Entity identification	"cetuximab' clearly fits the Drug definition as a therapeutic agent; 'colorectal cancer' → Disease; 'infusion reactions' → Side Effect; 'ER visit' → Treatment..."
Entity filtering	"'medical intervention' is too vague–not entity material;..."
Relation reasoning	"'cetuximab' causes 'infusion reactions' → is_side_effect_of; 'cetuximab' treats 'colorectal cancer' → treat..."
Schema constraints	"Rejected is_examination_for between ER and IRs – not diagnostic; did not create invented relations like 'discontinued_due_to'..."
Formatting awareness	"Ensured JSON format with two root keys (Entities and Relationships); original casing preserved; no explanatory text embedded..."

[a]LCoDR-KE: long chain-of-thought for drug repositioning knowledge extraction.

Step of Training Iterations

We also monitored the performance across 30 training iterations (from 100 to 3000 steps) using F_1 metrics (Figure 5) and showed a steady and stable improvement in Entity F_1, which reached a peak of 81.46% at the level of 1700. Notably, Entity F_1 remained consistently high beyond 2000 iterations without significant decline, indicating robust and stable convergence in the entity recognition task. Triplet F_1 reached its highest value of 69.34% at step 1500 and exhibited a slight decrease in subsequent iterations; however, it consistently stayed above 65%, suggesting that the model maintained a strong baseline for triplet extraction. This relatively stable performance postpeak indicated the potential for further optimization with continued training or minor adjustments. Overall, these results demonstrated the effectiveness and stability of the training approach, particularly for entity recognition while also highlighting a promising and resilient trajectory for triplet extraction performance. Detailed performances across training iterations are provided in Multimedia Appendix 7.

Figure 5. Entity and triplet F1 performance across 30 training iterations (100 - 3000 steps). Entity F_1 steadily improved and peaked at 81.46% (step 1700), maintaining stability thereafter. Triplet F_1 reached a maximum of 69.34% (step 1500) and remained consistently above 65%, indicating robust and stable model convergence for both extraction tasks.

Error Analysis

We conducted an error analysis by manually reviewing 100 randomly selected sentences from the model outputs to identify common types of mistakes and areas for improvement.

Error Examples

The errors were classified into 4 main types of entity extraction (ie, incorrect extraction, incorrect type, boundary errors, and missing entities) and 2 main types of triplet extraction (incorrect entity type and cross-sentence errors), with examples summarized in Table 10.

Table . Main error types in LCoDR-KE[a].

Error types	Definition	Sentences	Truth extraction	LCoDR-KE extraction
Entity extraction				
Incorrect extraction	Nonentity terms were incorrectly identified as entities	Available therapies are effective, associated with severe side effects.	NULL	[severe side effects, side effect]
Incorrect type	Entities were correctly identified but assigned the wrong entity type	In nearly half of cancer cells, there is an overexpression of MDM2 and MDMX, which inhibit p53 activity.	[p53, gene]	[p53, target]
Boundary errors	Which involved incorrect determination of the start and end positions of entities	The expression of BRCA1 and BRCA2 mutations was analyzed in the cohort.	[BRCA2, gene]	[BRCA2 mutations, gene]
Missing entities	Entities present in the text were not identified by the model	Other lung findings were ... or extensive hemorrhage.	[extensive hemorrhage, complication]	NULL
Triplet extraction				
Incorrect entity type	Relationships were correctly identified but assigned the wrong entity type	Docetaxel and gemcitabine might result in fewer adverse events.	NULL	[adverse events, side effect, is side effect of, Docetaxel, drug]
Cross- sentence error	Unable to recognize logical relationships across sentences	62% of subjects exhibited recurrent gastrointestinal distress (eg, nausea). Subsequent serological testing confirmed elevated anti-tTG antibodies, a hallmark of celiac disease.	[nausea, symptom, is symptom of, celiac disease, disease]	NULL

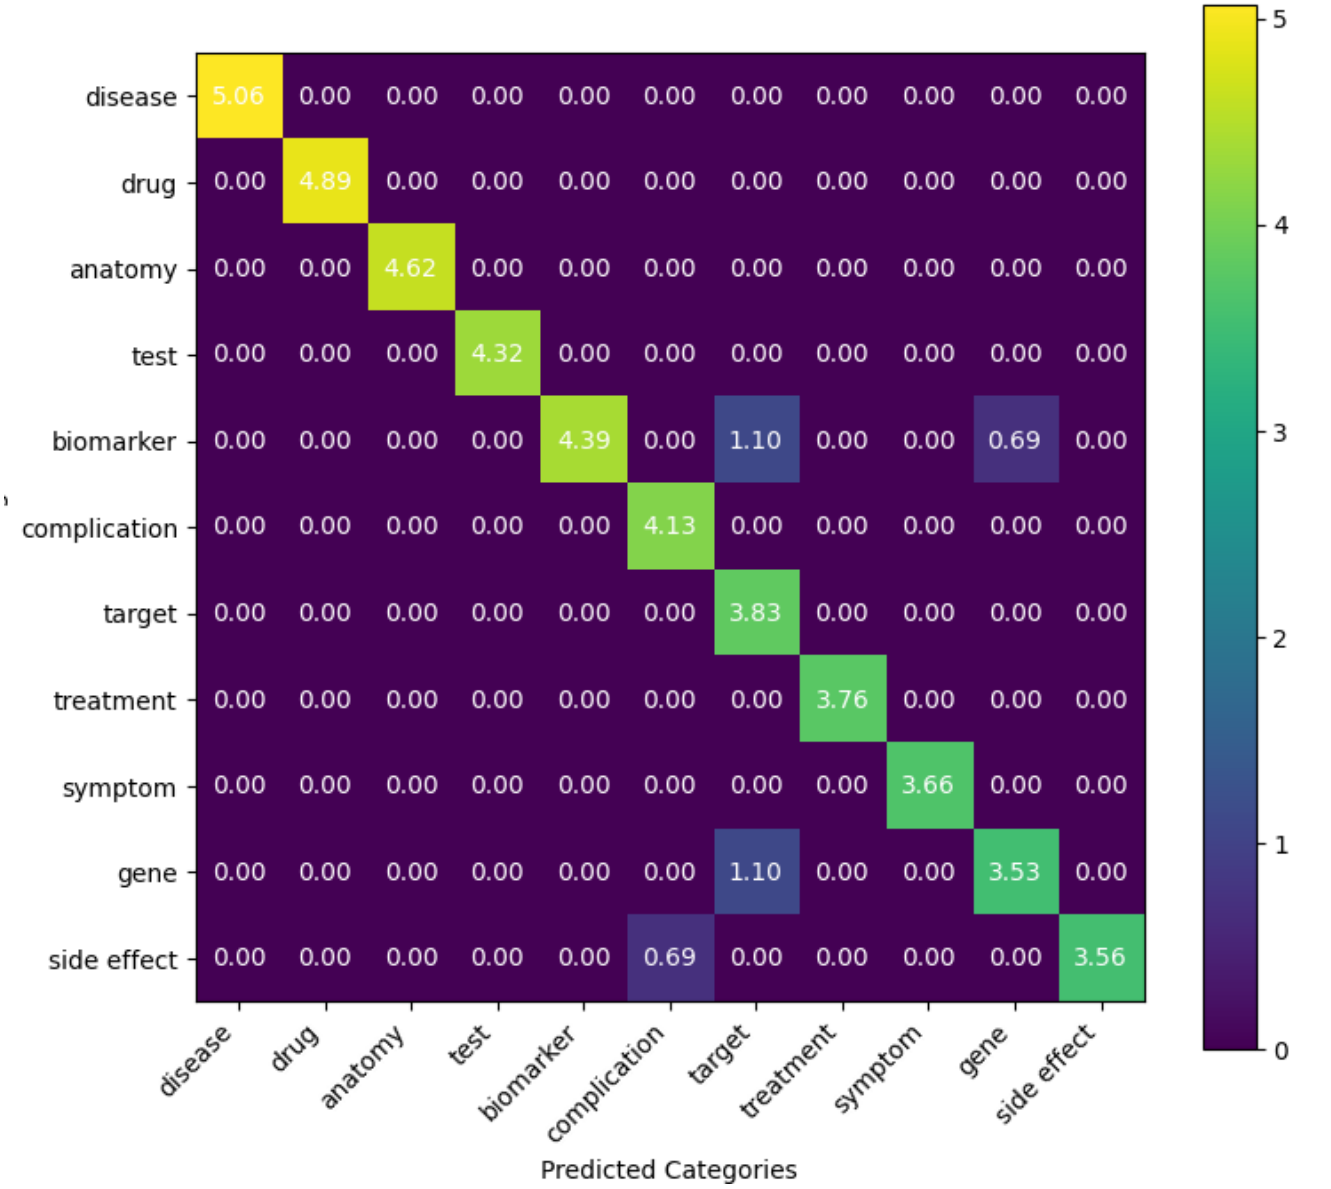
[a]LCoDR-KE: long chain-of-thought for drug repositioning knowledge extraction.

Error Statistics

We further quantified the frequency of each error type to assess their impact and guide future improvement strategies.

For entity extraction:

1. Incorrect extraction (n=10, 38.46%): This was the most common error, typically caused by semantically ambiguous phrases. For example, generic terms such as “severe side effects” were incorrectly extracted due to superficial similarity to defined entity types.
2. Incorrect type (n=6, 23.08%): These errors occurred when the model misclassified closely related concepts, such as mislabeling “p53” as a target instead of a gene.
3. Boundary errors (n=4, 15.38%): Often caused by inclusion of modifiers like “mutations” in entity spans, resulting in misaligned entity boundaries.
4. Missing entities (n=6, 23.08%): Frequently occurred when entities were embedded in complex phrases or lacked explicit semantic cues, leading to omission.



For triplet extraction:

1. Incorrect entity type (n=5, 38.46%): The relationship was correctly identified, but the entity types were misclassified (eg, “adverse events” mislabeled as side effect instead of a nonentity).
2. Cross-sentence error (n=8, 61.54%): The model failed to capture logical relationships spanning multiple sentences, especially when the subject and object were not co-located in the same sentence.

To further investigate the model’s behavior on entity classification, we constructed a confusion matrix (Multimedia Appendix 8) based on entity predictions. The results (Figure 6) showed strong diagonal dominance, indicating high accuracy across most entity types. However, misclassifications persist among semantically similar categories. Specifically, the biomarker was confused with the target (2 cases) and gene (1 case), while gene was misclassified as the target twice. In addition, 1 side effect instance was incorrectly labeled as a complication. These errors reflected the model’s difficulty in distinguishing biologically related concepts with overlapping semantics. In contrast, core categories, such as drug and disease, were classified with perfect accuracy.

XSL•FO
RenderX

Figure 6. Confusion matrix of entity type classification results (log-normalized). This log-scaled confusion matrix illustrated the model's entity classification performance across 11 biomedical entity types. Diagonal dominance indicated high overall accuracy, while off-diagonal cells highlight common misclassifications. Notably, errors were concentrated among semantically similar categories, such as biomarker, gene, and target.

Comparisons Between LCoDR-KE and DeepSeek-R1

Meanwhile, LCoDR-KE demonstrated comparable performance with DeepSeek-R1. Specifically, LCoDR-KE surpassed DeepSeek-R1 in the categories of incorrect type (6 vs 8), missing entity (6 vs 7), and incorrect entity type (5 vs 6). This advantage can be attributed to our meticulous definition of entities and relations for the drug repurposing task, as well as the provision of accurate examples during model training. Conversely, LCoDRKE performed slightly worse in the Incorrect Extraction (10 vs 8) and CrossSentence Error (8 vs 7) categories, indicating that its complex contextual understanding and reasoning capabilities warrant further improvement.

Discussion

Principal Findings

In this study, we introduced LCoDR-KE, a novel framework for drug repositioning knowledge extraction that significantly enhanced the adaptive learning capabilities of LLMs.

The effectiveness of our approach stemmed from 2 key innovations.

- First, we developed a refined semantic representation framework and used it to curate a high-quality training corpus, DrugReC, comprising 1000 expertly annotated abstracts. These annotations covered diverse drug repositioning entities and captured complex semantic relationships, providing a robust foundation for the model to learn accurate semantic understanding and contextual reasoning.

XSL•FO
RenderX

- Second, we proposed a long reasoning chain strategy: an iterative, multistep inference process reinforced through reward mechanisms and RL. By delivering explicit feedback at each reasoning step, this strategy enabled the model to progressively optimize its decision-making process, resulting in more accurate and coherent inference.

Collectively, these innovations contributed to the improved performance of LCoDR-KE in extracting drug repositioning knowledge.

Compared to pretraining approaches specifically designed for biomedical tasks, LCoDR-KE offered several advantages. Traditional methods typically required extensive domain adaptation, large annotated corpora, or multiple rounds of fine-tuning to achieve competitive performance [55]. In contrast, LCoDR-KE achieved performance optimization with a relatively small training dataset—comprising only 1000 literature abstracts—thereby significantly reducing the human and time costs associated with domain-specific annotation. Furthermore, LCoT decomposed semantic understanding into explicit and traceable reasoning steps. This approach mitigated hallucinations and enhanced model transparency, addressing 2 major challenges in the application of LLMs. Our ablation study further substantiated these findings.

Moreover, performance comparisons demonstrated that LCoDR-KE based on the Qwen-2.5-7B model matched the performance of the 671B -parameter DeepSeek-R1 in drug repurposing knowledge extraction. Specifically, F_1-scores achieved 81.46% versus 84.64% for entity extraction and 69.04% versus 69.02% for triplet extraction. This advance significantly narrowed the gap between large-scale models and resource-constrained environments, making it a practical solution for research institutes and hospital information centers with modest computing capabilities.

In addition to performance gains, LCoDR-KE enhanced model interpretability through CoT prompting. By generating intermediate reasoning steps, such as entity justification, schema validation, and relation filtering, the model made its decision process more transparent and traceable. This structured reasoning not only aided error diagnosis but also aligned model behavior with domain knowledge constraints, offering a more controllable and explainable framework for biomedical knowledge extraction.

Our expanded error analysis provided a more nuanced understanding of model behavior in biomedical knowledge extraction. By categorizing common error types, quantifying their frequency, and visualizing entity-level confusion patterns, we identified key challenges such as semantic ambiguity, long-range dependencies, and data sparsity. These insights not only explained performance bottlenecks but also informed future improvements, such as targeted data augmentation and schema-aware prompt refinement to reduce ambiguity and improve generalization.

LCoDR-KE demonstrated strong performance in low-resource settings through its schema design, cold-start SFT, and RL with a reward mechanism. It provides an efficient and feasible solution for biomedical knowledge extraction under resource-constrained conditions. In clinical research settings, LCoDR-KE could be deployed to mine structured knowledge from trial protocols, real-world evidence, or adverse event reports, assisting clinicians in therapeutic decision-making and safety monitoring. In early-stage drug development, it can support target identification and biomarker discovery by extracting mechanistic insights from scientific literature. Its lightweight design makes it particularly well suited for integration into domain-specific platforms where computational resources and labeled data are limited. Moreover, its task-specific schema could be readily tailored by redefining entities and relations, thereby accommodating new domains, languages, and even alternative LLM backbones. Its flexibility allowed LCoDR-KE to extend beyond drug repositioning to a broad range of biomedical knowledge extraction tasks.

Limitations

Despite the promising results, our study has some limitations. First, we limited the task to drug repositioning in this study. In the future, we will include other biomedical knowledge extraction tasks, such as gene–disease association identification and drug–drug interaction detection, thereby expanding its application value in diverse scenarios. Second, the model's balance between reasoning depth and computational efficiency remains suboptimal, particularly when processing intricate biomedical contexts requiring multistep logical inferences. Future optimizations will focus on lightweight architectural improvements.

Conclusions

This study introduced LCoDR-KE, a framework that enhanced LLMs' domain-specific adaptability for drug repositioning by integrating long-chain reasoning and RL. We constructed a publicly available DrugReC and a lightweight knowledge extraction model, offering critical resources for accelerating drug discovery and knowledge inference. The framework balances accuracy, interpretability, and computational efficiency, validated through stable training convergence and competitive performance against state-of-the-art models. Overall, LCoDR-KE not only advances drug repositioning research but also provides a scalable, transferable methodology applicable to diverse biomedical knowledge extraction tasks, knowledge reasoning, and even decision support, bridging gaps in low-resource, specialized domains.

Abstract

Background: Clinical natural language processing (cNLP) techniques are commonly developed and used to extract information from clinical notes to facilitate clinical decision-making and research. However, they are less established for rare diseases such as lymphoid malignancies due to the lack of annotated data as well as the heterogeneity and complexity of how clinical information is documented. In addition, there is increasing evidence that cNLP techniques may be prone to biases embedded in clinical documentation or model development. These biases can result in disparities in performance when extracting clinical information or predicting patient outcomes.

Objective: This study aims to report the development and validation of a cNLP pipeline that extracts clinical information such as performance status, staging, and diagnosis, as well as less common information such as substance use and military environmental exposures, from the clinical notes of veterans with lymphoid malignancies.

Methods: We developed a rule-based cNLP pipeline that integrates domain expertise. We tested and compared the performance of the cNLP pipeline on notes from 2 veteran patient cohorts: one from non-Hispanic White veterans and the other from non-Hispanic Black veterans.

Results: Overall, our pipeline achieved promising performance on our study data, especially for extracting entities that have standard clinical documentation, such as performance status. We also found that while the pipeline has robust performance across the two patient groups, the false-positive and false-negative rates were significantly associated with race for detecting the primary diagnosis (P=.001 for both); the false-negative rate was significantly associated with race for identifying substance use (P=.02).

Conclusions: The system exhibits satisfying and comparable performance for most clinical entities of interest except for (1) the primary diagnosis and (2) substance use. Future work will address the challenges encountered in developing and deploying the cNLP pipeline on the Department of Veterans Affairs data for rare cancers and enhance the performance of cNLP systems to avoid biases.

Introduction

Clinical notes contain rich information about patients' conditions and disease trajectories. As it is often tedious and time-consuming for clinicians to perform a manual chart review to retrieve such information, clinical natural language processing (cNLP) has served as a crucial tool to automate the process of extracting clinical elements from unstructured notes [1]. While cNLP is an established field with mature software such as the clinical Text Analysis and Knowledge Extraction System and Clinical Language Annotation, Modeling, and Processing, there is a lack of cNLP resources for extracting information from clinical notes of patients with rare cancers [2], which may be due to the difficulty of obtaining high-quality annotation data from rare disease experts.

Lymphoid malignancies (LMs) are rare cancers with only around 145,000 patients diagnosed in the United States per year [3-7]. Among US veterans who were deployed overseas, exposure to

XSL•FO
RenderX

environmental toxicants and chemical agents is a risk factor associated with LMs [8]. There is a need to capture past environmental exposures of veterans to better care for them. For example, the Promise to Address Comprehensive Toxics (PACT) Act, which passed in 2022, expands health care benefits and assists clinical research for veterans who have been exposed to environmental toxicants [9]. While the need for identifying and caring for veterans with environmental exposures increases, such information is often not well captured in structured electronic health records (EHRs). In fact, most of the clinical information that is vital to clinicians' decision-making is embedded in free-text, unstructured clinical notes [10]. Therefore, there is a need to develop cNLP tools that are specifically tailored to and validated on clinical notes for rare cancers so that they can capture unique clinical information. To the best of our knowledge, there is no existing cNLP pipeline or model that has been developed for and validated on clinical notes of LMs.

In this study, we developed and validated a rule-based cNLP pipeline to extract diagnoses, staging, performance status, substance use, and environmental exposures from clinical notes of veterans with LMs. We further assessed whether the cNLP pipeline may be prone to biases by comparing its performance on non-Hispanic White and Black patients. Finally, we discuss the opportunities and challenges of developing cNLP pipelines for extracting information from clinical notes of patients with LMs and implications for clinical documentation.

Methods

Data Source and Creating the Development Set

We extracted records of veterans diagnosed with LMs—as defined by the *International Classification of Diseases for Oncology, Third Edition*—from the Department of Veterans Affairs (VA) Corporate Data Warehouse (CDW) [11] (summarized in Multimedia Appendix 1). The VA CDW includes patient records from 173 medical centers within the VA system across the United States as well as clinics in Puerto Rico, Guam, and the Philippines, capturing different practice and documentation patterns [12]. In total, 80,245 patients were identified using the *International Classification of Diseases for Oncology, Third edition*. The development set included a random sample of 287 deidentified hematology and oncology clinic notes from veterans with LMs in the VA system after removing 13 duplicates from the initial 300 notes. The hematology and oncology notes contained the most relevant clinical information and were intended to reduce annotators' burdens.

Clinical Entities of Interest

We annotated and extracted the following clinical entities that were known to be prognostic in the care of patients with LMs but were often inconsistently documented in a structured format using a standardized dictionary:

1. Diagnosis: primary diagnosis related to LMs
2. Substance use: alcohol, drug, and tobacco use
3. Environmental exposure: Agent Orange, Vietnam, shipyards, and Marine Corps Base Camp Lejeune according to the PACT Act
4. Staging: stage, chronic lymphocytic leukemia Rai staging and Binet staging, the multiple myeloma International Staging System, and lymphoma Ann Arbor staging
5. Performance status: performance status, Karnofsky performance status (KPS), and Eastern Cooperative Oncology Group (ECOG) performance status

Annotation and Scoring

Clinicians annotated according to an annotation guideline, provided in Multimedia Appendix 2. The annotation guideline was continuously improved during the annotation process and aimed to capture common and recurring documentation patterns rather than a comprehensive list of documentation. Two independent medical experts annotated a random sample of 100 notes from the development set to calibrate. The interrater agreement ratio was calculated, and disagreements were discussed and resolved to finalize the annotation protocol. The annotation task was formulated as selecting a text span that indicates a clinical entity of interest and selecting the entity label (eg, stage and performance status). Therefore, each annotated entity can be represented as having the following: (1) a label *L* and (2) a text span with starting and ending indices (*i*, *j*). Two annotated entities *M* and *N* are considered a match if Label (M) = Label (N) ^ relaxed_match (span (M), span (N)).

We calculated the span-based F_1-score for measuring the level of agreement between the two annotators, following previous studies [13-15]. The span-based F_1-score is preferable in this case because it is not affected by the number of true negatives, which are prevalent in span-based annotations [16]. We calculated the metrics for span-relaxed matches, where 2 text spans need to overlap for at least two-thirds of the length of the shortest span. The microaveraged F_1-score is 0.85; the detailed statistics across different entity types are presented in Table 1.

Table . Interrater agreement of 100 annotated notes in the development set.

	Precision	Recall	F_1-score
Primary diagnosis	0.89	0.79	0.84
Performance status	0.90	0.87	0.88
Staging	0.90	0.98	0.94
Substance use	0.66	0.90	0.76
Environmental exposure	0.64	0.70	0.67

XSL•FO
RenderX

The clinician annotators met regularly to discuss and resolve disagreements and adjust the annotation guidelines accordingly. After reaching consensus, they proceeded to annotate the remainder of the development set, test set 1, and test set 2. The annotation task was formulated as named entity extraction, where annotators selected a text span and labeled it with a clinical entity such as diagnosis. For each note, there were multiple text spans with start and end indices and their associated clinical entity labels.

Confirmatory Test Sets

To develop and test the cNLP pipeline, we randomly selected 1000 patients from the patient cohort.

We included all the hematology and oncology notes of these patients, and these comprised notes from nurses, social workers, and pharmacists who document a wide range of information. This aimed to ensure that the cNLP pipeline we developed would not be tuned to work only on specific note types or from specific provider types. When constructing the test sets, we used 2 steps to compile the notes. First, from the patient cohort, we randomly selected 100 notes with at least 300 characters to ensure that they are long enough to contain useful information. After annotating a few notes, we noticed that for some clinical entities, especially performance status and environmental exposures, few notes mentioned them. Therefore, besides the 100 randomly selected notes, we also included notes that contained predefined keywords (eg, “ECOG” and “Agent Orange”) so that medical experts did not need to read notes without any clinical entities of interest. In this process, the random selection of notes helped to ensure the representativeness of the notes, and the use of keyword filtering helped to increase the recall and lower the annotator burden. This method of using keywords to prefilter notes had been used in previous work to extract infrequently documented information, such as housing eviction status, from clinical notes [17].

The first test set (test set 1) included 200 notes from all races and ethnicities, resulting in a sample of 89 notes with clinically relevant data from randomly selected non-Hispanic White patients. Given potential differences in documentation, we added a second group enriched for non-Hispanic Black patients. The second test set (test set 2) included a sample of 200 notes from randomly selected non-Hispanic Black patients, resulting in 106 notes containing clinically relevant data. The data selection and processing procedures are shown in Figure 1.

Development of the cNLP Pipeline

The goal of the study was to develop a cNLP pipeline that can accurately extract clinical entities of interest without extensive annotations. Therefore, we did not perform a comprehensive evaluation of pretrained language models, as most were not developed on notes from patients with LMs and fine-tuning them will require more annotated data.

We tested 2 zero-shot large language models (LLMs), FLAN-T5 by Google and Llama2 by Meta, with carefully curated prompts to extract the clinical entities of interest. We did not test OpenAI's GPT models due to the sensitive nature of our data and the requirements of sending the input data to the commercial servers of OpenAI. The zero-shot LLMs also did not produce a satisfactory and consistent identification for the named entity recognition task, which was also observed in a recent evaluation conducted by Lu et al [18]. We found that Llama2 had difficulty following the instructions, and FLAN-T5 was only able to correctly identify 16 out of 137 incidences of performance status and 263 out of 1347 diagnosis mentions. We reviewed samples of errors and found that FLAN-T5 tended to hallucinate and made up text snippets that were not in the original clinical notes. This could be because FLAN-T5 and similar general domain LLMs were not pretrained on clinical notes or data that contain language related to performance status or LMs. Fine-tuning these LLMs will require larger datasets of clinical notes and more extensive instruction tuning and supervised fine-tuning and is beyond the scope of this study. Therefore, we decided to develop rule-based modules based on expert input. Despite the limitations of rule-based methods, they are still widely used and implemented on tasks such as identifying cognitive assessment tests and biomarkers from notes of patients with Alzheimer disease and Alzheimer disease–related dementias [19] and extracting risk factors for pancreatic cancer [20].

Development of a Rule-Based cNLP Pipeline

The cNLP pipeline was iteratively developed by examining annotated texts in the development set as well as consulting the clinical experts on the study team. For example, "ECOG," "KPS," and "Performance Status" were included in the dictionary of the pipeline to capture potential mentions of performance status. Similarly, "Stage," "Stg," and "Rai" were included to identify mentions of staging information. "Tobacco," "smoke," "alcohol," "drug," "etoh," and other commonly used terms were included to extract substance use mentions. For environmental exposures, we used both chemical agents, such as "Agent Orange," and locations that are known to have toxicants, such as "Vietnam" or "shipyard." All clinical notes were preprocessed by converting words to lowercase. Punctuation was preserved. We accounted for misspellings or format issues (eg, extra or missing spaces) by curating the regular expressions. Examples of the final regular expressions are provided in Multimedia Appendix 3.

We added special modules in the cNLP pipeline after matching regular expressions to account for the errors we observed in the training set. For the primary diagnosis and performance status, we observed that most false positives (FPs) were due to the prevalent use of templates (eg, in disability benefit questionnaires). We excluded matched diagnoses and performance status that were present in a template format ("[ ] Multiple Myeloma"; "() ECOG 1 () ECOG 2"). Excluding matches from templates reduced the number of FPs in our study sample. In addition, for the primary diagnosis, as the diagnosis process for LMs is commonly complex and often undergoes numerous laboratory tests and positron emission tomography scans, we excluded mentions of LMs that were documented as differentials or assessment plans and needed further confirmation. This step ensured that the final extracted primary diagnosis is confirmed and can be directly used for secondary analysis. For performance status, we required all possible matches of performance status to be followed by numeric values so that ambiguous expressions such as performance status for postscripts are excluded. For ECOG performance status, the numeric values must be between 0 (indicating fully active) and 5 (indicating death), and for KPS, the numeric values must be between 0 (indicating death) and 100 (indicating normal). This ensures that only text chunks that indicate performance status will be included so that FPs can be reduced.

For staging, we observed that most FPs were due to their irrelevance to our diagnosis of interests, and it was common for stages of multiple comorbidities to be documented (eg, stage II for chronic kidney disease). Therefore, we checked whether the staging information identified is within the window of a surrounding primary diagnosis. We experimented with multiple values of the size of the window to look for the primary diagnosis. The performances for extracting staging using different window sizes are provided in Multimedia Appendix 3. Overall, we observed that as the window size increased, both test sets had higher precision but lower recall. We selected a window size of 30, as the F_1-scores for both test sets were optimized. The window sizes also enable more flexible configuration of the pipeline, depending on whether the priority is to extract all potentially relevant staging information (a larger window size) or to only extract highly relevant staging information (a smaller window size).

For identifying environmental exposures, we used multiple rules informed by the development data, as well as VA's official PACT Act recommendation [9] to capture potential exposure, as exact documentation containing the names of chemical toxicants, such as Agent Orange, is limited and does not capture all potential exposures. We also included services and deployments that are potentially associated with exposures, including service in Vietnam or Camp Lejeune. Finally, we included locations that may expose patients to toxicants, including shipyards, infantry, and chemical plant factories.

Performance Evaluation

The extracted tokens were evaluated based on the lenient matching criteria used in previous work [21,22], that is, 2 tokens were deemed as a match if they overlapped, to account for potential annotation issues and format irregularities. Precision was calculated as true positives/(true positives + FPs) and recall was calculated as true positives/(true positives + false negatives [FNs]). F_1-score is (2 × precision × recall)/(precision + recall). Misclassified entities in the test set were extracted and analyzed manually by the medical experts to identify potential sources of errors to improve the performance of the cNLP pipeline.

XSL•FO
RenderX

We further assessed whether the pipeline was prone to bias on the test sets. In this study, we focused on racial bias, and in particular, potential biases between non-Hispanic White and Black patient populations. We conducted chi-square tests on FPs and FNs using the cNLP pipeline. The null hypothesis was that the cNLP performance, measured by FP and FN, was independent of the patients' race.

Ethical Considerations

This study was approved by the institutional review board (VA IRB #1618998 and UCI IRB #1041) at both the VA Long Beach Healthcare System and the University of California, Irvine. Research was conducted in accordance with the Declaration of Helsinki. Waivers of informed consent and HIPAA (Health Insurance Portability and Accountability Act) compliance were approved by the institutional review board.

Results

NLP Performance on the Test Sets

For each clinical entity, the precision, recall, and F_1-score were calculated and presented in Table 2. For entities that have clear standards for documentation such as performance status, the performance is higher (F_1-score>0.90). For entities that generally lack a documentation standard such as substance use or environmental exposures, we observed lower performance. In addition, the high precision and recall for some entities were possibly due to overfits of the manually tuned model, which is a common issue for rule-based pipelines.

Table . Clinical natural language processing performance on test set 1 (89 notes) and test set 2 (106 notes).

