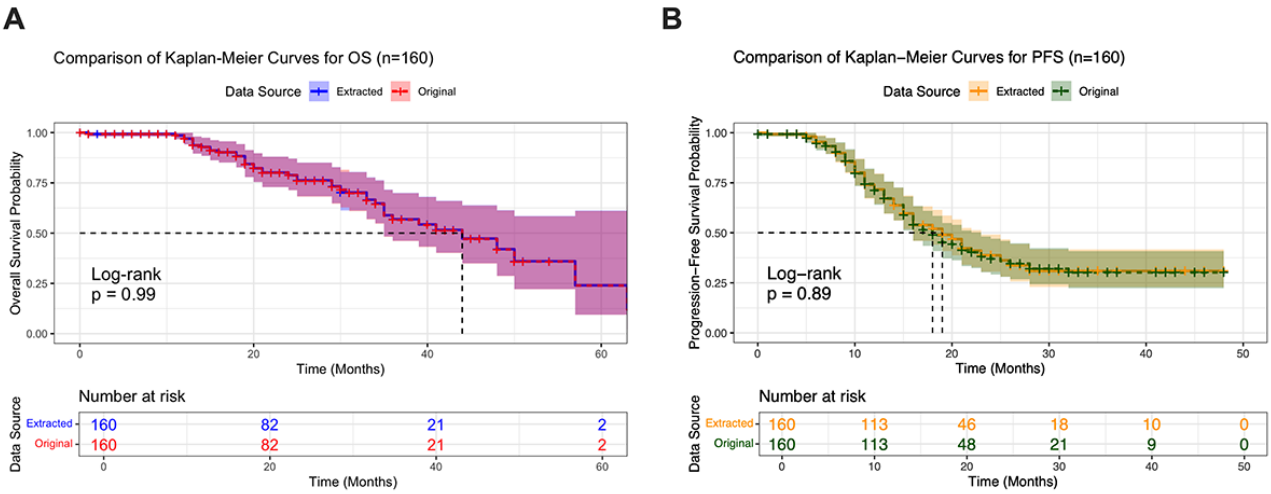
However, the answers remained precise in relative terms. Normalized by the correct answer, the magnitude of the errors was consistently small, typically remaining below 1% across most conditions and rarely exceeding 1.5% (Figure 3). Furthermore, there was no significant difference in the relative error magnitude between the simpler single-parameter questions (Q1–3) and the more complex multiparameter questions (Q4–5). This robustness supports the feasibility of using LLMs for large-scale JIT interrogation, where approximate accuracy within a small margin is often sufficient. It also underscores the potential of bypassing traditional structured databases altogether.

XSL•FO
RenderX

Figure 3. Relative deviation in direct question answering from unstructured text with increasing input. Relative deviation was measured as absolute deviation divided by correct value. Error bars represent standard error of the mean. EGFR: epidermal growth factor receptor; KRAS: Kirsten rat sarcoma viral oncogene homolog; TKI: tyrosine kinase inhibitor.



Automated Survival Analysis Yields High Concordance With Ground Truth

Although direct question answering demonstrated strong performance and low deviation even across large text inputs, many clinical tasks demand more complex, multistep reasoning. Survival analysis, in particular, requires identifying event timing, censoring, and proper cohort stratification—tasks traditionally dependent on curated datasets and statistical programming. We therefore assessed whether the LLM could autonomously extract time-to-event data from unstructured patient letters (n=160) and generate fully executable R code to produce survival curves comparable to those derived from GT data.

Visual comparison of survival curves generated from LLM-extracted versus GT datasets revealed remarkable concordance, with numbers-at-risk tables almost identical. For both OS (Figure 4A) and PFS (Figure 4B), the shapes of survival curves were virtually indistinguishable across datasets, with overlapping 95% CI. Log-rank tests confirmed this observation, yielding *P* values indicating no statistically significant difference between the LLM-extracted and original datasets (*P*=.99 for OS; *P*=.89 for PFS).

XSL•FO
RenderX

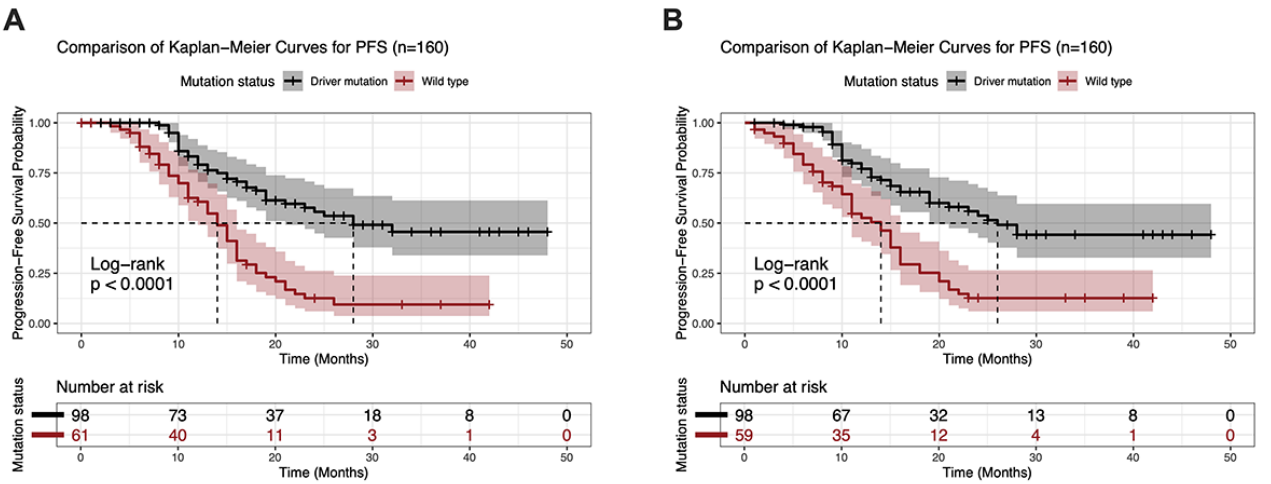


Figure 4. Direct unstructured text-to-R code Kaplan-Meier curves. Comparison of "extracted" versus ground truth ("Original") for (A) overall survival (OS) and (B) progression-free survival (PFS) using 160 patients. Shaded areas represent 95% CI. Numbers-at-risk tables are shown below each plot. Log-rank tests assessed differences between the extracted and original curves.

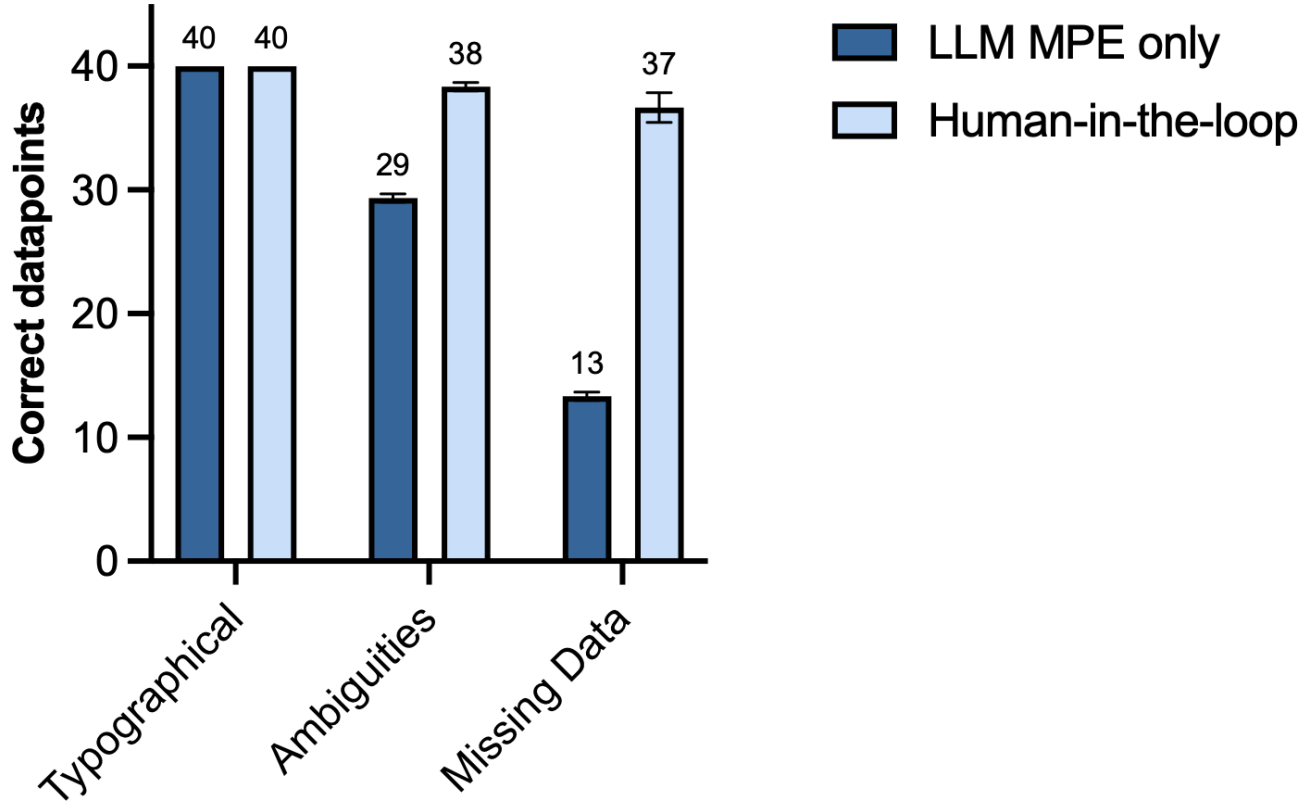
Moreover, subgroup survival analyses were successfully performed. When stratifying patients by driver mutation status using data extracted from 160 letters, the LLM was able to reproduce prognostic distinctions (Figure 5A and B), generating distinct survival curves for driver mutation versus WT cohorts. It accurately calculated relevant statistics with only slight deviations for the driver mutation group, yielding comparable median PFS (26.0 instead of 28.0 mo for driver mutation versus 14.0 mo for WT) and 2-year PFS estimates (53.7 instead of 55.6% for driver mutation versus 12.6% for WT). The LLM also correctly identified the highly significant difference between these molecularly defined subgroups via log-rank testing (P<.001).

To confirm the robustness and reproducibility of the survival analysis, we repeated the semiautomated process 12 independent times (Figure S4 in Multimedia Appendix 2). The resulting survival models showed high stability, with Harrell's C-index consistently ranging from 0.493 to 0.521, indicating that the LLM-extracted curves were statistically indistinguishable from the GT (C-index=0.500).

Figure 5. Direct unstructured text-to-R code subgroup analyses. Subgroup progression-free survival (PFS) analysis using the original data (A) and performed by the large language model (B) using data from 160 letters, comparing driver mutation (black) versus wild type (brown). Shaded areas represent 95% CI. Numbers-at-risk tables are shown below each plot. Log-rank *P* values test for differences between groups. Median and 2-year PFS estimates are provided.

XSL•FO
RenderX



Validation on an Independent Leukemia Cohort

Next, to assess the generalizability of our approach, we conducted a validation study on a second, independent synthetic cohort. This dataset comprised 80 patients with AML, a hematological malignancy with distinct clinical terminology and data structures (Table S2 in Multimedia Appendix 2). We repeated the core analytical tasks, including MPE, direct question answering, and automated survival analysis. The LLM's performance on the AML dataset was highly consistent with the NSCLC cohort, achieving an overall MPE accuracy of 99.7% on batches of 40 letters, answering complex questions with a relative deviation below 0.5%, and generating survival curves nearly identical to GT (Figure S5 in Multimedia Appendix 2).

Stress Testing the Framework Against Simulated Real-World Data Imperfections

Given the limitations of synthetic data, we sought to assess the framework's resilience to common real-world data challenges. We therefore conducted a stress test on a modified subset of 40 letters, where each letter was intentionally corrupted with one relevant typographical error, one data ambiguity or contradiction, and one missing data point. In the MPE task, the LLM demonstrated high resilience to typographical errors, with no impact on accuracy. However, data ambiguities, contradictions, and especially missing data substantially reduced performance (Figure 6). To address this, we evaluated a two-stage workflow: errors or missing data were first flagged by the LLM and then resolved by a human annotator. With the human-in-the-loop approach, almost all deliberately introduced ambiguities and missing data points were resolved.

Figure 6. Effect of data quality issues. Bar chart comparing direct LLM extraction ("LLM MPE only") against a "human-in-the-loop workflow" on a dataset corrupted with 40 typographical errors, ambiguities, and missing data. Bars show the mean correct data points (out of 40) from 3 independent repetitions; error bars represent the standard error of the mean. LLM: large language model; MPE: multiparameter extraction.

Hypothesis Generation Beyond Extraction

Having established the LLM's ability to replicate conventional analytic workflows, we turned to a more exploratory objective: could the model go beyond predefined tasks and autonomously generate novel, clinically meaningful hypotheses? To test this, we prompted the LLM to analyze the dataset (n=80 and n=160 letters) and independently propose potential associations or insights. One example for such a hypothesis (H1) was: "In patients with KRAS-mutated NSCLC treated with an immune checkpoint inhibitor-containing regimen, the presence of a concurrent serine/threonine kinase 11 loss-of-function mutation is associated with a significantly increased risk of developing severe (Grade 3) immune-mediated colitis."

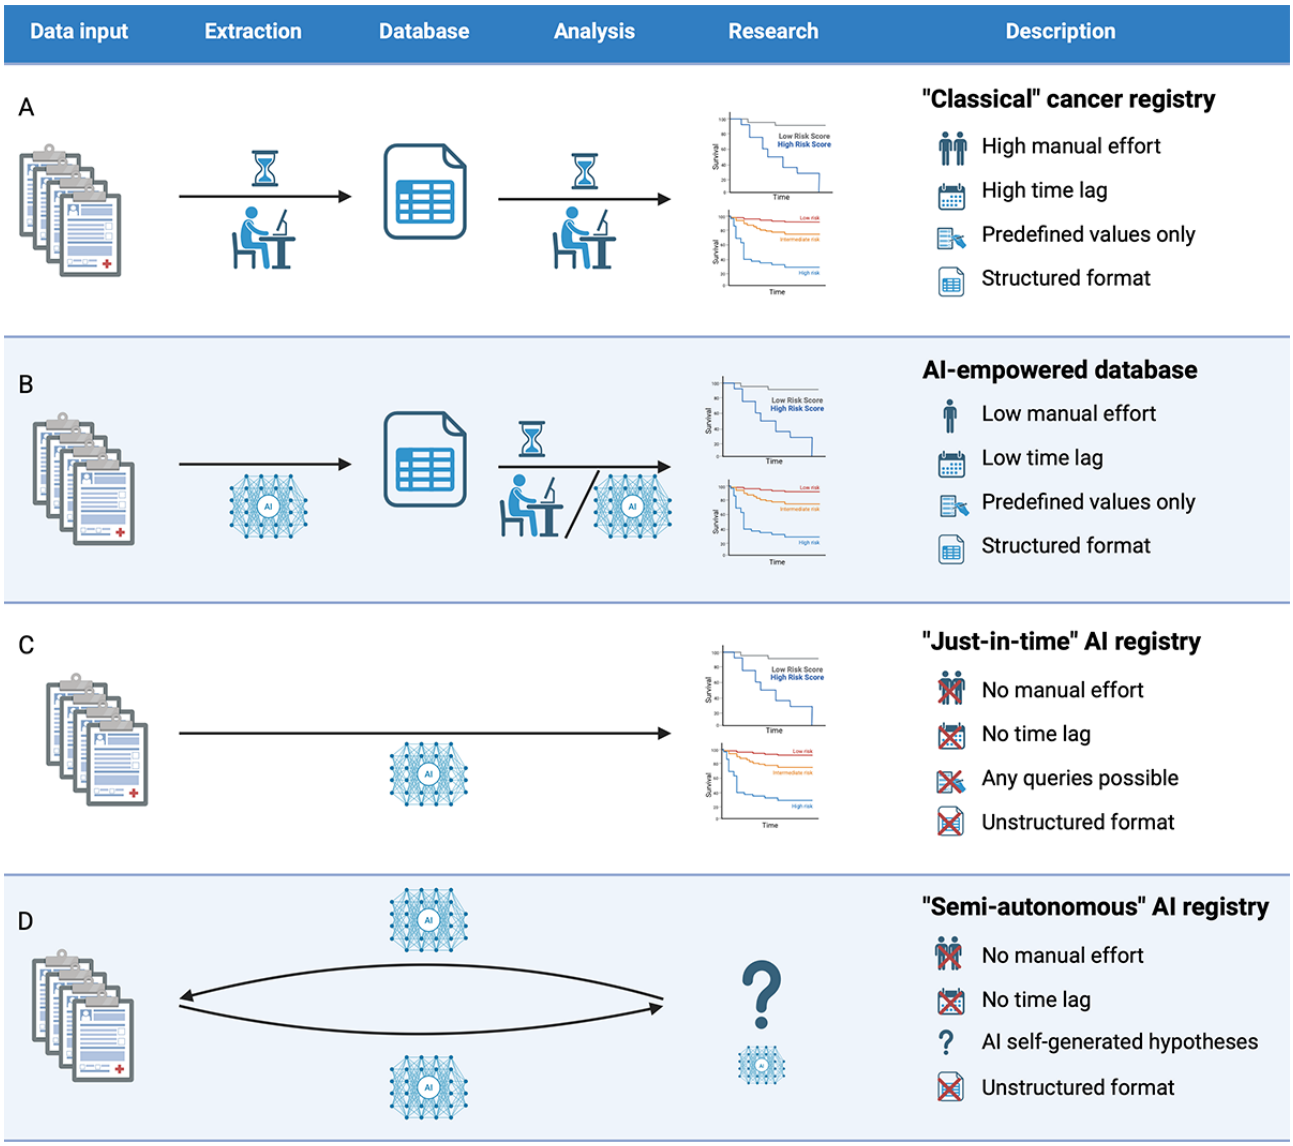
As shown in Table 2, with 80 letters, the LLM offered entirely correct justifications from the provided data. However, with 160 letters, performance dropped and most explanations were either only partly correct or incorrect. Moreover, biological plausibility was generally moderate to high, while the novelty of the offered hypotheses tended to be only moderate.

XSL•FO
RenderX

Table . Evaluation of hypothesis generation capabilities.

Hypothesis	Justification	Biological plausibility	Novelty
80 letters			
H1	Fully correct	Low-moderate	High
H2	Fully correct	Moderate	Moderate-high
H3	Fully correct	Moderate-high	Moderate
H4	Fully correct	High	Low-moderate
H5	Fully correct	High	Low-moderate
160 letters			
H6	Partly correct	Low-moderate	High
H7	Incorrect	High	Low-moderate
H8	Fully correct	High	Low
H9	Partly correct	High	Moderate
H10	Incorrect	High	Moderate

Discussion



Principal Results

This study provides proof-of-concept that LLMs can significantly advance the processing of unstructured clinical oncology data. Our results demonstrate the feasibility of this approach: we show that LLMs can not only reliably and efficiently extract structured parameters but also perform complex multistep analyses like Kaplan-Meier survival estimation. A stress test designed to simulate real-world ambiguities, noise, and missing data showed that while performance degrades under these conditions, this degradation can be effectively mitigated using a human-in-the-loop approach. Finally, for smaller batches, biologically plausible hypotheses were generated from unstructured data without any prior human annotations or prompts about specific associations. While this study did not formally test the proposed hypotheses, their justification from the data source and novelty reinforce the potential for LLMs to function not only as passive extractors but also as proactive scientific agents within the clinical workflow.

As conceptualized in Figure 7, these findings support a potential paradigm shift for oncology data management in the future: from static, delay-prone databases toward dynamic, JIT analysis of raw clinical documentation [14,15], potentially accelerating research [1,2,18].

XSL•FO
RenderX

Figure 7. Schematic overview of different cancer registry paradigms. Comparison of workflow and characteristics for (A) classical manual registry, (B) AI-empowered extraction feeding a structured database, (C) direct AI analysis of unstructured data ("Just-in-time"), and (D) a future concept of a semiautonomous, hypothesis-generating AI registry. AI: artificial intelligence.

While prior work has demonstrated LLM proficiency in extracting specific clinical end points like PFS [3,4], biomarkers [5], and TNM stage [1] from unstructured text, often focusing on single-task extraction to populate structured databases, our study extends these findings in several key dimensions. The novel contribution of our work is the systematic assessment of an LLM as an integrated interface for complex, multistep tasks in clinical oncology research, potentially obviating the need for intermediate structured databases for many analytical needs. In contrast to the limitations of manual methods or static natural language processing approaches, LLMs exhibit flexible reasoning, adapt to narrative variability, and synthesize context across documents [3,5,19,20]. Our work quantifies this fidelity at scale, showing LLMs maintain clinically acceptable error rates in high throughput, with multiple complex parameters extracted simultaneously. In addition to speed, LLMs offer crucial flexibility: new parameters can be readily incorporated, allowing analytical frameworks to evolve with scientific understanding—a significant advantage over static traditional registries.

However, the practical feasibility of a JIT approach hinges on specific economic and privacy considerations. Regarding cost, we estimated the computational expense on a single analytical run on our full 240-letter cohort at current application programming interface (API) pricing to be around US $0.30–$0.40. In line with our human benchmark, prior studies have reported 225 person-hours for manual abstraction of 100 complete patient records, making estimated labor costs for such tasks much higher [21]. Whether it is more economical to use LLMs to perform a one-time MPE to create a structured database, with subsequent analyses run on that database, or always interrogate the entire batch of unstructured data, will depend on future API pricing. Beyond cost, translating the JIT approach to real patient data necessitates strict attention to privacy and regulations like HIPAA or General Data Protection Regulation [22]. A primary pathway involves using secure, HIPAA-compliant cloud APIs from major providers, which are of state-of-the-art performance but rely on the provider's security architecture. An alternative is the deployment of local, on-premise LLMs, which provide maximum data security and

XSL•FO
RenderX

control but currently lag behind frontier models in analytical capability and require significant institutional investments in hardware and maintenance [23,24]. Therefore, a successful real-world implementation must carefully balance the analytical power of cloud models with the security of local solutions, potentially through hybrid approaches or advanced, LLM-based deidentification techniques [25].

Limitations

Our study has several limitations that must be considered when interpreting the results. First, and most importantly, our study was conducted exclusively on a synthetic dataset. While we took significant steps to create a heterogeneous and challenging benchmark—incorporating diverse linguistic styles, a wide range of document lengths, and varying levels of clinical detail—this dataset cannot fully replicate the complexity of real-world clinical records. Specifically, our synthetic data, despite its variability, likely lacks the idiosyncratic shorthand, nonstandard abbreviations, ambiguities, and internal contradictions across multiple documents for a single patient that are common in authentic electronic health record data [26,27]. The high accuracy reported here may be, in part, an artifact of testing an LLM on relatively clean data generated by other LLMs. Consequently, our results should be interpreted as an upper-bound estimate of performance in a controlled environment. Even our error-injection simulation may not fully capture the nuanced challenges of real-world data. Therefore, rigorous validation on large-scale, multi-institutional, deidentified real-world datasets is the essential next step before the clinical deployment of this JIT paradigm can be considered.

Second, our study's reliance on a single dataset of stage IV NSCLC raises questions about its generalizability. Although our validation on a smaller AML cohort showed consistent performance, the framework's robustness across different cancer types, disease stages, and institutional documentation practices remains unproven and requires further validation. Third, our study used a single LLM architecture, and performance is prompt-dependent; comparative studies with other models (eg, CancerLLM [28]) and RAG frameworks are needed. Our preliminary tests showed that other leading frontier models (including from OpenAI and Anthropic) and local models could not handle this data volume, returning truncated or incomplete results. While our large-context method differs from alternative architectures like RAG, we recognize that the LLM landscape is rapidly evolving. Therefore, future comparative studies are needed to benchmark different approaches as their capabilities expand. Fourth, the autonomous generation of hypotheses, while compelling, must be treated as exploratory. Fifth, real-world deployment of our JIT paradigm faces certain ethical and practical hurdles. LLMs can perpetuate biases, creating ethical challenges that necessitate robust human oversight and model transparency to ensure accountability and health equity [29,30]. Therefore, responsible clinical integration will depend on developing clear regulatory frameworks and maintaining a human-in-the-loop approach to ensure patient safety. Human–AI interaction also requires real-world evaluation [31].

Conclusion

In a controlled experiment using synthetic data, this study demonstrated that a frontier LLM can perform complex, multistep analytical tasks directly from unstructured text. The model successfully executed high-fidelity data extraction, answered multiconditional queries, and generated accurate end-to-end survival analyses. These results establish the technical feasibility of a JIT clinical analysis model under idealized conditions. The extent to which these capabilities generalize to the complexities of real-world clinical data remains unproven and requires rigorous, multi-institutional validation before any practical application can be considered.

Acknowledgments

The authors acknowledge the use of generative artificial intelligence (AI) in the preparation of this manuscript. Specifically, generative AI models were used to generate the synthetic patient letters that form the dataset of this study. Moreover, a large language model was used to proofread the manuscript for grammar, spelling, and clarity. The authors reviewed and edited all AI-generated contributions and assumed full responsibility for the final content of this work. This research received no external funding and was supported by internal institutional funds.

Data Availability

The datasets generated during the current study are available from the corresponding author upon reasonable request. To promote transparency, reproducibility, and community benchmarking, all 240 synthetic patient letters used in this study have been made publicly available in a GitHub repository [32]. We encourage other research groups to use this dataset for evaluating clinical language models.

Abstract

Background: The prevalence of chronic gastritis is high, and if not intervened in a timely manner, it may eventually lead to gastric cancer. Managing chronic gastritis essentially requires comprehensive lifestyle changes. However, the current health care environment does not support continuous follow-up by professional health care providers, making self-management a key component of postdiagnosis care. Increasingly, researchers are exploring the use of large language models (LLMs) for patient management. However, LLMs have limitations, including hallucinations, limited knowledge scope, and lack of timeliness. Artificial intelligence (AI) agents may provide a more effective solution. Nevertheless, it remains uncertain whether AI agents can effectively support postdiagnosis self-management for patients with chronic gastritis.

Objective: The purpose of this study was to explore the effectiveness of AI agents in the postdiagnosis management of patients with chronic gastritis from different perspectives.

Methods: In this study, we developed an agent framework for the health management of patients with chronic gastritis based on LLMs in conjunction with retrieval-augmented generation and a search engine tool. We collected real questions from patients with chronic gastritis in clinical settings and tested the framework's performance across different difficulty levels and scenarios. We analyzed its safety and robustness and compared it with state-of-the-art models to comprehensively evaluate its effectiveness.

Results: Using a dual-evaluation framework comprising automated metrics and expert manual assessments, our results demonstrated that AI agents substantially outperformed LLMs in addressing high-complexity questions (embedding average score: 82.849 for AI agents vs 77.825 for LLMs) and were particularly effective in clinical consultation tasks. Clinical evaluation of safety based on a 5-point Likert scale by physicians indicated that the safety of the agents was 4.98 (SD 0.15; 95% CI 4.96-4.99). After 30 repeated experiments, the mean absolute deviation of the AI agents in the embedding average score and BERTScore metrics were 0.0167 and 0.0387, respectively. Therefore, the safety and robustness analysis confirmed that the AI agents can produce safe, stable, and minimally variable responses. In addition, comparative results with those of advanced medical-domain LLMs (Baichuan-14B-M1 and MedGemma-27B) and general-domain LLMs (Qwen3-32B) also demonstrated that the AI agents in this study performed outstandingly in the field of chronic gastritis. Our findings underscore the superior reliability, interpretability, and practical applicability of AI agents over conventional LLMs in chronic gastritis management, offering a robust foundation for their broader adoption in health care settings.

Conclusions: AI agents based on LLMs have high application value in the management of chronic gastritis. They can effectively guide patients with chronic diseases in addressing common issues, which may potentially reduce the workload of physicians and improve the quality of patient home care.

(JMIR Med Inform 2025;13:e73857) doi:10.2196/73857

KEYWORDS

large language models; artificial intelligence agent; AI agent; chronic gastritis; health management; retrieval-augmented generation; artificial intelligence; AI

Introduction

Chronic gastritis is one of the most common disorders in the digestive system and is also the initial phase in the progression to gastric cancer [1-3]. It is characterized by insidious onset, a protracted disease course, high prevalence, and frequent recurrence, as well as substantial health care costs, all of which significantly compromise patients' quality of life [4]. Data show that nearly half of patients with chronic atrophic gastritis experience anxiety [5], and prolonged anxiety is also identified as a risk factor for the exacerbation of chronic gastritis. The management of chronic gastritis inherently requires comprehensive lifestyle modifications, and self-management has emerged as a critical component in chronic gastritis care.

XSL•FO
RenderX

Patients can achieve not only effective symptom control but also meaningful improvement in overall health-related quality of life through systematic self-monitoring, evidence-based lifestyle adjustments, and structured psychological support, ultimately progressing toward holistic wellness.

Current constraints within the health care system render continuous postdiagnosis management by medical professionals impractical and unsustainable. The substantial heterogeneity in patient demographics further compounds clinical workload burdens. Particularly in resource-limited settings and geographically remote areas with uneven health care distribution [6,7], temporal and financial constraints make regular in-person clinical follow-ups largely unfeasible. While patient self-management presents a viable strategy to mitigate these resource limitations, the selection of appropriate self-care modalities remains paramount. Inappropriate information-seeking behaviors may lead to the acquisition of erroneous medical knowledge, potentially yielding adverse clinical outcomes. For instance, exclusive reliance on search engines for medical guidance is problematic due to the absence of professional interaction, where inaccuracies in symptom interpretation or medical misinformation may precipitate serious consequences [8]. Online consultations in the internet era provide convenience for patient inquiries. However, patients often express concerns about the protection of their personal privacy and a lack of trust in the professionalism of online services [9,10]. In addition, the uncertainty surrounding patients' online medical needs and the availability of physicians is highly likely to intensify their hesitation and resistance toward online consultations.

Since 2018, when OpenAI introduced the first generative pretrained transformer model, GPT-1 [11], large language models (LLMs) have ushered in a golden age. In recent years, the surge in the development of LLMs has inevitably sparked transformative changes in the medical field [12]. Ayers et al [13] compared the performance of ChatGPT with that of physicians in responding to patient inquiries on social media. The results indicated that the responses generated by ChatGPT were of higher quality and received greater patient approval. In addition, LLMs are capable of maintaining continuous communication with patients around the clock, a level of availability that is nearly impossible for human responders to achieve and difficult to improve upon. Furthermore, LLMs can address sensitive questions posed by patients, which are often challenging to broach or are met with hesitation during face-to-face consultations.

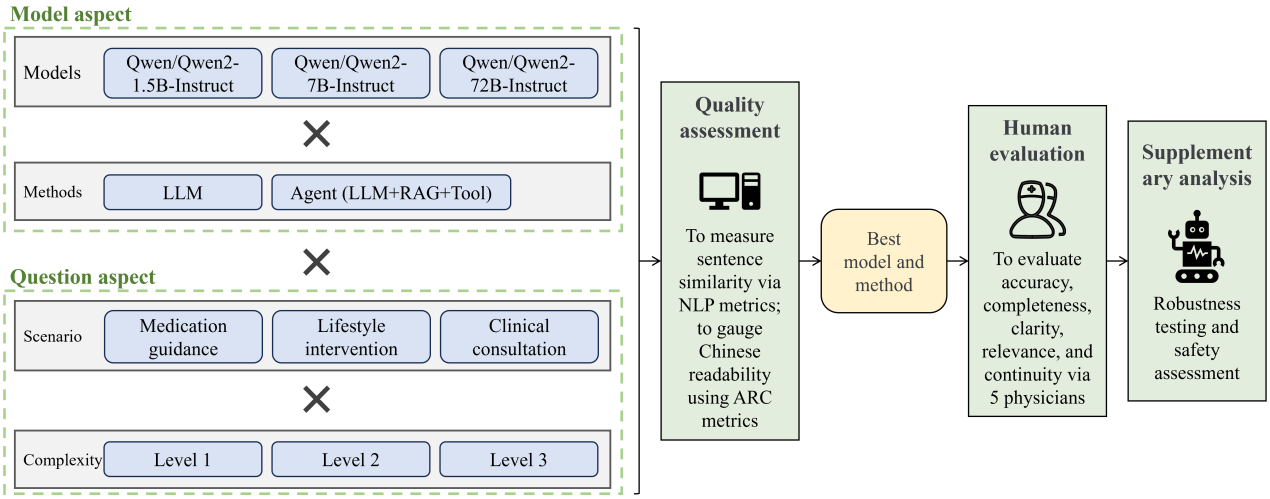
However, complete reliance on LLMs also carries certain risks as the issue of hallucinations cannot be overlooked, particularly in the health care domain. As hallucinations cannot be entirely eliminated, we can strive to minimize their occurrence. Research has shown that the agent framework [14] can significantly reduce the hallucination rate [15,16]. Meanwhile, the knowledge of LLMs is derived from their pretraining data, which inherently have limitations such as restricted scope and lack of timeliness [17]. To better address the complex and dynamic management needs of patients with chronic gastritis, an agent system built upon LLMs but not confined to the existing content in the training data may offer a more effective solution. As LLMs demonstrate remarkable capabilities and attract widespread attention, an increasing number of researchers are leveraging these models to develop artificial intelligence (AI) agent systems [18-20]. Agents have been proven to possess capabilities beyond those of LLMs [21-23]. Nevertheless, whether agents can be effectively used for the management of patients with chronic gastritis remains uncertain.

Our research specifically designed a question-and-answer (Q&A) dataset for chronic gastritis and analyzed the feasibility of applying agents in the medical field. Furthermore, by categorizing health management tasks, problem complexity, and the scale of LLMs, we compared the content of responses generated by LLMs and agents. This study aimed to provide guidance for the application of AI agents in the medical field and offer practical AI tools for the postdiagnosis management of patients with chronic gastritis.

Methods

Study Design

The effectiveness of chronic gastritis treatment depends to some extent on the patient's educational background, living environment, and personal habits. The actual circumstances of patients vary, leading to differences in the complexity of the questions they raise. In addition, prompts can significantly influence the performance of LLMs [24,25], and LLMs of different scales exhibit varying capabilities in processing prompts. Therefore, taking into account the characteristics of the disease, the scale of the model, and the needs of patients, we aimed to explore the following research questions:



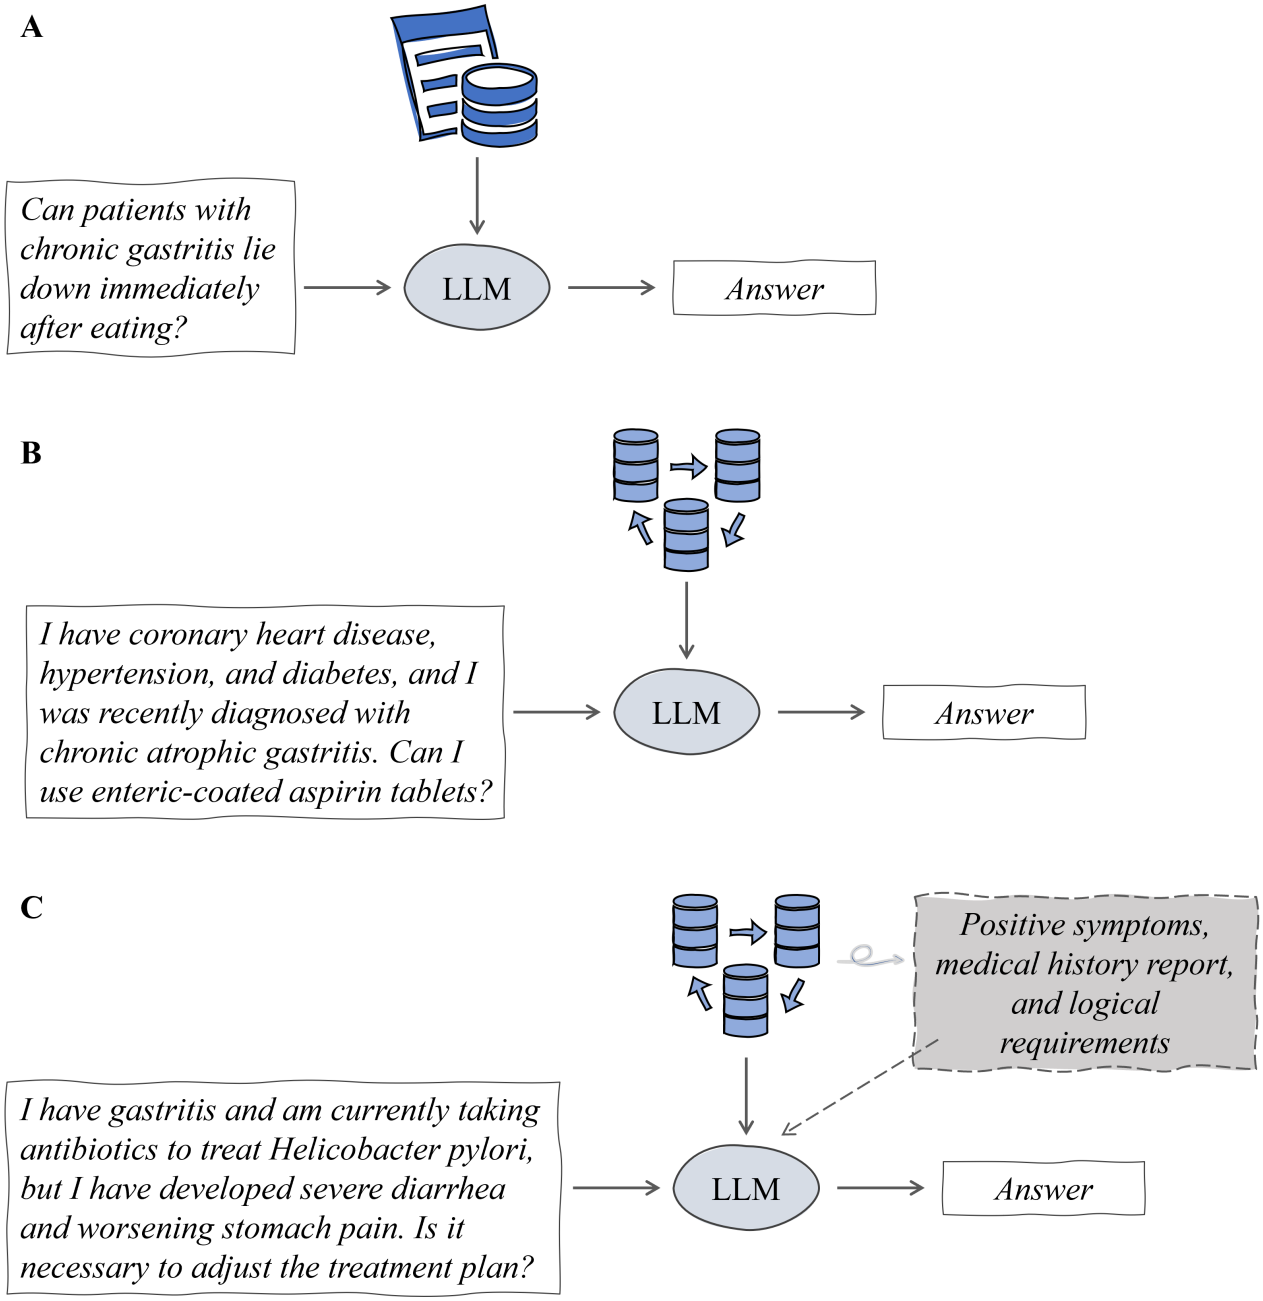
1. In the context of chronic gastritis management, does a larger LLM lead to better response content?
2. In chronic gastritis management, with a consistent parameter size, does an agent outperform an LLM?
3. How does the response content of Q&A models change as the difficulty of the questions increases?
4. Across different health management task scenarios, does an agent consistently outperform an LLM?

To address the aforementioned questions, we propose the methodological framework illustrated in Figure 1. On the basis of health management task scenarios (lifestyle intervention, medication guidance, and clinical consultation) and problem complexity (level 1, level 2, and level 3; more details can be found in the Preparation of the Q&A Dataset section), questions were categorized into 9 (3 × 3) dimensions. These questions were then tested using 3 scales of LLMs and agents (using retrieval-augmented generation [RAG] and a search engine tool; more details can be found in the Use of LLMs and Agents section) on real-world problems. The responses were evaluated using multiple assessment metrics (more details can be found in the Model Evaluation section), and the performance of the models was analyzed across various aspects, including model size, methodology, task scenarios, and problem difficulty. To ensure the safety of the generated answers, we assessed all responses for safety, mitigating potential risks associated with the experimental outcomes. Finally, to enhance the robustness

XSL•FO
RenderX

of the model, we conducted multiple tests on the same set of questions to confirm the stability of the results.

Figure 1. Study framework for the application of large language models (LLMs) in chronic gastritis management. ARC: Alpha Readability Chinese; NLP: natural language processing; RAG: retrieval-augmented generation.



Preparation of the Q&A Dataset

Q&A design was one of the most critical aspects of this study. The real-world questions selected must be representative. We classified the difficulty levels of the patient questions based on the cutting-edge methods proposed by Microsoft [26]. Microsoft's hierarchical approach is designed to identify pathways for finding answers and is tailored for general domains, which does not fully align with the classification of problem difficulty in medical scenarios. Building on this, we collaborated with clinical experts to define 3 difficulty levels appropriate for medical scenarios: low-difficulty questions (level 1; based on explicit facts), medium-difficulty questions (level 2; based on implicit facts), and high-difficulty questions (level 3; requiring reasonable inference). Figure 2 illustrates the rules for categorizing question difficulty.

XSL•FO
RenderX

Figure 2. Criteria for question difficulty classification. (A) Low-difficulty questions, which can be answered based on explicit facts, primarily require the model to locate and extract relevant information. (B) Medium-difficulty questions, which require implicit facts to derive the answer, may involve information scattered across multiple segments. (C) High-difficulty questions, where no explicit answer exists in any information segment, demand complex reasoning to uncover latent information. LLM: large language model.

Use of LLMs and Agents

As the models in the Qwen series have been proven to have excellent application performance [27,28], we selected the "instruct" models from the Qwen2 series with model sizes of 1.5B, 7B, and 72B as the foundational models (Qwen-1.5B, Qwen-7B, and Qwen-72B models) [29]. In 2020, Lewis et al [30] formally proposed and named the RAG framework, marking the birth of a new paradigm. Research has shown that, with the support of external knowledge, "instruct" models can generate more accurate and higher-quality responses [30,31]. Using domain-specific knowledge and external tools, we applied instruction prompting to these models to improve their specialization in the management of chronic gastritis. In addition, an agent was constructed based on the LLM framework, enabling the models to provide more professional responses to questions from patients with chronic gastritis. To enhance the capabilities of the agent, we used RAG and integrated search engine tools to prepare contextual information. The detailed process of RAG and the visualized integration of its components, as well as the prompt templates, are shown in Multimedia Appendix 1. Our preparatory work can be divided into the following components:

- Knowledge base: in light of the updates in clinical techniques, we conducted a search in the *National Medical Journal of China* for Chinese expert consensuses and clinical guidelines published from 2020 to 2024 using "gastritis" as the keyword. Subsequently, we invited experts

XSL•FO
RenderX

to manually screen and select 18 articles related to chronic gastritis. Using the zh_core_web_sm model, we segmented the long texts into sentences and further divided these sentences into chunks using a sliding window approach. Each chunk contained 20 sentences, with an overlap of 5 sentences between adjacent chunks to maintain contextual coherence. Subsequently, the all-MiniLM-L6-v2 model was used to map these chunks into a vector space, converting them into embedding vectors. Finally, using the Euclidean distance as the similarity metric, we created a Faiss index and added the embedding vectors to this index to enable rapid retrieval of the most similar vectors for a given query text.

- Agent tools: a defining feature of an agent, as opposed to a stand-alone LLM, is its ability to flexibly use external tools. In this process, we invoked the Google Search application programming interface to retrieve URLs and content summaries related to the input query. The summary texts were then ranked based on relevance to produce the final search results.
- Agent (with RAG and search tools): on the basis of the Faiss index and L2 distance, we retrieved the 5 most relevant text fragments from the knowledge base. The Google Search application programming interface sorted the organic results according to its internal ranking algorithm, and the 5 most relevant web page snippets were directly output. These 10 text fragments were then passed to the model as reference materials, whereas the decision of whether to use this reference content was autonomously made by the agents. Three agents were constructed based on the Qwen-1.5B, Qwen-7B, and Qwen-72B models. These agents shared identical network parameters, which were configured as follows: the maximum number of tokens was set to 800, the temperature was set to 0.4, the nucleus sampling parameter was set to 0.8, the truncation parameter was set to 5, and the frequency penalty was set to 0.5.

Model Evaluation

Relying on a single perspective for evaluation metrics may lead to biased results. To address this, we used 3 types of evaluation methods: natural language processing–based automatic evaluation metrics, manual scoring, and Chinese lexical evaluation metrics. The automatic evaluation metrics compared the system-generated answers with the standard answers (more details are provided in the Preparation of the Q&A Dataset section) to derive evaluation results. Among these, the embedding average score and BERTScore use cosine similarity between vectors to calculate the relevance to the standard answers, which has proven to be an effective approach [32-34]. In light of the unique nature of medical scenarios, we also designed a Likert scale and organized a panel comprising 5 clinical experts in relevant fields (including 1 certified clinical nutritionist), all of whom have over 10 years of work experience, to manually score the model-generated answers based on the following criteria [35]:

- Accuracy: the response contained specific and precise information rather than general or generic information.
- Completeness: the response covered all relevant medical information and details, with no omission of critical content.
- Clarity: the response was clearly expressed, easy to understand, readable, and free of ambiguity.
- Relevance: the response was closely related to the question, providing useful information and recommendations that aligned closely with the patient's needs.
- Continuity: the response maintained coherent and consistent phrasing throughout, with no logical jumps or inconsistencies.

The experts scored the responses generated by each model using each method ($3 \times 2 \times 63$) on a scale ranging from 1 to 5, where a higher score indicated better performance. In addition, we used a specialized evaluation framework designed for Chinese text to assess the richness and clarity of syntax and vocabulary [36]. This framework was originally developed for general Chinese contexts, but its evaluation metrics can be adapted and interpreted more granularly for medical scenarios:

- Lexical richness: the entropy values of all the words were calculated. The higher the entropy value, the greater the uncertainty associated with the words used in the text. This indicates a more diverse vocabulary, which in turn increases the reading difficulty level of the text.
- Syntactic richness: the entropy values of all the dependencies in the text were calculated. The higher the entropy value, the greater the uncertainty in the text's dependency relationships or syntactic structure. This suggests a more complex and varied syntax, which in turn makes the text more difficult to read.
- Semantic clarity: the semantic clarity value was calculated based on the skewness of the topic distribution probability extracted through latent Dirichlet allocation topic modeling [37]. The higher this value, the more concentrated the text's topics represented by nouns, resulting in clearer semantics.
- Semantic noise: the semantic noise value was calculated through the kurtosis of the topic distribution probability extracted through latent Dirichlet allocation topic modeling [37]. The higher this value, the more the text's topics represented by nouns are skewed toward unimportant topics, thereby increasing the semantic noise.
- Semantic richness: on the basis of the research by Lee et al [37], the semantic richness of the text was calculated by summing the probabilities of the occurrence of nouns in the text. The higher the value, the richer the topics of the text, and the lower its readability.

Ethical Considerations

This study aimed solely to evaluate the quality of responses generated by an AI agent for chronic gastritis queries and was therefore classified as nonhuman-participant research; institutional review board approval and full ethics review were waived. All patient questions were gathered during routine clinical operations, and no identifiable personal information was collected. Consequently, informed consent was not required and no compensation was provided. All analyses were performed on a secure server to safeguard the privacy and confidentiality of the questions submitted by patients.

Results

Influence of Model Scales and Methods on Response Content

Model Scale Comparison

The number of parameters is one of the primary factors influencing the performance of LLMs [38]. The results shown in Figure 3, Table 1, and Figure S3 in Multimedia Appendix 1 demonstrate that changes in model scales have a positive impact on the response content of LLMs. However, as the number of parameters increased, the improvement effect gradually diminished. Specifically, there was no statistically significant difference in response content between base models with 7B and 72B parameters. This phenomenon may be attributed to 2 reasons. First, general-purpose LLMs are suitable for answering questions in broad domains, but their actual performance in specialized fields such as medicine remains uncertain [39,40]. Second, the 7B model has already reached a bottleneck in understanding medical questions, and as our questions were all within the specialized medical domain, merely increasing the number of parameters did not significantly enhance the quality of the response content. Therefore, we further tested the relationship between model scale and response content using an agent. The results still indicated that the Qwen-72B model was the optimal choice for a health management Q&A model focused on chronic gastritis.

Figure 3. Statistical differences in evaluation indicators under different model parameters. Median differences were compared using bar charts. LLM: large language model.

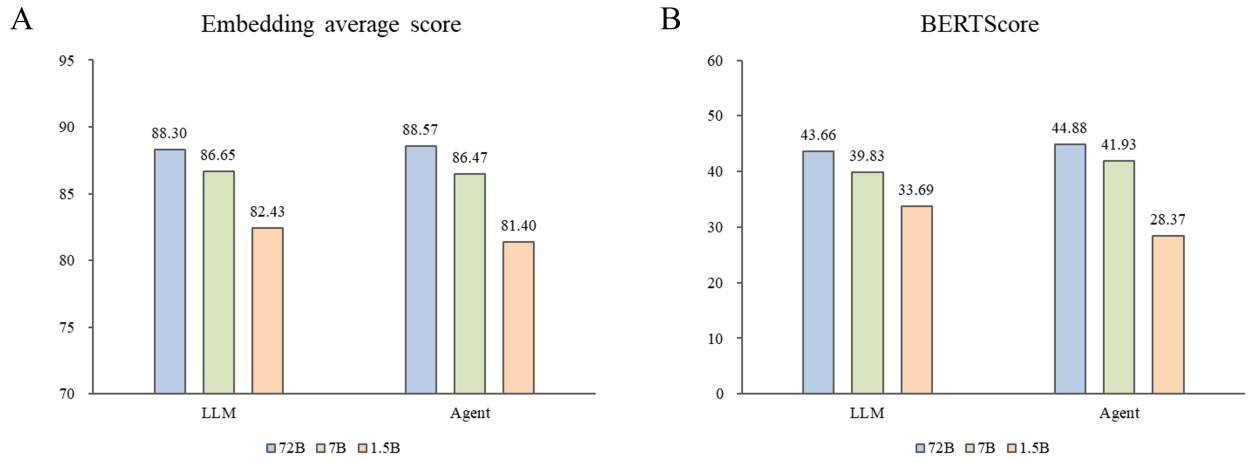

Table . Mann-Whitney *U* test results for evaluation indicators across different model parameters.

Indicator	*U* value	*Z* value	*P* value
Embedding average score			
LLM[a] 1.5B vs 7B	1376	−2.969	.003
LLM 1.5B vs 72B	1336	−3.164	.002
LLM 7B vs 72B	1840	−0.705	.48
Agent 1.5B vs 7B	1165	−3.999	<.001
Agent 1.5B vs 72B	873	−5.423	<.001
Agent 7B vs 72B	1534	−2.198	.03

Comparison of LLMs and Agents

Using the Qwen-72B model as the base model, we compared the response content of the LLM and the agent. The trend chart (Figure 4) shows that the response quality of the agent had an upward trend compared with that of the LLM. The linguistic evaluation results (Table 2) show that the responses generated by the agent had higher values in lexical richness, syntactic richness, semantic noise, and semantic richness and a lower value in semantic clarity. These Chinese evaluation indicators are comparative metrics that do not focus on individual results and do not have a defined range of values. This indicates that the responses generated by the agent were more complex in terms of vocabulary and syntax, had a higher reading difficulty level, and covered a broader range of topics compared to the responses generated by the LLM. This demonstrates that the agent not only outperformed the LLM in terms of alignment with the standard answers but also exceeded the LLM in terms of breadth of thinking and domain-specific expertise. This is one concrete example demonstrating the effectiveness of using the tool (Google search engine).

Figure 4. Method comparison: large language model (LLM) and agent. The blue line represents the median trend line, whereas the green and red lines represent the quartile trend lines.

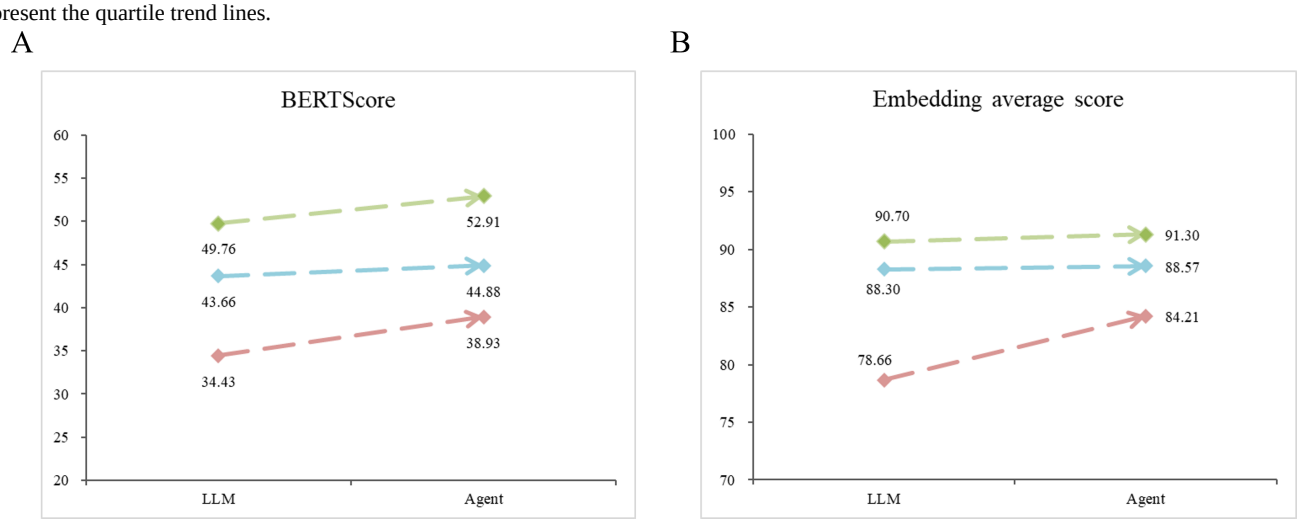

Table . Comparison of a large language model (LLM) and agent in Chinese-language dimensions.

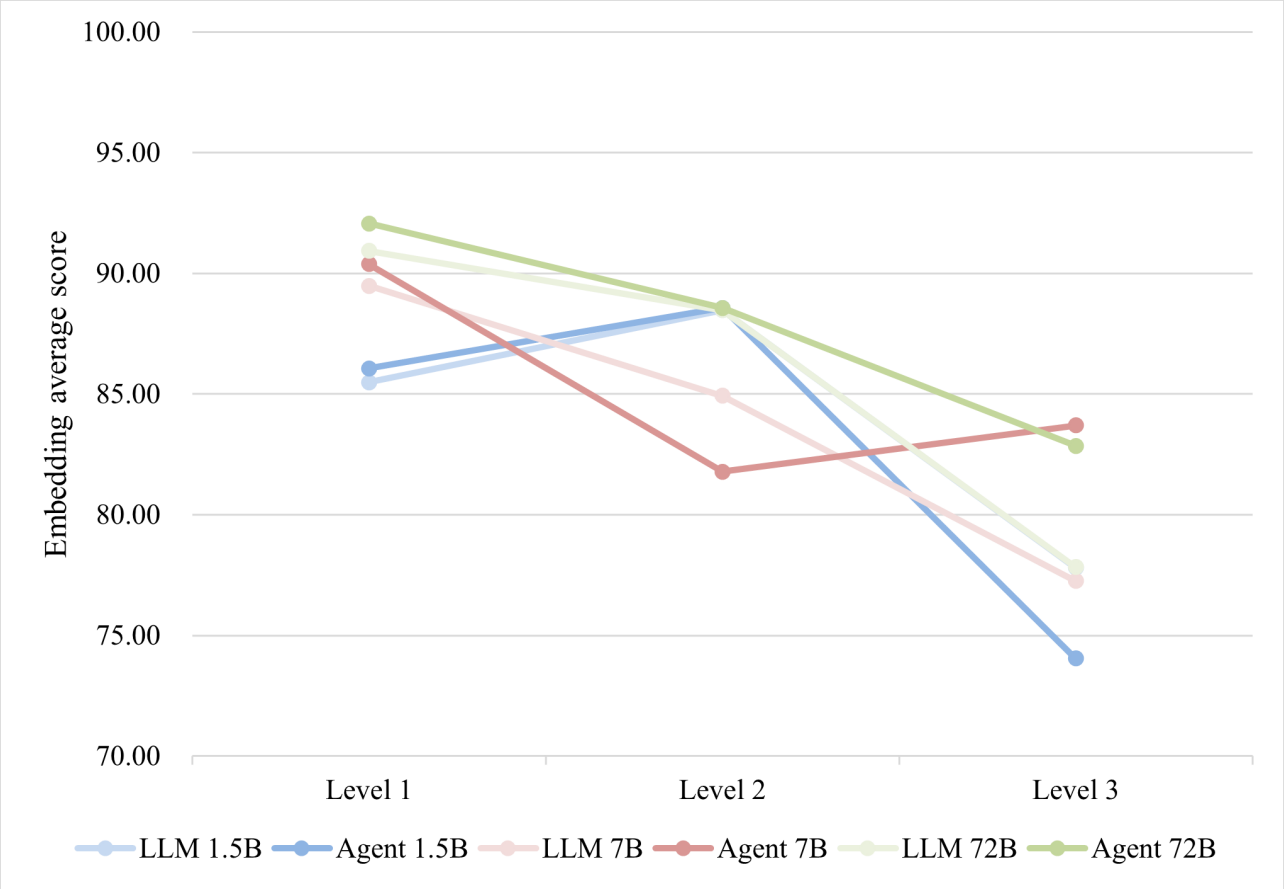
	LLM 72B	Agent 72B
Lexical richness	4.0707	4.2950
Syntactic richness	2.1529	2.1911
Semantic clarity	0.0707	0.0643
Semantic noise	5.8923	6.3081
Semantic richness	0.2411	0.2520



Influence of Question Difficulty and Medical Contexts on Answer Quality

Comparison of Response Content Across Different Difficulty Levels

Figure 5 shows the results stratified by difficulty level, which align with the previous conclusions: larger models outperformed smaller models, and the agents surpassed the LLMs. As question difficulty increased, the similarity between response content and reference answers showed a declining trend. Mann-Whitney *U* tests on the Embedding Average Scores of the 72B-Agent across difficulty levels revealed that the observed decreases from level 1 to level 2 and from level 2 to level 3 were statistically significant (*U* value=141.000, *Z* value=–2.000, *P*=.046; *U* value=121.000, *Z* value=–2.503, *P*=.01). Smaller models exhibited instability, which may be attributed to the limitations of LLMs in specialized domains, insufficient contextual comprehension by smaller models, and the negative impact of irrelevant information [41]. When domain-specific knowledge obtained through RAG and search engine tools was input into smaller agents, these models struggled to accurately understand the relevant information, resulting in noisier and less reliable outputs.

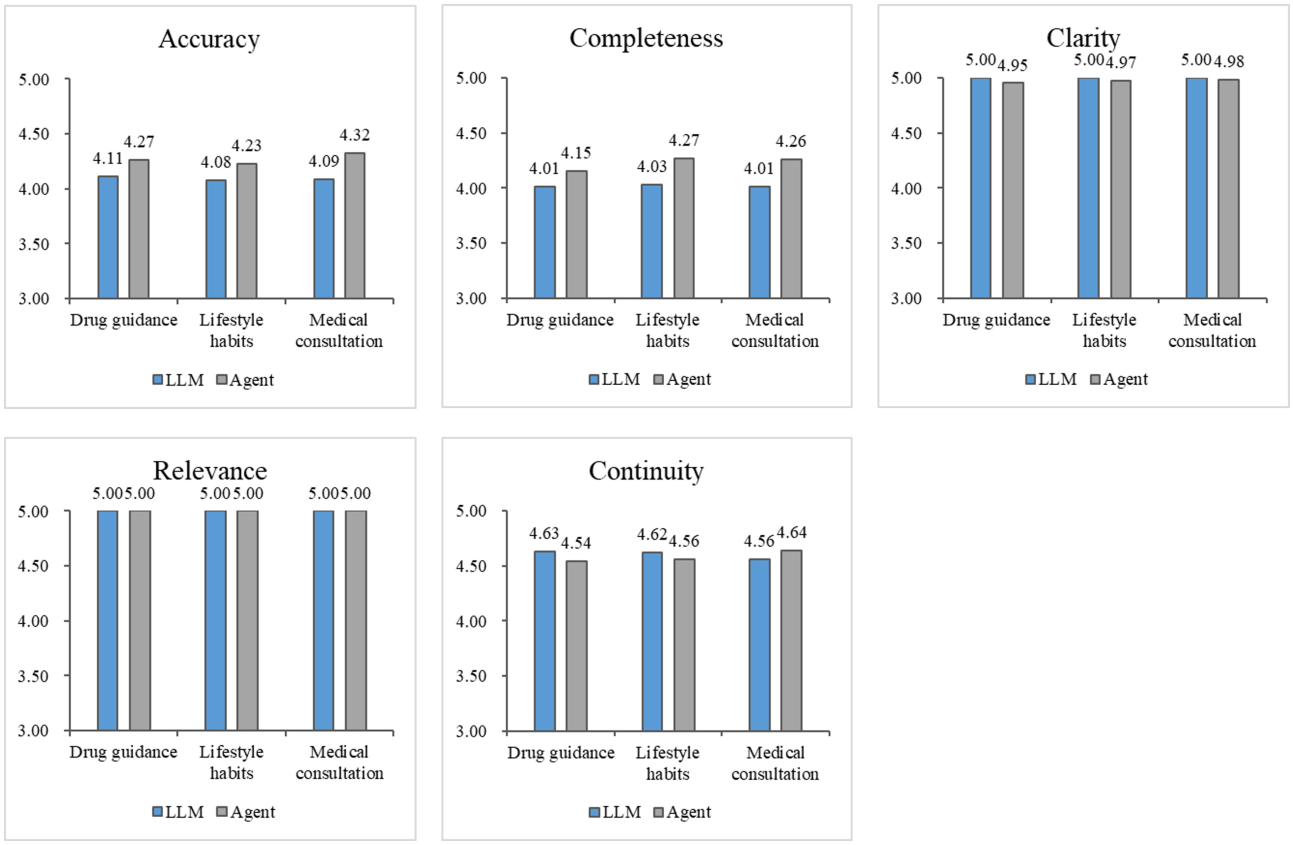
Figure 5. The trend in the impact of question complexity on answer quality. The points on the line represent the median of the embedding average score for all questions under that category. LLM: large language model.



Comparison of Response Content From the Qwen-72B Model Across Different Health Management Tasks

The manually assigned scores for the Qwen-72B model were aggregated and analyzed from the perspective of health management tasks (Figure 6). On the basis of the evaluation results of multiple experts, the clarity and coherence of the agent's responses were slightly inferior to those of the LLM, which was consistent with the previous findings. This is attributed to the agent's replies being more specialized, covering a broader range of topics, and having a higher reading difficulty level. Overall, across the 3 health management task scenarios, the agent demonstrated superior application performance compared to the LLM, with higher accuracy and completeness in its responses. Correspondingly, the increased reading difficulty level placed greater demands on patients' comprehension abilities. In medication guidance and clinical consultation tasks, the aggregate accuracy score of the agent exceeded that for lifestyle intervention tasks, indicating that the agent could more precisely understand questions with relatively fixed answers and generate targeted responses. However, the completeness of the agent's responses for medication guidance tasks was slightly inferior to that for lifestyle intervention and clinical consultation tasks. This suggests that the knowledge base and search engine tools provided to the agent need to be further enhanced in terms of drug-related knowledge to improve its capability in medication guidance.

Figure 6. Comparison of different health management tasks. On the basis of the statistical results of human evaluation, the mean score assigned by all experts to all questions under a specific category of health management tasks was calculated. LLM: large language model.

Comprehensive Evaluation of Q&A Models

The use of AI tools in medical scenarios carries unique considerations as medical assistance tools must meet stringent quality assurance standards. Figure 6 and Multimedia Appendix 1 show the expert ratings for the dimensions of health management and model characteristics, respectively. As the parameter size of the foundational model increased, expert ratings also gradually increased. However, agents based on smaller models, due to their limited ability to comprehend complex contexts, exhibited poorer performance compared to LLMs of equivalent size. When the size of the foundational model increased, the superiority of agents over LLMs became significantly more pronounced, whereas the increased reading difficulty level resulting from the enhanced professionalism of the responses also became evident. Multimedia Appendix 1 shows the results of the ablation experiment, indicating that the improvements in the agents stemmed from the synergistic effects of RAG and search tools.

A comparative analysis was conducted between the model with the strongest comprehensive capabilities (agent 72B) and 3 newly released LLMs in 2025: 2 medical LLMs, Baichuan-14B-M1 [42] and MedGemma-27B [43], and the 32B model from the Qwen3 series [44]. This study revealed that Baichuan-14B-M1 outperformed larger-scale models such as Qwen2.5-72B and Llama 3-70B in the medical domain [42]. Meanwhile, MedGemma-27B surpassed models such as BioMistral-7B-DARE and OpenBioLLM-70B [43]. As shown in Table 3, the BERTScore and embedding IQRs computed over 63 questions indicate that the agent 72B achieved the highest performance, surpassing both the latest general-domain LLMs and medical-domain LLMs on chronic gastritis health management tasks.

Table . Comparison of state-of-the-art models.

Model	BERTScore, median (IQR)	Embedding average score, median (IQR)
Baichuan-14B-M1	43.142 (37.151-48.233)	86.024 (80.914-89.266)
MedGemma-27B	40.448 (35.130-47.228)	86.887 (82.274-89.869)
Qwen3-32B	40.650 (33.372-47.909)	85.626 (81.589-89.156)
Agent 72B	44.884 (38.934-52.909)	88.574 (84.211-91.298)

Safety Analysis

In a survey of 11,004 adults, 6602 (60.0%) reported feeling uneasy about health care professionals using AI-assisted tools, underscoring the critical need to establish patient trust [45]. Ensuring safety is key to achieving this goal. Using the Likert scale mentioned previously, experts evaluated the safety (harmful outputs such as the fabrication of false information,

XSL•FO
RenderX

dissemination of erroneous data, presence of biases, associated risks, alterations, and plagiarism) of the models' outputs [46-48]. As shown in Table 4, base models with a size larger than 7B demonstrated sufficient capability to generate relatively safe responses for patients. Multimedia Appendix 1 presents a representative error case generated by agent 7B accompanied by expert commentary.

Table . Safety assessment results.

Model	Safety score (1-5; SD; 95% CI)
LLM[a] 1.5B	4.85 (0.62; 4.79-4.92)
Agent 1.5B	4.42 (1.06; 4.31-4.54)
LLM 7B	4.98 (0.13; 4.97-5.00)
Agent 7B	4.95 (0.27; 4.92-4.98)
LLM 72B	4.95 (0.21; 4.93-4.98)
Agent 72B	4.98 (0.15; 4.96-4.99)

[a]LLM: large language model.

Robustness Analysis

The stability of the responses generated by the Q&A model was also a critical factor in determining its suitability for clinical applications. To further analyze the robustness of the agent, we preserved the original parameters and conducted supplementary evaluations based on the preconfigured agent. We randomly selected 1 patient question from each difficulty level and each type of health management task, resulting in a total of 9 questions. Each of these 9 questions was input into the agent 30 times, yielding 270 (9 × 30) outputs. For each output, we calculated the embedding average score, BERTScore, and the corresponding mean absolute deviation (MAD). The results showed that the MAD for the embedding average score was 0.0167 and the MAD for the BERTScore was 0.0387. These findings indicate that the agent based on the Qwen-72B model performed with high stability, exhibiting minimal random fluctuations and demonstrating strong robustness.

Discussion

Principal Findings

The evidence from this study demonstrates that LLM-based agents possess considerable potential in the management of chronic gastritis. The responses generated by agents were generally superior to those produced by LLMs, effectively addressing the limitations of LLMs in handling high-complexity questions. Moreover, agents exhibited higher safety and stability and were capable of outperforming LLMs in the cutting-edge medical domain.

This study presents a comprehensive evaluation of LLM-based agents' effectiveness in chronic gastritis management across heterogeneous clinical scenarios and different scales. Our multimetric analysis revealed 4 critical findings that advance the understanding of AI-driven medical decision support systems. The first finding relates to model scaling effects. The quality of responses for chronic gastritis exhibited progressive enhancement with increasing base model sizes. Larger architectures (eg, Qwen-72B) demonstrated superior medical information processing capabilities through improved semantic comprehension and clinical reasoning. Conversely, smaller models showed inherent limitations in effectively integrating medical knowledge derived from RAG and search tools, resulting in suboptimal domain-specific performance. This parameter-performance correlation aligns with neural scaling laws while highlighting critical capacity thresholds for medical AI applications. The second finding relates to agent versus base LLM performance. When using base models with larger parameters (eg, Qwen-72B), the agents demonstrated better performance compared to the LLMs, particularly in terms of answer accuracy and completeness. However, due to the agents' stronger medical expertise in generating responses, as well as their higher lexical and syntactic complexity, the readability of their answers tended to be lower than that of the LLMs' answers. The third finding relates to the impact of problem complexity. As the difficulty of the questions increased, the response quality of both Q&A models showed a declining trend. However, overall, the agents outperformed the LLMs across all 3 difficulty levels, particularly in handling high-difficulty questions, where the agents significantly compensated for the LLMs' shortcomings in the medical domain. The fourth finding relates to performance on different tasks. When addressing different health management task scenarios, the agents demonstrated statistically significant superiority over the LLMs in both accuracy and completeness of responses, with the most notable improvement observed in clinical consultation scenarios. Lifestyle intervention questions were subjective and did not have a single standard answer, resulting in limited improvement from RAG and search tools. Drug information is complex and varied, as medications produced by different manufacturers may have differences in use details, and the current information is insufficient to fully cover all potential patient inquiries. Despite these challenges, the agents still exhibited higher practical value in chronic gastritis management compared to the LLMs.

This study has both theoretical and practical contributions. On the theoretical side, first, this study demonstrated that LLM-based agents outperform generalized LLMs in multiple scenarios of chronic gastritis management. Second, this study demonstrated that the larger the parameters of either the base model or the LLM-based agents, the better the performance of the model, even though the quality of the answers tended to decrease as the difficulty of the questions increased. Finally,

XSL•FO
RenderX

this study demonstrated that the LLM-based agents had better performance in multiple scenarios of chronic gastritis management. On the practical side, this study identified the value of LLM-based agents in chronic disease management. By using real-world problems and multiscenario chronic disease management tasks, we validated the capabilities of these agents. This provides a reliable LLM-driven approach to the management of chronic gastritis, paves the way for future LLM-based chronic disease management, and provides a more flexible form of counseling for patients.