	Test set 1				Test set 2			
	Frequency	Precision	Recall	F_1-score	Frequency	Precision	Recall	F_1-score
Performance status	54	0.96	0.96	0.96	73	0.85	0.96	0.90
Staging	71	0.94	0.69	0.80	116	0.85	0.60	0.71
Primary diagnosis	277	0.70	0.93	0.80	485	0.60	0.85	0.70
Substance use	104	0.65	0.61	0.63	148	0.66	0.76	0.70
Environmental exposures	29	0.72	0.62	0.67	5	0.5	0.6	0.54

Bias Assessment

The results from chi-square tests showed that the performance of the cNLP pipeline was not statistically different across test sets 1 and 2 for performance status and staging. However, the cNLP pipeline's FN rate for extracting substance use is significantly associated with patients' race (χ^2_1=5.9; P=.02). The pipeline's FP rate for extracting the primary diagnosis is significantly associated with race (χ^2_1=10.2; P=.001), and the FN rate is also associated with race (χ^2_1=10.4; P=.001). We were unable to run the test on environmental exposures due to the small number of observations available (5/106, 4.7%). Detailed statistics and confusion matrices are provided in Multimedia Appendix 2.

Error Analysis

Table 3 presents example snippets of FPs and FNs.

Table . Example snippets of false positive (FP) and false negative (FN)[a].

	FP example	FN example
Performance status	"*ECOG 0 - 1*"	"*PS>2*"
Staging	"Chronic kidney disease *stage 3* Multiple myeloma"	"At least *Stage IIIA*"
Primary diagnosis	"likely prostate cancer and *CLL*"	"with kappa light chain *MM*"
Substance use	"8. *Tobacco/Marijuana Use*–smoking cigarettes again"	"*crack use*"
Environmental exposures	"combat exposure"	"worked as an exterminator"

[a]Italicized texts indicate misalignment between natural language processing extraction and annotation.

Our qualitative analysis reveals the following two major types of errors:

1. Lack of documentation standards: many of the FNs were caused by inconsistent documentation, especially for environmental exposures. For example, while the cNLP pipeline captured common mentions such as "Agent Orange," "service in Vietnam," and "chemical plant factory," exposure-related information was often documented in various ways that made it difficult for the cNLP pipeline to capture exhaustively. Furthermore, some clinicians used locations such as "shipyards" to imply

XSL•FO
RenderX

potential exposures to toxicants, while some explicitly listed the chemical toxicants, such as “asbestos.”

2. Implicit association with the primary diagnosis: while our efforts in associating staging information with surrounding mentions of the primary diagnosis effectively reduced the number of FPs (ie, incorrectly identifying staging information), the pipeline also resulted in FNs where relevant staging information was not captured because there was no primary diagnosis mentioned around it. In reviewing the errors, we observed that not all LM-related staging information was explicitly documented together with the primary diagnosis.

Discussion

Principal Findings

We developed a rule-based cNLP pipeline to identify mentions of clinical information, including diagnoses, performance status, staging, substance use, and environmental exposures from clinical notes of veterans with LMs. The pipeline can be used in our future studies to produce weak labels, which can serve as fine-tuning datasets to improve the performance of LLMs in the domain of LMs.

In the literature, a study that reported better performance in extracting staging and substance use information from notes of patients with cancer [23]. However, the majority of these studies only used radiology and pathology notes, which were generally more structured and did not contain other clinical information unrelated to cancer [2]. In our study, the wider range of notes authored by a wide range of health providers introduced additional challenges to accurately identify clinical entities of interest due to the heterogeneity of information and documentation styles of these notes. In addition, none of the existing studies focused on rare cancers such as LMs but were related to more prevalent cancer types such as breast cancer and lung cancer. Some clinical entities and their documentation were therefore inherently different from those for LMs. For example, breast cancer documentation uses TNM staging system (where T, N, and M stand for tumor, node, and metastasis, respectively) to record staging, which is standard for most solid tumors, while LM uses histology-specific staging, such as Ann Arbor and Rai staging. The semantic rules for capturing LM-specific staging information can be used for other studies that aim to extract staging information from notes of patients with LMs. In addition, the performance of our rule-based system in extracting performance status is also comparable with the performances reported in prior studies [23,24].

Challenges of Developing cNLP Systems for LMs

Through this study, we observed several challenges to the development of high-performing cNLP systems for LMs and other rare cancers. Future efforts in developing cNLP for rare cancers should consider addressing these challenges to improve performance, alleviate medical experts’ burden in annotation, and facilitate the use of cNLP in real-world clinical settings.

First, relevant clinical information on rare cancers may be documented across many different note types, which creates challenges for cNLP systems to consistently identify all of them. Previous work often focused on specific note types such as radiology reports to simplify system development, with the assumption that certain clinical information often appears in a narrow set of notes.

Second, the characteristics of certain clinical entities make it challenging to extract using cNLP. For example, environmental exposure information was rarely documented in clinical notes in our study. Sparse documentation thus makes it difficult to identify notes that include potentially relevant information for medical experts to annotate. In addition, the documentation of environmental exposure information is highly inconsistent, with many mentions directly naming substances (eg, Agent Orange) as well as alluding to potential exposures through locations (eg, shipyards and combat sites) or deployment (eg, Vietnam or Camp Lejeune). As environmental exposure documentation has not been a routine component in clinical documentation until very recently because of the PACT Act, there are no standards for consistently documenting such information and further compiling a high-quality dataset for training cNLP models to extract them. To the best of our knowledge, this is the first study that set out to develop and use NLP to extract potential military environmental exposures in accordance with the PACT Act, despite prior studies that directly used structured data to infer such exposures [25]. In our future work, we will assess to what extent the NLP-extracted exposures overlap with those inferred from structured data and whether NLP can identify additional exposed patients that structured data misses.

Third, the heterogeneity of clinical information also raises challenges for cNLP systems to accurately identify all relevant information. For example, while our cNLP pipeline showed decent performance in identifying the primary diagnosis, it was unable to identify the myriad of secondary and differential diagnoses for patients’ comorbidities that span a wide range of diseases such as prostate cancer and bladder cancer. Therefore, we prioritized our efforts on optimizing the primary diagnosis rather than secondary and differential diagnoses, which are also underexplored in existing cNLP efforts. In our future work, we will continue to refine the cNLP pipeline to identify the various types of diagnoses from clinical notes, including optimizing for the capture of secondary and differential diagnoses.

Fourth, while LLMs such as Bidirectional Encoder Representations from Transformers and Llama have demonstrated superior performance in many cNLP tasks, they appeared to have poor transferability in our study. This may be due in part to the characteristics of clinical information that were unique to rare cancers such as LMs and how notes were composed within the VA system. A more comprehensive and in-depth evaluation of general and clinical LLMs on clinical notes for rare cancers is therefore needed to assess their performance and transferability and identify ways to adapt them to rare cancers.

Assessing Biases in Applying NLP on Clinical Notes for Rare Diseases

The results of this study suggest potential biases in cNLP performance in extracting substance use and the primary diagnosis from the notes of non-Hispanic White veterans versus non-Hispanic Black veterans. Several strategies could be used

XSL•FO
RenderX

to mitigate such potential biases. First, it may be desirable to use standardized documentation, that is, the type of substance and frequency or duration of exposure, such as "tobacco use, 3 packs per day for 50 years." Second, researchers may consider alternative sampling methods when selecting notes and patient samples for developing cNLP methods, especially when the patient population is already heavily dominated by patients with certain characteristics, such as older White adults in our patient cohort.

Clinical Impacts

The PACT Act aims to provide benefits for veterans who have been exposed to environmental toxicants that are associated with cancer diagnosis and progression, but we found that environmental exposure information is only scarcely and inconsistently documented in our study data. We observed that especially for non-Hispanic Black patients, the documentation rate is low. In addition, the ways environmental exposure information was documented also differ, with some being explicitly documented (eg, "exposure to Agent Orange") and many only alluding to exposures by documenting deployment sites and occupations that may expose veterans to toxicants. Toxic exposure screening was implemented as part of the PACT Act across VA systems nationwide [26], which could help capture environmental exposure information. Our study indicates that more consistent and comprehensive adherence to documentation of environmental exposure is needed in order to facilitate the efficient identification of eligible patients for clinical research, patient care, and benefit enrollment.

There were statistically significant differential performances in the FNs of extracting substance use information from notes for non-Hispanic White versus non-Hispanic Black patients. This may be due to the rich information and variations in documenting patients' substance use. The use of templates will help standardize how documentation occurs as well as how information is captured. This will also help improve the performance of cNLP extraction pipelines because fewer outliers will appear in the clinical documentation. Such templates will also help standardize the documentation of substance use. Templates that are autopopulated can also capture data more uniformly.

Limitations

As a preliminary effort for developing a cNLP system for LMs, our study had several limitations. By using nationwide VA EHR data, there was variability in data quality and completeness. As mentioned previously, documentation of elements such as environmental exposures did not have an established standard, resulting in inconsistent and heterogeneous documentation. Military exposure documentation was infrequent, which reflects the nuanced nature of this type of screening. However, the recently mandated screening implemented in August 2023 will improve documentation for future research and analysis. Our study only examined racial bias due to the limited number of annotated notes we had and may have overlooked other potential sources of bias such as age, gender, and geography. Finally, our data come from the national VA health care system. Despite being a single EHR system, the VA health care system spans the entire country as well as Puerto Rico, Guam, and the Philippines, and its EHR captures the heterogeneity in regional practice patterns. For our work in understanding military exposure and the association with developing LMs, it is a vertically integrated system that is unique in the patient population and prioritization of military service–connected conditions, suitable for our research objective.

Future Directions

Our future directions include improving the performance of the cNLP pipeline. To achieve this, we plan to leverage more advanced pretrained LLMs such as CancerBERT [27] and GatorTron [28] and fine-tune them on our dataset to extract the clinical entities. We will use the rule-based cNLP pipeline developed in this study to generate weak labels for fine-tuning these LLMs, without having medical experts to further annotate notes. We will also conduct a more thorough and large-scale review of the environmental exposure documentation to construct a more comprehensive terminology dictionary for identifying environmental exposures for patients with LMs. In addition, many clinical entities should be extracted in fine-grained forms (eg, substance use with frequency, amount, and status) and in relation to other information if available (eg, temporal information). Another next step is to use cNLP to identify and analyze the current documentation practices and potential biases for less common clinical entities. We will also apply cNLP-enabled analyses to all veterans with LMs in the VA CDW to assess the documentation patterns of the clinical information among different patient groups (by race, gender, branch, and socioeconomic status); provider types; and note types to identify potential biases. We will also apply the pipeline to clinical notes from health systems outside of the VA to assess its generalizability.

Another future direction is to design and implement a tool integrated into the EHR system and help clinicians improve their documentation quality and identify inconsistencies or inadequacies (eg, lack of documentation of environmental exposures) at the time of documentation.

Conclusions

In our rule-based cNLP pipeline that integrates clinical domain expertise, clinical entities such as performance status, staging, and the primary diagnosis were captured with satisfying accuracy. The primary diagnosis and substance use exhibit differential performance for non-Hispanic Black and White patients. Our future work will build upon the rule-based pipeline and leverage more advanced models to enhance the performance of extraction for substance abuse and environmental exposures, as well as ensuring that model performance is equitable across different racial groups.

Abstract

Background: Accurate staging of esophageal cancer is crucial for determining prognosis and guiding treatment strategies, but manual interpretation of radiology reports by clinicians is prone to variability and limited accuracy, resulting in reduced staging accuracy. Recent advances in large language models (LLMs) have shown promise in medical applications, but their utility in esophageal cancer staging remains underexplored.

Objective: This study aims to compare the performance of 3 locally deployed LLMs (INF-72B, Qwen2.5-72B, and LLaMA3.1-70B) and clinicians in preoperative esophageal cancer staging using free-text radiology reports.

Methods: This retrospective study included 200 patients from Shanghai Chest Hospital who underwent esophageal cancer surgery from May to December 2024. The dataset consisted of 1134 Chinese free-text radiology reports. The reference standard was derived from postoperative pathological staging. A total of 3 LLMs determined tumor classification (T1-T4), node classification (N0-N3), and overall staging (I-IV) using 3 prompting strategies (zero-shot, chain-of-thought, and a proposed interpretable reasoning [IR] method). The McNemar test and Pearson chi-square test were used for comparisons.

Results: INF-72B+IR achieved a superior overall staging accuracy of 61.5% and an F_1-score of 0.60, substantially higher than the clinicians' accuracy of 39.5% and F_1-score of 0.39 (all P<.001). Qwen2.5-72B+IR also demonstrated an advantage, achieving an overall staging accuracy of 46% and an F_1-score of 0.51, which was better than the clinicians' performance (P<.001). LLaMA3.1-70B showed no statistically significant difference in overall staging performance compared to clinicians (all P>0.5)

Conclusions: This study demonstrates that LLMs, particularly when guided by the proposed IR strategy, can accurately and reliably perform esophageal cancer staging from free-text radiology reports. This approach not only provides high-performance predictions but also offers a transparent and verifiable reasoning process, highlighting its potential as a valuable decision-support tool to augment human expertise in complex clinical diagnostic tasks.

KEYWORDS

large language model; esophageal cancer; cancer staging; tumor–node metastasis; TNM; radiology report

Introduction

Esophageal cancer is a type of malignant tumor in the digestive system and remains one of the leading causes of cancer-related death, seriously affecting human health worldwide [1-3]. Accurate preoperative staging of esophageal cancer is essential, as it directly impacts prognosis estimation and guides treatment decisions such as surgical resection, chemotherapy, or radiotherapy [4,5]. The tumor–node metastasis classification system is currently the standard for staging according to the eighth edition of the AJCC Tumor–Node Metastasis Classification of Malignant Tumors [6].

In clinical practice, preoperative staging of esophageal cancer relies predominantly on imaging modalities, with computed tomography (CT) and positron emission tomography (PET)–CT serving as the cornerstone examinations [7]. These imaging studies generate detailed radiology reports that contain crucial information about tumor characteristics, local invasion, and

XSL•FO
RenderX

metastatic spread. Clinical tumor–node metastasis (cTNM), determined from these imaging studies, is pivotal for formulating individualized treatment plans [8].

However, a major challenge is that radiology reports are usually documented in an unstructured, free-text format [9]. These narrative reports can be ambiguous, lack key details, or vary in descriptive style among radiologists. This may result in key findings being missed or misinterpreted, leading to significant discrepancies between cTNM and the gold-standard pathological tumor–node metastasis (pTNM) determined after surgery. Moreover, the complexity and variability inherent in these reports make the process of extracting structured, actionable staging information both time-consuming and prone to human error. Thus, automatic classification of esophageal cancer stage from free-text radiology reports may provide significant benefits.

Recent advances in artificial intelligence (AI), particularly large language models (LLMs), offer promising solutions for these challenges [10-14]. LLMs are capable of understanding and processing natural language, making them well-suited for extracting structured information from free-text medical documents and supporting complex reasoning tasks in medical natural language processing [15-17]. Their strengths include parsing unstructured narratives, performing multi-step reasoning, and learning from vast medical corpora, which have enabled progress in information extraction, report classification, and automated summarization in medical contexts [18,19].

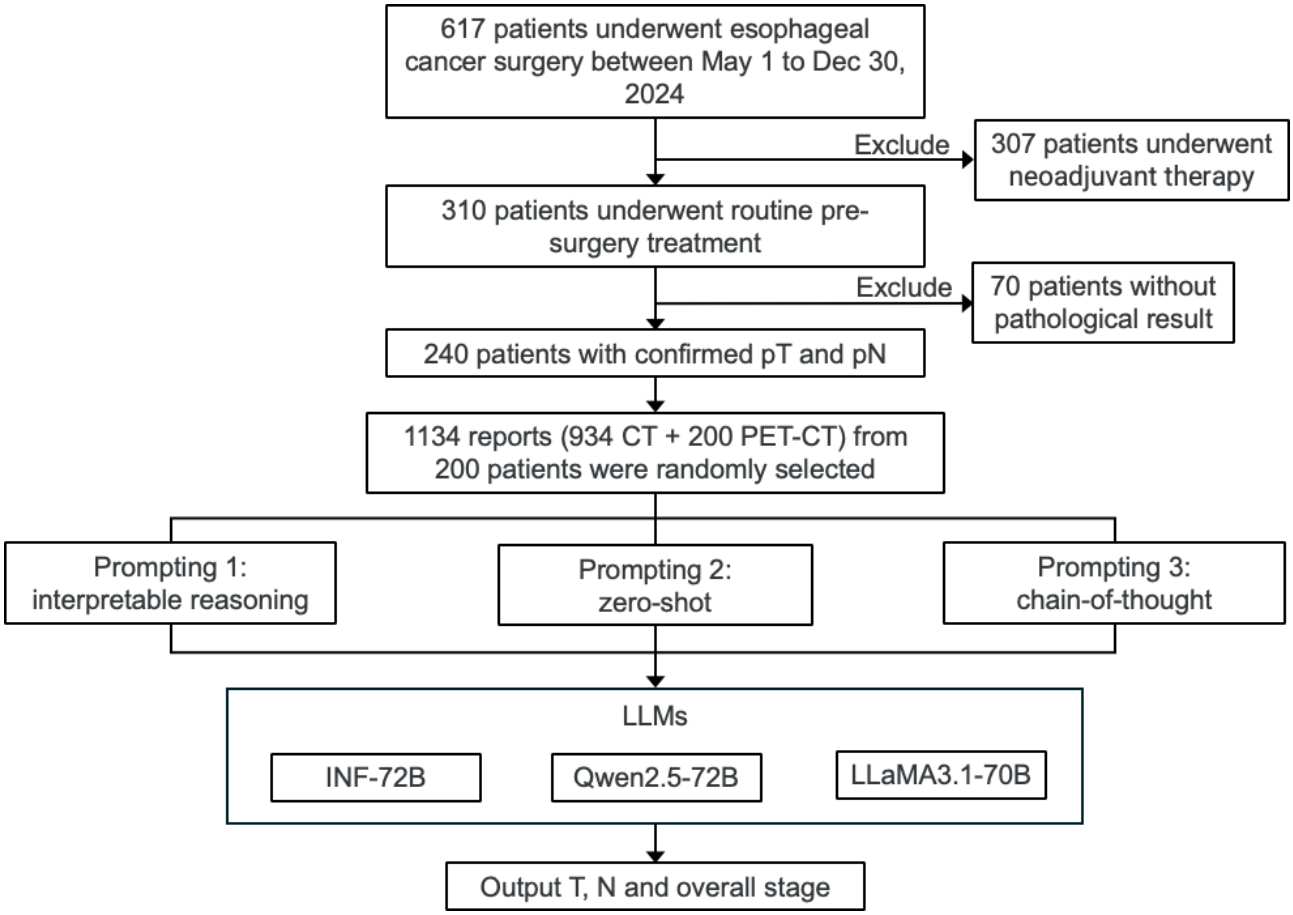
Despite these advances, research on the use of LLMs for cancer staging from radiology reports has largely focused on lung cancer, owing to the relatively straightforward criteria in imaging for that disease [20-22]. In contrast, esophageal cancer staging presents unique challenges: the anatomical complexity of the esophagus, its proximity to multiple vital structures, and the subtlety of early lymph node involvement make accurate staging from radiology reports considerably more difficult. This gap in the literature highlights the need for dedicated research into LLM applications for esophageal cancer staging.

While LLMs show great potential for medical applications, they are not without limitations. The hallucination effect, where models generate plausible but incorrect information, poses risks in health care settings where accuracy is paramount [23]. Recent studies have focused on optimizing prompting strategies and proposed approaches such as few-shot learning [24] and chain-of-thought (CoT) [25] to enhance the quality of model responses. However, as black-box models, LLMs often fail to provide transparent explanations for their outputs. This lack of explainability poses a significant challenge in gaining trust for health care applications, where a transparent decision-making process is critical.

This study aims to evaluate 3 LLMs (INF-72B, Qwen2.5-72B, and LLaMA3.1-70B) for automated esophageal cancer staging from Chinese free-text radiology reports. We introduce a novel prompting strategy called interpretable reasoning (IR) designed specifically to enhance both the accuracy and transparency of LLM-based staging decisions. By comparing LLM performance with that of clinicians, we aim to provide a foundation for future research and safe clinical translation of LLMs in cancer staging.

Methods

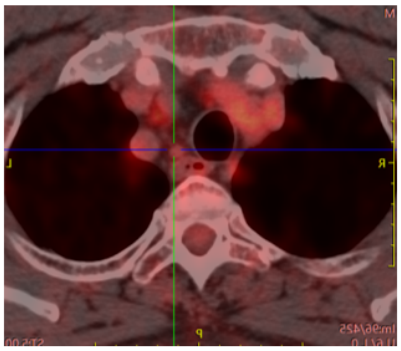
Data

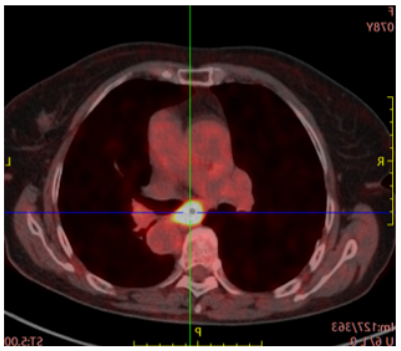


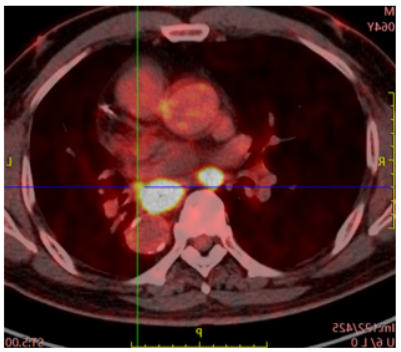
This retrospective study was conducted at Shanghai Chest Hospital with data collected from 617 patients who underwent esophageal cancer surgery between May and December 2024.

Exclusion criteria were applied systematically to ensure data quality and relevance to the study objectives. First, 307 patients who had received neoadjuvant therapy were excluded, as such treatment alters the assessment of tumor size and metastasis in radiology reports, and such patients are staged using the ycTNM staging system, which is not within the scope of the current dataset [26]. Second, 70 patients lacking pathological diagnosis were excluded.

Of these, 1134 reports (934 CT and 200 PET-CT), from 200 unique patients, were randomly selected for inclusion in the final sample. Figure 1 shows the flowchart of study design. All reports were unstructured, free-text documents (Figure 2). Each case comprised all reports from the patient's prior hospital visits, including both outpatient and inpatient records.







XSL•FO
RenderX

Figure 1. Flowchart of study design. CT: computed tomography; LLM: large language model; PET: positron emission tomography; pN: pathological node; pT: pathological tumor.

XSL•FO
RenderX

Figure 2. Here are 3 cases from the dataset, accompanied by the key information extracted from the free-text reports. To better illustrate the correlation between the reports and imaging, the corresponding PET-CT images are also presented. The staging of the 3 cases is T1N0 (Stage I), T2N0 (Stage II), and T3N0 (Stage III), respectively. CA: cancer; CT: computed tomography; FDG: fluorodeoxyglucose; JES: Japan Esophageal Society; PET: positron emission tomography; SUVmax: maximum standardized uptake value.

PET-CT Image	PET-CT Report	Cancer Stage
	The wall of the middle and lower thoracic esophagus was slightly thickened, with a longitudinal diameter of about 46 mm, increased contrast agent uptake, and SUVmax of about 4.7. JES classification (104L, 106recR, 106recL, 106pre, 106tbL, 107, 113, 109), multiple lymph nodes in the liver and stomach space were displayed or enlarged, and some FDG metabolism was increased.	**T1 N0 Stage I**
	The wall of the middle thoracic esophagus was thickened, the lumen was narrowed, the affected area was about 4.3*2.5*1.9cm, the contrast agent uptake was abnormally increased, and the SUVmax was about 20.5. The esophageal middle thoracic mass and increased FDG metabolism were consistent with the manifestation of esophageal CA. The JES zoning (106recL, 106recR) and the hepatogastric interstitial lymph nodes showed increased FDG metabolism.	**T2 N0 Stage II**
	The local wall thickening and lumen narrowing of the middle thoracic esophagus were about 37*26*48mm, and the imaging agent uptake was abnormally increased, with SUVmax of about 18.8. The local wall thickening and increased FDG metabolism of the middle thoracic esophagus were consistent with the manifestation of malignant lesions. The lymph nodes in the JES division (106recR, 107, 108 areas) were slightly larger or visible, and the FDG metabolism was increased.	**T3 N1 Stage III**

Reference Standard

The reference standard for this study was the pTNM staging information obtained from each patient's postoperative pathological report. This staging was determined by pathologists and documented within the structured pathological reporting system following surgical resection and histopathological examination.

For comparison purposes, we collected each patient's cTNM from the admission notes completed by the attending physician prior to surgery, representing the clinician's preoperative assessment based on available imaging reports and clinical data. After data collection, the cTNM information was reviewed by 3 attending thoracic surgeons, each with four years of clinical experience. The reviewers were not informed of the postoperative pathological staging, ensuring that their judgments relied solely on the preoperative radiology reports.

Given that our dataset consisted exclusively of surgical candidates, distant metastasis (M1) was absent, as patients with metastatic disease would not have undergone curative surgery. Therefore, our evaluation focused on tumor classification (T1-T4), node classification (N0-N3), and overall stage groups (I-IV) as determined by the combination of tumor and node categories.

Large Language Model

The LLMs were selected for evaluation based on their availability, performance benchmarks, and number of parameters. INF-72B is a homemade LLM developed by the INF team that combines the pattern recognition capabilities of neural networks with symbolic reasoning, offering advantages for structured medical tasks [27].

Qwen2.5-72B is an open-source LLM, exhibiting strong performance in Chinese language tasks [28]. LLaMA3.1-70B

XSL•FO
RenderX

is one of Meta's foundational model series, selected for its general-purpose capabilities and widespread adoption in the research community [29]. Both are open-source models, characterized by relatively large parameter sizes and strong performance, and have been the subject of substantial research in medical text natural language processing [30,31].

All models were deployed locally within the hospital's secure computing environment using 8 NVIDIA A30 GPUs. This local deployment was essential to ensure patient data privacy and comply with institutional data governance policies. Model inference was performed using greedy decoding (temperature=0) to maximize determinism.

Prompting Strategy

In this study, we propose a prompting strategy called IR, in which the model is instructed not only to provide its staging decision but also to output the underlying reasoning and explicitly cite relevant excerpts from the original radiology report. This design aims to improve transparency, facilitate verification by clinicians, and reduce the risk of unsupported or hallucinatory outputs.

Specifically, the model's cited excerpts from the radiology report were automatically checked against the original input text to ensure exact matches. If any cited text was not found in the original report, the output was rejected, and the model was prompted to regenerate its response. In addition, the model was instructed to perform internal reasoning before producing the final prediction and explanation, which encourages the use of evidence grounded in the report and further reduces the likelihood of hallucinations. In addition, the esophageal cancer staging rules were incorporated into the prompt in a structured format according to the AJCC Eighth Edition. The prompt template is presented in Figure 3.

A total of 2 additional prompting strategies, zero-shot (ZS) and CoT, were implemented for comparison with the proposed method. For ZS, the LLM was provided with the reports and instructions to directly return the predicted cancer stage. For CoT, the LLM was instructed to first "think step by step" to retrieve the reasoning and use it as context for predicting the cancer stage.

```
## Task
Assume you are an oncologist. Based on all the patient's CT and PET-CT reports from the past three years, determine the esophageal cancer TN classification according to the provided criteria.
The possible values for T are T1, T2, T3, T4. For N are N0, N1, N2, N3.

### Staging Guidelines
| Category  |  Description                                                                  |
|--------|-------------------------------------------------------------------------------|
| T1   | Tumor invades lamina propria or muscularis mucosae or submucosa |
| T2   | Tumor invades muscularis propria |
| T3   | Tumor invades the adventitia |
| T4   | Tumor invades adjacent structures (pleura, pericardium, azygos vein, diaphragm, pleura, aorta, vertebral body, trachea, etc.) |
| N0   | No regional lymph node metastasis |
| N1   | 1-2 regional lymph node metastases |
| N2   | 3-6 regional lymph node metastases |
| N3   | 7 or more regional lymph node metastases |

Reports: {reports}

Output the staging results and reasons in the following format:
{
  "T": {
    "grade": "T1",
    "explanation": {
      "grade_reason": "",  # Briefly explain the reason for this staging
      "report_text": ["", ""]  # Provide report excerpts used for this grading as a Python list; if multiple reports are involved, each report excerpt occupies one list element
    }
  },
  "N": {
    "grade": "N0",
    "explanation": {
      "grade_reason": "",  # Briefly explain the reason for this staging
      "report_text": ["", ""]  # Provide report excerpts used for this grading as a Python list; if multiple reports are involved, each report excerpt occupies one list element
    }
  }
}
Only output the answer in JSON format, without any additional content.
```

Statistical Analysis

For each LLM and clinical stage, the tumor category, node category, and overall stage groups were classified as correct if matching the reference-standard assignment (pathological staging). To measure the performance of cancer staging, accuracy, precision, recall, and F_1-score were used as key evaluation metrics. These metrics were calculated individually for each component (eg, T1-T4, N0-N3, and I-IV). Corresponding 95% CIs were derived using the Wilson method. Comparisons were performed using McNemar and Pearson tests. *P* values were 2-sided and considered statistically significant when less than .05.·

Ethical Considerations

This study was approved by the Ethics Committee of Shanghai Chest Hospital (IS25024). As this was a retrospective study, the Ethics Committee of Shanghai Chest Hospital waived the requirement for participants or their legal guardians or next of kin to provide written informed consent.

Results

Overview

This section presents the research findings. First, we evaluated the performance of 3 LLMs in the clinical staging of esophageal cancer and compared their results with clinicians. Next, we further analyzed the outcomes in terms of clinical management categories. Finally, we compared the runtime consumption of the 3 models.

Characteristics of Patients and Radiology Reports

A total of 200 patients (mean age 65.2, SD 7.4 years) comprising 145 males and 55 females. Within this group, a total of 1134 radiology reports (934 CT and 200 PET-CT) were collected.

XSL•FO
RenderX

The distribution of pathological tumors, pathological nodes, and overall stage groups is listed in Table 1.

Table . Characteristics of patients and radiology reports.

Categories	Values (N=200)
Patient information	
Gender, n (%)	
Male	145 (72.5)
Female	55 (27.5)
Age (years), mean (SD)	65.2 (7.4)
Report quantity, n (%)	
CT[a]	934 (82.4)

Performance of Large Language Models and Clinicians in Esophageal Cancer Staging

Table 2 shows the accuracies of the LLMs and clinicians in esophageal cancer staging. The clinicians achieved accuracy of 44.5%, 42%, and 39.5% for tumor classification, node classification, and overall staging, respectively. Among LLMs, INF-72B demonstrated the highest overall performance. Specifically, INF-72B+IR achieved the best accuracy, significantly outperforming the clinicians (68%, 65.5%, and 61.5%, respectively; $P<.001$). Qwen2.5-72B+IR achieved its best accuracy of 46% in overall staging, better than the clinician (46% vs 39.5%, $P<.001$). Although LLaMA3.1-70B+IR achieved higher accuracy than clinicians in tumor classification (55% vs 44.5%, $P<.001$), there was no statistically significant difference between the 2 in overall staging performance (39% vs 39.5%, $P=.99$).

[a]*P* values represent comparisons with the accuracies of clinicians.

[b]Not available.

Table 3 shows the performance of clinicians and LLMs using different prompting for determining overall stage groups. INF-72B+IR achieved the best performance, with the F_1-score of 0.62, significantly higher than clinician's 0.43 (P<.001). INF-72B+ZS and INF-72B+CoT also performed better than clinicians (0.56, 0.58, P<.001). Qwen2.5-72B performed well under CoT and IR, significantly better than clinicians (0.50, 0.51, P<.001). LLaMA3.1-70B showed no statistically significant differences from clinicians (0.42, 0.43, 0.44, all P>0.5). Tables S1 and S2 in Multimedia Appendix 1 present the precision, recall, and F_1-score of the LLMs and clinicians for determining tumor category and node category, respectively.

Table . Performance of clinicians and large language models using different prompting strategies in overall staging. Values in parentheses represent the 95% CI. The *P* values represent comparisons with the F_1-scores of clinicians.

Evaluator	Precision, (95% CI)	Recall, (95% CI)	F_1-score, (95% CI)	*P* value
Clinicians	0.45 (0.43-0.44)	0.40 (0.40-0.41)	0.43 (0.42-0.45)	—
INF-72B+ZS	0.57 (0.55-0.58)	0.52 (0.50-0.53)	0.56 (0.54-0.57)	<.001
INF-72B+CoT	0.59 (0.56-0.60)	0.54 (0.50-0.58)	0.58 (0.55-0.60)	<.001
INF-72B+IR	0.64 (0.61-0.65)	0.59 (0.58-0.61)	0.62 (0.60-0.64)	<.001
Qwen2.5-72B+ZS	0.46 (0.44-0.47)	0.41 (0.36-0.46)	0.44 (0.40-0.46)	.87
Qwen2.5-72B+CoT	0.51 (0.48-0.52)	0.49 (0.48-0.49)	0.50 (0.49-0.50)	<.001
Qwen2.5-72B+IR	0.52 (0.50-0.53)	0.50 (0.49-0.52)	0.51 (0.49-0.52)	<.001
LLaMA3.1-70B+ZS	0.54 (0.51-0.57)	0.36 (0.34-0.37)	0.42 (0.40-0.43)	.97
LLaMA3.1-70B+CoT	0.50 (0.49-0.51)	0.40 (0.40-0.41)	0.43 (0.41-0.45)	.99
LLaMA3.1-70B+IR	0.55 (0.51-0.57)	0.41 (0.38-0.43)	0.44 (0.42-0.45)	.89

Stratification by Clinical Management Categories

Table 4 summarizes the performance of LLMs using IR and clinicians in terms of clinical management categories. A total of 46 reports indicated early esophageal cancer, 132 indicated locally advanced esophageal cancer, and 22 indicated advanced esophageal cancer. For reports indicating early esophageal cancer, the proportion that was overstaged was 82.6% for clinicians versus 28.3%, 60.9%, and 82.6% for INF-72B, Qwen2.5-72B, and LLaMA3.1-70B using IR. For reports indicating locally advanced cancer, the proportion that was understaged was 2.3% for clinicians versus 9.1%, 3.8%, and 0% for the 3 LLMs, and the proportion that was overstaged was 6.8% for clinicians versus 3.0%, 2.3%, and 5.3% for the 3 LLMs. For reports indicating advanced cancer, the proportion that was understaged was 90.9% for clinicians versus 63.6%, 100%, and 77.3% for the 3 LLMs.

XSL•FO
RenderX

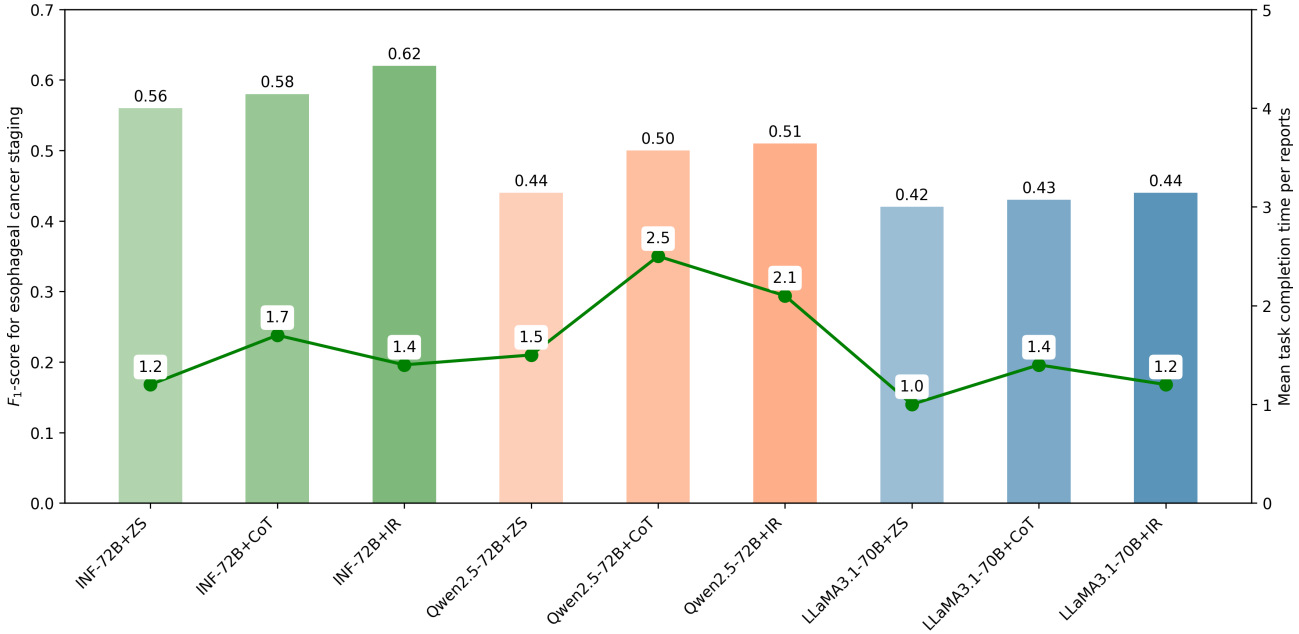

Table . Staging by large language models and clinicians, stratified by clinical management categories.

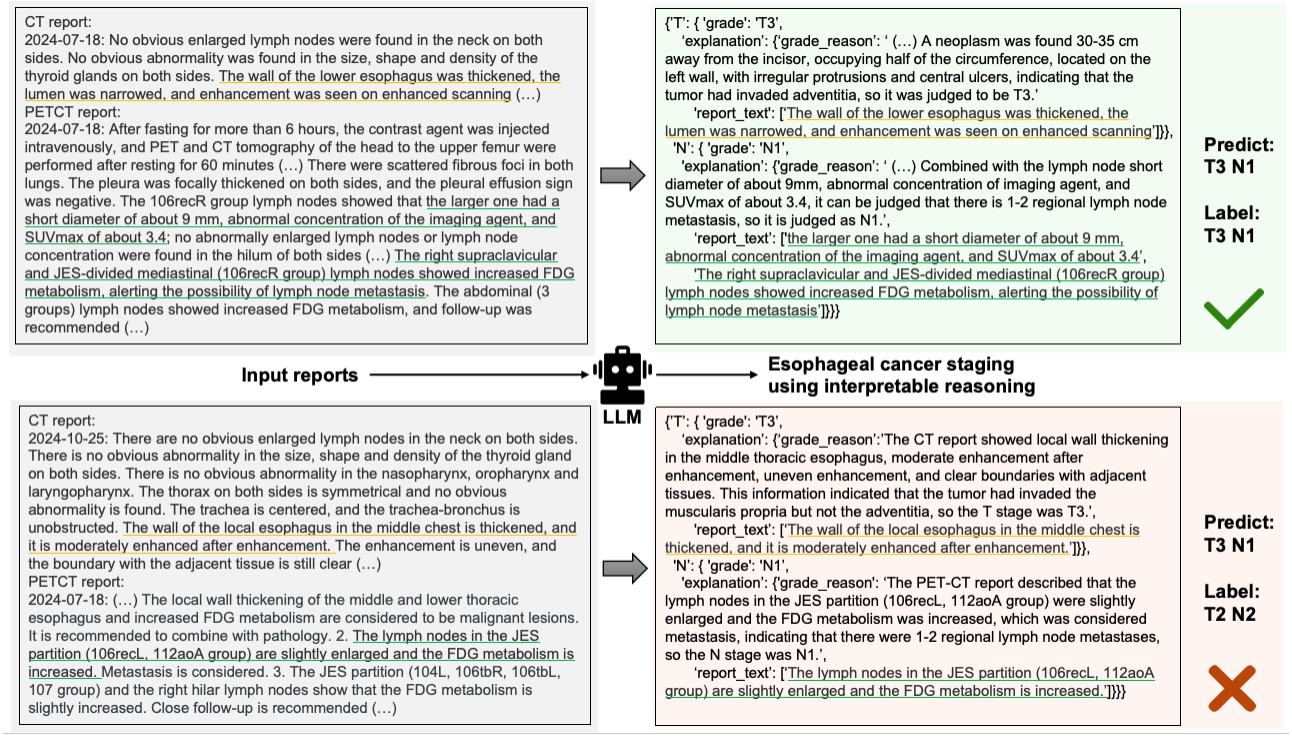
Categories	Early esophageal cancer (Stage I; n=46)		Locally advanced esophageal cancer (Stage II and III; n=132)			Advanced esophageal cancer (Stage IV; n=22)	
Evaluator	Correct	Overstaged	Correct	Overstaged	Understaged	Correct	Understaged
Clinicians	8 (17.4)	38 (82.6)	120 (90.9)	9 (6.8)	3 (2.3)	2 (9.1)	20 (90.9)
INF-72B+IR	33 (71.7)	13 (28.3)	116 (87.9)	4 (3)	12 (9.1)	8 (36.4)	14 (63.6)
Qwen2.5-72B+IR	18 (39.1)	28 (60.9)	124 (93.9)	3 (2.3)	5 (3.8)	0 (0)	22 (100)
LLaMA3.1-70B+IR	8 (17.4)	38 (82.6)	125 (94.7)	7 (5.3)	0 (0)	5 (22.7)	17 (77.3)

Task Completion Times

The mean task completion times per report were 1.2 (SD 0.56), 1.7 (SD 0.58), and 1.4 (SD 0.62) seconds for INF-72B with different prompting strategies, respectively; 1.5 (SD 0.44), 2.5 (SD 0.50), and 2.1 (SD 0.51) seconds for Qwen2.5-72B, respectively; and 1 (SD 0.42), 1.4 (SD 0.43), and 1.2 (SD 0.44) seconds for LLaMA3.1-70B, respectively. Figure 4 shows the variation across LLMs in overall staging F_1-score and mean task completion time per report.

Figure 4. The graph shows comparisons of F_1-score for esophageal cancer staging and mean task completion time per report for 3 large language models (INF-72B, Qwen2.5-72B, and LLaMA3.1-70B) with different prompting strategies (ZS, CoT, and IR). The green line and its associated values indicate mean task completion time in seconds per report for each evaluator. CoT: chain-of-thought; IR: interpretable reasoning; ZS: zero-shot.



Examples of Esophageal Cancer Staging Using Large Language Model + Interpretable Reasoning

Figure 5 shows 2 examples of esophageal cancer staging using LLM with IR, including 1 correct case and 1 incorrect case. Multimedia Appendix 1 presents the complete input and output of the model, including the prompts and the radiology reports. Appendix S2 and S3 in Multimedia Appendix 1 show another 2 error examples for tumor classifications and node classifications, including the original reports and the model's output.

XSL•FO
RenderX

Figure 5. A total of 2 example cases to show how LLMs read the radiology reports and provide cancer stage using interpretable reasoning. The yellow and green underlined texts represent the classification basis of the large language model cited from the computed tomography reports and positron emission tomography-computed tomography reports, respectively. In the first example (top row), the reference standard was T3N1. The large language model extracted relevant information from the reports and gave the correct stage. In the second example (bottom row), the reference standard was T3N1. The large language model extracted incomplete information from the reports, resulting in an incorrect stage (T2N2). CT: computed tomography; FDG: fluorodeoxyglucose; JES: Japan Esophageal Society; LLM: large language model; PET: positron emission tomography.

Discussion

Principal Findings

This study evaluated 3 LLMs for preoperative esophageal cancer staging from Chinese free-text radiology reports, comparing their performance with that of clinicians. Our proposed IR prompting strategy enabled INF-72B to achieve significantly higher accuracy and F_1-scores than clinicians in tumor classification, node classification, and overall staging. Qwen2.5-72B also demonstrated improvements in overall staging under IR strategies, while LLaMA3.1-70B showed no consistent advantage over clinicians.

Recent studies have demonstrated the potential applications of LLMs in medical data analysis. In the context of radiology reports, most research has focused on using LLMs to convert free-text radiology reports into structured formats [11,18]. LLMs have been used to extract cancer stage from pathology reports, which is a relatively straightforward task due to the clearer descriptions of tumors in pathology reports [32-34]. But these approaches do not aid in formulating preoperative treatment plans for patients. Thus, this study highlights the potential of LLMs for preoperative esophageal cancer staging from radiology reports. The findings support the effective use of LLMs in assisting clinicians in real-world clinical tasks.

In this study, the IR prompting strategy played a pivotal role in enabling LLMs to clearly articulate the reasoning process behind tumor and node classification. IR guided the models to provide not only their answers but also the supporting rationale, citing key information from the original reports—such as extracting tumor status and the number of lymph nodes. This approach made the model outputs more transparent and reliable, reduced hallucinations, and highlighted the advantages of IR in complex clinical decision-making tasks such as cancer staging. Moreover, when the model produced an incorrect answer, the reasoning provided allowed for analysis of the underlying causes of the error. Such a feature is particularly valuable in the highly rigorous context of medical applications.

Error Analysis

The predictive performance of all models for stage IV esophageal cancer was suboptimal, which may be attributable to multiple factors. First, T4 involves tumor invasion of adjacent critical structures (eg, major vessels, trachea, pericardium), where the boundaries of invasion can be difficult to delineate on imaging. Limitations in image resolution and acquisition techniques may further introduce diagnostic uncertainty, resulting in insufficient information in the radiology reports to support a T4 determination. Second, N3 is defined as distant or multiregional lymph node metastases. However, small metastatic foci or atypical lymph node morphology can be difficult to detect on conventional imaging, leading to false negatives. In addition, according to National Comprehensive Cancer Network guidelines, definitive concurrent chemoradiotherapy is recommended as the initial treatment for stage IV cases. Since this study included only patients who underwent surgery, the proportion of stage IV cases was relatively low, which limited further analysis of the contributing factors.

XSL•FO
RenderX

The models exhibited a high frequency of overstaging in cases of stage I esophageal cancer. In instances where T1 was misclassified as T2 or T3, a common pattern was LLMs often relied on report descriptions such as "localized irregular thickening of the esophageal wall with moderate, heterogeneous enhancement" as the primary basis for staging, while overlooking more critical information such as "clear demarcation from adjacent tissues" or "no mention of tumor invasion into the muscularis propria or adventitia." Notably, INF-72B demonstrated markedly better performance in identifying stage I esophageal cancer compared with the other 2 LLMs and the clinicians, suggesting that a model's reasoning capability can substantially influence the accuracy of esophageal cancer staging.

Errors in node classification were attributable to 2 primary causes. First, PET-CT reports sometimes lacked sufficient information to reconcile with pathological findings. Although the models correctly extracted the number of lymph node metastases documented in the PET-CT report, those counts did not always match the numbers reported in the pathology. Second, models sometimes misidentified the anatomic nodal regions when summing metastatic nodes, which led to incorrect node staging. For example, a PET-CT report might list the JES regions (104R, 104L, 106tbR, 107, 109L, 112ao, 113), whereas the model's cited evidence mentioned only "104R, 104L, 106tbR," omitting the other stations and thus producing a misclassification.

Operational and Clinical Implications

INF-72B+IR demonstrated superior performance compared with clinicians in identifying both early-stage and advanced-stage esophageal cancer. This has several potential clinical benefits. First, improved recognition of early-stage disease (eg, T1N0) can facilitate timely initiation of curative-intent interventions such as endoscopic mucosal resection, endoscopic submucosal dissection, or minimally invasive esophagectomy, thereby reducing surgical morbidity and improving long-term outcomes [4]. Early and accurate identification may also prevent unnecessary chemoradiotherapy or extensive surgical procedures, reducing treatment-related complications and health care costs. Conversely, precise identification of advanced disease (eg, T4 or N3) allows for prompt initiation of multimodal treatment strategies—including concurrent chemoradiotherapy, immunotherapy, and palliative interventions—while avoiding futile surgical attempts. By reducing the risk of misclassification, the model can help ensure that patients receive stage-appropriate treatment in a timely manner.

In addition, the model processes radiology reports and generates staging predictions within seconds. This capability can improve clinical workflow efficiency by enabling a "screen-then-review" approach, in which the model prescreens cases and flags high-risk patients for expedited review by clinicians. Such an approach is particularly valuable in high-volume oncology centers, as well as in resource-limited settings. Integrating the model into multidisciplinary team discussions could further streamline decision-making, as staging information would be immediately available without requiring additional report interpretation during the meeting.

Importantly, the implementation of this model should be viewed not as a replacement for clinicians, but as an intelligent decision-support tool. By augmenting human expertise with automated, high-accuracy staging predictions, it has the potential to enhance diagnostic accuracy, reduce inter-observer variability, and optimize patient management across the entire care pathway.

Ethical Issues in the Use of Large Language Models in Health Care

The first concern is privacy and data security. Medical information is inherently sensitive, requiring robust protection measures. In this study, all models were deployed locally within the hospital's secure computing environment to prevent data exposure. Future implementation must ensure strong network security, compliance with regulations such as Health Insurance Portability and Accountability Act (HIPAA) and General Data Protection Regulation (GDPR), and minimal data exposure during model training and deployment. Working within these legal and ethical parameters is crucial for maintaining the credibility and trustworthiness of AI applications in health care.

In addition, the emphasis on explainable artificial intelligence methods underscores the importance of transparency to build trust among health care providers and ensure the interpretability of AI-generated outputs [35]. Building trust in AI systems requires explainable outputs and clear accountability structures. Our IR approach addresses this by providing explicit rationales for staging decisions, allowing clinicians to verify and understand model predictions. However, ongoing assessment and performance monitoring are essential for long-term accountability. Regular audits, error analysis, and feedback mechanisms must be established to maintain trustworthiness.

Another important factor is compliance with regulations. The integration of AI in health care must align with regional and international standards. This requires comprehensive documentation of model training, validation, and clinical workflow integration processes. Clear, understandable documentation enables health care providers, patients, and regulators to evaluate the technology's ethical and legal sustainability. Our study represents an initial evaluation phase. Prospective clinical trials and regulatory approval would be necessary before deployment.

To comprehensively address these ethical considerations, ongoing assessment, open reporting, and collaboration between AI developers, health care providers, and regulators are essential. While our study demonstrates technical feasibility, the path to clinical deployment must prioritize patient rights, ensure equitable care delivery, and maintain the highest ethical standards. Only through such careful consideration can we realize the benefits of AI in health care while safeguarding the fundamental principles of medical ethics.

Limitations

This study has several limitations that should be acknowledged. First, the most significant limitation of this study is the imbalance in the dataset. Advanced esophageal cancer cases,

XSL•FO
RenderX

particularly those with T4 or N3 staging, are underrepresented because such patients often do not undergo surgical resection and thus lack postoperative pathological confirmation to serve as a reference label. This constraint prevented us from fully assessing the model's performance in predicting advanced cancer stage. In addition, the dataset size was relatively small, which not only limits the statistical power of our findings but also precludes the possibility of performing finetuning experiments to further optimize the model.

Second, the preoperative cancer staging in this work was derived exclusively from radiology reports, with pathological pTNM staging used as the reference standard. This approach assumes that radiology report–based classification can achieve equivalence to pTNM staging. However, radiology reports may not always contain sufficient detail or clarity to support an exact stage determination. The potential discrepancy between radiological descriptions and pathological findings could have contributed to misclassification.

Another limitation has to do with the model's generalization. The dataset was obtained from a single medical center. As a result, the linguistic style, terminology usage, and reporting conventions represented in the dataset may not fully capture the diversity of radiology reports in other hospitals, regions, or countries. This limits the immediate generalizability of the model, and further validation using multi-center, multi-national datasets is required to ensure robustness across different clinical and cultural contexts.

Future Work

Future research should focus on addressing these limitations to improve both the accuracy and generalizability of the proposed approach. Multi-center collaborations will be essential to collect a larger and more diverse dataset, particularly including advanced-stage cases. For patients who do not undergo surgical resection, alternative labeling strategies—such as consensus annotations by multiple radiologists or incorporation of longitudinal clinical follow-up data—could be explored to approximate reliable reference standards. Increasing the dataset size would also enable supervised fine-tuning of the model, potentially yielding further performance gains over the current ZS or prompt–based approach.

Moreover, integrating structured imaging-derived features with the unstructured radiology text may help bridge the gap between radiological descriptions and pathological staging, improving classification consistency. Finally, future validation should be conducted on datasets from different institutions, regions, and languages to ensure robustness across diverse clinical settings, thereby paving the way for practical integration of the model into routine multidisciplinary workflows. In addition to retrospective validation, prospective evaluation is essential before clinical deployment. We plan to integrate the proposed model into the hospital's information system, enabling automatic generation of stage recommendations when a patient is admitted and diagnosed with esophageal cancer. Selected clinicians will be invited to participate in a controlled pilot study to assess the model's impact on clinical decision-making, diagnostic efficiency, and inter-observer agreement. All such testing will strictly comply with institutional review board (IRB) and ethical requirements, ensuring that patient safety and data privacy remain paramount.

Conclusions

This study proposes an effective LLM-based approach for esophageal cancer staging. Through comparison with clinicians, INF-72B+IR demonstrated higher accuracy and F_1-scores in cancer staging, highlighting its potential as an assistive tool in clinical practice. These results suggest that LLM-based methods can serve as reliable decision-support systems, complementing human expertise and potentially improving the consistency and efficiency of oncologic care. Future work will prioritize expanding the dataset, enhancing multimodal integration of imaging and text data, and validating the model across diverse clinical settings through prospective studies. Beyond esophageal cancer, the proposed framework could be extended to staging and diagnosis in other malignancies, contributing to the broader advancement of intelligent health care systems.

Abstract

Background: The disease burden of breast cancer is increasing in China. Guiding people to obtain accurate information on breast cancer and improving the public's health literacy are crucial for the early detection and timely treatment of breast cancer. Large language model (LLM) is a currently popular source of health information. However, the accuracy and practicality of the breast cancer–related information provided by LLMs have not yet been evaluated.

Objective: This study aims to evaluate and compare the accuracy, practicality, and generalization-specificity of responses to breast cancer–related questions from two LLMs, ChatGPT and ERNIE Bot (EB).

Methods: The questions asked to the LLMs consisted of a patient questionnaire and an expert questionnaire, each containing 15 questions. ChatGPT was queried in both Chinese and English, recorded as ChatGPT-Chinese (ChatGPT-C) and ChatGPT-English (ChatGPT-E) respectively, while EB was queried in Chinese. The accuracy, practicality, and generalization-specificity of each inquiry's responses were rated by a breast cancer multidisciplinary treatment team using Likert scales.

Results: Overall, for both the patient and expert questionnaire, the accuracy and practicality of responses from ChatGPT-E were significantly higher than those from ChatGPT-C and EB (all *Ps*<.001). However, the responses from all LLMs are relatively generalized, leading to lower accuracy and practicality for the expert questionnaire compared to the patient questionnaire. Additionally, there were issues such as the lack of supporting evidence and potential ethical risks in the responses of LLMs.

Conclusions: Currently, compared to other LLMs, ChatGPT-E has demonstrated greater potential for application in educating Chinese patients with breast cancer, and may serve as an effective tool for them to obtain health information. However, for breast cancer specialists, these LLMs are not yet suitable for assisting in clinical diagnosis or treatment activities. Additionally, data security, ethical, and legal risks associated with using LLMs in clinical practice cannot be ignored. In the future, further research is needed to determine the true efficacy of LLMs in clinical scenarios related to breast cancer in China.

KEYWORDS

large language models; breast cancer; health education; cross-sectional study

Introduction

Breast cancer has become the most common malignant tumor globally, with an estimated 11.7% of all new cancer cases in 2020 [1]. The incidence of breast cancer has been rising in China, with 420,000 Chinese women diagnosed in 2020, accounting for 18% of global cases [2]. Breast cancer also contributes significantly to cancer-related deaths; however, early detection and timely treatment play a significant role in reducing its mortality rate [3-5]. Providing health education through appropriate channels and disseminating accurate medical health information to the public can help improve public awareness of breast cancer, thereby alleviating the burden of breast cancer in China. Currently, the internet is the primary source for people to obtain health information. Recent studies showed that 55% of Europeans aged 16‐74 years seek health-related information online, while in mainland China, nearly 79% of the population searches for health information on the internet [6,7]. However,

XSL•FO
RenderX

the quality of online health information varies considerably, and inaccurate or even erroneous health information may lead to patients making inappropriate medical decisions, posing a threat to public health [8-10]. Large language model (LLM) is a type of chatbot that combines artificial intelligence with natural language processing, are trained on massive text data [11]. ChatGPT, developed by OpenAI, has garnered global attention since its release and been applied across multiple fields. ERNIE Bot (EB; Chinese name: Wenxin-Yiyan), developed by Baidu, benefits from Baidu's strong influence in artificial intelligence and has achieved significant popularity and a user base in the Chinese market. These tools have recently become widely popular and demonstrated significant potential in the medical field [12]. Studies have shown that ChatGPT has greater potential for patient education in breast reconstruction and diabetes self-management, while also being able to accurately answer some cancer-related questions [11,13,14]. However, some scholars have questioned the accuracy and practicality of the medical health information provided by ChatGPT [12]. Currently, there is a lack of studies evaluating the educational potential of ChatGPT and EB—two of the most commonly used LLMs in China—among Chinese patients with breast cancer and their utility for Chinese breast cancer physicians. To address this gap, this study assesses whether these LLMs can serve as educational tools for Chinese patients with breast cancer and clinical assistance tools for Chinese breast cancer specialists by comparing the accuracy and reliability of responses to breast cancer–related questions between ChatGPT and EB.

Methods

Questionnaire Design and Data Collection

The questions asked to LLMs consisted of a patient questionnaire and an expert questionnaire, each containing 15 questions and covering aspects such as the diagnosis, treatment, prognosis, and follow-up of breast cancer. The patient questionnaire was derived by distributing a questionnaire to patients with breast cancer to investigate their most important concerns (Textbox 1). The expert questionnaire was summarized by two experienced breast surgeons, based on the National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines in Oncology for breast cancer and the International Consensus Guidelines for advanced breast cancer (Textbox 2) [15,16]. On January 15, 2024, all questions were input into ChatGPT (version 4.0) and EB (version 4.0). Each input was independently entered using the "new chat" function and inputted twice to detect its repeatability. To optimize the responses of the LLMs, prompt engineering was applied with the same lead-in statement: "Now that you are a breast cancer specialist, please answer the following questions," which was input into the LLMs along with each question. As ChatGPT was developed in the United States, we queried ChatGPT in both Chinese and English, denoted as ChatGPT-Chinese (ChatGPT-C) and ChatGPT-English (ChatGPT-E), respectively, and the EB, developed in China, was queried in Chinese only. The responses from ChatGPT and EB were recorded using Microsoft Excel (Multimedia Appendix 1).

Textbox 1. Specific contents of patient questionnaire.

Patient Questionnaire

1. Is breast cancer hereditary, and will it have an impact on my descendants?
2. What impact does the staging of breast cancer have on treatment and prognosis?
3. What are the treatment methods for breast cancer, and which one should I choose?
4. What are the various surgical treatment methods for breast cancer, and how do they each impact the appearance of the breast?
5. What is the total cost of treating breast cancer in China?
6. What aspects are included in the postoperative rehabilitation training for breast cancer, and what benefits does it bring to rehabilitation
7. Is breastfeeding possible during breast cancer treatment?
8. Why do I need systemic treatment (such as chemotherapy, endocrine therapy, or targeted therapy) after breast cancer surgery?
9. What are the adverse reactions of drugs used in breast cancer treatment?
10. How do I manage psychological and emotional health issues during the treatment of breast cancer?
11. What lifestyles contribute to the recovery of breast cancer patients?
12. What daily care is required for a subcutaneously implanted infusion port?
13. Can breast cancer patients have normal fertility after discharge?
14. What is the risk of recurrence and the corresponding monitoring methods after breast cancer treatment?
15. If a breast cancer patient has other chronic illnesses or new health issues that need to be addressed, how should these issues be coordinated with the treatment of breast cancer?

Textbox 2. Specific contents of expert questionnaire.

Expert Questionnaire

1. What are the screening methods for breast cancer?
2. What imaging and biomarkers will you use to assist in the preoperative diagnosis of breast cancer?
3. What are the requirements for the surgical margins in breast-conserving surgery for ductal carcinoma in situ?
4. For cN1 breast cancer patients who have converted to cN0 after neoadjuvant therapy, what are the requirements for sentinel lymph node biopsy at this stage?
5. What surgical methods do you know for stage I breast reconstruction?
6. What is the strategy for adjuvant chemotherapy in early-stage triple-negative breast cancer?
7. For early-stage high-risk breast cancer patients with strongly positive hormone receptors, which adjuvant endocrine therapy would you recommend?
8. What are the different classes of drugs for anti-HER2 therapy?
9. What is the first-line treatment of choice for stage IV or recurrent metastatic HR-positive/HER2-negative breast cancer?
10. What are the conditions for exemption from radiotherapy after breast-conserving surgery
11. What are the common regimens for neoadjuvant therapy in triple-negative breast cancer?
12. What are your basic principles for the treatment of metastatic breast cancer?
13. What are your recommendations for the management of bone health in patients during adjuvant endocrine therapy?
14. For young female breast cancer patients with HR-positive tumors who express a desire for fertility, what considerations do you have in the treatment plan?
15. How should long-term follow-up and monitoring be conducted for breast cancer patients?

Response Assessment

The breast cancer multidisciplinary treatment team scored the accuracy, practicality, and generalization-specificity of each response using a Likert scale, with the poorer of the two responses being included in the final score if the responses were inconsistent. The team consisted of 13 members, including 7 breast cancer specialists, 2 imaging specialists, 2 pathology specialists, and 2 nursing specialists. The Likert scale is a hierarchical scale, originally developed by Likert and has been used extensively in several research studies [17,18]. Accuracy was divided into 6 levels from 1 to 6, with higher scores indicating better accuracy (Table 1). Practicality was divided into 4 levels from 1 to 4, with higher scores indicating better practicality (Table 2). The generalization-specificity score (GSS) is divided into 5 levels from 1 to 5, with higher scores indicating better specificity (Table 3). To reduce bias caused by individual differences in understanding the scoring system, all experts reviewed and discussed the scoring criteria of the Likert scale before the assessment.

Table . Accuracy scoring standard.

Scoring description	Scoring
Completely incorrect	1
More incorrect than correct	2
Approximately equal correct and incorrect	3
More correct than incorrect	4
Nearly all correct	5
All correct	6

Table . Practical scoring standard.