There are some limitations to our study. First, we only used textual data, whereas data in the clinical setting also include modalities such as temporal, image, and video data. Future research could use multimodal data to evaluate the performance of LLMs in chronic disease management. Second, due to the privacy management requirements of health care data, we only used privately deployed models, which generally have a small number of participants. Future research can further explore models with a larger number of parameters, such as the GPT-4 family of models. Third, we did not use medical bigram models such as HuatuoGPT [49]. This is because these models have been fine-tuned using the medical corpus, and the unknown corpus may affect our evaluation and cause cognitive bias in specific scenarios. Fourth, the hallucination issue in LLMs cannot be overlooked. While agents can reduce the probability of hallucinations, to prevent potential adverse impacts on health care applications, we recommend incorporating a hallucination threshold control mechanism in future studies. This system would automatically suspend operations and initiate retraining when the false positive rate exceeds predefined safety thresholds. It should be noted that these findings are based solely on Chinese-language data. Future research could validate these results across different linguistic and cultural contexts. In addition, patient surveys and randomized controlled trials could be conducted to investigate factors influencing patients' use of AI tools in real clinical settings. Such studies would provide further guidance for enhancing the effectiveness of chronic gastritis self-management tools.

Conclusions

In this study, we compared the effectiveness of agents and LLMs on a chronic disease Q&A dataset across different levels of difficulty and various scenarios. Our multiperspective evaluation results show that the responses generated by the agents were often preferred over those of the LLMs due to their higher embedding average score, BERTScore, accuracy, and completeness values, as well as their higher values in other metrics. The LLM-based agents demonstrated advantages across different difficulty levels, particularly addressing the shortcomings of LLMs in handling high-difficulty questions. Furthermore, the LLM-based agents exhibited varying application effectiveness in different health management task scenarios, proving more suitable for questions with relatively fixed answers. Compared with state-of-the-art general-purpose models and medical-domain large models, the 72B agent further demonstrates its professional competence in the health management of chronic gastritis. The robustness and safety analyses we conducted explored the stability of the agents' responses and their safety for clinical application. The results of this study suggest that LLM-based agents have high value for application in the management of chronic gastritis and that they are effective in guiding patients with chronic diseases in solving common problems, thereby potentially reducing clinicians' workload and improving the quality of patients' home care.

Abstract

Background: Recent advances in large language models have highlighted the need for high-quality multilingual medical datasets. Although Japan is a global leader in computed tomography (CT) scanner deployment and use, the absence of large-scale Japanese radiology datasets has hindered the development of specialized language models for medical imaging analysis. Despite the emergence of multilingual models and language-specific adaptations, the development of Japanese-specific medical language models has been constrained by a lack of comprehensive datasets, particularly in radiology.

Objective: This study aims to address this critical gap in Japanese medical natural language processing resources, for which a comprehensive Japanese CT report dataset was developed through machine translation, to establish a specialized language model for structured classification. In addition, a rigorously validated evaluation dataset was created through expert radiologist refinement to ensure a reliable assessment of model performance.

Methods: We translated the CT-RATE dataset (24,283 CT reports from 21,304 patients) into Japanese using GPT-4o mini. The training dataset consisted of 22,778 machine-translated reports, and the validation dataset included 150 reports carefully revised by radiologists. We developed CT-BERT-JPN, a specialized Bidirectional Encoder Representations from Transformers (BERT) model for Japanese radiology text, based on the "tohoku-nlp/bert-base-japanese-v3" architecture, to extract 18 structured findings from reports. Translation quality was assessed with Bilingual Evaluation Understudy (BLEU) and Recall-Oriented Understudy for Gisting Evaluation (ROUGE) scores and further evaluated by radiologists in a dedicated human-in-the-loop experiment. In that experiment, each of a randomly selected subset of reports was independently reviewed by 2 radiologists—1 senior (postgraduate year [PGY] 6‐11) and 1 junior (PGY 4‐5)—using a 5-point Likert scale to rate: (1) grammatical correctness, (2) medical terminology accuracy, and (3) overall readability. Inter-rater reliability was measured via quadratic weighted kappa (QWK). Model performance was benchmarked against GPT-4o using accuracy, precision, recall, F_1-score, ROC (receiver operating characteristic)—AUC (area under the curve), and average precision.

Results: General text structure was preserved (BLEU: 0.731 findings, 0.690 impression; ROUGE: 0.770‐0.876 findings, 0.748‐0.857 impression), though expert review identified 3 categories of necessary refinements—contextual adjustment of technical terms, completion of incomplete translations, and localization of Japanese medical terminology. The radiologist-revised translations scored significantly higher than raw machine translations across all dimensions, and all improvements were statistically significant (P<.001). CT-BERT-JPN outperformed GPT-4o on 11 of 18 findings (61%), achieving perfect F_1-scores for 4 conditions and F_1-score >0.95 for 14 conditions, despite varied sample sizes (7‐82 cases).

Conclusions: Our study established a robust Japanese CT report dataset and demonstrated the effectiveness of a specialized language model in structured classification of findings. This hybrid approach of machine translation and expert validation enabled the creation of large-scale datasets while maintaining high-quality standards. This study provides essential resources for advancing

KEYWORDS

radiology reports; machine translation; structured findings; medical language models; computed tomography; multilingual datasets; radiology report classification

Introduction

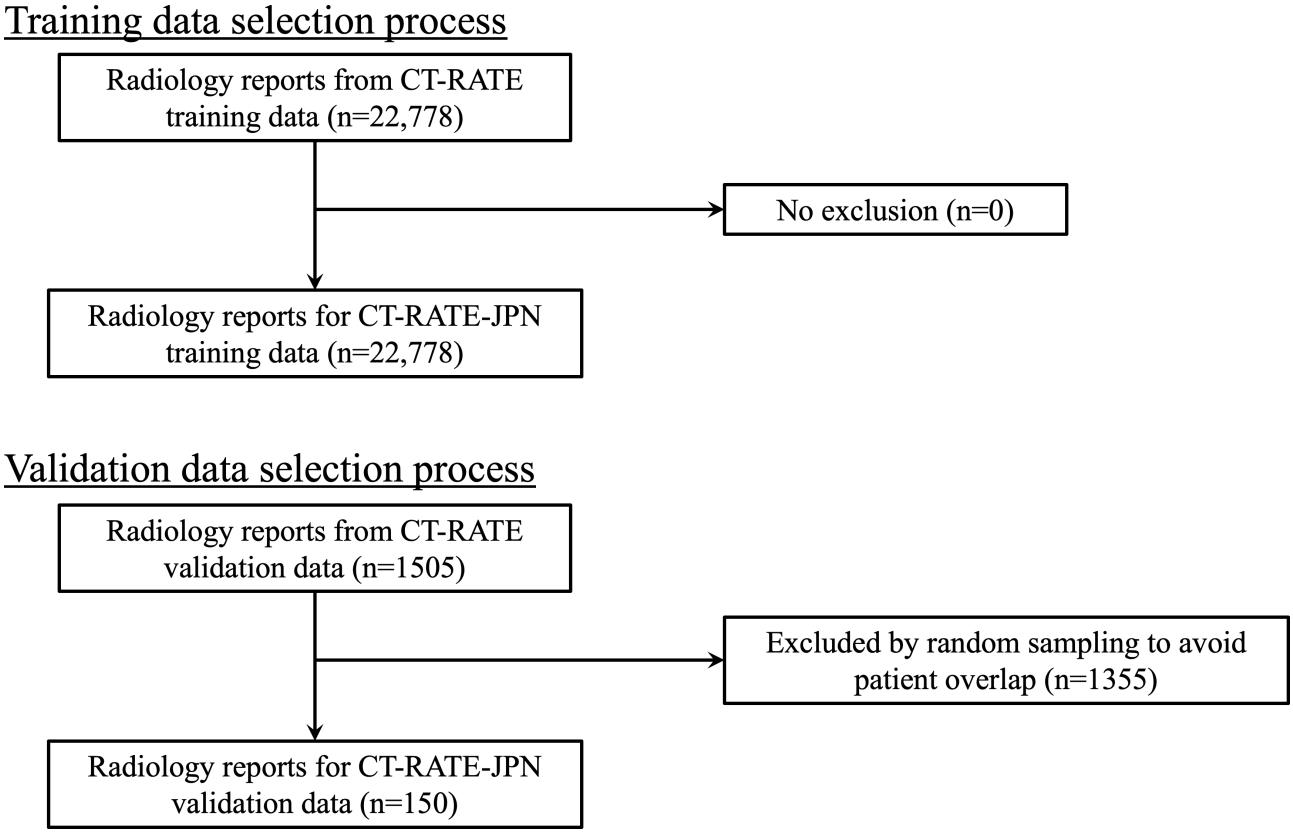
Recent advances in large language models (LLMs) have demonstrated remarkable capabilities across various domains [1], thereby increasing the focus on developing multilingual models to serve diverse linguistic communities [2]. This trend is exemplified by the release of specialized language models, such as Gemma-2-JPN, a Japanese-specific variant of Google's open LLM Gemma [3,4]. However, the development of such specialized models critically depends on the availability of high-quality domain-specific datasets in the target language. This requirement becomes particularly crucial in specialized fields, such as medical imaging [5-7], where the interpretation of diagnostic findings demands both technical precision and linguistic accuracy.

Computed tomography (CT) is indispensable in modern medical diagnostics, facilitating disease staging, lesion evaluation, and early detection. Japan has the highest number of CT scanners per capita and an annual scan volume surpassing that of most developed nations, presenting a vast reservoir of medical imaging data [8,9]. The extensive use of CT technology has positioned Japan as a pivotal contributor to global medical imaging resources. However, despite the proliferation of multilingual models and growing emphasis on language-specific adaptations, there remains a notable absence of large-scale Japanese radiology report datasets [10], which is a critical gap hindering the development of Japanese-specific medical language models.

To address this challenge, we constructed "CT-RATE-JPN," a Japanese version of the extensive "CT-RATE" dataset [11], which consists of CT scans and interpretation reports collected from 21,304 patients in Turkey. Although general academic knowledge benchmarks have been successfully adapted for Japanese, as evidenced by JMMLU (Japanese Massive Multitask Language Understanding) [12] and JMMMU (Japanese Massive Multi-discipline Multimodal Understanding) [13], which are Japanese versions of MMLU (Massive Multitask Language Understanding) [14,15] and MMMU (Massive Multi-discipline Multimodal Understanding) [16], respectively, and medical benchmarks, such as JMedBench [17], have emerged by combining translated English resources and Japanese medical datasets, a large-scale Japanese dataset specifically focusing on radiology reports, remains notably absent.

CT-RATE-JPN uses an innovative dataset construction approach by leveraging LLM-based machine translation to efficiently generate a large volume of training data. This addresses the fundamental challenge of the dataset scale in medical artificial intelligence (AI) development while maintaining quality through a strategic validation approach. A subset of the data undergoes careful revision by radiologists to create a rigorously verified validation dataset. This dual-track methodology, which combines machine-translated training data with specialist-validated evaluation data, establishes a robust pipeline for both training data acquisition and performance evaluation.

Both CT-RATE and CT-RATE-JPN retain licenses that allow free use for research purposes, thereby supporting broader research initiatives in medical imaging and language processing. To demonstrate the practical use of the CT-RATE-JPN dataset, we developed CT-BERT-JPN, a deep learning–based language model specifically designed for extracting structured labels from Japanese radiology reports. By converting unstructured Japanese medical text into standardized, language-agnostic structured labels, CT-BERT-JPN provides a scalable framework for integrating Japanese radiology data into the global medical AI development, thereby addressing a critical need in the rapidly evolving landscape of multilingual medical AI.



Methods

Dataset Overview

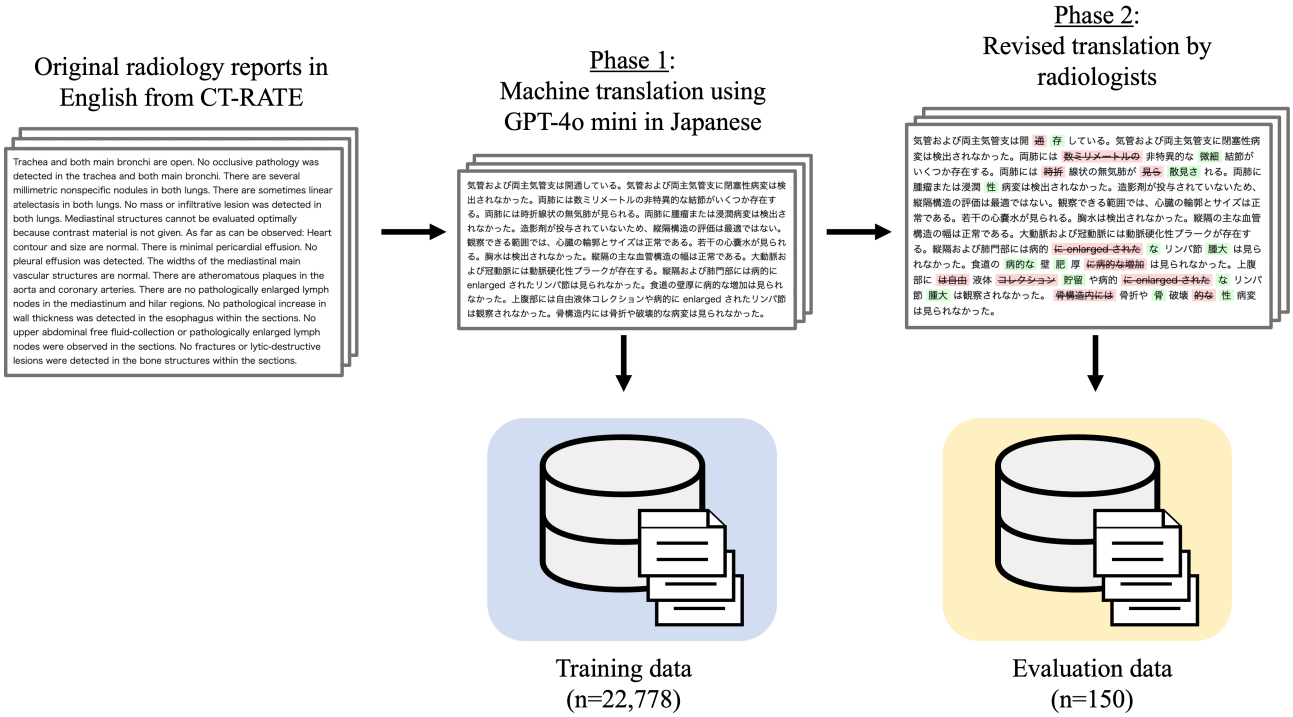
CT-RATE is a comprehensive dataset comprising 25,692 noncontrast chest CT volumes of 21,304 unique patients from the Istanbul Medipol University Mega Hospital [11]. We selected this dataset because it is uniquely positioned as the only publicly available large-scale dataset that pairs CT volumes with radiology reports and permits the redistribution of derivative works. This dataset includes corresponding radiology text reports (consisting of a detailed findings section documenting observations and a concise impression section summarizing key information), multi-abnormality labels, and metadata. The dataset is divided into 2 cohorts, 20,000 patients for the training set and 1304 patients for the validation dataset, allowing robust model training and evaluation across diverse patient cases [18,19]. The training dataset, comprising 22,778 unique reports, was used in constructing CT-RATE-JPN, a Japanese-translated version of the dataset created using machine translation. Independently, we randomly sampled 150 reports from the validation cohort (n=1304); this validation subset was never used during model training and was reserved solely for inference-time evaluation. Those 150 reports were first machine translated and then manually revised and refined by radiologists. The data selection process is illustrated in Figure 1.

XSL•FO
RenderX

Figure 1. Data selection process for CT-RATE-JPN training and validation datasets. The training dataset included all 22,778 radiology reports from CT-RATE without exclusion. For the validation dataset, 150 reports were randomly sampled from 1505 available reports, with 1355 reports excluded to avoid patient overlap between training and validation sets.

The CT-RATE dataset was annotated using 18 structured labels covering key findings relevant to chest CT analysis. These labels included "Medical material," "Arterial wall calcification," "Cardiomegaly," "Pericardial effusion," "Coronary artery wall calcification," "Hiatal hernia," "Lymphadenopathy," "Emphysema," "Atelectasis," "Lung nodule," "Lung opacity," "Pulmonary fibrotic sequela," "Pleural effusion," "Mosaic attenuation pattern," "Peribronchial thickening," "Consolidation," "Bronchiectasis," and "Interlobular septal thickening." The creators of the CT-RATE dataset developed a structured findings model based on the RadBERT architecture [20,21], trained on a manually labeled subset to label the remaining cases. This model achieved an F_1-score ranging from 0.95 to 1.00, demonstrating its efficacy in accurately structuring radiological findings from CT reports. This approach underscores the reliability of CT-RATE's structured annotations for developing high-performance diagnostic models. These structured labels were also used in the development of a Japanese structured findings model for CT-RATE-JPN, enabling the accurate structuring of radiological findings in Japanese CT reports.

Ethical Considerations



Given that CT-RATE is a publicly available dataset with deidentified patient information, and that our study focused on the translation and linguistic analysis of the existing dataset without accessing any additional patient data, institutional review board approval was not required for this research.

Translation for CT-RATE-JPN

For CT-RATE-JPN, machine translation was conducted using GPT-4o mini (API version, "gpt-4o-mini-2024-07-18") [22], which is a lightweight, fast version of OpenAI's GPT-4o model [23]. The GPT-4o mini produces high-accuracy translations at an affordable rate, making it suitable for large-scale dataset translations. Each radiological report was processed by translating the findings into short impression sections. The complete translation prompts used for GPT-4o mini are provided in Figures S1 (original Japanese prompt) and S2 (English translation) in Multimedia Appendix 1. Figure 2 shows the study workflow.

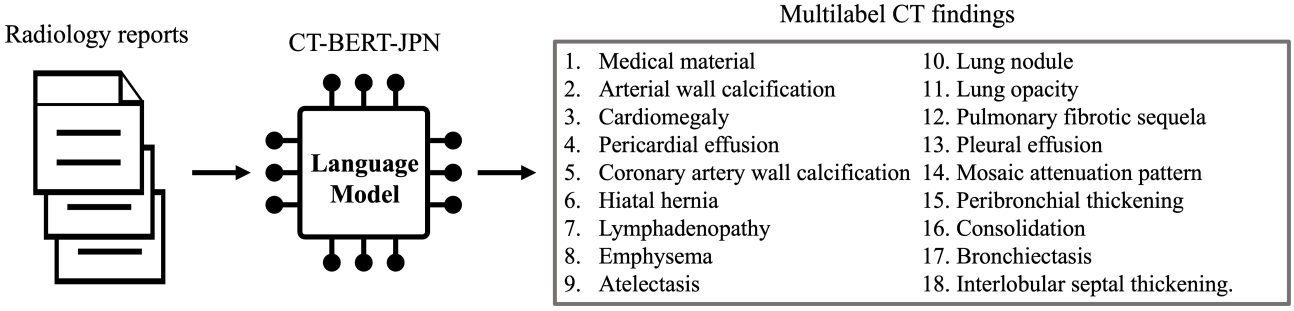
XSL•FO
RenderX

Figure 2. Workflow for translation and validation in constructing CT-RATE-JPN. The figure outlines machine translation application using GPT-4o mini for the training dataset and 2-phase manual correction for the 150 validation reports. Phase 1 involved initial revisions by radiology residents. Phase 2 consisted of expert review and refinement by board-certified radiologists.

To ensure the accuracy and reliability of the evaluation data, we conducted a comprehensive manual correction process on 150 reports from the validation dataset. This process consisted of 2 distinct phases. In the first phase, we assembled a team of 5 radiology residents, all between their fourth and sixth postgraduate years, to conduct an initial review and revision of the machine translations. The reports were systematically distributed among team members to optimize workflow efficiency. We intentionally chose a larger team to incorporate diverse clinical perspectives and minimize potential translation bias during the review process. The second phase involved a thorough expert review by 2 board-certified radiologists with extensive experience (10 and 11 postgraduate years). The senior radiologists divided the revised translations into final confirmation and refinement. The structured approach to task allocation combined with this rigorous 2-step review process ensured that the validation dataset for CT-RATE-JPN met the high-quality standards necessary for a robust model assessment.

For the training dataset, all translations were generated using GPT-4o mini without manual correction. This dataset was specifically designed for machine learning model training. The decision to rely exclusively on machine-translated data for the training set balanced the scale and practical constraints of the manual annotation.

Both CT-RATE and CT-RATE-JPN were released under a Creative Commons Attribution (CC BY-NC-SA) license, allowing free use for noncommercial research purposes with proper citation and shared terms for derivative works.



Development of CT-BERT-JPN for Structured Finding Classification

For model training, we randomly split the dataset in a 4:1 ratio, with 80% used for training and 20% for internal evaluation. The pretrained “tohoku-nlp/bert-base-japanese-v3” model from Hugging Face was used [24]. This model follows the architecture of the original BERT base model with 12 layers, 768 hidden dimensions, and 12 attention heads. It was pretrained on extensive Japanese datasets, including the Japanese portion of the CC-100 corpus [25,26] and Japanese version of Wikipedia [27]. BERT-based models have demonstrated significant success in downstream tasks in the medical domain [28,29], making them a promising choice for our research.

Training was conducted on Google Colaboratory equipped with an NVIDIA L4 GPU using the transformers library (version 4.46.2) with a learning rate of 2×10 , batch size of 8 for both training and evaluation, and weight decay of 0.01. Binary cross-entropy loss was applied to optimize the model for multilabel classification. Given the domain shift between the validation dataset (machine-translated) and test dataset (radiologist-revised), hyperparameter tuning was deliberately omitted to avoid overfitting, as such optimization may not contribute to performance improvement under domain shift conditions [30,31]. The model was trained over 4 epochs with internal evaluation and checkpoint savings at each epoch. The total training time was approximately 51.5 minutes (3090.54 s) across 4 epochs, with an average of 12.9 minutes (772.64 s) per epoch. The best-performing model on the internal evaluation data was selected and subsequently used for testing on the validation dataset of CT-RATE-JPN, to ensure a reliable performance assessment. Figure 3 shows the overall workflow for developing CT-BERT-JPN.

XSL•FO
RenderX

Figure 3. CT-BERT-JPN development workflow showing data preprocessing and model fine-tuning for structured computed tomography (CT) classification of findings.

Translated Radiology Reports Evaluation by Automatic Metrics

For basic text analysis, we examined the structural characteristics of the translated reports, including character, word, and sentence count, as well as lexical diversity. Unlike English, Japanese does not use spaces to delimit words. Therefore, we used MeCab (version 1.0.10) [32], one of the most widely used morphological analyzers for Japanese text processing, to accurately segment and count words. These metrics were calculated for both machine-translated and radiologist-revised texts to assess the consistency of textual characteristics across different stages of dataset creation.

For translation quality assessment, we computed the bilingual evaluation understudy (BLEU) [33] and recall-oriented understudy for gisting evaluation (ROUGE)-1, ROUGE-2, and ROUGE-L scores [34] using NLTK (version 3.9.1) and rouge-score (version 0.1.2) libraries.

The BLEU metric evaluates the accuracy of machine-translated text by comparing it to a reference translation. It measures how many words and short phrases in the machine translation match those in the reference translation, to assess the degree of similarity in wording and phrasing between the two texts.

The ROUGE metric assesses the quality of summaries or translations by measuring the overlap between machine-generated and reference texts. ROUGE-1 considers the overlap of individual words; ROUGE-2 examines the overlap of pairs of consecutive words; and ROUGE-L focuses on the longest matching sequence of words between two texts. These metrics emphasize recall by evaluating how much of the important content from the reference text is captured in the machine-generated text. These metrics were calculated by comparing machine-translated texts with radiologist-revised reference translations in the validation dataset.

Translated Radiology Reports Evaluation by Radiologists

To assess the quality of machine-translated radiology reports, we implemented a systematic evaluation by radiologists. A subset of reports was randomly assigned to radiologists for review, with each report evaluated by 2 reviewers: 1 senior radiologist (designated as rater 1, PGY 6‐11) and 1 junior radiologist (designated as rater 2, PGY 4‐5). To maintain objectivity, radiologists were never assigned to evaluate reports they had previously reviewed or corrected.

The evaluation used a 5-point Likert scale (1=poor to 5=excellent) across 3 distinct dimensions:

1. Grammatical correctness: Assessment of linguistic accuracy, including proper Japanese grammar and natural language usage. Presence of nonexistent words, unnatural English terms, or grammatical errors resulted in lower scores. Specialized terminology errors were evaluated separately.
2. Medical terminology: Evaluation of the accuracy and appropriateness of medical and radiological terminology in Japanese. This dimension specifically focused on technical terms and domain-specific language.
3. Overall readability: Subjective assessment of how comprehensible and fluent the translated text appeared to radiologists in clinical practice. While this dimension relates to the previous two categories, it captured the holistic impression of the text's utility in a clinical setting.

Inter-rater reliability was calculated using quadratic weighted kappa (QWK) to ensure consistency in evaluations across different radiologists, as this metric is particularly suitable for ordinal data such as Likert scales. This multi-dimensional evaluation approach provided comprehensive insights into both the technical accuracy and practical usability of machine-translated radiology reports in a Japanese clinical context.

CT-BERT-JPN Performance Evaluation

To evaluate the performance of the classification model in CT findings extraction, we used a test dataset comprising 150 radiology reports revised by radiologists to ensure accuracy. The key metrics calculated for model assessment included accuracy, precision, recall, F_1-score, area under the receiver operating characteristic curve (AUC-ROC), and average precision (AP). 95% CIs for these metrics were calculated using 1000 bootstrap resampling iterations. The Scikit-learn library (version 1.5.2) was used for the analyses.

Baseline Comparison With GPT-4o

To establish a baseline, we performed structured labeling using GPT-4o (API version, "gpt-4o-2024-11-20"), as it is widely adopted in various radiology tasks as a representative closed-source commercial LLM. We specifically chose GPT-4o because, to our knowledge, no existing open-source models were available for this particular task at the time of the study. We used a zero-shot prompting strategy that instructed GPT-4o to extract binary labels (0/1) for each of the 18 target findings from Japanese radiology reports and output results in JSON

XSL•FO
RenderX

format, without additional prompt engineering or few-shot examples. The input prompts used for GPT-4o are presented in Figures S3 (original Japanese version) and S4 (English translations) in Multimedia Appendix 1.

Statistical Analysis

The statistical comparisons were analyzed using the Wilcoxon signed-rank test. This nonparametric test was applied in two contexts: (1) comparing paired predictions from CT-BERT-JPN and GPT-4o on identical validation cases, and (2) comparing CT-BERT-JPN performance between radiologist-revised translated reports versus raw machine-translated reports as input, where each pair consisted of model outputs on the same test sample under different conditions. The Wilcoxon signed-rank test was chosen as it does not require the assumption of normal distribution and is appropriate for comparing paired model outputs. Statistical analysis was conducted using the scipy.stats library (version 1.11.3).

Results

Dataset Overview

The basic text statistics of the translated reports are summarized in Table 1, in separate sections for Findings and Impression. The training (n=22,778) and validation datasets (consisting of 150 machine-translated reports and 150 radiologist-revised reports) showed a consistent text structure across all metrics.

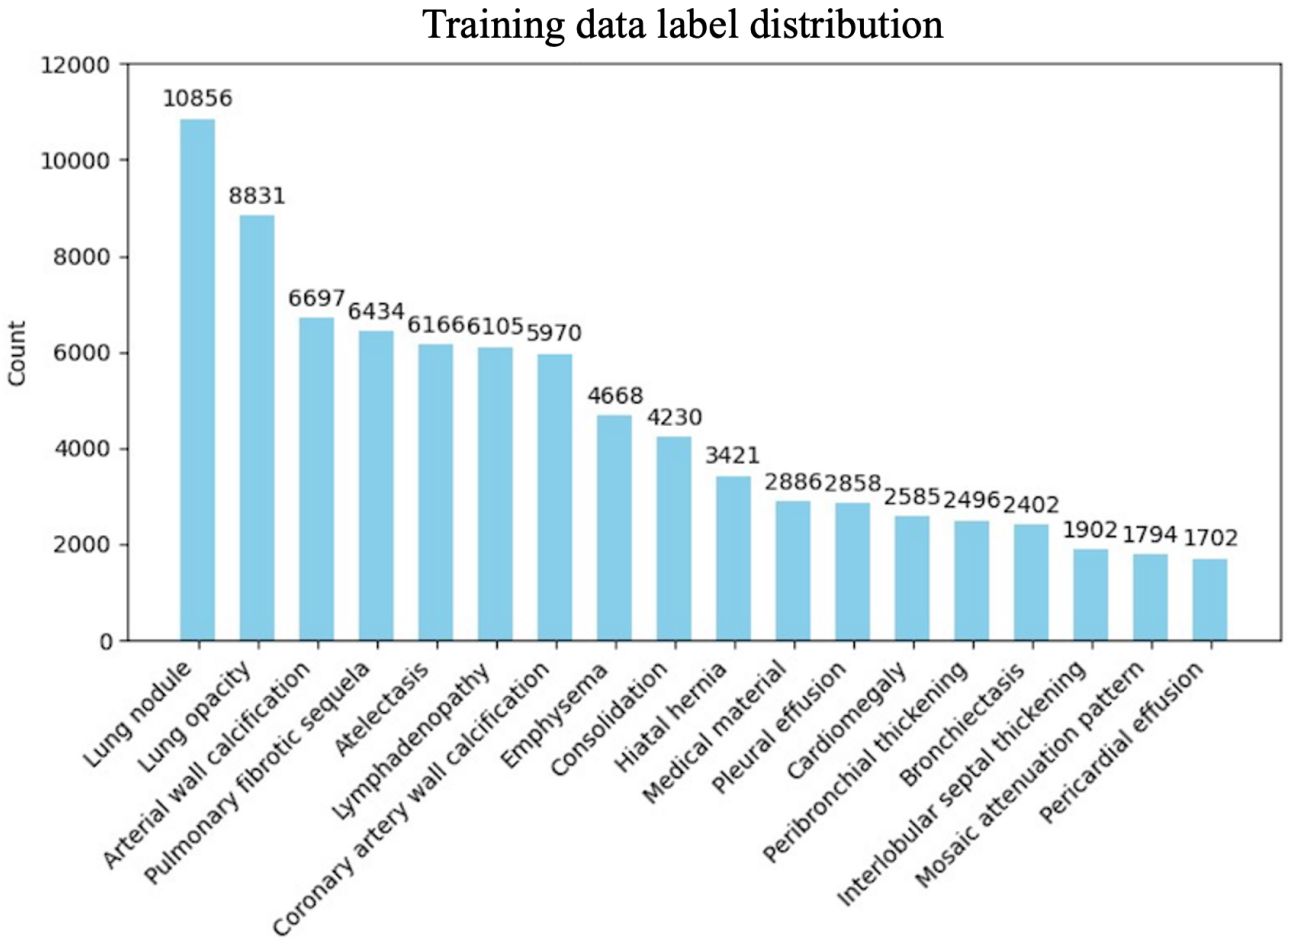
Table . Text statistics on CT-RATE-JPN across different datasets, including “Findings” and “Impression.”

Section	n	Characters, mean (SD)	Words, mean (SD)	Sentences, mean (SD)	Unique words, mean (SD)
Findings					
Training (MT[a])	22,778	467.0 (148.0)	303.3 (95.4)	15.5 (4.6)	126.8 (29.5)
Validation (MT[a])	150	475.0 (130.1)	307.0 (83.6)	15.7 (3.9)	128.9 (27.8)
Validation (Refined[b])	150	455.6 (122.6)	297.7 (80.8)	15.7 (4.0)	126.2 (27.4)
Impression					
Training (MT[a])	22,778	89.1 (68.9)	55.7 (43.6)	3.1 (2.2)	38.1 (23.4)
Validation (MT[a])	150	101.3 (76.0)	63.2 (48.1)	3.5 (2.6)	41.7 (24.3)
Validation (Refined[b])	150	97.8 (72.8)	61.2 (46.0)	3.6 (2.6)	40.9 (24.0)

[a]MT: machine-translated text using GPT-4o mini.

[b]Refined indicates text subjected to radiologist review and refinement.

The Findings section had character counts averaging around 455.6 - 475.0 characters, with slightly lower counts in radiologist-revised texts compared to machine translations. Word count followed a similar pattern, averaging approximately 300 words per report across all datasets. The Impression section was notably more concise, as expected from summary statements. Character counts averaged around 89.1 - 101.3 characters, with word counts of approximately 55.7 - 63.2 words per report. The sentence structure was also more condensed, with approximately 3.1 - 3.6 sentences per report.



Notably, in both sections, the overall text structure remained consistent between machine-translated and radiologist-revised versions, with similar patterns in sentence length and organization. Although the refined versions had slightly lower character and word counts than their machine-translated counterparts, the basic structural characteristics of the reports were preserved throughout the translation and refinement processes.

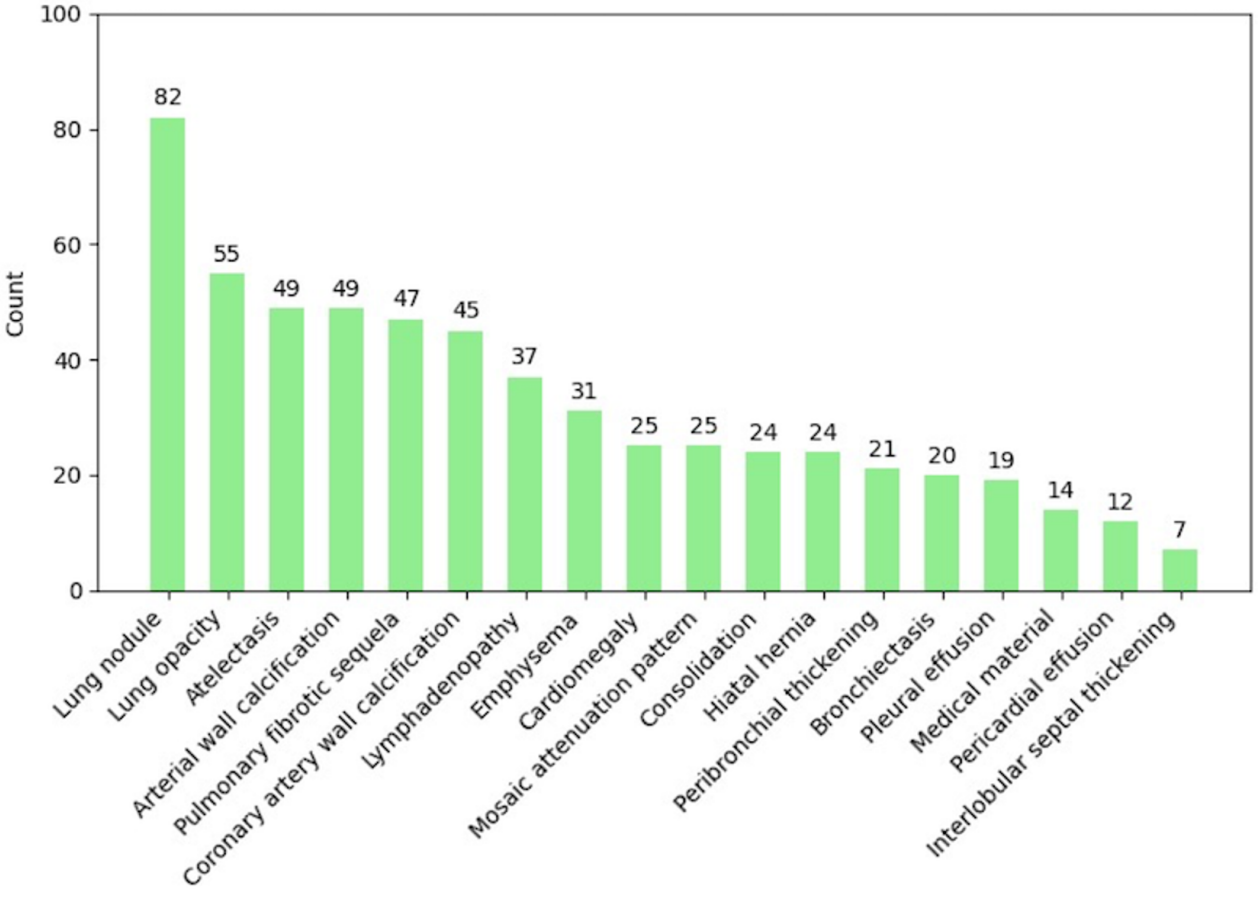


Figure 4 shows that the analysis of the label distributions revealed a significant class imbalance in both the training and validation datasets. In the training set, “Lung nodule” appears most frequently with 10,856 instances, whereas “Interlobular septal thickening” occurs least frequently with only 1702 instances, representing a ratio of approximately 6.4:1. This imbalance is even more pronounced in the validation dataset, where the ratio between the most frequent (82) and least frequent (7) class instances is approximately 11.7:1.

Translated Radiology Reports Evaluation

We evaluated the quality of machine-translated reports in CT-RATE-JPN using both automated metrics and expert assessments. For automated evaluation, we compared GPT-4o mini translations with radiologist-revised references in the validation dataset. The evaluation metrics for both sections are summarized in Table 2. These scores are high, indicating that the machine translation maintained the fundamental structure and meaning of the original reports.

Table . Automated evaluation metrics comparing GPT-4o mini translations with radiologist-revised references in the validation dataset.

Section	BLEU[a], mean (SD)	ROUGE-1[b], mean (SD)	ROUGE-2, mean (SD)	ROUGE-l, mean (SD)
Findings	0.731 (0.104)	0.876 (0.050)	0.770 (0.091)	0.854 (0.064)
Impression	0.690 (0.196)	0.857 (0.104)	0.748 (0.161)	0.837 (0.120)

[a]BLEU: bilingual evaluation understudy.

[b]ROUGE: recall-oriented understudy for gisting evaluation.

The evaluation of machine-translated radiology reports showed moderate inter-rater agreement with QWK values of 0.410 for grammar, 0.522 for terminology, and 0.408 for readability. These moderate agreement levels may reflect the inherent subjectivity of Likert-scale-based quality assessments. However, radiologist refinements resulted in substantial score improvements across all evaluation dimensions. The highest agreement between senior radiologists (Rater 1) and junior radiologists (Rater 2) was observed in terminology assessment. Figure 5 shows that both raters consistently scored radiologist-revised translations significantly higher than machine translations across all dimensions. Rater 1's evaluations were consistently higher than Rater 2's for both MT and radiologist-revised translations. Table 3 demonstrates that all improvements between MT and radiologist revisions were statistically significant (P<.001) across all evaluation criteria. While GPT-4o mini translations achieved moderate scores, radiologist revisions provided significant enhancements, particularly in terminology accuracy. This highlights the value of domain expertise in medical translation, even when using advanced language models. In addition, Table 4 shows the distribution of quality changes, with the majority of radiologist revisions (65% - 91% depending on rater and dimension) resulting in improved ratings compared to machine translation, while deterioration was minimal (0% - 6% across all categories).

Table . Evaluation of translated texts comparing mean Likert scale scores of GPT-4o mini translations (MT) and radiologist-revised translations.

Evaluation criteria	MT[a], mean (SD)	Radiologist, mean (SD)	P value[b]
Rater 1			
Grammar	3.44 (0.91)	4.64 (0.58)	<.001
Terminology	3.15 (0.81)	4.64 (0.65)	<.001
Readability	3.35 (0.91)	4.59 (0.69)	<.001
Rater 2			
Grammar	3.35 (0.71)	4.21 (0.64)	<.001
Terminology	2.73 (0.82)	4.06 (0.65)	<.001
Readability	2.73 (0.75)	3.91 (0.76)	<.001

[a]MT: machine-translated text using GPT-4 mini.

[b]P values were calculated using the Wilcoxon signed-rank test.

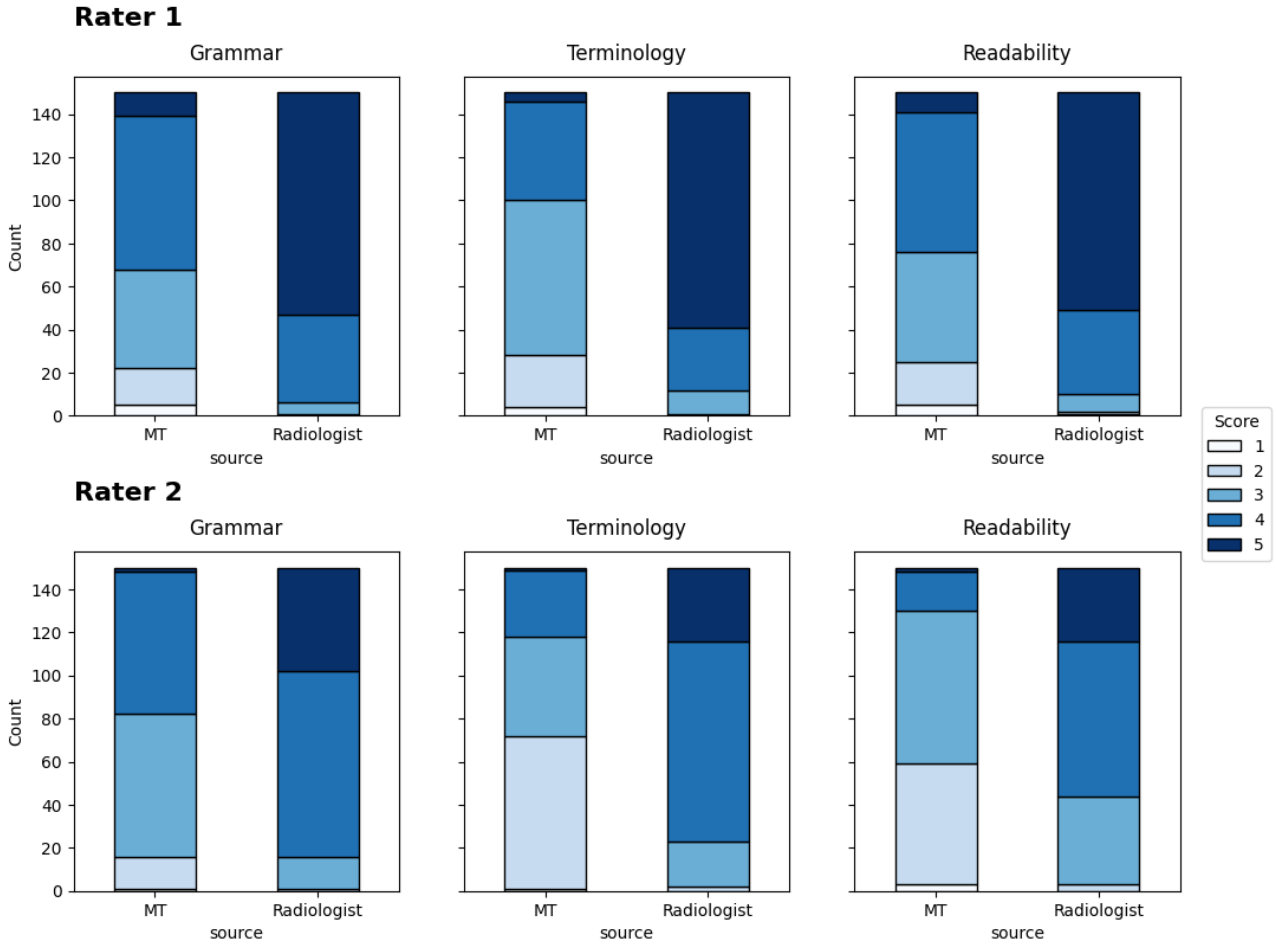
RenderX

Figure 5. Distribution of evaluation scores for machine-translated (MT) and radiologist-revised translations across 3 dimensions (grammar, terminology, and readability) by 2 rater groups. The upper panel shows evaluations by senior radiologists (Rater 1, postgraduate year 6 - 11) and the lower panel shows evaluations by junior radiologists (Rater 2, postgraduate year 4 - 5). Scores were assessed using a 5-point Likert scale (1=poor to 5=excellent).



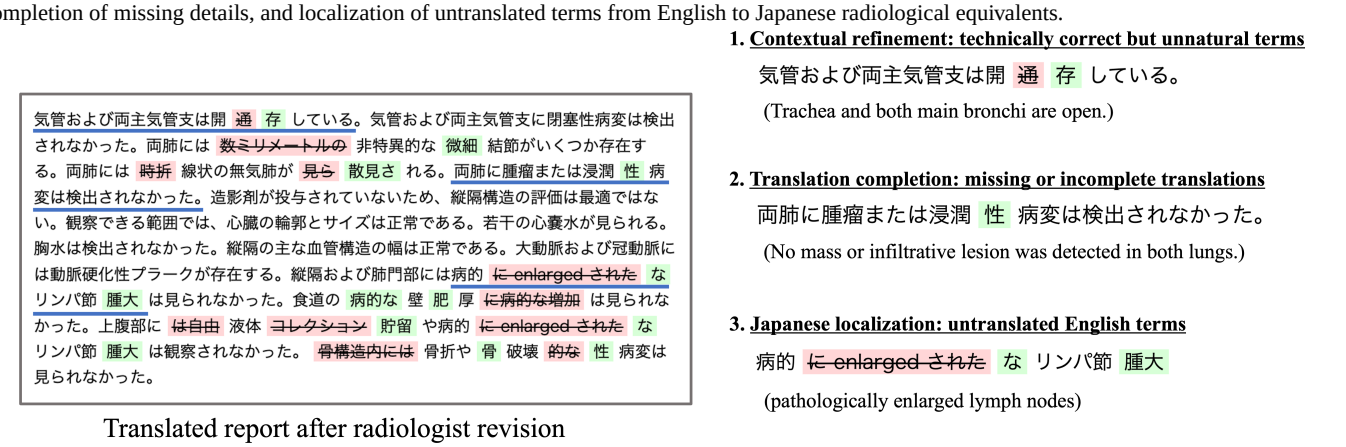


Table . Distribution of quality changes between machine translation and radiologist-revised translations across grammar, terminology, and readability dimensions.

Item	Rater 1			Rater 2		
	Worse	No change	Better	Worse	No change	Better
Grammar, n (%)	4 (2.7)	28 (18.7)	118 (78.7)	9 (6)	43 (28.7)	98 (65.3)
Terminology, n (%)	0 (0)	14 (9.3)	136 (90.7)	7 (4.7)	34 (22.7)	109 (72.7)
Readability, n (%)	1 (0.7)	29 (19.3)	120 (80)	9 (6)	30 (20)	111 (74)

Despite the high automated metric scores (see Table 2), expert scoring evaluation by radiologists revealed that substantial revisions were necessary for medical terminology, with significant improvements observed between machine translations and radiologist-revised versions. Radiologists' assessments identified the representative patterns of necessary modifications. This expert review revealed 3 major categories of improvements (see Figure 6; the original English reports used are shown in Figure S5 in Multimedia Appendix 1), which reflect typical challenges in medical translation: (1) contextual refinement of technically correct but unnatural terms, (2) completion of missing or incomplete translations, and (3) Japanese localization of untranslated English terms. Although not exhaustive, these patterns represent key areas where human expertise complements machine translation in medical contexts.

XSL•FO
RenderX

Figure 6. Representative examples of (computed tomography) CT report translation improvements in 3 categories: contextual term refinement, completion of missing details, and localization of untranslated terms from English to Japanese radiological equivalents.

The first category, contextual refinement, involved replacing technically accurate but clinically uncommon expressions with more natural medical terminology. For instance, direct translations of anatomical conditions were often revised to their proper radiological equivalents when describing vessel status, reflecting standard terminology in Japanese clinical practice. The second category addresses cases in which certain medical terms were either missing or incompletely translated, thereby requiring additional context-specific information. A typical example would be anatomical descriptions lacking specific diagnostic terminology that is common in radiological reporting. The third category focuses on proper localization of English medical terms that were initially left untranslated, such as converting technical descriptors of pathological findings into appropriate Japanese radiological counterparts.

CT-BERT-JPN Performance Evaluation

The CT-BERT-JPN model achieved a micro F_1-score of 0.9607 on the internal evaluation data, which served as the model selection criterion. When evaluated on the validation dataset, the model showed a micro F_1-score of 0.9695 with machine-translated inputs and 0.9520 with radiologist-revised inputs, representing a performance decrease of 0.0175. Table 5 presents the performance evaluation results of CT-BERT-JPN across 18 different findings from 150 chest CT radiological reports on the validation dataset. The model achieved perfect scores (1.000) across all evaluation metrics (accuracy, precision, recall, F_1-score, AUC-ROC, and AP) for pericardial effusion, hiatal hernia, and mosaic attenuation patterns. It demonstrated high accuracy exceeding 0.950 in 17 out of 18 findings, with AUC-ROC values surpassing 0.98 in all findings. Furthermore, AP remained consistently strong—ranging from 0.873 to 1.000—despite the imbalanced distribution of positive samples (7 cases for interlobular septal thickening up to 82 cases for lung nodules), underscoring the model's robust discriminative ability across all conditions.

compares the F_1-scores of CT-BERT-JPN and GPT-4o across the 18 conditions, displayed as bar charts. Table S1 in Multimedia Appendix 1 presents the detailed results for GPT-4o across the 18 conditions using valid data. CT-BERT-JPN had higher F_1-scores than GPT-4o in 11 findings and achieved equivalent performance in 2 findings, specifically the hiatal hernia and mosaic attenuation patterns, both of which attained perfect F_1-scores. Notably, CT-BERT-JPN showed a higher performance in lymphadenopathy (0.142 higher) and atelectasis (0.074 higher), with statistically significant differences confirmed by the Wilcoxon signed-rank test (P=.003 and P=.005, respectively). However, the model performed poorly in 5 findings—most notably peribronchial thickening (–0.051) and consolidation (–0.035)—although Wilcoxon signed-rank tests did not detect statistically significant differences. Detailed performance metrics for GPT-4o are presented in Table S1 in Multimedia Appendix 1.

A detailed analysis of the performance of CT-BERT-JPN was conducted by comparing 2 scenarios: radiologist-revised translated reports versus raw machine-translated reports as input. The differences in the metrics are detailed in Table 6 (the performance metrics for machine translation can be found in Table S2 in Multimedia Appendix 1). The analysis showed that for most findings, performance differences were less than 5%

XSL•FO
RenderX

with no significant variations, confirming the robustness of the model. However, peribronchial thickening showed notable decreases, with a decrease in recall of 0.238 and F_1-score reduction of 0.143. Statistical analysis using the Wilcoxon signed-rank test revealed a significant difference (P=.025). Similarly, consolidation experienced relatively significant performance declines, with precision decreasing by 0.179 and F_1-score by 0.092, with the Wilcoxon signed-rank test showing a significant difference (P=.034).

Table . Performance differences between CT-BERT-JPN models trained on radiologist-revised versus machine-translated inputs across multiple metrics.

Findings	Accuracy	Precision	Recall	F_1-score	AUC-ROC[a]	AP[b]	P value[c]

[a]AUC-ROC: area under the receiver operating characteristic curve.

[b]AP: average precision.

[c]P values were calculated using the Wilcoxon signed-rank test.

[d]Positive values indicate higher performance with radiologist-corrected translations, whereas negative values "-" indicate higher performance with raw machine translations.

[e]N/A indicates that the test was not performed because the predicted values were identical.

Our qualitative analysis of CT-BERT-JPN's performance revealed several illustrative examples of how translation quality impacts model predictions. For peribronchial thickening, we observed cases where CT-BERT-JPN incorrectly predicted negative results for truly positive cases when using radiologist-revised translations. A notable example involved subtle terminological changes from "bilateral peribronchial thickening is observed" in the machine translation to "bilateral bronchial wall thickening is observed" in the radiologist-revised version, where this minor linguistic variation caused the model to misclassify a positive case as negative, demonstrating how nuanced expression differences can significantly impact the model's detection performance. Conversely, for pericardial effusion, we found instances where radiologist refinement improved model accuracy, such as cases where "pericardial effusion" was incorrectly translated as "pleural effusion" in machine-translated reports, while radiologist refinement correctly rendered it as "fluid accumulation in the pericardial recess," leading to accurate CT-BERT-JPN predictions that would have been incorrect with the raw machine translation. In addition, for medical material—the condition with the third-lowest F_1-score—we identified systematic prediction

XSL•FO
RenderX

errors that persisted regardless of translation quality, particularly in cases containing expressions such as "changes associated with tracheostomy are observed," where both machine-translated and radiologist-revised versions retained identical phrasing, yet CT-BERT-JPN consistently predicted positive when the correct label should have been negative. While the presence of an endotracheal tube following tracheostomy would warrant a positive prediction for medical material, the description alone does not explicitly indicate the current presence of medical devices, suggesting that the model may be confounded by artificial interventions mentioned in the text, leading to false positive predictions based on procedural context rather than actual device presence.

Discussion

Principal Findings

The 3 key findings of our study regarding the development of Japanese medical imaging resources and analytical capabilities are:

First, an efficient workflow that combines machine translation with expert validation was established to successfully create a large-scale Japanese radiology dataset, maintaining high-quality standards through a radiologist's focused review.

Second, despite its relatively compact architecture, our specialized CT-BERT-JPN model demonstrated superior performance to GPT-4o in most structured finding extraction tasks, highlighting the effectiveness of domain-specific optimization.

Third, the model maintained robust performance across both machine-translated and radiologist-revised reports, suggesting the viability of machine translation for training data creation in specialized medical domains.

Dataset Development and Quality Assessment

In the field of medical imaging datasets, several English-language resources have been previously established, including the OpenI dataset [35] and MIMIC-CXR [36] for chest radiographs, and AMOS-MM [37] for chest-to-pelvic CT scans; however, these datasets are exclusively available in English, with limited multilingual adaptations. Although many LLMs and VLMs have multilingual capabilities [26,38,39], their performance is consistently degraded when handling non-English languages, including Japanese [40]. A significant factor contributing to this performance gap is the scarcity of non-English datasets, making the development of such resources an urgent priority.

Machine-translated reports showed minimal differences in basic structural elements compared with the original texts, with word counts and sentence lengths varying by less than 5%. Evaluation of translation quality using the BLEU and ROUGE metrics also demonstrated high performance, indicating that the overall structure and content of the reports were well preserved. However, a Likert-scale evaluation by radiologists on grammar, medical terminology, and readability revealed that raw GPT-4o mini outputs still required substantial refinement in all 3 areas. Radiologist-led corrections efficiently addressed these shortcomings, significantly boosting translation quality for our validation dataset. This limitation necessitated a rigorous refinement process involving expert radiologists, which proved crucial for establishing a reliable validation dataset.

Our efficient workflow enabled the review and correction of approximately 70,000 characters of machine-translated text, significantly reducing the time and effort required for extensive translation verification. This efficiency was achieved through a structured review process in which radiologists would focus primarily on medical terminology and critical semantic elements rather than reviewing every aspect of the translation. This systematic approach, which combines large language models with domain expert validation, presents a scalable methodology for dataset creation between distinctly different languages, such as English and Japanese. This hybrid process offers a promising framework that can be adapted not only to other languages but also to specialized domains beyond radiology, where precise terminology and domain expertise are critical.

Model Performance and Evaluation

When combined with CT volumes, CT-BERT-JPN demonstrated significant potential for various text-based applications in medical imaging analysis. Our comprehensive evaluation revealed exceptional performance in structured extraction of findings across diverse radiological conditions, with F_1-score consistently above 0.95 and perfect scores in several findings. More notably, CT-BERT-JPN outperformed GPT-4o in 11 out of 18 findings (61%), achieving higher F_1-score in significant conditions such as lymphadenopathy (+0.142) and atelectasis (+0.074). This superior performance is particularly remarkable considering that CT-BERT-JPN has approximately 110 million parameters, whereas recent large language models often employ hundreds of billions of parameters [41]. Our results demonstrate that a specialized, compact language model can achieve state-of-the-art performance in domain-specific tasks, even when compared with more sophisticated general-purpose models. While promising, our results should be interpreted cautiously given the limited validation dataset of 150 reports and notable class imbalance for certain findings (eg, 7 cases for interlobular septal thickening, 12 cases for pericardial effusion). Although we used both F_1-scores and AP metrics to address data imbalance, the 95% CIs reveal substantial variability for rare findings (eg, interlobular septal thickening: 0.933 [0.750 - 1.000]), where even high F_1-scores may be statistically unstable due to small sample sizes. Larger-scale validation studies will be necessary for more definitive performance assessment.

Furthermore, the model maintained stable performance across both unmodified machine translations and radiologist-revised reports. While some conditions showed moderate performance variations between machine-translated and radiologist-revised reports, particularly in findings where machine translation errors were common (F_1-score differences of -0.143 for peribronchial thickening and −0.092 for consolidation), with consolidation being notably affected by mistranslations of the related "infiltration," the overall robustness of the model suggests that effective clinical applications can be developed using machine-translated training data.

XSL•FO
RenderX

To contextualize our results within the broader radiology NLP field, we note that established models, such as RadGraph [42] and the CheXpert labeling tool [43], have demonstrated strong performance with English reports. Particularly relevant is the CheXpert labeler, which tackles the most similar task of multilabel finding classification in radiology reports, achieving F_1-scores ranging from 0.647 to 0.996 across different findings in chest X-ray analysis. Our CT-BERT-JPN shows comparable performance levels for the distinct task of Japanese CT finding extraction. While acknowledging the differences in imaging modality, language, and validation dataset size, these results represent promising performance and constitute the first openly available Japanese model for multilabel CT findings extraction. Nevertheless, because CT-BERT-JPN was trained and evaluated on a single, translation-derived dataset, its performance could degrade under real-world Japanese radiology reports due to domain shift.

Clinical Implementation and Impact

Previous studies have explored hybrid approaches that combine human and machine translations in the medical domain. Early research demonstrated the effectiveness of combining preexisting translation databases with machine translation for medical guidelines, particularly in updating existing documents [44]. Another study reported challenges in the quality of machine translation from English to Chinese of public health materials caused by linguistic structural differences [45]. However, recent advances in LLMs have been remarkable, with studies showing high performance in radiology report translation [46]. Our research successfully developed effective datasets through a combination of machine and expert translation. This approach enables efficient dataset construction even for languages with limited medical data, representing a significant advancement in multilingual medical data development.

The development of such a structured findings extraction model in Japan, where medical imaging usage rates rank among the highest globally, is expected to contribute substantially to both domestic health care advancements and international model development. Our implementation incorporated previous studies on Japanese radiology report processing, including end-to-end approaches for clinical information extraction [47], natural language processing systems for pulmonary nodule follow-up assessment [48], and BERT-based transfer learning methods for anatomical classification [49].

Our multilabel classification approach addresses several implementation challenges unique to Japanese health care. These include vocabulary standardization across institutions, integration with existing reporting systems, and development of specialized Japanese medical vocabulary handling mechanisms. The ability of the model to process Japanese-specific medical expressions and maintain high performance across different reporting styles demonstrates its potential for broad clinical applications. However, prospective validation across multiple Japanese institutions remains essential for both performance evaluation and capturing institution-specific reporting patterns for targeted model improvements.

Limitations and Future Directions

Several limitations exist in our study. First, although we demonstrated the effectiveness of our language model through rigorous evaluation, the usability of CT-RATE-JPN for vision-language models (such as CT-contrastive language image pre-training [CLIP] [18]), which require joint learning of CT volumes and text descriptions, remains to be empirically validated. Second, our reliance on the CT-RATE dataset may have introduced inherent biases in reporting styles and patterns, because radiology reports vary considerably across institutions and individual radiologists. Third, despite expert validation, the translation-based approach may not fully capture the nuanced expressions and specialized terminology commonly used in Japanese clinical practice. In addition, well-established parallel corpora for translation in the Japanese radiology domain are currently lacking, although projects such as “JMED-DICT” are working to address this gap by developing a comprehensive medical terminology dictionary of approximately 400,000 terms through the integration of existing medical dictionaries and resources [50]. Fourth, potential biases may stem from the multi-step translation process and dataset origin. The CT-RATE dataset originates from Turkish medical institutions and was translated into English before our Japanese translation. This process may introduce biases from demographic differences between Turkish and Japanese patient populations, Turkish-specific reporting styles that may not align with Japanese clinical practices, and linguistic biases accumulated through successive translations, despite our refinement procedures. These biases may contribute to inflated performance metrics for CT-BERT-JPN that do not accurately reflect the model’s expected performance on native Japanese radiology reports in real-world settings.

Building upon these considerations, several promising directions for future research emerge. The primary direction is the development of vision language models using CT-RATE-JPN in conjunction with the CT volumes of CT-RATE. Given the successful development of Japanese CLIP models for general domain tasks, which have demonstrated the feasibility of cross-lingual vision-language alignment in Japanese [51], extending this approach to medical imaging is particularly promising. While this endeavor requires substantial computational resources and sophisticated training strategies, various approaches can be explored, such as additional training on existing models, for example, CT-CLIP. Furthermore, the construction of a new dataset comprising pairs of Japanese radiology reports and CT volumes from Japanese medical institutions can enable a more direct assessment of model performance in the Japanese healthcare context and potentially reveal insights unique to this setting. Our benchmark dataset, validated by radiologists through a systematic review process, provides a valuable foundation for evaluating such Japanese-English and English-Japanese translation models in radiology.

Conclusion

In this study, we introduced CT-RATE-JPN, a comprehensive Japanese dataset of CT interpretation reports, and developed a specialized language model for structured labeling. Our model

XSL•FO
RenderX

demonstrated superior performance compared with GPT-4o, achieving higher F_1-scores in numerous categories of structured findings extraction. The creation of CT-RATE-JPN, along with our publicly available structured findings model, represents a significant contribution to Japanese medical imaging research. By making both the dataset and model freely accessible to the research community, we enable reproducibility and foster collaborative advancement in the field. This work not only provides essential resources for the medical AI community but also establishes a robust foundation for developing more sophisticated multilingual medical vision-language models. These openly available contributions are expected to support the development of AI-assisted diagnostic tools, while maintaining the high standards required for clinical applications in radiology.

GPT-4o from OpenAI was used for grammar corrections during the drafting phase, followed by proofreading from Editage.

Data Availability

The original CT-RATE dataset, which includes CT volumes and structured data, is publicly available through Hugging Face Datasets [52]. Our Japanese translation dataset, CT-RATE-JPN, is also publicly available through Hugging Face Datasets [53]. Both datasets were released under the CC BY-NC-SA license, allowing free use for non-commercial research purposes. The use of these datasets require proper citation and redistribution under similar license terms.

The trained CT-BERT-JPN model, together with its full training logs and hyperparameter configuration files, is publicly available through Hugging Face Models for research purposes only [54]. This model can be freely used and adapted for academic and research applications with appropriate citation. Commercial use of the model is not permitted.

Authors' Contributions

All authors agreed with the conceptualization and design of the research. YY conducted algorithm planning and implementation, model development, statistical analysis, and data curation, and drafted the manuscript. YN contributed to the algorithm planning and data curation. TK performed statistical analysis and data curation. YS, HH, SK, and SN contributed to data curation. SH, TY and OA supervised and revised the manuscript. All authors reviewed and approved the final version of the manuscript.

The research was supported by JSPS KAKENHI Grant JP25K03479.

Conflicts of Interest

The Department of Computational Diagnostic Radiology and Preventive Medicine of The University of Tokyo Hospital is sponsored by HIMEDIC Inc and Siemens Healthcare KK.

Multimedia Appendix 1
Supplementary materials including detailed performance evaluation tables for GPT-4o and CT-BERT-JPN across 18 pathological findings, machine translation and structured labeling prompts used in the study (both Japanese and English versions), and sample radiology reports.

Abstract

Background: Real-world data–based feasibility assessments enhance clinical trial design, but automating eligibility criteria conversion to database queries is hindered by challenges related to ensuring high accuracy and generating clear, usable outputs.

Objective: The aim of this study is to develop an automated system converting free-text eligibility criteria from ClinicalTrials.gov into Observational Medical Outcomes Partnership Common Data Model (OMOP CDM)–compatible Structured Query Language (SQL) queries and systematically evaluate hallucination patterns across multiple large language models (LLMs) to identify the optimal deployment strategies.

Methods: Our system employs a three-stage preprocessing pipeline (segmentation, filtering, and simplification) achieving 58.2% token reduction while preserving clinical semantics. We compared GPT-4 concept mapping performance against USAGI using 357 clinical terms from 30 trials. For comprehensive evaluation, we analyzed 760 SQL generation attempts (19 trials×8 LLMs×5 prompting strategies) using the SynPUF (Synthetic Public Use Files) dataset and validated selected queries against National COVID Cohort Collaborative reference concept sets using Asan Medical Center's OMOP CDM database.

Results: GPT-4 achieved a 48.5% concept mapping accuracy versus USAGI's 32.0% (P<.001), with domain-specific performance ranging from 72.7% (drug) to 38.3% (measurement). Surprisingly, the open-source llama3: 8b model achieved the highest effective SQL rate (75.8%) compared to GPT-4 (45.3%), attributed to lower hallucination rates (21.1% vs 33.7%). The overall hallucination rate was 32.7%, with wrong domain assignments (34.2%) and placeholder insertions (28.7%) being the most common. Clinical validation revealed mixed performance: high concordance for type 1 diabetes (Jaccard=0.81), complete failure for pregnancy (Jaccard=0.00), and minimal overlap for type 2 diabetes (Jaccard=0.03), despite perfect overlap coefficients in both diabetes cases. Moderate performance was observed for uncontrolled hypertension (Jaccard=0.18).

Conclusions: While LLMs can accelerate eligibility criteria transformation, hallucination rates of 21 - 50% necessitate careful model selection and validation strategies. Our findings challenge assumptions about model superiority, demonstrating that smaller, cost-effective models can outperform larger commercial alternatives. Future work should focus on hybrid approaches combining LLM capabilities with rule-based methods for handling complex clinical concepts.

Introduction

Clinical trials are essential for medical advancement and drug development, yet they face significant challenges in participant recruitment, with studies showing that 50% of trials fail to meet projected recruitment progress and one-third are terminated due to insufficient recruitment [1-3]. Moreover, only approximately 20% of trials successfully recruit the required participants within the planned timeline [4]. These issues result in delays in new drug approvals and increased research costs, ultimately hindering the development of new therapeutic options [5,6]. To address these challenges, researchers and the pharmaceutical industry are increasingly adopting feasibility assessments and simulations to enhance trial efficiency and success rates [7].

Feasibility assessments are crucial in evaluating the practical, regulatory, and operational aspects of a clinical trial, minimizing risks and setting the foundation for success [8]. By incorporating real-world data (RWD) into the trial design phase, researchers can make more informed decisions, potentially increasing the probability of trial success and reducing the time and costs associated with bringing new therapies to market [9-11]. Leveraging RWD for real-time feasibility assessments during the clinical trial design phase is an effective method to significantly reduce the likelihood of research failure and save time and costs [12,13]. However, the process of transforming clinical trial inclusion or exclusion criteria, which are mostly written in free-text format, into a form suitable for RWD analysis presents several challenges [13,14]. In particular, converting complex clinical concepts, temporal relationships, and elements requiring medical judgment into structured data formats demands considerable expertise and time.

To address these challenges, researchers have been exploring methods to directly query RWD using clinical trial criteria. One notable study by Liu et al developed a system called the Trial Pathfinder, which uses machine learning to evaluate and optimize eligibility criteria for oncology trials using RWD [15]. This approach not only identified opportunities to relax overly restrictive criteria but also demonstrated the potential to increase trial participation by 107% on average while maintaining or improving trial outcomes. However, despite these advances, the automated generation of structured queries from clinical trial criteria faces a critical reliability challenge: Large Language Models (LLMs) frequently generate nonexistent medical concept identifiers—a phenomenon known as hallucination—which can severely compromise query accuracy and patient safety [16].

Recent studies have shown that LLMs, while powerful for natural language understanding, exhibit hallucination rates of 15% - 55% when mapping clinical concepts to standardized vocabularies [17]. This reliability gap poses a significant barrier to clinical deployment, as incorrect concept mappings could lead to missed eligible patients or, worse, inclusion of ineligible participants. Furthermore, the choice of LLM and prompting strategy significantly impacts both performance and cost, yet systematic comparisons across models remain limited. Understanding these trade-offs is essential for developing practical, deployable systems that balance accuracy, efficiency, and economic feasibility.

This study addresses these challenges through a two-pronged approach. First, we present an end-to-end automated system that transforms free-text clinical trial eligibility criteria into Observational Medical Outcomes Partnership Common Data Model (OMOP CDM)-compatible SQL (Structured Query Language) queries using GPT-4 [18], validated with real patient data from Asan Medical Center. Second, we conduct a comprehensive evaluation of hallucination patterns across 8 LLMs (both cloud-based and local) using the Synthetic Public Use Files (SynPUF) [19] dataset, systematically analyzing how model selection and prompt engineering affect reliability. Our findings reveal that while LLMs can accelerate query generation from hours to minutes, hallucination rates of 21% - 50% highlight the need for careful model selection and validation strategies. Surprisingly, our evaluation demonstrated that model size does not necessarily correlate with performance, with smaller open-source models sometimes outperforming larger commercial alternatives in terms of effective SQL generation. By quantifying these trade-offs and identifying optimal model-prompt combinations for different clinical scenarios, this work advances the development of trustworthy and cost-effective AI systems for clinical trial optimization.

Methods

Study Design

We conducted a two-phase investigation to develop and validate an automated system for transforming clinical trial eligibility criteria into OMOP CDM [20] SQL queries, followed by systematic analysis of LLM hallucination patterns. The integrated workflow enables both functional validation and reliability assessment of LLM-generated queries in real-world clinical scenarios.

Data Sources and Study Population

Clinical Trials Dataset

We extracted eligibility criteria from the aggregate analysis of ClinicalTrials.gov (AACT) [21] database (accessed July 18, 2023). We utilized two distinct datasets: (1) Development Dataset and (2) Validation Dataset.

First, in the Development Dataset, 30 trials (10 each from breast cancer, diabetes mellitus, and cardiovascular disease domains) were used exclusively for concept dictionary construction and prompt optimization. From these trials, we extracted 357 unique clinical terms for comparative analysis of concept mapping approaches between GPT-4 and USAGI [22].