Scoring description	Scoring
Completely impractical	1
Slightly practical	2
Moderately practical	3
Very practical	4

XSL•FO
RenderX

Table . Generalization-Specificity Score (GSS) scoring standard.

Scoring description	Scoring
Fully generalized, with no specific details or targeted information provided	1
Primarily generalized but mentions some relevant details or information	2
Combines generalized content with some specific details or information	3
Rather specific, but the details or targeted information are insufficient and can be improved	4
Fully specific, with comprehensive details and highly targeted information	5

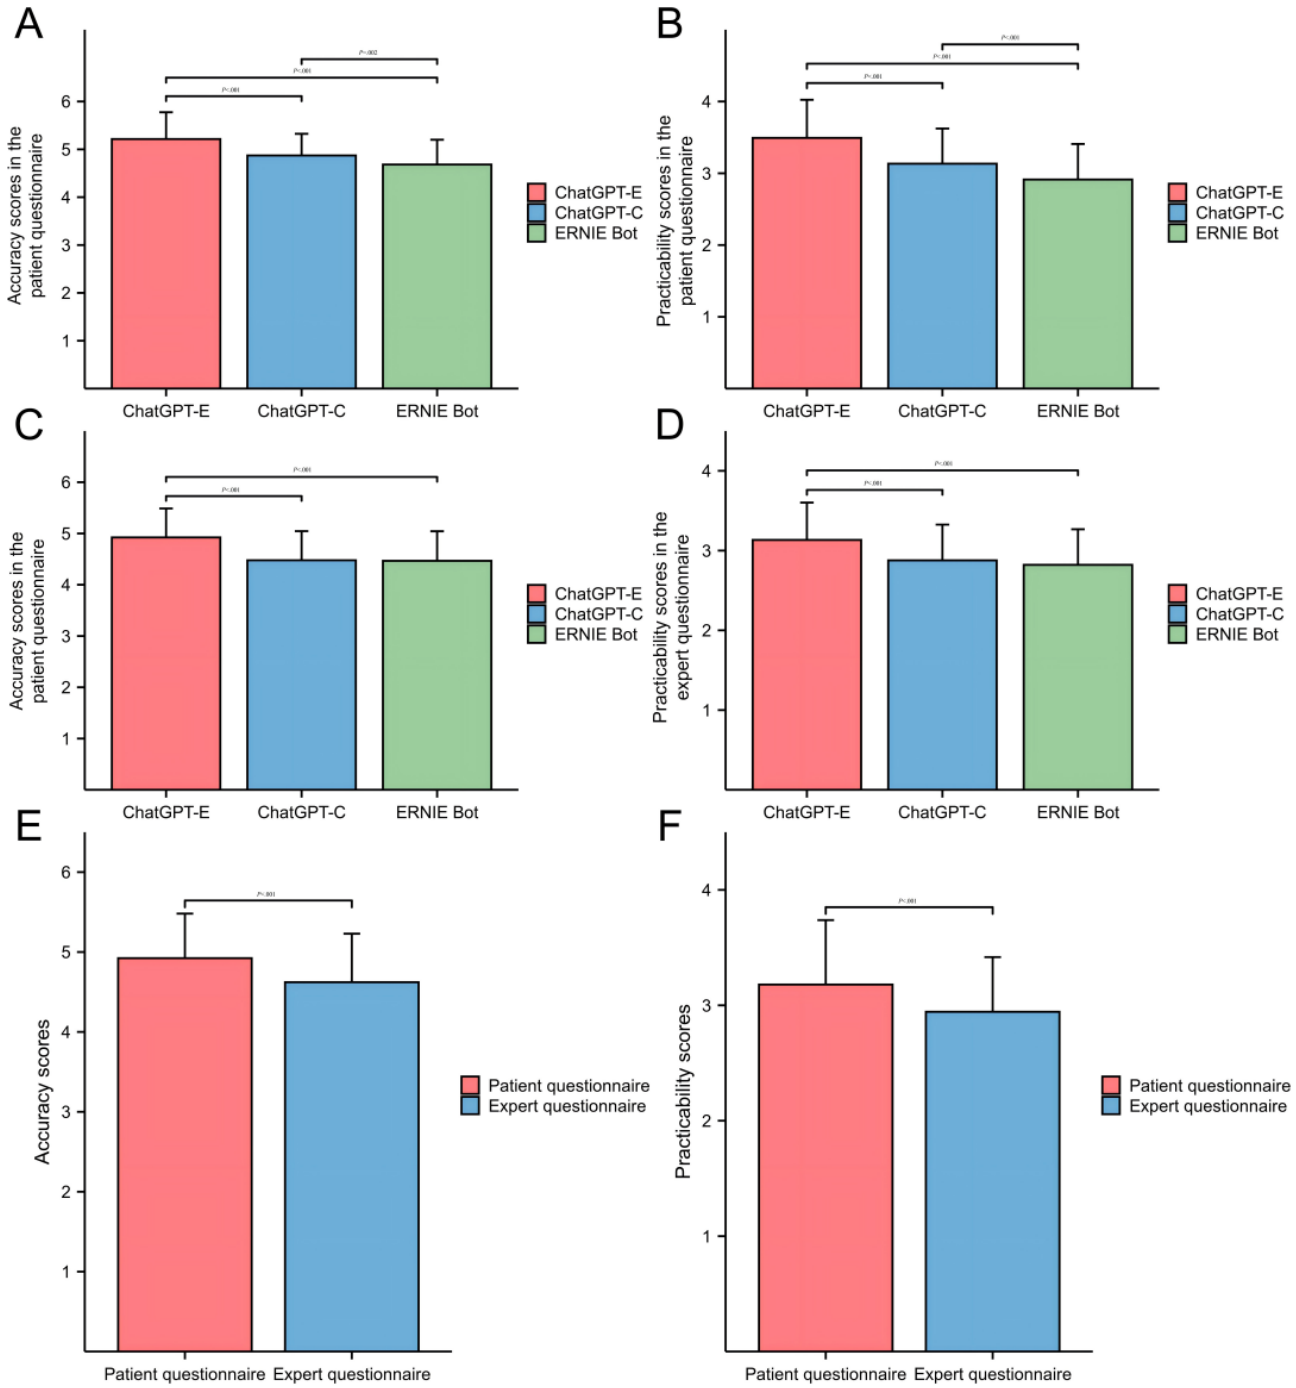
Statistical Analysis

The Shapiro-Wilk test was used to determine the normality of the scores and the Levene test was used to evaluate the homogeneity of variance. Differences between two groups were assessed using the Wilcoxon rank sum test. The Kruskal-Wallis test evaluated differences between three or more groups of variables, and the Dunn test was used for two-way between-group comparisons of variables that were not normally distributed. $P<.05$ was deemed statistically significant. The intraclass correlation coefficient (ICC) was used to evaluate the consistency of accuracy, practicality scores and GSS among 13 raters. An ICC ≥0.75 was considered to indicate good consistency. All statistical analyses were performed using R software (version 4.0.3; R Foundation for Statistical Computing).

Ethical Considerations

This study did not gather patient data and did not involve human subjects. Therefore, approval by the institutional review board of Chongqing Medical University was not required.

Results



In the patient questionnaire, the median accuracy scores of ChatGPT-E, ChatGPT-C, and EB were 5.00 (IQR 5.00-6.00), 5.00 (IQR 5.00-6.00), and 5.00 (IQR 4.00-5.00), respectively. The median practicality scores of ChatGPT-E, ChatGPT-C, and EB were 4.00 (IQR 3.00-4.00), 3 (IQR 3.00-3.00), and 3.00 (IQR 3.00-3.00), respectively; and the median GSS were 4.00 (IQR 3.00-4.00), 3 (IQR 3.00-4.00), and 3.00 (IQR 3.00-4.00), respectively. The accuracy and practicality of ChatGPT-E were significantly higher than those of ChatGPT-C and EB ($P<.001$). The accuracy and practicality of ChatGPT-C were also significantly higher than those of EB ($P=.002$ and $P<.001$, respectively; Figure 1A and B). The specificity of the ChatGPT-E responses was significantly higher than that of the ChatGPT-C and EB ($P=.002$ and $P<.001$, respectively), whereas no significant difference was found in the specificity of the ChatGPT-C and EB responses (Multimedia Appendix 2, parts A and B).

In the expert questionnaire, the median accuracy scores of ChatGPT-E, ChatGPT-C, and EB were 5.00 (IQR 5.00-5.00), 4.00 (IQR 4.00-5.00), and 4.00 (IQR 4.00-5.00), respectively; the median practicality scores for all three were 3.00 (IQR 3.00-3.00) and the median GSS were 4.00 (IQR 3.00-4.00), 3 (IQR 2.00- 4.00), and 3.00 (IQR 2.00-3.00), respectively. The accuracy and practicality of ChatGPT-E were significantly higher than that of ChatGPT-C and EB (all $P<.001$). However, there was no significant difference in the accuracy and practicality scores between ChatGPT-C and EB ($P=1.000$ and $P=.72$, respectively) (Figure 1). For response generalization and specificity, the ChatGPT-E score was significantly higher than ChatGPT-C and EB (both $P<.001$), whereas there was no significant difference between ChatGPT-C and EB. Overall, the median accuracy scores of the patient questionnaire and the expert questionnaire were 5.00 (IQR 5.00-5.00) and 5.00 (IQR 4.00-5.00), respectively; the median practicality scores were 3.00 (IQR 3.00-4.00), and 3.00 (IQR 3.00-3.00), respectively; the median practicality scores were 3.00 (IQR 3.00-4.00), and 3.00 (IQR 3.00-3.00), respectively, and the median GSS was 3.00 (IQR 3.00-4.00) for both questionnaires. The accuracy and practicality scores from the patient questionnaire were significantly higher than those from the expert questionnaire (all $P<.001$) (Figure 1), and their specificity scores were also significantly higher ($P<.001$) (Multimedia Appendix 2, parts C-E).

In addition, to quantify the frequency of ratings for accuracy, practicality, and specificity in LLM responses, we illustrated the rating distribution as percentages in Multimedia Appendix 3. For accuracy, responses rated as 6 (All correct) accounted for only 11.96% (70/585) in the patient questionnaire, 5.64% (33/585) in the expert questionnaire, and 8.8% (103/1170) overall. Notably, the hallucination rate—defined as responses rated ≤4 on the accuracy scale—was 19.7% (115/585) in the patient questionnaire and 28.9% (169/585) in the expert questionnaire. For practicality, responses rated as 4 (Very practical) accounted for 26.15% (153/585) in the patient questionnaire, 8.55% (50/585) in the expert questionnaire, and 17.35% (203/1170) overall. For generalization-specificity, responses rated as 5 (Fully specific) accounted for 5.64% (33/585) in the patient questionnaire, 2.39% (14/585) in the expert questionnaire, and 4.02% (47/1170) overall. The 13 raters exhibited excellent inter-rater agreement in their scoring of accuracy, practicality, and GSS, with ICC values of 0.878 (95%Cl 0.837 - 0.912), 0.823 (95%Cl 0.765 - 0.873), and 0.809 (95%Cl 0.758 - 0.855) respectively. Additionally, the statistical descriptive indices for all between-group comparisons are provided in detail in Multimedia Appendices 4-8.

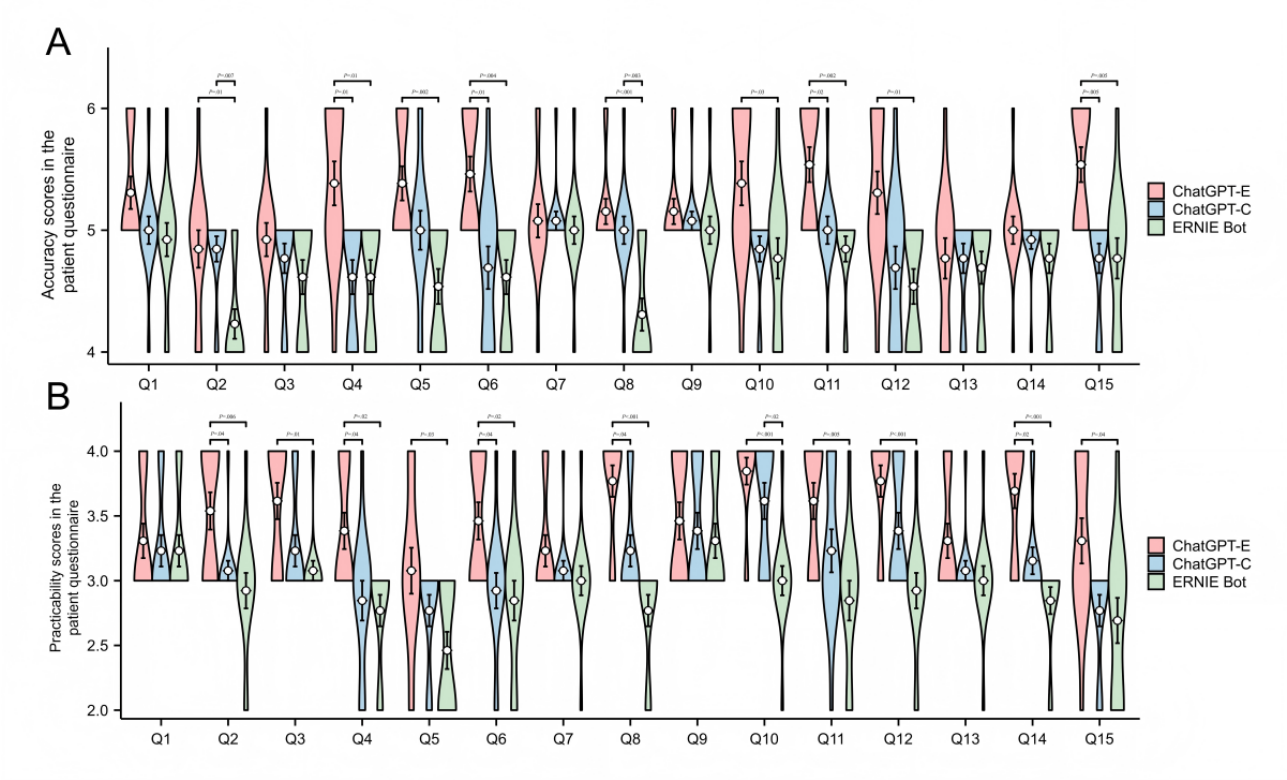
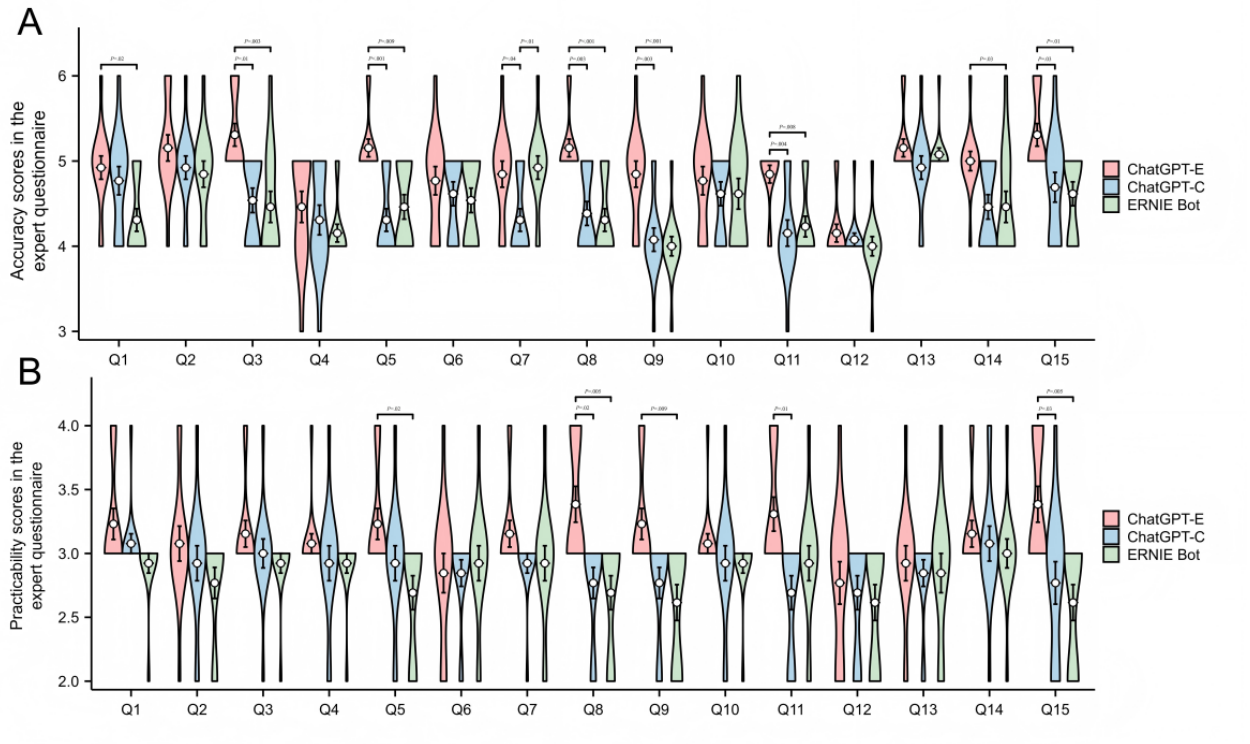
Discussion



Principal Findings

We have reported several important findings in this study. First, based on the patient questionnaire responses, ChatGPT-E demonstrated significantly higher accuracy compared to ChatGPT-C and EB in addressing questions related to breast cancer surgery treatment (Q4) and postoperative management (Q6, Q11, and Q15) (Figure 2A). Additionally, ChatGPT-E's responses to questions concerning breast cancer staging (Q2), treatment (Q4 and Q8), and postoperative management (Q6 and 14) were more comprehensive and practical (Figure 2). In the expert questionnaire, ChatGPT-E demonstrated similar advantages, especially for breast cancer drug treatment (Q8) and follow-up (Q15), with more comprehensive, accurate, and practical responses, reflecting higher efficiency (Figure 3). Overall, ChatGPT-E performed the best in both patient and expert questionnaires. Despite the advantages in training strategies that may have enabled ChatGPT-C to perform better than EB in answering general questions from patients with breast cancer, the performances of both models were unsatisfactory while answering comparatively specialized questions in the field of breast cancer in the Chinese-language context (Figure 1). For example, in response to the expert questionnaire Q5, both ChatGPT-C and EB only briefly mentioned several common methods of first-stage breast reconstruction. Only

XSL•FO
RenderX



ChatGPT-E mentioned "latissimus dorsi flap breast reconstruction" and briefly introduced the advantages of each surgical method. Although its response was not detailed enough, the basic framework was correct. Although the overall hallucination rate of ChatGPT-E was significantly lower than that of ChatGPT-C and EB (both $P<.001$), 11.79% (23/195) of its responses in the expert questionnaire still contained inaccurate information. This finding indicates that even models with relatively superior performance must further reduce hallucination rates in the specialized field of breast cancer to meet clinical requirements.

Figure 2. Scores and comparisons of LLMs' responses to specific questions in the patient questionnaire. A: Accuracy; B: Practicality. Error bars represent mean ± standard error. ChatGPT-E: ChatGPT-English ; ChatGPT-C: ChatGPT-Chinese; EB: ERNIE Bot.

Cross-Language Limitations of ChatGPT

In addition, we found that ChatGPT-C's responses to the 15 questions in the patient and expert questionnaire each contained one notable medical terminology translation error. For instance, "泛素酮 (Tamoxifen)" and "莱特罗唑 (Letrozole)" were mentioned in the response to expert questionnaire Q7. In patient questionnaire Q12, the term "port" in "subcutaneously implanted infusion port" was translated as "harbor" (ie, 港口 in Chinese). Patients may misinterpret postoperative care requirements due to this nonstandard translation, potentially leading to complications. In the medical domain, English is the primary language for international academic communication. ChatGPT's core training data is predominantly in English, including extensive English medical literature and clinical guidelines (eg, National Comprehensive Cancer Network and Advanced Breast Cancer). Compared with EB, ChatGPT has greater access to and understanding of these professional resources, enabling it to provide more comprehensive and accurate information when answering related questions. The inferior performance of ChatGPT-C compared to ChatGPT-E may stem from limitations in cross-language processing. Although ChatGPT supports multiple languages, the semantic structure and medical terminology in Chinese differ significantly from English. During cross-language processing, ChatGPT may rely on translation mechanisms rather than native Chinese training, leading to semantic distortion in specialized content and reduced answer quality. Preliminary testing in other languages such as Spanish and French has identified similar issues when dealing with proper nouns (eg, medications, surgical procedures) and compound terms. The model tends to rely on literal translation or the creation of neologisms rather than following localized standards, which may lead to ambiguities. However, a recent study by Tian et al [19] on CHIMED-GPT found that pretraining GPT using a specific Chinese medical dataset made CHIMED-GPT perform significantly better than other models in tasks such as multiple choice and open-ended responses. To address the translation errors in ChatGPT-C's responses to breast cancer–related questions, fine-tuning the model with Chinese medical datasets represents an effective improvement strategy. These datasets should include a wide range of Chinese medical literature, clinical guidelines, case reports, and patient-doctor dialogues specific to the field of breast cancer. By training the model on these specialized datasets would help it grasp the nuances and context of medical language better, leading to more accurate translations and responses. In addition, user error correction interfaces can be designed to allow physicians or patients to flag translation errors (eg, "莱特罗唑 → 来曲唑"), and the system could then automatically collect these error cases and add them into fine-tuning datasets, thus achieving continuous model optimization. In terms of response repeatability, the performance of ChatGPT-E (52/60, 86.67%) was significantly better than ChatGPT-C (50/60, 83.33%) and EB (40/60, 66.67%).

Challenges Encountered by LLMs

It is worth noting that we have also found a lack of corresponding empirical data and references to support the views of the two LLMs in their responses, which could undermine the credibility and practicality of their responses, especially in evidence-based clinical practice [20,21]. For example, in responses to the expert questionnaire Q14 and patient questionnaire Q7, both LLMs mentioned that "chemotherapy affects fertility or breastfeeding," but failed to provide any useful

XSL•FO
RenderX

references, resulting in compromised credibility and possibly inability to guide physicians and patients in making correct decisions. In addition, the responses of LLMs were relatively generalized, indicating that they were widely mentioned but lacked specificity, similar to the findings of the study by Giannakopoulos et al [22] who used LLMs to answer dental-related questions. This generalized responses also resulted in the LLMs being less accurate and practical in answering the expert questionnaire than the patient questionnaire (Figure 1). For example, in the responses to expert questionnaire Q15 and patient questionnaire Q14, although LLMs mentioned the need for regular follow-up and corresponding examinations for patients with breast cancer, they did not provide specific answers. These generalized responses are of limited value to clinical professionals, who require highly accurate, comprehensive, and professional information, similar to previous studies on ChatGPT's responses to mental health and liver cancer–related questions [23,24]. However, they may be beneficial for patients with breast cancer who lack medical expertise, as the responses from LLMs already covered the vast majority of the questions and were comparable to clinician responses, similar to the findings from a study by Endo et al [25] on the use of LLMs for answering questions related to liver transplantation. Generalized LLM–generated information poses risks ranging from clinical mismanagement to ethical violations, particularly in complex fields such as breast cancer. Given that in breast cancer treatment, timely decision-making is critical early diagnosis and intervention significantly improve cure and survival rates. Vague recommendations from LLMs may put patients at risk of missing the optimal therapeutic window, thus potentially exacerbating disease progression. While LLMs such as ChatGPT-E show promise in patient education, their utility depends on the patients' ability to contextualize and validate the outputs provided. Patients should maintain a cautious attitude toward responses generated by LLMs that lack personalized recommendations and refrain from relying on them exclusively. It is recommended that patients use the information provided by LLMs as a general reference, while promptly communicating with professional physicians. By integrating their specific clinical circumstances, patients can obtain accurate and personalized medical advice and guidance to safeguard their health and safety.

Ethics and Data Security in LLMs

Furthermore, LLMs have exposed potential ethical risks in responding to breast cancer–related questions. While clinical trials may offer access to the latest therapeutic regimens and advanced technologies, they inherently carry uncertainties and potential adverse effects. When responding to Patient Questionnaire Q2 and Expert Questionnaire Q6, LLMs encouraged patient participation in clinical trials without adequately explaining the risks and uncertainties involved. This could lead patients to assume unnecessary risks without being fully informed [26]. We recommend establishing a dedicated review team to systematically audit medical recommendations provided by LLMs, particularly regarding clinical trial recommendations and vague suggestions. This ensures that LLMs responses adhere to medical ethical standards and professional norms, and correct or block responses that do not meet the requirements. At the same time, the issue of data security involved in LLMs is becoming increasingly prominent [27]. Although the responses of the LLMs in this study did not inadvertently leak sensitive information and were based on general medical knowledge and standardized recommendations, some studies have shown that LLMs may inadvertently memorize and disclose original data in their responses [28,29]. In a study by Nasr et al [30], researchers were able to extract training data for various LLMs including ChatGPT through specific "attacks". Therefore, doctors or health care organizations should obtain informed consent from patients when using real patient data for model training and application to LLMs, while ensuring the anonymization and deidentification of data [26]. Patients should also be trained in data security awareness and instructed to avoid disclosing private personal information while using LLMs to obtain health information [31]. China has established a series of laws and regulations, including the Personal Information Protection Law (PIPL) to regulate data processing and applications. However, specific regulatory details for LLM–based medical applications are still being explored and refined. The effective implementation of these laws and regulations in the LLM–based medical applications is currently a concern [32]. Based on the results of this study, future regulation should focus on standardizing the LLM–based medical applications. It is essential to strictly regulate data processing procedures to ensure data security and privacy protection in compliance with laws and regulations such as the PIPL. Further, an ethical review mechanism for LLM–based medical applications should be established, clarifying ethical guidelines in aspects such as medical information provision and patient decision-making guidance to prevent ethical risks [33]. Additionally, explicit limitations should be imposed on the scope and modalities of PIPLs in health care to prevent their excessive involvement in core medical operations when sufficient reliability is not assured.

Conclusion

This study reflects some important issues that may arise when using LLMs in clinical scenarios related to breast cancer in China. Overall, LLMs can serve as effective tools for Chinese patients with breast cancer to obtain health information, helping to address the majority of concerns related to diagnosis, treatment, recovery, and follow up of this population. However, in the context of breast cancer specialists, the accuracy, practicality, and relevance of LLMs' responses need improvement. We propose a multidimensional optimization framework to enhance the utility and reliability of ChatGPT in breast cancer diagnosis and management. On the one hand, the model should be trained using high-quality medical data, such as the latest breast cancer research, clinical guidelines, and case reports, to improve its accuracy and practicality in the professional domain. On the other hand, under ethical compliance, ChatGPT should be connected to deidentified electronic health records, laboratory systems, and imaging databases to access real-time patient data and provide more personalized recommendations. Based on our research, ChatGPT-E demonstrates better repeatability, accuracy, and practicality in its responses compared to other LLMs. Therefore, it is recommended that Chinese patients with breast cancer

XSL•FO
RenderX

translate their questions into English before querying ChatGPT, to improve its effectiveness. In addition, considering the potential data security, ethical, and legal risks of LLMs in clinical practice, it is essential to strengthen regulation of the training and application of LLMs in the medical professional field [34]. This study has certain limitations as the response from LLMs were not applied in real time to address the questions of patients with breast cancer or to assist doctors in making clinical decisions. We also did not evaluate all issues related to breast cancer. The data collection for this study was completed in January 2024. However, certain models (eg, GPT-4-turbo and DeepSeek) had not been publicly released at that time or failed to provide stable interfaces for academic research applications and therefore were not included in this study. Additionally, this study used structured questionnaires to evaluate the responses of LLMs, which ensured standardized assessment but partially limited the assessment of LLMs' ability to handle open-ended, unstructured, and interactive questions. Future iterations could incorporate open-ended or interactive question types to better simulate real-world clinical consultations. Lastly, patient and expert user feedback can provide critical user-perspective data, address the limitations of existing expert-only evaluations, and enhance the application effectiveness and user experience of LLMs in health care. Further research is required to evaluate the real-world clinical effectiveness of LLMs and the real user experience of patients with breast cancer in China.

Abstract

Background: Disease name recognition is a fundamental task in clinical natural language processing, enabling the extraction of critical patient information from electronic health records. While recent advances in large language models (LLMs) have shown promise, most evaluations have focused on English, and little is known about their robustness in low-resource languages such as Japanese. In particular, whether these models can perform reliably on previously unseen in-hospital data, which differs from training data in writing styles and clinical contexts, has not been thoroughly investigated.

Objective: This study evaluated the robustness of fine-tuned LLMs for disease name recognition in Japanese clinical notes, with a particular focus on their performance on in-hospital data that was not included during training.

Methods: We used two corpora for this study: (1) a publicly available set of Japanese case reports denoted as CR, and (2) a newly constructed corpus of progress notes, denoted as PN, written by ten physicians to capture stylistic variations of in-hospital clinical notes. To reflect real-world deployment scenarios, we first fine-tuned models on CR. Specifically, we compared a LLM and a baseline-masked language model (MLM). These models were then evaluated under two conditions: (1) on CR, representing the in-domain (ID) setting with the same document type, similar to training, and (2) on PN, representing the out-of-domain (OOD) setting with a different document type. Robustness was assessed by calculating the performance gap (ie, the performance drop from in-domain to out-of-domain settings).

Results: The LLM demonstrated greater robustness, with a smaller performance gap in F_1-scores (ID–OOD = −8.6) compared to the MLM baseline performance (ID–OOD = −13.9). This indicated more stable performance across ID and OOD settings, highlighting the effectiveness of fine-tuned LLMs for reliable use in diverse clinical settings.

Conclusions: Fine-tuned LLMs demonstrate superior robustness for disease name recognition in Japanese clinical notes, with a smaller performance gap. These findings highlight the potential of LLMs as reliable tools for clinical natural language processing in low-resource language settings and support their deployment in real-world health care applications, where diversity in documentation is inevitable.

(JMIR Med Inform 2025;13:e76773) doi:10.2196/76773

KEYWORDS

clinical NLP; Japanese language; named entity recognition; large language models; out-of-domain robustness; clinical corpus; clinical natural language processing

Introduction

Clinical notes contain a vast amount of information that is not captured in structured fields of electronic health records (EHRs) [1,2]. Natural language processing (NLP) techniques have become essential for unlocking this rich, unstructured data [3].

Among these, named entity recognition (NER)—a task that identifies clinical entities such as disease names in text—plays a vital role in extracting key clinical information, which is essential for understanding patients' medical conditions [4-6]. For instance, disease name recognition can be leveraged to detect adverse drug reactions from EHRs for post-marketing surveillance [7].

Recent advances leveraging fine-tuned masked language models (MLMs) such as BERT, have achieved state-of-the-art performance in clinical NER tasks, often outperforming prompt-based in-context learning (ICL) of large language models (LLMs) [8,9]. However, MLMs fine-tuned for disease name recognition tend to experience notable performance drops

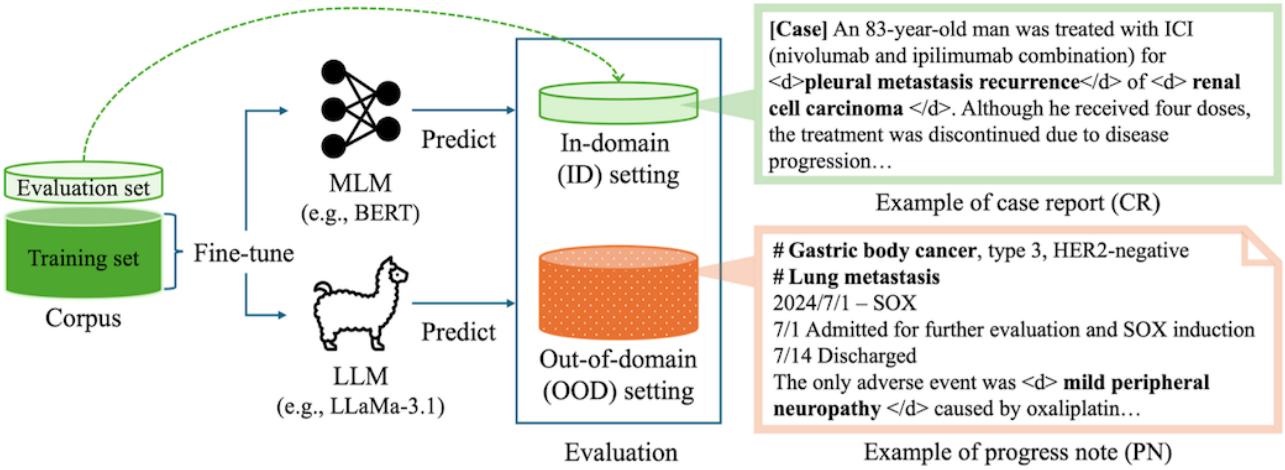
XSL•FO
RenderX

on unseen in-hospital data [10,11]. Given that clinical NLP systems are expected to operate reliably across diverse clinical settings, understanding and improving robustness—that is, whether models can perform reliably on previously unseen clinical notes—is a critical research objective.

When fine-tuned, LLMs have shown competitive or slightly superior performance compared to MLMs in NER tasks [12]. Given their exposure to a broader and more diverse range of linguistic patterns during pretraining, LLMs are expected to exhibit resilience to stylistic variations. However, the extent to which fine-tuning improves their robustness over MLMs remains underexplored, particularly in languages other than English [13]. One reason for this research gap is the lack of corpora that reflect the realistic documentation styles of in-hospital clinical notes. These data are challenging to obtain due to privacy concerns and institutional restrictions.

In this study, we investigate the robustness of fine-tuned LLMs with a focus on disease name recognition in Japanese clinical notes. To facilitate an evaluation of robustness to unseen in-hospital data, we constructed a dedicated clinical corpus comprising progress notes (PN) authored by ten individual physicians from different clinical institutions, reflecting diverse in-hospital documentation styles. To reflect real-world deployment scenarios, we trained the models on publicly available case reports (CR) and evaluated them under two conditions: (1) on CR, representing the in-domain (ID) setting with the same document type as in training, and (2) on PN, representing the out-of-domain (OOD) setting with a different document type. This cross-document evaluation allows us to assess the models' robustness to real-world variability in documentation styles, capturing the challenges introduced by the diverse writing practices found in in-hospital clinical notes.

Experimental results demonstrated that the fine-tuned LLM—specifically LLaMA-3.1 [14]—outperforms the MLM baseline (Bidirectional Encoder Representations from Transformers, BERT) [15], not only in the ID setting but also under OOD conditions. The LLM also exhibits a smaller performance gap between ID and OOD settings, indicating stronger robustness compared to the MLM. Further analysis reveals that LLMs are more resilient to stylistic diversity among clinicians, showing reduced performance fluctuation across different physicians. These findings underscore the potential of fine-tuned LLMs as more reliable tools for real-world clinical applications, particularly where robustness to diverse and previously unseen clinical notes is essential.



Methods

Overview

Our primary research question was to evaluate whether fine-tuned LLMs remain robust when applied to previously unseen clinical notes. To address this, we compared the performance gap, defined as the performance difference between ID setting and OOD settings between a fine-tuned LLM and a fine-tuned MLM, which serves as a state-of-the-art baseline for clinical NER.

The overview of the evaluation pipeline is shown in Figure 1. We evaluated model performance on the task of disease name recognition in Japanese clinical notes. Both LLMs and MLMs are first fine-tuned on a training set sampled from one document type (eg, case reports). Evaluation is then conducted on two distinct test sets: one ID set sampled from the same document type as the training data and one OOD set sampled from a different document type (eg, progress notes).

Figure 1. Overview of the evaluation pipeline. Models were fine-tuned on CR and evaluated on both CR, representing in-domain (ID) and PN, representing out-of-domain (OOD) test sets for disease name recognition in Japanese clinical notes. BERT: Bidirectional Encoder Representations from Transformers; HER2: human epidermal growth factor receptor 2; ICI: Immune checkpoint inhibitor; LLM: large language model; MLM: masked language model; SOX: SRY-related HMG-box.

Materials

To represent ID and OOD settings, we used two datasets: an existing publicly available corpus of case reports and a newly constructed corpus comprised of progress notes.

1. Case reports (CR): A publicly available dataset consisting of Japanese case reports comprising 1898 sentences across 148 documents annotated with clinical entities [16].
2. Progress notes (PN): A dedicated, newly constructed corpus of progress notes, comprising 1094 sentences across 100 documents annotated with disease entities.

XSL•FO
RenderX

For the construction of PN, we first curated 10 diverse board exam-style cases. To reflect real-world clinical documentation, these cases were then rewritten by ten physicians, each contributing ten unique documents. The physicians were instructed to adapt the cases to authentic in-hospital clinical note styles from their clinical practice, emphasizing realistic writing styles and varying levels of readability. In total, 1094 sentences (100 documents) across 10 physicians and 10 clinical cases were created. The created PN were then annotated for disease name entities by two experienced annotators, following the same annotation guidelines as CR [17]. We summarize the titles of the board exam-style cases and the top 3 most frequent disease entities per case in Table 1.

We assessed the annotation quality of PN by calculating interannotator agreement using two criteria: exact and partial span matching. Exact matching required both annotators to identify the same entity with identical span boundaries, while partial matching allowed for overlapping spans, acknowledging minor variations in boundary selection. Based on a comparison of annotations from 10 randomly sampled documents, the agreement between annotators was 0.70 (61/87) for exact matching and 0.82 (71/87) for partial matching, suggesting a high level of consistency and reliable annotation quality.

Models and Baselines

We evaluate fine-tuned MLMs and LLMs on the task of disease name recognition in Japanese clinical notes, comparing their performance under ID and OOD settings. In addition, we evaluated LLMs using in-context learning (ICL) through zero-shot and few-shot prompting to assess the contribution of fine-tuning to improving LLM performance.

Fine-Tuning: We fine-tuned two models for the NER task: (1) “bert-base-japanese-v3” [18], based on BERT [15] as a strong MLM baseline, and (2) Swallow-Instruct-v0.2 [19], based on LLaMA-3.1 (version 8B; Meta) [14], which is a Japanese-instruction-tuned LLM. Both were subsequently fine-tuned on the ID training set. “bert-base-japanese-v3” was chosen as a strong and widely used baseline for Japanese-language tasks, providing a representative benchmark for traditional transformer–based MLMs that had been validated in clinical NLP [20]. In contrast, “Swallow-Instruct-v0.2” (version 0.2; Tokyo Institute of Technology) was selected to evaluate the potential of recent instruction–tuned LLMs, which are designed to better follow task-specific instructions and generalize across diverse inputs. Built on Llama 3.1 8B through continual pretraining, it was trained on a curated instruction corpus featuring multiturn dialogue and multilingual tasks with a particular focus on enhancing Japanese language capabilities.

For BERT, we adopted a standard sequence labeling approach, using the “CLS” token representations followed by a linear classification layer to predict BIO-tagged labels for disease entities. In contrast, for LLaMA-3.1, we followed a generation-based NER framework: the model was prompted with an instruction and clinical note, and it generated the same sentence with inline entity tags, enabling span-level extraction in a natural language generation format. To adapt LLaMA-3.1 to the NER task efficiently, we applied additional fine-tuning using Low-Rank Adaptation (LoRA) [21], allowing parameter-efficient fine-tuning without modifying the full set of model weights.

In-context learning (ICL): We evaluated LLaMA-3.1 and GPT-4o [22] under zero-shot and few-shot settings as baselines. An example of a prompt used for ICL is presented in Textbox 1. Recently, extensive efforts have been made to optimize prompt design in the field of NLP [23-26]. In this experiment, we provide the models with an annotation guideline that included entity definitions, task instructions, and illustrative examples, following prior work on medical NER [9]. For zero-shot learning, the model was provided with task instructions and annotation guidelines only, without any annotated examples. For few-shot learning, a single annotated clinical note was randomly selected from the training data and included in the prompt. Here, LLaMA-3.1 represents an open-source LLM with accessible model weights, allowing evaluation across both fine-tuning and in-context learning scenarios. In contrast, GPT-4o was evaluated only in zero-shot and few-shot settings due to its proprietary nature, serving as a reference for the in-context learning performance of an LLM with the highest model capacity in our study.

Textbox 1. Textbox 1. Prompt example for ICL.

Annotation Guideline

Definition of disease names

1. When the lesion or symptom has actually been observed in the patient
2. When it is suspected that the patient may have the lesion or symptom (eg, proposed as a differential diagnosis)
3. …

Examples

Text: In November last year, pleural effusion appeared and increased, but decreased after starting furosemide.

Annotation: In November last year, <d pleural effusion </d>appeared and increased, but decreased after starting furosemide.

…

Task Instruction

Based on the above explanation and examples, please annotate the following text

…

Text: The nodule shadow in the right upper lobe of the lung slightly increased.

Comparison Settings

We used our clinical corpora in a cross-domain evaluation setup to assess both ID and OOD robustness:

ID: Samples from one document type were split 8:2 into training and evaluation sets. This setting reflects standard model development conditions, where training and test data share similar clinical notes.

OOD: The corpus from another document type was used in its entirety for evaluation. This reflects real-world deployment scenarios where models must process previously unseen clinical notes with varying writing styles and vocabularies.

In addition to the setting where CR are used for training and PN for evaluation, we also included the reverse scenario. This resulted in four distinct evaluation configurations: CR→CR, CR→PN, PN→PN, and PN→CR. The difference between ID and OOD performance (Δ) is calculated as Δ=ID−OOD. This

XSL•FO
RenderX

represents the performance gap, which measures how well the model generalizes to unseen clinical notes, compared to the data it was trained on. A smaller difference indicates that the model is robust, even when faced with clinical notes with different writing styles or from different clinical cases. Hyperparameters used for fine-tuning are summarized in Table 2.

Table . Hyperparameters used for fine-tuning.

Parameter description	LLaMa-3.1	BERT[a]
Evaluation batch size per device	_[b]	8
Learning rate	2e-4	2e-5
LoRA[c] dropout rate	0.05	–
LoRA rank (number of adaptation dims)	16	–
LoRA scaling factor	64	–
Maximum gradient norm (clipping)	0.3	–
Maximum sequence length	3000	512
Number of gradient accumulation steps	4	–
Number of training epochs	2	10
Optimizer used	AdamW	AdamW
Training batch size per device	4	8
Warmup ratio for learning rate	0.05	–
Weight decay for regularization	–	0.0
Number of warmup steps	–	0

[b]Not applicable.

[c]LoRA: Low-Rank Adaptation.

Ethical Considerations

This study did not involve experiments with human subjects, and no personally identifiable information was used at any stage. The clinical notes were physician-authored, based on board exam cases that are publicly available. Therefore, there are no ethical concerns related to patient privacy or informed consent in this research.

Results

Study Findings

Table 3 shows the findings of ID and OOD evaluation. All models were evaluated using the microaveraged F_1-score, focusing on exact span matches of disease name entities. All results are averaged over three runs with different random seeds. For GPT-4o, we set the generation temperature to zero to ensure deterministic outputs and only ran the evaluation once due to annotation budget constraints.

Comparison Between Fine-Tuning and ICL

The fine-tuned LLaMA-3.1 consistently outperformed its zero-shot and few-shot counterparts, achieving the highest F_1-scores across all evaluation settings. These results highlight the effectiveness of fine-tuning for clinical NER. In contrast, vanilla LLaMA-3.1 exhibited limited performance in zero-shot and few-shot scenarios. Notably, in the few-shot setting, the model showed a decline in performance when applied to OOD data.

GPT-4o demonstrated strong few-shot performance (ie, 53.4 on CR→CR and 56.2 on PN→PN) despite having no access to training data, highlighting the robustness of large-scale foundation models. However, these models still underperformed compared to the fine-tuned BERT, consistent with previous findings that task-specific fine-tuning often outperforms in-context learning in specialized domains like clinical NER [8,9]. These findings illustrate that while ICL can provide a competitive baseline with minimal data, fine-tuning remains essential.

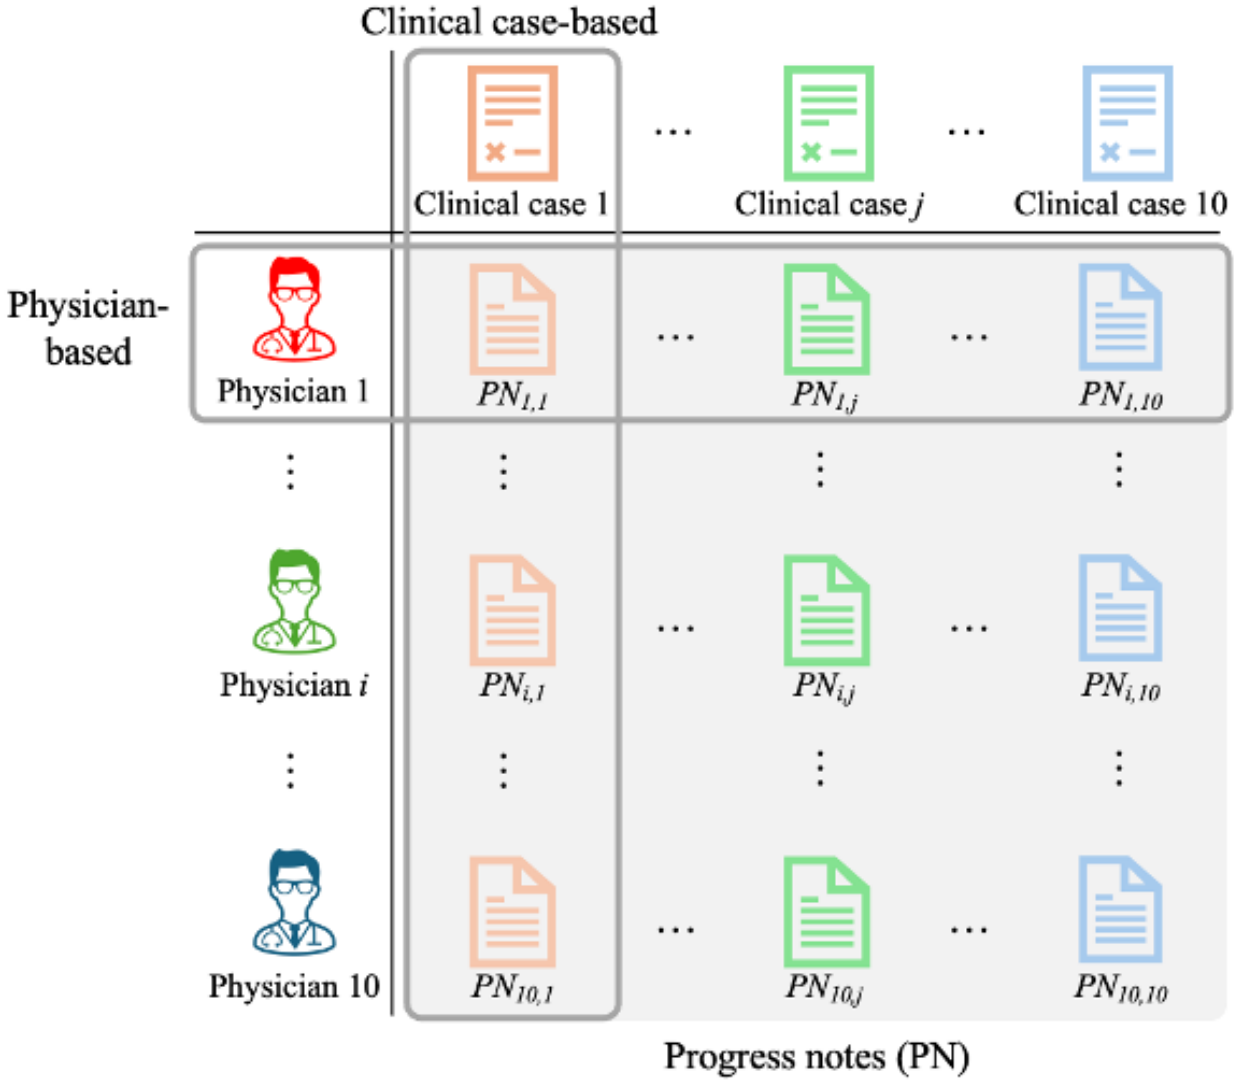
Comparison Between MLM and LLM

The fine-tuned LLaMA-3.1 outperformed the BERT baseline across all ID and OOD settings, demonstrating superior robustness to the previously unseen document type. Specifically, the fine-tuned LLaMA-3.1 exhibited a smaller performance gap (ΔCR=−8.6and ΔPN=−14.7) compared to BERT (ΔCR=−13.9 and ΔPN=−24.2), suggesting its greater stability for practical use in diverse clinical settings.

Discussion

Principal Findings

Experimental results demonstrate that the fine-tuned LLM exhibits strong robustness, maintaining relatively stable performance even when applied to previously unseen progress notes. To better understand the factors contributing to this robustness, we further decomposed it into two aspects: (1) robustness to stylistic variation, (ie, variations across physicians) and (2) robustness to variation across clinical cases. Our analysis reveals that the LLM was particularly robust to stylistic differences, while showing greater sensitivity to the differences in clinical cases.



We also conducted an error analysis to examine the qualitative improvements of the LLM over the MLM baseline performance. Our findings suggest that the LLM benefits from its generative approach, which allows it to mark entities inline within the sentence, as opposed to relying on a classification head over token representations, as in MLMs. This generative approach enables the LLM to more accurately extract entity spans, especially in stylistically diverse clinical notes.

Impact of Physician and Clinical Case Variation

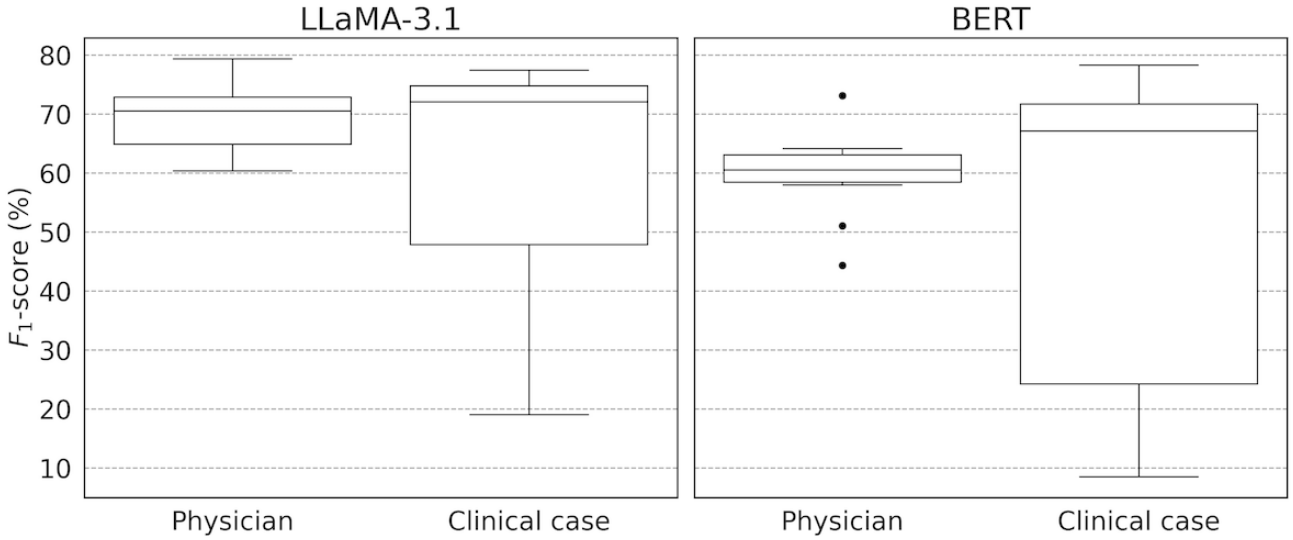
To examine the robustness of the fine-tuned LLM to variations in writing styles and clinical cases, we stratified the performance of the fine-tuned LLaMA-3.1 and BERT in the CR→PN setting by physician and clinical case. The stratification process is summarized in Figure 2.

XSL•FO
RenderX

Figure 2. Overview of the evaluation with stratification. Performance of fine-tuned LLaMA-3.1 and BERT was stratified by physician and clinical case to assess robustness to writing style and clinical case variations.

Physician-Based

Performance was evaluated for each physician, with ten clinical notes authored per individual. For instance, the performance of models is averaged across PNi,1 to PNi,10 for the i-th physician. The variation in these stratified results allows us to assess the model's sensitivity to variations in individual writing styles.



Clinical Case-Based

Performance was also evaluated for each clinical case modeled after board exam-style scenarios (eg, acute appendicitis). The model's performance was averaged over ten notes from different physicians, for example, PN1,j to PN10,j for the j-th clinical case. This stratification enables an analysis of the model's ability to generalize to clinical-case-specific disease entities.

Figure 3 presents the distribution of F_1-scores stratified by physician and clinical case in the CR→PN setting for both the fine-tuned LLaMa-3.1 and BERT. The spread of each box and the range of whiskers reflect performance variability, while dots indicate outliers beyond 1.5-times the interquartile range. Narrower boxes and smaller ranges indicate higher consistency, while outliers and wider spreads highlight sensitivity to writing style or clinical case variation.

XSL•FO
RenderX

Figure 3. Distribution of F_1-scores in CR→PN stratified by physician and clinical case. BERT: Bidirectional Encoder Representations from Transformers; CR: case report; PN: progress note.

Physician Variance

The fine-tuned LLaMA-3.1 demonstrated consistently strong performance across different physicians, with relatively low variance in F_1-scores. This is indicated in the narrow range between the maximum and minimum values in the box plot. In contrast, BERT's performance varied more widely, with significant performance drops in some physicians' notes, as indicated by extreme outliers and low minimum values. This suggests that the fine-tuned LLaMA-3.1 is more robust to stylistic differences, potentially due to its exposure to a broader and more diverse range of linguistic patterns during pretraining.

Clinical Case Variance

When stratified by clinical case, both models showed greater variability compared to writing style. This is evidenced by wider boxes and larger ranges between the maximum and minimum values in the box plots. These results highlight the increased difficulty of generalizing to domain-specific disease names. While the fine-tuned LLaMA-3.1 generally achieved higher average F_1-score across clinical cases, it also experienced sharp drops in certain cases, indicating that it remains sensitive to clinical-case-specific variation. This underscores the persistent challenge in processing previously unseen clinical cases, even for large instruction-tuned models.

These findings underscore the relative strength of the fine-tuned LLaMA-3.1 in handling clinical stylistic variation. At the same time, they point to the need for further work in addressing performance gaps in different clinical cases.

Error Analysis

To examine the qualitative improvements of the LLM over the MLM baselines, we conducted error analysis in the CR→PN setting. Based on the observation that the fine-tuned BERT has lower precision (51.8) compared to the fine-tuned LLaMA-3.1 (70.8), both models achieved similar recall scores (70.7 for BERT and 68.9 for LLaMA-3.1), we focused on false positive cases for the analysis.

Representative error examples are summarized in Table 4. From a manual inspection, we observed that BERT frequently misclassified nondisease clinical entities such as laboratory tests and biomarkers as disease mentions. For instance, in the sentence "Tumor markers also decreased gradually (徐々に腫瘍マーカーも低下し)," BERT incorrectly predicted two spans: "tumor markers (腫瘍マーカ"ー)" and "decrease (低下)." Both terms describe laboratory findings rather than disease entities. In another example, in the sentence "Therefore, with regard to platelets (このため血小板に対しては)," BERT erroneously extracted "platelets (血小板)," which refers to a blood cell type rather than a pathological condition. These examples illustrate that BERT often struggles to distinguish diagnostically relevant clinical phrases from true disease mentions, leading to false positive predictions.

In addition to entity type confusion, BERT also often struggled to capture the complete span of disease mentions, frequently producing boundary errors or partial matches that failed to align with the gold-standard annotations. For instance, in the sentence "Hb 8.1 g/dL and moderate nutritional disorder were observed (Hb8.1g/dlと中程度の栄養障害を認めた)," BERT incorrectly predicted only the prefix of a laboratory value, "Hb8," entirely missing the actual disease mention "栄養障害 (nutritional disorder)." In another example, "The drainage volume was excessive (排液量が過多であった)," BERT extracted only the character "多 (excessive)," omitting the full phrase "排液量が過多 (excessive drainage volume)." These examples illustrate how slight shifts in input text can lead to misaligned token representations in MLM's embedding space, resulting in fragmented or incomplete entity predictions.

In contrast, the LLM demonstrates greater flexibility in capturing complete spans of disease mentions. Unlike the MLM, which often struggles with partial matches, the LLM's generative approach allows entities to be marked directly and seamlessly within the sentence. For example, in the sentence "Hb8.1g/dlと中程度の<d>栄養障害</d>を認めた" (translated as "Hb 8.1 g/dL and moderate <d>nutritional disorder</d>were observed"), the disease mention "栄養障害 (nutritional disorder)" is correctly and fully captured within the sentence

XSL•FO
RenderX

using inline entity tags. This inline tagging strategy enables the model to stably extract entire disease names, even when clinical notes vary in writing style.

The LLM's ability to overcome the errors observed in BERT predictions likely stems from its different learning paradigm: rather than relying solely on token-level classification based on fixed input embeddings, the LLM generates structured outputs conditioned on the full context of the input. This generative approach allows the LLM to better maintain entity span prediction coherence over varying document types and incorporate broader sentence-level semantics into prediction. Consequently, the LLM achieves more robust and accurate extraction performance compared to the MLM baseline, particularly in OOD settings.

Table . Examples of BERT prediction errors in the CR→PN setting. Each row shows a sentence (left), predicted entity spans (middle), and the correct gold annotations (right).

Example sentence (English/Japanese)	Prediction	Gold annotation
Tumor markers also decreased gradually/腫瘍マーカーも低下し	tumor markers/腫瘍マーカー, decrease/低下	None
Therefore, with regard to platelets/このため血小板に対しては	platelets/血小板	None
Hb 8.1g/dL and moderate nutritional disorder were observed/Hb8.1g/dlと中程度の栄養障害を認めた	Hb8	nutritional disorder/栄養障害
The drainage volume was excessive/排液量が過多であった	excessive/多	excessive drainage volume/排液量が過多

Limitations

This study has several limitations. First, due to the annotation cost, our evaluation focused exclusively on disease name recognition. While disease entities are fundamental to clinical NLP tasks, real-world applications often require the extraction of a wider range of entities such as medications, procedures, and laboratory findings. Future research should expand the scope of entity types to provide a more comprehensive evaluation of model capabilities in diverse clinical information extraction tasks.

Second, we did not evaluate the computational efficiency or resource demands of the models. This is particularly relevant for LLMs, which often require substantial computational resources during both training and inference. Future studies should include a systematic comparison of computational cost, memory usage, and inference latency to guide more practical model deployment in clinical environments.

Lastly, we did not include comparisons with models pretrained on large-scale medical corpora, such as Bio-BERT [27] or its Japanese counterpart [28]. These models may have inherent advantages in understanding domain-specific terminology and context, and their inclusion could provide a clearer upper bound on MLM-based methods. Future work may incorporate medical-specific, pretrained models and a broader range of domain adaptation techniques in Japanese clinical settings.

Conclusions

This study evaluated the performance of fine-tuned LLMs on disease name recognition in Japanese clinical notes, with a focus on both ID and OOD robustness. Our results demonstrate that fine-tuned LLMs, specifically the fine-tuned LLaMA-3.1, consistently outperforms the strong baselines across OOD settings, demonstrating superior robustness to previously unseen clinical notes.

Stratified analyses revealed that the LLM exhibits greater robustness to stylistic variation among physicians, as reflected in its lower performance variance across physicians. However, variations across clinical cases continue to pose significant challenges, with both LLM and the baseline model showing considerable fluctuations. Error analysis highlighted the LLM's ability to consistently capture complete entity spans in stylistically diverse clinical notes. Its generative approach enables more context-aware span prediction, contributing to stable performance over the baseline model.

Overall, our findings underscore the potential of fine-tuned LLMs for clinical named entity recognition in low-resource languages such as Japanese, particularly in contexts with considerable variation in writing style. Nevertheless, challenges in cross-clinical case robustness remain. Future work should explore more targeted domain adaptation techniques and integration of external medical knowledge to further enhance robustness in real-world clinical NLP applications.

Abstract

Background: Adverse drug reactions (ADRs) pose serious risks to patient health, and effectively predicting and managing them is an important public health challenge. Given the complexity and specificity of biomedical text data, the traditional context-independent word embedding model, Word2Vec, has limitations in fully reflecting the domain specificity of such data. Although Bidirectional Encoder Representations from Transformers (BERT)–based models pretrained on biomedical corpora have demonstrated high performance in ADR-related studies, research using these models to predict previously unknown drug–side effect relationships remains insufficient.

Objective: This study proposes a method for predicting drug–side effect relationships by leveraging the parametric knowledge embedded in biomedical BERT models. Through this approach, we predict promising candidates for potential drug–side effect relationships with unknown causal mechanisms by leveraging parametric knowledge from biomedical BERT models and embedding vector similarities of known relationships.

Methods: We used 158,096 pairs of drug–side effect relationships from the side effect resource (SIDER) database to generate an adjacency matrix and calculate the cosine similarity between word embedding vectors of drugs and side effects. Relation scores were calculated for 8,235,435 drug–side effect pairs using this similarity. To evaluate the prediction accuracy of drug-side effect relationships, the area under the curve (AUC) value was measured using the calculated relation score and 158,096 known drug–side effect relationships from SIDER.

Results: The clagator/biobert_v1.1 model achieved an AUC of 0.915 at an optimal threshold of 0.289, outperforming the existing Word2Vec model with an AUC of 0.848. The BERT-based models pretrained on the biomedical corpus outperformed the vanilla BERT model with an AUC of 0.857. External validation with the FDA (Food and Drug Administration) Adverse Event Reporting System data, using Fisher exact test based on 8,235,435 predicted drug–side effect pairs and 901,361 known relationships, confirmed high statistical significance (P<.001) with an odds ratio of 4.822. In addition, a literature review of predicted drug–side effect relationships not confirmed in the SIDER database revealed that these relationships have been reported in recent studies published after 2016.