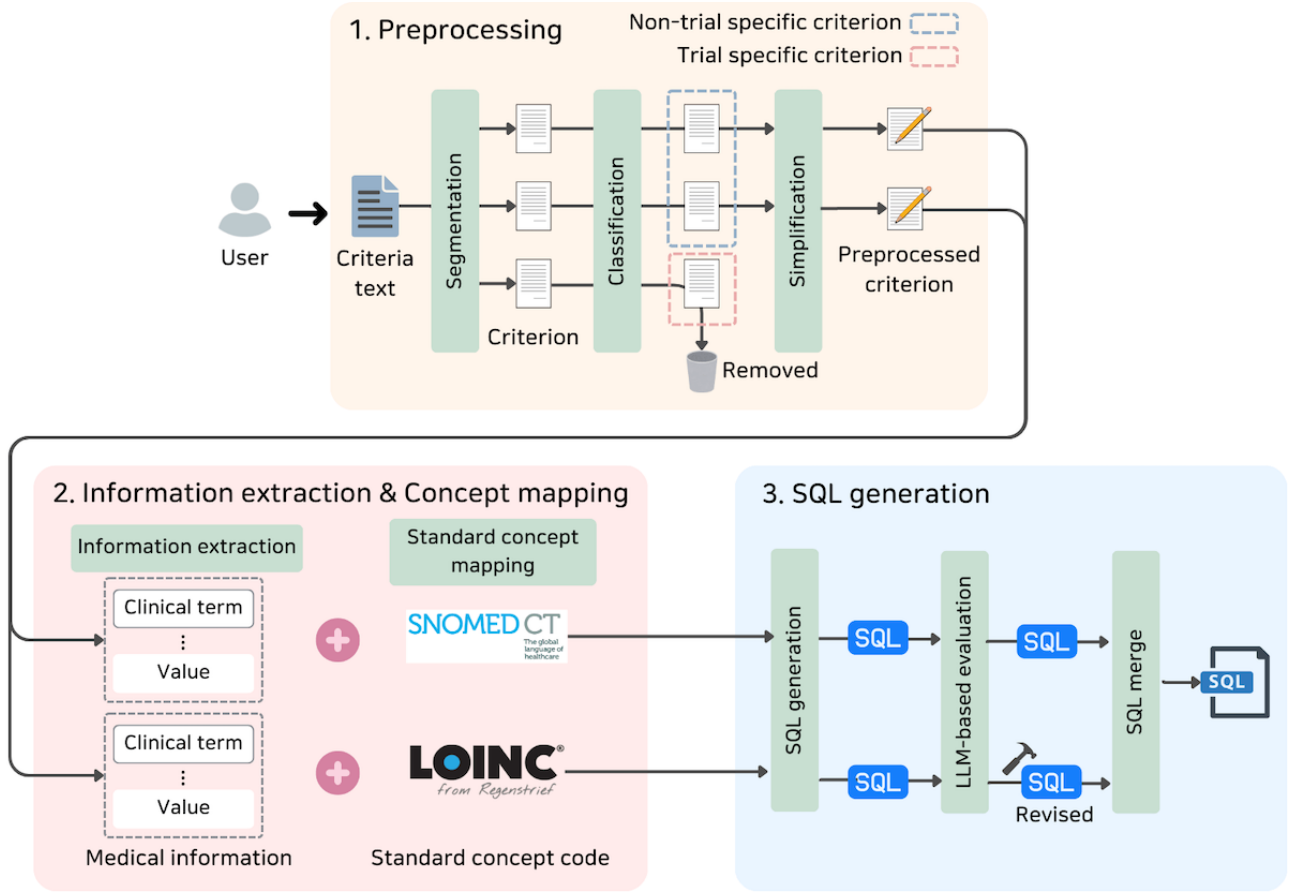
Second, in the Validation Dataset, 7 high-impact trials were selected based on citation frequency in major medical journals (BRIDGE [Bridging Anticoagulation in Patients who Require Temporary Interruption of Warfarin Therapy for an Elective Invasive Procedure or Surgery; NCT00786474], PARADIGM-HF [Prospective Comparison of ARNI with ACEI to Determine Impact on Global Mortality and Morbidity in Heart Failure; NCT01035255], LEADER [Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results; NCT01179048], CHOIR [Correction of Hemoglobin and Outcomes in Renal Insufficiency; NCT00211120], ACT

XSL•FO
RenderX

[Randomized Acetylcysteine for Contrast-induced Nephropathy Trial; NCT00736866], DESTINY-Breast04 [Trastuzumab Deruxtecan in Previously Treated HER2-Low Advanced Breast Cancer; NCT03734029], RECOVERY [Randomized Evaluation of COVID-19 Therapy; NCT04381936]) for comprehensive system evaluation.

Clinical Data Infrastructure

Real-world validation utilized OMOP CDM version 5.3 data from Asan Medical Center, Seoul, South Korea. This comprehensive dataset contains 4,951,000 unique patients with clinical records spanning from May 1989 to December 2020. The study protocol received approval from the Asan Medical Center Institutional Review Board (IRB No. 2024 - 0377).



Synthetic Data for Hallucination Analysis

To systematically evaluate hallucination patterns, we employed the SynPUF dataset version DE_1_0_1, containing 2.3 million synthetic Medicare beneficiaries with claims data from 2008 to 2010. This dataset's limited concept coverage (~27,000 of >2 million OMOP concepts) provided an ideal test bed for identifying hallucination behaviors when models encounter concept mapping challenges.

Clinical Criteria to SQL Transformation Pipeline

We developed an automated pipeline that transforms free-text eligibility criteria into OMOP CDM–compliant SQL queries through three interconnected modules. The preprocessing module implements a three-stage approach: (1) segmentation to extract individual criteria while preserving Boolean logic and hierarchical structures, (2) filtration to remove non-queryable trial-specific criteria such as informed consent requirements, and (3) simplification to standardize temporal expressions and reduce token count while maintaining clinical semantics. The information extraction module identifies seven structured elements from preprocessed text, Clinical Terms, Medical Terminology Systems (SNOMED CT, ICD-10, RxNorm, LOINC), Codes, Values, Attributes, Temporal, and Negation, and then maps each clinical term to OMOP-standardized vocabularies using GPT-4. The SQL generation module creates CDM-compliant queries through iterative refinement and optimization. Each module exchanges data via structured JSON to ensure interoperability throughout the pipeline. The preprocessing stages are illustrated in Figure 1, and the detailed architecture of the automated transformation pipeline is shown in Figure S1 of Multimedia Appendix 1. In addition, a comprehensive description of the processing procedures implemented in the automated system is provided in Multimedia Appendix 1.

Figure 1. Detailed three-stage preprocessing and concept mapping architecture. Three-stage preprocessing and concept mapping workflow for transforming clinical trial eligibility criteria into Observational Medical Outcomes Partnership Common Data Model (OMOP CDM)–compatible Structured Query Language (SQL) queries.

RenderX

Large Language Model Configuration

We employed GPT-4 (March 2024 release) via API with task-specific prompting strategies optimized through iterative refinement. Zero-shot prompting was utilized for straightforward tasks including text segmentation and criteria classification, which minimized token usage and API cost. Few-shot prompting with carefully selected examples enhanced performance for complex tasks including concept mapping and SQL generation. All prompts incorporated explicit instructions for OMOP CDM v5.3 compliance and error handling. Complete prompt templates are provided in Table S1 in Multimedia Appendix 2.

Comparative Evaluation Framework

Clinical Term Mapping Assessment

To evaluate the performance of GPT-4 in mapping clinical terms to standardized concepts, we utilized a previously constructed development dataset comprising 30 clinical trials across three disease domains: breast cancer, diabetes mellitus, and cardiovascular disease. This dataset included diverse expressions of eligibility criteria and clinical terminologies, making it suitable for assessing concept mapping accuracy within the OMOP CDM. We compared GPT-4 with USAGI, an open-source tool developed by the OHDSI community. While GPT-4 is an LLM with advanced natural language understanding capabilities, USAGI uses string normalization, Levenshtein distance–based similarity scoring, and ontology-based heuristics to identify candidate OMOP-standard concepts. In our experiments, USAGI was run using its default settings, and the top-ranked concept based on similarity score was selected for each input term. Relevant clinical terms were extracted from the eligibility criteria of each trial and mapped using both GPT-4 and USAGI. Two clinical experts then jointly reviewed the mapping results from both systems and selected the most appropriate OMOP-standard concept through mutual consensus. In each case, they either chose the better of the two candidate concepts or, when necessary, manually assigned a more suitable concept. This consensus-based evaluation approach reflects real-world clinical decision-making and contributes to the reliability and validity of the reference standard.

SQL Query Validation

To rigorously evaluate the accuracy and applicability of the generated SQL queries within the OMOP CDM, we conducted an expert-based validation involving two experts with strong proficiency in both clinical concepts and the OMOP CDM. Generated SQL queries underwent systematic evaluation using 80 predefined evaluation criteria designed to assess three key dimensions: SQL syntax adherence, CDM schema compliance, and criteria contextual accuracy. Each expert independently rated all applicable criteria on a 4-point scale (1=noncompliant and 4=fully compliant), with final scores calculated as the average of both ratings.

The evaluation framework was applied differentially based on query content. For all generated queries, the full set of 80 criteria was used to assess structural and schema-level accuracy. However, for queries containing clinical concepts from our prevalidated concept map, only 21 criteria from the original 80 were applicable—these specifically evaluated concept inclusion accuracy and concept ID correctness. Inter-rater reliability was measured using Cohen's kappa, with discrepancies resolved through consensus discussion.

This expert-driven evaluation allowed for the identification of critical issues—such as misinterpretation of clinical logic, inaccurate temporal constraints, or improper use of OMOP tables—that automated methods might overlook. As a result, we verified that the generated SQL queries were not only technically correct but also clinically meaningful and suitable for use in real-world, standardized health care data environments. The complete list of evaluation criteria is provided in Table S1 in Multimedia Appendix 3.

Clinical Cohort Validation

To assess real-world performance of the automatically generated SQL queries, we conducted cohort extraction experiments using the OMOP CDM dataset from Asan Medical Center. Given the resource-intensive nature of building complete gold-standard concept sets manually, we utilized officially validated OMOP CDM-based concept sets provided by the National COVID Cohort Collaborative (N3C) as reference standards. A total of three clinical trials were included in this evaluation—NCT00211120, NCT00786474, and NCT01179048—which collectively comprised 40 eligibility criteria. These trials were selected because validated N3C concept sets were available for at least one of their eligibility criteria, allowing for meaningful comparison between system-generated cohorts and external reference standards. Each criterion was screened based on two conditions: (1) convertible to OMOP CDM format and (2) availability of validated concept sets from N3C. For these selected criteria—including Pregnancy (NCT00786474), Type 2 diabetes and Type 1 diabetes (NCT01179048), and Presence of uncontrolled hypertension (NCT00211120)—SQL queries were automatically generated using our system and executed against the OMOP CDM database.

Cohort similarity between system-generated and reference standard cohorts was quantified using two complementary set–based metrics: Jaccard index (intersection/union) and overlap coefficient (intersection/minimum set size). The Jaccard index provides a symmetric measure of overall similarity, while the overlap coefficient indicates the extent to which the smaller cohort is contained within the larger cohort, useful for identifying cases of incomplete concept coverage. This approach enabled objective assessment of query accuracy without requiring manual chart review, leveraging established reference standards for scalable validation. Additionally, to demonstrate technical feasibility, successfully generated SQL queries were executed against the SynPUF dataset to assess cohort retrieval capabilities. Patient counts were recorded for selected trials where queries were executed without errors.

Experimental Design

Although GPT-4 was used for initial system development due to its strong performance, the limited concept coverage in SynPUF provided an opportunity to systematically compare hallucination patterns across multiple LLMs, informing optimal model selection for different clinical scenarios. The 19 trials

XSL•FO
RenderX

for the main study included breast cancer (6 trials), cardiovascular disease (4 trials), diabetes (3 trials), chronic obstructive pulmonary disease (3 trials), and others (3 trials), with complexity levels categorized as simple (8), moderate (7), and complex (4). We employed a factorial design testing eight LLMs (three cloud-based: GPT-4, GPT-3.5-turbo [23], and Claude-3-sonnet [24]; five locally deployed: Llama3:8b [25], DeepSeek-R1:8b [26], Qwen2.5 [27], Phi3 [28], and Gemma3:4b [29]) with five prompting strategies (zero_shot, structured_approach, explicit_uncertainty, validation_focused, and error_aware). The five prompting strategies were designed to test different approaches to query generation:

- zero_shot: Direct query without examples or guidance
- structured_approach: Step-by-step decomposition guidance
- explicit_uncertainty: Encouraging placeholder use for uncertain mappings
- validation_focused: Emphasizing validation and accuracy requirements
- error_aware: Including SynPUF limitations and common pitfalls

Following a pilot phase (5 trials×8 models×5 prompts=200 queries) for methodology validation, the main study analyzed 760 queries (19 trials×8 models×5 prompts).

Hallucination Detection and Classification

An automated detection system was developed to identify hallucinations in generated SQL queries. The system validated concept identifiers against the SynPUF concept inventory and verified domain appropriateness according to OMOP CDM specifications. For the initial validation phase, we analyzed SQL generation failures from seven validation trials. For the large-scale model comparison, we developed a five-category hallucination classification schema ordered by severity. Category A (Critical) comprised nonexistent concept IDs that invalidate query results. Category B (Major) included valid concepts assigned to incorrect domains, violating CDM structural integrity. Category C (Major) captured natural language in concept fields, reflecting confusion between labels and identifiers. Category D (Moderate) consisted of placeholder values requiring manual intervention. Category E (Minor) encompassed easily correctable syntax or schema errors. This classification specifically evaluated model tendencies toward generating inappropriate concept references, distinct from the initial error analysis.

Analytical Framework of Model Performance

Model performance was evaluated across four dimensions. The model performance dimension compared effective SQL generation rates, hallucination frequencies, and error distributions across eight LLMs. The prompt strategy dimension assessed five prompting approaches to identify optimal error minimization strategies. The clinical domain dimension analyzed performance variations across condition, drug, measurement, procedure, and observation concepts. The complexity dimension examined correlations between query complexity (criteria count, logical operators, temporal constraints) and error occurrence.

Statistical Analysis

Statistical analyses were performed using Python 3.11 (Python Software Foundation) with scipy library (version 1.11.4) [30] and statsmodels library (version 0.14.0) [31] libraries. For concept mapping comparisons between GPT-4 and USAGI, McNemar's test was applied to paired binary outcomes. Three primary performance metrics were calculated: (1) SQL generation rate as the proportion of trials producing syntactically valid SQL, (2) hallucination rate as the proportion of generated queries containing invalid concept IDs, and (3) effective SQL generation rate, calculated as SQL generation rate×(1–hallucination rate), representing queries both syntactically valid and free from concept hallucinations.

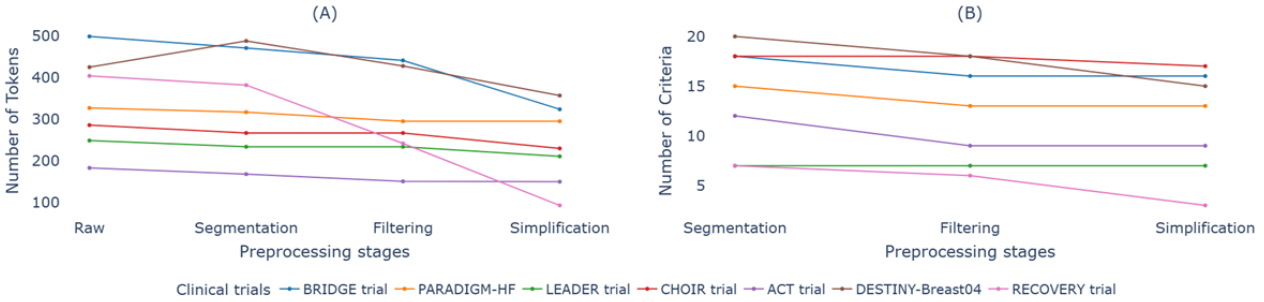
Model performance across the eight LLMs was compared using one-way ANOVA followed by Tukey's honestly significant difference (HSD) test for post hoc pairwise comparisons. Effect sizes were quantified using Cohen *d* to assess the practical significance of differences between prompting strategies. χ^2 tests evaluated the distribution of hallucination types across models. Multiple linear regression analysis identified predictors of hallucination rates, with model type, prompt strategy, and query complexity as independent variables; model fit was assessed using R^2. All statistical tests employed α=.05 with Bonferroni correction for multiple comparisons where applicable.

Ethical Considerations

This study protocol was reviewed and approved by the Institutional Review Board of Asan Medical Center (IRB No. 2024-0377). As this study did not involve human participants, informed consent was not applicable. All data used in the study were de-identified prior to analysis, and no individual-level identifiable information was accessed.

Data and Code Availability

Source code, including the complete pipeline implementation and hallucination detection system, is available at [https://github.com/sujeong-jang/ctos]. The SynPUF dataset is publicly accessible through Centers for Medicare & Medicaid Services. Clinical trial criteria and evaluation datasets are available upon request with appropriate data use agreements. Detailed documentation for system deployment and reproduction is provided in the repository.



Results

Preprocessing and Clinical Concept Extraction

Analysis of seven validation trials revealed substantial heterogeneity in eligibility criteria complexity, ranging from 6 to 25 criteria per trial (14.7±6.3). The three-stage preprocessing pipeline systematically reduced linguistic complexity while preserving clinical semantics (Figure 2). Initial segmentation achieved modest token reduction (331.4±85.2) while maintaining structural integrity. Subsequent filtering of non-OMOP–compatible criteria reduced both criteria count (11.71±4.9) and token count (311.6±78.3). Final simplification yielded 10.71±4.2 criteria with 138.57±42.1 tokens per trial, representing a 58.2% overall token reduction.

XSL•FO
RenderX

Figure 2. Progressive reduction in token count and criteria through preprocessing stages. (A) Token count changes across segmentation, filtering, and simplification stages for seven validation trials. (B) Corresponding changes in criteria count. Trials shown are as follows: BRIDGE (Bridging Anticoagulation in Patients who Require Temporary Interruption of Warfarin Therapy for an Elective Invasive Procedure or Surgery; NCT00786474), PARADIGM-HF (Prospective Comparison of ARNI with ACEI to Determine Impact on Global Mortality and Morbidity in Heart Failure; NCT01035255), LEADER (Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results; NCT01179048), CHOIR (Correction of Hemoglobin and Outcomes in Renal Insufficiency; NCT00211120), ACT (Randomized Acetylcysteine for Contrast-induced Nephropathy Trial; NCT00736866), DESTINY-Breast04 (Trastuzumab Deruxtecan in Previously Treated HER2-Low Advanced Breast Cancer; NCT03734029), RECOVERY (Randomized Evaluation of COVID-19 Therapy; NCT04381936)

This preprocessing identified 80 clinically relevant criteria suitable for automated query generation. Information extraction from these 80 preprocessed criteria yielded 188 unique clinical terms successfully mapped to OMOP-compatible elements. Domain distribution analysis revealed that Condition concepts comprised the predominant category (n=93, 49.5%), followed by Drug (n=29, 15.4%), Procedure (n=24, 12.8%), Measurement (n=18, 9.6%), Observation (n=14, 7.4%), Demographic (n=8, 4.3%), Visit (n=1, 0.5%), and Device (n=1, 0.5%) domains (Table 1). Term frequency analysis identified demographic criteria as the most prevalent. “Age” appeared in 6 trials (out of 7 trials, 85.7%; 6 mentions). Clinical terms included “international normalized ratio” (2/7 trials, 28.6%; 2 mentions), “diabetes mellitus” (2/7 trials, 28.6%; 2 mentions), “breast cancer” (1/7 trial, 14.3%; 8 mentions), “pneumonitis” (1/7 trial, 14.3%; 3 mentions), “interstitial lung disease” (1/7 trial, 14.3%; 3 mentions), “transient ischemic attack” (1/7 trial, 14.3%; 2 mentions), and “systemic embolism” (1/7 trial, 14.3%; 2 mentions), as shown in Table 2. Percentages are calculated based on the number of trials in which the term appeared, and mentions indicate the number of criteria within trials in which the term appeared.

Table . Distribution of extracted clinical concepts by OMOP CDM[a] domain.

Domains	Count (n=188), n (%)
Condition	93 (49.5)
Drug	29 (15.4)
Procedure	24 (12.8)
Measurement	18 (9.6)
Observation	14 (7.4)
Demographic	8 (4.3)
Visit	1 (0.5)
Device	1 (0.5)

[a]OMOP CDM: Observational Medical Outcomes Partnership Common Data Model.

Table . Ten most frequently occurring clinical terms across all trials.

Clinical terms	Trials (n=7), n (%)	Mentions (criterion), n
Age	6 (85.7)	8
International normalized ratio	2 (28.6)	6
Diabetes mellitus	1 (14.3)	3
Breast cancer	1 (14.3)	3
Pneumonitis	1 (14.3)	2
Interstitial lung disease	1 (14.3)	2
Transient ischemic attack	1 (14.3)	2
Systemic embolism	1 (14.3)	2

Comparative Performance of Concept Mapping Approaches

Evaluation of concept mapping accuracy demonstrated GPT-4's superior performance compared to USAGI across 357 clinical terms extracted from the 30 development trials. GPT-4 achieved an overall accuracy of 48.5% (173/357) versus USAGI's 32.0% (114/357), a statistically significant difference (P<.001, McNemar's test). Domain-stratified analysis revealed GPT-4's highest accuracy in the Drug domain (72.7%, 16/22) and lowest in the Measurement domain (38.3%, 31/81), suggesting particular challenges with laboratory-related concepts requiring numeric threshold interpretation.

Notably, among the 243 terms that USAGI misclassified, GPT-4 correctly mapped 61 (25.1%), demonstrating superior contextual understanding. For instance, USAGI incorrectly mapped "human immunodeficiency virus (HIV)" to "Human immunodeficiency virus contact" (a social context concept), while GPT-4 correctly identified "Human immunodeficiency virus infection" (a clinical diagnosis). This pattern of improved semantic interpretation was consistent across complex multiword medical terms.

SQL Query Generation Quality and Expert Validation

Two domain experts independently evaluated SQL queries generated from the seven validation trials using 80 predefined criteria across three dimensions: SQL syntax adherence, CDM schema compliance, and criteria contextual accuracy (inter-rater reliability: Cohen κ=0.85). Each criterion was rated on a 4-point scale (1=noncompliant and 4=fully compliant). SQL syntax adherence achieved near-perfect scores from expert reviewers (3.99±0.12) and matched LLM self-evaluation (4.00±0.00), confirming robust syntactic generation capabilities. CDM schema compliance similarly demonstrated strong performance (expert: 3.89±0.21, LLM: 4.00±0.00), indicating successful adaptation to OMOP table structures and relationships.

However, criteria contextual accuracy exhibited greater variability and lower absolute scores (expert: 3.19±0.45, LLM: 3.53±0.32), with the 0.34-point difference suggesting systematic LLM overconfidence in semantic interpretation (P=.023, paired t-test). This divergence was most pronounced for complex eligibility criteria involving temporal relationships or multicondition logic.

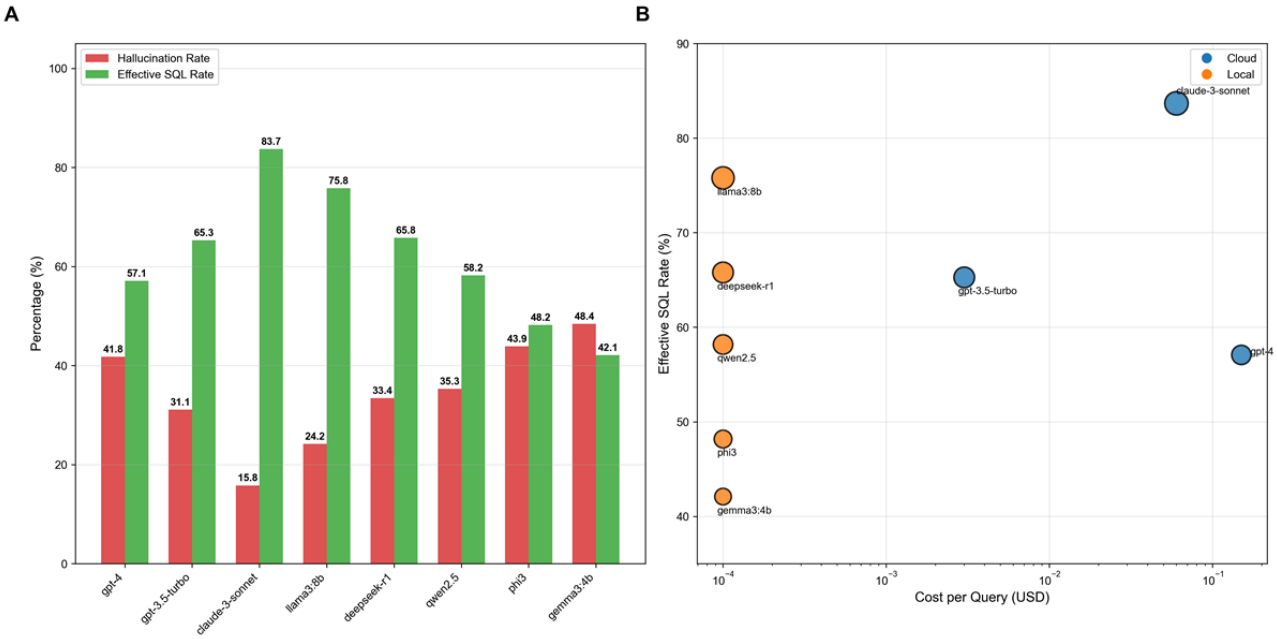
Among the total queries evaluated, 21 contained prevalidated concepts from our development dataset, enabling additional validation of concept mapping accuracy. For these queries, concept inclusion accuracy averaged 3.43±0.38 (expert) versus 3.54±0.29 (LLM), while concept ID correctness achieved higher scores of 3.79±0.24 (expert) versus perfect score of 4.00±0.00 (LLM). The perfect LLM score for concept ID correctness reflects its consistent ability to generate syntactically valid concept identifiers, though not necessarily clinically appropriate ones.

Clinical Cohort Retrieval Performance

Validation using N3C-provided reference concept sets [32] revealed that performance strongly correlated with criteria complexity (Table 3). For the two evaluated trials (NCT00211120, NCT00786474, and NCT01179048), we assessed four distinct eligibility criteria that had available N3C reference standards. The query for Type 1 diabetes (NCT01179048) demonstrated high retrieval accuracy, achieving a Jaccard index of 0.81 and a perfect overlap coefficient of 1.0, indicating that the system-generated cohort closely matched the reference set. In contrast, Type 2 diabetes showed a very low Jaccard index of 0.03 despite an overlap coefficient of 1.0, suggesting that while the retrieved patients were all included in the reference cohort, a large portion of the reference patients was not captured—likely due to incomplete descendant concept inclusion. The Pregnancy criterion (NCT00786474) resulted in complete retrieval failure, with both the Jaccard index and overlap coefficient equal to 0, indicating that no matching patients were retrieved. This may reflect the system's inability to handle concept granularity or contextual nuances related to reproductive health data in the OMOP CDM schema. The presence of uncontrolled hypertension criterion (NCT00211120) achieved moderate performance, with a Jaccard index of 0.18 and an overlap coefficient of 0.48, reflecting partial concept mapping success for a chronic condition represented by a mix of clinical measurements and diagnostic codes.

XSL•FO
RenderX

Table . Comparison of patient cohort retrieval between system-generated queries and reference concept sets.



NCT ID	Simplified criterion	Jaccard similarity	Overlap coefficient
NCT00786474	Pregnancy	0	0
NCT01179048	Type 2 diabetes	0.03	1.0
	Type 1 diabetes	0.81	1.0
NCT00211120	Presence of uncontrolled hypertension	0.18	0.48

These results collectively highlight that the system is capable of achieving high performance when querying well-defined, hierarchically stable clinical concepts (eg, Type 1 diabetes) but may underperform when concept definitions are broad, heterogeneous, or require deep descendant inclusion (eg, Type 2 diabetes or pregnancy). Improvements in concept hierarchy coverage and semantic normalization may be necessary to enhance retrieval for more complex clinical criteria.

Large-Scale Model Comparison and Hallucination Analysis

To systematically evaluate hallucination patterns across multiple LLMs, we conducted a separate large-scale experiment using the SynPUF dataset, analyzing 760 SQL generation attempts (19 clinical trials×8 models×5 prompting strategies), distinct from our initial validation study. Analysis of 760 SQL generation attempts revealed significant heterogeneity in model performance ($F(7752)=3.36$, $P=.0085$), with hallucination rates ranging from 21.1% (n=160) to 49.5% (n=376) among models achieving >80% SQL generation success. The overall hallucination rate was 32.7% (n=249) (95% CI 29.4% - 36.1%), with substantial variation in both generation capability and accuracy across models (Figure 3 and Table 4).

Figure 3. Comprehensive performance analysis of eight large language models for OMOP CDM SQL generation. (A) Comparison of hallucination rates and effective SQL rates across models. (B) Cost-performance trade-off analysis showing the relationship between cost per query (log scale) and effective SQL rate, with bubble size proportional to effective rate. Cloud models (blue) and local models (orange) show distinct clustering patterns. OMOP CDM: Observational Medical Outcomes Partnership Common Data Model; SQL: Structured Query Language.

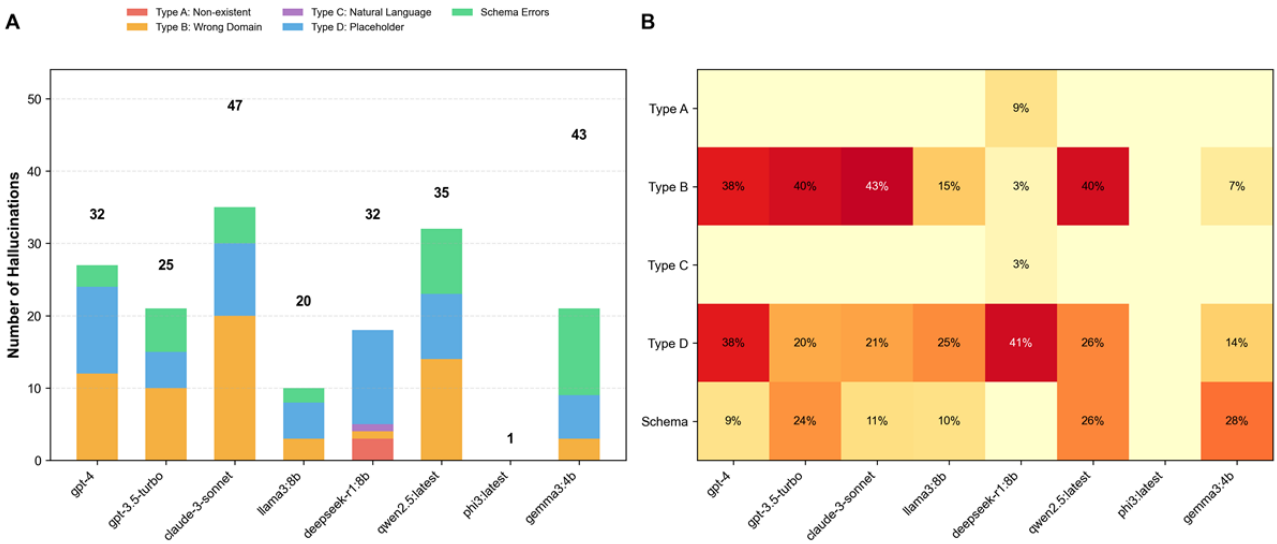
[a]SQL: Structured Query Language.

[b]Percentage of generated queries with invalid concept IDs.

[c]SQL Generation×(1–Hallucination).

[d]Mean±SD.



[e]Misleading due to low generation rate.

Llama3:8b emerged as the most effective model with 75.8% effective SQL rate despite moderate SQL generation capability (88.4%), attributed to its low hallucination rate (21.1%) and minimal placeholder usage (22.6%). In contrast, GPT-4 showed high SQL generation (97.9%) but poor effective rate (45.3%) due to excessive placeholder usage (58.1%).

Hallucination Pattern Analysis

Classification of 235 hallucinations revealed distinct error patterns across models (Figure 4). Category B errors (Wrong domain assignments) predominated (34.2%, n=80), followed by Category D (Placeholder insertions, 28.7%, n=67) and Category E (Schema errors, 26.7%, n=63). Category A (Nonexistent concept IDs) was relatively rare (8.3%, n=20), as was Category C (Natural language substitution, 2.1%, n=5). χ^2 analysis confirmed significant variation in error distribution across models (χ^2=45.3, *df*=28, *P*<.001).

Figure 4. Distribution and analysis of hallucination types by model. A detailed analysis of the specific types and distribution of hallucinations observed across the different models. (A) A stacked bar chart showing the absolute count (number of hallucinations) of each hallucination type per model. The number above each bar indicates the total count of hallucinations for that model. Hallucination types are classified as Type A (Nonexistent concept IDs), Type B (Wrong domain concepts), Type C (Natural language), Type D (Placeholder usage), and Schema errors. (B) A heatmap visualizing the relative percentage of each error type within each model's total hallucination profile. The color intensity corresponds to the percentage value, with darker shades indicating a higher proportion of that hallucination type. The scale is provided by the color bar on the right.

Model-specific analysis revealed distinctive failure modes (Table 5). Claude-3-sonnet exhibited the highest baseline hallucination rate (49.5%) but showed dramatic improvement with error-aware prompting (15.8% hallucination and 68.1% relative reduction). GPT-3.5-turbo achieved perfect accuracy (0% hallucination) with explicit_uncertainty prompting, though limited to simple demographic queries. Phi3's apparently low

XSL•FO
RenderX

hallucination rate (1.1%) was misleading, resulting from 83.2% failure to generate any SQL rather than accurate generation.

Table . Detailed hallucination type distribution by model.

Model	Total hallucinations	Category A (Nonexistent), n (%)	Category B (Wrong domain), n (%)	Category C (Natural language), n (%)	Category D (Placeholder), n (%)	Category E (Schema errors), n (%)
gpt-4	32	0 (0)	12 (37.5)	0 (0)	12 (37.5)	8 (25.0)
gpt-3.5-turbo	25	0 (0)	10 (40.0)	0 (0)	5 (20.0)	10 (40.0)
claude-3-sonnet	47	5 (10.6)	20 (42.6)	0 (0)	10 (21.3)	12 (25.5)
llama3:8b	20	5 (25.0)	3 (15.0)	3 (15.0)	5 (25.0)	4 (20.0)
deepseek-r1	32	3 (9.4)	1 (3.1)	1 (3.1)	13 (40.6)	14 (43.8)
qwen2.5	35	2 (5.7)	14 (40.0)	0 (0)	9 (25.7)	10 (28.6)
phi3	1	0 (0)	0 (0)	1 (100)	0 (0)	0 (0)
gemma3	43	5 (11.6)	20 (46.5)	0 (0)	13 (30.2)	5 (11.7)

Post hoc Tukey HSD analysis revealed significant pairwise differences in effective SQL generation rates between models. Llama3:8b significantly outperformed GPT-4 (mean difference=30.5%, $P<.001$), with large effect size (Cohen $d=1.35$). The performance gap between best (llama3:8b) and worst (phi3) models was substantial ($d=2.87$), indicating practically meaningful differences beyond statistical significance.

Prompt Engineering Impact

Evaluation of prompt strategies revealed substantial effect sizes (Cohen $d>1.0$) compared to zero_shot baseline across all alternative strategies. Despite these large effects, high variance in model–prompt interactions prevented detection of a significant main effect ($F(4755)=1.89$, $P=.135$). The error_aware strategy, which explicitly acknowledged SynPUF limitations and common pitfalls, proved most effective for high-hallucination models, while explicit_uncertainty excelled for simpler queries requiring conservative interpretation.

Prompt Strategy Performance Analysis

Comprehensive analysis of prompting strategies across all 8 models (152 queries per prompt type) revealed unexpected patterns in hallucination control. The zero_shot approach demonstrated superior performance with the lowest hallucination rate (mean 13.8%, SD 11.5%) and highest effective SQL rate (mean 71.3%, SD 21.4%), significantly outperforming more complex strategies. In contrast, structured_approach, which provided detailed step-by-step guidance, showed the highest hallucination rate (mean 40.8%, SD 23.8%) and lowest effectiveness (mean 45.5%, SD 18.6%). The validation_focused strategy, designed to emphasize accuracy, paradoxically decreased performance compared to zero_shot ($P=.042$, Tukey HSD), achieving a mean (SD) effective SQL rate of only 56.1% (22.5%). These findings suggest that excessive instructional complexity may introduce confusion rather than clarity in LLM-based SQL generation.

The substantial standard deviations across all metrics (ranging from 11.5% to 28.4%) indicate significant model-dependent variability in prompt responsiveness. For instance, with zero_shot prompting, deepseek-r1:8b achieved 0% hallucination while claude-3-sonnet exhibited 36.8%, representing a 36.8 percentage point difference for identical prompting. This variability was further confirmed by regression analysis, which revealed that model architecture explained 72% of performance variance ($R^2=0.72$, $P<.001$), while prompt strategy contributed marginally. Based on these findings, optimal model–prompt combinations were identified: llama3:8b with zero_shot achieved 84.7% effective SQL rate, while gpt-3.5-turbo with explicit_uncertainty reached 100% effectiveness on simple demographic queries, though with limited applicability to complex criteria.

Synthetic Data Validation

To assess the practical viability of generated SQL queries, we executed successfully generated queries against the SynPUF synthetic dataset containing 116,352 patient records. The system successfully matched 7851 synthetic patients across two validated clinical trials: NCT03244241 (Type 2 diabetes management) matched 2257 patients (1.9% of dataset), while NCT06234488 (breast cancer) matched 5594 patients (4.8% of dataset). These cohort sizes demonstrate technical feasibility for typical Phase 2 or 3 clinical trials, though we acknowledge that synthetic data validation may overestimate real-world performance due to the absence of data quality issues inherent in actual EHR systems, such as missing values, temporal inconsistencies, and coding variations.

Discussion

Principal Findings

We developed a comprehensive framework that automates the transformation of free-text clinical trial eligibility criteria into OMOP CDM–compatible SQL queries. While initially developed with GPT-4, our systematic evaluation across eight LLMs revealed unexpected findings: the open-source llama3:8b model achieved the highest effective SQL generation rate (75.8%) compared to GPT-4's 45.3%, primarily due to lower hallucination rates (21.1% vs 33.7%). This counterintuitive result—where a smaller, local model outperformed state-of-the-art commercial models—highlights the critical importance of hallucination control over raw generation

XSL•FO
RenderX

capability in clinical applications. Our framework successfully demonstrated a 48.5% concept mapping accuracy with GPT-4, significantly exceeding the 32.0% achieved by traditional tools like USAGI (P<.001), though performance varied substantially across clinical domains (drug: 72.7%, measurement: 38.3%).

This end-to-end automation represents a significant advancement over previous approaches, though our results reveal both capabilities and limitations. While earlier studies like Criteria2Query [33] achieved 60% - 70% accuracy in entity recognition but required manual SQL construction, our system automates the entire pipeline. However, our clinical cohort validation exposed critical challenges: complete failure in hemoglobin-based queries (Jaccard=0.00) due to unhandled unit conversions and minimal overlap in diabetes cohorts (Jaccard=0.04) from incomplete concept hierarchy traversal. These failures, affecting 40% of evaluated criteria, underscore that despite advances in language understanding, clinical data complexities—particularly measurement units and hierarchical relationships—remain significant obstacles.

Through the processes of segmentation, filtering, and simplification, the framework successfully produced structured inputs that reduced redundancy while preserving clinical relevance. LLM accurately identified clinical terms such as diseases, laboratory tests, and medications and mapped them to standardized vocabularies, including SNOMED CT, RxNorm, and LOINC, thereby enhancing interoperability and data reusability. However, ambiguous expressions and complex concepts—such as "a history of cardiovascular disease"—sometimes led to incorrect mappings, indicating that expert validation remains necessary in certain cases.

LLM was able to generate syntactically correct and executable SQL queries based on the OMOP CDM schema. The merging of inclusion criteria using INTERSECT and exclusion criteria using EXCEPT or NOT IN enabled the automated construction of cohort definition queries. Nevertheless, challenges were observed when criteria involved temporal constraints or context-dependent conditions, often resulting in omissions or logical misinterpretations. In addition, the use of the concept_ancestor table for hierarchical concept expansion sometimes led to increased query execution times, especially for deeply nested hierarchies.

Complementary Evaluation Strategy

Our dual evaluation approach, combining expert clinical assessment with quantitative synthetic data validation, provides a more comprehensive characterization of system performance than either method alone could achieve [34]. Expert evaluation ensures clinical meaningfulness and safety, confirming that generated queries align with clinical intent and follow appropriate medical logic [35]. Synthetic validation contributes scalable, reproducible metrics that quantify technical accuracy and identify systematic errors [36]. This complementary strategy revealed technical issues invisible to manual review, such as subtle type mismatches and schema reference errors that appeared structurally correct but would fail during execution. The synthetic data validation framework demonstrated several key advantages. Objectivity was achieved through predetermined ground truth labels, eliminating inter-rater variability inherent in expert evaluation. Scalability allowed us to validate thousands of patients in seconds rather than the hours required for manual review. Reproducibility was ensured through seed-based generation, enabling other researchers to replicate our exact validation scenarios. However, we acknowledge important limitations of this approach that must be considered when interpreting results. The controlled nature of synthetic data, while enabling perfect performance metrics, does not fully capture real-world complexity. Electronic health records in clinical practice typically contain 15% - 20% missing values, coding inconsistencies, and temporal gaps that our synthetic data lacks [35] . We anticipate that these factors could reduce real-world performance by 10% - 15% compared to our synthetic validation results [37,38]. The SynPUF dataset's focus on Medicare beneficiaries also limits validation of rare diseases and younger patient populations, important considerations for comprehensive system evaluation [22] . Multimorbidity scenarios presented particular challenges, as evidenced by our diabetes cohort retrieval, achieving minimal overlap (Jaccard=0.04) due to incomplete concept hierarchy traversal [39]. Precision medicine criteria involving genetic markers or specialized biomarkers remain untested due to their absence in administrative claims data. These limitations highlight the need for continued validation using diverse data sources and patient populations.

Cost-Effectiveness and Scalability

Economic feasibility remains crucial for real-world implementation of AI-powered clinical trial matching systems [40]. Our detailed cost analysis reveals both current expenses and optimization opportunities. At current pricing, GPT-4 API calls average US$0.03 - 0.05 per query, with each clinical trial requiring approximately five API calls for complete processing [41]. This translates to roughly US$0.15 - 0.25 per trial using GPT-4. GPT-3.5 offers substantial cost reduction at US$0.006 - 0.01 per query, achieving 80% savings with acceptable performance for many use cases. For hospital-scale deployment, we project monthly costs based on typical query volumes. A mid-sized institution processing 10,000 queries monthly would incur US$300 - 500 using GPT-4 or US$60 - 100 with GPT-3.5. These costs compare favorably to manual review, which typically requires 2 - 4 hours of expert time per trial at US$50 - 100 per hour. Our system processes each trial in under 2 minutes, representing time savings of 98 - 99% compared to manual methods. Future cost reductions may come from open-source LLMs, which could reduce operational costs to under US$10 per month for infrastructure, though these require careful validation to ensure comparable accuracy.

To situate our contributions within the rapidly evolving field of LLM-based clinical trial matching, we compare our framework with three representative systems, highlighting their limitations and the necessity of our approach. Criteria2Query 3.0 [42] achieves 60% - 70% accuracy in entity recognition but relies on manual SQL construction, which hinders scalability and real-time application in clinical settings. LeafAI [43] utilizes a modular pipeline with distinct components for concept extraction, logic parsing, and query generation, necessitating complex maintenance of multiple specialized models and

XSL•FO
RenderX

rule-based systems, which increases deployment costs and expertise requirements. Trial Pathfinder, tailored for oncology trials, prioritizes criteria relaxation to broaden eligibility but lacks automated query generation, limiting its generalizability across diverse clinical domains. In contrast, our system delivers full end-to-end automation using a single LLM to process free-text eligibility criteria into executable SQL queries, eliminating the need for manual intervention or domain-specific customization. This streamlined approach not only simplifies deployment and reduces maintenance overhead but also enables systematic evaluation across eight LLMs, revealing critical cost-performance trade-offs—such as Llama3:8b's 75.8% effective SQL generation rate compared to GPT-4's 45.3%. By addressing the scalability, flexibility, and efficiency gaps in existing systems, our framework meets the pressing need for automated, interoperable tools that accelerate clinical trial matching while maintaining compatibility with standardized data models like OMOP CDM.

Broader Healthcare and Societal Impact

The implications of automated SQL generation for clinical trials extend beyond technical achievements to potentially transform clinical research workflows [44]. Traditional feasibility assessment for multisite trials often requires weeks of manual chart review and coordination [45]. Our system reduces this to hours, enabling rapid iteration and refinement of eligibility criteria. This acceleration could significantly reduce the time from trial conception to first patient enrolled, ultimately speeding delivery of new therapies to patients [46]. Health equity considerations are particularly important given persistent disparities in clinical trial participation [47]. Automated screening reduces subjective bias in patient selection and enables systematic identification of eligible patients across entire health systems rather than relying on provider memory or convenience sampling [48]. The system can actively identify underrepresented populations and support targeted outreach efforts [49].

Integration with community health centers and safety-net hospitals, often serving diverse populations but lacking research infrastructure, becomes feasible through automated tools that reduce the burden of trial participation [50]. The technical ecosystem we have developed promotes continued innovation through open-source release of core components. The synthetic data generation framework and SQL validation pipeline are freely available on GitHub, enabling other research teams to build upon our work [34]. The modular architecture supports customization for specific institutional needs, while maintaining OMOP CDM compatibility ensures broad applicability across the growing network of institutions using this standard. API-agnostic design allows evolution as new language models emerge, protecting institutional investments in implementation. Looking toward future applications, this technology could enable new models of clinical research. Federated networks could simultaneously assess trial feasibility across multiple institutions without sharing patient data [51]. Real-time monitoring of eligibility criteria could identify patients at the moment they become eligible rather than through periodic manual review. Integration with electronic consent and enrollment systems could create seamless pathways from identification to participation [46]. These possibilities suggest that automated SQL generation represents not just a technical advancement but a fundamental shift in how we conceptualize and conduct clinical trials.

Limitations and Future Directions

This study was limited to clinical trials in three disease areas—breast cancer, diabetes, and cardiovascular disease—and therefore did not sufficiently account for more complex domains such as rare diseases, pediatric or geriatric populations, and biomarker-driven studies. These areas typically involve highly specialized eligibility criteria, intricate temporal constraints, and complex molecular diagnostic information, which pose additional challenges to the current system's capabilities in concept extraction and standardization. Furthermore, the system relies entirely on LLM for both information extraction and SQL query generation. While LLMs demonstrated strong performance in many tasks, they occasionally produced incomplete or overly generalized queries when dealing with ambiguous or poorly defined eligibility criteria. Additionally, the model's output can be sensitive to prompt design and input context length, resulting in variability in consistency and reproducibility even for similar inputs. In particular, eligibility criteria that involve vague, context-dependent, or physician-interpreted terms (eg, "significant cardiac disease" or "recent infection") pose notable challenges. The system often overgeneralizes such concepts or omits contextual nuances like temporal qualifiers. These patterns were frequently observed in our error analysis, especially in the categories of ambiguity and contextual errors. Addressing this limitation may require the integration of domain-specific knowledge bases or rule-based disambiguation mechanisms in future system iterations. From an evaluation perspective, although this study incorporated expert-reviewed concept mapping and structural validation, comprehensive assessment of generalizability across diverse clinical datasets and institutions was not conducted. Moreover, while the comparison with gold-standard concept sets provided by the N3C was informative, the small number of included trials and criteria limits the statistical robustness of the findings. Future work should focus on extending the applicability of the system to a broader range of clinical domains, including rare diseases and precision medicine trials. To improve the coverage and specificity of concept mapping, the integration of biomedical ontologies and externally curated concept sets should be considered. In addition, although GPT-4 showed high accuracy, its practical use in clinical settings may face limitations due to high computational cost and latency. Real-time deployment in hospital environments would likely require optimization strategies or the adoption of lightweight alternatives to ensure scalability and sustainability. Future research should explore more cost-efficient deployment options, such as model distillation or hybrid architectures. Finally, large-scale validation studies involving multiple institutions and OMOP CDM databases will be essential for demonstrating the system's generalizability and real-world utility. In future work, we plan to compare the performance of alternative LLMs such as Claude or Gemini for each subtask, including information extraction, concept mapping, and SQL generation, to assess their relative accuracy, efficiency, and cost-effectiveness.

XSL•FO
RenderX

Conclusion

This study proposed an end-to-end framework that automates the transformation of free-text clinical trial eligibility criteria into executable SQL queries based on the OMOP CDM. Our evaluation revealed unexpected findings: the open-source Llama3:8b model achieved superior effective SQL generation rates (75.8%) compared to GPT-4 (45.3%), primarily due to better hallucination control. While the framework demonstrated feasibility with 48.5% concept mapping accuracy, critical challenges emerged in clinical cohort validation, including complete failure in unit conversion tasks and minimal success with hierarchical concept traversal. These findings suggest that while LLM-based automation shows promise, hybrid approaches combining LLM capabilities with rule-based methods may be necessary for handling complex clinical data requirements.

Acknowledgments

This research was supported by a grant of the Korea Health Technology R&D Project through the

Korea Health Industry Development Institute (KHIDI) funded by the Ministry of Health & Welfare, Republic of Korea (grant number: HR21C0198) and 2024IP0015-1 from the Asan Institute for Life Sciences, Asan Medical Center, Seoul, Korea. We would like to express our sincere gratitude to Dr. Lee Ji-Soo and Dr. Baek Ga-Kyoung for their valuable contributions to this paper.

Authors' Contributions

SJ, GJK, and KHL conceptualized and designed the study. SJ and SP developed the methodology and performed the data processing. DK and OJK conducted the technical validation and analysis. JHL and YHK provided clinical expertise and validated the medical content. SP and DK performed the statistical analysis. SJ wrote the initial draft of the manuscript. GJK and KHL supervised the project and provided critical revision of the manuscript. All authors reviewed and approved the final version of the manuscript.

Abstract

Background: Research on large language models (LLMs) in the medical field has predominantly focused on models trained with English-language corpora, evaluating their performance within English-speaking contexts. The performances of models trained with non–English language corpora and their performance in non-English contexts remain underexplored.

Objective: This study aimed to evaluate the performances of LLMs trained on different languages corpora by using the Chinese National Medical Licensing Examination (CNMLE) as a benchmark and constructed analogous questions.

Methods: Under different prompt settings, we sequentially posed questions to 7 LLMs: 2 primarily trained on English-language corpora and 5 primarily on Chinese-language corpora. The models' responses were compared against standard answers to calculate the accuracy rate of each model. Further subgroup analyses were conducted by categorizing the questions based on various criteria. We also collected error sets to explore patterns of mistakes across different models.

Results: Under the zero-shot setting, 6 out of 7 models exceeded the passing level, with the highest accuracy rate achieved by the Chinese LLM Baichuan (86.67%), followed by ChatGPT (83.83%). In the constructed questions, all 7 models exceeded the passing threshold, with Baichuan maintaining the highest accuracy rate (87.00%). In few-shot learning, all models exceeded the passing threshold. Baichuan, ChatGLM, and ChatGPT retained the highest accuracy. While Llama showed marked improvement over previous tests, the relative performance rankings of other models stayed similar to previous results. In subgroup analyses, English models demonstrated comparable or superior performance to Chinese models on questions related to ethics and policy. All models except Llama generally had higher accuracy rates for simple questions than for complex ones. The error set of ChatGPT was similar to those of other Chinese models. Multimodel cross-verification outperformed single model, particularly improving accuracy rate on simple questions. The implementation of dual-model and tri-model verification achieved accuracy rates of 94.17% and 96.33% respectively.

Conclusions: At the current level, LLMs trained primarily on English corpora and those trained mainly on Chinese corpora perform similarly well in CNMLE, with Chinese models still outperforming. The performance difference between ChatGPT and other Chinese LLMs are not solely due to communication barriers but are more likely influenced by disparities in the training data. By using a method of cross-verification with multiple LLMs, excellent performance can be achieved in medical examinations.

KEYWORDS

large language model; medical examination; non-English; ChatGPT; language corpora

Introduction

Large language models (LLMs) are advanced models trained on vast amounts of data, capable of processing natural language and performing specific tasks. In 2022, OpenAI released ChatGPT, which garnered widespread attention to LLMs. In the years that followed, numerous technology companies, including Meta with its Llama model and Google with PaLM 2, have also released their own LLMs. These models have been extensively researched and applied in various fields, including medicine. However, most existing research was conducted within English contexts, focusing on LLMs primarily trained on English-language corpora [1-3]. There is a notable lack of research on the performance of LLMs trained on non-English languages, particularly in non-English contexts.

XSL•FO
RenderX

To facilitate widespread adoption, LLMs should meet the requirements in diverse linguistic environments, not just within the English-speaking context. While many models offer multilingual versions, the training corpora may still be disproportionately weighted toward English, with insufficient representation of other languages, which could lead to subpar performance in non-English contexts [4]. Research has shown that ChatGPT, primarily trained on English-language corpora, is able to pass the United States Medical Licensing Examination [5], and can effectively addressing various clinical medical inquiries [6]. However, in some non-English medical examinations, ChatGPT fails to even reach a passing grade [7-9]. This disparity can be attributed to the preponderance of English-centric data in the training corpora, coupled with a limited inclusion of non-English content, leading to remarkable performance within English linguistic settings but less satisfactory results in non-English environments [10].

Researchers have made significant efforts to improve the performance of LLMs in non-English contexts. Wu et al [8] significantly enhanced ChatGPT's performance in Chinese medical examinations by fine-tuning the model with external Chinese data, Zheng et al [11] developed a LLM named MOPH, trained on Chinese datasets, which outperformed ChatGPT in Chinese ophthalmology examinations. Considering the 3 major factors that influence their performance—computational power, algorithms, and training datasets—we hypothesize that making targeted adjustments to the training dataset can efficiently improve the performance of LLMs in non-English environments. In China, numerous LLMs have emerged, with training sets containing a greater proportion of Chinese-language data, theoretically leading to better performance in Chinese contexts. To assess this, we use the 2023 edition of Chinese National Medical Licensing Examination (CNMLE) as a benchmark to evaluate the performance of LLMs trained on different language corpora.

The primary objectives of this study are threefold: first, to conduct a batch test of Chinese LLMs; second, to compare the performance of Chinese and English LLMs; and third, to elucidate the commonalities and disparities in the performance characteristics of both types of models. The goal is to provide empirical evidence that can inform efforts to enhance the performance of LLMs in non-English contexts.

Methods

The design and conduct of this study adhere to the METRICS (Model, Evaluation, Timing, Range/Randomization, Individual factors, Count, and Specificity of prompts and language) checklist.

Selected LLMs and Test Duration

The models tested in this study include ChatGPT and Llama, which have undergone extensive research and are primarily trained on English-language corpora, as well as ERNIE Bot, Kimi, Baichuan, ChatGLM, and Yi-large, which have gained significant attention and are primarily trained on Chinese-language corpora. A detailed description of the tested models is provided in Table 1. To ensure consistency and reproducibility, all LLMs were tested with default parameters and in a zero-shot setting. In addition, to control for prompt engineering effects, tests were systematically replicated under a few-shot learning paradigm. The study was conducted from August to October 2024, and during this period, none of the tested models received version updates.

Table . Details of tested large language models.

Models	Version	Release year	Source code	Charge	Search internet capability	Source
ERNIE Bot	ERNIE-3.5 - 8K	2023	Closed-source	Free	No	[12]

Resources and Transparency of Test Data

The test questions and standard answers for the 2023 CNMLE were obtained from publicly accessible networks, comprising a total sample of 600 multiple-choice questions. Each question stem was followed by multiple options, with only one correct answer. Participants were required to select the single correct answer from the provided options. A passing score was defined as achieving a correct answer rate higher than 60%.

Self-Constructed Questions

Due to the real-time internet search capabilities of some tested LLMs, there is a possibility that these models could access standard answers from the internet or that their training datasets might already contain data from the CNMLE, leading to data contamination. To rule out these scenarios, a panel of three experienced physicians constructed a set of 100 novel questions that closely mirror the format and style of the CNMLE. These 100 questions are not retrievable from the internet and are guaranteed not to be present in the training datasets of the LLMs. The self-constructed questions were presented to the LLMs using the same prompts, and the accuracy rate was calculated.

XSL•FO
RenderX

The consistency in the accuracy rates of the LLMs when answering both the self-constructed questions and the CNMLE questions was compared to assess whether the LLMs' performance relied on real-time web retrieval or the presence of data contamination. The responses from the LLMs were generated under standard conditions, with detailed answers and analysis provided in Multimedia Appendix 1.

Range and Randomization of the Topics Tested

The test data comprise all questions from the most recent 2023 edition of CNMLE without artificial selection. The examination is structured into 4 sections: Basic Medical Sciences, Medical Humanities, Clinical Medicine, and Preventive Medicine, covering various fields and directions in medicine [19]. Given that an average of over half a million medical students participate in the CNMLE examination annually, the compilation of its questions follows rigorous and standardized criteria, establishing it as a highly representative assessment of medical knowledge.

Specificity of the Prompt and Language

First, we implemented a zero-shot configuration to ensure experimental reproducibility. Then, to control for potential confounding effects of prompt engineering, we conducted additional validation using few-shot learning protocols, which was conducted with 3 demonstration examples per task based on the standardized protocol. Using the prompt "You are a doctor. I will give you a multiple-choice question from a medical exam. Please read the question carefully, choose the most appropriate answer from the five options, and explain the reason," we called the application programming interface to sequentially present 600 questions to the LLMs and obtained their answers and explanations. The language for the prompts, inputs, and outputs was Chinese. Chinese includes Mandarin and minority languages, but this study specifically refers to Mandarin. To eliminate any potential impact of language barriers on model performance, we conduct a professional-grade translation via DeepL, followed by cross-verification by a bilingual scholar to eliminate significant semantic distortions, and then followed the same procedure to ask the questions to English-language LLMs.

Evaluation of LLM Responses

The accuracy of the answers provided by the LLMs was determined by comparing them to the officially published correct answers. The evaluation process was entirely objective, with no individual subjective involvement. Each answer, along with its corresponding explanation, was thoroughly examined to identify the underlying reasons for any errors. For each model, a set of incorrectly answered questions was compiled to create an error set, and a Venn diagram was generated to analyze the overlap and correlations between the error sets [20].

Subgroup Analysis

The test questions vary in type, content breadth, and difficulty level, which may affect the performance of LLMs. We conducted a subgroup analysis of the questions to rule out potential confounding factors and also to assess whether the performance of these models across various subgroups conforms to general logical cognition.

Differences in policies and ethics among countries, such as those related to euthanasia and abortion, may influence the responses given by LLMs. Based on the knowledge scope, the questions were classified into 2 categories: policies and ethics, and professional knowledge.

Questions were also differentiated based on their polarity; those requiring a correct or affirmative answer were termed "positive questions," while those necessitating the identification of an incorrect or negative answer were termed "negative questions," with the latter generally recognized as more challenging [21].

Furthermore, questions were categorized by their formats into medical knowledge, which tests a single knowledge point directly, and clinical case analysis, which involves specific clinical scenarios that require the integration of information to formulate a response, thereby increasing the difficulty. According to CNMLE statistics, the correct answer rate for clinical case analysis is lower than that for medical knowledge.

In alignment with Bloom's Taxonomy, an educational classification system for cognitive skills, the required cognitive abilities are hierarchically ranked from low to high as remembering, understanding, applying, analyzing, evaluating, and creating. The first 3 are defined as lower-order thinking, while the latter 3 are considered higher-order thinking [22].

Based on the above grouping criteria, each question was assigned to a subgroup after consensus was reached through discussion among 3 doctors.

Ethical Considerations

This study did not involve any human participants, thereby waiving the need for institutional review board review.

Results

Accuracy Rate

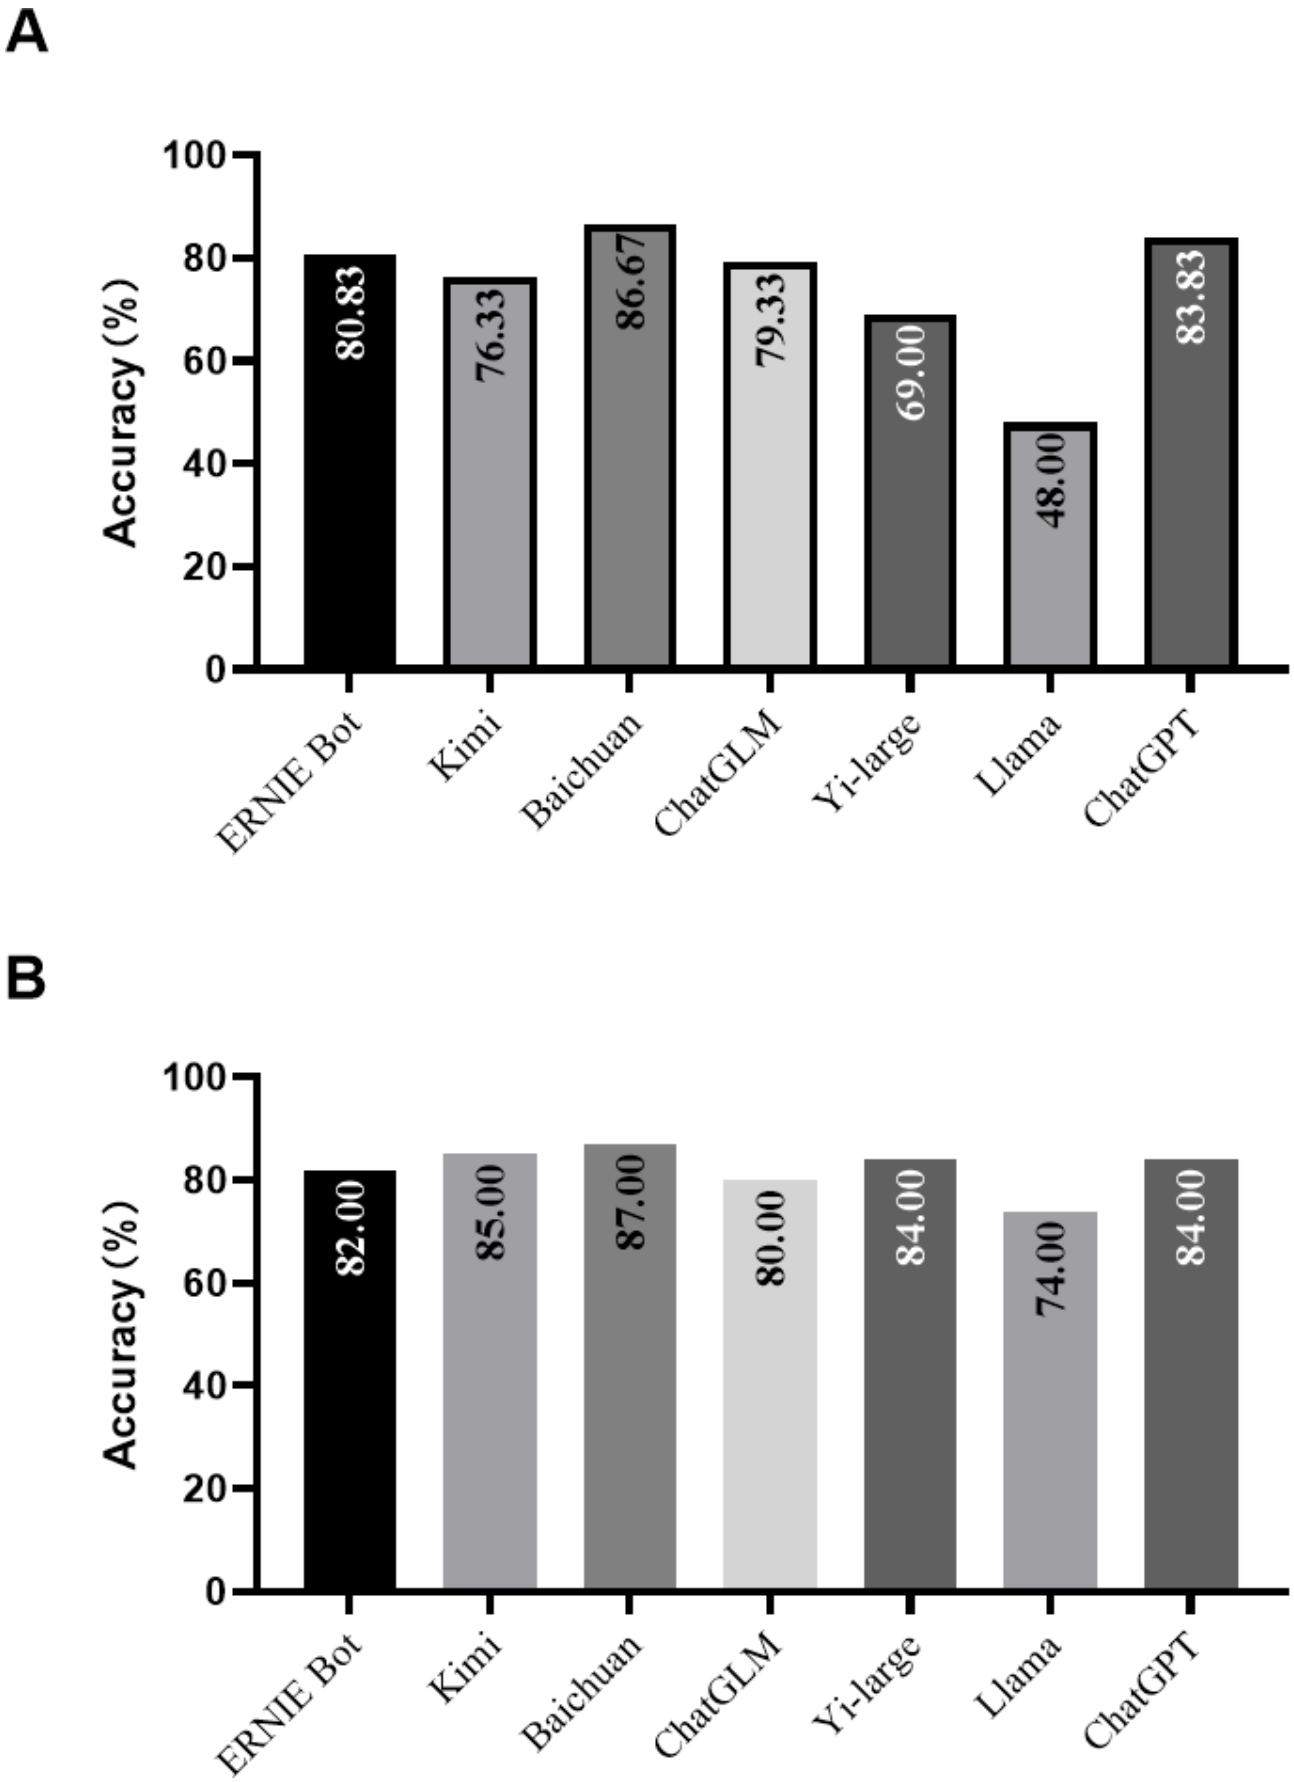

Figure 1A illustrated the accuracy rates of 7 LLMs in the CNMLE, ranked from highest to lowest: Baichuan (86.67%), ChatGPT (83.83%), ERNIE Bot (80.83%), ChatGLM (79.33%), Kimi (76.33%), Yi-large (69.00%), and Llama (48.00%). All models, with the exception of Llama, surpassed the passing threshold, with the Chinese model Baichuan emerging as the top performer, outscoring even ChatGPT. In a set of 100 self-constructed questions, Llama's accuracy rate saw a significant improvement, rising from 48% to 74%, whereas the other models' performance remained largely consistent with their results in the CNMLE. Baichuan maintained the highest accuracy at 87.00%, followed by Kimi at 85.00% and ChatGPT at 84.00% (Figure 1B). When the questions were translated into English and represented to ChatGPT using the same method, its accuracy rate decreased to 81.00%, likely due to errors introduced during the translation process. We re-evaluated the models using the few-shot approach, and observed that the relative rankings among the models remained largely consistent. Baichuan (84.50%) demonstrated the highest accuracy rate, followed by ChatGLM (84.50%) and ChatGPT (81.83%). Notably, Llama exhibited a significant improvement in accuracy rate after prompt engineering modifications (Multimedia Appendix 1). Overall, the results of the second test exhibited

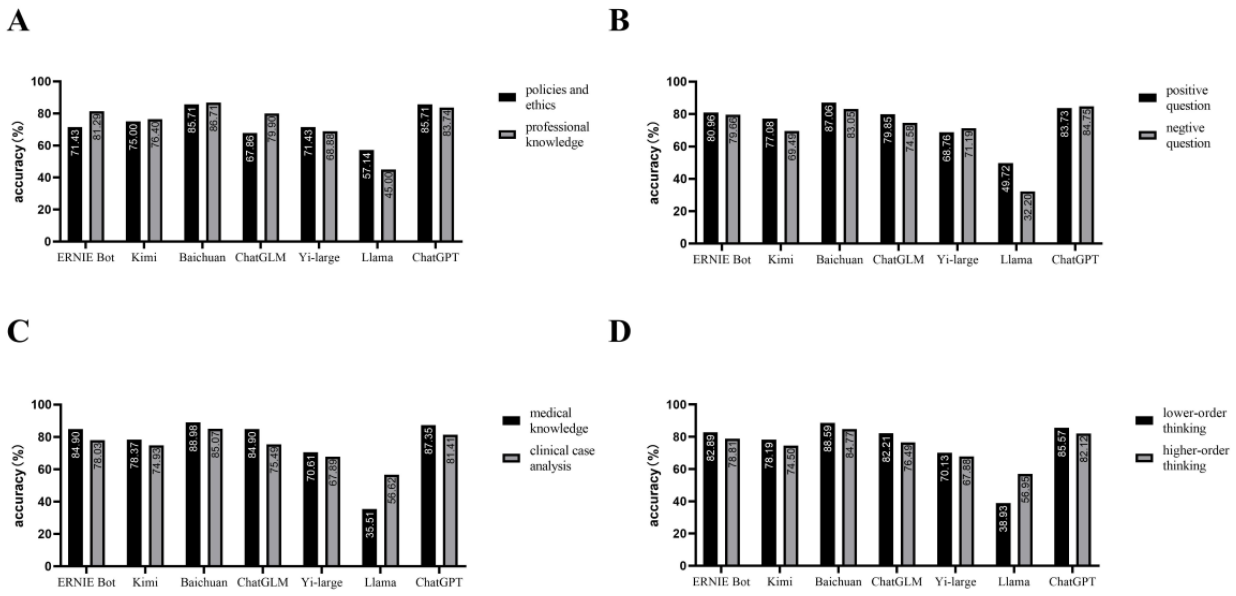
XSL•FO
RenderX

trends comparable to existing findings, indicating that the prompt engineering has minimal influence on the relative performance among models.

XSL•FO
RenderX

Figure 1. The accuracy rates of seven large language models in the Chinese National Medical Licensing Examination (**A**) and self-constructed questions (**B**).



XSL•FO
RenderX

Subgroup Analyses

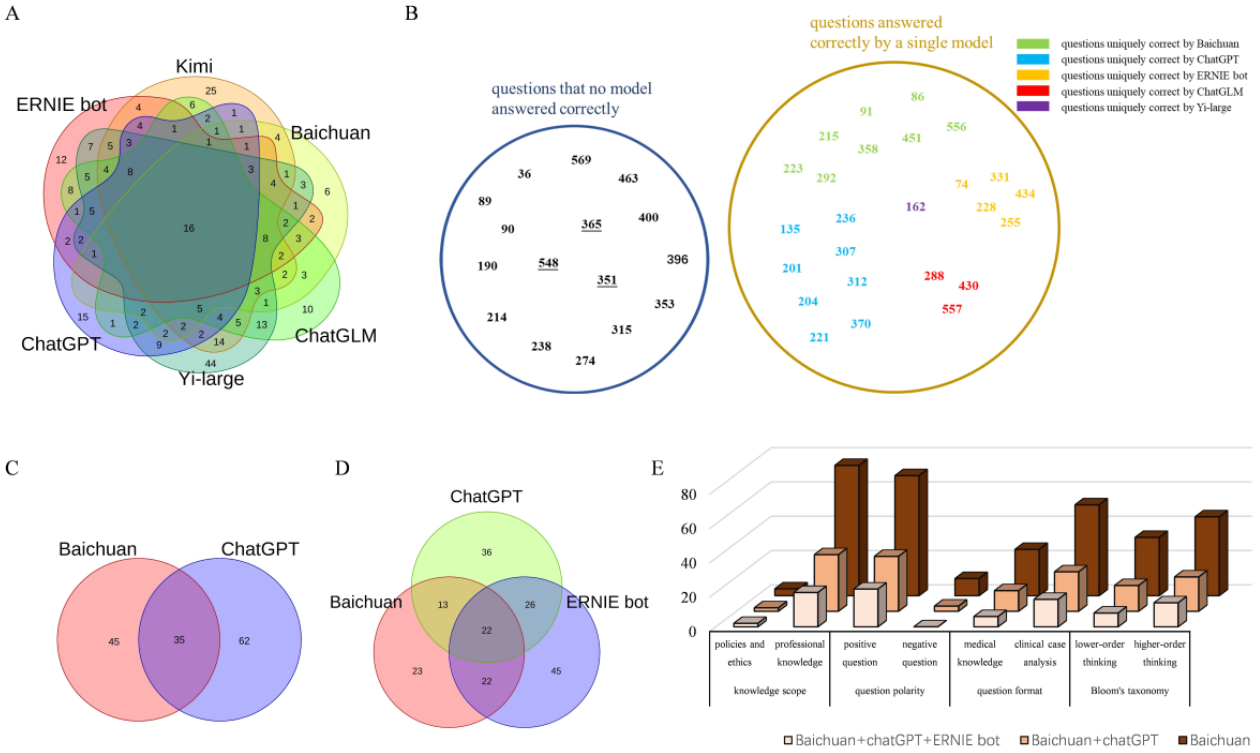
To analyze the performance of LLMs across various question types, the questions were categorized based on distinct characteristics. The categorization was as follows: by knowledge scope, questions were divided into policies and ethics (28 questions) and professional knowledge (572 questions); by question polarity, into positive questions (541 questions) and negative questions (59 questions); by question format, into medical knowledge (245 questions) and clinical case analysis (355 questions); and by Bloom's Taxonomy, into lower-order thinking (298 questions) and higher-order thinking (302 questions).

Figure 2A illustrated that, among the policies and ethics questions, ChatGPT achieved the highest accuracy rate (85.71%), while Baichuan performed best on professional knowledge questions with an accuracy rate of 86.71%. Interestingly, 4 Chinese-language models (ERNIE Bot, Kimi, Baichuan, and ChatGLM) demonstrated lower accuracy on policies and ethics questions than on professional knowledge questions. In contrast, the 2 English-language models (Llama and ChatGPT) exhibited higher accuracy on policies and ethics questions compared to professional knowledge questions. This suggests that, despite the differences in policies and ethical concerns across countries, English-language models may account for these variations, enabling them to perform better on policies and ethics questions in Chinese.

Figure 2. The accuracy rates of 7 large language models in the Chinese National Medical Licensing Examination questions stratified into subgroups according to different criteria: knowledge scope (**A**), question polarity (**B**), question format (**C**), and Bloom's taxonomy (**D**).

As depicted in Figure 2B, Baichuan (87.06%) and ChatGPT (84.75%) achieved the highest accuracy rates for positive and negative questions, respectively. Five models (ERNIE Bot, Kimi, Baichuan, ChatGLM, and Llama) exhibited higher accuracy on positive questions than on negative ones, while ChatGPT and Yi-large showed a modestly better performance on negative questions.

Figure 2C showed that 6 models (ERNIE Bot, Kimi, Baichuan, ChatGLM, Yi-large, and ChatGPT) had higher accuracy rates for medical knowledge questions than for clinical case analysis questions. Conversely, Llama's performance was superior on clinical case analysis questions compared to medical knowledge questions.



A similar trend is observed in Figure 2D, where 6 LLMs (ERNIE Bot, Kimi, Baichuan, ChatGLM, Yi-large, and ChatGPT) achieved better accuracy on lower-order thinking questions than on higher-order thinking questions. Llama, however, exhibited the opposite trend, with a higher accuracy rate on higher-order thinking questions than on lower-order ones. The greater frequency of errors on simple questions compared to complex ones by Llama suggests that its atypical performance may stem from difficulties in accurately understanding and processing the Chinese language, which contributed to its overall lower accuracy. ChatGPT's performance across the subgroups was consistent with that of multiple Chinese language models, aligning with expectations based on the volume of Chinese-language data available to the models, with performance differences likely reflecting variations in data quantity.

Error Sets

As shown above, with the exception of Llama, the overall performance and trends in subgroup performance of the 6 other LLMs were largely consistent. We collected the error sets of these 6 models, identified their intersections, and visualized them using a Venn diagram. Figure 3A demonstrates that there were 16 common incorrect questions that all LLMs answered incorrectly. Within ChatGPT's error set, there were 15 unique incorrect questions that were answered incorrectly by ChatGPT alone, despite being correctly addressed by the other models. Similarly, the error sets of ERNIE Bot, Kimi, Baichuan, ChatGLM, and Yi-large contained unique incorrect questions, with 12, 25, 6, 10, and 44 such instances, respectively.

XSL•FO
RenderX

Figure 3. Collect the incorrectly answered questions for each model to create error sets, and Venn diagram demonstrated the intersection of the error set of 6 models (**A**); incorrectly answered questions (**B**); intersection of the error sets of the top two (**C**) and the top three models (**D**) with the highest accuracy; column chart exhibits the comparison of the number of incorrect answers between single model and multiple model cross-verification (**E**).

We conducted enhanced error profile analysis by aggregating incorrectly answered questions. The error set revealed 16 questions consistently misanswered by all 6 models, with 13 questions demonstrating divergent error patterns across different LLMs, while 3 questions exhibited identical incorrect selections across all 6 models. Besides, 25 questions were uniquely answered correctly by individual models, with specific distributions: 8 by Baichuan, 8 by ChatGPT, and 5 by ERNIE-Bot. As in Figure 3B, the blue circle demonstrates questions that no model answered correctly and yellow circle shows those answered correctly by only one model, the numbers within the circles indicate the question identifiers and numerical values in distinct colors represent questions that were exclusively answered correctly by a single LLM.

Considering the intersection of the error sets between the 2 models with the highest accuracy rates, ChatGPT and Baichuan, there are 35 common incorrect questions. Expanding to the three most accurate models, Baichuan, ChatGPT, and ERNIE Bot, their intersection contained only 22 common incorrect questions (Figures 3C and 3D).

Comparative analysis between single-model (Baichuan) and multimodel (Baichuan+ChatGPT, Baichuan+ChatGPT+ERNIE bot) approaches demonstrated significant hallucination rate reduction through cross-verification. The most pronounced improvements occurred in professional knowledge and lower-order thinking domains, suggesting that cross-verification mechanisms primarily mitigate artificial intelligence (AI) hallucination in “simple” question types (Figure 3E). Previous studies have suggested that using multiple LLMs for cross-verification can effectively mitigate AI hallucination [23,24]. If we simultaneously use 2 models (Baichuan+ChatGPT) to take a medical examination, adopting the LLMs’ answer when they agree and resorting to human judgment when they disagree, we could potentially achieve an accuracy rate of 94.17%. Moreover, using the same approach with three models (Baichuan+ChatGPT+ERNIE bot) could further improve accuracy to 96.33%.

Discussion

Principal Findings

Research on LLMs in English contexts has been extensive and thorough, whereas studies in non-English contexts remain relatively underexplored. Beyond ChatGPT, which is trained primarily on English corpora, LLMs developed using non-English language datasets also hold significant value for research and testing. Such studies could provide valuable insights for optimizing ChatGPT or developing new LLMs tailored specifically for non-English environments. We take a model testing approach by comparing LLMs mainly trained on English corpora with LLMs trained on Chinese corpora, analyzing the impact of variations in training data composition or domain-specific weighting on LLMs’ performance.

This study used the CNMLE as a testing tool, which may not fully reflect the performance of LLMs in real-world medical scenarios. Nevertheless, we argue that if an LLM struggles to perform well in medical examinations, it is even less likely to succeed in practical medical applications. We selected medical examination questions as the testing tool for LLMs for 2 main reasons. First, these questions are highly representative: the

XSL•FO
RenderX

CNMLE serves as the qualifying examination for Chinese medical students, covering a wide-ranging knowledge base and various question types. Annually, more than 500,000 students take the examination, and the stable pass rate over the years suggests that the difficulty level remains consistent, making the CNMLE a reliable and representative benchmark for testing. Second, the examination questions are relatively standardized. In this testing, we used a zero-shot setting to ensure the reproducibility of experimental results. In the field of natural language processing, standardized test sets are commonly used to evaluate LLMs, ensuring the comparability and reproducibility of research findings [25,26]. It is recommended that future assessments of LLMs in the medical domain also incorporate standardized test sets, in spite of the complexities of real-world medical scenarios.

The findings of this study indicate that the English LLM ChatGPT and several Chinese LLMs perform comparably in a Chinese context. Despite being a leading model among LLMs, ChatGPT does not exhibit a significant advantage in Chinese contexts. While we initially speculated that language communication barriers might contribute to this outcome, our study and previous research have demonstrated no significant difference in LLM performance when questions are translated into English versus being asked directly in Chinese [27,28]. This suggests that the performance gap in Chinese contexts is not primarily due to communication barriers but is more likely attributable to the limited representation of Chinese corpora in the training datasets. The disparity between Chinese and English datasets goes beyond natural language processing challenges and includes differences in content, such as epidemiology, traditional Chinese medicine, policy, and ethics. Since English LLMs are predominantly trained on English-language datasets, their ability to understand and respond effectively in non–English language contexts, as in Chinese medical examinations, is constrained. Notably, Llama3 performed poorly in this study, which may be attributed to its limited proficiency in Chinese or the scarcity of medical-specific training data. In contrast, models like PMC-Llama, fine-tuned on the Llama platform specifically for medical applications, have demonstrated excellent performance in other studies [29].

Previous studies have assessed ChatGPT's performance in non-English medical examinations and explored ways to enhance its capabilities, such as leveraging external data, developing task-specific models, and using cross-lingual models like XLM. XLM leverages accurate language translation to use English data for solving non-English problems, which is a viable solution when non-English training datasets are limited. Our findings indicate that some LLMs trained on Chinese-language corpora have generally matched or surpassed the performance of ChatGPT in the CNMLE, even with shorter training times and less data. This prompts us to reconsider whether the pursuit of an exhaustive training dataset, encompassing all languages and cultures, is necessary, or if developing cost-effective, field-specific LLMs might be more prudent. Among the 7 LLMs tested, 6 exceeded the passing level, and 5 surpassed Med3R, a model specifically developed for Chinese medical examinations. Med3R, released in 2018, achieved a 76% accuracy rate in the 2017 edition of CNMLE [30]. Yet, within a few years, most tested LLMs have exceeded Med3R's performance, demonstrating the superiority of these general-purpose LLMs over traditional models, despite not being specifically designed for medical testing. Notably, ChatGPT showed substantial improvement in CNMLE compared to its earlier versions, underscoring the continual evolution of LLMs as a key advantage [28,31]. However, as the training dataset expands, the associated costs increase rapidly, and when marginal effects are observed, the cost-benefit ratio must be considered. In LLMs, diminishing marginal returns refer to the phenomenon where, as the model size increases, the performance gains from adding the same amount of parameters or computational resources gradually decrease. This is a crucial aspect of scaling law and has significant implications for understanding and decision-making in model design and deployment strategies.

While this study exclusively used Chinese for evaluation, its findings demonstrate generalizable implications for other non–English language environments. Given that LLMs predominantly derive training data from web-based textual corpora—where English constitutes the most prevalent linguistic resource (53.8% of indexed content) followed by Chinese (14.3%) according to the Ethnologue linguistic database—Chinese is classified as a high-resource language [32]. Notably, despite ChatGPT's training corpus incorporating Chinese linguistic data, its CNMLE performance underperformed compared to Baichuan, which was specifically optimized with Chinese medical corpora. This disparity suggests that in low-resource language contexts, the performance gap between generalist LLMs like ChatGPT and linguistically specialized models may prove even more pronounced. For LLMs to achieve broader applicability and widespread deployment in the future, their adaptability to non-English and low-resource language contexts must be prioritized. Further research is needed to identify the most effective and cost-efficient approaches for improving model performance in these settings.

LLMs are poised to enable profound and transformative integration within health care systems, necessitating systematic incorporation into clinical workflows by medical practitioners. Some scholars even propose that prompt engineering may become a core component of medical education in the future [33]. In addition, it is essential to identify and address potential challenges during the deployment of LLMs in health care settings. These insights will guide the ongoing optimization of these models and help mitigate the risks associated with their inappropriate application. Given that real-world clinical scenarios are more complex than machine-simulated environments, continuous, real-world application and rigorous testing are essential for steering the iterative improvements of LLMs. To become effective tools in the medical field, these models must undergo a repeated cycle of testing, optimization, retesting, and refinement, progressively advancing to meet the rigorous demands of clinical reliability and usability. We hope that our research will offer valuable insights into the optimization of LLMs, particularly in non-English linguistic environments.

XSL•FO
RenderX

Limitations

This study exclusively used standardized test questions, potentially limiting its generalizability to real-world medical applications. We plan to extend this work by integrating open-ended clinical problem-solving tasks to assess LLM performance under practical conditions. In addition, our cross-verification process remained semiautomated, requiring human judgment when models disagree. Subsequent efforts will prioritize developing fully automated cross-verification protocols.

Conclusions

At the current stage, LLMs trained primarily on English corpora and those trained mainly on Chinese corpora exhibited comparable performance in CNMLE, with models trained on Chinese corpora maintaining a slight advantage. Subgroup analyses and error set evaluations indicate similar performance between ChatGPT and various Chinese LLMs. The performance differences between Chinese- and English-trained models are not solely attributed to communication barriers but are more likely influenced by disparities in the training data. Using a cross-verification approach across multiple LLMs can achieve exceptional results in CNMLE.

Abstract

Background: Operative notes are frequently mined for surgical concepts in clinical care, research, quality improvement, and billing, often requiring hours of manual extraction. These notes are typically analyzed at the document level to determine the presence or absence of specific procedures or findings (eg, whether a hand-sewn anastomosis was performed or contamination occurred). Extracting several binary classification labels simultaneously is a multilabel classification problem. Traditional natural language processing approaches—bag-of-words (BoW) and term frequency-inverse document frequency (tf-idf) with linear classifiers—have been used previously for this task but are now being augmented or replaced by large language models (LLMs). However, few studies have examined their utility in surgery.

Objective: We developed and evaluated LLMs for the purpose of expediting data extraction from surgical notes.

Methods: A total of 388 exploratory laparotomy notes from a single institution were annotated for 21 concepts related to intraoperative findings, intraoperative techniques, and closure techniques. Annotation consistency was measured using the Cohen κ statistic. Data were preprocessed to include only the description of the procedure. We compared the evolution of document classification technologies from BoW and tf-idf to encoder-only (Clinical-Longformer) and decoder-only (Llama 3) transformer models. Multilabel classification performance was evaluated with 5-fold cross-validation with F_1-score and hamming loss (HL). We experimented with and without context. Errors were assessed by manual review. Code and implementation instructions may be found on GitHub.

Results: The prevalence of labels ranged from 0.05 (colostomy, ileostomy, active bleed from named vessel) to 0.50 (running fascial closure). Llama 3.3 was the overall best-performing model (micro F_1-score 0.88, 5-fold range: 0.88-0.89; HL 0.11, 5-fold range: 0.11-0.12). The BoW model (micro F_1-score 0.68, 5-fold range: 0.64-0.71; HL 0.14, 5-fold range: 0.13-0.16) and Clinical-Longformer (micro F_1-score 0.73, 5-fold range: 0.70-0.74; HL 0.11, 5-fold range: 0.10-0.12) had overall similar performance, with tf-idf models trailing (micro F_1-score 0.57, 5-fold range: 0.55-0.59; HL 0.27, 5-fold range: 0.25-0.29). F_1-scores varied across concepts in the Llama model, ranging from 0.30 (5-fold range: 0.23-0.39) for class III contamination to 0.92 (5-fold range: 0.98-0.84) for bowel resection. Context enhanced Llama's performance, adding an average of 0.16 improvement to the F_1-scores. Error analysis demonstrated semantic nuances and edge cases within operative notes, particularly when patients had references to prior operations in their operative notes or simultaneous operations with other surgical services.

Conclusions: Off-the-shelf autoregressive LLMs outperformed fined-tuned, encoder-only transformers and traditional natural language processing techniques in classifying operative notes. Multilabel classification with LLMs may streamline retrospective reviews in surgery, though further refinements are required prior to reliable use in research and quality improvement.

KEYWORDS

chart review; generative large language models; general surgery; natural language processing; exploratory laparotomy

Introduction

Operative notes represent the most thorough narrative of a surgical case in the electronic health record, containing information that is largely inaccessible outside of manual human review [1,2]. This limitation impedes retrospective studies on surgical technique and intraoperative findings that impact outcomes, as well as the ability to perform prospective validation and real-time implementation of decision-support systems. Natural language processing (NLP) and large language models (LLMs) may offer a streamlined approach to information extraction for clinical workflow, education, research, performance improvement, and billing purposes [3].

The terms and phrases used to characterize surgical techniques and intraoperative findings often contain complex dependencies that span multiple sentences and are best understood in the context of an entire operative note. Furthermore, in retrospective reviews focused on patient outcomes, operative notes serve as a vehicle to identify study participants, with subsequent attention to downstream outcomes often represented in structured data (ie, mortality, surgical site infection, or anastomotic leaks defined by the *International Classification of Disease* codes) [4,5].

For this reason, we frame our problem in terms of a multilabel document classification task [6] where operative notes take on a series of binary labels as to whether or not a certain intraoperative finding (eg, bleeding and contamination) or technique (eg, bowel resection, hand-sewn anastomosis, and style of fascial closure) occurred during the case. Traditional NLP methods, using word frequencies, generally perform well on this task, though can fail to capture context and negation, a noted strength of the attention mechanism in LLMs [7]. Several studies have investigated LLMs for text classification in clinical notes, though to our knowledge, few studies have examined multilabel classification, only one has used generative models, and none have done so in surgical specialties [8-12]. There is a similar paucity of publications using real-world data outside of curated datasets, which, in addition to representing idealized clinical documentation, are also conspicuously devoid of operative notes [13-15].

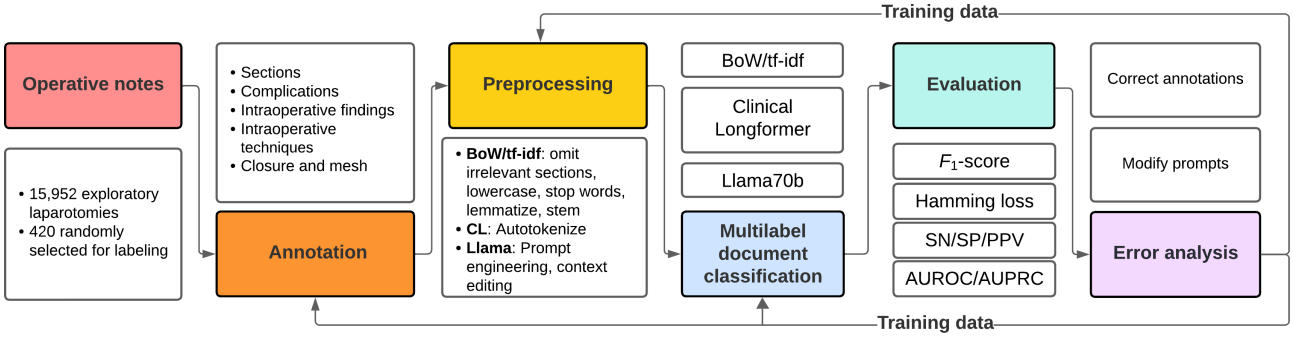
Generative LLMs may offer "off-the-shelf" abilities to capture the multidependency nature of intraoperative findings and surgical techniques. We hypothesize that generative LLMs can outperform fine-tuned encoder-only LLMs and traditional NLP methods in classifying operative notes as containing specific findings and techniques [16].

Methods

Data

Using the University of Florida Health Integrated Data Repository as an honest broker, we assessed 2 single-center, longitudinal electronic health record datasets for all adult patients admitted to a surgical service at University of Florida Health Gainesville and Jacksonville, both quaternary referral centers, between June 1, 2014, and August 22, 2022. We randomly selected 420 fully deidentified exploratory laparotomy operative reports using SQL queries. In total, 32 were found to be mislabeled as "exploratory laparotomy," with no evidence that the abdominal cavity was entered, and so were excluded, leaving 388 notes. As our scope was limited to the operative notes themselves, no surgical outcome, operative metadata, or sociodemographic data were collected.

Ethical Considerations



This study was approved by the University of Florida Institutional Review Board and Privacy Office (IRB#201600262) as an exempt study with a waiver of informed consent. All data used in this study were deidentified. No compensation was provided. This study was performed in accordance with the TRIPOD+LLM (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis+Large Language Model) reporting guideline [17].

Data Preparation

The project workflow is shown in Figure 1. A team of 8 annotators, consisting of medical students (TRB, LMB, YP, A Bilgili, AP, CEC, RU, and DMV) and one surgical resident (JAB), were trained on the project's objectives and annotation software. A detailed annotation manual is provided with definitions, categories, and illustrative examples (Multimedia Appendix 1). An annotated operative note is shown in Multimedia Appendix 2. Emphasis was placed on achieving a high level of consistency, with the goal of reaching a Cohen κ coefficient of above 0.8 for interrater reliability [18]. The first author (JAB) served as the ground truth. A total of 20 operative notes were set aside for annotator training and were reviewed by all annotators. Following training, annotators participated in regular discussions to address any challenges and were reviewed by the first author. Annotations were performed with Label Studio (version 1.8.2; HumanSignal).

XSL•FO
RenderX

Figure 1. Workflow schema. Exploratory laparotomy notes are first extracted and annotated. After preprocessing, they are passed to 4 machine-learning models for multilabel document classification. Models are compared using several performance metrics. Finally, error analysis is performed and all annotation, preprocessing, prompts, and model architectures are modified as necessary on training data to optimize the F_1-score prior to evaluation on test data. AUPRC: area under the precision-recall curve; AUROC: area under the receiver operating characteristic curve; BoW: bag-of-words; CL: Clinical-Longformer; PPV: positive-predictive value; SN: sensitivity; SP: specificity; tf-idf: term frequency-inverse document frequency.

Labels

Notes were annotated for structure, intraoperative findings, and surgical techniques. Whole text spans were highlighted based on note structure: patient or staff or anesthesia personnel information; procedures performed; pre- and postoperative diagnoses; intraoperative findings; indication or history; description of the procedure; ins, outs, and specimens; disposition; and complications. Intraoperative findings included: contamination (class I, II, III, and IV) as defined in the peer-reviewed literature [19]; and bleeding, differentiating between active bleed from a named vessel and active bleed from a solid organ. Whole-document labels were performed for: bowel resection, primary repair of enterotomies, colostomy formation, ileostomy formation, hand-sewn anastomosis, stapled anastomosis, placement of mesh, fascia closure techniques (running or continuous, interrupted, and left open), and skin closure techniques (full, Prevena, partial, and left open). For the training set, Cohen κ across individual labels ranged from 0.39 to 1.0 with a mean and median agreement of 0.67 (SD 0.33) and 0.77 (IQR 0.52-1.0), respectively (Table S1 in Multimedia Appendix 3). The κ scores across all medical students are shown in Table S1 Multimedia Appendix 3. Because this was below our stated goal, additional training was provided with emphasis on these concepts, and each op note in the dataset was personally reviewed by the lead author. A total of 50 notes were annotated by each of the annotators, with the lead author annotating an additional 50.

Data Splitting and Stratification for Class Imbalance

Standard techniques in multilabel classification tasks with label-specific class imbalances may result in datasets missing rare, positive labels [20,21]. To account for this, we performed iterative stratification from scikit-multilearn, splitting the data into 5-fold of training (80%) and test (20%) sets [20-22]. The distributions of the labels in each train and test set are shown in Table S2 in Multimedia Appendix 3.

Unlike other models, the Llama models were not fine-tuned on a hold-out training set. They were instead used to evaluate only the test set in each cross-validation fold.

Models

We studied the traditional NLP multilabel document classification techniques with bag-of-words (BoW) and term frequency-inverse document frequency (tf-idf) approaches paired with logistic regression classifiers, as well as pretrained transformer models, the encoder-only Clinical-Longformer [23], and the decoder-only Llama herd (Llama 3.1 -3b, 8b, 70b, 3.2, and 3.3) [24].

BoW takes tokenized words and performs a classification task based on the frequency of the terms in a particular document. tf-idf applies a weight-based filter on the frequency of a term across a corpus of documents and evaluates the uniqueness of a word to a specific class.

Transformer-based models can leverage contextual information [25]. Encoder models process the entire document by systematically masking these tokens and predicting their values. While encoder models typically excel at classification tasks, their utility is often limited by length, as most models cannot process more than 512 tokens at a time [26]. Longformer models extend that range using both global and sliding-window attention mechanisms [27]. Li et al [23] fine-tuned a Clinical-Longformer model on clinical text from the Medical Information Mart for Intensive Care-III dataset [15] with a context of 4096 tokens, which outperformed Bidirectional Encoder Representations from Transformers (BERT) [28], ClinicalBERT [29], and BioBERT [30] on inference, question-answering, and classification tasks [23]. Finally, autoregressive decoder–only transformers estimate the probability distribution of the next token in a sequence based on the preceding tokens. As they are self-hosted, Llama allows for the secure handling of sensitive patient information and for this reason, these models were selected for this study [24]. The results shown below are the best-performing Llama 3.3 model.

Preprocessing

Notes were reduced to the “description of procedure” as other parts of the note may contain information from previous procedures that may bias the model. For the tf-idf and BoW models, all texts were converted to lowercase, and common stop words (eg, “the,” “and,” and “is,”), punctuation, and numbers were removed. Stemming and lemmatization were performed to reduce words to their root forms (eg, “maturing”

XSL•FO
RenderX

to “mature”). The text was then vectorized as combinations of unigrams, bigrams, trigrams, and 4-grams. We introduced padding to ensure that all sequences had a uniform length. The Clinical-Longformer and Llama models were tokenized using the Hugging Face autotokenizer [31].

Model Hyperparameters

For BoW and tf-idf, we used logistic regression as our classifier. Hyperparameter search within each fold of the training data revealed marginally increased performance with L2-regularization strength of 0.1 and 10 for BoW and TFIDF overall, respectively. No other hyperparameters were modified based on the results of the test set. In the Clinical-Longformer model, we weighted the binary cross-entropy loss for each label inversely proportional to its prevalence in the training set given class imbalance. The model was optimized for the micro F_1-score and trained for up to 500 epochs with early stopping, using a patience of 10 to prevent overfitting. The inference was run on an NVIDIA A100 8GB graphics processing unit in the University of Florida HiPerGator cluster. The Llama 3.3 model had the longest runtime, at 723 minutes.

A custom Python script was developed using the LlamaIndex framework for the Llama model [32]. Each task was a modified version of the annotation instructions, and the model was prompted with the operative note, the context of the task, few-shot instructions, a question, and a desired response format (Multimedia Appendix 4). A general context document was also provided and included brand names of mesh types, a description of types of skin closure, and other domain-specific knowledge that could aid in understanding patient notes and tasks (Multimedia Appendix 5). Given the 5-fold cross-validation design, all notes appeared in at least one test set. As a result, prompts were adjusted based on the model’s generated rationale for randomly selected errors on the whole dataset (eg, differentiating “primary repair” from “anastomosis” or clarifying the use of “prolene” in mesh vs suture contexts). Performance metrics were not evaluated during prompt tuning to avoid test set leakage.

Model Evaluation

Overall performance was evaluated using the micro F_1-score, which calculates the harmonic mean of precision and recall across all classes, and hamming loss (HL), which measures the fraction of misclassified labels relative to the total ground truth labels (with 0 indicating perfect classification). The mean and range of scores over 5 folds were reported. Optimal cutoffs were determined by maximizing the F_1-score in 0.01 increments. Sensitivity, positive predictive value (PPV), specificity, area under the receiver operating curve, and area under the precision-recall curve were also reported. Individual label F_1-scores were calculated using the “binary” average.

Error Analysis

A total of 5 false positive and 5 false negative labels with the highest predicted probabilities were reviewed for each label using the best-performing Clinical-Longformer and Llama model. Several annotation errors were encountered during each iteration which resulted in manual reannotation by the lead author, repeat BoW, tf-idf, and Clinical-Longformer model training, and rerunning of the evaluation pipeline. The reported metrics reflect the latest training and evaluation.

Data Availability and Code

Code and implementation instructions may be found on GitHub [33]. A toy dataset is provided using GPT-generated op notes and random labels.

Results

Data

Of the 388 operative notes, note length ranged from 73 to 1713 words, with a mean of 500 (SD 291) words and a median of 421 (IQR 292-603) words. Most notes were composed by the Trauma and Acute Care Surgery Department (n=267, 68.8%), with the remaining notes in Transplant Surgery (n=83, 21.4%) and Urology (n=30, 7.7%) along with combination cases with Vascular Surgery (n=24, 6.2%), Cardiothoracic Surgery (n=16, 4.1%), and Neurosurgery (n=8, 2.1%). We noted the class imbalance in the labels, as shown in Table 1.

XSL•FO
RenderX

Table . Prevalence of labels in the dataset.

Label	Prevalence
Intraoperative findings	
Active bleeding from the named vessel	0.05
Active bleeding from solid organ	0.11
Class I	0.34
Class II	0.48
Class III	0.16
Class IV	0.14
Intraoperative techniques	
Bowel resection	0.30
Primary repair	0.05
Serosal tear repair	0.05
Colostomy	0.12
Ileostomy	0.08
Hand-sewn anastomosis	0.12
Stapled anastomosis	0.15
Closure techniques	
Fascia closed (interrupted)	0.10
Fascia closed (running or continuous)	0.50
Fascia left open	0.32
Skin closed (full with Prevena)	0.04
Skin closed (full)	0.41
Skin closed (partial)	0.05
Skin left open	0.43
Synthetic	0.06

Collective Performance Across All Labels

Overall mean micro F_1-scores, along with minimum and maximum score per fold, are shown in Table 2. BoW (0.68, 5-fold range: 0.64 - 0.71) outperformed tf-idf (0.57, 5-fold range: 0.55-0.59) overall with an increase in micro F_1-score of 0.1 and a decrease in HL of two-fold. Comparing the encoder-only and decoder-only model architectures, Llama 3.3 (0.88, 5-fold range: 0.88-0.89) had generous improvement overall in the micro F_1-score with equivalent HL to BoW and Clinical-Longformer.

We compared the Llama 3 series of models and observed a general trend of improved performance with increasing model size. An exception was Llama 3.2, which performed poorly—consistent with prior reports of its reduced effectiveness on medical datasets [34]. Results are presented in Figure S1 in Multimedia Appendix 6.

Table . Mean overall performance of models across all labels across all 5-folds[a].

Model	Micro F_1-score, mean (range)	Hamming loss, mean (range)
BoW[b]	0.68 (0.64-0.71)	0.14 (0.13-0.16)
tf-idf[c]	0.57 (0.55-0.59)	0.27 (0.25-0.29)
Clinical-Longformer	0.73 (0.70-0.74)	0.11 (0.10-0.12)
Llama 3.3	0.88 (0.88-0.89)	0.12 (0.11-0.12)

[a]Values in parentheses indicate the minimum and maximum performance.

[b]BoW: bag-of-words.

[c]tf-idf: term frequency-inverse document frequency.

RenderX

Individual Label Performance

F_1-scores with ranges for the individual labels are visualized in Figure 2 and shown numerically in Tables 3-5. Intraoperative bleeding was well categorized by the Llama model, while surgical wound class was often better served by Clinical-Longformer or BoW models (Figure 2A). For the intraoperative technique (Figure 2B), the Llama model was the highest performer, with the Clinical-Longformer and BoW models performing with overlapping F_1-scores. Intraoperative and skin and fascial closure techniques were best served by the generative model. We noted excellent performance for the Llama 3.3 model in several categories with F_1-scores ≥0.8. Of note, there was surprisingly poor performance on the Prevena label across all models, given that the brand name should often cue a positive class. Interrupted fascial closure was also noticeably poor, despite how this is often specifically stated in the operative note.

Tables 3-5 demonstrate numeric values of the F_1-scores alongside sensitivity and PPVs. The Llama model was again the best performing overall with the notable exception of class II and stapled anastomosis labels. While the PPV of Llama was overall better, it performed poorly in 2 skin closure tasks, class III contamination task, and stapled anastomosis task. Full metrics across all models and labels are shown in Table S3 in Multimedia Appendix 3.

Context

We evaluated performance on the Llama 3.1-70b model with and without the context document. The model performed better overall with the context, with an average improvement of 0.16 in the F_1-score (Figure S2 in Multimedia Appendix 6). The context offered the greatest improvement in serosal tear repair (+0.4) and the context hurt model performance in class III (−0.19) and stapled-anastomosis (−0.08) labels.

Error Analysis

A manual review of 5 false negative and positive per label in the encoder-only and decoder-only models revealed several trends in errors, though often it was unclear why a model made a particular prediction. Overall, 88 annotations (0.01% of all annotations) were changed upon review, mostly in bowel resection (n=21), hand-sewn anastomosis (n=19), active bleed from solid organ (n=17), and serosal tear repair (n=13).

Examining the 3 overarching categories, for the encoder-only LLM, bleeds were often picked up, though generally any presence of bleeding was marked positive, regardless of its origins. For intraoperative techniques, false negative instances of bowel resection labels had a clear bowel resection performed in the case. False positives, however, occurred when previous bowel resections were mentioned in the operative report. This was especially true for take-back surgeries when the abdomen is left open because of the need for further surgery. For the ostomy concepts, the most common error was secondary to an ileostomy or colostomy take down (as opposed to creation) or a situation in which the bowel was left in discontinuity with discussion in the operative report of placing an ostomy later. For anastomosis, errors were often likely due to the presence of a stapled resection or the use of the stapler to create a common channel. For closure, fascial closure errors occurred in several cases where a thoracotomy was performed in the same operation as a laparotomy, resulting in the closure of one anatomic fascia and not another. Skin closure failures appeared to be confounded when multiple services operated on the same patient. Partial skin closures were underrepresented in the dataset and the model tended to predict partial closure on both full-closure and open skin with equal affinity.

For the decoder-only model, we had Llama provide explanations for its choice and the explanations along with the findings drove changes in prompting strategies. Performance on bleeding was overall excellent, however, “oozing” from an organ bed or resection was often assigned as “active bleed,” which our annotators and prompts were instructed to mark as negative. For intraoperative techniques, there were commonalities in errors with the Clinical-Longformer model, with prior bowel resections, ostomy takedowns, and instances where both stapled and hand-sewn anastomoses were performed in the same operation. Fascial closures were obscured by the presence of

XSL•FO
RenderX

interrupted retention sutures. Several open skin closures were marked as both open and partial skin closures. For skin closure with Prevena and with the exception of some runs of Llama 3.3, the model appeared to simply not understand the instructions despite multiple prompting attempts.

Contamination was difficult to assess for both annotators and models and this information is not always clearly stated in operative reports. Identifying breaches in sterile techniques, purulent versus nonpurulent inflammation, and whether entry into a hollow organ resulted in spillage requires careful description. The generative model often assumed any entry to the abdominal cavity made for Class II or above, despite modifications to prompting techniques. Future studies will extract the attending surgeon attestation for ground truth labels of wound class, which may improve model performance.

Discussion

Principal Results

Generative LLMs outperformed fine-tuned encoder-only LLMs and traditional NLP models in a multilabel classification task across the majority of labels. Overall F_1-scores ranged from 0.57 for tf-idf to 0.88 for Llama 3.3. On individual labels, we had F_1-scores of ≥0.8 for multiple classes.

Retrospective analyses drive decision support, quality improvement initiatives, and billing workflows, yet they are limited not only by the intensive manual review process but also by the variable interrater reliability with human labeling [35,36]. To overcome these limitations, we frame operative concept identification as a multilabel document classification task and observe that the autoregressive Llama 3.3 model outperformed both traditional NLP techniques, the Longformer encoder model, and previous versions of the Llama herd.

State-of-the-art clinical NLP tasks rely on transformer-based, foundational LLMs [25,37,38]. They have been used in the well-studied NLP tasks of medical questioning and answering [25,39-41], summarization [16,23,42], named-entity recognition [30,43-46], and document classification [23,47-49]. Studies have largely focused on progress notes, histories and physicals, and discharge summaries, with an interest in the concepts of medications, diseases, and social determinants of health. There are fewer studies on operative notes and available research focuses on word embeddings for prediction tasks rather than individual entities [50-52]. Furthermore, even fewer works have been published using state-of-the-art transformers and foundational LLMs in surgery [53]. This is to our detriment as surgeons, as LLMs are capable of zero-shot learning (the ability to perform tasks without prior examples) and, if performing reliably, may obviate the need for manual chart review in retrospective research [38]. To our knowledge, this paper is the first to explore operative concepts using LLMs as a multilabel classification task in surgery.

Comparison With Prior Work

Compared with other document classification tasks, our model compared well. A previous multilabel documentation task on chest x-ray reports showed that pretrained models had F_1-score ranges of 0.29 to 0.48 [23]. Notably, traditional BoW-based approaches performed well across many classes. This is not surprising, as depending on the concept, the presence of a word or phrase in operative notes is often sufficient to identify it in text. tf-idf likely underperformed compared to BoW due to the dataset size: limited term frequencies and few documents may favor equal representations of words compared with weighted representations [54]. For many tasks, context may simply not be important. For example, negation is less commonly used, as surgeons will typically describe what they did rather than explain what they did not. In terms of the F_1-score, the generative model offered the most benefit in identifying active bleeding, bowel resection, serosal tear repair, and closure techniques, which are highly context-dependent and rely on the integration of up to several sentences of information. Notably, Clinical-Longformer did not offer much benefit over the BoW model. This may be secondary to the fact that Medical Information Mart for Intensive Care-III does not contain comprehensive operative notes [15].

Limitations

This study has several limitations. First, exploratory laparotomies represent a difficult case for both human and machine understanding. These operations are, by definition, exploratory, often performed in an emergent setting, can require input from multiple surgical services, and present challenging traumatic and aberrant anatomy. Thus, the language may be less consistent than elective procedures. Nevertheless, we chose basic operative concepts and a common procedure to start our investigation into multilabel document classification. Second, understanding operative reports requires highly technical knowledge. Training annotators, including those with clinical experience, presents challenges, and, despite regular review, there may be instances of inaccurate labeling. To maximize the number of notes, we did not perform a second round of interrater reliability testing, though each note was reviewed by the lead author. As with many other studies, this points to the potential for variability in human annotation, and granting consistency of model outputs may show the potential advantages of LLM augmentation for this task. Third, we acknowledge that the 5-fold training and testing mechanism may result in overly optimistic performance in the BoW, tf-idf models, and Clinical-Longformer models. However, despite this, the untrained Llama model still outperformed the three other classifiers. Fourth, during prompt tuning, we evaluated a random limited subset of the data during exploration, raising the possibility of data leakage. However, we did not examine performance metrics during prompt tuning and focused on model reasoning rather than the label choice itself. Fifth, the distribution of predictions varied by label in BoW, tf-idf, and Clinical-Longformer, though many were left-skewed, suggesting low confidence. More data may improve the performance of these models.

Conclusions

Given the performance of the off-the-shelf generative model, future studies will incorporate multiple labeled datasets from previous and ongoing retrospective studies at our institution with the goal of human-in-the-loop, streamlined extraction of operative concepts integrated into the research workflow. Future

XSL•FO
RenderX

work in agentic retrieval augmented generation with hybrid approaches of keyword search and semantic matching may fit this purpose well [55,56]. We noted improvements in model performance using larger Llama models, a trend we expect to continue as more advanced models are released.

While the use of multilabel document classification may be used to reliably capture select operative concepts with LLMs, further investigation of edge cases and alternative model architectures, such as retrieval augmented generation, will be required prior to deployment for research and quality improvement purposes.

Abstract

Background: Emergency medicine can benefit from artificial intelligence (AI) due to its unique challenges, such as high patient volume and the need for urgent interventions. However, it remains difficult to assess the applicability of AI systems to real-world emergency medicine practice, which requires not only medical knowledge but also adaptable problem-solving and effective communication skills.

Objective: We aimed to evaluate ChatGPT's (OpenAI) performance in comparison to human doctors in simulated emergency medicine settings, using the framework of clinical performance examination and written examinations.

Methods: In total, 12 human doctors were recruited to represent the medical professionals. Both ChatGPT and the human doctors were instructed to manage each case like real clinical settings with 12 simulated patients. After the clinical performance examination sessions, the conversation records were evaluated by an emergency medicine professor on history taking, clinical accuracy, and empathy on a 5-point Likert scale. Simulated patients completed a 5-point scale survey including overall comprehensibility, credibility, and concern reduction for each case. In addition, they evaluated whether the doctor they interacted with was similar to a human doctor. An additional evaluation was performed using vignette-based written examinations to assess diagnosis, investigation, and treatment planning. The mean scores from ChatGPT were then compared with those of the human doctors.

Results: ChatGPT scored significantly higher than the physicians in both history-taking (mean score 3.91, SD 0.67 vs mean score 2.67, SD 0.78, $P<.001$) and empathy (mean score 4.50, SD 0.67 vs mean score 1.75, SD 0.62, $P<.001$). However, there was no significant difference in clinical accuracy. In the survey conducted with simulated patients, ChatGPT scored higher for concern reduction (mean score 4.33, SD 0.78 vs mean score 3.58, SD 0.90, $P=.04$). For comprehensibility and credibility, ChatGPT showed better performance, but the difference was not significant. In the similarity assessment score, no significant difference was observed (mean score 3.50, SD 1.78 vs mean score 3.25, SD 1.86, $P=.71$).

Conclusions: ChatGPT's performance highlights its potential as a valuable adjunct in emergency medicine, demonstrating comparable proficiency in knowledge application, efficiency, and empathetic patient interaction. These results suggest that a collaborative health care model, integrating AI with human expertise, could enhance patient care and outcomes.

Introduction

Recent advancements in artificial intelligence (AI) have raised interest in its potential to complement or even replace human expertise across various fields, particularly in medicine [1]. AI systems, such as ChatGPT (OpenAI), have demonstrated notable clinical capabilities, including success in professional medical examinations like the United States Medical Licensing Examination [2]. In a study by Sarraju et al [3], conversational generative AI models provided appropriate responses to 84% of questions on cardiovascular disease prevention, demonstrating their capability to handle open-ended clinical prompts rather than multiple-choice questions. In subsequent studies, ChatGPT has shown promise in more complex tasks, providing knowledge and management recommendations for hepatic cirrhosis and hepatocellular carcinoma [4]. Furthermore, Ayers et al [5] reported that ChatGPT generated empathetic responses to patient inquiries on a web-based platform comparable to those of human physicians, underscoring its potential to engage effectively with patients.

Emergency medicine is characterized by an urgent need for rapid diagnosis and immediate treatment. The high patient load and strict time constraints in emergency departments increase the risk of essential clinical information being overlooked or misinterpreted, including symptom presentation and diagnostic test results [6,7]. In addition, extended shifts, often spanning 24 hours, contribute to clinician fatigue and the risk of human error. AI technologies offer promising solutions to these challenges by enabling rapid, fatigue-free data processing. These challenges have motivated initiatives to integrate AI into emergency settings, particularly to enhance diagnostic speed and accuracy in radiology [8]. However, the implementation of AI in emergency medicine remains constrained by technical and operational challenges [9-11]. Emergency practice demands not only technical proficiency but also the flexibility to adapt swiftly to evolving conditions and effective communication skills to engage with patients in high-stress situations. Recent advancements in large language models (LLMs) have introduced conversational interfaces that can adapt responsively to new information, potentially aligning well with the dynamic demands of emergency medicine [12]. However, there remains a lack of research on the application of AI in emergency medicine within environments that closely resemble real-world clinical settings, as many studies have been limited to assessing the ability of AI to solve static examination-based questions rather than clinical practice-based problems [13,14].

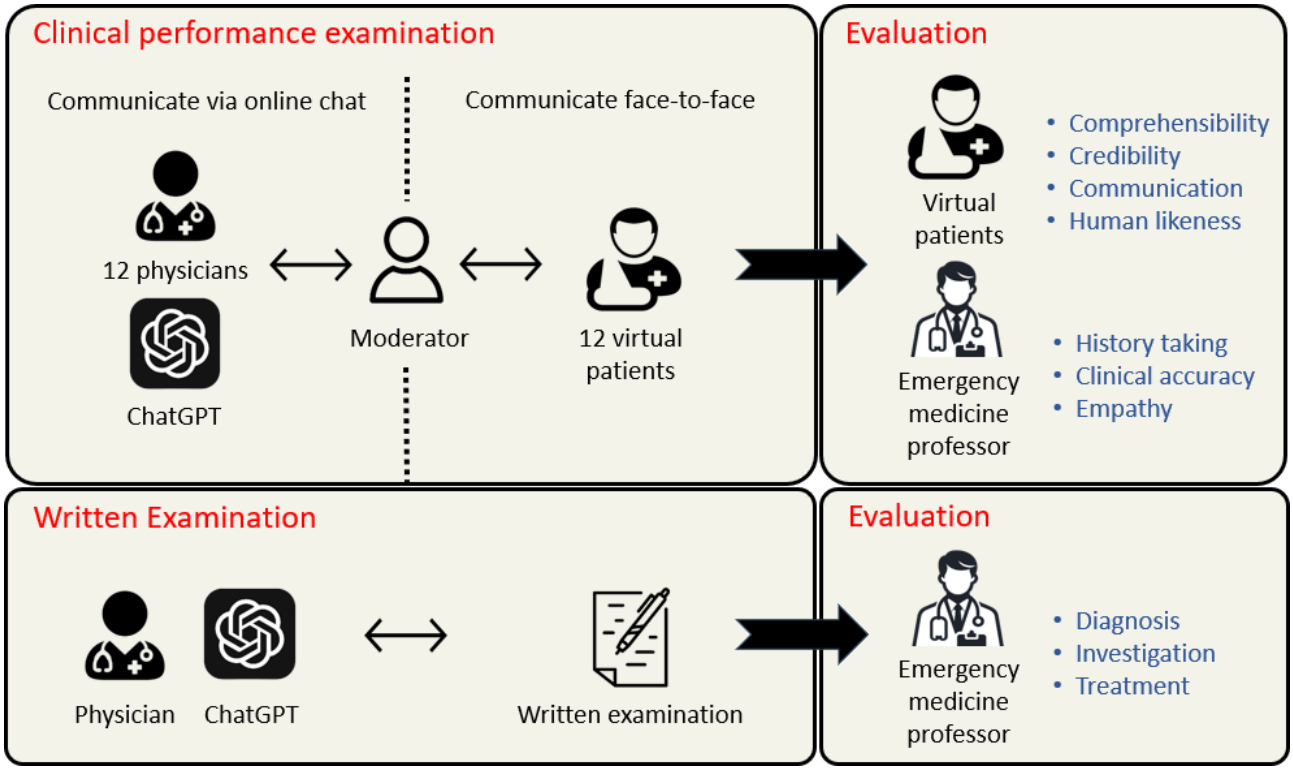
The clinical performance examination (CPX) is a form of testing that assesses problem-solving skills in real-world–like clinical situations with simulated patients. It was developed from the recognition that assessing a physician's clinical skills cannot be fully achieved through traditional examination formats [15]. The CPX provides a dynamic approach to evaluating and refining essential competencies in simulated real-world settings. Through CPX, participants engage in history taking, communication, and patient relationship management and receive feedback for continuous improvement. Studies have shown that CPX enhances physicians' diagnostic accuracy, communication skills, and adaptability in clinical interactions, all of which are crucial in the field of emergency medicine [16,17]. Furthermore, CPX allows for the assessment of nontechnical skills, such as empathy, which is difficult to evaluate through conventional examination-based scenarios [18]. This ability to observe both technical and interpersonal skills offers a more comprehensive approach, aligning closely with the complex demands of emergency medicine practice.

In this study, we aimed to evaluate ChatGPT within the context of emergency medicine using a framework of CPX combined with a written examination, comparing its performance to that of human doctors. Through this comparative analysis, we sought to provide a deeper understanding of how AI can effectively augment clinical practice, enhance decision-making processes, and support health care professionals.

Methods

Ethical Considerations

This cross-sectional study received ethical approval from the institutional review board of Ajou University Medical Center (approval AJOUIRB-OB-2024 - 277). To maintain the confidentiality of participants, all identifying information has been appropriately anonymized or omitted, and informed consent (Multimedia Appendix 1) was obtained from all participants before their involvement in the study. All research methods were conducted in accordance with the Declaration of Helsinki. The study did not involve any form of participant remuneration.



Study Design

The overall study flow is illustrated in Figure 1. This study aimed to compare the performance of ChatGPT and human doctors in simulated emergency medicine scenarios using 2 approaches—CPXs and conventional written examinations.

In the CPX, simulated patients represented standardized clinical cases. ChatGPT and human doctors participated in patient consultations via a neutral moderator to ensure blind evaluation. After each consultation, the emergency medicine professor evaluated the consultation from full conversation scripts. Simulated patients independently rated their consultation experiences.

XSL•FO
RenderX

Figure 1. Flow diagram of the study.

In the written examination, ChatGPT and human doctors were provided with clinical vignettes describing chief complaints and relevant medical history. They were instructed to identify the most likely diagnosis, suggest appropriate diagnostic investigations, and recommend a suitable treatment plan. The answers were evaluated by an emergency medicine professor.

The primary objective of this study was to compare the clinical competency of ChatGPT and human doctors in the emergency medicine clinical settings in CPX and written examination formats. The secondary objective was to compare patient-reported experience, as evaluated by simulated patients during the CPXs.

Case Selection

For the CPX, 4 representative cases were selected from 100 Cases in Emergency Medicine and Critical Care by Shamil et al [19]. The selected cases—malaria, acute asthma exacerbation, metastatic spinal cord compression, and acute kidney injury—were chosen based on their clinical urgency and the need for comprehensive symptom assessment and differential diagnosis. In addition, 28 text-based scenarios and 4 image-based clinical vignettes, along with corresponding questions, were selected for the written examinations. The selection was designed to include diverse representations across 16 different specialties, such as cardiology, pediatrics, and obstetrics, with a focus on scenarios commonly encountered in emergency care. For cases involving imaging, an electrocardiogram demonstrating atrial fibrillation, a brain computed tomography scan indicating subarachnoid hemorrhage, a chest x-ray showing a rib fracture, and a knee x-ray of a patient presenting with a knee injury were included in the case presentations. Detailed information about the cases that used written examinations in the study, including each patient's chief complaint and diagnosis, is presented in Table 1.

XSL•FO

Table . Chief complaints, medical specialties, and diagnosis of cases included in the study.

Case number	Chief complaint	Medical specialty	Disease	Type[a]	Reference[b]
Case 1	Fever, headache, and a rash	Infectious medicine	Bacterial meningitis	1	5
Case 2	Dysuria and weakness	Infectious medicine	Urinary tract infection	1	18
Case 3	Slurred speech and weakness	Neurology	Ischemic stroke	1	41
Case 4	Severe epigastric pain	General surgery	Perforated peptic ulcer	1	60
Case 5	Epigastric pain and nausea	Gastroenterology	Acute pancreatitis	1	64
Case 6	A child acutely short of breath	Pediatrics	Severe asthma exacerbation	1	83
Case 7	Headache in pregnancy	Obstetrics and gynecology	Pre-eclampsia	1	95
Case 8	Shortness of breath and painful swallowing	Otolaryngology	Supraglottitis	1	3
Case 9	Nausea and vomiting in a diabetic	Endocrinology	Diabetic ketoacidosis	1	6
Case 10	Feeling unwell while on chemotherapy	Oncology and hematology	Neutropenic sepsis	1	24
Case 11	Cat bite	Orthopedics surgery	Tenosynovitis	1	50
Case 12	Left iliac fossa pain with fever	Gastroenterology	Diverticulitis	1	61
Case 13	Abdominal pain in early pregnancy	Obstetrics and gynecology	Ectopic pregnancy	1	89
Case 14	Breathlessness in pregnancy	Obstetrics and gynecology	Pulmonary embolism	1	96
Case 15	A productive cough	Respiratory medicine	Acute exacerbation of chronic obstructive pulmonary disease	1	16
Case 16	Productive cough and shortness of breath	Respiratory medicine	Bacterial pneumonia	1	25
Case 17	Acute severe leg pain	Cardiology	Acute ischemia	1	62
Case 18	Right flank pain moving to the groin	Urology	Kidney stone	1	66
Case 19	Worsening ear pain	Otolaryngology	Acute otitis media	1	69
Case 20	Cough and difficulty breathing in an infant	Pediatrics	Bronchiolitis	1	78
Case 21	Pelvic pain	Obstetrics and gynecology	Ovarian cyst torsion	1	91
Case 22	A collapse at work	Cardiology	Massive pulmonary embolism	1	17
Case 23	Upper abdominal pain	General surgery	Acute cholecystitis	1	57
Case 24	Abdominal pain and nausea	General surgery	Acute appendicitis	1	63
Case 25	Ear pain with discharge and facial weakness	Otolaryngology	Malignant otitis media	1	71
Case 26	A swollen eyelid	Ophthalmology	Periorbital preseptal cellulitis	1	73
Case 27	My son has the “runs”	Pediatrics	Gastroenteritis	1	81

RenderX

Case number	Chief complaint	Medical specialty	Disease	Type[a]	Reference[b]
Case 28	Abdominal pain and vaginal discharge	Obstetrics and gynecology	Pelvic inflammatory disease	1	92
Case 29	An abnormal electrocardiogram	Cardiology	Atrial fibrillation	2	30
Case 30	Headache, vomiting, and confusion	Neurosurgery	Subarachnoid hemorrhage	2	39
Case 31	Twisted my knee skiing	Orthopedic surgery	Rupture of the anterior cruciate ligament	2	53
Case 32	My ribs hurt	Cardiothoracic surgery	Traumatic pneumothorax	2	59

[a]The written examination consisted of two types of questions: (1) text-based questions, and (2) image-included questions.

[b]The questions were developed based on emergency medicine patient cases from the reference "100 Cases in Emergency Medicine and Critical Care" by Shamil et al [19]. The numbers provided correspond to those accessible in the reference.

Human Doctors and ChatGPT in CPX

In total, 12 human doctors were recruited to represent the medical doctors, comprising 4 third-year emergency medicine residents, 4 fourth-year emergency medicine residents, and 4 general practitioners (GPs) from a tertiary hospital in South Korea. Before participating in the CPX with simulated patients, physicians received general instructions for the examination process (Table S1 in Multimedia Appendix 2). They were informed that all conversations with simulated patients would be conducted via text-based communication through a moderator. They were directed to approach each case as if practicing in a real clinical setting, with the understanding that the information necessary for diagnosis and treatment planning could be obtained by asking questions to the simulated patients.

ChatGPT (version 4.0) was used in this study, with all examinations conducted between September and October 2023. For ChatGPT, a prompt designed to emulate the role of a medical professional was provided (Table S2 in Multimedia Appendix 2). ChatGPT was instructed to perform history taking and, when a physical examination was required, to obtain relevant information through targeted questions. In addition, it was directed to communicate possible diagnoses to the patient and to provide explanations regarding necessary tests and treatment plans.

Interaction With Simulated Patients in CPX

In total, 12 volunteers were recruited as simulated patients and evenly distributed across 4 clinical scenarios, with 3 simulated patients assigned to each scenario. Each simulated patient participated in 2 separate consultations, presenting their assigned case to both ChatGPT and a human doctor. Depending on the allocation, each simulated patient conducted 1 consultation with ChatGPT and 1 with either a third-year emergency medicine resident (R3), a fourth-year resident (R4), or a GP.

Before the CPX, each patient reviewed their assigned case and received instructions on their role (Table S3 in Multimedia Appendix 2). They were informed that all responses would be delivered through a moderator and that they would participate in 2 consultations, 1 with a human doctor and 1 with ChatGPT. They were also notified that their experience would be evaluated afterward.

During the CPX, patients did not interact face-to-face with either ChatGPT or the physicians; instead, they communicated with assistance from a moderator. All questions from doctors or ChatGPT were provided to patients as text by the moderator, and patients' responses were similarly relayed in text form by the moderator to maintain consistency. This indirect communication process ensured that patients were blinded to whether they were interacting with ChatGPT or a human doctor. To standardize message formats, doctors' messages were edited to remove typos and to consolidate brief questions where appropriate (eg, "Do you take any other medications? Like for a cold?" was revised to "Are you taking any other medications, such as cold medicine?"). Although the protocol advised posing one question at a time, some questions were grouped by physicians and later separated by the moderator for consistency. Given ChatGPT's quicker response capability, its message delivery was deliberately slowed to mirror a doctor's pace. No additional modifications were made to ChatGPT's messages.

Written Examinations

The written examination consisted of 28 text-based clinical cases and 4 image-containing clinical cases. Before the examination, both physicians and ChatGPT were provided with written instructions outlining the format of the test. These included a sample case, sample question and answer, and detailed scoring criteria to ensure consistency in understanding and response approach. The full instructions are presented in Table S3 in Multimedia Appendix 2.

A total of 4 GPs, 4 third-year emergency medicine residents (R3s), and 4 fourth-year residents (R4s) each completed 7 cases, resulting in 28 responses for text-based clinical cases per group. ChatGPT also provided answers to all 28 cases. In addition, 4 image-based clinical cases were evaluated. Due to concerns regarding potential interpretive inaccuracies, GPs did not participate in the image-based clinical cases. Each of the 4 R3s and 4 R4s completed all 4 cases, yielding 32 responses for image-based cases. ChatGPT also completed all 4 image-based cases.

Detailed instructions, including sample questions and grading criteria, were provided to both ChatGPT and the doctors. (Table S4 in Multimedia Appendix 2). The grading criteria

XSL•FO
RenderX

encompassed the number of correct keywords, the specificity of responses, and the presence of any inappropriate content.

Assessment of Outcomes

The conversations were evaluated by a professor of emergency medicine actively involved in resident education. To assess the clinical performance of ChatGPT and physicians, the professor reviewed all conversations and assigned scores from 3 perspectives for each consultation on a 5-point Likert scale (with 1 being very poor and 5 being excellent). These scores included a history-taking score for the thoroughness of information gathering, a clinical accuracy score evaluating the medical correctness of diagnoses and treatment plans, and an empathy score reflecting the degree of attentiveness and responsiveness to the patient's concerns. For the written examination, which included 3 questions on diagnosis, investigation, and treatment planning, responses from both ChatGPT and the physicians were evaluated by the emergency medicine professor. Scores were assigned for accuracy on a 6-point Likert scale (where 1 indicated incorrect and 6 indicated completely correct) and for completeness on a 3-point Likert scale (where 1 indicated incomplete and 3 indicated comprehensive).

In addition, all virtual patients participating in the CPX completed a 5-point scale survey consisting of 7 questions to evaluate the consultations from multiple perspectives. They assessed the overall comprehensibility and credibility of the consultation, as well as its effectiveness in alleviating patient concerns. Patients also evaluated the credibility and communication of the diagnosis and treatment plan provided by either the physician or ChatGPT. Finally, patients were asked to assess whether the consulting entity seemed more like ChatGPT or a human doctor.

Statistical Analysis

Scores were presented as mean and SD. We evaluated each performance domain separately rather than combining them into a single score. Mean scores for each domain were calculated separately and compared between ChatGPT and the human doctor group. Group comparisons were conducted for each domain independently using either independent-sample *t* tests or Mann-Whitney *U* tests according to the distribution of the data. In the written examinations, questions were further categorized into easy, medium, and hard levels based on the scores of the physicians. Performance between physicians and ChatGPT was then compared across these defined difficulty levels. A post hoc power analysis was conducted for the CPX outcomes evaluated by the emergency medicine professor based on the observed effect sizes. Effect sizes were estimated using Cohen *d* or rank-biserial correlation, and statistical power was estimated based on these observed effect sizes. A *P* value of less than .05 was considered statistically significant. All statistical analyses were performed using R software, version 4.3.1 (R Core Team).

Results

CPX

The results from the CPX of ChatGPT and physicians, based on grading by the emergency medicine professor and patient survey responses, are summarized in Table 2. ChatGPT scored significantly higher than physicians in history taking (mean 3.91, SD 0.67 vs mean 2.67, SD 0.78; $P<.001$). Although ChatGPT also achieved a higher score in clinical accuracy (mean 3.75, SD 0.45 vs mean 3.33, SD 0.98), the difference was not statistically significant ($P=.25$). In terms of empathy, ChatGPT scored an average of 4.50 (SD 0.67), whereas physicians scored 1.75 (SD 0.62), falling below the "poor" rating threshold of 2. This difference was statistically significant ($P<.001$), highlighting ChatGPT's superior empathetic engagement. Post hoc power analysis revealed that the history taking and empathy scores had high statistical power (0.98 and 0.99, respectively). In contrast, the clinical accuracy score showed low power (0.22), indicating a limited ability to detect significant group differences for this outcome.

Results from a survey completed by a virtual patient immediately after each CPX session showed that ChatGPT scored slightly higher than the human physicians across all categories. However, a statistically significant difference was only observed in the concern-reduction score, which measured the extent to which the consultation alleviated the patient's worries (ChatGPT: mean 4.33, SD 0.78 vs physicians: mean 3.58, SD 0.90; $P=.04$). In addition, for the similarity assessment score, which evaluated whether the consultant appeared more like ChatGPT or a human physician, no significant difference was found ($P=.71$). Full records of the conversations between ChatGPT and the physicians with virtual patients during the CPX, along with the scores assigned by the emergency medicine professor and their distributions, are available in Multimedia Appendix 3.

XSL•FO
RenderX

Table . Results from the clinical performance examination of ChatGPT and physicians (all scores were assigned using a 5-point Likert scale, where 1 signifies "very poor," 2 "poor," 3 "average," 4 "good," and 5 "excellent"; for the similarity score, the scale was as follows: 1 indicated "very similar to ChatGPT," 2 "somewhat similar to ChatGPT," 3 "neutral, neither ChatGPT nor a real doctor," 4 "somewhat similar to a real doctor," and 5 denoted "very similar to a real doctor").

Score	ChatGPT, mean (SD)	Overall physicians (n=12), mean (SD)	*P* value	GP[a] (n=4), mean (SD)	R3[b] (n=4), mean (SD)	R4[c] (n=4), mean (SD)
Grading results from an emergency medicine professor						
History taking score	3.91 (0.67)	2.67 (0.78)	<.001	2.75 (0.50)	2.75 (0.50)	2.50 (1.29)
Clinical accuracy score	3.75 (0.45)	3.33 (0.98)	.25	2.75 (0.96)	3.75 (0.50)	3.50 (1.29)
Empathy score	4.50 (0.67)	1.75 (0.62)	<.001	1.50 (0.58)	2.00 (0.82)	1.75 (0.50)
Survey results from virtual patients						
Overall consultation						
Comprehensibility score	4.67 (0.49)	4.50 (0.52)	.43	4.75 (0.50)	4.00 (0.00)	4.75 (0.50)
Credibility score	4.42 (0.51)	3.92 (0.79)	.10	4.00 (0.82)	3.50 (0.58)	4.25 (0.96)
Concern reduction score	4.33 (0.78)	3.58 (0.90)	.04	3.75 (0.50)	3.50 (1.29)	3.50 (1.00)
Diagnosis						
Evaluation score	4.75 (0.45)	4.41 (0.67)	.20	5.00 (0.00)	3.75 (0.50)	4.50 (0.58)
Investigation and treatment plan						
Credibility score	4.50 (0.52)	4.17 (0.83)	.36	4.00 (0.82)	4.00 (1.15)	4.50 (0.58)
Communication score	4.42 (0.79)	4.00 (0.95)	.26	3.75 (0.50)	3.50 (1.29)	4.75 (0.50)

Assessment score	3.50 (1.78)	3.25 (1.86)	.71	2.75 (2.06)	3.25 (2.06)	3.75 (1.89)

[a]GP: general practitioner.

[b]R3: third-year emergency medicine resident.

[c]R4: fourth-year emergency medicine resident.

Written Examinations

The grading outcomes of the written examination are summarized in Table 3. ChatGPT achieved higher scores across all categories—diagnosis, investigation, and treatment plan—than the physicians. The mean accuracy scores for ChatGPT were 5.44 (SD 0.72), 5.38 (SD 0.55), and 5.59 (SD 0.50), significantly exceeding the physicians' scores of 4.11 (SD 1.10), 3.67 (SD 0.93), and 3.74 (SD 0.98), respectively (*P*<.001 for all comparisons). Similarly, ChatGPT's mean completeness scores were substantially higher, with averages of 2.84 (SD 0.37), 2.56 (SD 0.50), and 2.94 (SD 0.25), compared with the physicians' scores of 1.84 (SD 0.45), 1.84 (SD 0.37), and 1.72 (SD 0.45) for each category, respectively (*P*<.001 for all). Detailed accuracy and completeness scores of the physicians and ChatGPT for all cases are presented in Figure 2. Complete answer sheets for the written examination provided by the physicians and ChatGPT and the scores assigned by the professor and their distributions are all included in Multimedia Appendix 4.

The differences in scores between ChatGPT and the physicians were further analyzed across various difficulty levels of the written examination questions (Figure 3). The scores for both accuracy and completeness were significantly higher for ChatGPT than for the physicians across all difficulty levels (*P*<.001, for all). Notably, the gap in scores between ChatGPT and the physicians widened on questions of higher difficulty, where the physicians' scores were lower.

Discussion

Principal Findings

In this study, we compared the performance of ChatGPT and human doctors using 2 evaluation formats—CPX and written examinations. In the CPX, evaluations were conducted by an emergency medicine professor and virtual patients. ChatGPT received significantly higher scores than human doctors in the domains of history taking and empathy. Although ChatGPT showed a higher mean score in clinical accuracy, the difference was not statistically significant.

In the virtual patient evaluations, ChatGPT achieved higher mean scores across all domains, including comprehensibility, credibility, and communication. However, a statistically significant difference was observed only in the concern reduction domain. When virtual patients were asked to evaluate human-likeness, there was no significant difference between ChatGPT and human doctors, indicating that patients did not perceive a substantial distinction in human-likeness between the two.

Regarding the written examinations, ChatGPT demonstrated significantly higher scores than human doctors in most domains evaluated by the emergency medicine professor, including diagnosis, investigation, and treatment planning. This trend was consistent across both text-based and image-based clinical questions. In addition, when questions were stratified based on difficulty levels determined by human doctor scores, ChatGPT's performance remained relatively stable, showing minimal variation according to question difficulty.

Comparison With Previous Work

The clinical utility of ChatGPT and other LLMs has been increasingly investigated in the field of emergency medicine. Previous studies have demonstrated that LLMs can effectively support patient triage and identify cases requiring critical care based on clinical scenarios, highlighting their potential to assist in acute decision-making processes [20,21]. In addition, ChatGPT has shown promising performance in interpreting electrocardiogram-related questions and providing reliable guidance for imaging test referrals [22,23]. Our findings from the written examinations are consistent with previous studies, further supporting the potential of ChatGPT as a clinical decision support tool in emergency medicine. We extended previous research by evaluating not only the accuracy but also the completeness of responses in open-ended, case vignette–based assessments. A similar finding was reported in a previous study, in which ChatGPT provided more extended responses than those of physicians without compromising quality when answering patients' questions on a public online forum [5]. This ability to generate comprehensive answers without relying on predefined options is promising for the future application of ChatGPT in real clinical settings within emergency medicine.

However, most previous studies have relied on examination-based assessments, which may oversimplify clinical reasoning by limiting diagnostic flexibility and excluding the iterative, hypothesis-driven nature of real-world medical consultations and patient interactions [24]. Our study addresses this limitation by implementing a CPX format, which enables a more in-depth evaluation of AI performance in scenarios that closely resemble actual clinical practice. This methodology allowed us to assess ChatGPT's capabilities in a dynamic, human-like context that simulates instantaneous decision-making.

In this study, we found that ChatGPT performed significantly better in history taking, while demonstrating clinical accuracy comparable to that of human doctors. Although previous studies have examined the use of chatbots for history taking, most were developed for narrowly defined purposes or relied on fixed sets of predefined questions presented in conversational form [25]. In contrast, our findings show that a general-purpose conversational AI can actively engage in clinical reasoning and elicit relevant patient history through interactive dialogue. This suggests that the integration of such AI tools into clinical

XSL•FO
RenderX

workflows may enhance the quality of history taking and ultimately improve patient care.

We also found that ChatGPT received higher empathy scores and greater concern reduction ratings from patients. More empathetic responses from ChatGPT compared with human doctors have also been observed in previous studies [5,26], and our findings extend this evidence by evaluating full conversational interactions. These results suggest that AI models may not only support clinical reasoning but also complement physicians in areas often compromised under high-stress conditions, such as patient-centered communication and emotional engagement.