Conclusions: This study introduces a method for extracting drug–side effect relationships embedded in parameters of language models pretrained on biomedical corpora and using this information to predict previously unknown drug–side effect relationships. We found that BERT-based models pretrained with biomedical corpora consider contextual information and achieve better performance in drug–side effect relationship prediction. External validation using the FDA Adverse Event Reporting System dataset and the literature review of certain cases confirmed high statistical significance, demonstrating practical applicability. These results highlight the utility of natural language processing–based approaches for predicting and managing ADR.

Introduction

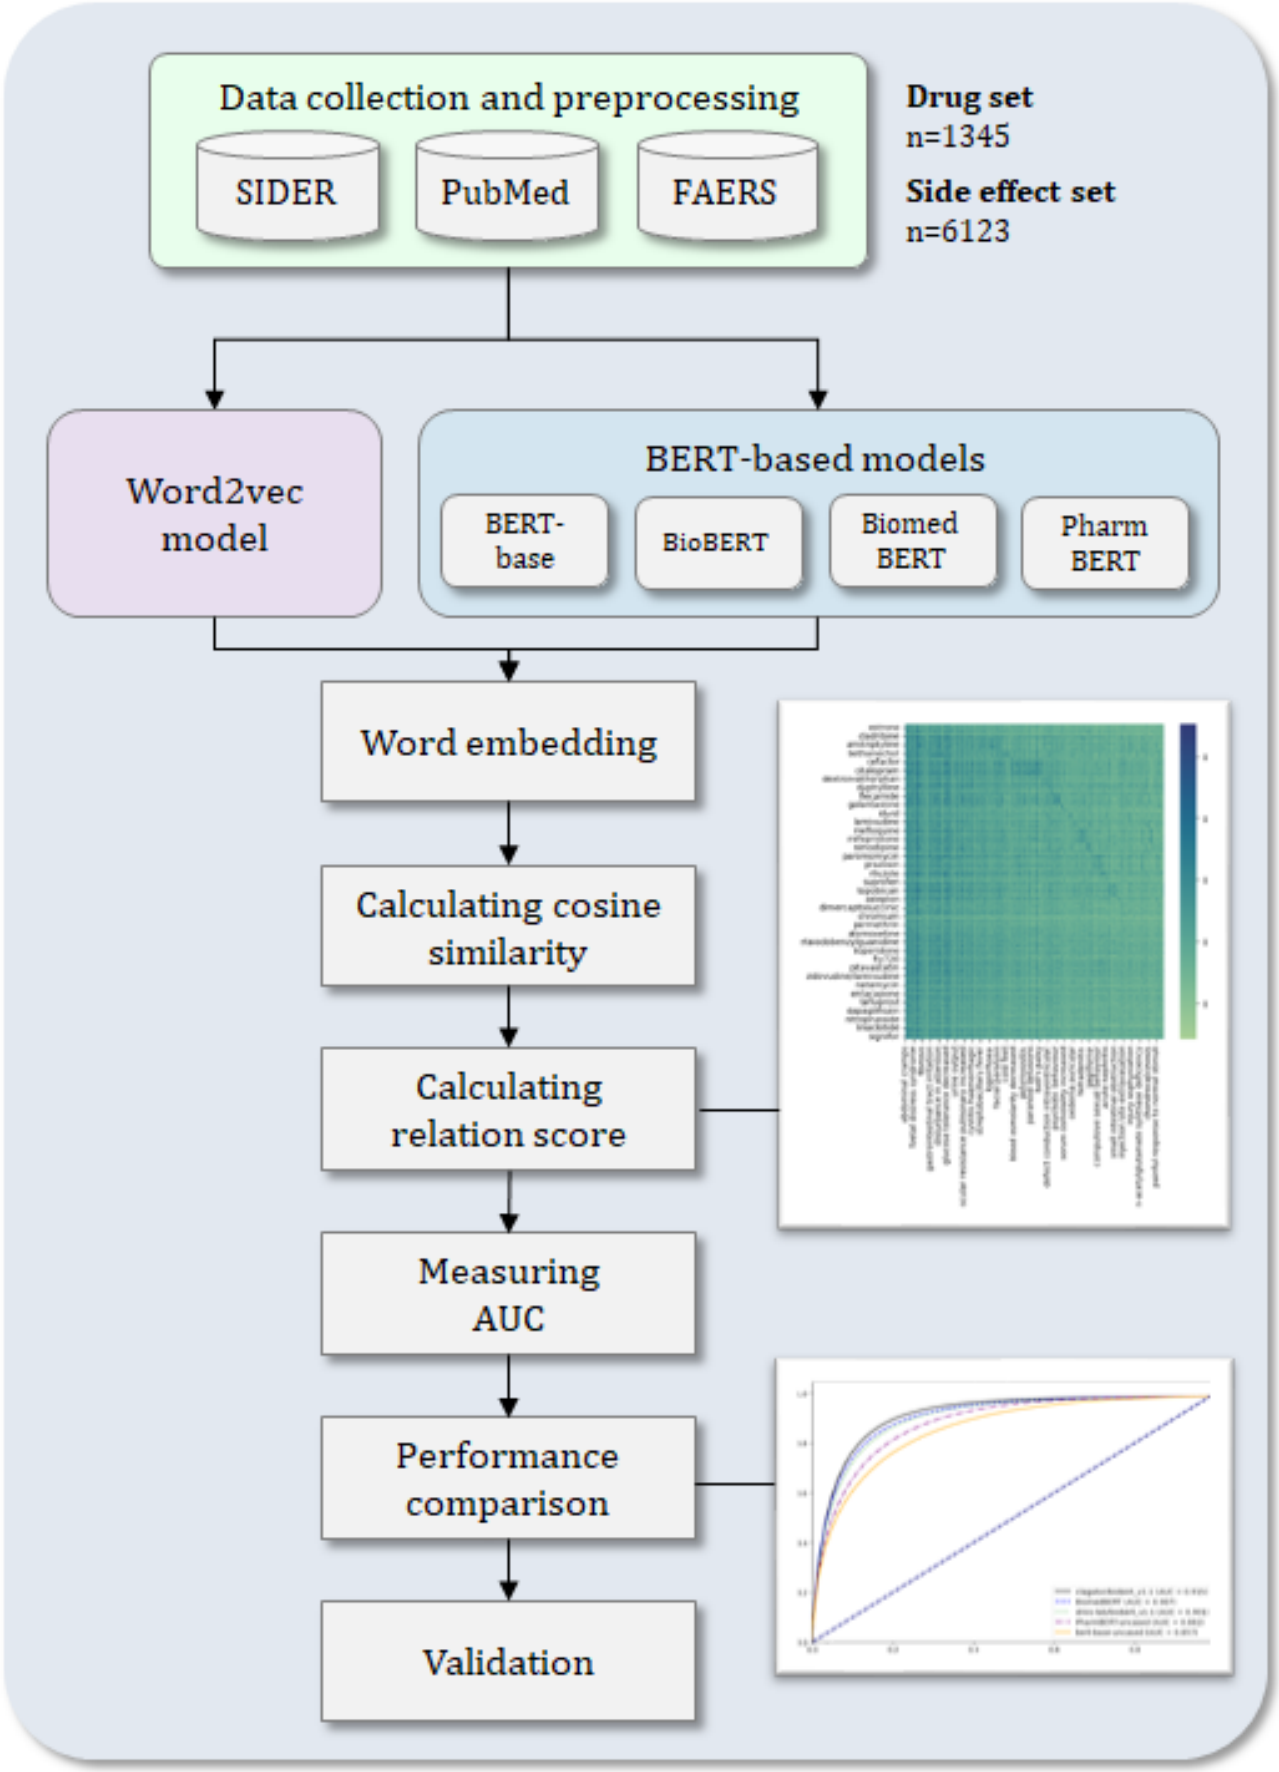
An adverse drug reaction (ADR) is a harmful, unintended reaction that occurs despite the proper use of medication [1]. In addition to causing serious health problems, ADRs are known to be one of the leading causes of prolonged patient hospitalization and increased health care spending [2]. Approximately 2 million cases of serious ADRs are reported annually in the United States, resulting in 100,000 deaths [3]. Therefore, early prediction and prevention of ADRs during drug development is a critical challenge for patient safety and public health.

Traditionally, ADR prediction has been based on approaches that analyze the chemical structure, mechanism of action, and pharmacokinetic properties of drugs [4]. Subsequently, ADR prediction methodologies using machine learning techniques have been developed [5-7], and with advances in natural language processing (NLP) techniques, attempts have been made to automatically extract and predict drug-side effect relationships from vast amounts of biomedical literature data [8-10]. The prediction of ADRs using these techniques is accelerating, especially with the advent of word embedding methods such as Word2Vec [11], which can effectively vectorize semantic information embedded in textual data [12,13].

However, biomedical text data are characterized by a much more specialized and complex set of terms and concepts compared with the general literature, and the interactions between them are also highly diverse and dynamic [14]. In fact, it has been pointed out that traditional word embedding models such as Word2Vec, which do not consider contextual information, do not sufficiently represent the relationships between complex biomedical concepts [15,16]. Therefore, models that do not adequately reflect domain specificity are limited in their ability to accurately capture drug–side effect relationships.

One solution to this problem is to use language models based on Bidirectional Encoder Representations from Transformers (BERT) [17] to perform word embedding. BERT is a language model based on the transformer [18] architecture, which has recently gained attention; unlike traditional one-way language models, it has richer language expressiveness by learning context in both directions. In addition, because we trained on large corpora, domain-specific pretrained models using large biomedical corpora can fully reflect the domain specificity of the biomedical text data [19-22]. Recently, several BERT-based models have been proposed that use large biomedical corpora such as PubMed and PMC for domain-specific pretraining. Examples include BioBERT [19], BioMedBERT [20], and PharmBERT [23], which have demonstrated high performances in various bio-NLP tasks.

BERT models and BERT-based models pretrained on biomedical corpora have demonstrated high performance in ADR-related studies [22,24-27]. However, there is a lack of research leveraging these models to predict previously unknown drug–side effect relationships. Therefore, this study aims to use a biomedical domain-specific BERT language model based on the ADR prediction relation score methodology proposed by Seungsoo et al [12]. Specifically, we calculate the similarity between embedding vectors of known drug–side effect relationships and derive promising candidates for potential relationships. In other words, our objective is to efficiently identify drug–side effect relationships whose causal associations have not yet been clearly established, by computing relation scores from biomedical language model embeddings grounded in known relationships. Furthermore, we examine whether replacing the Word2Vec model with a BERT-based model leads to an actual improvement in ADR prediction accuracy, thus validating the performance advantages of context-dependent language models.



Methods

System Overview

Figure 1 presents an overview of this study and illustrates the overall research flow from data collection to validation.

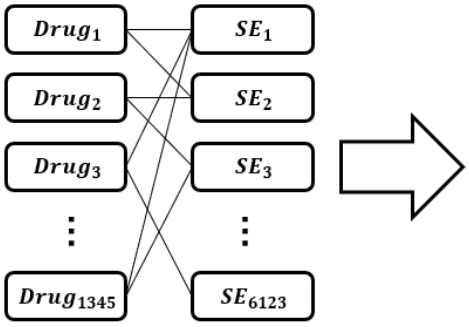
Figure 1. System overview: the predictive performance of drug-side effect relationships was evaluated using area under the curve. AUC: area under the curve; BERT: Bidirectional Encoder Representations from Transformers; FAERS: FDA (Food and Drug Administration) Adverse Event Reporting System; SIDER: side effect resource.

XSL•FO
RenderX

First, we collected and refined the data for this study from the Side Effect Resource (SIDER), PubMed, and the FDA Adverse Event Reporting System (FAERS). From the abstract sentences collected from PubMed, we selectively extracted only sentences containing drugs and side effects mentioned in SIDER. These extracted sentences were used to train a Word2Vec model, from which embedding vectors for drugs and side effects were derived. Based on the drug–side effect relationships in SIDER, BERT-based models were used to derive the embedding vectors of drugs and side effects.



Based on the derived embedding vectors, the cosine similarity between the drug and side effect pairs was calculated. Using the cosine similarity of drug and side effect pairs and existing known drug–side effect relationships, a relation score was calculated for all drug–side effect combinations. Drug–side effect combinations with high relation scores were predicted to have a higher likelihood of being actually related [12]. To evaluate the accuracy of these predictions, we calculated area under the curve (AUC) values and compared the results of the Word2Vec model pipeline with those of the BERT-based model pipeline. Statistical significance between predicted results and FAERS was assessed using the Fisher exact test.

Data Collection and Preprocessing

SIDER is a database that provides information on marketed drugs and their side effects [28]. The drug names recorded in SIDER followed those approved by the Food and Drug Administration (FDA), and side effect names used the Medical Dictionary for Regulatory Activities (MedDRA) terminology [29]. To minimize data leakage that could occur from the same drug being listed under different names, we collected and integrated synonyms for each drug using PubChem compound identifiers provided by SIDER. We also ensured terminology standardization through MedDRA-based side effect names.

Using version 4.1 of SIDER, we collected 158,096 unique pairs of drug–side effect relationships after removing duplicates. To use these 158,096 pairs as input values in the BERT-based models and for relation score calculations, we derived an adjacency matrix with drugs as rows and side effects as columns (Figure 2). In addition, 1345 drug names and 6123 side effect terms that appeared in the collected drug–side effect relationships were extracted and used as dictionaries for drugs and side effects.

Figure 2. Drug-SE adjacency matrix. This is a method to derive an adjacency matrix using drug–side effect relationships in the side effect resource. The relation R has the value of 1 if the drug–side effect relationship exists and 0 if it does not. SE: side effect.

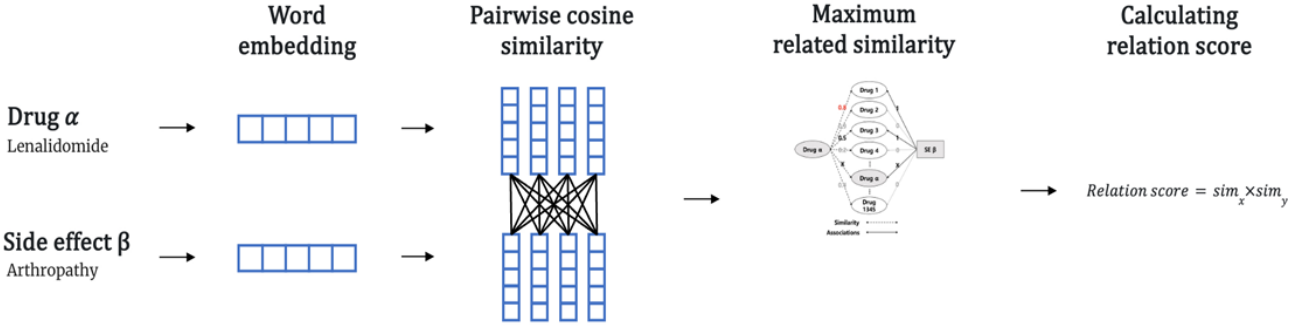
	SE_1	SE_2	SE_3	SE_4	⋯	SE_{6123}
$Drug_1$	$R_{1,1}$	$R_{1,2}$	$R_{1,3}$	$R_{1,4}$	⋯	$R_{1,6123}$
$Drug_2$	$R_{2,1}$	$R_{2,2}$	$R_{2,3}$	$R_{2,4}$	⋯	$R_{2,6123}$
$Drug_3$	$R_{3,1}$	$R_{3,2}$	$R_{3,3}$	$R_{3,4}$	⋯	$R_{3,6123}$
$Drug_4$	$R_{4,1}$	$R_{4,2}$	$R_{4,3}$	$R_{4,4}$	⋯	$R_{4,6123}$
⋯	⋯	⋯	⋯	⋯	⋯	⋯
$Drug_{1345}$	$R_{1345,1}$	$R_{1345,2}$	$R_{1345,3}$	$R_{1345,4}$	⋯	$R_{1345,6123}$

We collected biomedical literature from PubMed, a biological literature database [30]. A total of 42,515,246 paper abstracts updated on December 8, 2022, were collected, and for training the Word2Vec model, only sentences in which the drugs and side effects mentioned in SIDER were mentioned at least once were extracted [12]. There were 14,289,160 sentences in which a drug was mentioned at least once and 32,107,327 sentences in which a side effect was mentioned at least once.

Calculating Cosine Similarity

For the 1345 drugs and 6123 side effects recorded in the adjacency matrix, we performed word embedding using BERT-based models and calculated the cosine similarity for all drug and side effect vector pairs. In this case, the cosine similarity is calculated using equation (1).

$$\text{CosineSimilarity}=A\cdot B/\|A\|\ \|B\|=\sum_{i=1}^{n}A_i\times B_i/\sqrt{\sum_{i=1}^{n}(A_i)^2}\times\sqrt{\sum_{i=1}^{n}(B_i)^2} \quad (1)$$



This process yielded 1,809,025 drug vector pairwise similarities and 37,491,129 side effect vector pairwise similarities.

Calculating Relation Score

Figure 3 shows the process of calculating the relation score. For all drug–side effect pairs embedded as vectors, the cosine similarity values obtained in the previous step were used to calculate the drug–side effect's relation score. The process of calculating the relation score between a specific $Drug_{\alpha}$ and a specific side effect SE_{β} was done using equations (2) to (6).

XSL•FO
RenderX

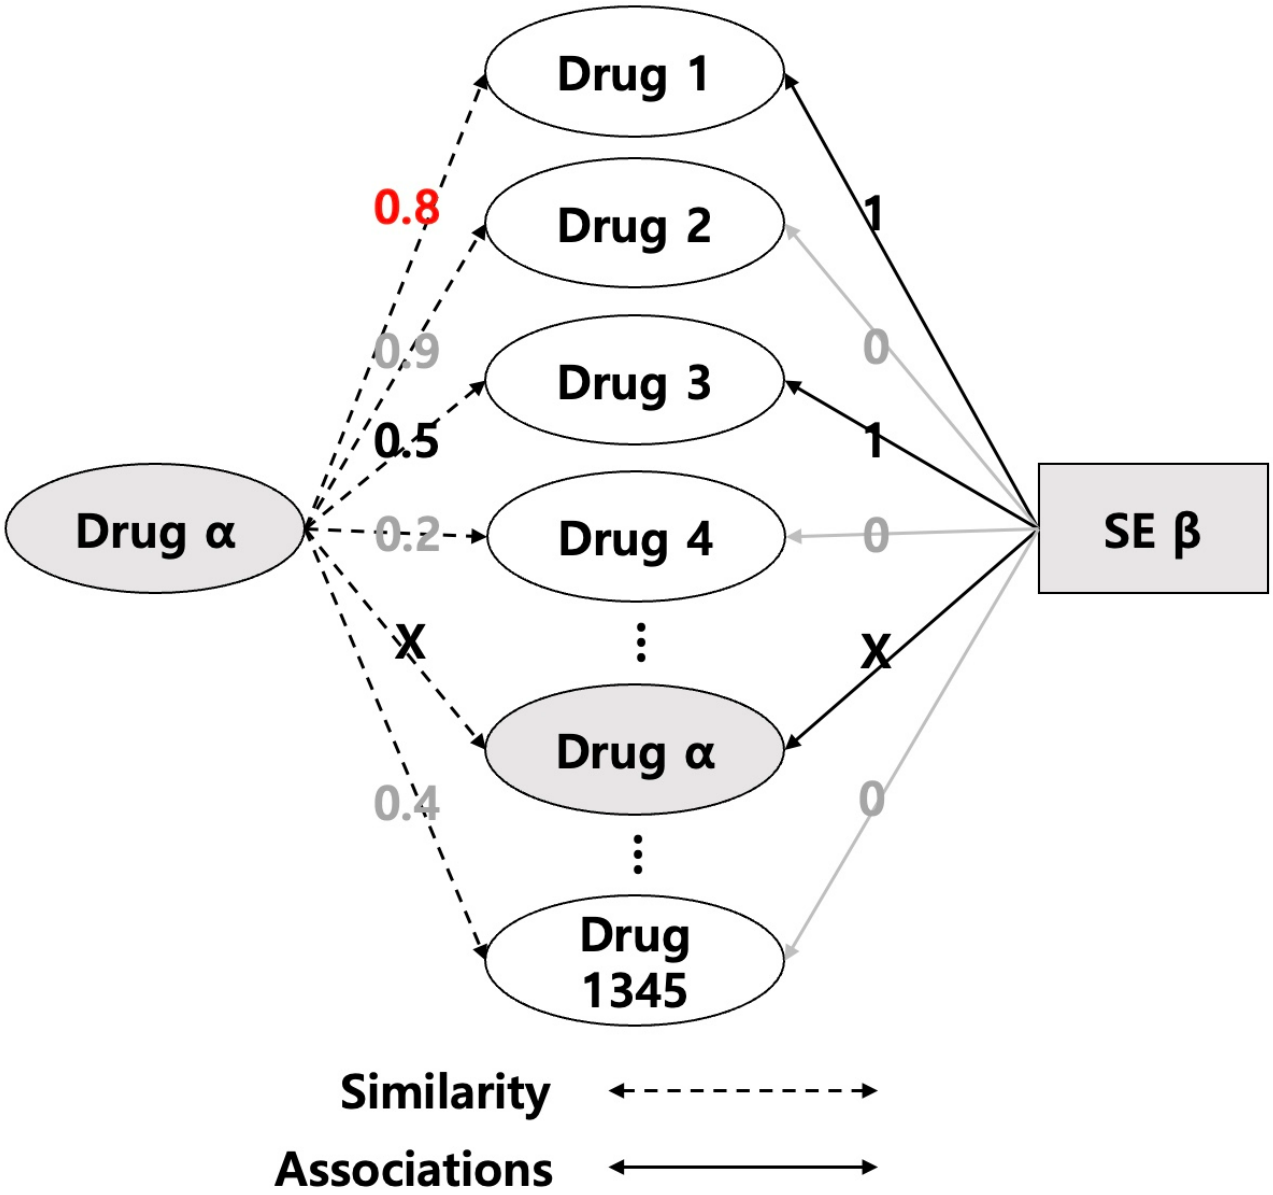
Figure 3. Illustration of the computation of the relation score between a specific $Drug_{\alpha}$ and a specific side effect SE_{β}.

$$si\ mx=max\{\sim(Da,Di)\vee Di \in RelatedDrugs\} \quad (2)$$

$$RelatedDrugs=\{Di\vee Adjacency(SE\beta,Di)=1\ for\ i=1,2,...,1345\} \quad (3)$$

$$si\ my=max\{\sim(S\ E\beta,S\ Ei)\vee S\ E\ i\ \in RelatedSE\} \quad (4)$$

$$RelatedSE=\{S\ Ei\vee Adjacency\ (Da,S\ Ei)=1\ for\ i=1,2,...,6123\} \quad (5)$$



$$Relation\ score=si\ mx\times si\ my \quad (6)$$

Similarity sim_x takes the maximum of the similarity values of $Drug_{\alpha}$ with Drug D_i in $Related_{Drugs}$, the set of drugs known to be associated with side effect SE_{β}, using equation (2). The set $Related_{Drugs}$ is obtained using equation (3), and by referring to the values in the adjacency matrix consisting of 1345 drugs and 6123 side effects, we construct the set of drugs associated with that side effect by including in the set $Related_{Drugs}$ those drugs that have side effect SE, and a value of 1 in the adjacency matrix, out of a total of 1345 drugs. In other words, the highest similarity value to drugs known to be associated with side effect SE is called similarity sim_x.

Figure 4 shows the process of obtaining similarity sim_x using equation (2) and equation (3). Based on the values in the adjacency matrix, the computational process was to maximize the similarity of only those drugs that were related to the side effect SE out of the total 1345 drugs. If $Drug_{\alpha}$ is in the $Related_{Drugs}$ set, exclude $Drug_{\alpha}$ from the similarity calculation.

XSL•FO
RenderX

Figure 4. Process of calculating similarity sim_X. SE: side effect.

Similarity sim_y uses equation (4) to take the maximum of the similarity values of side effects SE_β and SE_i in $Related_{SE}$, a set of side effects known to be related to the $Drug_\alpha$. The set $Related_{SE}$ is obtained using equation (5), and by referring to the values of the adjacency matrix mentioned above, we construct the set of side effects associated with the $Drug_\alpha$ out of the total 6123 side effects by including in the set $Related_{SE}$ the drugs that have a value of 1 in the adjacency matrix with the $Drug_\alpha$. In other words, the highest similarity value to the side effects that are known to be related to the drug is called the similarity sim_y.

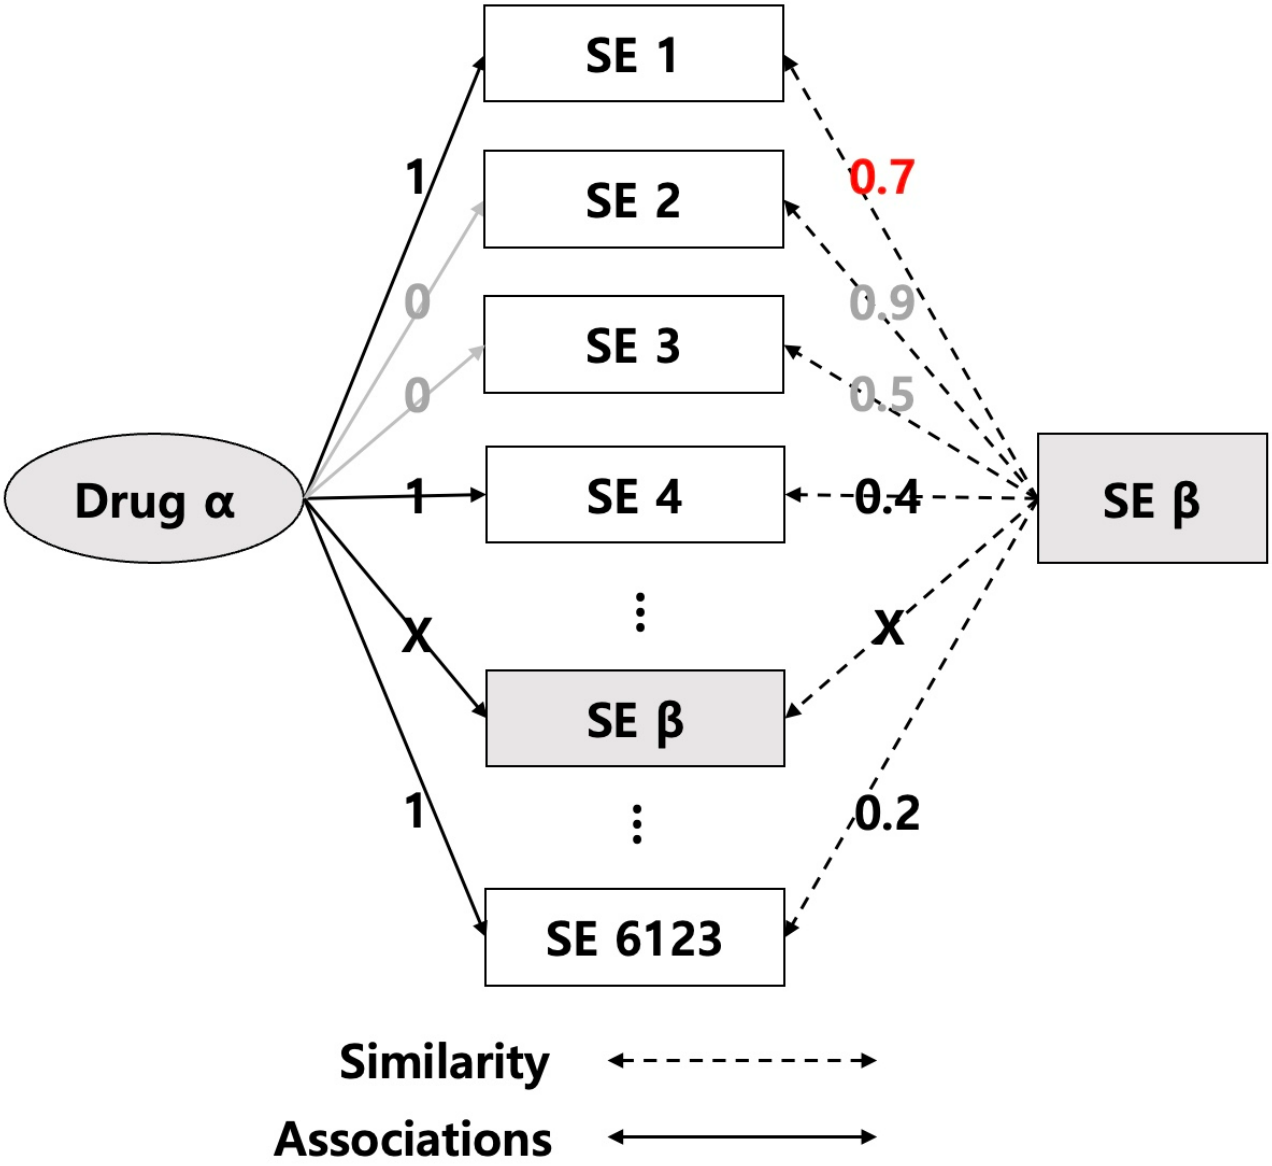


Figure 5 shows the process of obtaining similarity sim_y using equation (4) and equation (5). Based on the values in the adjacency matrix, the computational process is to extract the similarity of only the side effects that are related to the $Drug_\alpha$, out of the total 6123 side effects, and take the maximum value. If an SE_β belongs to the $Related_{SE}$ set, exclude the SE_β from the similarity calculation.