Interestingly, patients were unable to distinguish whether they were interacting with ChatGPT or a human physician, yet the resulting empathy scores were significantly higher for ChatGPT. This suggests that communication quality may outweigh the communicator's identity in shaping perceived empathy. However, previous studies indicate that patient satisfaction can decline when AI-generated responses are explicitly disclosed, underscoring the complexity of transparency in clinical AI use [27]. Determining when and how to disclose AI involvement remains an important ethical and practical challenge, warranting further research into its impact on patient trust and acceptance.

Ethical and Educational Implications

While our study demonstrates that ChatGPT can perform reasonably well in clinically simulated settings, several barriers must be addressed before independent deployment in real-world practice [28]. A major concern is liability for inaccurate or harmful recommendations, with uncertainty over whether responsibility would fall on software developers, health care providers, or end users [29,30]. Furthermore, the black-box nature of LLMs makes it difficult even for professionals to fully evaluate AI-generated outputs [31]. Robust legal and ethical frameworks will be essential for the safe integration of AI into clinical care [32].

Data privacy also presents a critical challenge. Many LLMs, including ChatGPT, operate through cloud-based services, raising concerns about the transmission and storage of sensitive health information [33,34]. One potential solution is the development of open-source models that can operate within closed, local systems without cloud dependence. However, further research is needed to assess the feasibility, security, and clinical applicability of such approaches.

With the growing integration of AI into clinical practice, its role in medical education has also expanded [35]. AI models such as ChatGPT have been used not only to deliver factual knowledge but also to enhance patient communication skills. They can be useful for simulating patient interactions and providing immediate feedback [36]. However, concerns remain that excessive reliance on AI may undermine the development of independent critical thinking and clinical reasoning skills [37]. To address this, AI-integrated curricula must be designed to harness the strengths of AI while actively cultivating human competencies in critical thinking, clinical judgment, and ethical decision-making [38]. Balancing these elements will be essential to maintain independent expertise in an increasingly AI-augmented health care environment.

Limitations

This study has several limitations. First, the CPX format used in this study does not fully replicate the real-world clinical environment in which physicians interact with patients in the emergency department. The simulations were conducted via text-based messenger in a blinded format, which limited access to nonverbal cues and other clinically relevant information typically available during face-to-face encounters. As a result, participants could not demonstrate the full range of clinical skills required in actual patient care. In addition, while moderation was necessary to anonymize participants and correct typographical errors, the process occasionally involved segmenting and restructuring physicians' input for clarity. These adjustments may have disrupted the natural flow of conversation and removed pauses and hesitations, which are essential for conveying empathy [39]. For example, splitting long, intricate sentences into shorter, specific segments can give patients the impression that the conversation is overly focused on medical facts and interaction is less patient-centered. Future research should compare human performance and AI in more realistic settings including voice-based or in-person interactions to reflect nonverbal cues and conversational dynamics. Second, all CPX evaluations were performed by a single emergency medicine professor. Although the assessor was experienced, the use of a single evaluator may have introduced bias or subjectivity in scoring, particularly in domains such as empathy or communication quality. To address this issue, the evaluator calibrated the scoring process by applying the rubric to CPX manuscripts previously used for educational purposes and discussing borderline ratings with other physician investigators to ensure consistent interpretation. Future research should involve multiple independent raters to reduce subjectivity and enhance scoring consistency. Third, the relatively small number of participants may have limited the statistical power to detect modest differences between groups. Larger studies are needed to validate and extend these findings. Fourth, the clinical scenarios used in both CPX and written examinations were limited to a predefined set of representative cases. While selected to reflect a range of emergency conditions, the findings may not be generalizable to all clinical contexts or specialties. Future studies should include a broader range of clinical situations and patient presentations to enhance generalizability. Finally, this study did not include structured interviews or surveys of participating physicians to capture their perspectives on ChatGPT. Instead, we conducted brief debriefings after CPX sessions, which revealed that physicians initially underestimated ChatGPT's capabilities. They highlighted its continuous availability and rapid response generation as key strengths and noted that lower empathy scores served as a reminder of the importance of empathic communication in practice. Clinicians also emphasized that legal and liability issues must be resolved before broader AI adoption. Future research should incorporate formal clinician interviews to systematically explore these insights and guide safe AI integration.

XSL•FO
RenderX

Conclusion

In conclusion, the AI model demonstrated robust capabilities in clinical reasoning, diagnostic accuracy, and empathic communication in simulated emergency medicine scenarios. These findings highlight the potential of AI to serve as a supportive role in clinical practice. Future efforts should focus on developing collaborative frameworks that integrate AI into existing clinical workflows and harness AI's strengths safely and effectively in real-world practice.

Abstract

Background: The integration of artificial intelligence (AI) into clinical workflows holds promise for enhancing outpatient decision-making and patient education. ChatGPT, a large language model developed by OpenAI, has gained attention for its potential to support both clinicians and patients. However, its performance in the outpatient setting of general surgery remains underexplored.

Objective: This study aimed to evaluate whether ChatGPT-4 can function as a virtual outpatient assistant in the management of puerperal mastitis by assessing the accuracy, clarity, and clinical safety of its responses to frequently asked patient questions in Turkish.

Methods: Fifteen questions about puerperal mastitis were sourced from public health care websites and online forums. These questions were categorized into general information (n=2), symptoms and diagnosis (n=6), treatment (n=2), and prognosis (n=5). Each question was entered into ChatGPT-4 (September 3, 2024), and a single Turkish-language response was obtained. The responses were evaluated by a panel consisting of 3 board-certified general surgeons and 2 general surgery residents, using five criteria: sufficient length, patient-understandable language, accuracy, adherence to current guidelines, and patient safety. Quantitative metrics included the DISCERN score, Flesch-Kincaid readability score, and inter-rater reliability assessed using the intraclass correlation coefficient (ICC).

Results: A total of 15 questions were evaluated. ChatGPT's responses were rated as "excellent" overall by the evaluators, with higher scores observed for treatment- and prognosis-related questions. A statistically significant difference was found in DISCERN scores across question types (P=.01), with treatment and prognosis questions receiving higher ratings. In contrast, no significant differences were detected in evaluator-based ratings (sufficient length, understandability, accuracy, guideline compliance, and patient safety), *JAMA* benchmark scores, or Flesch-Kincaid readability levels (P>.05 for all). Interrater agreement was good across all evaluation parameters (ICC=0.772); however, agreement varied when assessed by individual criteria. Correlation analyses revealed no significant overall associations between subjective ratings and objective quality measures, although a strong positive correlation between literature compliance and patient safety was identified for one question (r=0.968, P<.001).

Conclusions: ChatGPT demonstrated adequate capability in providing information on puerperal mastitis, particularly for treatment and prognosis. However, evaluator variability and the subjective nature of assessments highlight the need for further optimization of AI tools. Future research should emphasize iterative questioning and dynamic updates to AI knowledge bases to enhance reliability and accessibility.

Introduction

Puerperal mastitis, also known as lactation mastitis, is a disorder that affects approximately 30% of breastfeeding women and may vary from mild inflammation to bacterial abscess formation [1]. This disease, which adversely affects breastfeeding, is monitored by the World Health Organization (WHO) and represents a substantial proportion of outpatient clinic applications in general surgery [2,3].

Artificial intelligence (AI)-based systems are currently regarded as capable of enhancing the workflow and aiding the decision-making process [4]. The health care system, particularly in outpatient management, aims to alleviate the patient burden and thereby enhance patient satisfaction [5]. Recent studies have shown that ChatGPT is capable of providing accurate differential diagnoses in 93.3% of common clinical scenarios, and its responses have achieved high accuracy in fields such as retinal diseases, gynecology, and hepatic disorders. These findings underscore the expanding role of AI-powered tools in enhancing diagnostic reasoning and clinical communication across a wide spectrum of medical disciplines [6-8]. In the future, AI is expected to progress as a conduit between clinical practice and data, thereby enhancing patient care and operations [9].

This study aimed to evaluate whether ChatGPT-4 could function as a virtual outpatient assistant in the management of puerperal mastitis. We assessed the content of its responses in Turkish to commonly asked patient questions, focusing on their adequacy, clarity, adherence to medical literature, and potential safety implications.

Methods

Study Design and Hypotheses

In this study, we aimed to evaluate whether ChatGPT can function as a competent assistant in general surgery outpatient settings by managing frequently encountered clinical conditions such as puerperal mastitis. The rationale behind this study is based on the dual expectation from ChatGPT: to provide clinically reliable information grounded in current medical literature and to effectively communicate this information in a clear, understandable manner suitable for patient interaction.

ChatGPT-4 was selected as the AI model for evaluation due to its widespread adoption in recent health-related studies and its extensive documentation in the current literature. Using ChatGPT-4 allowed for comparability with prior research, ensuring consistency and alignment with similar investigations examining large language models' (LLMs') performance in medical information delivery.

Our study was guided by three hypotheses: (1) the responses provided by ChatGPT regarding puerperal mastitis are adequate for daily clinical practice, (2) the quality of responses varies depending on the context and category of the question, (3) using language that is easier to understand may reduce adherence to current clinical literature and accuracy, thereby potentially compromising patient safety.

Ethics committee approval was not sought for this study, as no clinical or personal information about patients was used. However, preliminary permission was obtained from the affiliated hospital.

Question Identification

Fifteen of the most frequently asked and clinically relevant questions about puerperal mastitis were identified through a review of publicly available health care websites, patient forums, and social media platforms. The decision to include 15 questions was based on a review of similar studies in the literature that used a comparable sample size to allow for focused qualitative and quantitative evaluation. This number was deemed sufficient to simulate a realistic outpatient consultation experience and to provide variability across clinical themes.

The questions were categorized to reflect the breadth of clinical concerns typically encountered in general surgery outpatient settings. These categories were general information (n=2), symptoms and diagnosis (n=6), treatment (n=2), and prognosis (n=5). Categorization aimed to allow structured evaluation across different domains of clinical relevance.

To reflect the linguistic and cultural context of our primary patient population, all questions were written in Turkish. The questions were then input into ChatGPT-40 mini, an AI chatbot, on September 3, 2024. A newly created user account was used to ensure that no prior interactions influenced the generated responses. The system was accessed under a standard free-tier usage scenario, without premium settings, plugins, or enterprise features enabled. This setup was intended to simulate how a general user or outpatient might realistically interact with the tool. Each question was entered only once, without any follow-up or clarification prompts. Responses were recorded without modification (refer to Multimedia Appendix 1 and Multimedia Appendix 2).

Response Evaluation

The responses generated by ChatGPT were evaluated by a panel of 5 medical professionals, comprising 3 board-certified general surgeons (OFA, FD, and AHK) and 2 general surgery residents (MHB and EK). Detailed evaluation scores and comparative analyses are provided in Multimedia Appendix 3 and Multimedia Appendix 4.

Each response was independently scored using a 5-point Likert scale (1=poor and 5=excellent) according to the following 5 criteria: (1) sufficient length, (2) use of language understandable to the patient, (3) accuracy in answering the inquiry, (4) compliance with the most recent clinical guidelines, (5) patient safety. These criteria were selected based on methodologies used in similar studies within the literature that evaluated AI-based responses in medical contexts. The aim was to holistically capture both the technical validity and the patient communication aspects of the responses.

Based on total scores, responses were classified as (1) 5 - 10: inadequate, (2) 11 - 15: average, (3) 16 - 20: adequate, and (4) 21 - 25: excellent.

XSL•FO
RenderX

Objective Assessment Tools

To further ensure objectivity and align with methodologies frequently used in similar literature evaluating AI-generated medical information, we used three standardized tools:

DISCERN Instrument

DISCERN is a standardized and validated tool developed by the University of Oxford for assessing the quality of consumer health information, particularly regarding treatment choices. Widely cited in the evaluation of online medical content, it consists of 15 questions that evaluate the publication's reliability, objectivity, and clarity in describing treatment options. Each item is rated on a 5-point scale. Total scores categorize information quality as very poor (<27), poor (27-38), fair (39-50), good (51-62), and excellent (63-75) [10].

Journal of the American Medical Association Benchmark Criteria

Published by the *Journal of the American Medical Association* (*JAMA*), this benchmark is a qualitative framework used to assess the credibility of online health information. It includes four domains: authorship (clearly identified sources), attribution (references to content sources), disclosure (ownership and conflicts of interest), and currency (dates of publication or last update). In our study, the *JAMA* benchmark score was found to be zero, which reflects an inherent limitation of ChatGPT's output—it does not include cited authors, publication dates, or institutional disclosure information in its responses. This has similarly been observed in other studies evaluating AI-generated health content and is a recognized limitation of current language models [11].

Flesch-Kincaid Grade Level Test

This tool was used to assess the complexity of language in the ChatGPT responses. The readability score was calculated using the following formula: Grade Level=(0.39× Total Sentences/Total Words)+(11.8× Total Words/Total Syllables)−15.59 to assess the complexity of language used by ChatGPT [12]. This assessment evaluates text understanding and target audience appropriateness; scores ranging from 0 to 5 indicate primary school level, 6 to 8 indicate secondary school level, 9 to 12 indicate high school level, and 13 and above indicate university level.

Statistical Analysis

The normality of the data distribution was examined using the Shapiro-Wilk test. For the comparison of evaluator scores across more than 2 independent groups, one-way ANOVA and least significant difference multiple comparison tests were used for features showing normal distribution, while the Kruskal-Wallis test and all-pairwise multiple comparison tests were used for non-normally distributed features. Interobserver agreement among the 5 doctors for each parameter was measured using the intraclass correlation coefficient (ICC) (single measure and two-way random model). ICC values were classified as follows: "excellent" (above 0.90), "good" (0.75 - 0.90), "moderate" (0.50 - 0.75), and "poor" (less than 0.50) [13]. The relationships between the question scales were analyzed using the Spearman correlation coefficient. A correlation coefficient between 0.8 and 1 indicates a very strong relationship, values between 0.6 and 0.8 represent a strong relationship, values between 0.4 and 0.6 indicate a moderate relationship, and values between 0.2 and 0.4 signify a weak relationship. Differences between scores within the questions were examined using the Friedman test, with post-hoc tests corrected using the Bonferroni method. Descriptive statistics are presented as mean (SD) for numerical variables, and as counts and percentages for categorical variables. Statistical analyses were performed using SPSS for Windows (version 24.0; IBM), and statistical significance was set at $P<.05$.

Ethical Considerations

This study did not involve human participants, identifiable personal data, clinical interventions, or medical record review; therefore, approval from an institutional review board or ethics committee was not required. In accordance with institutional and national guidelines governing noninterventional research, studies based solely on publicly available, nonidentifiable content—such as online health information and AI-generated responses—are exempt from ethics committee review. Nevertheless, prior administrative permission was obtained from Kahramanmaras Necip Fazıl City Hospital before the commencement of the study.

Results

Differences in scores were analyzed according to the clinical categories of the questions and the evaluation methods (Table 1). A statistically significant difference was observed in DISCERN scores across question types (general information, symptoms and diagnosis, treatment, and prognosis) ($P=.01$). Treatment and prognosis questions received higher DISCERN ratings compared to general information and symptom/diagnosis questions ($P<.05$). In contrast, no significant differences were detected in evaluator-based ratings (sufficient length, understandability, accuracy, guideline compliance, and patient safety), *JAMA* benchmark scores, or Flesch-Kincaid readability levels ($P>.05$ for all comparisons).

Table 2 presents the interrater agreement and score distribution across key evaluation criteria. The overall ICC across all parameters was 0.772, indicating good consistency among evaluators. When assessed individually, moderate agreement was observed for understandable language (ICC=0.519) and total scores (ICC=0.570), whereas sufficient length (ICC=0.400), accuracy (ICC=0.405), compliance with literature (ICC=0.414), and patient safety (ICC=0.400) demonstrated poor agreement. Statistically significant differences among evaluators were found for sufficient length, accuracy, compliance with literature, and patient safety (all *P*<.001), suggesting subjective variability in scoring across these domains.

Table . Comparison of evaluator scores across key assessment criteria with interrater agreement values.

Assessment criteria	Enes Karademir, mean[a] (SD); median (IQR)	Fatih Dolu, mean (SD); median (IQR)	Aydın Hakan Kupeli, mean (SD); median (IQR)	Hüseyin Buyukavci, mean (SD); median (IQR)	Oguzhan Fatih AY, mean (SD); median (IQR)	*P*[b] value	ICC[c]

Patient safety	4.73 (0.46); 5.00 (4.50-5.00)	4.67 (0.49); 5.00 (4.00-5.00)	4.93 (0.26); 5.00 (5.00-5.00)	3.93 (0.26); 4.00 (4.00-4.00)	4.87 (0.35); 5.00 (5.00-5.00)	.001[abcd]	0.400
Total	20.87 (2); 21.00 (20.50-22.00)	23 (1.13); 23.00 (22.00-24.00)	24.53 (0.64); 25.00 (24.00-25.00)	20.8 (1.15); 21.00 (20.50-21.50)	24.33 (1.91); 25.00 (25.00-25.00)	.001[abcd]	0.570

[a]Means followed by distinct small letters (a, b, c, and d) in the same line are significantly different (*P* <.05).

[b]*P* value obtained from the Kruskal-Wallis test.

[c]ICC: intra-correlation coefficient.

[d]Superscript letters (a, b, c, d, and ab) indicate results of pairwise comparisons. Means sharing the same letter are not significantly different (*P*<.05). For example, “ab” denotes no significant difference from both “a” and “b” groups.

Table 3 shows the evaluator-based scoring patterns across different clinical categories. The overall agreement was poor (ICC=0.199) when clinical categories were not considered separately. However, moderate agreement was found for general information (ICC=0.537) and prognosis-related questions (ICC=0.648), while symptom-based questions demonstrated good agreement (ICC=0.828). Treatment-related questions exhibited moderate consistency (ICC=0.654). These findings suggest that evaluator agreement was strongest for symptom-related questions and weakest for general information questions. Statistically significant differences between evaluators were observed across all clinical categories (*P*<.05).

[a]Means followed by distinct small letters (a, b, c, and d) in the same line are significantly different ($P < .05$).

[b]*P* value obtained from Kruskal-Wallis test.

[c]ICC: intraclass correlation coefficient.

[d]Means followed by different superscript letters (a, b, and c) in the same row are significantly different ($P<.05$). The notation "ab" indicates no significant difference from both "a" and "b" groups; "bc" indicates no significant difference from both "b" and "c"; and "abc" indicates no significant difference from groups "a," "b," and "c."

One of the key hypotheses of this study was that the use of highly understandable language might be inversely related to patient safety and adherence to clinical guidelines. Correlation analyses were performed to investigate these associations. Table 4 summarizes the correlations between evaluator ratings for understandability, literature compliance, and patient safety across individual questions, reflecting subjective expert assessments. Table 5 presents the correlation between these evaluator-based parameters and objective assessment tools (DISCERN scores and Flesch-Kincaid readability scores). While no statistically significant overall correlations were found, a strong positive correlation between literature compliance and patient safety was observed for question 8 ($r=0.968$ and $P<.001$), suggesting that in certain contexts, enhanced clinical accuracy may directly benefit patient safety.

Discussion

Principal Findings

This study assessed the competence of ChatGPT in relation to puerperal mastitis. In our evaluation, all evaluators classified the responses provided across the scope of questions as "excellent." The DISCERN scoring system indicated that ChatGPT performs better when answering questions related to treatment and prognosis. The Flesch-Kincaid classification indicated that the responses from ChatGPT were comprehensible at the university graduate level (Table 1).

Statistically significant differences were observed in the scores assigned by evaluators across various criteria—including sufficient length (*P*=.001), accuracy (*P*<.001), adherence to the literature (*P*<.001), and patient safety (*P*<.001)—as well as across different question types, such as general information (*P*=.015), prognosis (*P*<.001), symptoms (*P*=.001), and treatment (*P*=.031). These findings suggest that the evaluation of ChatGPT responses was influenced by the evaluators' individual perspectives, especially for broader and more context-dependent inquiries. The relatively smaller difference among raters in the criterion of understandable language (*P*=.060) suggests that this parameter may be more amenable to objective assessment. Taken together, the inter-rater variability highlights an inherent limitation of subjective evaluation frameworks and underscores the need for the development of more standardized and objective rating tools for assessing AI-generated health content. Establishing validated scoring protocols may improve consistency and reliability in future assessments involving human raters.

Comparison With Prior Work

The literature contains numerous evaluations of ChatGPT's accuracy in response to inquiries about both malignant and benign diseases. AI-generated data has shown precise detection of osteoarthritis, though technical support is still necessary for some specific questions [14]. Data regarding urothelial carcinoma from AI are currently limited, with reliable information mainly focused on the epidemiology and risk factors [15]. In breast cancer oncology treatment, AI offers restricted insights into particular clinical scenarios and postoperative conditions [16]. In the pediatric field, Wei noted that while ChatGPT's performance was adequate for general inquiries, it was insufficient in specific clinical contexts [17]. Our study represents the first assessment of ChatGPT's responses regarding puerperal mastitis, with no existing research available for comparison.

In relation to another one of our hypotheses, in our analysis of the correlation among understandable language, patient safety, and compliance with the literature, we observed a positive correlation between the parameters of compliance and patient safety related to the 8th question, which is focused on symptoms and diagnosis (Table 4). The inability to statistically verify one of our hypotheses may stem from the limited number of questions (n=15) and the subjective nature of the raters' evaluations. Nonetheless, no statistically significant relationship was identified between the DISCERN score, a relatively objective indicator of technical proficiency, and the Flesch-Kincaid Reading Difficulty score, which assesses comprehensibility, for each question (Table 5). However, Al-Ashwal et al [18] indicated that using simple language may result in the omission of critical information regarding disease. Various indexes, such as the Flesch-Kincaid Index, Simple Measure of Gobbledygook index [19], and Gunning Fog Index [17], have been used in the literature to assess readability and understandability. Valencia [20] stated that the AI response might be effective for the Flesch-Kincaid index in the context of kidney donation information and studies related to ChatGPT. He noted that this was a quantitative evaluation and may not encompass all nuances; thus, it may lack generalizability. It is noted that unclear online health information negatively affects patient adherence to treatment [8,21]. We believe that it is essential for the information supplied by ChatGPT to be both precise and comprehensible to patients. At present, it has been argued that ChatGPT has the potential to enhance patient outcomes and health literacy [22]. In our study, we used the Flesch-Kincaid Index and determined that the responses provided by ChatGPT were comprehensible at the university level. While this suggests a high level of linguistic and grammatical complexity, it may limit accessibility for patients

XSL•FO
RenderX

with lower health literacy. Although the Flesch-Kincaid Index has its limitations—particularly in evaluating medical jargon and sentence structure—it remains one of the most widely accepted readability tools in digital health research. Previous studies evaluating AI-generated content have reported similar findings [8,17,23][]. We believe that improving the readability of ChatGPT responses, particularly by simplifying language without compromising medical accuracy, is essential for optimizing patient education and safety.

One of our central hypotheses was that ChatGPT could contribute meaningfully to clinical decision-making and patient management in outpatient settings. Beyond its role in health education and patient information, recent studies have highlighted ChatGPT's emerging potential in various clinical domains. In abdominopelvic surgery, it has been proposed as a tool for enhancing patient-physician communication, preoperative counseling, and postoperative care guidance [24]. Similarly, in gastroenterology, its capacity for triage support, education on endoscopic procedures, and initial interpretation of laboratory findings has been explored, though concerns remain regarding accuracy and source citation [25]. The cardiology field has also recognized its utility for drafting discharge summaries and answering patient queries, particularly in heart failure management and preventive care [26]. Furthermore, in a comparative study within evidence-based dentistry, ChatGPT-4 demonstrated superior performance over other LLMs, particularly in alignment with clinical guidelines, suggesting its value as a supportive assistant in routine decision-making [27]. These findings collectively underline that while ChatGPT is not a replacement for clinical judgment, its structured integration into practice—especially for low-risk guidance and standardized educational content—may enhance efficiency, patient comprehension, and adherence to evidence-based care models. One of the hypotheses of this study was that ChatGPT could contribute meaningfully to clinical decision-making and patient management. However, the integration of AI into health care practices raises several ethical concerns that warrant careful consideration. First, the uncertainty regarding liability in the event of harm resulting from AI-generated recommendations remains unresolved. It is unclear whether responsibility would lie with the clinician, the AI developer, or the institution using the system. This issue has been widely discussed across different fields of medicine, emphasizing the necessity for clear accountability structures [28]. Second, transparency in AI decision-making is a fundamental requirement for clinical trust [28,29]. It is recommended that AI systems not only disclose their involvement in clinical processes but also provide a traceable rationale for their outputs. This approach may help reduce ambiguity related to AI-derived recommendations and enhance professional confidence in their use. Third, algorithmic bias—arising from limitations or imbalances in the datasets used to train AI—can lead to inequitable outcomes for certain patient populations. Although this dimension was not directly evaluated in our study, it is a well-recognized risk and must be considered in future applications of AI in medicine [28,29]. Moreover, long-term dependence on AI may lead to the phenomenon of "automation bias," in which clinicians overly rely on AI recommendations, potentially diminishing their own diagnostic acumen and clinical judgment [30]. This may affect future training and critical thinking in medical education, especially if AI systems are perceived as replacements rather than adjuncts to human expertise.

These considerations underline the need for specialty-specific ethical guidelines that address transparency, accountability, bias mitigation, and appropriate use of AI in clinical practice. While our study found that ChatGPT may provide accurate and comprehensible responses in the context of puerperal mastitis, further ethical and regulatory frameworks are essential to ensure its safe and equitable integration into health care delivery.

Limitations

This study has several notable limitations. First, each question was submitted to ChatGPT only once, and the initial response was evaluated without any iterative prompting or follow-up queries. In real-world clinical settings, both health care professionals and patients often engage in multiturn interactions to clarify ambiguities, which may lead to more comprehensive or accurate outputs. Our single-response approach, while practical for standardization, may not fully capture the potential of conversational AI tools in dynamic outpatient scenarios. Second, the assessment was conducted on a specific version of ChatGPT (GPT-4o mini) at a single time point using the publicly accessible platform. Since LLMs are frequently updated and refined, the findings of this study may not be generalizable to future versions or other AI models. In addition, because the chatbot does not cite references or provide source transparency, its outputs may lack traceability—particularly relevant when considering adherence to clinical guidelines and patient safety. Third, although the evaluation was conducted by a team of general surgeons and surgical residents, the rating process remains subject to individual clinical judgment. Parameters such as "accuracy" or "patient safety"—despite being guided by current literature—may still reflect inherent evaluator bias. Although inter-rater reliability was statistically analyzed, the subjective nature of certain domains introduces variability and limits reproducibility. Finally, the number of questions (n=15) was based on prior literature and feasibility considerations; however, it limits the breadth of topics and clinical diversity that could be assessed. Broader question sets and diverse clinical domains would be valuable in future studies to enhance generalizability.

Conclusion

Our findings indicate that ChatGPT has the potential to serve as an effective assistant in general surgery outpatient settings by providing responses that are not only comprehensible for patients but also largely aligned with current clinical literature. This dual competency—offering medically relevant and literature-consistent information while maintaining clarity—positions ChatGPT as a promising tool in supporting clinical decision-making and enhancing the efficiency of patient management.

To fully realize this potential, future research should focus on improving the consistency and reliability of AI outputs across diverse clinical topics. Further studies should also explore strategies for ensuring up-to-date medical knowledge within

XSL•FO
RenderX

language models and evaluate their integration into real-time clinical workflows. These efforts are essential for safely expanding the role of AI in evidence-based, patient-centered care.

We assessed ChatGPT's performance in addressing questions related to puerperal mastitis, a condition that represents a substantial portion of the workload in general surgery outpatient clinics, in the context of the prospective role of AI in the health care system. Our findings indicate that ChatGPT provides adequate information regarding puerperal mastitis. While the parameters used to assess for understandability have inherent limitations, it is essential to use more comprehensible language to achieve favorable outcomes that may be broadly disseminated within society. There is a need for more comprehensive, technical, and methodologically sound studies to integrate AI into health care systems.

Abstract

Background: Most artificial intelligence (AI) models for thyroid nodules are designed to screen for malignancy to guide further interventions; however, these models have not yet been fully implemented in clinical practice.

Objective: This study aimed to evaluate AI in real clinical settings for identifying potentially benign thyroid nodules initially deemed to be at risk for malignancy by radiologists, reducing unnecessary fine needle aspiration (FNA) and optimizing management.

Methods: We retrospectively collected a validation cohort of thyroid nodules that had undergone FNA. These nodules were initially assessed as "suspicious for malignancy" by radiologists based on ultrasound features, following standard clinical practice, which prompted further FNA procedures. Ultrasound images of these nodules were re-evaluated using a deep learning–based AI system, and its diagnostic performance was assessed in terms of correct identification of benign nodules and error identification of malignant nodules. Performance metrics such as sensitivity, specificity, and the area under the receiver operating characteristic curve were calculated. In addition, a separate comparison cohort was retrospectively assembled to compare the AI system's ability to correctly identify benign thyroid nodules with that of radiologists.

Results: The validation cohort comprised 4572 thyroid nodules (benign: n=3134, 68.5%; malignant: n=1438, 31.5%). AI correctly identified 2719 (86.8% among benign nodules) and reduced unnecessary FNAs from 68.5% (3134/4572) to 9.1% (415/4572). However, 123 malignant nodules (8.6% of malignant cases) were mistakenly identified as benign, with the majority of these being of low or intermediate suspicion. In the comparison cohort, AI successfully identified 81.4% (96/118) of benign nodules. It outperformed junior and senior radiologists, who identified only 40% and 55%, respectively. The area under the curve (AUC) for the AI model was 0.88 (95% CI 0.85 - 0.91), demonstrating a superior AUC compared with that of the junior radiologists (AUC=0.43, 95% CI 0.36 - 0.50; *P*=.002) and senior radiologists (AUC=0.63, 95% CI 0.55 - 0.70; *P*=.003).

Conclusions: Compared with radiologists, AI can better serve as a "goalkeeper" in reducing unnecessary FNAs by identifying benign nodules that are initially assessed as malignant by radiologists. However, active surveillance is still necessary for all these nodules since a very small number of low-aggressiveness malignant nodules may be mistakenly identified.

KEYWORDS

thyroid nodules; artificial intelligence; fine needle aspiration; risk stratification; ultrasound

Introduction

The prevalence of thyroid nodules has been consistently high, with a correspondingly high detection rate [1-3]. Notably, only a tiny proportion of these nodules are malignant [4].

In the real world, fine needle aspiration (FNA) has long been the favored diagnostic method in the management of suspicious thyroid nodules [5]. Before that, different regions used various Thyroid Imaging, Reporting, and Data System guidelines to screen suspicious thyroid nodules that need to receive further FNA [6,7]. However, the decision process of the Thyroid Imaging, Reporting, and Data System results in a significant number of unnecessary FNAs performed for benign lesions [8].

Although false-positive cases cannot be entirely avoided, a recent retrospective study has revealed a higher-than-expected rate of benign thyroid nodules identified after FNAs, reaching up to 50%, and consequently, some of them received unnecessary lobectomy or thyroidectomy [9]. Since these invasive procedures carry significant risks, complications, economic burdens, and psychological distress for patients [4], a better decision-making process is needed to avoid unnecessary FNA. Recent advancements in the management of thyroid nodules, including the use of the multimodality US model and the incorporation of molecular markers for more accurate risk stratification, have contributed to enhancing the precision of diagnostic decisions [10,11]. However, some limitations, including operator dependence, low concordance, invasive procedures, and high expenses, restrict their widespread application.

Many recent studies have shown that artificial intelligence (AI) has the potential to improve thyroid cancer detection [12-15]. Through extensive training on large datasets of annotated thyroid nodule ultrasound images, these AI models provide valuable assistance for the differentiation between benign and malignant [16-19]. Under this background, some commercial AI applications have been approved for clinical use.

Nevertheless, due to the indolent nature of thyroid cancer, the problem of overdiagnosis, similar to unnecessary FNA, is becoming a more concerning issue [4]. Most commercial AI applications have been developed to screen for potentially malignant lesions. However, despite their maturity, these AI tools are still challenging to implement in routine clinical practice as replacements in determining the benign or malignant nature of thyroid nodules. Several key barriers hinder their integration into real-world settings, including lack of interpretability in decision-making, potential disruption to clinical workflows, and concerns surrounding regulatory approval and ethical considerations.

To address these challenges, our study used the ITS100 (MedAl Technology) AI system not as a replacement for radiologists, but as a second-opinion tool. In clinical practice, radiologists typically identify potentially malignant nodules and, after obtaining informed consent, proceed with FNA for confirmation. Due to the subjective judgment of radiologists, this workflow inevitably results in some benign nodules undergoing unnecessary FNA.

With the hope of improving the clinical diagnostic workflow to avoid overdiagnosis, we conducted this study to test whether AI could act as a safeguard against overdiagnosis by preventing unnecessary FNAs and to identify the patient populations that may benefit most from its use.

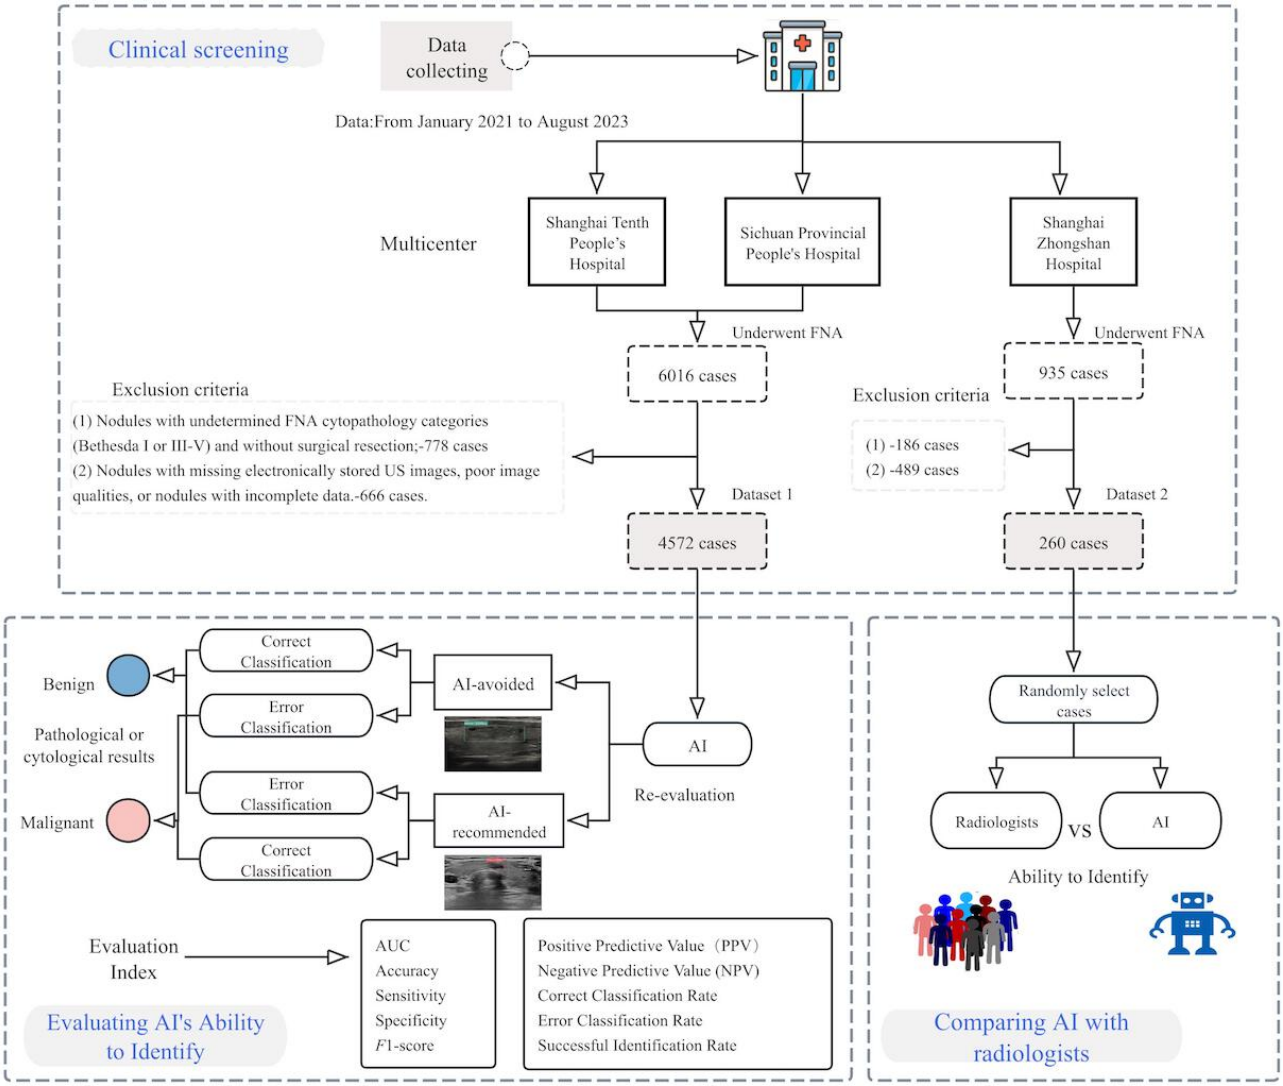
Methods

Overview

This study is a retrospective multicenter study. The validation cohort consists of data from Shanghai Tenth People's Hospital and Sichuan Provincial People's Hospital (dataset 1), and the comparison cohort consists of data from Shanghai Zhongshan Hospital (dataset 2) retrospectively.

Ethical Considerations

This study was approved by the institutional ethics committees of the participating centers (approval SHSY-IEC-5.0/22XJS36/P01). Written informed consent, including a statement of FNA's risks and data collection, was obtained from patients before undergoing FNA. All participant data were de-identified, stored with restricted access, and analyzed anonymously; no financial compensation was provided for participation.



Study Cohorts

Consecutive ultrasound screenings with clear images, complete clinical information, and pathological results were collected from January 2021 to August 2023 at Shanghai Tenth People's Hospital, Sichuan Provincial People's Hospital, and Shanghai Zhongshan Hospital in China. All nodules included in this study were initially assessed as suspicious for malignancy by radiologists based on ultrasound features, following standard clinical practice, which prompted further FNA procedures. A subset of these nodules also received surgical treatment based on clinical assessment and ultrasound evaluation. FNA cytology results were categorized according to the 2017 Bethesda System [20]. Among all eligible cases, a nodule was selected based on the following criteria: if there was only one nodule, it was chosen; if there were multiple nodules with the same malignant risk classification, the one with the largest diameter was selected; if the malignant risk classifications differed, the nodule with the highest malignant risk classification was chosen. The inclusion and exclusion criteria are listed in Textbox 1.

A detailed flowchart of patient selection is presented in Figure 1.

Figure 1. Overview of the study design. AI: artificial intelligence; AUC: area under the curve; FNA: fine needle aspiration.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria:

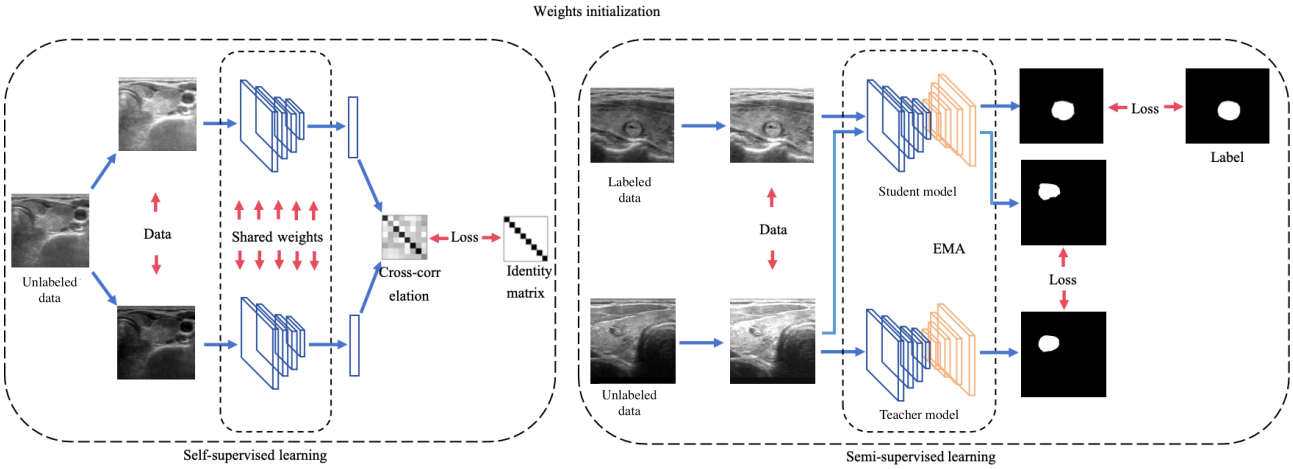
- Patients aged 18 years or older.
- Nodules that underwent fine needle aspiration (FNA) prompted by radiologists' suspicion based on ultrasound assessment.
- Participants underwent FNA or surgical procedures to confirm the pathological results, including cytological or histological findings.
- Bethesda II nodules with follow-up data available for more than 12 months.

Exclusion criteria:

- Nodules with indeterminate FNA cytopathology categories (Bethesda I or III-V) without pathological results.
- Nodules with missing electronically stored ultrasound images, poor image quality, or incomplete clinical data.

Grayscale Ultrasound Examination

All nodules underwent ultrasound examinations within 1 week before FNA. The ultrasound examinations were performed using high-frequency linear transducers of real-time ultrasound systems (Multimedia Appendix 1). At least 2 grayscale ultrasound images for each target nodule (the largest transverse and sagittal planes) were routinely recorded.



Foundation of the AI Algorithm

It is well known that deep learning models require huge amounts of labeled data. To address this challenge in thyroid nodule recognition, an innovative approach has been developed that combines self-supervised learning [21], transfer learning [22], and semisupervised learning [23]. This strategy significantly reduces the demand for labeled data while maintaining high performance.

XSL•FO
RenderX

With the help of the feature extraction capability of convolutional neural networks, the model accurately fits the complex relationship between the content of ultrasound images and the location and nature of thyroid nodules, thus realizing high-precision recognition of thyroid nodules. The flowchart of development is illustrated in Figure 2.

Figure 2. Flowchart of the procedures in the development of artificial intelligence model for thyroid nodule recognition. EMA: exponential moving average.

The model development process is divided into 2 phases—pretraining and fine-tuning. In the pretraining phase, a self-supervised learning approach is used to train the model's encoder network using abundant unlabeled data to learn complex feature representations of ultrasound images. The training strategies of self-supervised learning are inspired by previous studies [21]. The fine-tuning phase introduces a teacher-student model architecture, where both models share the same structure. This phase proceeds as follows: first, initialization—the encoder networks of both the teacher and student models are initialized with the weights obtained from the pretraining phase. In contrast, the decoder networks start with default weight initializations. Second, training—the student model undergoes training using labeled and unlabeled data. For the unlabeled dataset, pseudolabels generated by the teacher model are used. Third, model updates—the teacher model's parameters are regularly updated using an exponential moving average of the student model's parameters, ensuring a stable and consistent learning process.

The AI used in this study is called ITS100 and is manufactured by MedAl Technology. The ITS100 system diagnoses thyroid nodules from a real-time ultrasound video, providing "benign" or "malignant" as the label of each nodule. Its core utility has been developed based on state-of-the-art deep learning algorithms, consisting of more than 300,000 images and hundreds of additional videos. Previous studies have demonstrated that this AI has significant value and accuracy in distinguishing between benign and malignant thyroid nodules [24,25].

Task 1: Evaluating the Ability of AI to Identify Benign Nodules Initially Deemed at Malignant Risk by Radiologists

Nodules deemed to be at risk for malignancy by radiologists in dataset 1 were used to validate the AI. For this AI system, if the AI model classified a nodule as benign, it was hypothesized as "AI-avoided," and FNA was considered unnecessary. Conversely, if the AI classified a nodule as malignant, it was hypothesized as "AI-recommended" and subsequently underwent FNA. In addition, we defined 3 new metrics to evaluate the AI's ability to distinguish benign nodules and reduce unnecessary FNA. Furthermore, we define the following metrics to evaluate AI's abilities:

- Unnecessary FNA rate = True Benign Total FNA

defined as the proportion of FNAs performed on nodules that were ultimately confirmed to be benign.

- Correct classification rate = True Benign AI Classification AI Classifications as Benign

defined as the proportion of nodules correctly identified as benign among all nodules classified as benign by the AI.

- Error classification rate = True Malignant AI Classification as Benign All AI Classifications as Benign

defined as the proportion of malignant nodules incorrectly classified as benign among all nodules classified as benign by the AI.

- Successful identification rate = True Benign AI ClassificationAll True Benign

defined as the proportion of truly benign nodules correctly identified as benign by the AI out of all benign nodules.

Task 2: Comparison Between Radiologists and AI

Dataset 2 was used to compare the performance of the AI system with that of radiologists in identifying potential benign nodules from those initially deemed at malignant risk by radiologists. A total of 21 radiologists participated in this analysis, including 10 senior and 11 junior practitioners. We randomly selected 30 cross-sectional or longitudinal images of thyroid nodules that had been previously flagged as malignant risk by radiologists in real clinical settings. The radiologists were tasked with identifying nodules that were likely benign and for which FNA could have been avoided, based solely on the imaging data provided, without any external prompts or guidance. This setup

XSL•FO
RenderX

aimed to assess their ability to discern unnecessary FNA within a risk cohort.

Statistical Analysis

In task 1, to evaluate the performance of the AI, the ROC curve was constructed. Sensitivity, specificity, positive predictive value, negative predictive value, accuracy, area under the curve (AUC), and F_1-score were also calculated. The AUC was calculated along with 95% CIs. In task 2, the Delong test was performed to compare radiologists' and AI's AUCs. The specific numbers of nodules where the prediction results of the AI were inconsistent with the confirmed pathological results were determined using the confusion matrix. The successful identification rate and correct classification rate were calculated along with 95% CIs. The Mann-Whitney *U* test was used to compare the successful identification rate and correct classification rate between senior radiologists and junior radiologists.

All statistical analyses were conducted using SPSS (Version 22.0, IBM Corporation), R software (Version 4.2.1, R Foundation for Statistical Computing), and Python (version 3.7.13, Python Software Foundation). Results were considered statistically significant at the $P<.01$ level.

Results

Characteristics of Data

A total of 6016 cases in dataset 1 and 935 in dataset 2 were recruited. After applying the exclusion criteria, a total of 4572 cases were included in dataset 1 and 260 cases were included in dataset 2, as demonstrated in the workflow in Figure 1. Table 1 illustrates the clinical characteristics of the dataset comprising 4572 patients assessed for malignant risk by radiologists. The cohort predominantly consists of female patients, accounting for 75.3% (3444/4572), with a mean age of 49.4 (SD 13.75) years, reflective of a middle-aged population. The number of lesions in the right lobe was the highest among the cohort. American Thyroid Association (ATA) guidelines categorization revealed 3508 nodules in category 3, a total of 730 nodules in category 4, and 334 nodules in category 5, indicating that most nodules present with low to intermediate suspicion of malignancy. Bethesda categorization yielded the following distribution: category II (n=3106), III (n=137), IV (n=10), V (n=348), and VI (n=971), with a predominance of benign diagnoses (Bethesda category II). The definitive diagnosis classified 3134 nodules as benign and 1438 as malignant.

Table . Patient demographics and characteristics of thyroid nodules.

Characteristics	Total (age: mean 49.4, SD 13.75 years), n	Benign (age: mean 51.5, SD 13.6 years), n (%)	Malignant (age: 48.5, SD 13.8 years), n (%)
Patients	4572	3134 (68.5)	1438 (31.5)

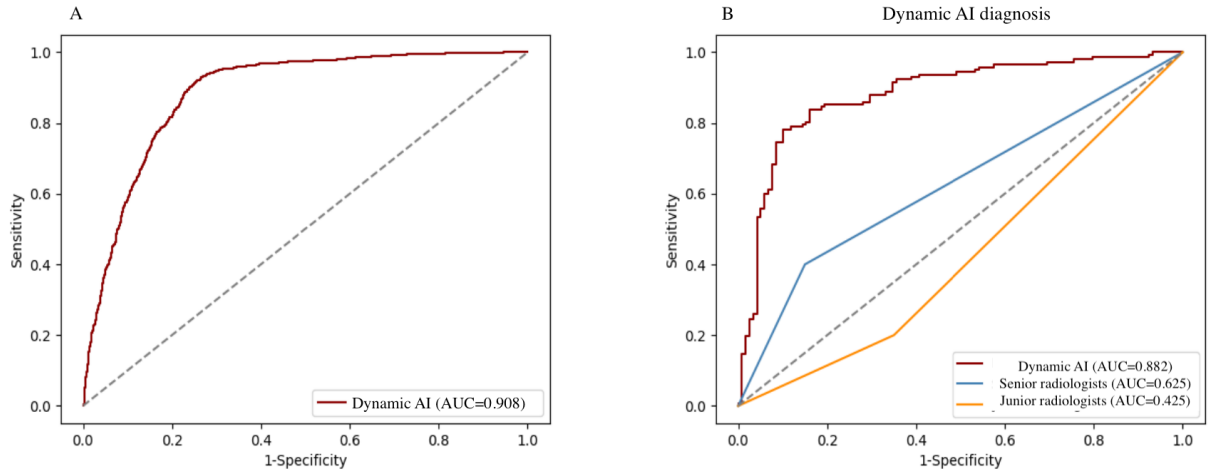
Accuracy Data of AI



We evaluated the performance of the AI in identifying potential benign nodules from those initially classified as at malignant risk by radiologists in dataset 1. The AUC of the AI was 0.91 (95% CI 0.88 - 0.93; Figure 3A). The AI's sensitivity was 91.4% (1315/1438), while its specificity was 86.8% (2719/3134). The positive predictive value was 76% (1315/1730) and the negative predictive value was 95.7% (2719/2842), reflecting a high likelihood that negative test

XSL•FO
RenderX

results are accurate. Overall accuracy was 88.2% (4034/4572), demonstrating the AI's efficacy across 4572 cases. The F_1-score, a harmonized measure of test accuracy, was 0.83, indicating a balanced precision and recall. After applying AI, the number of unnecessary FNAs significantly decreased to 415 (9.1%), compared with 3134 (68.5%) in real-world human readings.

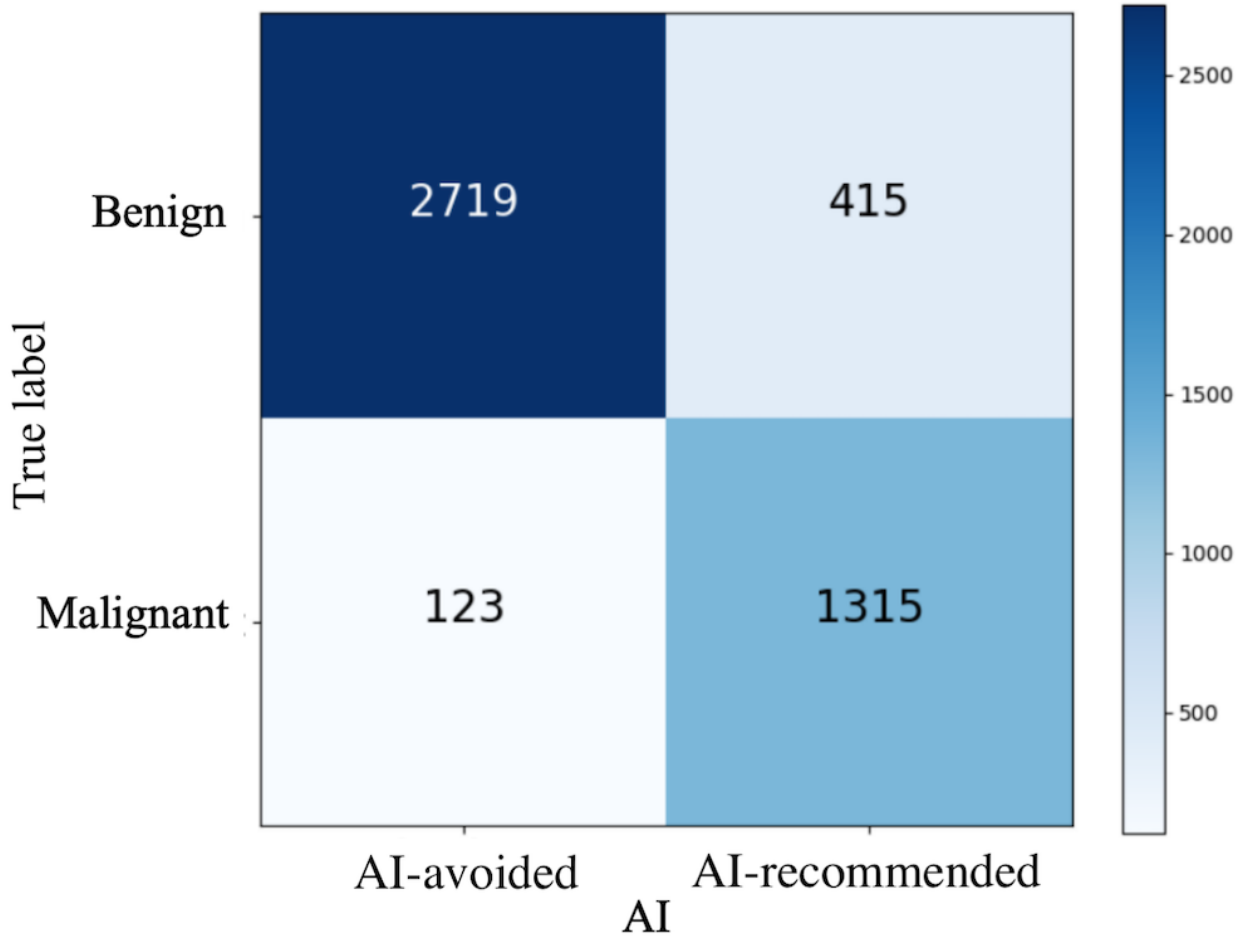


Figure 4 displays the confusion matrix, showing that the AI correctly identified 2719 benign nodules and 1315 malignant nodules. It also demonstrates a relatively low rate of false negatives. Figure 5A shows the scatter plot comparing the AI's positive and negative predictions against the Bethesda system's classifications, which range from benign (Bethesda II) to suspicious for malignancy (Bethesda III-V) to malignant (Bethesda VI). The dots represent individual cases, with red indicating a positive prediction (malignant) and blue indicating a negative prediction (benign). For Bethesda 2, there are many blue dots (AI negative) in the lower left quadrant, suggesting strong agreement on benign diagnoses. For Bethesda 6, the concentration of red dots in the upper right quadrant indicates a high level of agreement on malignant diagnoses. Figure 5B displays a scatter plot of the AI predictions based on the ATA classification, with the "low suspicion" category indicating probably benign nodules, the "intermediate suspicion" category indicating suspicious nodules, and the "high suspicion" category indicating highly suspicious nodules for malignancy. The low suspicion category predominantly shows blue dots, suggesting that the AI largely agrees with the benign diagnosis of these nodules. The intermediate category shows a dense mix, with many cases classified as suspicious by radiologists also being predicted as AI-avoided nodules. The high suspicion category, which should theoretically contain the most malignant nodules, shows a high concentration of red dots, highlighting the AI's ability to accurately identify highly suspicious cases.

AI: artificial intelligence.

Rates of Unnecessary FNAs and Other Metrics

The majority of nodules recommended for FNA were classified in Bethesda category VI, accounting for 51.1% (884/1730) of the total, while most of the nodules identified as benign by AI were in Bethesda category II, comprising 94% (2671/2842; Table 2). The unnecessary FNA rates based on human readings for ATA guideline categories were 81.3% for low suspicion, 27.7% for intermediate suspicion, and 24.3% for high suspicion, with an overall unnecessary FNA rate of 68.5% (Table 3).

Table . Bethesda classification of artificial intelligence–avoided and artificial intelligence–recommended nodules.

Bethesda category	AI[a]-recommended (N=1730), n (%)	AI-avoided (N=2842), n (%)
II	435 (25.1)	2671 (94)
III-V	411 (23.8)	84 (3)
VI	884 (51.1)	87 (3.1)

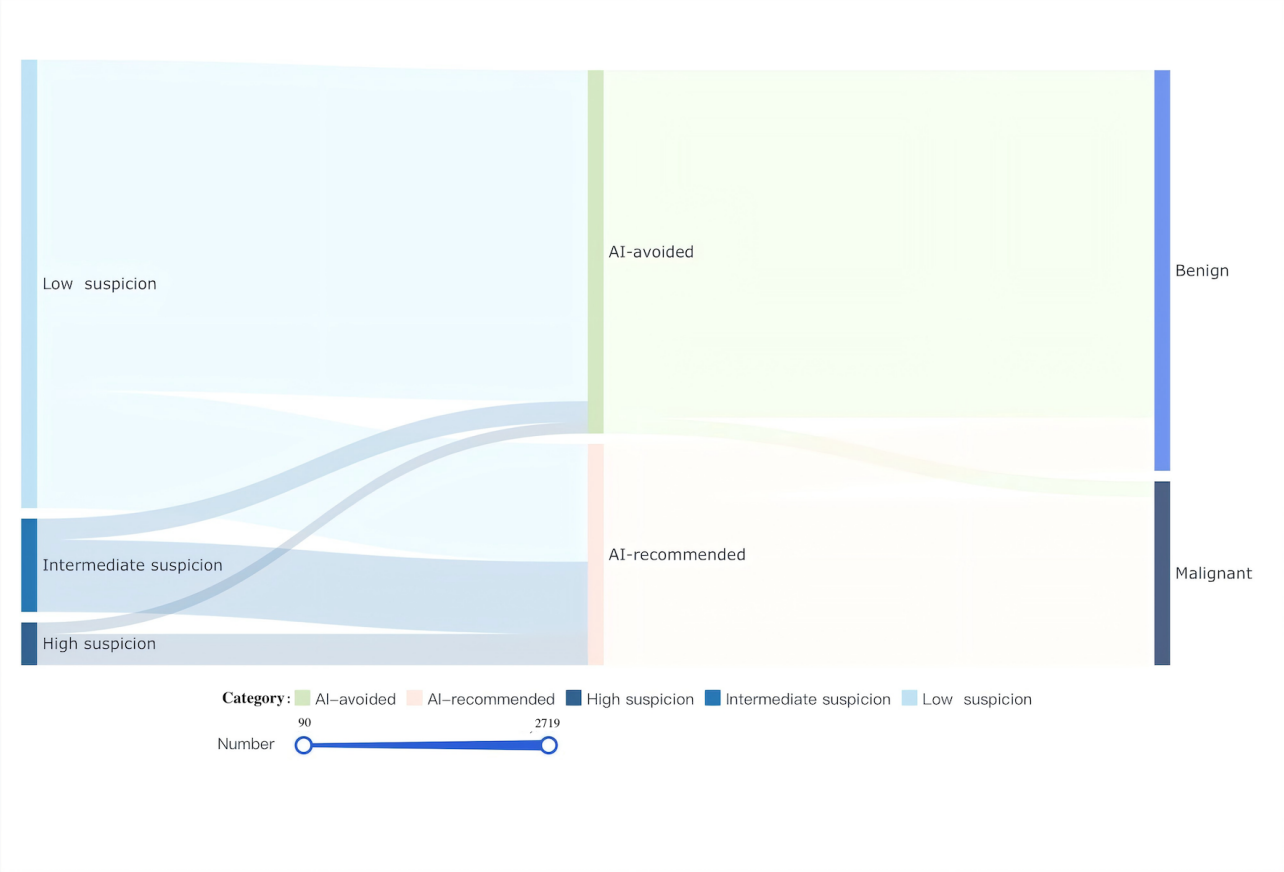
Table . The performance of artificial intelligence across different American Thyroid Association guideline categories.

	Low suspicion	Intermediate suspicion	High suspicion	All
Total	3508 (76.7)	730 (16)	334 (7.3)	4572 (100)
Benign	2851 (81.3)	202 (27.7)	81 (24.3)	3134 (68.5)
Malignant	657 (18.7)	528 (72.3)	253 (75.7)	1438 (31.4)
Unnecessary FNAs[a]	2851 (81.3)	202 (27.7)	81 (24.3)	3134 (68.5)
AI[b]-avoided	2587 (73.7)	165 (22.6)	90 (26.9)	2842 (62.2)
Benign	2510 (97)	137 (83)	72 (80)	2719 (95.7)
Malignant	77 (3)	28 (17)	18 (20)	123 (4.3)
Correct classification rate	2510 (97)	137(83)	72 (80)	2719 (95.7)
Successful identification rate	2510 (88)	137 (67.8)	72 (88.9)	2719 (86.8)
Error classification rate	77 (3)	28 (17)	28 (20)	123 (4.3)

[a]FNA: fine needle aspiration.



[b]AI: artificial intelligence.

The AI system demonstrated promising performance across different ATA guideline categories. For low suspicion nodules, the AI avoided 73.7% (2587/3508) of thyroid nodules, with a correct classification rate of 97%. In the intermediate suspicion category, the AI avoided 22.6% (165/730) of thyroid nodules and achieved a correct classification rate of 83%. For high suspicion nodules, the AI avoided 26.9% (90/334), with a correct classification rate of 80%. However, the error classification rates increased with malignancy likelihood, being 3% for low suspicion, 17% for intermediate suspicion, and 20% for high suspicion. The successful identification rates were 88%, 67.8%, and 88.9% for the low, intermediate, and high suspicion categories, respectively (Table 3).

The Sankey diagram (Figure 6) highlights that most benign nodules (n=2719, 86.8% of all benign nodules) were successfully avoided by the AI system, with low suspicion nodules comprising 91% (2587/2842) of all AI-avoided nodules. However, 415 benign nodules (9.1% of all nodules) were not identified. Notably, the AI misclassified 123 malignant nodules (2.7% of all nodules) as benign.

XSL•FO
RenderX

Figure 6. Sankey diagram illustrating the artificial intelligence's performance across low, intermediate, and high suspicion categories in thyroid nodule evaluation. Links represent the flow between entities. The width of the link corresponds to the amount of flow, with values ranging from 90 to 2719. Colors are used to differentiate between different types of flows. The terms "benign" and "malignant" refer to the results of pathological or cytological tests. AI: artificial intelligence.

Further analysis of the 123 malignant nodules misclassified by AI, as detailed in Table 4, revealed that all were papillary thyroid carcinomas, with 56.9% (70/123) being papillary thyroid microcarcinomas. Among these, 20.3% (25/123) exhibited extrathyroidal extension, 18.7% (23/123) presented with central lymph node metastases, and 74% (91/123) carried the BRAF V600E mutation. Multimedia Appendix 2 shows that the error classification rates of the AI system increased with higher malignancy risk, being lowest for low suspicion nodules (3%) and highest for high suspicion nodules (20%).

Table . Composition of malignant nodules identified as artificial intelligence–avoided.

Clinical and pathological features	Number, n (%)
Papillary thyroid microcarcinoma	70 (56.9)
Other thyroid carcinoma (FTC[a], MTC[b], and ATC[c])	0 (0)
Extrathyroidal extension	25 (20.3)
Central lymph node metastasis	23 (18.7)
Lateral lymph node metastasis	0 (0)
Distant metastasis	0 (0)
BRAF V600E mutation	91 (74)
TERT[d] promoter mutations	0 (0)

Comparison of Radiologists' and AI Performance

Task 2 compares the performance of radiologists and AI in identifying benign nodules initially assessed as malignant by radiologists, using the correct classification rate and successful identification rate as evaluation metrics. The violin diagram (a) in Multimedia Appendix 3 reveals that junior radiologists exhibited a median successful identification rate of 0.40 (95% CI 0.28 - 0.53), while senior radiologists demonstrated a median successful identification rate of 0.55 (95% CI 0.38 - 0.71; *P*=.001). AI achieved a successful identification rate of 0.81, surpassing the performance of both junior and senior radiologists. According to the violin diagram (b) in Multimedia Appendix 3, the median correct classification rate for junior radiologists was 0.54 (95% CI 0.44 - 0.62), whereas senior radiologists exhibited a median correct classification rate of 0.64 (95% CI 0.48 - 0.72; *P*=.13). Furthermore, the datasets indicate that AI achieved a successful identification rate of 0.828, which exceeded the correct classification rate of both junior and senior radiologists (Multimedia Appendix 3).

Figure 3B illustrates the performance of junior and senior radiologists, as well as the AI, in task 2. The AUC values for the AI model were 0.88 (95% CI 0.85 - 0.91), demonstrating superior performance to that of junior radiologists with an AUC of 0.43 (95% CI 0.36 - 0.49; *P*=.002) and senior radiologists with an AUC of 0.63 (95% CI 0.55 - 0.70; *P*=.003).

Discussion

Principal Findings

Thyroid nodules, frequently detected during ultrasound, require accurate characterization to assess malignancy and guide patient care. However, the subjective nature of radiological interpretation and the difficulty in distinguishing benign from malignant nodules often lead to unnecessary FNAs. AI holds significant potential in overcoming these challenges by identifying complex patterns and subtle features in ultrasound images that may be missed by human observers [26,27].

In this study, the rate of unnecessary FNAs stood at a high level in dataset 1, as high as the previous study reported [28], which was understandable. The high rate of overdiagnosis aligns with real-world clinical experiences, where various factors, such as human judgment, environmental influences, psychological aspects, and inherent subjectivity in radiological interpretations, play a significant role. Fortunately, based on our findings, after integrating an AI re-evaluation step before performing FNA, the system correctly identified 2719 out of 3134 (86.8%) benign nodules. As a result, the proportion of unnecessary FNAs among all nodules decreased from 3134 out of 4572 (68.5%) to 415 out of 4572 (9.1%).

We found that 2587 out of 3508 (73.7%) low-suspicion nodules based on ultrasound features were identified by AI, with 2510 out of 2587 (97%) correctly classified. In contrast, only 90 out of 334 (26.9%) high-suspicion nodules were identified, with 72 out of 90 (80%) correctly classified. These results suggest that AI re-evaluation is particularly beneficial for low-suspicion nodules and could be routinely implemented before FNA, especially for these cases.

Compared with radiologists, the AI demonstrated superior ability in identifying benign nodules initially assessed as being at malignant risk, surpassing the median performance of both senior and junior radiologists. Senior and junior radiologists were categorized by years of practice rather than absolute expertise. While senior radiologists had a higher correct classification rate than the juniors, the internal dispersion remained large, with most still falling below the AI's level and only 2 approaching or exceeding its performance. Cultivating senior radiologists is exceedingly challenging and takes a long time, whereas AI effectively compensates for the shortage of senior radiologists.

This underscores AI's significant potential for clinical application, reducing unnecessary FNAs and optimizing nodule management. It saves both human resources and time while ensuring high accuracy and minimizing missed diagnoses. Integrating AI into clinical practice ensures more consistent identification, reduces unnecessary health care costs, eases the burden on the health care system, and saves time and effort for radiologists.

From another perspective, AI re-evaluation resulted in 123 erroneous identifications (incorrectly labeling them as benign) among 4572 (2.7%) nodules. These malignant nodules represent a risk in AI re-evaluation. Balancing the risks and benefits of AI re-evaluation is crucial. Fortunately, our subgroup analysis revealed that all of these errors were papillary thyroid carcinomas, with 70 out of 123 (56.9%) being papillary thyroid microcarcinomas. Although the error classification rate was significantly lower than the correct classification rate and papillary thyroid cancer, especially microcarcinoma, is generally indolent with low mortality, we recommend active surveillance for these nodules. Given the error classification rate in intermediate- and high-suspicion nodules (28/165, 17% and 18/90, 20%, respectively), intensified surveillance is clinically warranted for these cohorts. Conversely, low-suspicion nodules demonstrated significantly higher diagnostic reliability (77/2587, 3%), justifying extended surveillance intervals.

This study has several limitations. First, the data were obtained exclusively from 3 centers in China, limiting the generalizability of the findings. We anticipate that expanding the datasets to include real-world data from other regions will enable a more comprehensive validation of the AI model's performance. Second, the AI system we tested was limited to analyzing grayscale images, leaving valuable information such as clinical data and color Doppler features insufficiently evaluated. Third, since this study reflects the application of AI in real clinical settings, there is a potential for bias introduced by biopsy decisions influenced by clinical judgment or patient preferences. Fourth, no prospective studies have been conducted to further validate the AI's application and its impact in clinical practice.

Conclusions

In conclusion, we conducted a retrospective study to evaluate the potential of AI in clinical practice for identifying benign nodules from those initially classified as at malignant risk by radiologists. Our findings demonstrated that incorporating AI in the pre-FNA stage can significantly reduce the number of unnecessary FNAs, optimize the management of thyroid

XSL•FO
RenderX

nodules, and outperform the average diagnostic accuracy of both junior and senior radiologists. Thus, including AI in the management of thyroid nodules may be a new and promising exploration to reduce the rate of unnecessary FNAs. To fully explore the potential of AI in thyroid nodule diagnosis, continued collaboration among AI developers, radiologists, and clinicians is essential.

Abstract

Background: Large language models (LLMs) have made significant advancements in natural language processing (NLP) and are gradually showing potential for application in the medical field. However, LLMs still face challenges in medicine.

Objective: This study aims to evaluate the efficiency, accuracy, and cost of LLMs in handling complex medical cases and to assess their potential and applicability as tools for clinical decision support.

Methods: We selected cases from the database of the Department of Cardiothoracic Surgery, the Third Affiliated Hospital of Sun Yat-sen University (2021 - 2024), and conducted a multidimensional preliminary evaluation of the latest LLMs in clinical decision-making for complex cases. The evaluation included measuring the time taken for the LLMs to generate decision recommendations, Likert scores, and calculating decision costs to assess the execution efficiency, accuracy, and cost-effectiveness of the models.

Results: A total of 80 complex cases were included in this study, and the performance of multiple LLMs in clinical decision-making was evaluated. Experts required 33.60 minutes on average (95% CI 32.57 - 34.63), far longer than any LLM. GPTo1 (0.71, 95% CI 0.67 - 0.74), GPT4o (0.88, 95% CI 0.83 - 0.92), and Deepseek (0.94, 95% CI 0.90 - 0.96) all finished under a minute without statistical differences. Although Kimi, Gemini, LLaMa3-8B, and LLaMa3-70B took 1.02 - 3.20 minutes, they were still faster than experts. In terms of decision accuracy, Deepseek-R1 had the highest accuracy (mean Likert score=4.19), with no significant difference compared to GPTo1 (P=.699), and both performed significantly better than GPT4o, Kimi, Gemini, LLaMa3-70B, and LLaMa3-8B (P<.001). Deepseek-R1 and GPTo1 demonstrated the lowest hallucination rates—6/80 (8%) and 5/80 (6%), respectively—significantly outperforming GPT-4o (7/80, 9%), Kimi (10/80, 12%), and the Gemini and LLaMa3 models, which exhibited substantially higher rates ranging from 13/80 (16%) to 25/80 (31%). Regarding decision costs, all LLMs showed significantly lower costs than the Multidisciplinary Team**,** with open-source models such as Deepseek-R1 offering a zero direct cost advantage.

Conclusions: GPTo1 and Deepseek-R1 show strong clinical potential, boosting efficiency, maintaining accuracy, and reducing costs. GPT4o and Kimi performed moderately, indicating suitability for broader clinical tasks. Further research is needed to validate LLaMa3 series and Gemini in clinical decision.

KEYWORDS

large language models; artificial intelligence; clinical decision support; complex medical cases; cross-sectional studies

Introduction

Background

With the development of artificial intelligence (AI) and deep learning technologies, large language models (LLMs) have demonstrated remarkable potential across various fields, particularly in natural language processing (NLP) tasks such as summarization, paraphrasing, generating new text content, and writing program code [1,2]. Additionally, LLMs can act as personal assistants, helping users answer a wide range of questions.

The primary goal of LLMs was not initially to serve the medical field, but some studies have already shown that LLMs have significant potential in medicine [3,4]. For example, research

XSL•FO
RenderX

has found that ChatGPT can pass the United States Medical Licensing Examination (USMLE) [5] and the Advanced Cardiovascular Life Support (ACLS) exam [6]. In addition to exam simulations, ChatGPT's potential advantages in daily medical applications have also been confirmed, such as extracting information from electronic health records and assisting with literature searches [7]. However, the training knowledge base of LLMs may have issues such as incompleteness, information bias, or generation of misleading information, and the application of general-purpose LLMs in medicine has not yet undergone large-scale clinical studies. Therefore, it is essential to explore the application of LLMs in medicine in greater depth.

Previous studies have verified the diagnostic capabilities of GPT-3.5, GPT-4, and other LLMs [8-12], such as its ability to generate detailed differential diagnosis lists for common clinical cases. Additionally, research teams tested the GPT-4 ability to make accurate diagnoses from medical records [9], and the results showed that the generative AI GPT-4 chose the correct diagnosis as the primary diagnosis in nearly 40% of cases and provided the correct potential diagnosis in 64% of challenging cases. However, complex cases are common in hospitals, especially in cardiothoracic surgery. Due to population aging and insufficient medical resources, providing timely and high-quality clinical decision support has become a major challenge for health care systems worldwide. Delivering accurate and effective clinical decisions for complex cases typically requires substantial human, time, and money. Although some studies are currently exploring the application of LLMs in medicine, a recent review [13] published in a *Journal of the American Medical Association* subjournal of 519 studies assessing LLMs in the medical field found that only 5% of studies used real-world data. This exposes the limitations of current research and the potential disconnect from clinical reality. In this context, whether LLMs can provide effective clinical decision support for doctors in complex cases still requires further investigation.

Objectives

Therefore, this study aimed to preliminarily evaluate the utility of LLMs in complex medical decision-making by assessing their efficiency, accuracy, and cost in real-world clinical cases, and exploring their practical potential in clinical decision support.

Methods

Study Design and Data Source

To ensure that the study is based on representative and unbiased real-world cases, we screened a total of 140 cases from the complex case database of the Department of Cardiothoracic Surgery of the Third Affiliated Hospital of Sun Yat-sen University (2021 - 2024). These cases are sourced from the complex case database of a tertiary hospital, which is not publicly available, ensuring the accuracy of the study to the greatest extent and preventing any generic LLMs from being exposed to relevant data during their training, thus ensuring the objectivity and fairness of the evaluation. Most of the cases have a consistent structure, including medical history, current symptoms, examination methods and findings, diagnosis, and clinical decision. All cases were reviewed by an experienced physician, and only those that met the following criteria were included in the further analysis: the clinical case data records the entire diagnostic and treatment process, complex clinical case, and the cases are not duplicates. In this study, a complex case was defined as a patient scenario that disease involved at least 2 organ systems, required multidisciplinary input for diagnosis or treatment, and presented with conflicting or uncertain therapeutic pathways. These criteria were established by 2 senior cardiothoracic specialists.

LLMs Evaluation

To evaluate the recently launched LLMs, we selected the following models for benchmarking: Deepseek-R1, GPTo1, GPT-4o, Kimi, Gemini, LLaMA3-70B, and LLaMA3-8B. Model setup and prompting strategy details are provided in Multimedia Appendix 1. The reviewers included 2 board-certified cardiothoracic surgeons, each with more than 10 years of clinical experience and active participation in weekly Multidisciplinary Team (MDT) discussions. Reviewers were blinded to the identity of the LLM models generating each response to minimize bias.

Clinical Decision Efficiency Evaluation

We evaluate the execution efficiency of Deepseek-R1, GPTo1, GPT4o, Kimi, Gemini, LLaMA3-70B, and LLaMA3-8B in clinical decision-making tasks. This is done by recording the time taken by each model from receiving the instructions to generating a complete decision recommendation and comparing it with the time taken by several experts to complete the same task.

Clinical Decision Accuracy Evaluation

Two independent clinical experts were invited to evaluate the clinical decision outputs generated by Deepseek-R1, GPTo1, GPT-4o, Kimi, Gemini, LLaMA3-70B, and LLaMA3-8B. The evaluations were based on the consistency with expert decisions, using a 5-point modified Likert scale. The scoring standards and the scale are presented in Table 1 [14,15].

XSL•FO
RenderX

Table . Scoring standards for the 5-point modified Likert scale.

Likert score	Relevance of decisions	Redundancy of decisions
1	Most of all relevant decisions were not mentioned.	All or most decisions were redundant or unjustified.
2	Some or many relevant decisions were not mentioned.	Some decisions were redundant or unjustified.
3	Most relevant decisions were mentioned.	Some decisions were redundant or unjustified.
4	Most relevant decisions were mentioned.	Few decisions were redundant or unjustified.
5	All relevant decisions were mentioned.	No redundant or unjustified decisions.

Hallucination Evaluation

Each LLM output was reviewed by two independent clinical experts to identify statements that were factually incorrect, clinically implausible, or not supported by the case information. A hallucination was defined as a recommendation or rationale inconsistent with current clinical guidelines or contradicting the provided case data. The hallucination rate was calculated as the proportion of cases where at least one hallucinated item was present in the model's response.

Each expert independently scored the output of each model, and the final score was the average of the two experts' ratings. To ensure scoring consistency, we calculated the inter-rater reliability (Cohen kappa coefficient—a statistic that measures inter-rater agreement for categorical items while accounting for chance agreement) [16] to validate the reliability of the evaluation.

Clinical Decision Cost Evaluation

The usage costs of each LLM were calculated and compared with the costs of the MDT. The MDT costs were calculated based on the hospital's MDT fee.

Statistical Analysis

Patient baseline characteristics were described using frequencies and percentages for categorical variables, and medians or means for continuous variables. For continuous variables with approximate normal distribution, Student *t* test (2-tailed) was used for comparisons; for nonnormally distributed continuous variables, the Mann-Whitney *U* test was used for comparisons between two groups, and the Kruskal-Wallis test was used for comparisons between three or more independent samples. For categorical data, Fisher exact test, chi-square test, or Wilcoxon signed-rank test was used. All statistical tests were 2-tailed, and a P value<.05 was considered statistically significant. Statistical analysis and plotting were performed using Python 3.13.1, with libraries including scipy.stats, pandas, seaborn, and matplotlib.

Ethical Considerations

This study was approved by the ethics committee of the Third Affiliated Hospital of Sun Yat-sen University (approval ID II2025-257-03; approval date March 2025). Written informed consent was obtained from all participants. To protect privacy, personal identifiers were removed or coded before analysis, and all data were stored on an encrypted, password-protected server accessible only to the research team. Participants did not receive any financial or material compensation. All procedures involving human participants were conducted in accordance with the Declaration of Helsinki and relevant institutional guidelines.

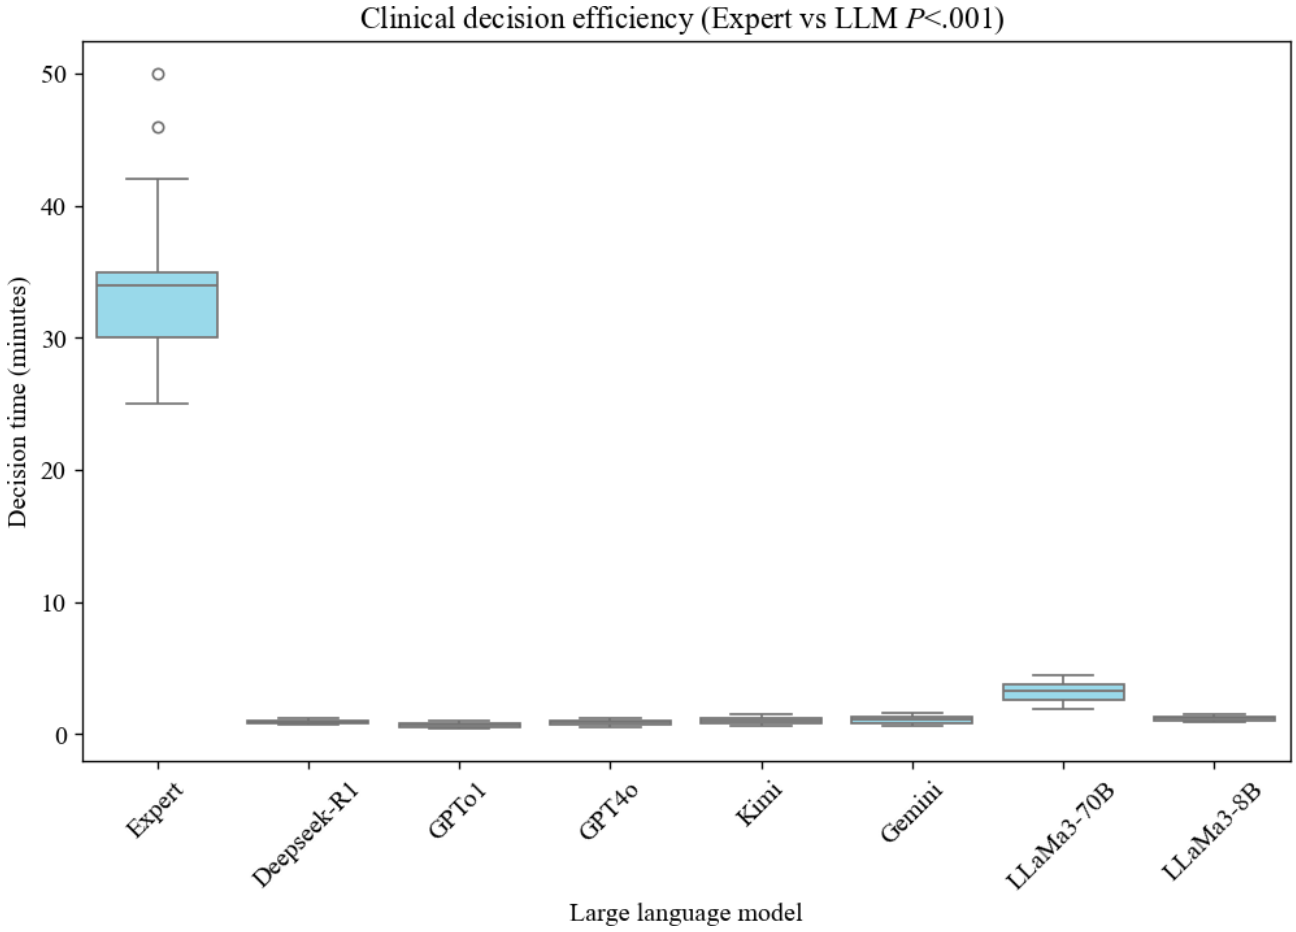
Results

Baseline Characteristics

A total of 140 patients from the Cardiothoracic Surgery Department of the Third Affiliated Hospital of Sun Yat-sen University were initially included in the study. After excluding 60 patients who did not meet the inclusion criteria, 80 patients remained. The median age of the study population was 60 (IQR 14 - 79) years, with 58 (72%) males and 22 (28%) females. The most common complex conditions were thoracic tumors combined with respiratory system disorders (25/80 cases, 31%), followed by thoracic tumors combined with circulatory system disorders (19/80 cases, 24%). As shown in Table 2, other conditions accounted for the remaining 45% (36/80 cases), and the median number of experts involved in the MDT was 7 (range 5 - 9). Table S2 in Multimedia Appendix 1 illustrates 2 representative complex clinical cases, including the final expert consensus from MDT discussions and the corresponding responses generated by LLMs.

XSL•FO
RenderX

Table . Baseline characteristics of the study cohort.



Characteristics	Values (N=80)
Age (years), median (range)	60 (14 - 79)
Sex, n (%)	
Male	58 (72)
Female	22 (28)
Complex conditions, n (%)	
Thoracic tumors+ respiratory disorders	25 (31)
Thoracic tumors+ circulatory disorders	19 (24)
Other conditions	36 (45)
Number of experts in MDT[a], median (range)	7 (5-9)

[a]MDT: Multidisciplinary Team.

Clinical Decision Efficiency Evaluation

The data analysis revealed that the average decision-making time for the expert group was significantly longer than for all LLMs (P<.001), with a mean of 33.6 (95% CI 32.57 - 34.63) minutes. In contrast, the decision-making time for LLMs was notably shorter. GPTo1 demonstrated the best decision-making efficiency, with an average time of only 0.71 (95% CI 0.67 - 0.74) minutes, followed by GPT4o (0.88, 95% CI 0.83 - 0.92 minutes) and Deepseek (0.94, 95% CI 0.90 - 0.96 minutes), all of which completed decisions in under 1 minute. Kimi, Gemini, and LLaMa3-8B also exhibited relatively fast decision-making abilities (1.02 - 1.18 minutes), although slightly slower than GPTo1 and GPT4o. LLaMa3-70B had the longest decision time at 3.20 (95% CI 3.04 - 3.37) minutes, but it was still significantly better than the expert group's 33.6 minutes. These results indicate that AI-driven LLMs significantly enhance the efficiency of clinical decision-making, as illustrated in Figure 1.

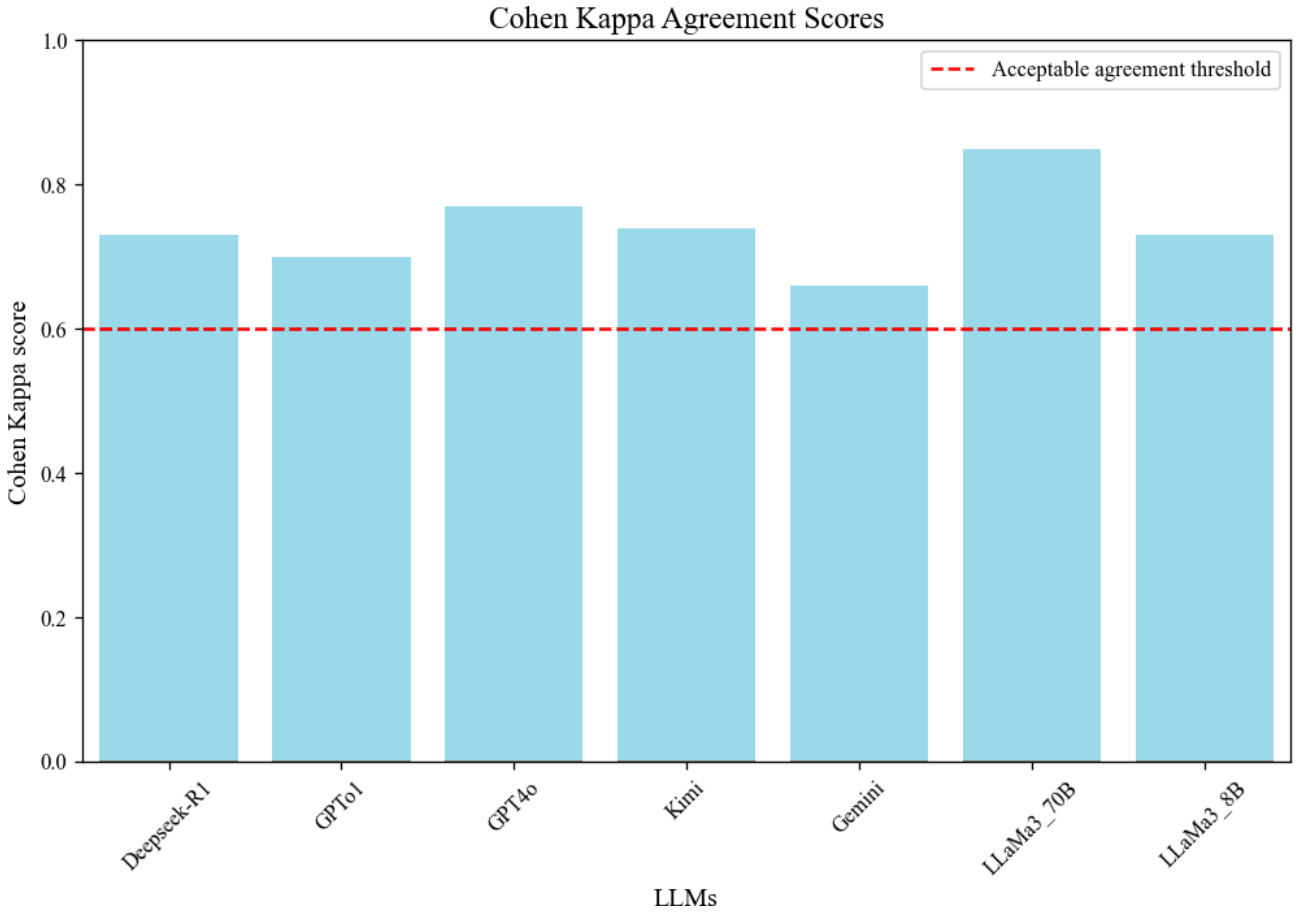
Figure 1. Clinical decision efficiency comparison between experts and large language models. LLM: large language model.

XSL•FO
RenderX

Clinical Decision Accuracy Evaluation

According to the classification standards of Landis et al [16], which are based on Cohen kappa coefficient, the results indicate strong agreement between two senior independent clinical experts, with kappa values ranging from 0.66 to 0.85. This suggests a high level of consistency in model evaluation. Detailed results are presented in Figure 2.

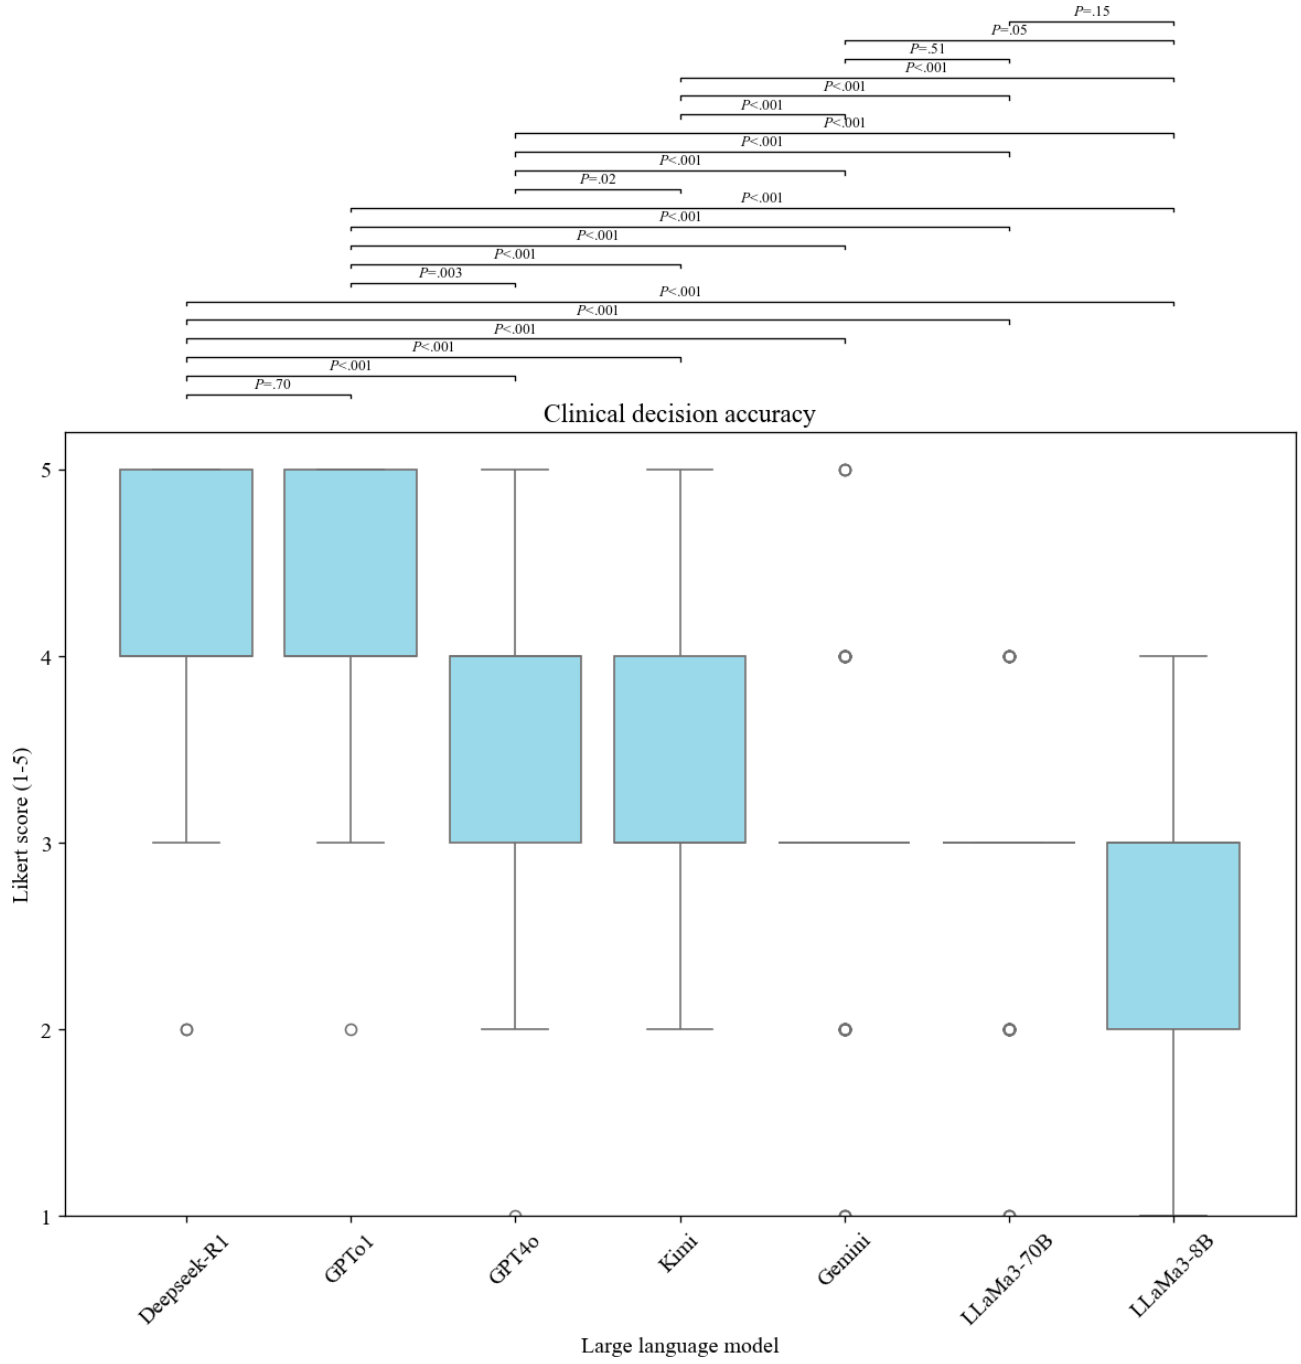
As shown in Figure 3, pairwise comparisons in clinical decision accuracy assessment revealed that Deepseek-R1 achieved the highest accuracy, with a mean Likert score of 4.19 (95% CI 4.02 - 4.35), significantly outperforming GPT4o, Kimi, Gemini, LLaMA3-70B, and LLaMA3-8B (all P<.001). However, no significant difference was found between Deepseek-R1 and GPTo1 (mean 4.15, 95% CI 3.99 - 4.31; P=.70). GPTo1 performed comparably to Deepseek-R1 and significantly better than GPT4o (P=.003), Kimi, Gemini, LLaMa3-70B, and LLaMa3-8B (all P<.001). Both Deepseek-R1 and GPTo1 exhibited the highest Likert scores, approaching expert-level performance, indicating suitability for clinical decision tasks.



GPT-4o achieved moderate performance with a mean Likert score of 3.76 (95% CI 3.57 - 3.95) but still significantly outperformed Kimi (P=.02), Gemini, LLaMa3-70B, and LLaMa3-8B (all P<.001), suggesting adequate feasibility for clinical decision-making. Kimi (mean 3.48, 95% CI 3.31 - 3.64) had higher scores compared to Gemini, LLaMa3-70B, and LLaMa3-8B (all P<.001), although it demonstrated significantly lower decision-making ability than Deepseek-R1, GPTo1, and GPT4o.

Gemini (mean 2.96, 95% CI 2.78 - 3.14) showed marginally better performance compared to LLaMa3-70B (mean 2.86, 95% CI 2.71 - 3.02; P=.047), but no significant difference was observed between Gemini and LLaMa3-8B (mean 2.7, 95% CI 2.54 - 2.86; P=.52). The LLaMa3 series consistently showed the lowest clinical decision accuracy, significantly below all other models (all P<.001).

We further assessed the hallucination rates of LLMs and found that Deepseek-R1 and GPTo1 had the fewest hallucinations, with 6/80 (8%) and 5/80 (6%) cases, respectively. GPT-4o and Kimi followed, with 7/80 (9%) and 10/80 (12%) cases, respectively. In contrast, Gemini and both LLaMa3 variants demonstrated significantly higher hallucination rates, ranging from 13/80 (16%) to 25/80 (31%) (Figure 4.



These findings demonstrate that Deepseek-R1 and GPTo1 not only achieved the highest Likert scores but also exhibited the lowest hallucination rates, underscoring their strong potential as AI-assisted tools for clinical decision-making. GPT-4o exhibited moderate yet consistent performance, supporting its applicability to more complex clinical scenarios. Kimi demonstrated intermediate performance, potentially useful in selected clinical situations but requiring further optimization. Conversely, Gemini, LLaMa3-70B, and LLaMa3-8B showed relatively poor performance, limiting their immediate clinical utility and highlighting the need for substantial improvement.

Clinical Decision Cost Evaluation

In this study, we compared clinical decision-making costs between MDT discussions and various LLMs (Figure 5). Our analysis revealed that the mean cost per MDT discussion conducted by experts was approximately 1000 Chinese Yuan Renminbi (about US $140), significantly higher than the decision-making costs associated with all evaluated LLMs ($P<.001$).

Within the LLM group, GPT4o and GPTo1 incurred direct costs of approximately 150 Chinese Yuan Renminbi (about US $20 for the Plus version), representing an 85% cost reduction compared to expert-led MDT discussions, thus demonstrating significant economic advantages. Additionally, Kimi and Gemini are proprietary models currently available without charge, whereas Deepseek-R1, LLaMa3-8B, and LLaMa3-70B are open-source models suitable for clinical decision support. These open-source LLMs potentially incur zero direct costs.

Discussion

Principal Findings

This study provides a preliminary assessment demonstrating that LLMs can significantly enhance the efficiency of clinical decision-making in complex clinical cases, while maintaining high decision accuracy and substantially reducing costs compared to traditional MDT discussions.

Performance and Potential Clinical Utility of LLMs

Our study results demonstrate that, compared to human experts, all LLMs significantly shortened decision-making time. The expert group had an average decision time of 33.6 (95% CI 32.57 - 34.63) minutes per case and involved a median of 7 clinical experts in the MDT discussion, while the most efficient model, GPTo1, took only 0.71 minutes, followed by GPT4o (0.88 minutes) and Deepseek (0.94 minutes). Even the longest decision time, observed in LLaMa3-70B, was only 3.20 minutes (which may be related to the insufficient GPU memory of the workstation in this study), still much faster than the expert group. Previous studies [17] also suggest that AI, through automating parts of the decision process, maintains accuracy in 88% of cases and provides quick, real-time feedback, thus improving efficiency and saving significant time and resources. This result highlights the potential application value of AI-assisted decision tools in high-demand clinical environments, especially in scenarios requiring rapid decision-making. Furthermore, the time differences among LLMs indicate that optimizing model architecture and inference time is critical to enhancing the real-time application capabilities of clinical decision-making.

In addition to improving decision efficiency, the reliability and accuracy of LLMs in clinical applications are equally crucial. This study found that Deepseek-R1 and GPTo1 performed the best in clinical decision accuracy, with decision levels comparable to that of human experts. However, there were still significant performance differences among the models. GPT-4o and Kimi showed moderate performance, suggesting that they may be suitable for general clinical tasks. For example, the accuracy of Gemini, LLaMa3-70B, and LLaMa3-8B was significantly lower, indicating limited applicability in critical clinical decision-making. Notably, Deepseek-R1 and GPTo1 demonstrated the lowest hallucination rates (8% and 6%, respectively), showing significantly better performance compared to GPT-4o (9%), Kimi (12%), and the Gemini and LLaMa3 models, whose rates ranged from 16% to 31%. These results underscore significant variability in content reliability among LLMs, aligning with prior studies [18] that reported hallucination rates ranging from 29% to 91% across different models. Interestingly, reasoning-optimized models such as Deepseek-R1 and GPTo1 showed a marked reduction in hallucinations, suggesting they may be more suitable for high-stakes medical applications where factual accuracy is critical. Beyond quantitative metrics, our study found qualitative differences in the reasoning styles of different LLMs. For example, Deepseek-R1 and GPTo1 tended to follow structured, guideline-concordant approaches, often closely mirroring the logic used by human MDT experts. GPT-4o and Kimi occasionally generated broader differential diagnoses. In

XSL•FO
RenderX

contrast, Gemini, LLaMa3-70B, and LLaMa3-8B responses included more redundant or loosely justified recommendations. These observations are preliminary and illustrative. A more comprehensive and systematic comparison of LLM reasoning will be conducted in future studies. These findings reaffirm that LLMs require rigorous validation before being applied to clinical decision-making. Our findings are consistent with recent studies by other researchers [11], which suggest that LLMs can serve as auxiliary tools to provide reference advice to clinical medical experts, rather than completely replacing human experts.

Currently, MDT discussions are still in their early stages in China [19]. High costs remain one of the barriers to their widespread application. Studies show that the average cost of each MDT discussion by experts is approximately 1000 Chinese Yuan Renminbi (about US $140) in a tier 3 grade A hospital in China, while the decision cost for GPT4o and GPTo1 is only around 150 Chinese yuan renminbi (Plus subscription version US $19.99), representing an 85% cost reduction. Moreover, Kimi and Gemini, as closed-source models, are currently available for free, while Deepseek-R1, LLaMa3-8B, and LLaMa3-70B are open-source models with the potential advantage of zero direct costs. This makes open-source LLMs more promising in environments with limited health care resources. Although LLMs show significant advantages in terms of economic efficiency, their clinical application still needs to consider indirect costs, such as equipment costs, model fine-tuning, and ethical oversight.

Risks and Deployment Strategies

It is also important to address privacy and security concerns when deploying LLMs in health care settings. In this study, some open-source models were deployed locally in a closed-loop environment without internet access or external application programming interface calls, effectively minimizing the risk of patient data leakage. In contrast, proprietary models such as GPT-4o, Kimi, and Gemini required data to be submitted via HTTPS after anonymization, which, despite encryption, still introduces potential risks of data exposure during transmission. For future clinical deployment, it is essential to implement privacy-preserving strategies such as on-premise inference, secure application programming interface gateways, and strict data de-identification.

While LLMs can significantly improve decision efficiency, maintain high diagnostic accuracy, and drastically reduce costs, some experts remain concerned about the potential misuse of LLMs and the lack of supervision [20]. At present, LLMs still have some imperfections, such as biases and hallucinations [21], which may be related to the Transformer architecture itself [22,23]. To address these challenges, several mitigation strategies should be considered, including deploying LLMs under expert supervision, conducting fine-tuning based on medical-specific datasets, and incorporating human-in-the-loop mechanisms to ensure clinical relevance and safety. Establishing robust ethical and governance frameworks is also imperative to support responsible and transparent deployment. In the short term, continued involvement of human experts remains critical, and the most pragmatic approach is a collaborative model in which LLMs assist clinicians rather than operate independently or autonomously.

Limitations

This study also has some limitations. First, our evaluation focused on LLMs' execution efficiency, decision accuracy, and costs, without in-depth exploration of the models' limitations, interpretability, and ethical implications. Future studies will adopt more comprehensive evaluation frameworks, such as Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis-LLM extension [24], to incorporate additional dimensions including reproducibility, bias, and potential harm. Second, the data used in this study were obtained from a single institution, necessitating further external validation to assess the generalizability of LLMs across diverse health care settings. Third, we did not explore the integration of LLMs into hospital information systems in this study. While LLMs demonstrate significant transformative potential in clinical decision-making, further clinical trials and real-world validation are needed before their formal adoption in practice.

Conclusions

The study indicates that LLMs, particularly GPTo1 and Deepseek-R1, have immense potential in clinical decision-making, significantly improving efficiency, maintaining high diagnostic accuracy, and reducing costs. These models can serve as powerful auxiliary decision-making tools. GPT-4o and Kimi demonstrated moderate performance, suggesting that they may be suitable for general clinical tasks. However, the application of the LLaMa3 series and Gemini in clinical decision-making requires further investigation.

Acknowledgments

This study was supported by the National Natural Science Foundation of China (grant number 82373186). We would like to express our deepest gratitude to all those who have provided their support and assistance in the completion of this project.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

YHH conceived the study. YHH, GZY, and YHS collected clinical data and analyzed clinical data, and wrote articles. XJL, YHW, KZ, JNX, HGC, and JZ participated in clinical data collection and large language model clinical decision evaluation.

Abstract

Background: The capabilities of large language models (LLMs) to self-assess their own confidence in answering questions within the biomedical realm remain underexplored.

Objective: This study evaluates the confidence levels of 12 LLMs across 5 medical specialties to assess LLMs' ability to accurately judge their own responses.

Methods: We used 1965 multiple-choice questions that assessed clinical knowledge in the following areas: internal medicine, obstetrics and gynecology, psychiatry, pediatrics, and general surgery. Models were prompted to provide answers and to also provide their confidence for the correct answers (score: range 0% - 100%). We calculated the correlation between each model's mean confidence score for correct answers and the overall accuracy of each model across all questions. The confidence scores for correct and incorrect answers were also analyzed to determine the mean difference in confidence, using 2-sample, 2-tailed *t* tests.

Results: The correlation between the mean confidence scores for correct answers and model accuracy was inverse and statistically significant (r=−0.40; P=.001), indicating that worse-performing models exhibited paradoxically higher confidence. For instance, a top-performing model—GPT-4o—had a mean accuracy of 74% (SD 9.4%), with a mean confidence of 63% (SD 8.3%), whereas a low-performing model—Qwen2-7B—showed a mean accuracy of 46% (SD 10.5%) but a mean confidence of 76% (SD 11.7%). The mean difference in confidence between correct and incorrect responses was low for all models, ranging from 0.6% to 5.4%, with GPT-4o having the highest mean difference (5.4%, SD 2.3%; P=.003).

Conclusions: Better-performing LLMs show more aligned overall confidence levels. However, even the most accurate models still show minimal variation in confidence between right and wrong answers. This may limit their safe use in clinical settings. Addressing overconfidence could involve refining calibration methods, performing domain-specific fine-tuning, and involving human oversight when decisions carry high risks. Further research is needed to improve these strategies before broader clinical adoption of LLMs.

Introduction

With their capacity to understand and generate human-like text, large language models (LLMs) are poised to support health care professionals in complex clinical decisions [1-3]. A wide array of LLMs is now accessible, including open-source models, offering solutions that cater to both the public and medical professionals [1,4].

The efficacy of these models has been demonstrated in a variety of tasks, albeit with some limitations [5,6]. For instance, LLMs, such as GPT, have shown promise in providing diagnostic assistance and answering medical queries [5,7-9]. Katz et al [10] demonstrated that GPT-4 not only improved clinically when compared to its predecessor, GPT-3.5, but also matched physician performance in certain areas. However, there is evidence of hallucinations and inaccuracies in model outputs, which could lead to harm in clinical decision-making [11,12]. Specifically, LLMs have occasionally generated completely

XSL•FO
RenderX

fabricated evidence (eg, information and references) and have presented such evidence as factual [11,12].

One way of building confidence in applying models within health care is the use of explainable artificial intelligence (AI) [13,14]. However, easily explainable outputs are difficult to evaluate due to the complexity of how LLMs process and output data [13,15,16]. Recent work revealed that these models often exhibit high confidence even when presenting incorrect information [17]. This raises questions about the underlying mechanisms that prompt an LLM to label certain statements as "more factual." For example, one possible explanation could be that data-rich or frequently discussed topics in training sets may be perceived as more certain [18], even if this does not translate into clinical accuracy. Additionally, retrieval-augmented generation (RAG) has been proposed to ground LLM outputs in external data, which potentially mitigates hallucinations [19]. Nevertheless, these approaches do not fully resolve whether models can reliably judge their own correctness. Accurate and well-calibrated confidence scores may be vital for establishing trust in these systems, as such scores can alert users to approach certain responses with caution. If a model consistently shows undue confidence in wrong answers, it poses a subtle but potentially dangerous form of hallucination. Clinicians might adopt decisions based on erroneous advice that is delivered with overt certainty. By investigating how these models generate and express their confidence, we aimed to illuminate whether LLMs can reliably self-assess correctness.

The goal of this study was to benchmark LLMs (both proprietary LLMs, like GPT-4o and Claude 3.5 Sonnet, and open-source LLMs, like Qwen) in terms of accuracy and associated confidence in answering clinical questions. Our aim was to determine if these models can accurately judge when to be confident in their responses and, in doing so, allow for better explainability in their application.

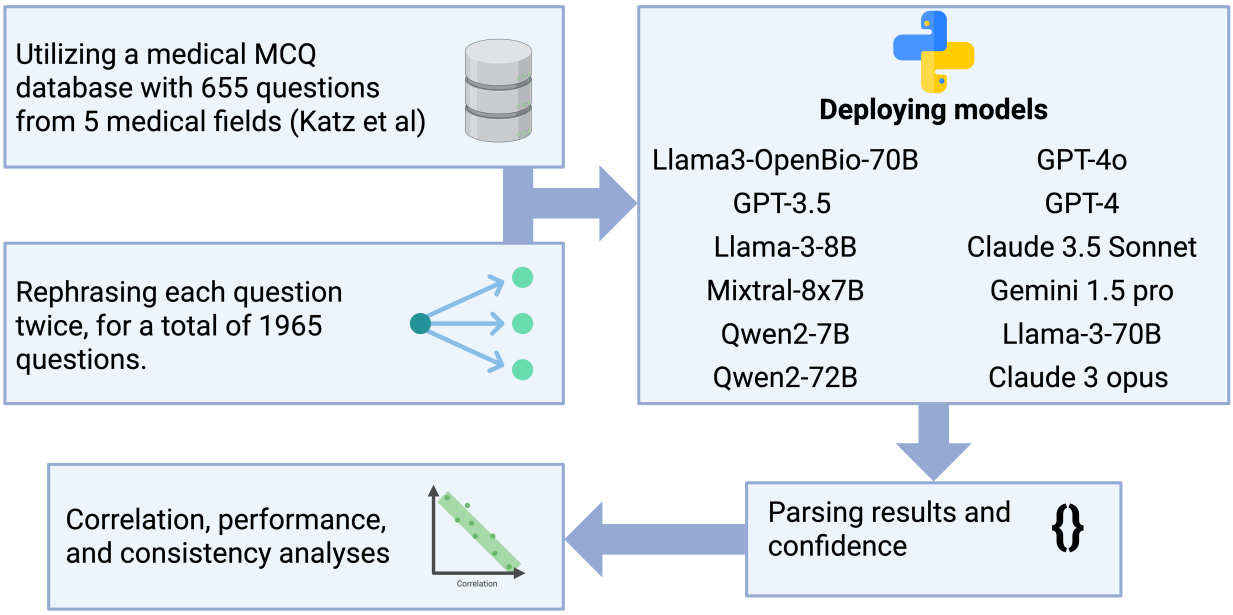
Methods

Study Design and Data Source

This study used a public compiled dataset from a previous study by Katz et al [10], which includes 655 questions for the following five medical specialties: internal medicine, obstetrics and gynecology (OBGYN), psychiatry, pediatrics, and general surgery. These questions were sourced from official 2023 licensing examinations for each field and were crafted from internationally recognized textbooks and guidelines. This dataset serves as a standardized framework for assessment [20-24].

To enhance benchmarking reliability, each original question was rephrased twice by using the GPT-4 application programming interface (API) in Python (Python Software Foundation), yielding 1965 questions (we include the full prompt in Multimedia Appendix 1). The prompts were carefully designed to modify only the writing style, without altering any clinical details, such as medical terms, laboratory values, or answer choices [25]. This approach aimed to preserve all clinical details, ensuring that rephrased questions stayed faithful to the original intent and information. To confirm this, 2 board-certified physicians separately reviewed a 20% random sample of questions from each specialty. They compared the rephrased and original questions side by side, focusing on consistency in medical terminology, laboratory values, and answer choices. Both reviewers concluded that the paraphrased items remained unchanged in terms of clinical meaning and required no further edits, thereby confirming overall integrity and accuracy.

Model Setup and Configuration



The LLMs used in this study were prompted (using 1 structured prompt) to return the correct answer, along with a confidence score for each choice ("A," "B," "C," and "D"), in JSON format. These confidence scores were expressed as percentages between 0% and 100% for each option, resulting in a total confidence score of 100% for all options combined. The open access models were executed by using API codes in a dedicated server with 4 H100 80-GB graphics processing units; the corresponding codebase is accessible on GitHub for the original database by Katz et al [10], and we provide the full prompts, which can be used locally, in Multimedia Appendix 1. We used Python 3.10 for data analyses. The commercial models were used via the corresponding companies' API interfaces. We used several Python libraries to facilitate data processing, model interaction, and analysis—NumPy 1.26.4, Pandas 2.1.4, Scikit-Learn 1.3.0, Hugging Face's Transformers 4.37.2, and torch 2.2.2+cu121—as well as JSON module 2.0.9. We used the default hyperparameters for each model to reflect typical user settings and provide a balanced baseline [26]. For the open access models, we used the "instruct" versions, which perform better on zero-shot questioning.

Benchmarked LLMs

We selected 12 LLMs that varied in terms of size, architectures, and intended domains (Figure 1). This set included established "household" models and newly introduced or domain-focused alternatives, ensuring diverse coverage (Figure 1). The benchmarked models are shown in Table S1 in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 1. A flowchart representing the evaluation methodology. The 655 questions were sourced from a study by Katz et al [10]. MCQ: multiple-choice question.

Statistical Analysis

The Pearson correlation coefficient was used to correlate models' mean confidence scores for correct answers and accuracies across models and medical fields. Chi-square tests assessed overall performance differences within each field, using proportions of correct responses. Post hoc pairwise comparisons with Bonferroni correction identified specific intermodel differences. Confidence levels were compared between correct and incorrect responses for each model, using 2-sample, 2-tailed *t* tests. Mean confidence scores were calculated for higher-tier and lower-tier models, as well as across all models. Performance consistency was evaluated by comparing confidence gaps between correct and incorrect responses. All statistical tests used a significance level of α=.05. Analyses were performed using R version 4.1.2 (R Foundation for Statistical Computing).

Results

Confidence Analysis

Table 1 summarizes accuracies and confidence levels across the models, and Table S2 in Multimedia Appendix 1 presents the data across all inspected fields and all models. An inverse correlation between the mean confidence scores for correct answers and the overall accuracy of the models is demonstrated (r=–0.40; P=.001); better-performing models generally showed lower confidence.

Table . Accuracies and confidence levels across the models.

Model	Accuracy, %	Total confidence, %	Confidence for correct answer, %	Confidence for incorrect answer, %
Claude 3.5 Sonnet	74	69.7	70.5	67.4
GPT-4o	73.8	63	64.4	59
Claude 3 Opus	71.7	68.5	68.9	67.3
GPT-4	66	84.1	84.5	83.3
Llama-3-70B	63.4	57.3	59.5	53.6
Llama OpenBio	59.2	77.9	77.7	78.1
Gemini	59.1	86.5	87.2	85.5
Qwen2-72B	57.8	57.7	58.6	56.5
Mixtral-8×7B	50.6	84.3	85.5	83
GPT-3.5	49	82.3	81.6	82.9
Llama-3-8B	48.4	80	79.7	80.3
Qwen2-7B	46	75.5	74.4	76.4

XSL•FO
RenderX

The mean confidence score for all 12 models was 76.1% when they were correct and 74.4% when they were incorrect. The 6 top-performing models showed a mean confidence score of 72.5% when they were correct and a mean confidence score of 69.4% when incorrect, while the 6 lowest-performing models displayed 79.6% confidence when they were correct and 79.5% confidence when they were incorrect (Table 2).

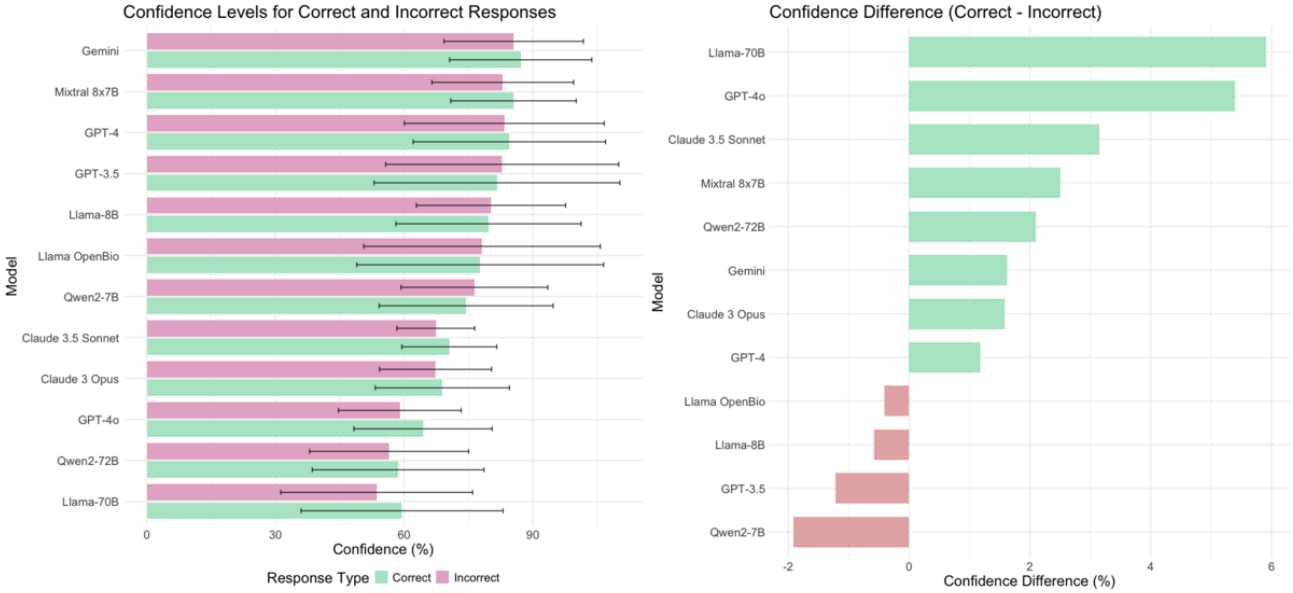


Table . Large language models' mean confidence scores for correct and incorrect answers.

Model	Confidence when incorrect (%), mean (SD)	Confidence when correct (%), mean (SD)	*P* value
GPT-4o	58.99 (14.31)	64.38 (16.11)	.006
Llama-3-70B	53.59 (22.38)	59.50 (23.54)	.006
Claude 3.5 Sonnet	67.37 (9.08)	70.52 (11.07)	.003
Gemini	85.55 (16.23)	87.17 (16.58)	.35
Claude 3 Opus	67.32 (13.06)	68.90 (15.65)	.61
GPT-4	83.34 (23.30)	84.52 (22.43)	.07
Qwen2-72B	56.49 (18.55)	58.59 (20.03)	.004
Qwen2-7B	76.37 (17.11)	74.45 (20.30)	.01
Mixtral-8×7B	82.99 (16.52)	85.49 (14.62)	.04
Llama-3-8B	80.25 (17.40)	79.67 (21.59)	.31
Llama OpenBio	78.14 (27.59)	77.73 (28.78)	.83
GPT-3.5	82.85 (27.17)	81.63 (28.66)	.81

Four models (GPT-4o, Llama-3-70B, Claude 3.5 Sonnet, and Qwen2-72B) demonstrated significantly higher confidence when they were correct (all *P* values were <.01) across the different fields and subsets. Gemini exhibited the highest overall confidence levels (when incorrect: mean 85.6%, SD 16.2%; when correct: mean 87.2%, SD 16.6%). Qwen2-7B was unique in that it displayed higher confidence when incorrect (mean 76.4%, SD 17.1% vs mean 74.5%, SD 20.3% when correct; *P*=.01).

GPT-3.5 and Llama-OpenBio-70B revealed minimal differences in confidence between correct and incorrect answers (*P*=.80). The largest confidence gap was observed in GPT-4 (5.4%, SD 2.3%; *P*=.003), while Llama-3-8B had the smallest gap (0.6%; Figure 2).

Figure 2. Large language models' confidence results for correct and incorrect answers. The left graph displays the average confidence and 95% CIs for each model, categorized by correct answers (green) and incorrect answers (red). The right graph shows the differences in average confidence for each model, where green indicates higher confidence in correct answers, and red indicates higher confidence in incorrect answers.

Models' Performances Across Fields

Significant differences were seen in model performance across all 5 medical specialties (at the *P*<.01 level). GPT-4o and Claude 3.5 Sonnet consistently outperformed other models. For internal medicine, GPT-4o (accuracy: 70.9%) and Claude 3.5 Sonnet (accuracy: 73.5%) showed no significant difference (*P*>.99) but outperformed lower-tier models, such as Qwen-7b (accuracy:

XSL•FO
RenderX

43.7%; *P*<.001). For OBGYN, Claude 3.5 Sonnet (accuracy: 71.0%) significantly outperformed most models, including GPT-4 (accuracy: 54.0%; *P*<.001). For pediatrics, the top 5 models (GPT-4o, Llama-3-70b, Claude 3.5 Sonnet, Claude 3 Opus, and GPT-4) showed no significant differences among themselves (all *P* values were >.05) but outperformed lower-tier models. Psychiatry results mirrored this pattern, with GPT-4o (accuracy: 84.4%) and Claude 3.5 Sonnet (accuracy: 82.4%) showing the best performance. For surgery, GPT-4o (accuracy: 70.9%) and Claude 3.5 Sonnet (accuracy: 70.5%) again showed no significant difference (*P*>.99) but outperformed lower-performing models, such as Qwen-7b (accuracy: 45.6%; *P*<.01; Tables S3 and S4 in Multimedia Appendix 1).

Discussion

In our evaluation, accuracy and confidence were inversely correlated for LLMs. Some lower-complexity models were notably more confident in incorrect answers. Despite GPT-4o showing the best performance, its largest observed gap between confidence scores for correct and incorrect answers was only 5.4%. This indicates that it may be insufficient for reliably guiding clinical choices, although the difference was statistically significant, and the model's confidence levels for correct and incorrect responses were generally high. Consequently, this gap does not provide a meaningful threshold for differentiating safe decision-making from potentially harmful decision-making in real-world practice. These results highlight potential risks in clinical applications, where model confidence, regardless of answer correctness, could lead to misinformed decisions.

We think that the observed miscalibration between correctness and confidence may pose risks in daily clinical practice if it remains unresolved. Overconfident models may recommend unsafe dosages or overlook key signs in a patient's presentation, especially under the fast-paced pressures of modern practice. This could lead to incorrect prescriptions or treatments. For example, the model might prescribe an incorrect antibiotic for a resistant infection, thereby delaying proper care. In other cases, a model's unwarranted confidence in a wrong triage decision could divert urgent attention from a critical patient. Such errors can increase morbidity and may undermine trust in AI-assisted clinical tools.

A brief comparison across models of various sizes did not reveal a consistent relationship between model size and confidence gaps. For instance, Qwen2-72B showed about a 2% difference in confidence between correct and incorrect responses, while Qwen2-7B exhibited a similarly small difference. This pattern was noted across multiple specialties, suggesting that architecture or domain-specific factors may play a more pivotal role than sheer model size in determining confidence behaviors.

Katz et al [10] reported that GPT-4 outperformed physicians in psychiatry and performed comparably to physicians in general surgery and internal medicine. Our study corroborates GPT-4's strong performance, particularly in psychiatry, where GPT-4o achieved 84.4% accuracy. However, our findings suggest that more cautious interpretation is needed, given the high confidence levels observed for incorrect answers. Xiong et al's [17] work on LLM confidence elicitation aligns with our observations of overconfidence. They noted improved calibration and failure prediction as model capability increased, which parallels our finding of better confidence calibration in more complex models.

If prompted confidence scores are truly driven by a model's internal representations and are not random or uncontextualized outputs, then consistently arbitrary numbers would suggest a disconnect between the model's knowledge state and its confidence estimates. Such misalignment can arise if the model's architecture, training data, or prompting strategies do not calibrate confidence with genuine certainty [17]. In other words, a system might systematically generate high confidence, regardless of accuracy, if it lacks mechanisms or fine-tuning for self-regulating uncertainty [27]. Even larger models sometimes yield small or inconsistent confidence gaps, indicating that domain-specific refinements or improved calibration may be required. Without such refinements, confidence levels may remain weakly tied to actual reasoning processes, meaning that they would not reflect well-grounded internal assessments.

The implications for clinical practice warrant careful consideration. Although the performance leap of newer models is promising, their inability to accurately self-assess confidence across wrong answers poses risks. Two possible strategies for addressing these challenges can be the use of human-in-the-loop protocols and the implementation of ensemble methods [28].

Human-AI collaboration may offer a balanced approach to leveraging AI strengths while maintaining necessary human oversight in health care [29]. Sezgin [29] suggested a human-in-the-loop approach for ensuring that AI systems are supervised via human expertise. However, the effective implementation of this approach faces challenges. The careful design of user interfaces is important for preventing automation bias [29,30]. There are also concerns about the potential erosion of clinical skills as a result of overreliance on AI [31].

Emerging evidence also suggests that some prompt engineering techniques can reduce but not completely eliminate sociodemographic bias in model outputs [32]. However, studies continue to reveal significant sociodemographic biases in LLMs, such as a large-scale study by Omar et al [33]. These biases may affect patient prioritization, treatment recommendations, and mental health screening across different groups, potentially driving disparities in care [33]. Simply removing demographic variables (eg, gender and race) may also risk overlooking clinically relevant distinctions. In the context of our study, better-calibrated confidence outputs may help to mitigate such biases by allowing models to reliably signal uncertainty, which is especially important for sensitive medical decisions. Nonetheless, the comprehensive evaluation of these strategies requires longitudinal studies that monitor the evolution of biases and large-scale, globally diverse datasets, which can be used to refine mitigation approaches.

Ensemble methods, which aggregate multiple models, present another possible strategy [34]. Mahajan et al [35] conducted a review of ensemble learning techniques for disease prediction. They found that stacking—an ensemble method that combines multiple classifiers—showed the most accurate performance in 19 out of 23 cases. The voting approach was identified as the

XSL•FO
RenderX

second-best ensemble method. However, ensemble methods are computationally intensive and may introduce latency in real-time clinical applications [36]. In some scenarios, a slight increase in overall accuracy might justify extra processing time, yet in urgent applications (eg, emergency triage), even brief delays can be problematic. Ensemble methods aggregate outputs from multiple models, distributing the "confidence load" so that individual sources of skewed certainty are less influential. However, our findings suggest that many current models show miscalibrated confidence levels. If all component models in an ensemble are prone to the same calibration issues, combining them may amplify rather than correct erroneous certainty.

Both strategies—human-in-the-loop protocols and the implementation of ensemble methods—would require extensive clinical trials for validation and the development of model-specific calibration curves for each medical specialty.

Our study has several limitations. The dataset was limited to 1965 multiple-choice questions for 5 medical specialties; therefore, the dataset may not fully represent the breadth of clinical scenarios. Further, the combination of automatic rephrasing and manual validation could have introduced bias [25]. We also used default model hyperparameters, which potentially limited performance optimization. To address these constraints, future work could expand the question sets (eg, by including a broader array of medical domains) and adopt real-world clinical data rather than purely examination-style questions. Additionally, custom hyperparameter tuning or advanced methods, such as RAG and fine-tuning, could be used to further refine model accuracy and confidence calibration [37], as the use of default hyperparameters, which may have varied across the evaluated LLMs, could have influenced their reported confidence levels. Finally, investigating computational cost and the time efficiency of deploying these models in clinical workflows would help to clarify practical feasibility.

In conclusion, better-performing LLMs show more aligned overall confidence levels, yet even the most accurate models still display minimal variation between right and wrong answers. This highlights a limitation in current self-assessment mechanisms and calls for further research. Future efforts could include larger and more diverse clinical datasets, domain-specific calibration strategies, and real-world testing to refine confidence estimates. Such work is critical before broader implementation of LLMs in clinical settings.

Abstract

Background: Patient-reported experience surveys allow administrators, clinicians, and researchers to quantify and improve health care by receiving feedback directly from patients. Existing research has focused primarily on quantitative analysis of survey items, but these measures may collect optional free-text comments. These comments can provide insights for health systems but may not be analyzed due to limited resources and the complexity of traditional textual analysis. However, advances in machine learning–based natural language processing provide opportunities to learn from this traditionally underused data source.

Objective: This study aimed to apply natural language processing to model topics found in free-text comments of patient-reported experience surveys.

Methods: Consumer Assessment of Healthcare Providers and Systems–derived patient experience surveys were collected and linked to administrative inpatient records by the provincial health services organization responsible for inpatient care. Unsupervised topic modeling with automated labeling was performed with BERTopic. Sentiment analysis was performed to further assist in topic description.

Results: Between April 2016 and February 2020, 43.4% (43,522/100,272) adult patients and 46.9% (3501/7464) pediatric caregivers included free-text responses on completed patient experience surveys. Topic models identified 86 topics among adult survey responses and 35 topics among pediatric responses that included elements of care not currently surveyed by existing questionnaires. Frequent topics were generally positive.

Conclusions: We found that with limited tuning, BERTopic identified care experience topics with interpretable automated labeling. Results are discussed in the context of person-centered care, patient safety, and health care quality improvement. Furthermore, we note the opportunity for the identification of temporal and site-specific trends as a method to identify patient care and safety concerns. As the use of patient experience measurement increases in health care, we discuss how machine learning can be leveraged to provide additional insight on patient experiences.

Introduction

Patient-reported experience measurements (PREMs) offer opportunities to understand and improve the patient experience with the goal of ultimately improving health care. PREMs for inpatient experiences typically evaluate a single clinical encounter using survey items that assess different aspects of the care experience using Likert-type scales to determine the range of patient experiences on individual items (eg, “Did doctors treat you with respect?”) that are summed to

XSL•FO
RenderX

domain-level composites (eg, overall experience with nurses, hospital environment, and discharge process) [1]. As the majority of questions on PREMs tend to use numerical scoring, the use of PREMs in health care quality improvement tends to focus on the tracking and improvement of quantitative scores. For example, regulations in the United States requires many hospitals to publicly report Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) scores [2]. However, a focus on quantitative summaries means that administrators, providers, and researchers could be missing out on experiences or concerns not being measured through existing quantitative domains [3-6].

In addition to the rating scales, patient experience surveys often include free-text comment responses where patients can share additional feedback and context on their experiences with health care services. These free-text comments can provide additional insight into patient experiences and how health care can be improved. Routine analysis of free-text comments may not be widely adopted for many reasons, possibly due to an unfamiliarity with methods for textual analysis and limited resources with which to conduct quality assurance in health care service settings [7,8].

In recent years, methodological developments in machine learning have enabled automated, efficient analysis of previously underused text data in health care. Natural language processing (NLP) refers to methods for representing text (and language) in ways that computers can understand and process. For example, researchers have used NLP methods with electronic medical records to predict clinical outcomes such as disease progression and health service utilization [9-11]. In the context of patient-reported outcome and experience measures, NLP could be applied to free-text comments to identify common themes and emerging concerns for specific hospitals or patient populations. Specifically, topic modeling can be used to identify distinct care experience topics and sentiment analysis can describe the emotional valence (positivity or negativity) of free text.

To date, few studies have applied NLP to patient experience data. In a systematic review, Khanbhai et al [12] identified 5 studies that used NLP to analyze routinely collected patient-reported measures, including the Press Ganey, HCAHPS, and 2 measures specific to experiences with cancer care. Furthermore, several studies applied NLP to nonstandard patient-reported experience data, such as forum or social media posts [12]. In our own literature review, we have identified 4 additional studies that have applied NLP to pre-existing, routinely collected patient experience measures [6,13-15]. We found that researchers have taken different approaches to topic modeling of patient-reported experience, including latent Dirichlet allocation (LDA), nonnegative matrix factorization, Top2Vec, and BERT (bidirectional encoder representations from transformers). Many of these studies trained new models or otherwise involved what could be considered a high degree of model tuning. Despite the promise of NLP methods for understanding patient experiences, the pace of innovation and the relative methodological complexity may present barriers to adoption in health care organizations. Organizations looking to implement routine analysis of open-ended text could benefit from knowing whether "off-the-shelf" pretrained topic models can provide useful insight without significant up-front costs. Furthermore, existing research on this topic focuses exclusively on the care experiences of adults. To address both gaps, the aim of this study was to (1) apply and evaluate unsupervised NLP with limited hyperparameter tuning to identify and describe topics found in the free-text comments of patient-reported experience surveys for hospital stays in Alberta, Canada, which cover (2) care experiences of adult and pediatric patients.

Methods

This study relied on data collected by Alberta Health Services (AHS) as part of ongoing health care quality monitoring. At the time the study was conducted, AHS was the provider of inpatient health care in Alberta, a Canadian province with 4.7 million residents.

Patient-Reported Experience Surveys

AHS uses 2 surveys to assess patient experiences with inpatient care—the Canadian Patient Experiences Survey on Inpatient Care (CPES-IC) survey and the Alberta Pediatric Inpatient Experience Survey (APIES). These surveys assess patient experience by asking questions on topics such as provider interactions (eg, doctors and nurses), the hospital environment (eg, noise levels and cleanliness), and the discharge process (eg, receiving written information). During the surveys, patients are also prompted for free-response comments (CPES-IC: "Is there anything else you would like to share with us about your hospital stay?"; APIES measure: "Is there something else you would like to share about your child's and your family's hospital experience? Please explain.") which are recorded by the telephone operators.

The CPES-IC is a modified version of the HCAHPS, a survey commonly used in the United States to assess patient-reported experiences with inpatient care [1]. Details on the CPES-IC can be found at the Canadian Institute for Health Information website [16]. The APIES is a modified version of the Child HCAHPS, an extension of the HCAHPS designed to assess pediatric patient and family inpatient experiences [17]. While many questions are identical and the experience domains are comparable between the CPES-IC and the APIES, the pediatric survey has additional questions on experiences specific to the child and family experience. All questions used in this analysis are common between the CPES-IC, APIES, and the (Child) HCAHPS surveys. We used the date (year) of the survey, the respondent's willingness to recommend a hospital (coded as most positive, "Definitely yes"), and the free-text comments. Responses were linked to administrative health data to provide descriptive statistics for the sample [18]. From this administrative data, we summarized admission category (urgent, elective), length of stay, sex, and age at discharge.

Sampling Procedure

The survey sampling procedure is consistent between adult and pediatric populations. For each institution, AHS operators randomly dial patients (or caregivers of the same) meeting the eligibility criteria until 10% of the eligible discharges are included. Pediatric surveys were administered to eligible

XSL•FO
RenderX

discharges from 16 institutions and adult surveys were administered to eligible discharges from 96 institutions. AHS makes multiple attempts to contact eligible patients. Data are collected exclusively via telephone. Respondents who agreed to answer the survey did so with the knowledge that these surveys are used for quality improvement and research purposes. More details on the sampling strategy and inclusion criteria have been published previously [19,20].

Textbox 1 describes the criteria for survey eligibility [20,21]. Patients were eligible to participate in the survey if they had a hospital stay lasting more than 24 hours, were not admitted to a psychiatric unit (or treated by a psychiatrist during inpatient stay), and did not die during the hospital stay. The eligibility criteria for pediatric inpatient visits are comparable. Caregivers (typically parents) of pediatric patients are contacted if pediatric patients meet the same conditions (for comparability with other jurisdictions, this study excludes pediatric surveys completed for newborn admissions with a length of stay less than 6 days).

Textbox 1. Survey eligibility criteria.

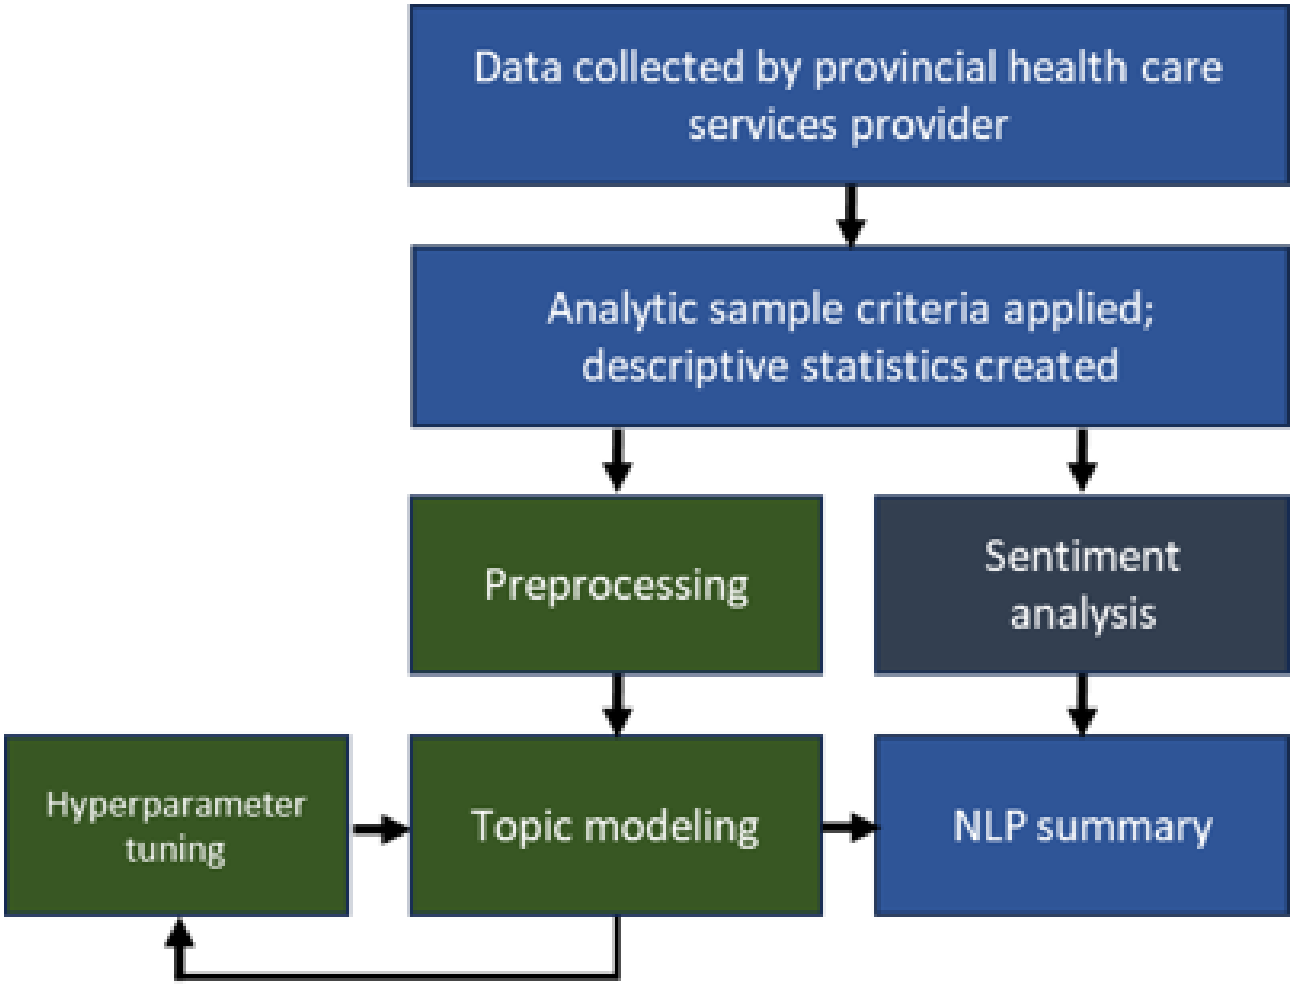
Common eligibility criteria

- Length of stay >24 hours.
- No psychiatric unit or psychiatrist on inpatient record for current stay.
- No death during inpatient stay.

Specific eligibility: adult

- Patient ≥18 years of age (at hospital discharge).
- Did not meet one of the conditions screened out on compassionate grounds (eg, still-births, babies tied to length of stay >6 days).

Specific eligibility: pediatric



- Patient <18 years of age (at hospital discharge).
- Caregiver not recorded as “no-publicity” (do not contact) in record.

Analysis

Figure 1 displays the analytic pipeline for this study. Data were linked by AHS Data and Analytics; data cleaning and descriptive statistics were conducted in SAS 9.4 and R (R Core Team; 4.2.1) [22]. After importing data into R and applying the analytic criteria (eg, date range and admission categories associated with newborns), white space was trimmed to identify and exclude any comments that may have contained only blank spaces. Additional checks based on comment length were used to check comment lengths and improperly coded missingness (eg, “N/A” instead of “”). Descriptive statistics were calculated for variables from patient experience surveys and linked administrative health data.

XSL•FO

Figure 1. Analytic pipeline. NLP: natural language processing.

Topic Modeling

Topic modeling was completed using the BERTopic package in Python [23]. BERTopic requires minimal preprocessing and accounts for semantic context by creating document embeddings and using a class-based term frequency-inverse document frequency method [23]. We used the default pretrained embeddings model ("all-MiniLM-L6-v2" from sentence-transformers). Other popular methods for topic modeling (such as LDA) focus on word frequency and do not account for the order and relationship of words [23,24]. Using embeddings-based models allow for comparisons with previous NLP PREMs work that have used Top2Vec and BERT-based models [6,14]. BERTopic can apply multiple representation models to generate multiple automated topic labels, allowing for a qualitative comparison of the interpretability of these topic labels.