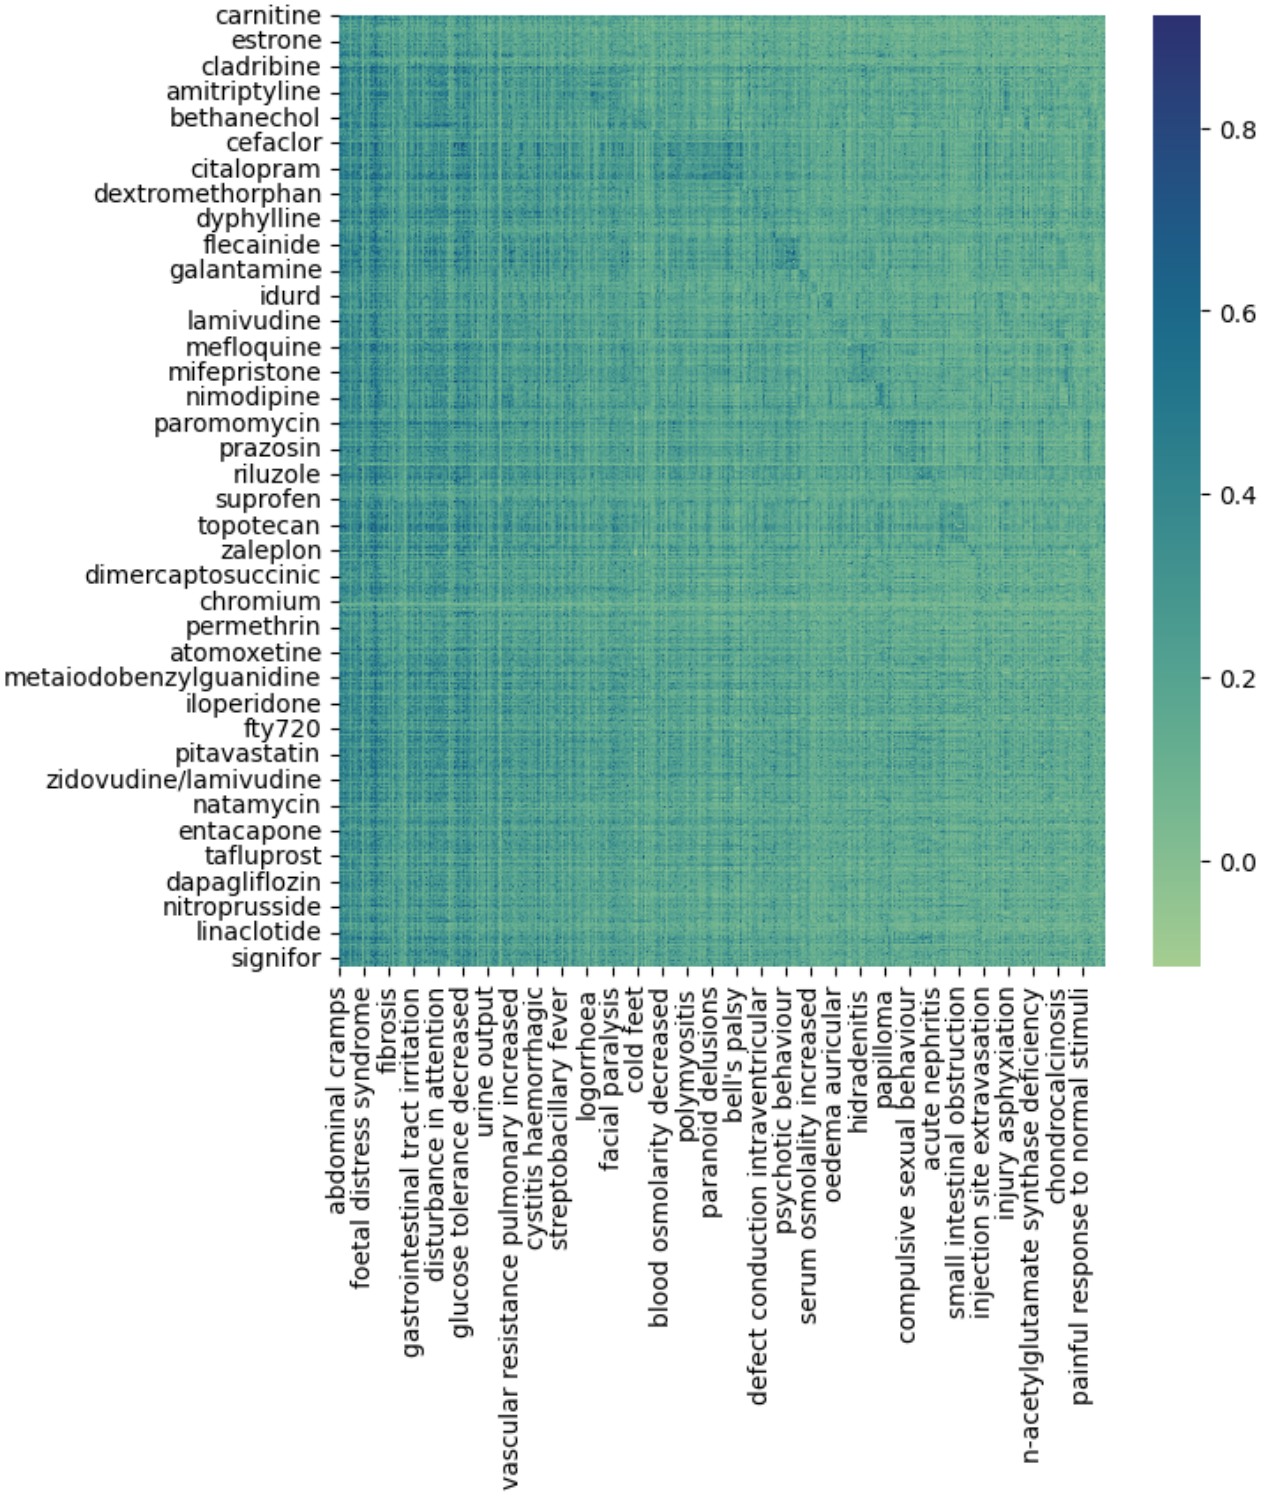
Finally, the relation score between Drug and SE was obtained by multiplying sim_x and sim_y as shown in equation (6).

We applied the above calculation method to 1345 drugs and 6123 side effects to calculate the relation scores for all drug–side effect pairs, resulting in a total of 8,235,435 drug–side effect pairs. Figure 6 illustrates the heatmap of the calculated relation scores.



XSL•FO
RenderX

Figure 5. Process of calculating similarity sim_y. SE: side effect.

Measuring AUC

In this study, AUC values were measured using 158,096 known drug–side effect relationships provided by SIDER to evaluate the accuracy of predicting relationships based on scores calculated for a total of 8,235,435 drug–side effect pairs. Of the 8,235,435 calculated drug–side effect pairs, we assigned a class value of true to pairs that belonged to known drug–side effect relationships in SIDER and false to pairs that did not. All drug–side effect pairs were sorted by score, and a single receiver operating characteristic curve was calculated. The generated receiver operating characteristic curves and AUC values were used to establish the optimal threshold for predicting whether a drug–side effect pair had a true relationship. If the drug–side effect relation score exceeds this diagnostic threshold, it is predicted that there is a relationship between the drug and the side effect [12].

RenderX

Ethical Considerations

This study uses the publicly accessible and anonymized SIDER and FAERS databases, which contain no personally identifiable information and do not involve human participant experimentation. Therefore, institutional review board approval is not required for this study.

Results

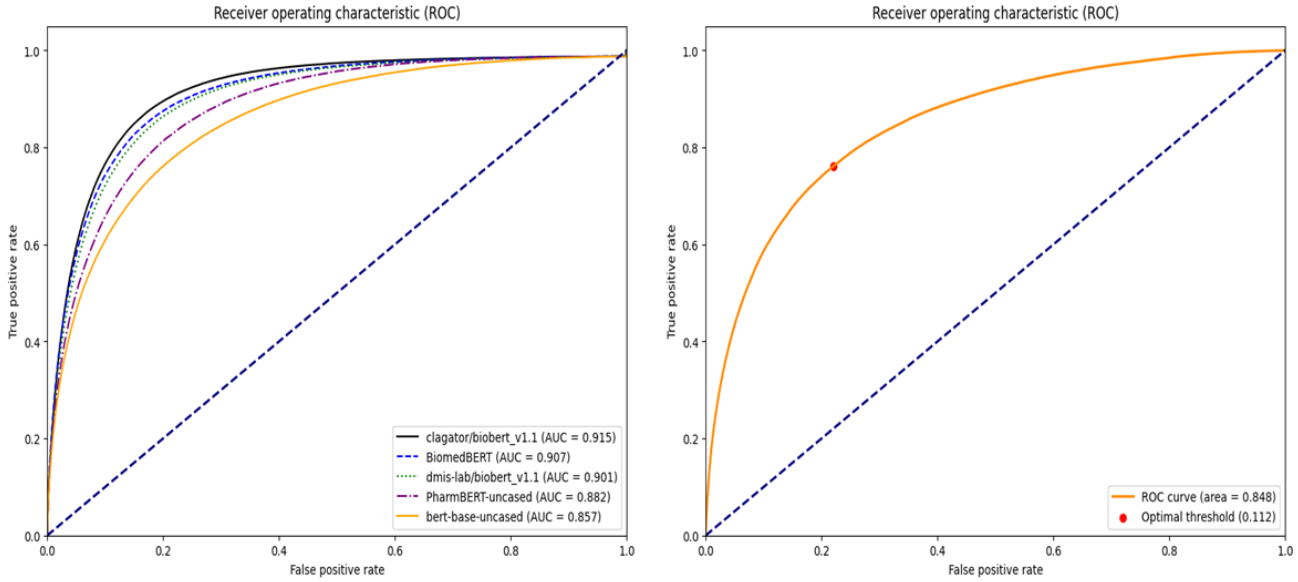
Performance Comparison

The AUCs of the BERT-based models and the Word2Vec model using the proposed method are compared in Table 1 and Figure 7. The optimal threshold for prediction was set as the point at which the sum of the sensitivity and specificity was maximized. The models used in this study included clagator/biobert_v1.1 [31], BiomedBERT [20], dmis-lab/biobert_v1.1 [19], PharmBERT-uncased [23], bert-base-uncased [17], and Word2Vec [11]. dmis-lab/biobert-v1.1 is the original BioBERT model pretrained on biomedical text, while clagator/biobert_v1.1 is a model based on it, which has been additionally fine-tuned on natural language inference and semantic textual similarity tasks to enhance its ability to recognize semantic relationships.

Table . Performance comparison of Bidirectional Encoder Representations from Transformers (BERT)–based models and Word2Vec model.

Model	AUC[a]	Optimal threshold	Sensitivity	Specificity
clagator/biobert_v1.1	0.915[b]	0.289	0.870	0.830
BiomedBERT[c]	0.907	0.925	0.857	0.821
dmis-lab/biobert_v1.1	0.901	0.780	0.851	0.814
PharmBERT-uncased	0.882	0.460	0.817	0.796
bert-base-uncased[d]	0.857	0.617	0.769	0.793
Word2Vec	0.848[e]	0.112	0.762	0.780

[a]AUC: area under the curve.



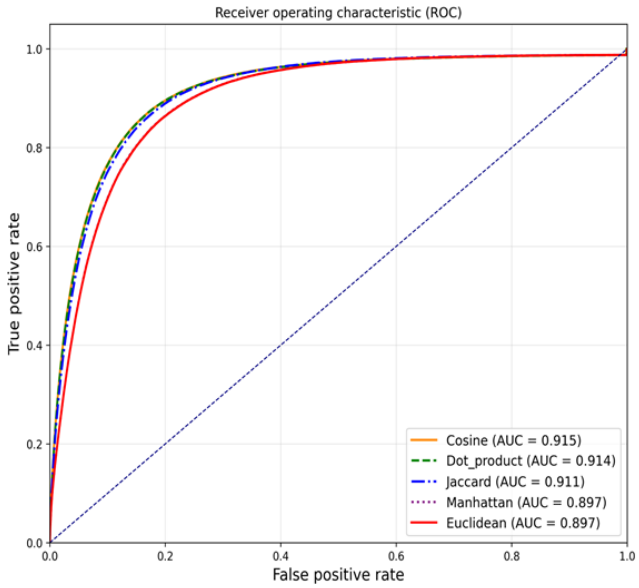
[b]Highest value.

[c]The old model was named PubMedBERT.

[d]Vanilla BERT model.

[e]Lowest value.

Figure 7. Receiver operating characteristic curves for Bidirectional Encoder Representations from Transformers (BERT)–based models (left) and Word2Vec model (right). AUC: area under the curve.



The clagator/biobert _v1.1 model achieved the highest AUC value of 0.915 at an optimal threshold of 0.289. In contrast, the bert-base-uncased model, a vanilla BERT model pretrained on general corpora, showed an AUC of 0.857 at an optimal threshold of 0.617. In other words, BERT pretrained on the biomedical corpus outperformed vanilla BERT. In addition, the Word2Vec model recorded an AUC of 0.848, which was lower than those of the BERT-based models and was the lowest among all models used in this study.

Figure 8 (left) shows the performance comparison results to evaluate the effectiveness of the cosine similarity-based extraction approach. The comparison was conducted using the clagator/biobert_v1.1 model, which achieved the highest

XSL•FO
RenderX

performance. Other vector similarity-based extraction methods used for comparison included Euclidean distance, Manhattan distance, Jaccard similarity, and dot product. The results demonstrate that the cosine similarity-based relation extraction method used in this study exhibited the highest performance with an AUC of 0.915, outperforming all other methods.

Figure 8. Receiver operating characteristic curves for comparing vector similarity metrics (left) and evaluating the efficacy of our dual-similarity approach (right). AUC: area under the curve.

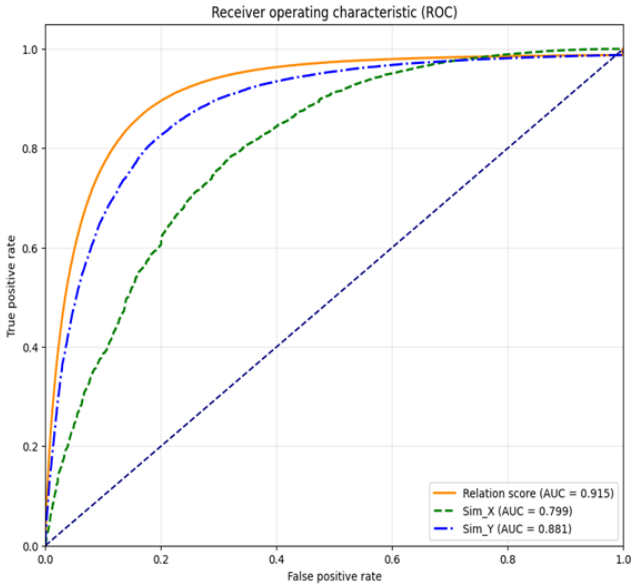


Figure 8 (right) evaluates the effectiveness of our dual-similarity approach against single-similarity methods. Using the same clagator/biobert_v1.1 model, we compared 3 extraction strategies: using only drug similarity information (Sim_X), using only side effect similarity information (Sim_Y), and our dual-similarity approach (relation score). Our dual-similarity approach significantly outperformed single-similarity methods with an AUC of 0.915 compared with 0.799 and 0.881, demonstrating the effectiveness of leveraging information from both similarity perspectives.

Validation

To validate the similarity between drug–side effect relationships predicted by our model based on SIDER data and relationships derived from FAERS data, we extracted drug–side effect relationships from FAERS, a database not used in our Methods. FAERS is a database containing adverse event information for drugs submitted to the FDA [32]. In this study, we used FAERS data from October 2012 to June 2023. By leveraging the list of 1345 drugs and 6123 side effects registered in SIDER to extract relationships from FAERS data, we obtained a total of 901,361 known relationships.

For validation, we used the results from clagator/biobert_v1.1 [31], which performed best in our study. We constructed a contingency table using the predicted results based on relation scores from 8,235,435 drug–side effect pairs, along with 901,361 known drug–side effect relationships and unknown relationships extracted from FAERS. However, due to the data imbalance where unknown relationships outnumbered known relationships, we randomly sampled unknown relationships to match the number of known relationships. Based on this selected list of drug–side effect pairs, we conducted the Fisher exact test between FAERS data and our study's predictions, repeating this process 2000 times and calculating the average of all results. The results showed a P value of $P<.001$, confirming that the drug–side effect relationships predicted in our study were statistically significant.

Furthermore, the odds ratio, calculated as the ratio of the odds of an event occurring to the odds of it not occurring, was 4.822. This means that the odds of our model predicting a relationship for known relationships in FAERS were 4.822 times higher than the odds of predicting a relationship for unknown relationships. In other words, relationships reported in FAERS were significantly more likely to be predicted as related by our model, demonstrating that our model's predictions are reliable when compared with external data.

To validate the utility of our model's predictions, we conducted case studies on drug–side effect relationships not present in the SIDER database that were ranked within the top 1000 according to relation scores calculated by our model. For these candidates, we performed literature searches using Google Scholar and verified whether these relationships had been mentioned in case reports or research [33]. In addition, following the input from an author specializing in pharmacoepidemiology, we excluded steroid-class drugs that are used despite their side effects from a clinical utility perspective, thereby enhancing the reliability of our ability to detect meaningful signals in actual clinical environments. Table 2 illustrates the cases of lenalidomide-arthropathy, rosuvastatin-sleep disturbance, gadolinium-acute pulmonary edema, and cefazolin-hepatic failure. Upon conducting a literature review of the drug–side effect relationships presented in Table 2, we confirmed that these associations were reported in research findings published after 2016 [34-37].

XSL•FO
RenderX

Table . Case studies of model predictions.

Drug α	Side effect β	Similarity *x*	Similarity *y*	Relation score	Model prediction
Lenalidomide	Arthropathy	0.953	0.837	0.799	True
Rosuvastatin	Sleep disturbance	0.952	0.825	0.786	True
Gadolinium	Acute pulmonary edema	0.891	0.866	0.771	True
Cefazolin	Hepatic failure	0.861	0.857	0.738	True

Discussion

Principal Findings

In this study, we propose a method to extract information about drug–side effect relationships inherent in the pre–trained parameters of language models and predict relation scores, indicating the possibility of unknown drug–side effect relationships. This is accomplished using known drug–side effect relationship data and embedding vectors from language models trained on biomedical corpora.

Our study confirmed that BERT-based models demonstrated superior performance in predicting drug–side effect relationships. We evaluated the performance of BERT-based models using the relation score methodology proposed by Seungsoo et al [12], and the clagator/biobert_v1.1 model [31] achieved the highest performance with an AUC of 0.915 at an optimal threshold of 0.289. This suggests that BERT-based models perform better in predicting drug–side effect relationships compared to the 0.85 AUC achieved by the Word2Vec model in a previous study. Therefore, our findings support the notion that context-aware BERT-based models outperform context-independent Word2Vec models in terms of embedding performance [38].

In addition, our study demonstrates that BERT models pretrained on biomedical corpora outperform vanilla BERT models pretrained on general corpora. Vanilla BERT models, trained on general corpora, have limitations in fully reflecting the specificity of the biomedical field [20]. In contrast, BERT-based models pretrained on large biomedical corpora, such as PubMed and PMC, more richly reflect drug mechanisms of action and biological relationships observed in clinical settings [19-21]. The results of this study demonstrate that BERT models specialized for biomedical applications can provide more accurate drug–side effect relationship predictions based on a deeper understanding of the domain. This aligns with previous studies that emphasize the importance of domain-specific models in BERT model applications [19,23,39]. While this study evaluated the effectiveness of the proposed extraction method using BERT-based models, considering the rapid advancements in the field of NLP, models with different architectures or more recent models have the potential to understand the complexity of relationships more effectively and provide further performance improvements.

We performed external validation using FAERS data and found a high statistical significance (P<.001) between 8,235,435 predicted drug–side effect relationships and 901,361 actual data extracted from FAERS. In addition, to verify the real-world applicability of the model's predicted results, we conducted case studies on drug–side effect relationships that were not confirmed in the SIDER database. We found that these drug–side effect relationships have been reported in recent research findings published after 2016. This suggests that our methodology using the BERT-based model proposed in this study is applicable to the prediction of ADRs in practice. Considering this, we expect that our proposed methodology will allow for earlier detection of potential ADRs, increasing the likelihood of success in the drug development process and reducing the time and cost of ADR studies.

In the field of biomedical NLP, standardized terminology systems and synonym processing are important [15,40]. In this study, we minimized the risk of data leakage by integrating drug synonyms using PubChem compound identifiers. We used MedDRA-based side effect names to ensure terminology standardization and reduce the likelihood of the model merely reidentifying variations of known relationships. However, we have not explicitly integrated the hierarchical information from MedDRA, and in future research, we plan to enhance our methodology by actively using MedDRA hierarchical information to integrate similar terms, further mitigating the reidentification issue.

In this study, we recognize that non–dose-dependent adverse reactions present particular challenges for prediction models, and drug similarity may not necessarily be the main component in the development of such ADRs. While our dual-similarity approach partially addresses this by incorporating adverse event similarity patterns, future research would benefit from integrating NLP-based approaches with the chemical structure and mechanism of action of drugs. This multimodal approach would leverage literature-derived contextual relationships, molecular properties, and biological pathway insights to more accurately classify drug–side effect relationships and would be particularly valuable for addressing current methodological limitations, including novel compound prediction and idiosyncratic reaction detection.

Limitations

One of the primary limitations of this study is the lack of up-to-date data in the drug–side effect database used. The SIDER database was last updated in 2015, meaning that despite using BERT-based models trained on the latest biomedical corpus, our prediction process may not fully reflect current drug–side effect relationships. Consequently, incorporating more recent drug–side effect data would likely improve the performance of our prediction model significantly.

XSL•FO
RenderX

Another significant limitation relates to the nature of case reports themselves. Such reports typically rely on a single clinically reported case, thereby making it difficult to establish clear causal relationships between drugs and side effects. In addition, their small sample sizes often limit their generalizability. These considerations become particularly relevant when extending our work to clinical applications, where patient care involves complex interactions of multiple factors, including diverse reporting patterns and polypharmacy. Although our model provides a systematic method for prioritizing potential associations for further investigation, all predictions should therefore be interpreted with appropriate caution and validated through additional pharmacovigilance methods before clinical application. For this reason, future research should utilize systematic clinical data or large-scale cohort studies to enhance the reliability of predictive models.

Furthermore, while our approach shows promise for identifying potential drug–side effect relationships through vector space similarities, we recognize 2 additional important limitations. First, the current methodology provides generalized, population-level predictions and does not account for idiosyncratic reactions dependent on individual patient factors. As such, future work should explore integrating patient-specific data to enable more personalized adverse event predictions. Second, for entirely novel drug candidates absent from existing literature, the embedding vectors generated would be based primarily on semantic inference rather than established knowledge, potentially limiting prediction reliability. This underscores the importance of complementary approaches, particularly for new chemical entities.

Conclusions

This study presents a novel approach for extracting drug–side effect relationship information embedded within pretrained language model parameters and leveraging this information to predict unknown adverse reactions. Our methodology, using context-aware BERT-based language models, demonstrates that BERT models pretrained on biomedical corpora outperform vanilla BERT and Word2Vec. These results highlight how the contextual embedding capabilities of BERT architectures, coupled with domain-specific adaptation, enhance predictive performance in drug–side effect relationship tasks. Furthermore, external validation using FAERS data and a literature review of selected cases confirmed the practical applicability of the proposed methodology.

Abstract

Background: Standardized registries, such as the *International Classification of Diseases* (*ICD*) codes, are commonly built using administrative codes assigned to patient encounters. However, patients with fall injury are often coded using subsequent injury codes, such as hip fractures. This necessitates manual screening to ensure the accuracy of data registries.

Objective: This study aimed to automate the extraction of fall incidents and mechanisms using natural language processing (NLP) and compare this approach with the *ICD* method.

Methods: Clinical notes for patients with fall-induced hip fractures were retrospectively reviewed by medical experts. Fall incidences were detected, annotated, and classified among patients who had a fall-induced hip fracture (case group). The control group included patients with hip fractures without any evidence of falls. NLP models were developed using the annotated notes of the study groups to fulfill two separate tasks: fall occurrence detection and fall mechanism classification. The performances of the models were compared using accuracy, sensitivity, specificity, positive predictive value, negative predictive value, F_1-score, and area under the receiver operating characteristic curve.

Results: A total of 1769 clinical notes were included in the final analysis for the fall occurrence task, and 783 clinical notes were analyzed for the fall mechanism classification task. The highest F_1-score using NLP for fall occurrence was 0.97 (specificity=0.96; sensitivity=0.97), and for fall mechanism classification was 0.61 (specificity=0.56; sensitivity=0.62). Natural language processing could detect up to 98% of the fall occurrences and 65% of the fall mechanisms accurately, compared to 26% and 12%, respectively, by *ICD* codes.

Conclusions: Our findings showed promising performance with higher accuracy of NLP algorithms compared to the conventional method for detecting fall occurrence and mechanism in developing disease registries using clinical notes. Our approach can be introduced to other registries that are based on large data and are in need of accurate annotation and classification.

Introduction

With 3 million emergency room visits, 300,000 hospitalizations, and 30,000 fatalities annually, falls pose a major threat to public health [1,2]. The financial impact is also substantial, with an estimated US $50 billion medical expenses for nonfatal falls [3]. Therefore, researching and understanding the nature of falls and fall-related injuries are crucial for developing effective

XSL•FO
RenderX

prevention and treatment strategies as populations age [4]. Given the multifactorial nature of falls and the difficulties involved in conducting prospective research in the field, developing fall registries comprised of large and accurate medical data is very important [5,6]. Standardized registries are commonly built using administrative codes, such as the *International Classification of Diseases* (*ICD*), assigned to patient encounters, and Current Procedural Terminology (CPT) codes[7]. Previous studies have used these codes to extract patients with a history of falls [8-10]. However, this method has limitations that may lead to an underestimation of actual fall frequency and might not reveal the history of falls in patients [11]. Reporting falls using the External Causes of Morbidity codes is usually recommended but not mandatory in all health care settings. Since falls are not typically considered stand-alone conditions, many health care providers may rather use the diagnosis *ICD* codes and assign codes to the end result of a fall, for example, a hip fracture, rather than the fall itself [12,13]. This makes it difficult for investigators to identify falls in the patient's medical history and the true frequency of falls within populations. Given these limitations, clinical notes were suggested as a more reliable method of detecting falls, fall mechanisms, and fall-induced injuries [14]. This process, however, is expert-dependent and time-consuming, particularly if the dataset is large. To address these obstacles, natural language processing (NLP), which combines computational linguistics and deep learning models to process narrative data, can be used to automate the review process of clinical notes to detect falls [14].

Several studies have demonstrated the capability of supervised models to detect fall incidents, which have been documented in clinical notes [15-17]. Although these models are effective at identifying fall events, they fall short of providing detailed insights into fall-related *ICD* codes that capture the specific mechanisms (eg, how the fall occurred) or the physical consequences (eg, the force of the impact) [11]. Gaining a better understanding of these factors is essential for designing strategies to prevent falls since individuals who experience severe or high-impact falls often face a higher risk of recurrent falls and injuries [9,18]. Tremblay et al [11] highlighted the importance of studying fall mechanisms as a research priority. However, automated methods for extracting detailed fall mechanisms and their impact from clinical notes remain largely unexplored in the current literature.

This study aimed to assess the performance of NLP algorithms compared to conventional methods for detecting fall incidence and the mechanism of falls obtained from clinical notes of patients with hip fractures. We hypothesize that NLP algorithms outperform fall ICD codes in detecting falls and their mechanisms in patients with hip fractures.

Methods

Study Design and Cohort

A retrospective case-control study was conducted, including the data from 4 tertiary hospitals in Greater Boston, Massachusetts. Data were retrieved from the institution's data repository using CPT codes for hip fractures (27125, 27130, 27226, 27228, 27235, 27236, 27244, 27245, and 27248) between January 2010 and December 2019.

Patients ≥18 years old who were hospitalized because of hip fracture as a result of an outpatient fall (cases) or other reasons (controls) were included in the study. Falls resulting from violent encounters, animal attacks, significant external forces such as car or motor vehicle accidents, high-impact sports like skiing, and fractures caused by underlying pathological conditions were excluded to reduce the heterogeneity of fall mechanics. This exclusion helps avoid the influence of confounding injuries that differ significantly from typical accidental falls, ensuring that the study focuses on more clinically relevant fall types (). Given that the majority of hip fractures happen due to falls, we had a reasonable number of patients in the case group and included a single note for each patient. In contrast, multiple notes were reviewed and included per patient in the control group.

Data Labeling

Expert annotations, serving as the ground truth for training the NLP models, were derived directly from clinical notes. The annotations embraced two specific tasks: (1) fall occurrence and (2) mechanism of falls (the way falls happened). One expert orthopedic researcher (AT) conducted the annotations, and the decisions for equivocal or debatable cases were made by a senior scientist (SAE). All clinical notes were evaluated in chronological order, starting from the date of the hip fracture CPT code. The first note documenting a fall was selected for analysis. A fall was defined as "an unintentional event that results in the person coming to rest on the ground or another lower level" [19]. The mechanisms of fall were defined by 3 categories: same level (occurring on the same plane or surface), multilevel (descent from one level to a different one), and unclassified (not classifiable due to lack of sufficient information) [20]. In rare cases, discrepancies between the documented fall mechanisms in the clinical notes and the corresponding fall *ICD* codes compromised the validity of comparisons between *ICD* and NLP-based approaches. Consequently, patients with conflicting information between clinical notes and ICD codes regarding the fall mechanism were excluded to ensure the integrity of the analysis ().

Data Preprocessing

A variety of inpatient unstructured clinical notes, including history and physical examination, discharge summary, progress, operation, and emergency department notes, were obtained. Due to the diverse formatting of these clinical notes, specialized preprocessing methodologies were required, which diverged significantly from the conventional text-processing approaches. Following annotation, the clinical notes underwent various preprocessing steps, including de-identification, segmentation, and cleaning [21]. The specific techniques used in preprocessing, which address the unique challenges posed by the clinical notes' formatting, are outlined in Table 1. Detailed information about the segmentation process is provided in Tables S1 and S2 in Multimedia Appendix 1. This detailed account ensures the data are optimally prepared for the subsequent analytical phases.

XSL•FO
RenderX

Table . An overview of the data preprocessing stages.

Stages	Tool or Method	Purpose	Output
De-identification	• Stanford de-identifier	• Remove personal identifiers to ensure privacy and compliance with data protection regulations. This involves replacing all Protected Health Information entities with synthetic variants to maintain data integrity and eliminate biases. The model chosen was the Stanford-de-identifier-base-model developed by Chambon et al [21], with an F_1-score of 98.9 on the I2b2 2014 test set [22].	Anonymized text ready for analysis.
Segmentation	• Bespoke parser, Finite State Machine, and regular expressions	• Segment notes into distinct sections for enhanced text processing accuracy. The parser identifies section headings and concatenates segments, refined through manual evaluation and iterative improvements. More details are provided in Multimedia Appendix 1.	Accurately segmented text with sections tagged for reassembly.
Filtering uninformative data	Identification and removal: • Duplicates • Uninformative sections • Administrative content	• Remove duplicated sections from notes to prevent skewing results. • Discard sections containing only headings without informative text. • Remove document finalization and signature sections marked with terms like “signed” and “FINAL.”	Dataset free of redundant and uninformative sections.
Elimination of non-essential elements	• Regular expressions and manual filtering	• Exclude conversion error notifications, Unicode or hexadecimal sections, and other irrelevant elements.	Dataset without non-contributory headers, unreadable sections, and irregular patterns.
Removal of irrelevant metadata	• Manual filtering	• Remove timestamps, de-identified placeholders, and other non-analytical metadata.	Dataset without timestamps and placeholder text, ensuring grammatical consistency.
Splitting the data	• Random allocation	• Partition the dataset into training and testing subsets for unbiased model evaluation.	Training and testing subsets for model development and performance evaluation.

Model Development

Models were developed to automate two distinct tasks: fall occurrence and fall mechanism classification. All models besides Bidirectional Encoder Representations from Transformers (BERT) used a Term Frequency-Inverse Document Frequency (TF-IDF) representation of the text data. Specifically, TF-IDF vectorization with unigrams, bigrams, and trigrams (ngram_range=(1,3)) was applied to transform the processed text into numerical features before training these models. For the binary task of fall occurrence (fall vs no fall), a data split of 80:20 was used for training and testing purposes, respectively. The split was stratified by the binary outcome (fall vs no fall) to ensure a balanced representation of both classes in the training and testing subsets. Our methodology harnessed the text analysis capabilities of a modified BERT model described by Fu et al [17] We used a maximum sequence length of 512 tokens, consistent with the recommendations in the original study by Devlin et al [23], used a batch size of 8, and conducted training over 3 epochs. Moreover, the adaptive boosting (AdaBoost) algorithm was used for fall identification, using single-layer decision trees (stumps) as described by Quinlan et al [23], [24]. AdaBoost assigns coefficients based on each classifier’s performance and adjusts sample weights during training to emphasize previously misclassified samples. Finally, extreme gradient boosting (XGBoost) was used, which is a refined

XSL•FO
RenderX

version of gradient boosting recognized for its precision and versatility. XGBoost constructs additive training models in stages and optimizes a differentiable loss function, making it suitable for handling structured data derived from text [25].