The initial analytic process followed many of the suggested defaults from "best practices" in BERTopic documentation [25]. These included pre-extracting embeddings using a sentence transformer, removing English stopwords (common words), removing infrequent words (in this case, words used in fewer than 2 documents), setting the n-gram size to range between 1 and 2 words (identifying single words and 2-word terms), and setting a reproducible seed for the dimensionality reduction process. Before topic modeling, we removed duplicate comments. Each comment is assigned to a single topic. Topic labels (frequent words that describe a topic) are assigned by the model using representative terms. We did not provide any manual labeling at any stage in the topic modeling.

In the first model, we did not adjust parameters that would limit the number of potential topics beyond BERTopic's automated topic reduction as a method for reducing outliers. In addition to the base representation, KeyBERTInspired was selected as an additional representation model backend with the hope of creating more interpretable topic labels.

To balance the competing priorities of creating topic representations with interpretable labels (eg, extracted keywords) and avoiding redundant topics, we tuned model hyperparameters to reduce the total number of topics. In the second iteration of our model, clustering parameters were adjusted to generate a smaller number of topics (minimum cluster size using Hierarchical Density-Based Spatial Clustering of Applications with Noise) and the term range was increased (n-gram: 2 - 4). In the third (and final) model, term (n-gram) size was expanded to 1 - 4. To compare additional automated topic labeling methods, PartOfSpeech and MarginalMaximumRelevance were added as representation models to complement existing base and KeyBERT topic representations.

Sentiment analysis was completed using the {sentimentr} package in R to calculate the free-text response length (in words)

XSL•FO
RenderX

and sentence-averaged sentiments [26]. This package calculates sentence-level sentiments and evaluates linguistic context that modulates the positive or negative emotion (valence shifting). Specifically, sentimentr identifies polarized words in a sentence by referencing a sentiment dictionary, examines surrounding words for their relation (eg, negation and amplification), and weights the estimate of the sentiment accordingly. Sentiment strength is indicated by the absolute value of the sentiment score; positive and negative sentiment are indicated by positive or negative number. Neutral comments have sentiment scores closer to 0. Whole-comment sentiment was calculated to describe topics but were not incorporated into topic modeling.

To summarize the findings, we reported the 5 most frequently assigned, most positive, and most negative topics. We also summarize topics not currently measured on the patient experience surveys.

Ethical Considerations

Research ethics approval was granted with a waiver of consent by the Health Research Ethics Board at the University of Calgary (adult experience survey approval REB22-0810; pediatric experience survey approval REB17-0769).

Records were linked and deidentified by AHS for privacy and confidentiality. Data were provided to the research team as part of a research agreement with AHS.

Results

Overview

Between April 2016 and March 2020, AHS collected 100,272 adult experience surveys and 7464 pediatric experience surveys that were linked to administrative data and provided to the researchers. Of these surveys, 43,522 (43.4%) adult surveys and 3501 (46.9%) pediatric surveys included free-text comments. Descriptive statistics are presented in Table S1 in Multimedia Appendix 1.

Most comments were short; 54% (23,503/43,522) of CPES-IC comments and 44.1% (1543/3501) of APIES comments were 25 words or less. After deduplication, the CPES-IC contained 94.6% (41,152/43,522) distinct comments and the APIES contained 99.1% (3471/3501) distinct comments.

Table 1 presents the number of topics per model. The final (third) model contained 86 CPES-IC topics and 35 APIES topics. As noted in the Methods section, hyperparameters were tuned to reduce the total number of topics and combine similar topics. Between models 1 and 2, there was a large reduction in the number of topics among the adult surveys (168 fewer topics; 27/195, 13.8% of model 1). The most frequent, positive, and negative topics were generally consistent between the 3 models; however, topics in the second model were relatively coarse in comparison with the other 2. Full results of the 3 models are presented in Multimedia Appendices 2 and 3.

Table . Topics per model. BERTopic-, KeyBERTInspired-, and MaximumMarginalRelevance-assigned labels were relatively consistent, PartOfSpeech labels were not assigned for any of the adult topics and many of the pediatric topics.

Model	CPES-IC[a]	APIES[b]
Model 1	195 topics (from 328)	29 topics (from 51)
Model 2	27 topics (from 86)	20 topics (from 35)
Model 3	86 topics (not reduced further)	35 topics (not reduced further)

[a]CPES-IC: Canadian Patient Experiences Survey on Inpatient Care.

[b]APIES: Alberta Pediatric Inpatient Experiences Survey.

Model Topics

Tables S2-S4 in Multimedia Appendix 2 presents the most frequent topics (based on distinct comments).

Table S3 and Table S4 in Multimedia Appendix 2 present the most positive and most negative topics (based on the full sample). Below, we describe the topics according to model-extracted keywords.

Topics – Adult Inpatient Stays

The most frequent topics for adult stays included positive experiences with multiple aspects of care (topic 1), positive and negative reports about food (topic 3), childbirth (topic 4), hospital cleanliness (topic 5), positive experiences with staff (topic 7) and overall stay (topics 2 and 6), the discharge process (topic 8), and noise (topic 9). Topic 10 appears to be a combination of several topics.

The most positive topics for adult stays included reported general satisfaction and positive experiences (topics 13, 81, 75, 23, 15, 79, 25, and 71), positive experiences with nursing staff (topic 76), and organized and efficient care (topic 86).

The most negative topics for adults included topics specific to hospital-acquired infection (topic 74), theft (topic 80), the admission process (topic 11), the hospital environment (temperature – topic 28; noise – topic 9), parking (topics 42 and 53), negative communication experiences with nursing staff (topic 45), and pain medication or medication mistakes (topic 20).

Topics – Pediatric Inpatient Stays

The most frequent topics for pediatric stays included positive experiences with multiple elements of care (topic 1), the hospital (topic 3), nurses (topics 7 and 8), surgery (topic 9), and overall experiences (topic 10). Topic 6 was specific to pediatric hospitals. Topic 4 focused on rooms, including sleeping, shared rooms, and noise. Topic 5 focused on food and breastfeeding.

The most positive topics for pediatric surveys included excellent care and satisfaction (topics 35, 12, 23, 21, 10, 24, and 13),

XSL•FO
RenderX

positive experiences with staff (topic 17), positive experiences with care for babies (topic 27). Topic 32 focused on care at the Stollery Children's Hospital.

The most negative topics for pediatric surveys included those for the emergency room (topics 25 and 34), parking (topic 11), negative communication experiences with nursing staff (topic 16), needles and pain (topic 20), medication and pain (topic 2), hospital rooms (topic 4), the discharge process (topic 15), and food and breastfeeding (topic 5). Topic 31 appears to be a combination of several topics.

Novel Topics

Here, we summarize identified topics that do not correspond to questions on the patient experience surveys (excluding topics for specific facilities).

Among the adult surveys, the final model identified birth and delivery (topic 4), ultrasounds and communication about diagnoses (topic 16), beds and mattresses (topic 18), surgery (topic 19), temperature (topic 28), facilities needing upgrades or funding (topic 30), desire for private rooms (topic 48), concerns about shared-between-gender rooms (topic 32), overcrowding (topic 85), perceptions of insufficient staffing levels (topics 34 and 73), needles and intravenous placement (topic 37), hip and knee replacements (topic 4), parking (topic 53), night or day shift staffing (topic 55), electronics or entertainment (topic 59; television, internet, or Wi-Fi), mobility or wheelchairs (topic 62), language and communication barriers (topic 64), physiotherapy (topic 67), hospital-acquired infection (topic 74), and theft (topic 80).

Among the pediatric surveys, the final model identified topics related to neonatal intensive care units or intensive care units (topic 19 and 33), social workers (topic 30), surgery (topic 9), parking (topic 11), and food and breastfeeding (topics 5 and 21).

Discussion

Principal Findings

In this paper, we applied easy-to-use and computationally efficient machine learning-based NLP to identify and describe patient-reported experiences in free-text survey responses. To the best of our knowledge, this work is the first to describe the application of topic modeling to routinely collected patient-reported experience measures among both adult and pediatric experience surveys. By following best-practices documentation, tuning parameters to prevent overlap and reduce the total number of topics, and applying automated labeling, this application of BERTopic identified experience topics not currently evaluated using existing survey instruments.

Many of the 10 most frequent topics were related to positive ratings of care (adult sample: 5/10, 50%; pediatric sample: 6/10, 60%). This is perhaps unsurprising, as most patients in Alberta report a high level of satisfaction [21,27]. In our analytic sample, we note that 72% (30,996/43,522) of adult survey respondents with comments would "definitely" recommend the facility to others and that the proportion was even higher (2837/3501 81%) among pediatric survey respondents with comments.

One of our main goals for this study was to create topic representations with interpretable automated labeling. Of the 4 representation models used to model topics, the topic labels were largely consistent between BERTopic, KeyBERTInspired, and MaximalMarginalRelevance. However, the PartOfSpeech method failed to apply labels to all the adult survey topics and many of the pediatric survey topics. As our comments are transcribed by operators, the comments may not represent natural speech and therefore may not have been suited to the default PartOfSpeech method [28]. Still, the consistency of labels among most of the topic labeling suggests that several methods can provide interpretable labeling with no manual classification.

Many distinct topics were generated among the CPES-IC respondents. The pediatric experience survey asks about needles and IVs, but we also found that they were also identified as a topic within adult experiences. Several topics concerned accommodations, with topics about shared between gender rooming, overcrowding, and desires for private rooms, as well as beds and mattresses, temperature, and electronics. Currently, the CPES-IC questions on the hospital environment only include those about noise and cleanliness. Patients also reported concerns about facilities and staffing, with topics noting that the facilities needed repair, perceptions of insufficient staffing levels, comparisons between day and night shift staffing, and concerns about language and communication barriers. We identified a single topic on hospital-acquired infection. Future studies could evaluate whether these topics could have relevance as part of broader indicators of patient safety.

APIES respondents are the parents or caregivers of pediatric patients and reflect the experiences and priorities of both the patient and their family. While many of the topics were common between adult and pediatric surveys (eg, reporting excellent care and communication experiences with health care providers), we identified topics related to intensive care, social workers, and food and breastfeeding. While 33% (1139/3501) of the pediatric patients surveyed were under the age of 1 (Table S1 in Multimedia Appendix 1), the specific needs of parents of newborns and nursing infants are not evaluated using the APIES survey. In addition, while the survey evaluates communication with health care providers, APIES does not evaluate whether the psychosocial needs of patients and families are being met while in hospital. The "social worker" topic identified in this analysis suggests opportunities for further evaluation.

In addition to the unique experience topics within each sample, we identified 2 categories of topics that were shared between adult and pediatric respondents—food and parking. The topics that focused on food may warrant further investigation and survey item development; whether patients are reporting experiences about the quality or options for those with dietary restrictions, meals are an important element of the patient's experience. Previous research using other survey instruments have identified that parking is a relevant factor that affecting overall patient satisfaction [29,30]. Parking (or other topics related to transportation) may not be immediately actionable by administrators but could suggest issues with health care accessibility.

XSL•FO
RenderX

Connection to Previous Work

Studies using more traditional qualitative methods have identified similar topics of care that are not assessed by Consumer Assessment of Healthcare Providers and Systems (CAHPS)–derived surveys. Nepal et al [5] conducted interviews with patients to identify priorities around inpatient experiences. Among the themes identified in the study, investigators noted that patients reported topics around privacy and room-sharing, cleanliness, food, and access to television. Furthermore, a study of patient comments on the Child HCAHPS (the analogue of APIES) identified several topics that closely mirrored those in our study, including "poor vein management/IV care," "sleeping/comfort for parent/family," "Hospital services/amenities (ie, food, parking)," "Security/safety issues," and "physical/bodily privacy" [3]. An example comment in the manually classified "physical/body privacy" topic included the privacy to breastfeed [3].

There is also consistency between our work and other studies applying NLP to routinely collected PREMs. Gallan et al [6] applied topic modeling to a set of HCAHPS surveys with additional Press Ganey survey items that included multiple free-text response boxes. Whereas our summary of topics relied on the automated topic labels with representative words from each underlying representation model, Gallan et al [6] used top2vec followed by manual classification of multiple free-text comments. Despite our different topic modeling and labeling approach, the novel topics on the hospital environment identified in our study were aligned with those from their work (topics on "room temperature," "bed and visitor comfort," "facility and room design and condition," and "roommate"). We identified a single study applying completely unsupervised models to routinely collected inpatient PREMs. Cammel et al [15] modeled topics with nonnegative matrix factor and used sentiment and topic frequency to describe and classify the priority of topics in 2 Dutch hospitals. Our results are not directly comparable as we focused on absolute values of positivity and negativity and the researchers explicitly reported the most frequent positive, negative, and neutral topics within each hospital. While the translation from Dutch to English may present challenges in comparison, we did note some overlapping topics with our own work (specifically, communication with staff, satisfaction with care, concerns about temperature, and perceptions of how busy the hospital was).

Recent work suggests that respondents who provide comments may be willing to share more feedback than what is currently collected. In a comparison with a sample of surveys with only single-item responses, Quigley and Predmore [4] reported that comments provided on the narrative items were more likely to contain actionable topics. These researchers also found that when multiple opportunities for free-text responses are offered as part of inpatient experience validation, a majority of parents provide more information. For researchers or providers interested in applying NLP in specific clinical settings, the development of multiple open-ended questions and validation with end users may be able to provide more actionable information [31]. For health systems currently administering CAHPS surveys, there are currently 2 sets of Narrative Item Sets (like those used by Quigley and Predmore [4]) that have been developed for use with ambulatory care and pediatric inpatient settings [32]. As Narrative Item Sets are developed for other are adopted among health systems administering CAHPS surveys, we anticipate that NLP methods will see further integration for monitoring patient experiences to drive quality improvement.

NLP can also be used to classify topics according to existing guidelines or themes. Ish et al [14] report on BERT and bag-of-words models to identify topics in CAHPS primary care surveys with free-text responses. Manual labeling of a training sample resulted in 26 potential classes. The researchers found that BERT outperformed the bag-of-words models, but note limitations based on the small sample size, complexity of topics, and potential actionability of these methods. Using a supervised approach based on a subset of manually labelled comments, Khanbhai et al [13] compared the performance of 6 machine learning models' ability to classify free-text comment themes and sentiment from 2 questions assessing patient-reported experience in multiple care settings. None of their methods included embeddings-based methods (eg, BERT and Top2Vec), but the researchers found that a support vector machine approach had the highest accuracy. NLP may also enhance existing topics or themes in patient-reported experience data. Fairie et al [33] applied a novel label enhanced LDA method to categorize patient complaints and concerns submitted to a provincial health authority in Canada. This method used an existing manual (coarse) framework for comment classifications, LDA, and consensus by authors to determine topic labels. While the study is not directly comparable with our evaluations of topic novelty relative to existing survey questions, many topics in the concerns dataset were similar or identical to those identified in our work.

Patient-reported outcome measures (PROMs) can also contain free-text responses. We identified a single preprint that applied BERTopic to free-text comments from PROMs. Linton et al [34] used a weakly supervised text classification model on PROM comments to classify topics for health-related quality of life in colorectal cancer care. Using predefined themes and seed terms, the researchers compared 5 different topic models and found that BERTopic performed poorly on classification, relative to other methods. Experts (clinicians and scientists) who evaluated the results reported that the BERTopic-selected representative keywords were generally not relevant to the predefined themes, did not include the seed words, and that this differed from the keywords selected by other models. While the keywords applied to topics in our study were generally relevant, the work by Linton et al [34] suggests that researchers interested in applying NLP to patient-reported free text may need to evaluate multiple approaches for semisupervised topic modeling.

Future Directions

This initial descriptive study explored how a fully unsupervised NLP model could identify novel topics. Based on the concordance of our results with previous literature, administrators and patient experience survey developers may benefit from developing survey items for future PREM. Several studies have applied semisupervised models by incorporating existing labels or themes based on operational needs or clinical

XSL•FO
RenderX

relevance [13,14,33,34]. We could anticipate working more closely with patients, providers, and administrators to identify priorities and to guide NLP implementation.

As part of their evaluation of topic modeling for patient experience, Ish et al [14] discuss the issue of rare cases for training topic models. For example, the CPES-IC topic with the most obvious relevance for patient safety—the topic regarding hospital acquired infection—was classified in just 57 of the deduplicated comments. In this study, the focus on coarse topics reduces topic outliers but may prevent identification of rare but meaningful topics (eg, specific concerns on safety, communication, and hospital environment; elements of care most-relevant for specific clinical populations; or reasons for inpatient stays). In the model with the most finely detailed topics (for Model 1 for CPES-IC, refer to Multimedia Appendix 3), 71% (138/195) of topics were present in 50 or fewer deduplicated comments. Future studies could evaluate the relative frequency of topics by patient-population, hospital service, and institution as well as their relevance and actionability in these settings.

Beyond the identification of emerging patient-experience topics and integration into health care quality monitoring, comments may also assist in understanding patient care experiences. For example, a 2024 study with free-text Child HCAHPS comments manually coded for actionability and valence found that including these features as independent variables improved modeling overall experience outcomes [35]. Research also suggests that patient-reported experiences may be associated with unplanned readmission after discharge [19,36,37]. Future work could investigate how relevant survey items, comment topics, and sentiment may assist in understanding overall patient experiences and whether features assigned through NLP are associated with patient safety or readmission.

Strengths and Limitations

This paper has several strengths. First, it is one of the first to apply NLP to a widely adopted patient-reported experience measure for both adult and pediatric patient settings. The use of NLP with routinely administered patient experience surveys presents the ability to incorporate patient comments into learning health systems [38]. Model hyperparameters (eg, n-gram size and cluster size) were adjusted only through recommendations in the best practices documentation, suggesting that a (relatively) off the shelf solutions can work without devoting significant resources to technological implementation. Second, the models were able to identify novel topics within single comments from existing surveys without additional data collection or instrument development (eg, narrative interviews and multiple open-ended questions) using an approach that requires computing resources already accessible inside most or all health systems. This suggests that health systems currently using CAHPS surveys can gain additional insight on patient experiences without implementing new survey methods. Finally, the application of topic modeling could assist in identifying health system–specific and patient population–specific elements of the patient experience. This study used surveys from a Canadian province with a publicly-funded health care system, but the findings are relevant for multiple health care system settings and countries. While CAHPS surveys were developed for use in the United States, CAHPS-derived surveys (those sharing the same or similar items) have been translated and adopted across several countries and clinical settings [39-43]. Our paper may contribute to larger efforts focused on identifying common elements of the patient-reported experience in multiple health care systems and settings.

There are also several limitations to the paper. This project aimed to identify and describe topics found in existing data and within a general population. We did not split the data to examine classification accuracy, nor did we examine applicability and relevance for patients or administrators. The majority of patients report positive in-hospital experiences on the survey and comments reflected those experiences, which likely introduced “noise” and prevented the identification of actionable topics. Uniquely actionable topics may not be identifiable within a general population approach; additional work is required to determine how these findings can translate to quality improvement efforts within specific patient subpopulations. While multiple topics may be discussed within a single patient comment, BERTopic will label these comments with a single classification based on predicted probabilities. The representation model-assigned keyword labels were generally interpretable, but other studies have found mixed results on their relevance [34]. Finally, measurement error was likely as comments were transcribed by telephone operators rather than by patients themselves [44].

Conclusion

This paper provides the groundwork for future investigations within the Canadian context and beyond. It serves as both a descriptive report of observed topics and associated sentiments, but it also provides a technical proof-of-concept for researchers, policy makers, and administrators who may be looking for solutions to get the most out of patient-reported data using low-resource NLP approaches. We anticipate that partnering with patients and health care providers could help shape the development of future, semisupervised topic models with increased relevance for both patients and health systems.

Acknowledgments

The authors would like to thank Alberta Health Services for collecting and providing these data. The views expressed in this article are those of the authors’ and do not represent the opinions of Alberta Health Services. The authors would also like to thank the patients and their families who completed the surveys used in this paper.

Abstract

Background: Informed consent forms (ICFs) for clinical trials have become increasingly complex, often hindering participant comprehension and engagement due to legal jargon and lengthy content. The recent advances in large language models (LLMs) present an opportunity to streamline the ICF creation process while improving readability, understandability, and actionability.

Objectives: This study aims to evaluate the performance of the Mistral 8x22B LLM in generating ICFs with improved readability, understandability, and actionability. Specifically, we evaluate the model's effectiveness in generating ICFs that are readable, understandable, and actionable while maintaining the accuracy and completeness.

Methods: We processed 4 clinical trial protocols from the institutional review board of UMass Chan Medical School using the Mistral 8x22B model to generate key information sections of ICFs. A multidisciplinary team of 8 evaluators, including clinical researchers and health informaticians, assessed the generated ICFs against human-generated counterparts for completeness, accuracy, readability, understandability, and actionability. Readability, Understandability, and Actionability of Key Information indicators, which include 18 binary-scored items, were used to evaluate these aspects, with higher scores indicating greater accessibility, comprehensibility, and actionability of the information. Statistical analysis, including Wilcoxon rank sum tests and intraclass correlation coefficient calculations, was used to compare outputs.

Results: LLM-generated ICFs demonstrated comparable performance to human-generated versions across key sections, with no significant differences in accuracy and completeness (P>.10). The LLM outperformed human-generated ICFs in readability (Readability, Understandability, and Actionability of Key Information score of 76.39% vs 66.67%; Flesch-Kincaid grade level of 7.95 vs 8.38) and understandability (90.63% vs 67.19%; P=.02). The LLM-generated content achieved a perfect score in actionability compared with the human-generated version (100% vs 0%; P<.001). Intraclass correlation coefficient for evaluator consistency was high at 0.83 (95% CI 0.64-1.03), indicating good reliability across assessments.

Conclusions: The Mistral 8x22B LLM showed promising capabilities in enhancing the readability, understandability, and actionability of ICFs without sacrificing accuracy or completeness. LLMs present a scalable, efficient solution for ICF generation, potentially enhancing participant comprehension and consent in clinical trials.

Introduction

Ethical codes and regulations have been established globally to guide researchers in conducting studies involving human subjects. In the United States, the Belmont Report and the Common Rule are key frameworks for ensuring ethical research practices. The Common Rule, formally known as the "Basic Department of Health and Human Services (HHS) Policy for the Protection of Human Research Subjects," requires that participants receive comprehensive information about the study's purpose, allowing them to make informed and autonomous decisions about their participation [1]. This process of obtaining informed consent is fundamental to responsible conduct in research involving human subjects [2]. However, in recent years, the inclusion of mandatory scientific content, legal

XSL•FO
RenderX

jargon, and increasing length has turned the informed consent form (ICF) into a barrier to study participation [3,4].

Although many institutional review boards (IRBs) require investigators to develop documents written at the eighth-grade reading level [5], research has found that research ICFs are frequently written at reading grade levels that far exceed readers' abilities [2,5-9].

In response to the increasing complexity and length of informed consent documentation, the Health and Human Services Office for Human Research Protections added a new requirement to the 2018 Common Rule, stipulating that ICFs must begin with "a concise and focused presentation of the key information that is most likely to assist prospective subjects in understanding the reasons why one might or might not want to participate in the research" and that it "must be organized and presented in a way that facilitates comprehension" [1]. The Secretary's Advisory Committee on Human Research Protections has recommended conducting empirical research to guide the writing of the new key information section in light of the new consent requirement, ensuring that its goals are effectively met [10].

With the advancement of large language models (LLMs), a possible solution to improving ICF has emerged. LLMs show significant potential in health informatics, including tasks such as name entity extraction [11], patient trial matching [12,13], biomedical reasoning and classification [14], prediction of admissions [15], automation of administrative tasks [16], and so forth. Studies have also shown that LLMs can effectively enhance the documentation of risks, benefits, and alternatives for common surgical procedures [17]. The integration of LLMs in clinical workflows could significantly reduce administrative burden by automating labor-intensive tasks such as ICF creation. However, for successful implementation, models must not only improve readability and actionability but also align with current regulatory requirements and ethical guidelines.

The ability for LLMs to generate a complex clinical trial ICFs from a research protocol remains unexplored. This paper aims to evaluate the performance of the Mistral 8x22B LLM in generating the key information sections of ICFs with improved readability, understandability, and actionability. Specifically, our objectives are to assess the model's effectiveness in producing ICFs that meet readability standards, enhance understandability, and support actionable content while maintaining accuracy and completeness. Furthermore, we hypothesize that LLM-generated ICFs outperform human-generated counterparts in readability, understandability, and actionability, without compromising on the accuracy or completeness of information.

Methods

Study Design

We sourced 4 research protocols from the UMass Chan IRB, along with their corresponding ICFs. These protocols were then processed by our LLM model to generate artificial intelligence (AI)–generated ICFs, resulting in a total of 8 ICFs—4 human-generated and 4 AI-generated. Each research protocol, along with its respective human and AI-generated ICFs, was randomly assigned to evaluators for assessment. We had 8 evaluators in total, ensuring that each protocol set was reviewed twice by 2 different evaluators. A multidisciplinary team of 8 evaluators, including health informaticians, clinical researchers, and physicians, was assembled to review the outputs. Importantly, the evaluators were not investigators in the clinical trials whose ICFs they assessed and were not directly affiliated with the specific studies under review. Care was also taken to ensure that the evaluators and the investigators for each protocol were from different departments within the institution. Furthermore, none of the evaluators were members of the IRB that reviewed and approved the protocols. These measures were implemented to minimize potential bias and ensure objective evaluation.

Each protocol set was evaluated by 2 different reviewers, ensuring comprehensive assessment. The evaluation focused on key criteria: completeness, accuracy, readability, understandability, and actionability of the generated content. To mitigate potential evaluator bias, we ensured that each protocol was randomly assigned and evaluated by multiple individuals from different disciplines. This multidisciplinary approach, combined with random assignment, reduces the risk of personal bias and ensures a more comprehensive assessment of both LLM and human-generated ICFs.

Study Protocols

The 4 protocols included in this study were selected to ensure diversity in study design, therapeutic areas, and patient populations. This approach was aimed at evaluating the generalizability of LLM-generated ICFs across varied research contexts. Table 1 summarizes the key attributes of the protocols.

Table . Summary of study protocols.

Study title	Study type	Domain

LLM Model

We chose the Mistral 8x22B model, the latest offering from Mistral [18], for several compelling reasons:

1. Large Context Window: With a 64K token context window, this model can manage extensive research protocols. It is ideal for accurately recalling information from large documents such as clinical trial research protocols.
2. Multilingual Fluency: The Mistral 8x22B excels in multiple languages, aligning with our objective of using LLMs to create ICFs that ensure fair recruitment and serve underrepresented populations. Producing ICFs in various languages, such as Spanish, is highly advantageous.
3. Open-Source License: The Mistral 8x22B is available under an Apache 2.0 open-source license [19], allowing unrestricted deployment. This flexibility is beneficial as we roll out the final product.

ICF Key Information Section Integration

We downloaded ICF templates from various institutions, including the University of California San Francisco, Yale University, Duke University, New York University, the University of Pennsylvania, Johns Hopkins University, Partners HealthCare, Stanford University, Vanderbilt University, and the UMass Chan Medical School. We then consolidated the key information section instructions provided by these institutions into a comprehensive format. To reinforce this format, we made modifications following the Readability, Understandability, and Actionability of Key Information (RUAKI) indicator, ensuring that our consolidated key information sections create more accessible information. The final version of this format serves as the key information section instruction input for the LLM model.

Prompt Engineering

To create the ICF key information content, we used Mistral artificial intelligence (AI) in conjunction with prompt engineering guidance developed by the Research Informatics Core as part of a human-in-the-loop process. This team included the chief research information officer, 2 clinical data scientists, and an IRB officer. The prompt creation followed a backward design instructional approach [20]. The consolidated key information section instructions were used to design the prompts. The data scientists then took this guidance and crafted prompts to align with these instructions.

We used a Least-to-Most approach to guide the AI through the process of creating the consent forms. This step-by-step approach ensured that the AI received small, manageable instructions at each stage, helping it produce more accurate and reliable outputs. By breaking down tasks into smaller steps rather than overwhelming the AI with multiple instructions at once, we reduced confusion and enhanced the quality of the AI-generated forms. After designing and developing the key information section, the output was rated and reviewed by the Research Informatics Core team. Based on their feedback, the prompts were edited to enhance the model's performance.

We started by creating the chatbot prompt detailed in Supplementary 1 in Multimedia Appendix 1 to extract relevant information for each key section from the research protocol. Next, as described in Supplementary 2 in Multimedia Appendix 1, we refined the output using RUAKI indicators. In Supplementary 3 in Multimedia Appendix 1, we adjusted the content to achieve Flesch-Kincaid grade levels below 8. Finally, in Supplementary 4 in Multimedia Appendix 1, we formatted the output to align with our preferred forms, again guided by RUAKI indicators.

Measurements of Accuracy and Completeness

To evaluate accuracy and completeness, we developed a scoring system based on recommendations from LeapFrog (VTech Group), The Joint Commission, the American College of Surgeons, and relevant available literature (Multimedia Appendix 2) [21-24]. Key information sections, including study purpose, duration and procedures, risks and discomforts, benefits, and alternatives, were assessed as complete, incomplete, absent, or incorrect, with corresponding scores of 3, 2, 1, and 0, respectively.

Measurements of Readability, Understandability, and Actionability

We used the RUAKI indicator to evaluate readability, understandability, and actionability presented in ICFs key information section [25]. This indicator consists of 18 items, each assessed with a binary rating of "yes" (scored as 1) or "no" (scored as 0) (Table 2). To determine the final score, we sum the number of "yes" responses, divide by the total number of items (18), and multiply by 100 to yield a percentage score. The section score for readability, understandability, and actionability was derived by dividing the final score of each section by the total number of relevant items. A higher percentage indicates that the key information is more accessible, comprehensible, and actionable.

XSL•FO
RenderX

Table . Readability, understandability, and actionability of key information evaluation criteria.

Category and item number		Description	Rating
Readability			
	1	Active voice: uses active verbs (eg, will use) rather than passive verbs (eg, will be used) all or most of the time, more than 90% of the time.	Yes=1/No=0
	2	Word choice: avoids scientific jargon (eg, hypertension). Uses words readers are familiar with (eg, high blood pressure) all or most of the time, more than 90% of the time.	Yes=1/No=0
	3	Topic definition: provides a definition of the main disease or topic the study is about.	Yes=1/No=0
	4	Numbers: avoids mathematical calculations including comparison of numeric probability of risk.	Yes=1/No=0
	5	Eighth grade or below: reading grade level calculated in Microsoft Word is Flesch-Kincaid grade level 8.9 or below.	Yes=1/No=0
	6	Headers: sections or chunks of information are labeled with headers. Headers clearly describe sections so that readers can scan and find information.	Yes=1/No=0
	7	Font type and size: font type or style is easy to read. Font size is at least 11 - 12 point.	Yes=1/No=0
	8	White space: uses bulleted or numbered lists to increase white space on the page.	Yes=1/No=0
	9	Image: contains at least 1 image that is related to the topic of the study. Not a logo.	Yes=1/No=0
Understandability			
	10	Purpose of the study: includes a statement that says, “the purpose of the study is…” Purpose of the study is stated, rather than implied.	Yes=1/No=0
	11	Main reason to join the study—benefits: includes description or list of potential benefits to participants or others.	Yes=1/No=0
	12	Main reasons not to join the study—risks: includes description or list of potential side effects or risks to participants.	Yes=1/No=0
	13	Information being collected: describes the information that will be collected from participants and about participants.	Yes=1/No=0
	14	Study procedures: describes what participants will need to do AND how much time it will take.	Yes=1/No=0

XSL•FO
RenderX

Category and item number		Description	Rating
	15	Study is research: includes a statement that says, "study is research" or "research study" not just consenting to treatment.	Yes=1/No=0
	16	Participation is voluntary: states that participation is voluntary and that participants have a choice to be in the study or not.	Yes=1/No=0
	17	Costs and compensation: describes any financial payments (or costs) to study participants.	Yes=1/No=0
Actionability			
	18	Consent process: describes the process by which the reader gives his or her consent by signing a document, verbal agreement, via computer, or other.	Yes=1/No=0

Statistical Analysis

We reported mean accuracy and completeness scores for human-generated and LLM-generated ICF key information sections. We compared the mean accuracy and completeness scores of human-generated and LLM-generated ICF key information sections using Wilcoxon rank sum tests. Furthermore, we compared the RUAKI indicators between the 2 groups using the Wilcoxon rank sum test. Moreover, we measured the intraclass correlation coefficient (ICC) to assess the consistency among raters. An ICC below 0.5 indicates low reliability, between 0.5 and 0.74 indicates moderate reliability, from 0.75 to 0.9 suggests good reliability, and above 0.9 signifies excellent reliability [26].

Ethical Considerations

This study qualifies as nonhuman subjects research under applicable institutional and regulatory guidelines, as it exclusively involved evaluators who are also coauthors of this work. No external participants were involved, and no identifiable private information was collected, analyzed, or shared. Consequently, this work did not require review or approval from an IRB.

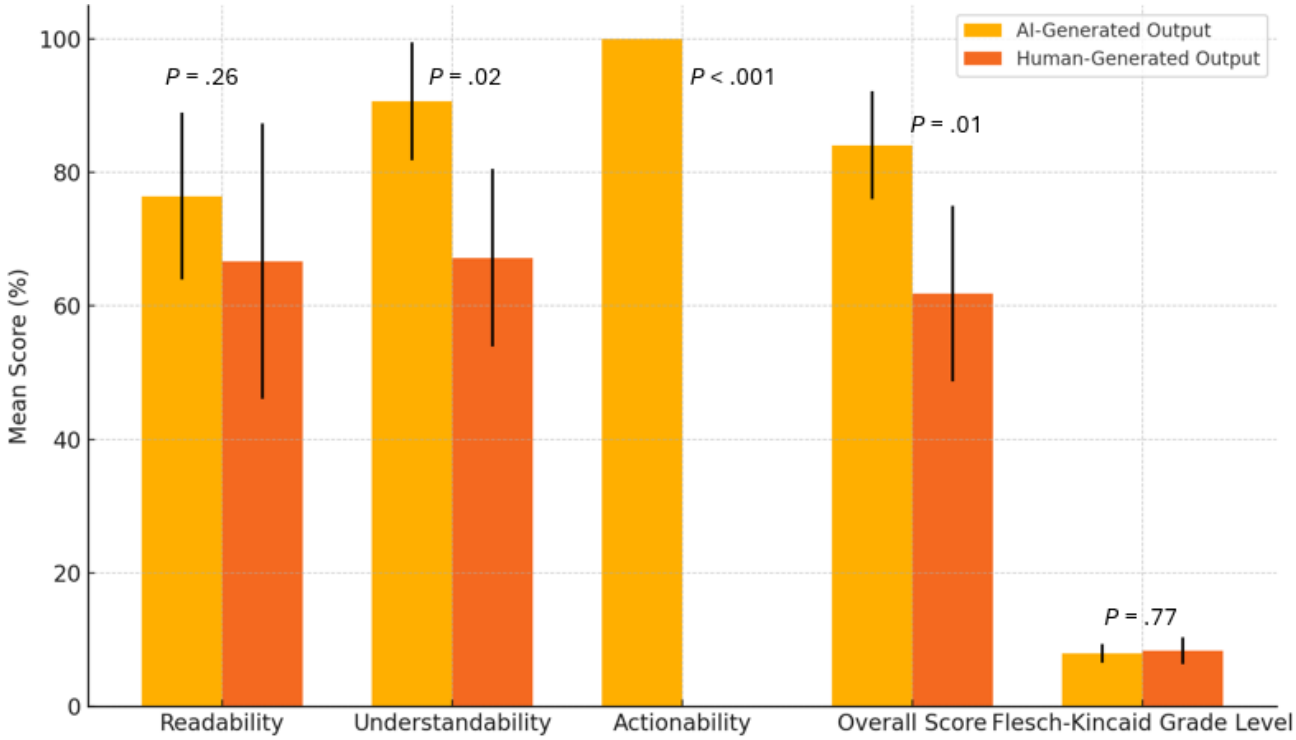
Results

The accuracy and completeness of the LLM- and human-generated outputs were comparable across key sections of the ICFs (Table 3). Both the LLM and human outputs achieved similar scores for conveying the study purpose (2.88 vs 2.63), with no significant difference (*P*=.16). For the duration and procedures, the scores were also close (2.5 vs 2.38), with no statistically significant difference (*P*=.56). The LLM slightly outperformed the human output in explaining the risks and discomforts (2.63 vs 2.38), but again, this difference was not statistically significant (*P*=.32). In terms of benefits, the LLM achieved a perfect score of 3.0 compared with the human output's 2.57, although this difference approached but did not reach statistical significance (*P*=.10). Both the LLM and human outputs were identical in discussing alternatives, scoring 2.75 (*P*≥.99). For the overall impression, the LLM scored 2.63 compared with the human output's 2.31, with no statistically significant difference (*P*=.32). Overall, both outputs displayed comparable levels of performance across these key sections.

Table . Mean accuracy and completeness scores for human and large language model evaluations across key informed consent sections.

	LLM output, mean score (SD)	Human output, mean score (SD)	Wilcoxon rank sum tests, *P* value
Study purpose	2.88 (0.35)	2.63 (0.52)	.16
Duration and procedures	2.5 (0.53)	2.38 (0.52)	.56
Risks and discomforts	2.63 (0.52)	2.38 (0.52)	.32
Benefits	3 (0)	2.57 (0.79)	.10
Alternatives	2.75 (0.46)	2.75 (0.46)	≥.99
Overall impression	2.63 (0.52)	2.31 (0.59)	.32

The comparison of Mean RUAKI scores for ICF key information generated by LLMs versus human output reveals that the LLM consistently outperforms human-generated content in critical areas (Figure 1). Although both the LLM and human outputs achieved relatively high readability scores, with the LLM slightly ahead (76.39% vs 66.67%), this difference approached but did not reach statistical significance (*P*=.26). The LLM demonstrated significantly better understandability, scoring 90.63% compared with the human score of 67.19%, with a statistically significant *P* value of .015. Moreover, the LLM



XSL•FO
RenderX

consistently included an actionable next step at the end of the document, a crucial element that the human output failed to provide, as evidenced by the LLM's perfect actionability score of 100% compared with 0% for the human output. Overall, the LLM's content achieved a significantly higher combined score (84.03% vs 61.82%), with a statistically significant *P* value of .008, demonstrating that LLM-generated text is generally more effective in producing ICF key information sections that are not only easier to read but also more understandable and actionable for participants.

While both the LLM- and human-generated ICFs exhibited similar grade levels, the LLM generated content at a slightly lower grade level (7.95 vs 8.375), indicating that it is easier to read and better aligned with the recommended reading level for general audiences. However, this difference was not statistically significant (*P*=.77), suggesting comparable readability between the two. Nonetheless, the LLM's content remains closer to the target readability level, providing a subtle advantage in ensuring accessibility for a wider audience.

The ICC score for the average ratings across the raters was found to be 0.83 (95% CI 0.64-1.03). According to the general interpretation guidelines for ICC values, this score indicates good reliability.

Figure 1. Comparison of AI- and human-generated informed consent form performance: mean Readability, Understandability, and Actionability of Key Information scores with CIs and Wilcoxon signed rank test *P* values for readability, understandability, actionability, and Flesch-Kincaid grade level. AI: artificial intelligence.

Discussion

Principal Results

This study evaluated the performance of the Mistral 8x22B LLM in generating key information sections for ICFs in clinical trials. The comparison between LLM-generated content and human-generated ICFs revealed that LLMs demonstrate considerable potential for improving the efficiency, readability, and actionability of ICFs, while maintaining comparable accuracy and completeness across most assessed categories.

Accuracy and Completeness

The LLM-generated ICFs achieved comparable performance to human-generated content across most areas. Both LLM and human outputs were similar in conveying the purpose of the study. They also performed equally well in describing the duration and procedures. While the human-generated content slightly outperformed the LLM in discussing alternatives, the LLM performed better in explaining the benefits. The overall impression score favored the LLM slightly. These results suggest that while the LLM performs similarly to humans in most areas, further refinement in prompt engineering may be required to improve its performance in more complex sections, such as alternatives. With additional fine-tuning, LLMs could potentially match or exceed the quality of human-generated ICFs across all categories.

Readability

The LLM outperformed human-generated ICFs in readability, as demonstrated by higher RUAKI scores. Both LLM- and human-generated ICFs exhibited good readability according to the Flesch-Kincaid grade level, but the LLM achieved a lower average grade level, reflecting superior readability and closer alignment with institutional requirements for eighth-grade reading level content. This highlights the LLM's strength in tackling one of the primary challenges of ICF creation: producing documents that are both comprehensive and easily understood by a general audience. Given that many ICFs often exceed the recommended reading level, the LLM's consistent

XSL•FO
RenderX

ability to generate readable content is a significant advantage, ensuring accessibility without sacrificing detail.

Understandability and Actionability

The LLM significantly outperformed human-generated ICFs in both understandability and actionability, as reflected in the higher RUAKI scores. The LLM's output was not only more comprehensible but also consistently included actionable next steps, a critical component that was often missing from the human-generated content. The perfect actionability score of the LLM-generated ICFs suggests that these models can enhance participant comprehension and facilitate informed decision-making. These findings demonstrate the potential of LLMs to create ICFs that are not only easier to read but also more effective in guiding participants through the consent process.

Rater Consistency

The ICC of 0.83 indicates a very high level of agreement among raters, reflecting the reliability of the evaluation process. The narrow CI further supports the robustness of these ratings, ensuring the consistency and validity of the results across different protocols.

Lessons Learned

Lesson 1: The Importance of Precise Temperature Settings

For all LLMs, the model temperature parameter controls the diversity of responses. A higher temperature, such as 0.8, produces more varied answers, while a lower temperature, such as 0.2, results in more focused and deterministic outputs. In our experiments, we found that setting the temperature to 0 was the most effective choice for this task. Temperatures introduce a level of randomness that can lead to hallucinations—unwanted deviations from the source material. Since our goal is to extract information directly from the research protocol and treat it as the sole source of truth, it is essential to minimize any creative output from the LLM. Although a temperature of 0.2 is already fairly focused [27,28], the need for absolute accuracy in clinical trial documents led us to set the temperature to 0, ensuring that the content remains strictly aligned with the provided data.

Lesson 2: Addressing Readability Challenges With Cross-Model Few-Shot Prompting

It was observed that Mistral struggled to generate content at a Flesch-Kincaid grade level of 8 when prompted directly with instructions such as, "The content should meet literacy standards, specifically an 8th-grade reading level or lower." To overcome this challenge, unlike the other zero-shot prompts used in this project, additional prompts and a technique known as "few-shot training" [29] were introduced. This involved providing the model with examples of text at both below 8 and above 9 Flesch-Kincaid grade levels, helping to guide the model in producing content at the desired reading level. These examples, generated using ChatGPT 4, were incorporated (as shown in Supplementary 3 in Multimedia Appendix 1) enabling Mistral to produce content more consistently at the desired grade level 8 or below. This approach, known as cross-model few-shot prompting, involves using one model to generate examples (or "shots") that are subsequently fed into another model to enhance its performance on a specific task. It is essential to apply this step after any content-editing prompts are used, as further content edits could inadvertently raise the reading level above the target. Format editing should be the final step in the process, as any subsequent prompts could alter the formatting.

Lesson 3: Least-to-Most Prompt Engineering

Effective prompt engineering involves breaking down tasks into manageable steps. When LLMs are given multiple instructions in a single prompt, they often struggle to follow all directions accurately. By adopting a Least-to-Most approach [30]—where each prompt contains a focused set of instructions and builds on the previous output—we achieved more consistent and reliable results. This is analogous to how clinical workflows are built iteratively in electronic health record (EHR) systems to ensure accuracy in decision-making. Much like building clinical templates or order sets, prompt engineering ensures that each phase of content generation is guided to avoid ambiguity, ensuring accuracy and relevance to the context of informed consent. For example, if we were building a medication alert in an EHR, breaking the alert logic into separate steps—from checking allergies to suggesting alternatives—ensures clarity and avoids overwhelming the user. Similarly, breaking down the prompt for generating ICF sections helps the LLM focus on retrieving the right information from the protocol. This method involves 2 stages: first, decomposing a complex problem into a series of simpler subproblems and then sequentially solving these subproblems, with each solution informed by the answers to the previous ones. By guiding the LLM to work incrementally, we not only enhanced its accuracy but also ensured that human oversight remained integral to the process, leading to optimal outcomes and greater control over the final product. For instance, one reviewer noted that the LLM-generated procedures were missing some procedure information. This issue likely stemmed from the lengthy and poorly structured procedure section in the original research protocol. To address this, we designed a workflow in which we first asked the LLM to summarize the study's procedures and timeline. We then instructed the LLM to extract the necessary information from this summarized output. This step-by-step Least-to-Most approach allowed us to successfully extract the missing information and integrate it into the key information.

Lesson 4: Real-World Application and Integration Challenges

Implementing LLMs in clinical workflows requires more than just improving readability or accuracy—it necessitates seamless integration with existing clinical systems and processes, such as EHRs and IRB workflows. For LLMs to have a real-world impact, models need to be adaptable to diverse clinical environments and meet regulatory and ethical standards. One way to ensure this is by developing interfaces that allow researchers to fine-tune LLM outputs while ensuring compliance with clinical trial guidelines.

XSL•FO
RenderX

Lesson 5: The Need for Detailed Source Material and Human Oversight

In one research protocol, a reviewer found that the human-generated ICF was more accurate in detailing risks and discomforts compared with the LLM-generated version. This discrepancy was evident in the omission of common discomforts associated with COVID-19 tests in the LLM-generated ICF, which occurred because this information was not included in the original research protocol. This underscores a key lesson: "garbage in, garbage out." For LLMs to produce a comprehensive and accurate ICF, the original research protocol must be thorough and detailed. Furthermore, this finding highlights the importance of having a human-in-the-loop to review and refine the output from LLMs. While LLMs can significantly reduce the effort required to create an ICF—potentially saving up to 90% of the work—the final product still benefits from human oversight. For example, after generating a well-structured ICF key information section with the LLM, researchers can easily tweak the content to better suit their specific audience. One reviewer noted that the LLM-generated ICF had a more technical and clinical tone than the human-generated version. By having researchers to customize the LLM-generated content, the ICF can be tailored to the study audience, while most of the heavy lifting has been accomplished by the LLM.

Lesson 6: Ethical and Regulatory Considerations for LLM-Generated Content

With the increasing role of LLMs in generating participant-facing documents, ethical and regulatory concerns must be addressed. Key considerations include ensuring that AI-generated ICFs do not inadvertently introduce bias or misinformation. Furthermore, as LLMs take on more responsibility in clinical settings, regulatory bodies may need to establish guidelines to govern their use. These guidelines could include stipulations on the necessity of human oversight to verify that LLM-generated content is accurate, participant-friendly, and compliant with ethical standards for informed consent.

Lesson 7: Techniques for Structured and Accurate Information Extraction

By using effective prompt engineering strategies [31,32] and crafting prompts that were precisely focused on extracting information from the research protocol, we were able to generate a well-structured and neatly formatted output. Key components—such as the introduction, study purpose, procedures, risks and discomforts, benefits, alternatives, cost and compensation, and consent process—were clearly delineated with headers, which improved the organization of the document and made it easier to locate specific information. When crafting the initial prompt to extract key information, we used a combination of techniques:

1. Delimiter usage: Delimiters like ### and [] were used to clearly define boundaries between different sections of the text.
2. Role-playing: Assigning the LLM a specific role, such as "As a Clinical Trial Informed Consent Writer," provided contextual guidance, resulting in improved performance by making the model's responses more relevant and focused.

Lesson 8: Addressing Practical Benefits and Cost-Savings

Beyond improving the quality of ICFs, LLMs offer the potential to reduce operational costs and administrative burdens in clinical trials. Automating the creation of ICFs can significantly cut down the time spent on document preparation while maintaining compliance with regulatory standards. By quantifying these savings—such as estimating the reduction in hours spent on ICF creation—future studies could further demonstrate the tangible benefits of incorporating LLMs into clinical workflows.

Lesson 9: Anticipating Future Advances

As of this publication, GPT-4o mini [33], Mistral Large 2 [34], and Meta Llama 3.1 [35] have been released, each featuring an expanded context window of 128k tokens, making them ideal for these tasks. However, they were not available during the development phase. While 64k tokens are sufficient for handling most clinical research protocols, for more extensive content, these new models would be preferable. That said, the prompts are compatible with all of these models.

Implications for Practice

The use of LLMs to generate ICFs offers considerable potential for streamlining the informed consent process. By producing more readable, understandable, and actionable content, LLMs can enhance participant comprehension and engagement, potentially improving recruitment and retention in clinical trials. Furthermore, the time savings associated with automated ICF generation can reduce the workload on researchers while ensuring that ICFs remain aligned with regulatory standards for readability and content clarity.

Limitations and Future Directions

This study's findings must be interpreted in light of certain limitations. The LLM's performance is closely tied to the quality of the input research protocol. The LLM's performance is closely tied to the clarity and completeness of the source material. Ambiguities or inconsistencies in the research protocols can hinder the model's ability to capture all relevant details to generate accurate and comprehensive ICFs. Future research should focus on improving the clarity of source materials and refining prompt-engineering strategies to optimize LLM performance, particularly in more complex sections such as study procedures.

To address these challenges with procedural details, we used a targeted prompt-engineering approach, which involved having the LLM first summarize the study's procedures and timeline, and then extract specific details from the summarized text. This method improved accuracy, but ongoing refinement of these strategies is needed to enhance the LLM's ability to process complex and lengthy sections more effectively.

Another limitation relates to the potential recognizability of LLM-generated text. Although evaluators were blinded to the source of the ICFs and presented with human- and LLM-generated documents in a randomized order, the distinctive textual style of LLM outputs—characterized by active voice,

XSL•FO
RenderX

well-organized structure, simplified language, and consistent adherence to readability guidelines—may have inadvertently revealed their origin. This recognizability could introduce subconscious bias into the evaluation process. To address this in future studies, we plan to use text obfuscation techniques, such as paraphrasing or reformatting outputs, to minimize stylistic differences and ensure true blinding. This approach will help strengthen the validity of future comparisons.

Another important limitation of this study is the small sample size, which consisted of only 4 clinical trial protocols. While these protocols provided a useful test bed, the relatively small sample size limits the generalizability of the findings. Future studies should incorporate a broader range of clinical trials from diverse therapeutic areas, phases, and levels of complexity to fully validate the model's performance. Furthermore, the limited sample size may have contributed to some statistically nonsignificant results, such as those related to procedural details or study alternatives. A larger sample would provide greater statistical power, enabling the detection of smaller but practically significant differences between human- and LLM-generated ICFs.

A larger sample would also better capture the diversity of challenges involved in ICF creation, such as variations in regulatory requirements, medical procedure complexity, and considerations for vulnerable populations. Future research should aim to assess the LLM's robustness and adaptability across a wider array of clinical trial contexts.

The process of designing and refining prompts, as well as generating the AI-generated ICFs, required a moderate time investment during initial development. However, leveraging the existing prompts and lessons learned in this study would enable future users to complete the process more efficiently and at reduced cost, enhancing the scalability of this approach.

The 0% actionability score for human-generated ICFs reflects a structural issue rather than a methodological flaw. Most institutions do not include explicit actionable sections in the key information portions of their templates. Updating these templates to include actionable instructions would likely improve scores significantly. This highlights a strength of LLM-generated ICFs, which inherently include actionable elements, enhancing the clarity and use of consent forms.

While the LLM demonstrated strong performance, there were instances where it missed details related to the duration and procedural elements of the study. This likely stems from 2 primary challenges: ambiguous or inconsistent presentation of these sections in the research protocols and the verbosity of the text, which can hinder the LLM's ability to process details efficiently. Our targeted approach of summarizing and then extracting procedural details helped address this issue, but further enhancements are needed to ensure that the LLM can consistently handle such challenges.

Looking ahead, our next goal is to automate the creation of entire ICFs directly from research protocols. This would significantly reduce the time and effort required for ICF development while maintaining consistency and quality. While this study highlights the potential for human oversight to address issues in LLM-generated content, our future research will aim to quantify the time and effort required for revisions to better assess the practical efficiency gains of integrating these models into clinical workflows. We also plan to explore the LLM's multilingual capabilities to generate ICFs in multiple languages, broadening the recruitment base and promoting diversity and equity in clinical trials. Ensuring that non–English-speaking participants receive ICFs that are as readable and understandable as those in English is crucial for improving inclusivity and representation in research. Future work should also prioritize a thorough examination of ethical concerns, including potential biases in AI-generated content, the need for transparency in AI decision-making processes, and the legal implications of deploying LLMs in clinical trial workflows, to ensure that these tools are implemented responsibly and equitably.

Conclusions

This study highlights the potential of LLMs to improve the efficiency and quality of ICF generation in clinical trials. While human oversight remains necessary to ensure accuracy in complex sections, and the findings are constrained by the small dataset and evaluation of a single LLM model, LLMs demonstrated potential advantages in producing more readable, understandable, and actionable ICF content. As LLM technology continues to evolve, it holds the promise of further enhancing the informed consent process by facilitating the creation of ICFs that are both participant-friendly and compliant with regulatory standards, thereby improving ethical conduct in clinical research.

Abstract

Background: Chronic kidney disease (CKD) is a prevalent condition with significant global health implications. Early detection and management are critical to prevent disease progression and complications. Deep learning (DL) models using retinal images have emerged as potential noninvasive screening tools for CKD, though their performance may be limited, especially in identifying individuals with proteinuria and in specific subgroups.

Objective: We aim to evaluate the efficacy of integrating retinal images and urine dipstick data into DL models for enhanced CKD diagnosis.

Methods: The 3 models were developed and validated: eGFR-RIDL (estimated glomerular filtration rate–retinal image deep learning), eGFR-UDLR (logistic regression using urine dipstick data), and eGFR-MMDL (multimodal deep learning combining retinal images and urine dipstick data). All models were trained to predict an eGFR<60 mL/min/1.73 m², a key indicator of CKD, calculated using the 2009 CKD-EPI (Chronic Kidney Disease Epidemiology Collaboration) equation. This study used a multicenter dataset of participants aged 20 - 79 years, including a development set (65,082 people) and an external validation set (58,284 people). Wide Residual Networks were used for DL, and saliency maps were used to visualize model attention. Sensitivity analyses assessed the impact of numerical variables.

Results: eGFR-MMDL outperformed eGFR-RIDL in both the test and external validation sets, with area under the curves of 0.94 versus 0.90 and 0.88 versus 0.77 (P<.001 for both, DeLong test). eGFR-UDLR outperformed eGFR-RIDL and was comparable to eGFR-MMDL, particularly in the external validation. However, in the subgroup analysis, eGFR-MMDL showed improvement across all subgroups, while eGFR-UDLR demonstrated no such gains. This suggested that the enhanced performance of eGFR-MMDL was not due to urine data alone, but rather from the synergistic integration of both retinal images and urine data. The eGFR-MMDL model demonstrated the best performance in individuals younger than 65 years or those with proteinuria. Age and proteinuria were identified as critical factors influencing model performance. Saliency maps indicated that urine data and retinal images provide complementary information, with urine offering insights into retinal abnormalities and retinal images, particularly the arcade vessels, being key for predicting kidney function.

XSL•FO
RenderX

Conclusions: The MMDL model integrating retinal images and urine dipstick data show significant promise for noninvasive CKD screening, outperforming the retinal image–only model. However, routine blood tests are still recommended for individuals aged 65 years and older due to the model's limited performance in this age group.

Introduction

Chronic kidney disease (CKD) is a pervasive and potentially irreversible condition that afflicts more than 10% of the global population [1,2]. It is diagnosed based on the presence of decreased glomerular filtration rate (GFR) or markers of kidney damage, such as proteinuria, persisting for over 3 months [3]. In clinical practice, estimated glomerular filtration rate (eGFR) is widely used and typically calculated based on demographic factors and serum creatinine levels. A drop in eGFR below 60 mL/min/1.73 m^2 significantly elevates the risk of cardiovascular diseases, mortality, and progression to end-stage kidney disease [4-6]. Proteinuria, indicative of kidney damage, further compounds these risks and affects cardiovascular outcomes and patient survival [6,7]. Efficient CKD screening is critical, as patients are often asymptomatic until the disease reaches advanced stages [8].

Remarkably, the eye and kidney share developmental, structural, physiological, and pathological similarities, hinting at a potential link between ocular and renal diseases [9]. Notably, both organs are highly vascularized and susceptible to conditions affecting the vascular system, such as aging, diabetes, and hypertension [10]. Evidence suggests that individuals displaying retinal microvascular signs, including retinopathy, arteriolar narrowing, and venular dilatation, exhibit an increased predisposition for CKD, and vice versa [1,11-14]. Fundus imaging allows for the convenient assessment of the retinal microvasculature, making it a potential screening modality for incident CKD. However, conventional fundus photography analysis has limitations in predicting CKD incidence or progression due to population heterogeneity and sensitivity issues [1].

To address these limitations, the integration of artificial intelligence, particularly deep learning (DL), with retinal imaging has emerged as a promising approach. Recent studies using DL models (convolutional neural networks, cCondenseNet, or ResNet-50) have demonstrated moderate to good performance in identifying individuals with decreased eGFR or CKD based on retinal photographs [15,16]. Nevertheless, the performance diminishes when detecting isolated proteinuria compared with overall CKD [16].

Convenient and cost-effective proteinuria assessment can be accomplished using a simple urine dipstick test [3]. Combining a retinal image deep learning (RIDL) model for eGFR decline identification with urinalysis for proteinuria detection would eliminate the need for invasive blood tests, thereby significantly improving convenience and practicality. In addition, XGBoost-based machine learning models, including 7 features (age, sex, and 5 urine dipstick measurements: protein, blood, glucose, pH, and specific gravity), successfully detect eGFR decline, especially among nondiabetic individuals younger than the age of 65 years [17].

In this study, we aimed to develop a multimodal deep learning (MMDL) model using 2 noninvasive data sources: retinal images and urine dipstick tests. We anticipate that this integration will enhance the RIDL model performance. The integration of fundus images with other data modalities in DL classifiers has been shown to improve diagnostic accuracy in some cases. For instance, a study demonstrated that combining retinal fundus images with participant metadata (such as race, age, sex, and blood pressure) enhanced the accuracy of anemia detection using DL, indicating that both metadata and fundus images contributed significantly to the prediction [18]. However, in the context of CKD detection, other studies have reported that adding clinical data to fundus image–based models does not necessarily improve performance. Further, one study used a DL algorithm for CKD detection that combined fundus photos with risk factors such as age, sex, ethnicity, diabetes, and hypertension, while another study combined fundus photos with clinical metadata such as age, sex, height, weight, BMI, and blood pressure [15,16]. In both cases, the additional data do not enhance the performance compared to models using fundus images alone.

The synergy between retinal images and urine data was assessed by comparing the performance of a urine-only model and an MMDL model with that of an RIDL model. Additionally, we comprehensively evaluated the model performance across diverse subgroups defined by well-established risk factors, such as age, diabetes, and hypertension [1,19-22]. Identifying data subgroups plays a critical role in model testing and assessing model fairness, as these subgroups can exhibit distinct or unexpected behaviors compared with the overall dataset [23]. Previous studies have explored DL and machine learning model performance within subgroups with varying outcomes. Some studies on DL models observed improved performance in patients with diabetes or high hemoglobin A_{1c}, whereas others found consistent performance across diabetes and hypertension subgroups [15,24]. However, no assessment has been conducted for eGFR<60 mL/min/1.73 m^2, a critical CKD diagnostic threshold [3]. The machine learning model, assessing eGFR<60 mL/min/1.73 m^2 using urine dipstick tests, exhibited compromised performance in diabetes, especially without proteinuria, but performed well in hypertension, especially in those younger than 65 years of age [17]. Therefore, our study systematically evaluated the model performance in 4 subgroups, including proteinuria, age ≥65 years, diabetes, and hypertension, to provide a comprehensive understanding of its capabilities and limitations in real-world scenarios.

Methods

Preparation of Study Data

Retinal images, serum creatinine levels, urine dipstick results, and demographic data (age, sex, diabetes, and hypertension) were collected from multiple departments at CHA Bundang Medical Center over 12 years (2008 - 2019; Figure 1). External validation involved using identical datasets from the Severance Checkup Health Promotion Center (SCHPC) for 8 years (2013 - 2020).

Figure 1. Study flowchart from data preparation to deep learning modeling and validation. Images with abnormal brightness or haziness were excluded. CHA: CHA Bundang Medical Center; eGFR: estimated glomerular filtration rate; eGFR-MMDL: multimodal deep learning model for estimated glomerular filtration rate<60 mL/min/1.73 m²; eGFR-RIDL: retinal image deep learning model for estimated glomerular filtration rate<60 mL/min/1.73 m²; SCHPC: Severance Checkup Health Promotion Center.

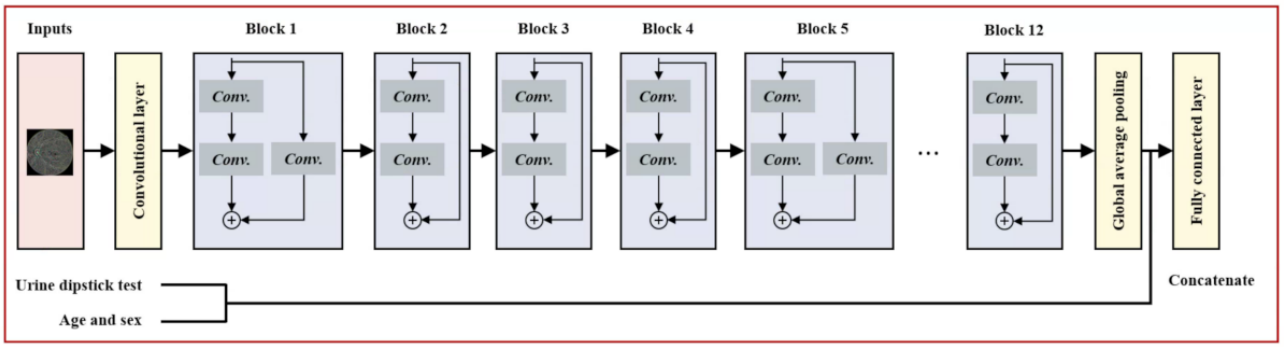
The people aged 20 - 79 years were selected without duplication. The age range for adulthood was defined as 20 - 79 years, with outliers older than 79 years removed using the IQR method. Macula-centered retinal images were taken from CHA Bundang Medical Center using 1 of 2 cameras (TRC-NW8, Topcon; nonmyd 7, Kowa) at the health promotion center or endocrinology department without pupil dilation, or using VX-10i (Kowa) at the ophthalmology department with or without pupil dilation. The same style of retinal images was acquired from SCHPC using different camera models without pupil dilation (CT-80A, Topcon; AFC-210). Cases with unilateral retinal images were not collected to create ensemble models using bilateral retinal images. Serum creatinine and urine dipstick tests were performed on the same day, and retinal images were selected within 35 days before or after these tests. eGFR was calculated using a 2009 CKD-EPI (Chronic Kidney Disease Epidemiology Collaboration) formula based on serum creatinine levels [25].

In Supplementary Methods (Multimedia Appendix 1), we outlined the criteria for diabetes and hypertension, shared details about the urine analyzers used in the model, explained the scoring method for urine dipstick tests, and provided comprehensive information on image preprocessing, including algorithms for excluding abnormal images based on brightness and haziness.

Ethical Considerations

Ethical approval was granted by the institutional review boards of the Bundang CHA Medical Center (2019-01-032) and Severance Hospital (4-2020-0231), and written informed consent was not required as the data were anonymized.

Model Training



This study aimed to predict eGFR<60 mL/min/1.73 m² using retinal images and urine dipstick tests. The development dataset was divided into train, validation, and test sets (Figure 1).

XSL•FO
RenderX

Further, 2 Wide Residual Network (WRN) models were built: eGFR-RIDL and eGFR-MMDL [26].

Macula-centered retinal images were processed through a WRN-28-4 [26] and initialized with He initialization (Figure 2). Random left- and right-flip augmentation of the image was performed. In the case of eGFR-RIDL, the 256-dimensional feature vector from the convolutional layers was processed through a fully connected layer with a sigmoid activation function. Conversely, for eGFR-MMDL, the 256D feature vector from the convolutional layers analyzing retinal images was concatenated with a 12D vector representing age, sex, and urinalysis measurements using a joint fusion approach. This combined vector was then fed into a fully connected layer with a sigmoid activation function (Figure 2) [27]. Standardization was performed by removing the mean and scaling all numerical variables, except sex, before concatenation.

Figure 2. Wide Residual Network architecture for detecting kidney function decline using retinal images. For the multimodal model, the urine dipstick measurements, age, and sex were concatenated with the feature vector from the image. Conv: convolutional layer.

The binary cross-entropy function was used to calculate the loss values, and the model parameters were updated using the gradient descent method with the AdamW optimizer. To overcome the issue of imbalanced data, where the eGFR<60 mL/min/1.73 m² class was outnumbered by the eGFR>60 mL/min/1.73 m² class, the loss function was scaled by a "sample_weight" coefficient, which was calculated as the ratio of cases with eGFR>60 mL/min/1.73 m² to those with eGFR<60 mL/min/1.73 m². Model training was monitored using plots of losses and area under the curve (AUC) from the training and validation datasets to avoid overfitting, and the best epoch was identified. Our model algorithm is deployed on GitHub [28] in a runnable form, which takes in retinal images and urine analysis data.

Development of Urine Dipstick Logistic Regression Model

A logistic regression model was generated solely with numerical variables, including urine dipstick measurements, age, and sex, for comparison with the eGFR-RIDL model. Standardized numerical values were used for training and validation across both test and external validation datasets. When building the logistic regression model, we used the class_weight="balanced" option to adjust for class imbalance, ensuring that each class was appropriately weighted in the analysis.

Validation and Subgroup Analysis of the Model Performance

The probabilities from both eyes were averaged to calculate the probability of eGFR<60 mL/min/1.73 m². If only 1 eye image remained after excluding the other eye (Figure 1), the probability of the eye was used. We evaluated the model performance through internal and external validation. Internal validation used the unseen test set from the development data, whereas external validation used the SCHPC dataset. The model's performance was evaluated using AUC comparisons against the AUC of eGFR-RIDL. Additionally, the performance across various subgroups was assessed by stratifying the test set based on age, diabetes, hypertension, and proteinuria status (trace or higher urine protein). Statistical comparisons of the AUCs were made using the DeLong test, with Bonferroni correction applied when necessary.

The sensitivity and specificity were calculated by finding the best threshold using the Index of Union method, and a 95% CI was determined using bootstrap resampling. Saliency maps for retinal images and sensitivity analysis of numerical variables were used for model interpretation. Software and calculation specifics are detailed in the Supplementary Methods in Multimedia Appendix 1.

Statistics

A statistically significant difference between the 2 statistics was determined if the *P* value was below .05, or if there was no overlap between the CIs.

Results

Baseline Characteristics of the Participants

We initially screened 73,158 people from CHA and 59,650 from SCHPC, excluding those aged <20 years, >79 years, and those with low-quality images. This resulted in 128,938 images from 65,082 people with CHA and 113,279 images from 58,284 SCHPC people, ensuring that each person had at least 1 eligible image for analysis. Table 1 shows the baseline demographics and laboratory parameters of the CHA and SCHPC datasets. The developmental dataset exhibited a greater proportion of individuals younger than the age of 65 years, as well as a higher prevalence of diabetes, hypertension, and eGFR below 60 mL/min/1.73 m² compared to the external validation dataset. The distribution of measurements for the 7 urine tests (blood, protein, glucose, ketone, urobilinogen, bilirubin, and leucocyte) varied between the developmental and external datasets, as

Performance Difference Between Unimodal and Multimodal Models

Despite the inclusion of numerical variables in the retinal image data, the training curves revealed a faster learning rate without overfitting in the eGFR-MMDL model than in the eGFR-RIDL model (Figure S3 in Multimedia Appendix 1). Figure 3 highlights the superior performance of the eGFR-MMDL model over the eGFR-RIDL model on internal and external datasets. Moreover, the eGFR-MMDL model demonstrated a notable increase in AUC across all subgroups compared with the eGFR-RIDL model (Figure 4).

Figure 3. ROC curves and AUC of low-eGFR detection models. The AUCs of the eGFR-MMDL and eGFR-UDLR models were compared with the AUC of eGFR-RIDL in (**A**) the test set and (**B**) the external validation set (DeLong test with Bonferroni correction). *P=.002; ***P<.001. AUC: area under the curve; eGFR: estimated glomerular filtration rate; MMDL: multimodal deep learning model; RIDL: retinal image deep learning model; ROC: receiver operating characteristic; UDLR: urine dipstick logistic regression.

In addition, the eGFR-UDLR (urine dipstick logistic regression) performed better than the eGFR-RIDL and was comparable to the eGFR-MMDL model, especially in external validation (Figure 3). However, no significant improvement was observed within subgroups in internal validation (Figure 4).

Age influenced the performance of the eGFR-MMDL model. For the overall population, the model performed better in individuals without diabetes or hypertension compared to their respective control groups, while proteinuria had no impact on performance (Figure 4B, 4C, and 4D). When stratified by the age of 65 years, no significant differences in AUC were observed between the nondiabetes and diabetes groups or the nonhypertension and hypertension groups (Figure S4 in Multimedia Appendix 1). However, the AUC increased in the presence of proteinuria (Figure S4 in Multimedia Appendix 1). These changes appeared to be driven by higher model performance in younger individuals without diabetes, hypertension, or proteinuria (Figure 4A).

Table 2 presents the sensitivity and specificity of the eGFR-MMDL model for both the entire study population and its subgroups. The thresholds for the age group of 65 years and older, as well as for individuals with diabetes and proteinuria, were significantly higher than the overall threshold. Table S1 in Multimedia Appendix 1 provides case counts for each subgroup.

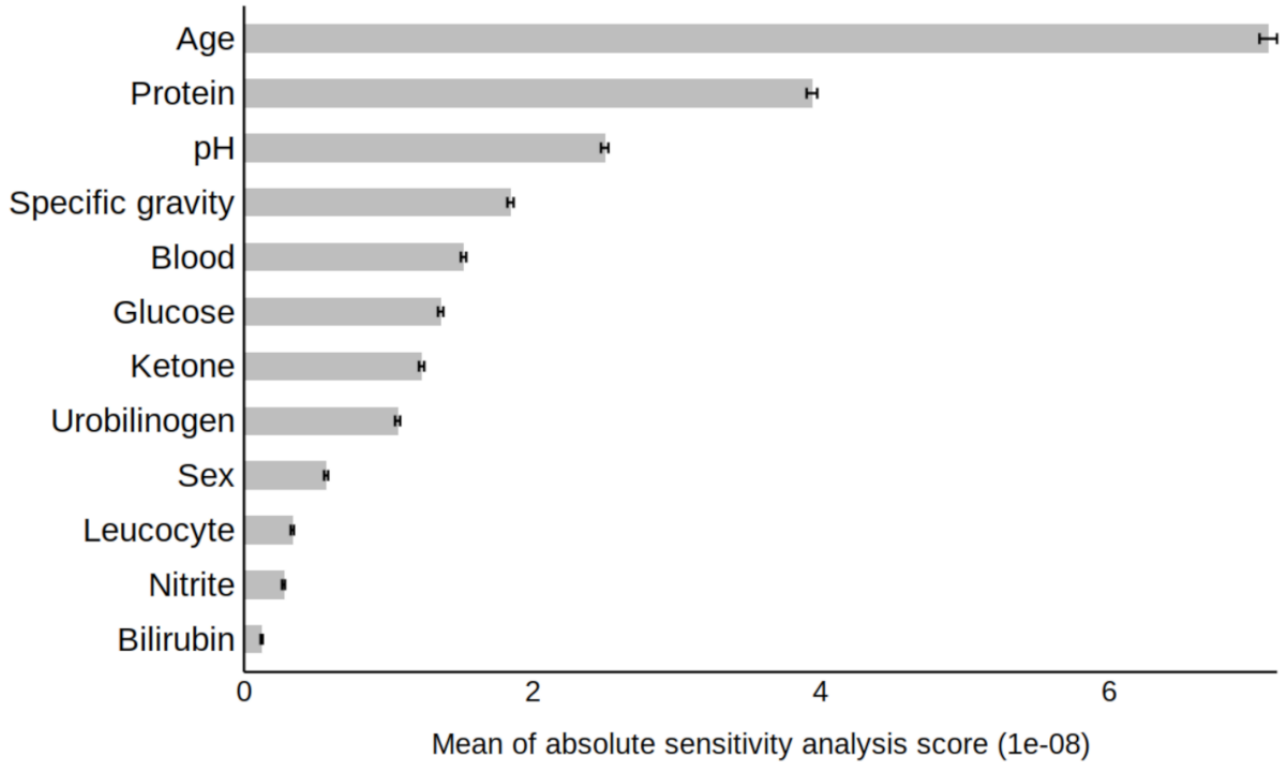
Model Explanation Using Saliency Maps and Sensitivity Analysis

To assess the ability of our algorithm to incorporate retinopathy findings in predicting eGFR decline, we examined fundus photographs of patients with diabetic retinopathy (Figures 5B and 5C). The saliency maps from the eGFR-RIDL and eGFR-MMDL models displayed different hot spot distributions. The eGFR-RIDL map highlighted hot spots of retinal abnormalities (hard exudates, retinal hemorrhages, and arteriovenous nicking), small arteries, and veins. Conversely, the eGFR-MMDL map primarily featured hot spots along the central vascular arcade.

XSL•FO
RenderX

Figure 5. Saliency map results from the eGFR-RIDL and eGFR-MMDL models for eGFR decline detection. (**A**) A nondiabetes male aged 60 years with proteinuria level 3 (2+). (**B**) A male with diabetes and proteinuria level 4 (3+) aged 54 years. (**C**) A male with diabetes and proteinuria level 4 (3+) aged 60 years. (**D**) A male without hypertension or diabetes aged 60 years, with a proteinuria level of 0 (negative). From left to right: original retinal image, retinal image postpreprocessing via CLAHE and color normalization, eGFR-RIDL–generated saliency map, and eGFR-MMDL–generated saliency map. CLAHE: Contrast Limited Adaptive Histogram Equalization; eGFR: estimated glomerular filtration rate; MMDL: multimodal deep learning; RIDL: retinal image deep learning.



To explore the factors used by our algorithm to predict eGFR decline in the absence of definite pathological findings, we analyzed fundus photographs of patients without diabetes (Figures 5A and 5D). Hot spots were observed in the branches of arteries and veins in both the eGFR-RIDL and eGFR-MMDL models, with differing locations between the 2 models.

In the sensitivity analysis of eGFR-MMDL, age and urine protein level were the most influential factors among the numerical variables, followed by urine pH, specific gravity, hematuria, and glycosuria (Figure 6).

XSL•FO
RenderX

Figure 6. Sensitivity analysis: feature importance of age, sex, and 10 urine measurements in predicting the probability of eGFR decline by eGFR-MMDL using a test set. The sensitivity analysis scores indicate the relative impact of each variable on the predicted probability. Higher sensitivity analysis scores correspond to a greater influence. The error bars on the right end represent 95% CIs. 1e-08: 0.00000001; eGFR: estimated glomerular filtration rate; MMDL: multimodal deep learning.

Discussion

Principal Findings

This study found that the eGFR-MMDL model, which integrates retinal imaging with urine dipstick data, achieved higher diagnostic performance for CKD than the retinal image-only eGFR-RIDL model. The eGFR-MMDL model demonstrated superior accuracy across subgroups, particularly in younger individuals and those without proteinuria. Sensitivity analysis identified age and proteinuria as key factors from urine dipstick data, while saliency maps indicated that retinal vessels provided additional diagnostic information unavailable from urine dipstick data, demonstrating how each modality contributed unique and valuable insights for CKD detection.

Addressing Variability in Fundus Images for Robust DL Models

In practice, fundus images vary in size, quality, format, and color across different devices [29]. This variability poses a challenge for the creation of effective DL models. Training a model based solely on data from specific devices can limit its compatibility with others. To address this, we used 3 camera models from 2 companies for training and evaluated the model using 2 different nontraining camera models. We standardized the images across devices through preprocessing techniques, including circular border adjustment, boundary removal via cropping, Contrast Limited Adaptive Histogram Equalization–based quality enhancement, and color normalization (Supplementary Methods in Multimedia Appendix 1). Nevertheless, the effectiveness of the model diminished during the external validation, which can be partially attributed to the diversity observed in the retinal images. Notably, the eGFR-UDLR model, leveraging numerical variables, exhibited enhanced generalization compared with the eGFR-RIDL model using retinal images (Figure 3B). Therefore, a multimodal approach incorporating urine dipstick tests could partly address the generalization problem of the eGFR-RIDL model.

In addition, when used on images of poor quality, there is a notable decline in performance owing to the disruption of both the structural and statistical properties of neighboring pixels caused by image degradation [30]. Therefore, our workflow involved image quality management and preprocessing for model accuracy and reliability [1]. Abnormal images, defined as those with haziness, extreme brightness, or darkness, were excluded (additional methods in Multimedia Appendix 1). Our approach assesses clarity using haze grading, which combines high-pass filtering and power spectrum integration across spatial frequencies and gauges intricate detail visibility [31]. Unlike previous methods that manually exclude subpar images or use unspecified techniques for DL, our innovation emphasizes practical, real world, and applicable image quality control processes [15,16,24].

Enhancement of the Model Performance in MMDL

During internal validation, the eGFR-RIDL model achieved an AUC of 0.9 (Figure 3), indicating its statistical comparability with prior models of retinal images. For example, AUCs were observed at 0.826 (95% CI 0.818 - 0.833; ResNet18 model) for eGFR<60 mL/min/1.73 m² with diabetes [32], 0.911 (95% CI 0.886 - 0.936; cCondenseNet model) for eGFR<60 mL/min/1.73

XSL•FO
RenderX

m² [15], and 0.918 (95% CI 0.905 - 0.933; ResNet-50 model) for eGFR<60 or>60 mL/min/1.73 m² with albuminuria [16]. However, the eGFR-MMDL model performed significantly better than the eGFR-RIDL model during the internal and external validations (Figure 3).

The eGFR-UDLR model demonstrated performance comparable to the eGFR-MMDL model (Figure 3), and the superior performance of eGFR-MMDL over eGFR-RIDL can be attributed to the inclusion of urine dipstick data. However, in the subgroup analysis, the eGFR-MMDL model outperformed eGFR-RIDL across all subgroups, while the eGFR-UDLR model showed no significant improvement across subgroups (Figure 4). This suggests that the synergy between the 2 modalities in the eGFR-MMDL model likely resulted from the effective integration of multimodal data through joint fusion (Figure 2) [33]. This method combines feature representations from neural network layers with data from various sources, such as retinal images and urine analysis, thereby enhancing the model performance. Type 2 joint fusion in eGFR-MMDL improves the correlation across modalities, facilitating more efficient shared representation learning [33]. This approach continually updates the feature representations, thereby enhancing its effectiveness [33]. Furthermore, research has consistently emphasized the advantages of multimodal approaches over unimodal approaches [27]. Multimodal models leverage information from different sources and create comprehensive and robust data representations [27]. This overcomes the limitations associated with individual modalities, including noise [27].

The subgroup analysis highlighted the improved performance of eGFR-MMDL, especially in those aged <65 years without proteinuria (Figure 4). This is crucial because this age group often skips check-ups because of perceived good health and lack of symptoms [34]. Detecting CKD in young individuals is vital, as it can be linked to rare conditions, such as glomerulopathy, where treatments greatly impact outcomes [35]. Furthermore, the good performance of the eGFR-MMDL model in individuals without proteinuria indicated its ability to identify nonproteinuria CKD cases, which usually necessitates invasive blood tests for screening purposes. Thus, eGFR-MMDL may replace blood tests with retinal images and urine dipsticks, offering a convenient, noninvasive screening method for newly diagnosed CKD in young patients.

Unveiling the Role of Retinal Features and Numerical Variables in Model Prediction

To elucidate these models, we used saliency maps for retinal images and conducted a sensitivity analysis of numerical variables. Kang et al [24] reported that a DL model using saliency maps from retinal images successfully identified common retinal abnormalities, aiding the assessment of renal function. These features, which are routinely used by ophthalmologists for diagnosing retinal diseases, were similarly observed in eGFR-RIDL saliency maps (Figure 5). However, the eGFR-MMDL saliency map notably accentuated arcade vessels over exudation or hemorrhage, which could be attributed to the inclusion of numerical features, such as urine data, age, and sex (Figure 5A). These findings align with those of existing studies that emphasize a strong association between retinal vascular changes and CKD development [36-40]. Joo et al [41] also noted a more pronounced presence of arcade vessels on saliency maps in individuals with higher CKD risk. This suggests that, while urine data provide insights into common retinal abnormalities, retinal images, particularly those focusing on arcade vessels, are pivotal for predicting kidney function. The distinct information yielded by these 2 modalities likely accounted for their complementary roles in the eGFR-MMDL model.

The saliency maps further underscored the significance of the retinal vessel features (Figure 5). Even in cases with healthy retinal images, prominent retinal vessel features indicate their value in predicting renal function (Figures 5A and 5D). These observations align with the findings of Zhang et al [16], emphasizing the relevance of vascular health through saliency maps. However, despite the presence of these features, eGFR-MMDL outperformed eGFR-RIDL (Figure 3), suggesting that retinal vessel features alone may not be sufficient to predict eGFR decline accurately.

In our sensitivity analysis, we assessed the impact of each numerical variable (age, sex, and 10 urine variables) on eGFR<60 mL/min/1.73 m² predictions. The findings on feature importance from the eGFR-MMDL model were consistent with a previous study using XGBoost for eGFR decline prediction, which highlighted urine protein, blood, glucose, pH, specific gravity, and age as important features [17]. In our study, age emerged as the primary contributor, consistent with epidemiological studies, owing to its association with GFR decline [42]. The second most influential factor was urine protein positivity, supported by evidence linking it to kidney function deterioration [43,44]. Urine pH and specific gravity, ranking third and fourth, have been investigated as relevant CKD indicators, with acidic urine pH (5 - 5.5) positively correlated with CKD, and low urine specific gravity indicating reduced kidney function [45,46]. Hematuria, the fifth-ranked urine variable, correlates not only with proteinuria but also with CKD risk factors [45,47]. Additionally, glycosuria (urine glucose) may be linked to kidney dysfunction in Fanconi syndrome and diabetes, as indicated in a previous study [45].

Limitations

First, the performance of eGFR-MMDL in individuals aged ≥65 years did not achieve a satisfactory AUC (Figure 4A), despite the high CKD prevalence in this group (Table 1) [48]. These findings corroborate with those of a previous study, revealing limited predictive capabilities among those aged 65 years and older using urine dipstick-based models [17]. Potential reasons for this underperformance may include issues with the retinal image quality, particularly haziness. However, our analysis revealed no significant difference in eGFR-MMDL performance between the high- and low-haziness groups in individuals aged ≥65 years (Figure S5 in Multimedia Appendix 1).

Furthermore, signs of organ damage, such as retinal abnormalities or proteinuria, may not manifest in older individuals with an eGFR<60 mL/min/1.73 m². This is supported by a higher positive proteinuria ratio in individuals younger than 65 years than in those aged 65 years or older with eGFR<60

XSL•FO
RenderX

mL/min/1.73 m² (263/474, 55.5% vs 243/611, 39.8%, respectively; $P<.001$, chi-square test on the CHA dataset). In people younger than 65 years of age, eGFR<60 was possibly linked to mechanisms causing proteinuria, whereas in those aged 65 years or older, this might be attributed to age-related GFR decline [20]. Given the high prevalence of CKD and the limited performance observed among individuals aged ≥65 years, we recommend conducting routine blood tests for effective CKD screening in this subpopulation.

Second, various medications prescribed for diabetes and hypertension can influence urine dipstick test outcomes, potentially impacting the predictive model accuracy. For example, SGLT2 inhibitors, commonly used in diabetes management, cause glycosuria and may alter urinary specific gravity, while renin-angiotensin-aldosterone inhibitors can decrease proteinuria [49,50]. Unfortunately, due to limited information on specific medication classes, such as renin-angiotensin-aldosterone inhibitors and SGLT2 inhibitors, we were unable to conduct a thorough analysis of their effects on the model performance. Although the eGFR-MMDL model showed robustness to the presence of hypertension or diabetes when age was controlled (Figure S4 in Multimedia Appendix 1), further investigation into medication effects is warranted.

Third, this study's participants were exclusively Korean, limiting generalizability to diverse ethnic populations. CKD epidemiology and clinical presentations vary across countries, possibly affecting the model performance [51]. Fourth, a gap existed between the dates of retinal imaging and serum or urine tests. However, the absolute difference in dates was small, with a mean of 0.6 (SD 3.7) days.

Benefits of CKD Screening With Retinal Imaging and Urine Dipstick

The use of noninvasive tests such as retinal imaging and urine dipstick assessments significantly enhances the effectiveness, accessibility, and efficiency of CKD screening, benefiting both patients and health care providers. For patients, these tests reduce discomfort and anxiety, leading to higher compliance with regular screenings and enabling earlier detection of CKD, which is crucial for preventing progression to end-stage kidney disease. This is particularly valuable in resource-limited settings where traditional blood tests may not be readily available [2,52].

For health care providers, these models streamline the screening process by reducing the time and resources needed for blood collection and analysis. The multimodal approach integrates retinal images with urine dipstick data, mirroring the comprehensive assessments made in clinical practice, such as evaluating diabetic or hypertensive retinopathy alongside CKD [27]. This holistic view not only improves diagnostic accuracy but also allows for concurrent evaluation of eye health, providing a more complete picture of the patient's overall condition.

Conclusion

The MMDL model, incorporating age, sex, urine measurements, and retinal images, improved the eGFR reduction prediction of an RIDL model. This achievement stemmed from the diverse features of the multiple sources. However, the DL model using retinal images showed limited performance in old-age patients. Our model offers a noninvasive and convenient screening tool for enhancing kidney health in specific populations.

Abstract

Background: Prediction models have demonstrated a range of applications across medicine, including using electronic health record (EHR) data to identify hospital readmission and mortality risk. Large language models (LLMs) can transform unstructured EHR text into structured features, which can then be integrated into statistical prediction models, ensuring that the results are both clinically meaningful and interpretable.

Objective: This study aims to compare the classification decisions made by clinical experts with those generated by a state-of-the-art LLM, using terms extracted from a large EHR data set of individuals with mental health disorders seen in emergency departments (EDs).

Methods: Using a dataset from the EHR systems of more than 50 health care provider organizations in the United States from 2016 to 2021, we extracted all clinical terms that appeared in at least 1000 records of individuals admitted to the ED for a mental health–related problem from a source population of over 6 million ED episodes. Two experienced mental health clinicians (one medically trained psychiatrist and one clinical psychologist) reached consensus on the classification of EHR terms and diagnostic codes into categories. We evaluated an LLM's agreement with clinical judgment across three classification tasks as follows: (1) classify terms into "mental health" or "physical health", (2) classify mental health terms into 1 of 42 prespecified categories, and (3) classify physical health terms into 1 of 19 prespecified broad categories.

Results: There was high agreement between the LLM and clinical experts when categorizing 4553 terms as "mental health" or "physical health" (κ=0.77, 95% CI 0.75-0.80). However, there was still considerable variability in LLM-clinician agreement on the classification of mental health terms (κ=0.62, 95% CI 0.59 - 0.66) and physical health terms (κ=0.69, 95% CI 0.67 - 0.70).

Conclusions: The LLM displayed high agreement with clinical experts when classifying EHR terms into certain mental health or physical health term categories. However, agreement with clinical experts varied considerably within both sets of mental and physical health term categories. Importantly, the use of LLMs presents an alternative to manual human coding, presenting great potential to create interpretable features for prediction models.

Introduction

Recent advances in health informatics have led to the development of machine learning models that are trained on data from electronic health records (EHRs). These models have proven to be effective across a range of health domains, including predicting the spread of disease [1], hospital readmission rates [2], and suicide risk [3,4]. Predictive models

XSL•FO
RenderX

have been implemented in EHR systems to identify high-risk patients and alert clinicians to critical health events [5].

EHR systems are filled with unstructured text data, including clinical notes and discharge summaries, which are not easily categorized into clinically interpretable groupings for use in predictive models. Although the use of this data can greatly enhance prediction model performance and the interpretability of decision-support tools [6,7], the coding process is labor intensive and requires expert consultation and extensive training [8]. These challenges hinder the development and scalability of clinical prediction models that incorporate unstructured EHR data [9,10].

Large language models (LLMs), like OpenAI's GPT models, can streamline the classification and coding of unstructured EHR text due to their massive training data sets and advanced text processing [11,12]. LLMs have been used to categorize unstructured text from EHR systems [13], assist with qualitative analysis [14,15], and perform deductive coding with and without context [16]. Preliminary evidence shows that LLMs outperform crowd workers in annotation of health texts [17,18].

The reliability of LLMs in replicating clinical judgment for coding classification tasks in mental health remains uncertain, particularly given the inherent complexities of mental health disorders [19,20]. Prior research highlights that while LLMs can process large volumes of text, their ability to discern subtle differences in clinical presentations, such as differentiating between comorbid conditions like depression and anxiety, is still unproven. This challenge is exacerbated by the frequent overlap of symptoms across diagnoses, which complicates classification efforts [21]. Patients with mental health disorders may present with unique clinical characteristics that challenge an LLM's ability to accurately identify and code physical and mental health symptoms [11,22,23].

We used a large EHR data set of individuals admitted to the emergency department (ED) for a mental health disorder, to assess the ability of a state-of-the-art LLM to classify EHR terms into categories defined by experienced mental health clinicians. We assessed the extent to which a LLM replicates clinical judgment and the practicality of using a LLM to assist in creating clinically interpretable features for prediction models.

Methods

Data

We extracted de-identified EHR data from the Optum Labs Data Warehouse, a longitudinal, real-world data asset, from >50 US healthcare provider organizations that encompass >700 hospitals. We included individuals aged ≥10 years who were admitted to the ED from 2016 to 2021 and had an International Classification of Disease-9 or -10 code for a mental health diagnosis, suicidal ideation, or self-harm, resulting in approximately 6.2 million unique patient episodes. A natural language processing (NLP) algorithm integrated into the Optum Labs Data Warehouse extracted from unstructured free-text fields in the EHR, clinical terms for signs, symptoms, and diseases based on the National Library of Medicine's Unified Medical Language System dictionary. We identified physical and mental health terms that appeared in at least 1000 unique patient episodes.

Coding

A board-certified psychiatrist and licensed clinical psychologist categorized each EHR term into 1 of 61 categories including 42 mental health-related categories and 19 physical health-related categories which were generated from the Clinical Classifications Software Refined [24] and the International Classification of Disease-10 diagnosis coding system, respectively. Coding each EHR term involved: (1) initial classification by 1 clinician coder, (2) a review of all coding decisions by a second clinician coder with suggestions for revisions; (3) a final consensus reconciliation involving both coders. The coding of physical health terms was supported by an LLM, which suggested coding decisions that were refined and reconciled (5% of terms required reconciliation) by the 2 clinician coders. All study procedures were approved by the Institutional Review Board of University of Pennsylvania.

Classification Tasks

We used the Python module "openai" [25] to run the GPT-4 LLM in a Python environment. We used OpenAI's most sophisticated GPT-4 that was then publicly available ("gpt-4-turbo-2024-04-09") and set model parameters to maximize output consistency (eg, temperature=0).

We prompted the model with 3 "zero-shot" classification tasks, wherein the model is provided codes without examples: (1) classify all (n=4553) EHR terms as either "mental health" or "physical health," (2) classify each of the (n=846) mental health terms into 1 of the 42 mental health categories, and (3) classify each of the (n=3707) physical health terms into 1 of the 19 physical health categories. The prompt described the task, listed the possible categories, and provided the EHR terms. The model then confirmed that the predicted category was among the list of possible categories. For full reproducibility, the complete prompt provided to the model, including the task description and category list, is detailed in Multimedia Appendix 1. In task 2, the model was given an unstructured clinical term from an EHR such as "depressive symptoms." Then, the prompt described the classification task and provided the following list of possible mental health categories (eg, "depression," "anxiety," "eating disorder symptoms," and "substance use"). The process was repeated for all 846 mental health terms, and similarly for the 3707 physical health terms in task 3.

Performance Metrics

We compared GPT-4's predicted categories with the categories determined by clinical judgment using the Python library scikit-learn "metrics" module [26]. For each task, we report the overall Cohen κ and weighted average of precision, recall, and F_1-score, accounting for label imbalance. We computed 95% CIs for Cohen κ, precision, recall, and F_1-score using a bootstrap procedure with 1000 resamples [27].

Ethical Considerations

Ethical approval (IRB Protocol #848806) for this study was waived by the University of Pennsylvania Institutional Review Board via 45 CFR 46.104, category 4.

Results

Overview

EHR terms (n=4553) were categorized by GPT as "mental health" or "physical health." Overall, classification performance was strong with κ of 0.77 (95% CI 0.75-0.80), precision of 0.93 (95% CI 0.92 - 0.94), recall of 0.93 (95% CI 0.92 - 0.94), and F_1-score of 0.93 (95% CI 0.92 - 0.94). The GPT-4 classified 18.3% (n=833) of the EHR terms as "mental health" and 81.7% (n=3720) as "physical health" (Table 1). The clinician coders and model disagreed on the categorization of 164 (19.7%) mental health terms (eg, "gunshot wound," "chronic fatigue syndrome," and "IV drug use") and 149 (4%) physical health terms (eg, "activity issues," "lethargic," and "food issues").

Table . Recall, F_1-score, and total mentions among terms in the data set across health domains.

Health domain (n)	Recall (95% CI)[a]	F_1-score (95% CI)	Total mentions in data set (thousands)
Physical health (n=3707)	0.96 (0.95 - 0.97)	0.96 (0.95 - 0.96)	255,573
Mental health (n=846)	0.81 (0.78 - 0.83)	0.81 (0.79 - 0.83)	85,081

[a]Recall indicates the proportion of terms in a clinician-coded category that were classified by the model as belonging to that category.

Mental Health

Mental health terms (n=846) were classified into 42 categories with κ of 0.62 (95% CI 0.59-0.66), precision of 0.71 (95% CI 0.68 - 0.74), recall of 0.64 (95% CI 0.61 - 0.68), and F_1-score of 0.65 (95% CI 0.62 - 0.69). Table 2 includes category-wise recall, F_1-score, and a set of the most frequent categories into which terms from the true category were misclassified (Multimedia Appendix 2).

Table . Mental health term categories: recall, F_1-score, total mentions in the dataset, and most common misclassification (in descending order of recall). Categories with <5 terms were excluded.

Term category (n)	Recall (95% CI)[a]	F_1-score (95% CI)	Total mentions in dataset (thousands)	Misclassifications (n)
Eating disorder or symptoms (n=16)	1 (0.81 - 1)	0.91 (0.80 - 1)	582	None
Living situation (n=11)	1 (0.74 - 1)	1 (1 - 1)	1259	None
ADHD[b] spectrum (n=11)	1 (0.74 - 1)	0.73 (0.52-0.88)	810	None
OCD[c] symptoms or disorder (n=10)	1 (0.72 - 1)	0.87 (0.67 - 1)	207	None
Somatization symptoms (n=6)	1 (0.61 - 1)	0.86 (0.57 - 1)	62	None
Neurocognitive disorders (n=20)	0.95 (0.76 - 0.99)	0.62 (0.47 - 0.75)	1225	Neurocognitive symptoms (n=1)
Sleep wake symptoms or disorder (n=37)	0.95 (0.82 - 0.99)	0.86 (0.78 - 0.94)	1833	Miscellaneous psychiatric symptoms (n=1) and depressive symptoms (n=1)
Substance-related symptoms or disorder (n=90)	0.92 (0.85 - 0.96)	0.95 (0.91 - 0.98)	8783	Neurocognitive disorders (n=4), neurocognitive symptoms (n=1), and psychotic symptoms or disorder (n=1)
Abusive behavior (n=26)	0.89 (0.71 - 0.96)	0.84 (0.71 - 0.93)	3053	Aggressive symptoms (n=1), miscellaneous psychiatric symptoms (n=1), and personality disorder (n=1)
Unipolar depressive disorder (n=8)	0.88 (0.53 - 0.98)	0.78 (0.50 - 0.96)	944	Mood disorder (n=1)
Autism spectrum disorder (n=7)	0.86 (0.49 - 0.97)	0.71 (0.38 - 0.92)	132	Mood disorder (n=1)
Impulsive behavior (n=6)	0.83 (0.44 - 0.97)	0.83 (0.50 - 1)	414	Aggressive symptoms (n=1)
Personality disorder (n=5)	0.80 (0.38 - 0.96)	0.47 (0.11 - 0.73)	158	OCD symptoms or disorder (n=1)
Injury (n=76)	0.78 (0.67 - 0.88)	0.84 (0.77 - 0.90)	10,470	Self harm (n=8), miscellaneous psychiatric symptoms (n=3), and stress-related symptoms or disorder (n=2)
Psychotic symptoms or disorder (n=50)	0.76 (0.63 - 0.86)	0.76 (0.66 - 0.85)	6074	Miscellaneous psychiatric symptoms (n=5), neurocognitive symptoms (n=2), and impulsive behavior (n=1)
Stress-related symptoms or disorder (n=11)	0.73 (0.43 - 0.90)	0.57 (0.32 - 0.77)	480	Stressor symptoms (n=2) and anxiety symptoms (n=1)
Anxiety disorder (n=14)	0.71 (0.45 - 0.88)	0.71 (0.50 - 0.90)	683	Anxiety symptoms (n=1), social situation (n=1), and somatization symptoms (n=1)
Suicidal symptoms (n=12)	0.67 (0.39 - 0.86)	0.73 (0.46 - 0.92)	6167	Self-harm (n=3) and psychotic symptoms or disorder (n=1)
Self-harm (n=12)	0.67 (0.39 - 0.86)	0.47 (0.23 - 0.67)	2126	Abusive behavior (n=3) and suicidal symptoms (n=1)
Anxiety symptoms (n=22)	0.64 (0.43 - 0.80)	0.54 (0.36 - 0.69)	7481	Stress-related symptoms or disorder (n=2), sensory disturbances (n=2), and anxiety disorder (n=2)

[a]Recall indicates the proportion of terms in a clinician-coded category that were classified by the model as belonging to that category.

[b]ADHD: attention deficit hyperactive disorder.

[c]OCD: obsessive compulsive disorder.

[d]psych ADE: psychiatric adverse drugs events.

The model exhibited the best classification performance for categories of: "living situation" (F_1-score=1, n=11 terms), "substance use related symptoms and disorder" (F_1-score=0.94, n=90 terms), "eating disorder or symptoms" (F_1-score=0.95, n=16 terms), "OCD symptoms or disorder" (F_1-score=0.87, n=10 terms), and "sleep wake symptoms or disorder" (F_1-score=0.86, n=37 terms). Conversely, the model performed poorly on "miscellaneous psychiatric symptoms" (F_1-score=0.39, n=156 terms), "antisocial behavior" (F_1-score=0.17, n=10 terms), "sensory disturbances" (F_1-score=0.09, n=10 terms), "psychiatric adverse drug events" (F_1-score=0, n=11 terms), and "stressor symptoms" (F_1-score=0, n=5 terms).

The most mislabeled mental health terms included "psychiatric adverse drug events" as "neurocognitive symptoms" (n=6 misclassifications) or "pharmacological symptoms" (n=5

XSL•FO
RenderX

misclassifications). The model also commonly mislabeled terms in "miscellaneous psychiatric symptoms." There were 111 terms in the "miscellaneous psychiatric symptoms" category that were misclassified across 28 of 41 other categories (Multimedia Appendix 3).

Physical Health

Physical health terms (n=3707) were classified into 19 categories with κ of 0.69 (95% CI 0.67-0.70), precision of 0.76 (95% CI 0.74 - 0.77), recall of 0.71 (95% CI 0.70 - 0.73), and F_1-score of 0.72 (95% CI 0.70 - 0.73). Table 3 includes category-wise recall, F_1-score, and a set of the most frequent categories into which terms from the true category were misclassified (Multimedia Appendix 3).

XSL•FO
RenderX

Table . Physical health term categories: recall, F_1-score, total mentions in the dataset, and most common misclassification (in descending order of recall).

Term category (n)	Recall (95% CI)[a]	F_1-score (95% CI)	Total mentions in dataset (thousands)	Most frequent misclassifications (n)
Oncological conditions (n=45)	0.91 (0.79 - 0.96)	0.61 (0.51 - 0.70)	4549	Autoimmune and inflammatory conditions (n=1), gastrointestinal symptoms (n=1), and other physical symptoms and conditions (n=1)
Sensory problems (n=41)	0.90 (0.78 - 0.96)	0.35 (0.27 - 0.43)	3113	Neurological symptoms (n=4)
Cardiovascular symptoms (n=401)	0.88 (0.85 - 0.91)	0.88 (0.85 - 0.90)	30,930	Other physical symptoms and conditions (n=14), neurological symptoms (n=9), and respiratory symptoms (n=8)
Respiratory symptoms (n=139)	0.84 (0.77 - 0.89)	0.72 (0.66 - 0.77)	27,775	Sensory problems (n=6), gastrointestinal symptoms (n=5), and other physical symptoms and conditions (n=4)
Infectious symptoms (n=145)	0.84 (0.77 - 0.89)	0.63 (0.57 - 0.68)	15,079	Hepatobiliary conditions (n=7), sensory problems (n=3), and skin and soft tissue disorders (n=3)
Metabolic disorders (n=63)	0.84 (0.73 - 0.91)	0.68 (0.59 - 0.76)	3136	Hepatobiliary conditions (n=7), endocrine symptoms (n=1), and other physical symptoms and conditions (n=1)
Hematological symptoms (n=122)	0.83 (0.75 - 0.89)	0.81 (0.75 - 0.86)	6321	Oncological conditions (n=11), gastrointestinal symptoms (n=3), and hepatobiliary conditions (n=3)
Neurological symptoms (n=413)	0.82 (0.78 - 0.85)	0.79 (0.76 - 0.82)	22,540	Sensory problems (n=38), other physical symptoms and conditions (n=8), and infectious symptoms (n=5)
Gastrointestinal symptoms (n=279)	0.81 (0.76 - 0.85)	0.77 (0.72 - 0.81)	24,878	Hepatobiliary conditions (n=18), autoimmune and inflammatory conditions (n=10), and infectious symptoms (n=9)

Respiratory disorders (n=173)	0.40 (0.33 - 0.47)	0.55 (0.48 - 0.63)	7120	Respiratory symptoms (n=50), infectious symptoms (n=28), and other physical symptoms and conditions (n=10)

[a]Recall indicates the proportion of terms in a clinician-coded category that were classified by the model as belonging to that category.

The model exhibited the best classification performance for categories of: “cardiovascular symptoms” (n=401 terms), “hematological symptoms” (n=122 terms), and “genitourinary symptoms” (n=201 terms), with recall and F_1-score values >0.80. Conversely, the model performed poorly on “sensory problems” (F_1-score=0.35, n=41 terms), “hepatobiliary conditions” (F_1-score=0.45, n=54 terms), and “other physical symptoms and conditions” (F_1-score=0.54, n=559 terms).

The model commonly predicted the category “sensory problems” in terms of the categories “other physical symptoms and conditions” (n=68 misclassifications) and “neurological symptoms” (n=38 misclassifications). The model also commonly mislabeled “other physical symptoms and conditions.” There were 299 “other physical symptoms and conditions” terms that were misclassified across 18 other categories (Multimedia Appendix 3).

Discussion

Principal Findings

We investigated a GPT-4’s ability to replicate clinical judgment when classifying EHR terms from a dataset of mental health patients into interpretable clinical categories. A recent review of NLP studies found the agreement of human coding of EHR data to range from 0.72 to 0.94 (Cohen κ) [28]. Based on this benchmark, GPT-4 showcases human-like agreement with clinical experts when classifying EHR terms as either mental or physical health. Yet, GPT-4’s classification performance varied widely across mental health and physical health categories and had high error rates for certain categories (eg, “sensory problems” and “stressor symptoms”). Misclassifications highlighted GPT-4’s biases, such as the tendency for broad categories (eg, “other physical symptoms and conditions”) to be underselected. Instead, terms from these categories were allocated to more specific categories (eg, “cutting” was allocated to “injury” instead of “self-harm”).

Nevertheless, GPT-4 was able to rapidly transform a feature set of 4553 individual EHR terms into 61 clinically valid groups which can be readily implemented into prediction models. State-of-the-art LLMs have already been used alongside traditional NLP methods, such as named entity recognition, text clustering, and supervised machine learning models trained on text data [29-31]. Additionally, LLMs can explain categorization decisions, providing valuable insights for end users of integrated clinical tools.

XSL•FO
RenderX

Limitations

LLMs occasionally "hallucinate", generating outputs that are off-task, nonsensical, or contradictory. Although we prompted the model to validate the output and correct for hallucinations, as the creativity and complexity of tasks increase so does the risk of aberrant outputs [32]. Moreover, recent studies have found that LLM performance on certain clinical tasks can substantially improve when given 1 or multiple examples for codes, a process known as "few-shot" learning [33,34]. In contrast, our study used "zero-shot" learning, where GPT-4 was asked to classify clinical terms without being provided with any specific examples or definitions for the coding system. This method was chosen to assess the model's baseline classification performance, without introducing any more task-specific bias. However, we recognize that because the coding system was developed by only 2 clinicians, bias may be introduced due to their unique sets of clinical experiences, institutional practices, and personal preferences. The LLM may be biased as well. An ad hoc analysis indicated a tendency for the model to underuse "other" categories (eg, "other physical symptoms and conditions" and "miscellaneous psychiatric symptoms") relative to clinician coders (Multimedia Appendix 3). Nonetheless, we acknowledge that many clinical terms in EHR are inherently ambiguous and may be classified under multiple categories depending on the context. Without knowing the sample is among people hospitalized with a mental health disturbance, it is not necessarily a misclassification for GPT-4 to label "gunshot wound" as a physical injury and not an indicator of suicide. The task of assigning a single, mutually exclusive label may limit one's ability to capture the full complexity of the clinical term. While this study provides a preliminary framework for exploring the feasibility of using LLMs for unstructured EHR classification, future research should aim to involve a varied set of coding methods, classification approaches (eg, multi-label classification), and a larger cohort of clinician-coders to enhance generalizability. Finally, we note that several categories in the mental health domain had too few terms (<5) to yield stable estimates of agreement and were removed from the analysis.

Implications

The accuracy of clinical term classification is essential for downstream predictive models that rely on structured data, as inaccuracies can propagate through the model pipeline. Understanding the sensitivity of these models to variations in input labels is key, especially when distinguishing between random errors and systematic misclassifications. Systematic errors, where specific categories are consistently mislabeled, may significantly affect the robustness of models trained on such data, potentially more so than a random error (ie, noise) [35-37]. Moreover, the assumption that accurate categorization of clinical terms is a necessary intermediate step is worth reconsidering. As LLMs advance, there is potential for these models to bypass the traditional 2-stage process and make direct predictions from unstructured text [30]. Future research is needed to determine whether bypassing the intermediate categorization step entirely might enhance or hinder model performance, depending on the specific clinical application.

Conclusion

As LLMs continue to advance, the time and human resources required to distill a large corpus of EHR terms into clinically meaningful groups can be greatly reduced. LLMs have the potential to be integrated into EHR systems to create text-based features for prediction models in real time. This study found that a state-of-the-art LLM achieved high agreement with classifications of experienced clinicians across terms from numerous physical and mental health categories.

Abstract

Background: In this study, we evaluate the accuracy, efficiency, and cost-effectiveness of large language models in extracting and structuring information from free-text clinical reports, particularly in identifying and classifying patient comorbidities within oncology electronic health records. We specifically compare the performance of gpt-3.5-turbo-1106 and gpt-4-1106-preview models against that of specialized human evaluators.

Objective: We specifically compare the performance of gpt-3.5-turbo-1106 and gpt-4-1106-preview models against that of specialized human evaluators.

Methods: We implemented a script using the OpenAI application programming interface to extract structured information in JavaScript object notation format from comorbidities reported in 250 personal history reports. These reports were manually reviewed in batches of 50 by 5 specialists in radiation oncology. We compared the results using metrics such as sensitivity, specificity, precision, accuracy, F-value, κ index, and the McNemar test, in addition to examining the common causes of errors in both humans and generative pretrained transformer (GPT) models.

Results: The GPT-3.5 model exhibited slightly lower performance compared to physicians across all metrics, though the differences were not statistically significant (McNemar test, P=.79). GPT-4 demonstrated clear superiority in several key metrics (McNemar test, P<.001). Notably, it achieved a sensitivity of 96.8%, compared to 88.2% for GPT-3.5 and 88.8% for physicians. However, physicians marginally outperformed GPT-4 in precision (97.7% vs 96.8%). GPT-4 showed greater consistency, replicating the exact same results in 76% of the reports across 10 repeated analyses, compared to 59% for GPT-3.5, indicating more stable and reliable performance. Physicians were more likely to miss explicit comorbidities, while the GPT models more frequently inferred nonexplicit comorbidities, sometimes correctly, though this also resulted in more false positives.

Conclusions: This study demonstrates that, with well-designed prompts, the large language models examined can match or even surpass medical specialists in extracting information from complex clinical reports. Their superior efficiency in time and costs, along with easy integration with databases, makes them a valuable tool for large-scale data mining and real-world evidence generation.

Introduction

Real-world data (RWD) holds immense potential for advancing health care by providing a comprehensive view of patient health, disease progression, and treatment outcomes [1]. However, RWD presents significant challenges due to its diverse sources and formats, such as electronic health records, medical imaging, and laboratory results, each with different standards and terminologies. Much of this data is unstructured, like free-text clinical notes, which are difficult to process and analyze. Additionally, missing information is common, leading to gaps that hinder accurate analysis. Advanced methodologies and technologies are needed to effectively extract, standardize, and analyze RWD, ensuring its potential to improve health care outcomes is fully realized.

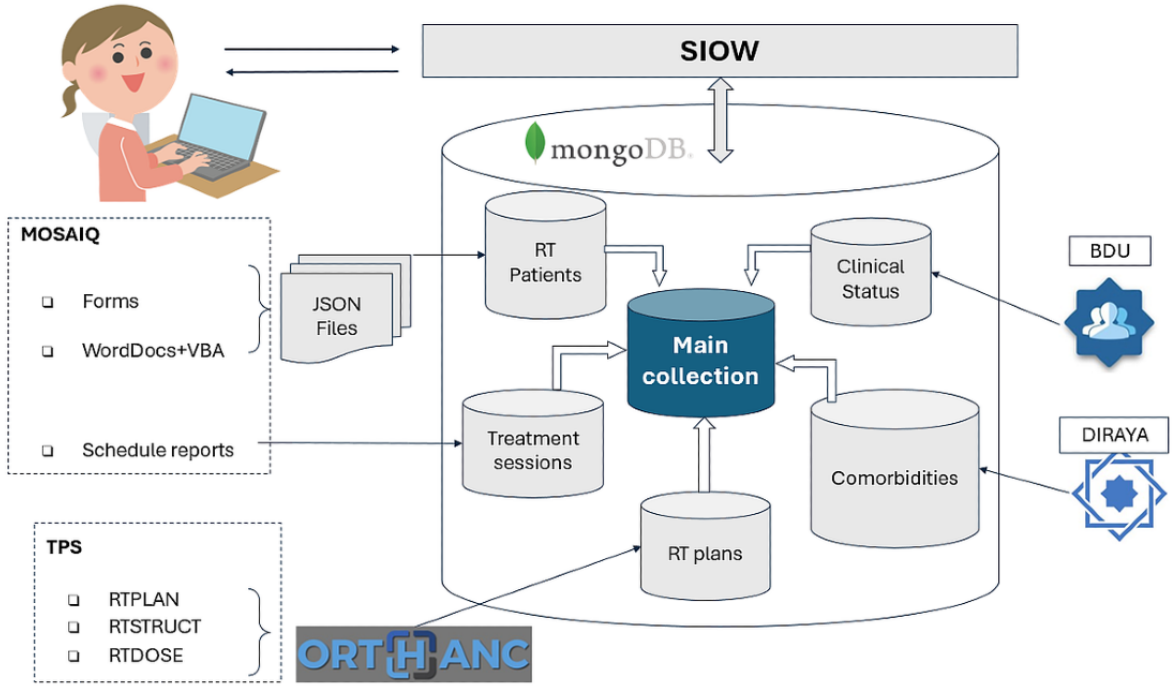
Extracting information from clinical texts has traditionally relied on manual methods, where trained health care professionals review and annotate clinical notes to identify relevant information such as diagnoses, treatments, and patient outcomes. This manual process is not only time-consuming and labor-intensive but also prone to human error, leading to inconsistencies and inaccuracies. Additionally, statistical and rule-based approaches have been used, which depend on predefined patterns and keywords to extract information. However, these methods often fall short in handling the complexity and variability inherent in natural language, resulting in incomplete or inaccurate data extraction.

The rise of artificial intelligence, driven by advances in computing power, has propelled the development of natural language processing (NLP). NLP algorithms can automatically structure information from unstructured clinical texts, facilitating analysis and integration with other clinical data [2-5]. Earlier NLP systems often relied on rule-based systems and simpler machine learning models, implying limitations such as the need for extensive customization, deep computer science knowledge, significant computational resources, and large volumes of high-quality labeled data. These challenges hinder their widespread adoption and optimal performance across different applications.

Transformer models, a deep learning architecture introduced in the paper “Attention is All You Need” by Vaswani et al [6], have revolutionized the field of NLP, establishing themselves as the foundation upon which modern large language models (LLMs) have been developed. LLMs, such as OpenAI's generative pre-trained transformers (GPTs), are models trained on vast amounts of text to learn complex linguistic patterns. This enables them to generate text, understand context, perform translations, and carry out other tasks with unprecedented accuracy and fluency. Thanks to this capability, users can interact with these models, instructing them to tackle various problems without the need for additional training.

The GPT-3 model, released in 2020, and its successor, GPT-4 [7], introduced in 2023, represent significant advancements in the ability to understand and generate coherent text. The progression from GPT-3 through GPT-3.5 to GPT-4 marks a significant evolution in OpenAI's language model capabilities. GPT-4 offers enhanced understanding and generation of text due to its larger training dataset and more refined architecture, resulting in responses that are more accurate, contextually aware, and nuanced compared to its predecessors. This latest version also demonstrates improved performance on a broader array of tasks, including complex reasoning and problem-solving. Additionally, it is multimodal, capable of processing not only text but also images and audio. However, it is important to note that these models are not specifically designed for medical diagnostic purposes.

Currently, there are numerous LLMs available, such as LLaMA, Mistral, Claude, or BioBERT. However, in the medical field, the ChatGPT models have been the most extensively studied [8], demonstrating strong capabilities in various applications, including interpreting clinical guidelines and enhancing evidence-based medicine [9], or table summarization in clinical study reports [10]. Despite their potential, concerns about the applicability of these general-purpose models in the medical domain persist [11,12], particularly due to their lack of transparency in training data, which remains largely unknown. Therefore, it is essential to evaluate their performance for each specific application.



In the context of extracting and structuring information from free-text clinical reports, studies have shown promising results with OpenAI models. For instance, Fink et al [13] demonstrated the effectiveness of these models in extracting data from computed tomography reports related to lung cancer, where they outperformed traditional NLP models in classifying disease progression.

Focusing on the significance of appropriate instructions (prompts), studies such as that of Choi et al [14] highlighted that the gpt-3.5-turbo model exhibited an accuracy rate of 87.7% in extracting information from pathology and ultrasound reports of breast cancer patients. Additionally, the LLM methods demonstrated superior efficiency in terms of time and costs compared to manual approaches.

In 2018, the Department of Radiation Oncology at Hospital Universitario Virgen Macarena initiated the implementation of the Mosaiq system, transitioning toward a paperless workflow and centralizing all radiation therapy treatment data within the application. As detailed by Bertolet et al [15], this data was automatically exported to JSON files via Word documents and Visual Basic for Applications code. Figure 1 depicts a diagram illustrating the flow and organization of the described data.

XSL•FO
RenderX

Figure 1. Representative diagram of the Web Oncological Information System (SIOW). It illustrates the integration of data from MOSAIQ and TPS into the MongoDB database and its subsequent management through SIOW, including the collection of administrative data from the Users Data Base (BDU) and clinical data from the electronic health record system DIRAYA. JSON: JavaScript object notation; RT: radiotherapy.

Motivated by the capabilities of LLMs, we aimed to investigate their potential application in extracting and structuring information from clinical reports. Our overarching objective is to integrate LLM-based tools into our information system, enhancing the richness of our real-world datasets. Specifically, in this study, we assess the capability of the GPT-3.5 turbo and GPT-4 models as tools for data mining applied to the identification and classification of comorbidities and relevant lifestyle risk factors in oncological texts. We compare their performance against that of specialized human evaluators to gauge their efficacy and suitability for clinical use.

Methods

OpenAI Models

The application programming interface (API) of OpenAI [16] allows interaction with their advanced LLMs, facilitating various language processing tasks such as generating automatic textual responses, conducting sentiment analysis, and summarizing texts. In our study, we leveraged the *chat completions API* function of the API to extract structured information from unstructured clinical reports.

OpenAI offers a comprehensive library of natural language processing models. Each model features unique characteristics in terms of size, language comprehension ability, speed, and cost. In our study, we have used 2 models from the library: *gpt-3.5-turbo-1106* and *gpt-4-1106-preview*, with the latter being the most advanced model available at the time the study was conducted. While the GPT-3.5 model is a faster and more economical option for general tasks, GPT-4 stands out for its higher accuracy, contextual understanding, and ability to handle more complex and specific applications.

For this study, we used clinical reports in Spanish, exclusively interacting with OpenAI's LLMs in this language. Although LLMs typically exhibit superior performance in English [17], owing to the predominance of this language in training data, recent comparisons indicate notable effectiveness in other languages, including Spanish. The GPT-4 technical report [7] highlights this multilingual capability, demonstrating that performance in Spanish closely approaches that of English, with a minimal difference of only 1.5 percentage points in the MMLU evaluation [18].

Prompt Generation

To interact with the LLM models, we first created a prompt that will guide the model through the specific task. The context provided to the model establishes a scenario in which it is asked to assume the role of a specialist in radiation oncology. This setting serves as a reference framework, enabling the model to adopt the appropriate perspective and apply its natural language understanding capabilities in a manner consistent with the medical domain.

Our request is a direct instruction to the model, directing it to process the text of the provided clinical report and return the relevant information in a structured format. Specifically, the model is instructed to use the clinical report provided at the end of the prompt to complete a predefined dictionary in JSON format. This dictionary contains keys related to comorbidities and lifestyle risk factors. The model is tasked with updating the values of these keys with “YES” or “NO” as appropriate. For individuals who are ex-smokers, the model should use “EX” instead. Additionally, the model must identify and add any other relevant comorbidities not classifiable under the provided categories, assigning them to the “Other” key.

The prompt generated for the task is shown in Textbox 1.

XSL•FO
RenderX

The dictionary mentioned in the request is structured with keys labeling the specific comorbidities and lifestyle risk factors we seek to identify. These comorbidities, along with their potential values, are outlined in Table 1.

During a postprocessing phase, we divided the category labeled as “smoker” into 2 distinct categories: “smoker” (representing current smokers) and “ex-smoker.” This division was implemented to ease the subsequent analysis of the results.

It is important to highlight that the prompt does not provide context or additional instructions regarding how the specified comorbidities of interest should be interpreted.

The development of this prompt was achieved through an iterative process applied to a group of 50 reports that were specifically reserved for this purpose. The methodology included the following steps (Textbox 2):

Textbox 1. Prompt generated for the task.

- **Context:** “Act as a specialist in radiation oncology.”
- **Request:** “Use the clinical report provided at the end of this prompt to return in JSON format the dictionary [...] with the values 'YES' or 'NO'. For the 'Smoker' field: 'YES' if they smoke, 'NO' if they have never smoked, 'EX' if they are an ex-smoker. For the 'Other' field, return a list of comorbidities found that cannot be classified in any of the categories of the keys of the provided dictionary, or empty if there are no other comorbidities. Return only the dictionary with the updated values, DO NOT ADD OR MODIFY KEYS. Clinical report: [text of the clinical report]”

Table 1. List of the labels, possible values, and description of the comorbidities and lifestyle risk factors considered in this study.

Label	Values	Description
Diabetes	Yes or no	Elevated blood glucose levels
HBP	Yes or no	High blood pressure
Smoker	Yes or no or ex	Smoking habit.
Dyslipidemia	Yes or no	Lipid metabolism disorder
Liver disease	Yes or no	Liver disease
COPD	Yes or no	Chronic obstructive pulmonary disease
Depression	Yes or no	Mood disorder
Kidney disease	Yes or no	Kidney disease
Fentanyl	Yes or no	Use of WHO step 3 analgesics (opioids)
Heart disease	Yes or no	Heart disease
Hyperthyroidism	Yes or no	Thyroid disease with increased thyroxine
Hypothyroidism	Yes or no	Thyroid disease with decreased thyroxine
Dependent	Yes or no	Patient in need of continuous care
Other	Text list	Other past comorbidities detected not listed above

Textbox 2. Prompt development methodology.

- **Prompt definition:** Establishing the parameters and structure of the prompt to guide the model's responses.
- **Information extraction:** The developed prompt was applied to 50 reports using the *gpt-4-1106-preview* model.
- **Verification of structure:** It was ensured that the model's responses adhered to the requested structure, with previous steps being repeated in case of deviations.
- **Accuracy evaluation:** A specialist physician (AW) verified the accuracy of the model's responses. This process was repeated until the accuracy met or exceeded that of a manual analysis performed by the same physician.

Python Script

The Python script developed uses the OpenAI API to automatically structure textual clinical information. All the code developed for this work is publicly available in a GitHub repository [19].

Clinical Report Acquisition Procedure

The clinical reports for our study were provided by the hospital's Innovation & Data Analysis department. These reports were delivered in an Excel spreadsheet format, organized into 2 essential columns: one containing the clinical history number of each patient and another with the text of the medical personal history report. The department responsible for data collection

XSL•FO
RenderX

undertook a process of anonymization and randomization of the reports to ensure an unbiased selection.

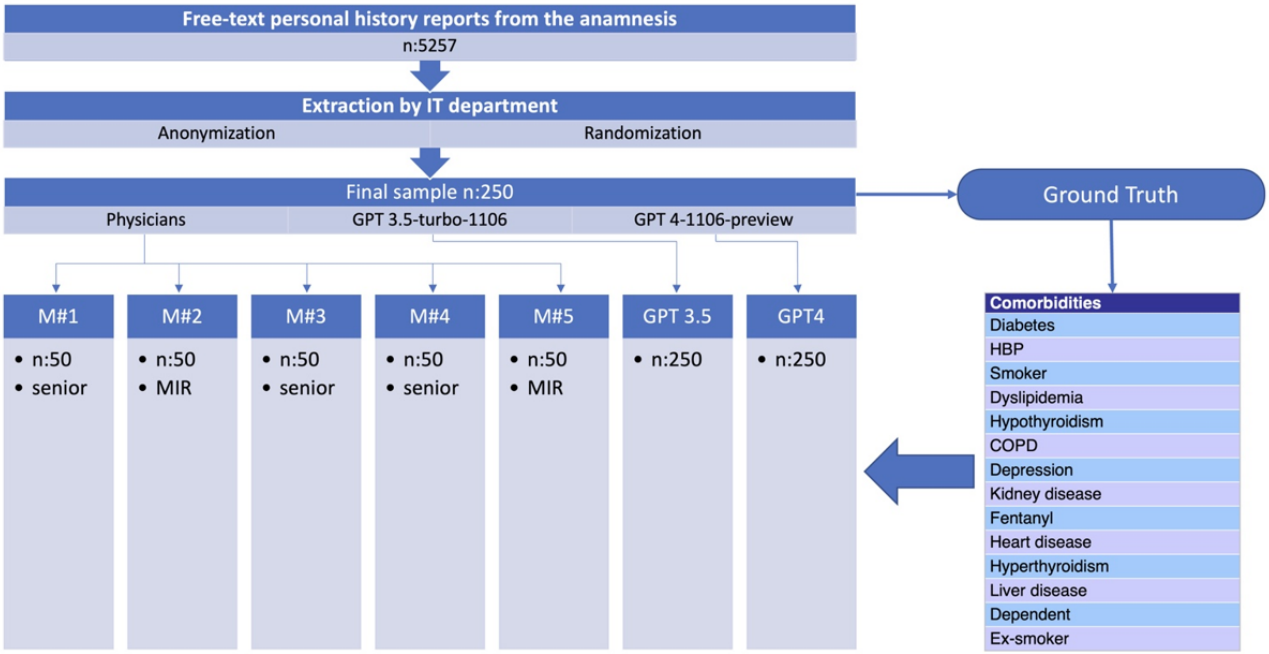
Sample Selection Criteria

For estimating the sample size, we relied on the proportion of comorbidities (80%) obtained from a prior analysis of a dataset of 5257 personal history reports from patients treated in our service between May 2018 and October 2022.

The comorbidities selected for the study were chosen based on prior knowledge of prevalences in the general population and those presented by our patients according to the aforementioned analysis. We also considered those that could most significantly impact the clinical outcome of oncological treatments.

With these considerations, we conducted a preliminary calculation that established the need to include 250 clinical reports (see below in the statistical analysis section). Based on this calculation, we selected the first 250 patients from the provided list who had a nonempty personal history report. Before proceeding with the analysis, we verified that our script was capable of correctly interpreting an empty report as equivalent to the absence of comorbidities, thereby avoiding biases in the study results.

Ethical Considerations



The text processed by the selected LLMs is strictly confined to personal history reports. These reports were stripped of any information that could lead to patient identification, ensuring confidentiality and anonymity. The model's interpretation of the texts focuses solely on identifying and structuring data relevant to the study without compromising individual privacy.

The study's design, synthesized in Figure 2, and methodology were previously communicated to and reviewed by the hospital's ethics committee. The research received the necessary approval, confirming that it adheres to the ethical standards required for patient data research.

This retrospective study adheres to the guidelines outlined in the *seventeenth additional provision, specifically Health Data Processing, Section d) of the Organic Law 3/2018, dated December 5, on Personal Data Protection and Guarantee of Digital Rights*. This law governs the use of pseudoanonymized personal data for health research purposes. The study was granted an exemption from requiring informed consent due to its exclusive use of nonidentifiable data.

On January 18, 2024, the Ethics Committee of the University Hospitals Virgen Macarena and Virgen del Rocío issued a favorable opinion for our study, under the reference EC_IA_V1 (version 1-Dec-2023).

Figure 2. Flowchart of the study design. COPD: chronic obstructive pulmonary disease; HBP: high blood pressure.

Data Extraction

For the manual data extraction, the 250 patient clinical reports were divided into 5 groups, each consisting of 50 reports. These groups were randomly assigned to 5 physicians, including 3 specialists in radiation oncology with more than 15 years of experience and 2 medical residents in the same specialty, one in their first year and the other in their fourth year.

To ensure uniform and accurate data collection, the physicians were provided with a specially designed template for this task. The template features a table where the first column contains the full texts of the clinical reports. The subsequent columns of the table are labeled with the comorbidities of interest. The cells corresponding to each comorbidity only allow the selection of predefined values, as stipulated in Table 1. This restriction ensures consistent annotation and reduces the possibility of errors or variations in the entries.

XSL•FO
RenderX

For the automatic analysis, the 250 clinical reports in the sample were analyzed using our script with the *gpt-3.5-turbo-1106* and *gpt-4-1106-preview* models. To maintain a consistent structure in the study, these reports were organized into the same 5 groups of 50 reports that were assigned to the physicians. The results were recorded in a document that mirrored the structure of the template used in the manual extraction. This uniformity in documentation facilitates a direct comparison of results between manual and automatic extraction methods.

Establishing the Ground Truth

To assess the comparative accuracy and effectiveness of the LLMs used in this study against the evaluations performed by physicians, it is crucial to establish a reference dataset containing the ground truth. To construct this reference dataset, we first compared the results obtained from the physicians and the *gpt-4-1106-preview* model across all 250 reports, identifying and recording any discrepancies between the 2 sources. The radiation oncologist expert AW, with more than 30 years of experience, reviewed several times the whole set of reports, with a particular focus on these discrepancies. For each report where discrepancies in the results were found, physician AW assessed both responses (from the physician and the AI) and determined which one was correct.

It is important to note that the ground truth in this study is based solely on the information explicitly reported in the clinical texts. This means that some patients may have unreported comorbidities, or conversely, conditions may be mentioned that are not actually present. This limitation reflects a common challenge when working with RWD. However, for the purposes of this study, these potential discrepancies are irrelevant, as our primary focus is on evaluating the models' ability to accurately interpret and extract information from the provided texts.

Assessing Reproducibility in Results

The nondeterministic nature of LLMs, such as GPT-3.5 and GPT-4, means they can generate different responses to identical requests [7]. This phenomenon, coupled with the potential for periodic retraining of the models, significantly impacts the reproducibility of results. Therefore, it is crucial to consider the need for rigorous quality control for algorithms that use LLMs, especially to assess the impact of any changes in the models.

A well-defined and explicit prompt can increase the reproducibility of responses [14]. However, variability remains a possibility, particularly in situations where the information is ambiguous or the prompt is not clear or specific enough.

To measure the consistency of our automatic extraction method, we repeated the analysis of the 250 clinical reports 10 times over 10 consecutive days. This approach allows us to observe the stability of the model responses to the same input.

Statistical Analysis

To ensure the statistical validity of the study, a significance level of 5% (alpha error) and a power of 80% (beta error of 20%) were established. Additionally, a 5% error margin was applied for 95% confidence intervals. With these considerations in mind, it was determined that the sample size (n) should include 245 patient records. To adjust the sample to a practical number, it was rounded up, resulting in a final sample size of 250.

For a comprehensive analysis, we consolidated the results from the 250 reports into a single category named “Physicians,” representing the aggregated findings of the 5 doctors involved in the study. Subsequently, we compared this category and the results from the GPT-3.5 and GPT-4 models with the reference dataset, considered as the ground truth. In this process, a confusion matrix was created for each report and comorbidity, from which several key statistical estimators were derived.

To assess the agreement, we used the κ index. The McNemar test was used to determine if there were significant differences in the proportions of discordance between the classifications. We chose the F-score as a measure of balance between precision and sensitivity, which is crucial in a classification model. The calculated metrics are presented in Table 2.

Table 2. Metrics used in the study with their descriptions.

Metric	Description
TP	True positives
TN	True negatives
FP	False positives
FN	False negatives
Sensitivity	TP/(TP+FN)
Specificity	TN/(FP+TN)
Precision	TP/(TP+FP)
Prevalence	(TP+FN)/(TP+TN+FP+FN)
Accuracy	(TP+TN)/(TP+TN+FP+FN)
Kappa	(P*obs*–P*esp*)/(1–P*esp*)
F-score	(2×precision×sensibility)/(precision+sensibility)
McNemar	Exact *P* value from McNemar test (binomial distribution)

XSL•FO
RenderX

For some of these metrics, we calculated their CI using the bootstrapping method [20]. This approach starts from the frequencies of true positives, true negatives, false positives, and false negatives to generate 1000 resamples. With these resamples, we recalculated the metrics to obtain a distribution that allows us to calculate the 95% CI.

Additionally, a detailed analysis was conducted on the groups of 50 reports assigned to each physician. This analysis focused on measuring the variability in evaluations among different physicians. For each patient and comorbidity, Cohen κ index was calculated in comparison with the ground truth for the results of each physician.

The reproducibility of the GPT-3.5 and GPT-4 models was assessed by quantifying the number of different responses for each patient and comorbidity across the 10 repeated analyses conducted on successive days.

Analysis of Discrepant Results

A detailed analysis of discrepancies between the evaluators' results and the established Ground Truth was conducted by the same physician who defined the reference dataset. This analysis covered each report with discrepancies in the identification of comorbidities, identifying the probable causes of each deviation.

Discrepancies were classified according to the nature of the detected errors (Textbox 3).

Textbox 3. Nature of the detected errors.

- **Differences in criteria:** Variations in the interpretation of the relevance of reported pathologies.
- **Incorrect interpretation:** Misunderstandings caused by confusing wording.
- **Incorrect inference:** Erroneous deductions when the comorbidity is not explicitly mentioned.
- **Ambiguous text:** Textual ambiguity that allows for multiple interpretations.
- **Error or hallucination:** Unjustified errors, attributed to human distractions or AI hallucinations.
- **Error in ground truth:** Corrections made upon review that validate the evaluator's interpretation.
- **Explicit omission:** Overlooking direct mentions of comorbidities.
- **Omission by context:** Failure to notice comorbidities deducible from the context or medication.
- **Unrecognized acronyms:** Inability to interpret specific medical acronyms.

Results

Cost and Time Analysis

Table 3 details the cost and total time invested in analyzing the 250 reports using the GPT-3.5 and GPT-4 models. Given that both the models and their associated costs can fluctuate over time, it is important to note that the reported results are specific to the usage period from January to February 2024. It is noted that GPT-4, being a larger and more complex LLM compared to GPT-3.5, incurs longer processing times and a cost approximately 10 times higher. Extrapolating the costs to the entire set of 7500 patients currently registered in our database, processing with GPT-4 would require about 24 hours and would cost approximately 76 dollars. On the other hand, using GPT-3.5 would reduce the processing time to about 9 hours, with a significantly lower cost of around 7 dollars.

Table 3. Execution times and costs in dollars for the analysis of the 250 reports with each of the models used (usage period of the models: between January and February 2024).

Model	N report	Time (hour)	Cost (US $)
gpt-3.5-turbo-1106	250	0.31	0.23
gpt-4-1106-preview	250	0.79	2.53

Prevalences

The analysis of our Ground Truth sample reveals a wide range of prevalences in comorbidities and lifestyle risk factors among oncological patients. These are detailed in Table 4, where both the number of cases and the prevalence for each comorbidity are reported. The most common conditions include high blood pressure and dyslipidemia, present in almost half and a third of the cases, respectively. On the other hand, conditions like hyperthyroidism and liver disease show relatively low prevalence. Categories related to smoking are also highly frequent, accounting for almost 50% of the cases. Interestingly, the proportion of ex-smokers significantly exceeds that of current smokers.

RenderX

Table 4. Number of reports, out of the total 250 in the sample, that indicate each comorbidity and the corresponding prevalence.

Condition	Cases, n	Prevalence
Diabetes	64	25.6%
HBP[a]	116	46.4%
Smoker	37	14.8%
Dyslipidemia	77	30.8%
Hypothyroidism	21	8.4%
COPD[b]	17	6.8%
Depression	25	10.0%
Kidney disease	39	15.6%
Fentanyl	19	7.6%
Heart disease	43	17.2%
Hyperthyroidism	1	0.4%
Liver disease	13	5.2%
Dependent	12	4.8%
Ex-smoker	85	34.0%

[a]HBP: high blood pressure.

[b]COPD: chronic obstructive pulmonary disease.

Evaluation Metrics

Table 5 displays the values of true positives, false positives, true negatives, and false negatives, detailed by comorbidity, derived from the comparison with the ground truth dataset.

Figure 3 illustrates the performance of the physicians, GPT-3.5, and GPT-4 classifiers, broken down by comorbidity, across various metrics. The “Total” category, which consolidates the results for all studied comorbidities, enables direct comparison between the 3 evaluators on each assessed metric (Textbox 4).

The application of McNemar's test to the “Total” category, comparing Physicians with GPT-3.5 and Physicians with GPT-4, yielded P values of .79 and 10^{-6}, respectively. This confirms that the performance differences between the physicians and the GPT-3.5 model are not statistically significant, while the differences between the physicians and GPT-4 are significant.

Textbox 4. Summary of the metrics evaluated.

- **Sensitivity:** The GPT-4 model (96.8%) outperforms both GPT-3.5 (88.2%) and the physicians (88.8%) in most categories, showing notable effectiveness in detecting comorbidities. Although GPT-3.5 presents slightly lower results than the physicians, the difference is not statistically significant, as indicated by the overlap of the 95% confidence intervals shown in Figure 3.
- **Specificity:** All evaluators achieve high specificity values, which is expected given the low prevalences of the studied comorbidities and the relative ease of identifying the absence of a comorbidity in texts. The physicians (99.6%) excel in this metric, often achieving perfection, while both models (99.4%) score slightly lower due to a higher rate of false positives.
- **Precision:** The physicians get the highest score (97.7% vs 96.4% and 96.8%) assessing the proportion of correct positive identifications, possibly also influenced due to the models generating a higher number of false positives.
- **F-score:** Representing the harmonic mean between precision and sensitivity, the F-score is particularly relevant in asymmetric samples like in our study. The GPT-4 model achieves the highest score (96.8%) on this indicator, surpassing both GPT-3.5 (92.1%) and the physicians (93%).
- **Accuracy (Agreement):** In the proportion of correct identifications, GPT-4 shows superior performance (99%), while GPT-3.5 (97.5%) and the physicians (97.8%) achieve similar results.
- **Cohen κ index:** This index, measuring agreement adjusted for chance, reveals that GPT-4 reaches the highest scores (0.962), demonstrating greater consistency compared to the ground truth. The GPT-3.5 score of 0.907, while marginally lower, does not significantly differ from the physicians' score of 0.917.

Variability Among Physicians' Performance

Table 6 displays the Cohen κ index values obtained in the detection of various comorbidities for each of the 5 physician evaluators. It is important to note that each physician analyzed a different group of 50 reports.

Overall, there was considerable similarity in the physicians' responses, except when the comorbidity to be detected was a broader concept, as in the case of "kidney disease" (κ=0.51) or "liver disease" (κ=0.77). It is important to note that no further instructions or explanations were provided beyond finding the comorbidity in the presented text. Therefore, some physicians considered that renal lithiasis was not a relevant "kidney disease" and reserved this category for conditions describing an alteration in renal function (such as chronic renal failure, for example).

Interestingly, the senior physicians scored lower than the medical residents in the overall calculation for the κ index.

Table 6. Concordance values for each comorbidity, calculated using Cohen κ index for each medical evaluator. The "Total" categories summarize the aggregated concordance across all comorbidities and medical evaluators. A dash indicates that the κ index could not be computed because the comorbidity was not present in the corresponding set of reports.

	M1 senior	M2 resident	M3 senior	M4 senior	M5 resident	*Total human evaluators*
Diabetes	1.00	0.95	1.00	1.00	0.95	*0.98*
HBP[a]	1.00	0.96	0.83	0.96	0.96	*0.94*
Smoker	1.00	1.00	0.88	0.86	0.93	*0.94*
Dyslipidema	0.91	1.00	0.75	0.77	1.00	*0.90*
Hypothyrodism	0.66	1.00	0.90	1.00	1.00	*0.95*
COPD[b]	1.00	1.00	1.00	0.66	1.00	*0.97*

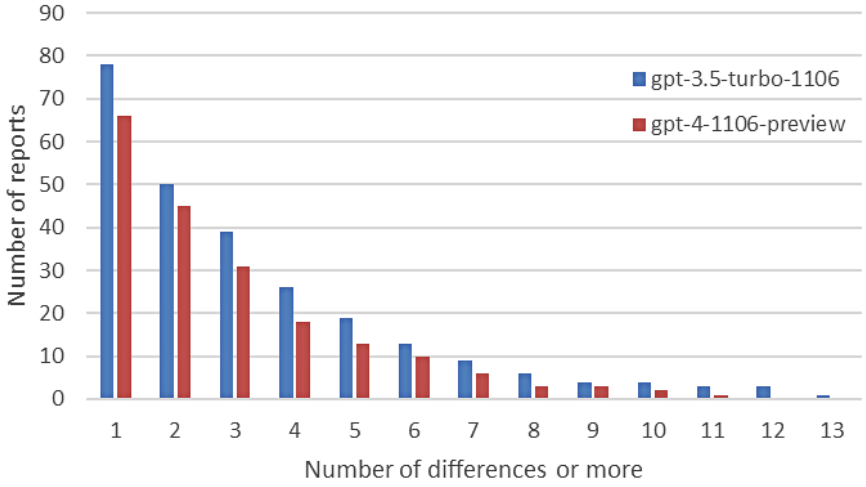
Reproducibility of Models' Responses



In our reproducibility study, each report was analyzed 10 times by the GPT-3.5 and GPT-4 models. For each comorbidity, we counted the number of different responses generated in these repeated analyses, as well as the total number of variations for each report.

Figure 4 presents a histogram illustrating the number of reports that generated at least the specified number of different responses. This histogram reveals that, in all instances, the GPT-4 model exhibited fewer differences in responses compared to GPT-3.5, suggesting greater consistency and reliability in its results.

Furthermore, it was found that 73.6% of the reports analyzed with GPT-4 reproduced the same result across all comorbidities during the 10 analyses, compared to 59.2% for GPT-3.5. This notable difference in reproducibility underscores the superiority of GPT-4 in maintaining consistency in its responses across multiple executions.