To address the challenges posed by the complex multiclass scenario in the fall mechanism classification task, which involved detailed classification into 3 categories (same level, multilevel, and unclassified classes), we designated 70% of the data for training and 30% for testing, ensuring stratification to maintain class distribution. We used a comprehensive suite of advanced machine learning models, including AdaBoost, support vector machine (SVM), XGBoost, and random forest (RF). Each model was chosen for its proven ability to decipher complex data relationships and offer detailed insights into the correlated factors of falls across the varied categories [26-31]. The SVM model is a two-layer recognition method that excels in high-dimensional spaces and allows for class weighting to address class imbalance, which makes it suitable for detecting fall mechanisms from clinical notes [32] RF is an ensemble learning method that constructs multiple decision trees during training and merges their results to improve predictive accuracy and control overfitting. RF is also effective in handling class imbalance through class weighting [33].

The hyperparameter configurations used for the models are provided in Table S3 in Multimedia Appendix 1.

Statistical Analysis

Comparison of the baseline characteristics was made using SPSS software (version 28.0; IBM Corp), where the *t* and chi-square tests were used for continuous and categorical data, respectively. Several metrics were used to evaluate the models' performance in identifying and classifying falls. These metrics included sensitivity, specificity, F_1-score, positive predictive value (PPV), negative predictive value (NPV), accuracy, and area under the receiver operating characteristic curve (AUC-ROC). A weighted-averaging approach was used for multiclass classifications to report the overall model performance [34]. Furthermore, the percentage of the notes correctly classified for each task by machine learning and ICD approach were calculated and compared through chi-square test. A 0.05 type 1 error probability was considered significant.

Ethical Considerations

The study protocol was approved by Mass General Brigham Institutional Review Board (number 2023P000741). The board waived participant consent due to the retrospective nature of the study. All the notes were de-identified in the preprocessing stage to avoid the inclusion of any protected health information (PHI) and to ensure patient privacy and compliance with HIPAA regulations.

Results

A total of 1,769 clinical notes were analyzed for the fall occurrence task. Of these, 791 notes corresponded to the case group (one note per patient, n=791), and 978 notes were from the control group (representing 317 individuals with multiple notes per individual) (Figure 1). Moreover, for the fall mechanism classification task, 783 notes (one note per patient, n=783) were included, comprising 511 same-level falls, 151 multilevel falls, and 121 unclassified falls. The case group comprised older individuals with a mean age of 77.7 (SD 14.3) years versus 65.3 (SD 19.6) years of the control group (P<.001; Table 2). Furthermore, although both groups had a higher proportion of females, the case group had a notably higher percentage of female patients than the control group (P=.01; Table 2).

All 3 models performed well for detecting fall occurrences, with the BERT model showing a lower F_1-score and AUC-ROC (Table 3, Figure 2). The models could successfully classify a significant portion of patient notes (XGBoost=97%, AdaBoost=98%) as opposed to the *ICD* approach, which could find 26% of them (P<.001; Table 4).

Regarding fall mechanism classification, the RF model slightly outperformed the others with an AUC-ROC of 0.70 and an F_1-score of 0.60 (Table 3, Figure 3). Moreover, the RF model correctly classified fall mechanism in 65% of the fall notes compared to the 12% of the *ICD* method (P<.001, Table 4.). However, all 4 NLP models showed high classification performance in identifying small-level class falls only (Table 4).

Figure 3. Receiver operating characteristics curve for the fall mechanism.AdaBoost: adaptive boosting; ROC: receiver operating characteristic; SVM: support vector machine; XGBoost: extreme gradient boosting.

Discussion

This study aimed to automate fall identification and classification based on its mechanism from clinical notes and subsequently compare the results with the traditional *ICD* approach for building fall registries. Our results demonstrated the superior performance of NLP models, which correctly identified 98% of the notes for fall occurrence compared to the 26% detected by the *ICD* approach. Furthermore, the models could classify 65% of fall mechanisms, while the ICD approach detected 12% of these cases.

Automated identification of fall incidents from clinical notes is an emerging topic in biomedical sciences. It serves multiple purposes, such as insurance claim processing, cost analysis for falls, and enhancing fall prevention measures for inpatient safety [35-37]. Despite these varied objectives, there are commonalities in the methodologies and models used. However, the interpretation of results can vary significantly and must be tailored to the specific study goals. Cheligeer et al [38] highlighted the superior performance of BERT and machine learning models in detecting inpatient falls compared to traditional *ICD* coding. Their findings underscored these models' ability to accurately identify nonfall cases, as evidenced by high NPV and specificity. Nevertheless, when aiming to develop a comprehensive registry, achieving optimal sensitivity to maximize the inclusion of fall patients, alongside a high F_1-score to balance PPV and sensitivity, becomes crucial.

Classical machine learning methods are commonly used in fall classification studies. Luther et al developed an SVM model using free-text clinical notes and a term-document matrix for feature selection, achieving an F_1-score of 0.87 [39]. Our study extends this by using a TF-IDF feature selection method, which weighs terms based on their importance in capturing nuanced information from the notes. We found that ensemble methods achieved optimal performance with an F_1-score of up to 0.98. Santos et al demonstrated superior performance of neural networks over classical machine learning methods [40]. This finding is supported by Fu et al, who showed high performance of context-aware models like BERT in fall detection tasks [17]. However, in our study, BERT did not outperform other machine

XSL•FO
RenderX

learning models. BERT's effectiveness depends on the availability of sufficient training data due to its deep learning architecture [41]. Therefore, the sample size in our study may have influenced the effectiveness of training within this framework.

Identifying fall mechanisms from patient records presents a significant challenge, which, if addressed properly, can provide invaluable information for clinical and quality improvement purposes. Roudsari et al investigated the acute cost of care for falls in patients over 65 years of age, categorized by *ICD* codes for mechanisms [13]. They found that same-level falls were the most common mechanism of injury (28%). However, most falls (60%) were coded as unspecified falls without mentioning the mechanism. In our study, only 11% of the notes were coded specifically for falls, and surprisingly, there were occasional discrepancies between the coded mechanisms and those described in clinical notes. Whether this discrepancy stems from insufficient clinical information or a tendency among providers to prioritize documenting immediate medical needs requires further investigation. Relying solely on medical coding is unreliable for identifying fall mechanisms.

While NLP has shown promise in retrieving data from medical records, its application in fall mechanism extraction remains underexplored. Liu et al automated the extraction of inpatient fall severity from incident reports, leveraging structured features to improve the F_1-score by 8%, achieving 0.78 [22]. Our study incorporated diverse types of unstructured clinical notes, including discharge summaries and progress notes. These notes were authored by various medical professionals with differing styles and descriptions of falls, introducing significant variability that posed challenges for extracting features. Our results indicated that the XGBoost and RF models achieved the highest F_1-scores (0.6). These findings are consistent with previous research demonstrating improved disease classification accuracy using ensemble methods applied to medical notes [22]. Additionally, using ensemble methods, Albano et al have shown promise in enhancing the classification accuracy when dealing with rare classes [42]. However, our study revealed suboptimal performance of the models in managing the "multilevel" and "unclassified" subclasses, likely due to the overall limited number of notes available for these classes. Although reflective of real-life scenarios, the imbalance in fall mechanism classes may have impacted the performance of the models. Ensemble models like XGBoost and RF are prone to overfitting patterns in the training data, especially when managing imbalanced datasets. Similarly, even after fine-tuning, BERT may carry over biases from its general-purpose pretraining, limiting its ability to capture domain-specific nuances in clinical notes fully. To address these challenges, we applied weighted evaluation metrics to ensure a fair performance assessment across all classes. Additionally, hyperparameters were systematically optimized to mitigate class imbalance, and BERT was fine-tuned explicitly on clinical notes to enhance its applicability to the domain. However, relying on weighted metrics and fine-tuning may not entirely overcome the inherent limitations of dataset imbalance and pretraining biases. Future work should focus on augmenting the dataset to improve class balance and explore alternative architectures or pretraining strategies to reduce bias and overfitting.

Different approaches can be adopted for planning health care registries based on the registry's purpose, target population, and source data structure [43]. Administrative codes are commonly used to build retrospective registries when using health records. However, the accuracy of this method is not universally reliable across all medical conditions [44,45]. For example, a study by Dal et al evaluated the accuracy of the *ICD*-based Danish National Registry of Patients in identifying individuals with acromegaly, reporting a PPV of only 54.2% (CI 48.3 - 60) compared to expert-confirmed diagnoses [46]. Similarly, *ICD* codes for falls are often inconsistently applied, making them an unreliable sole method for identifying fall incidents. Our results highlight the potential of automated clinical note screening using NLP as an alternative for building registries. However, NLP can be computationally intensive due to the broad scope of falls, which spans diverse patient populations and clinical scenarios. This study proposes a combined approach using administrative codes related to fall conditions as a prescreening step to narrow the dataset, followed by NLP-based automated screening of clinical notes. This strategy balances computational efficiency with improved accuracy in registry development. Furthermore, this approach offers the advantage of extracting additional clinical details, such as the fall mechanism, which are often unavailable in administrative codes but crucial for understanding and preventing falls [47].

Although this study made important strides in developing fall registries, there are a few areas for improvement. The sample size was adequate for a retrospective analysis; however, larger and more diverse populations would enhance the robustness of machine learning models. Additionally, our dataset was predominantly composed of individuals of White race, reflecting the demographic characteristics of the region. This provides an opportunity to expand the research to include more diverse groups. We also acknowledge recent advancements in data preprocessing, including automated entity resolution and noise handling, which can be used in future studies to enhance robustness and scalability [48]. To address these issues, our future efforts will be focused on external validation, incorporating broader and more representative populations to improve the generalizability and impact of the findings.

In conclusion, our findings demonstrated a promising performance of NLP methods in identifying patients with a history of falls and hip fractures and their fall mechanisms from clinical notes. This approach can significantly enhance the accuracy and efficiency of developing fall registries. Moreover, the models were particularly effective in classifying the mechanisms of falls in patients who experienced same-level falls. Future studies with larger sample sizes and a broader spectrum of pathologies can further validate these findings and address the class imbalance issue. If well-expanded and developed, our approach can be introduced to the health care systems as an efficient and cost-effective approach for developing valid and reliable registry systems of diseases or clinical conditions that greatly burden the health care systems and the patients.

Abstract

Background: Labeling unstructured radiology reports is crucial for creating structured datasets that facilitate downstream tasks, such as training large-scale medical imaging models. Current approaches typically rely on Bidirectional Encoder Representations from Transformers (BERT)-based methods or manual expert annotations, which have limitations in terms of scalability and performance.

Objective: This study aimed to evaluate the effectiveness of a generative pretrained transformer (GPT)-based large language model (LLM) in labeling radiology reports, comparing it with 2 existing methods, CheXbert and CheXpert, on a large chest X-ray dataset (MIMIC Chest X-ray [MIMIC-CXR]).

Methods: In this study, we introduce an LLM-based approach fine-tuned on expert-labeled radiology reports. Our model's performance was evaluated on 687 radiologist-labeled chest X-ray reports, comparing *F*1 scores across 14 thoracic pathologies. The performance of our LLM model was compared with the CheXbert and CheXpert models across positive, negative, and uncertainty extraction tasks. Paired *t* tests and Wilcoxon signed-rank tests were performed to evaluate the statistical significance of differences between model performances.

Results: The GPT-based LLM model achieved an average *F*1 score of 0.9014 across all certainty levels, outperforming CheXpert (0.8864) and approaching CheXbert's performance (0.9047). For positive and negative certainty levels, our model scored 0.8708, surpassing CheXpert (0.8525) and closely matching CheXbert (0.8733). Statistically, paired *t* tests indicated no significant difference between our model and CheXbert (*P*=.35) but a significant improvement over CheXpert (*P*=.01). Wilcoxon signed-rank tests corroborated these findings, showing no significant difference between our model and CheXbert (*P*=.14) but confirming a significant difference with CheXpert (*P*=.005). The LLM also demonstrated superior performance for pathologies with longer and more complex descriptions, leveraging its extended context length.

Conclusions: The GPT-based LLM model demonstrates competitive performance compared with CheXbert and outperforms CheXpert in radiology report labeling. These findings suggest that LLMs are a promising alternative to traditional BERT-based architectures for this task, offering enhanced context understanding and eliminating the need for extensive feature engineering. Furthermore, with large context length LLM-based models are better suited for this task as compared with the small context length of BERT based models.

Introduction

Background

Radiology reports consist of expert observations of the radiologist based on the Chest X-ray images of the patient. These reports consist of free-text and unstructured information in the form of long paragraphs. The extraction of labels from unstructured radiology reports is the task of radiology report labeling and it provides us structured information which can be used for many downstream tasks such as medical report generation and natural language explanation generation. It also enables training of large-scale medical imaging models [1]. Previous works for labeling of radiology reports involve use of complicated feature engineering of medical domain knowledge [2]. and Bidirectional Encoder Representations from Transformers (BERT) based approaches [3]. Transformers have

XSL•FO
RenderX

also demonstrated success in radiology report labeling [4,5]. However, all these methods have limitations which hinders their adoption in the clinical setting. In case of methods which use complex feature engineering, these methods have leveraged manual annotation to shift the burden from feature engineering, requiring considerable time and expertise. Furthermore, these methods do not take advantage of existing feature-engineered labelers, which are state-of-the-art on many medical tasks. On the other hand for methods using BERT based models, the models are limited by the inherent limitations of BERT models such as their noncausal nature and limited context length. BERT-based models, despite their effectiveness in text classification tasks, have two key architectural limitations that constrain their performance in radiology report labeling. First, BERT's bidirectional nature focuses on context aggregation but lacks the ability to model causal relationships in sequential data. This noncausal nature can hinder its ability to fully capture the hierarchical and temporally dependent structure of radiology reports, where findings are often sequentially described. Second, BERT's limited input context length (typically 512 tokens) prevents it from effectively processing the long and detailed narratives commonly found in radiology reports. As a result, crucial information in extended texts may be truncated, leading to incomplete or suboptimal labeling. These limitations reduce the adaptability of BERT-based methods to real-world radiology settings, where comprehensive understanding of the entire report is often required.

Large language models (LLMs) such as Qwen address these challenges by offering extended context lengths (several thousand tokens), allowing the model to process full radiology reports without truncation. In addition, their ability to incorporate causal reasoning and handle instruction-based tasks makes them particularly suitable for medical labeling tasks, where nuanced and ambiguous language is prevalent. Although BERT based methods have shown increased abilities in the classification and other natural language tasks, their architecture poses a hindrance to their use.

Smit et al [3] introduced a combination of existing radiology report labelers and expert annotations to achieve highly accurate automated radiology report labeling . Their approach consists of a bio-medically pretrained BERT model [6,7], which is trained on the outputs of an existing labeler. They call their resulting model CheXbert. While CheXbert has generated considerable results, it has been unable to capture the full diversity, complexity and the ambiguous nature of natural language in the radiology reports. Their BERT-based solution while providing remarkable performance on the task of labeling is limited in its context length and noncausal nature. Which means for longer radiology reports it fails to provide a solution.

In our work we propose an LLM based radiology report labeler. LLMs have proven to be successful in their natural language generation capabilities. These models also have longer context lengths which makes them highly suitable for natural language generation tasks. Furthermore, these LLMs are adept at following instructions and given proper instructions these LLMs can be made good labelers for the radiology reports. Our LLM-based model inherently provides ease of use in other LLM-based solutions for the medical domain enabling clinical automation.

Our generative pretrained transformer (GPT)-based LLM beats the BERT-based CheXbert model on many pathologies and with a far bigger context length can handle long reports as compared with CheXbert. Our model outperforms the previous labelers [8] for many pathologies on an external dataset, MIMIC-CXR [9]. Our method of training medical report labelers opens room for other labels and longer textual input which makes it broadly useful for natural language processing tasks within the medical domain.

Related Work

Many natural language processing systems have been developed to extract structured labels from unstructured free-text radiology reports [2,10-16]. Mostly, these methods rely heavily on feature engineering and include strict vocabulary and grammatical rules to find and classify radiological reports. NegEx [17], a popular rule-based method, uses simple regular expressions for detecting negation of findings and is often used in combination with the Unified Medical Language System [18]. NegBio [19], an extension to NegEx, uses universal dependencies and subgraph matching for pattern definition and graph traversal search. It includes uncertainty detection in addition to negation detection for multiple pathologies in radiology reports, and is used to label the ChestX-Ray14 dataset [1]. The CheXpert labeler [8] improves upon NegBio on chest x-ray report classification by more controlled extraction and an improved Natural Language Processing framework and rules for uncertainty and negation extraction. The CheXpert labeler has been applied to generate labels for the CheXpert dataset and MIMIC-CXR [9], which are among the largest chest x-ray datasets publicly available. We use the MIMIC-CXR dataset to train our LLM-based framework and report our findings on a subset of the test set of MIMIC-CXR which has been labeled by expert radiologists.

Previous approaches have also been trained using radiology reports annotated by expert radiologists [20]. In these approaches, training data is limited by radiologist time and expertise. Chen et al [21] trained convolutional neural networks with Global Vectors for Word Representation [22] on 1000 radiologist-labeled reports for classification of pulmonary embolism in chest computed tomography scan reports and improved upon the previous rule-based peFinder [23,24]. trained both recurrent and convolutional networks in combination with attention mechanisms on 27,593 expert-annotated radiology reports. Transformer-based models have also been applied to the task of radiology report labeling [4], trained BERT [6] and XLNet-based [25] classifiers on 3856 radiologist labeled reports to detect normal and abnormal labels. Wood et al [5] proposed ALARM, an MRI head report classifier on head MRI data using BioBERT model [26] trained on 1500 radiologist-labeled reports. They demonstrate improvement over previous fixed embedding and word2vec-based [27] models [28] CheXbert labeler [3]. Also proposed a BERT based model which is trained on expert annotated radiology reports and achieves state of the art results for radiology report labeling. However, their method has limitations which include restriction to the context length of 512 which is the limitation of BERT based models.

RenderX

Recent advancements in the application of LLMs across various domains, including medical informatics, have demonstrated their versatility and efficacy. Models such as GPT-3 and GPT-4 have been used for diverse tasks, including automated clinical note generation, question answering in health care, and medical coding, showcasing their ability to handle complex and domain-specific language tasks. In radiology, LLMs have been explored for summarizing imaging findings, generating patient-friendly explanations, and aiding in clinical decision-making, highlighting their potential beyond classification tasks. Furthermore, instruction-tuned LLMs, such as ChatGPT and specialized variants like BioGPT, have been shown to adapt effectively to biomedical domains, opening avenues for tasks such as multimodal data interpretation and real-time clinical assistance. These advancements emphasize the need for further exploration of LLMs' contextual understanding and adaptability, particularly in radiology report labeling and other biomedical text processing tasks.

In our work we propose an LLM based solution to solve the task of biomedical text labeling. We not only propose an alternative to BERT based models which achieves better scores on certain labels and has far bigger context length than BERT based models but our approach can also be applied to other biomedical text labeling.

Methods

Task

Radiology report labeling is a critical task involving the extraction of information on the presence or absence of specific thoracic pathologies, such as consolidation or edema, from free-text radiology reports. This process enables the transformation of unstructured diagnostic text into structured data, facilitating clinical decision-making, research and the development of predictive models. In this task, a labeler processes the free-text radiology report as input and assigns 1 of 4 classes, blank, positive, negative, or uncertain, to each of 14 predefined observations, reflecting the certainty level for each prediction. A "positive" label indicates the presence of a pathology, while "negative" denotes its absence, and "uncertain" is used when the report is ambiguous about the condition. The "blank" class is assigned when no relevant information is available for an observation. By converting radiology reports into labeled data, this approach supports streamlined access to essential diagnostic insights and provides a valuable structured dataset that can be used to train and validate machine learning algorithms in medical imaging.

Data

In radiology, there exist 2 large datasets of chest x-rays, CheXpert [8] (consisting of 224,316 images), and MIMIC-CXR [9] (consisting of 377,110 images). Both datasets have corresponding radiology reports that have been labeled for the same set of 14 observations using the CheXpert labeler [8] from the Impression section, or other parts of the radiology report. Furthermore, a subset of both datasets also contain manual annotations by expert radiologists. On CheXpert, a total of 1000 reports (CheXpert manual set) were reviewed by 2 board certified radiologists with disagreement resolution through consensus. On MIMIC-CXR, a total of 687 reports (MIMIC-CXR test set) were reviewed by 2 board certified radiologists and manually labeled for the same 14 medical pathology labels as in CheXpert. However, the radiology reports for the Chexpert dataset have not been made public. Due to nonavailability of radiology reports for the Chexpert dataset, we used the MIMIC-CXR test set for evaluation.

Large Language Models

LLMs are built upon stacked decoder layers from the transformer architecture, often referred to as "auto-regressive models" because of their causal structure. This auto-regressive nature enables these models to predict each token sequentially, relying only on the preceding tokens as context. During training, LLMs learn the task of next-token prediction, where they must accurately anticipate the subsequent token in a sequence given the previous tokens as input. This prediction task is essentially a binary classification problem, where the model assesses whether its predicted token matches the correct ground truth token. The accuracy of each prediction is evaluated by calculating a cross-entropy loss, which measures the difference between the model's output and the correct token. This loss is then back-propagated through the model to update its weights, refining its ability to generate contextually accurate and coherent responses over time.

LLMs are pretrained on extensive amounts of diverse text data from vast resources available on the internet. This extensive pretraining enables the models to capture complex patterns and detailed knowledge present in language, making them highly effective at understanding and generating natural language. Their exceptional performance in natural language generation, coupled with their ability to handle longer text inputs, motivates their application in various specialized domains, such as radiology report labeling.

In our work, we specifically use the Qwen model [29], particularly the Qwen1.5‐0.5B variant. This model demonstrates significant capabilities in various natural language generation tasks relative to its moderate size, making it both efficient and powerful. One of the Qwen model's key advantages is its extensive context length of 32,000 tokens, meaning it can handle considerably larger text inputs as context compared with BERT-based models, which are typically limited to a 512-token context. This increased context capacity allows the Qwen model to process lengthy radiology reports or extended medical dialogues without truncating important information.

The enhanced context length in LLMs is particularly beneficial in clinical settings, where maintaining continuity in patient information, such as previous history or ongoing conversations, is essential. As LLM-based frameworks are increasingly adopted in health care, often in the form of biomedical chatbots and other automated systems, the capacity to retain extensive context is critical. Our model addresses this need, providing a solution that integrates seamlessly with existing LLM-driven tools in clinical environments. This ensures that radiology report labeling and other clinical tasks benefit from both accuracy and the ability to preserve a comprehensive, context-aware understanding of patient data.

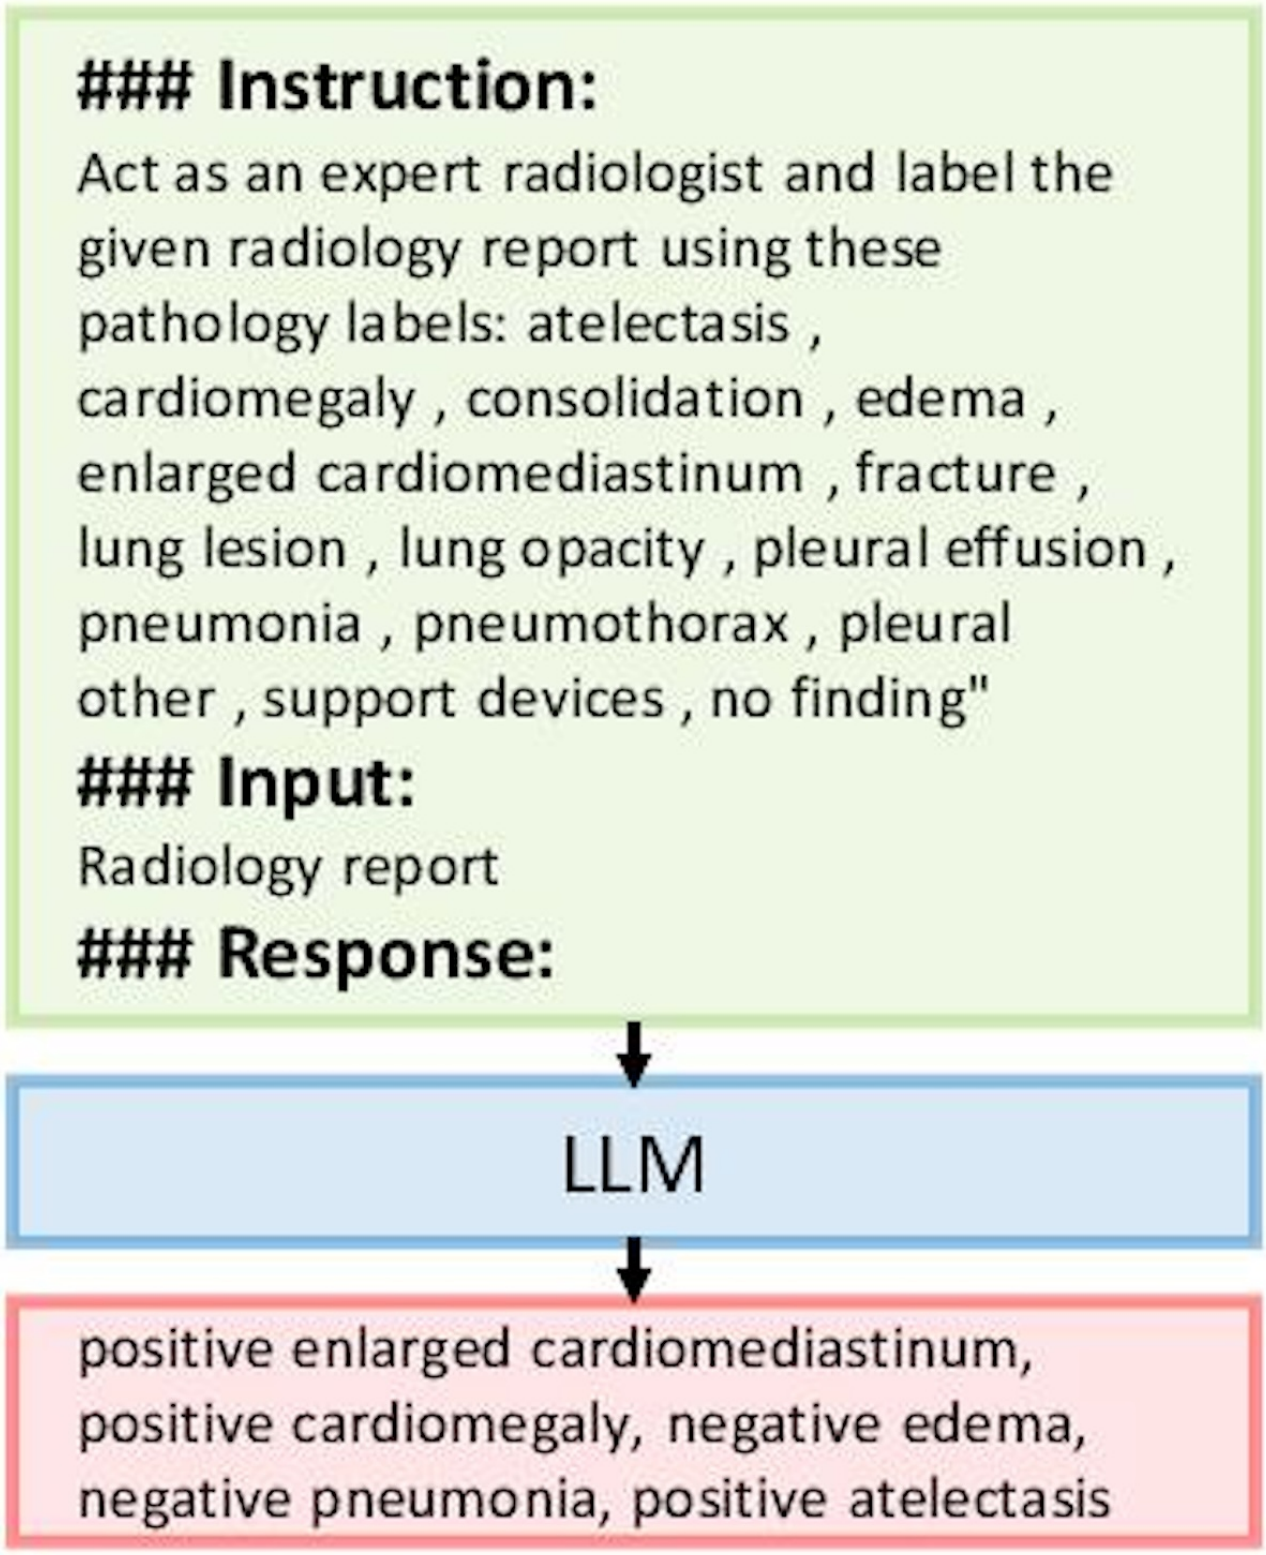
Instruction Fine-Tuning

To fully use the capabilities of our pretrained LLM, we fine-tune it using a specialized instruction dataset. This dataset is constructed from radiology reports paired with corresponding pathology labels, each with an associated certainty level from the MIMIC-CXR dataset. The goal of this instruction tuning is to guide the pretrained LLM to understand the relationships within radiology reports, enabling it to accurately identify pathologies and assign certainty levels. By providing targeted instructions, we aim to refine the LLM's ability to interpret the clinical language and nuanced patterns within radiology reports, thereby enhancing its performance in radiology report labeling.



The structure of the instruction dataset is designed to facilitate clear guidance for the LLM. As illustrated in Figure 1, each data instance consists of an instruction in the form of a prompt to the LLM, an input value (the radiology report), and output values (the pathology labels along with their certainty levels). This structured approach helps the LLM understand both the format and task requirements, allowing it to generate accurate labels from free-text radiology reports.

To prepare the data for model processing, each instance in the instruction dataset is tokenized using the LLM's tokenizer, converting text into a sequence of tokens suitable for input. The tokenized data is then fed into the LLM, which generates predictions based on its learned representations. Following this, we calculate the cross-entropy loss, which measures the difference between the model's predicted outputs and the ground truth labels. This loss value indicates how closely the model's predictions align with the actual labels. By back-propagating the loss, we adjust the LLM's weights which gradually enhances its accuracy and reliability in producing pathology labels with certainty levels.

Through this fine-tuning process, our LLM becomes adept at associating the textual features of radiology reports with relevant pathology labels, allowing it to accurately and efficiently label clinical data. This approach ensures that the model is optimized specifically for radiology report labeling, enabling it to perform well even on complex clinical information.

Figure 1. Instruction fine-tuning process for a large language model to label radiology reports. The dataset includes prompts structured to guide the large language model, input radiology reports, and corresponding pathology labels annotated with certainty levels. This method was applied to the MIMIC Chest X-ray dataset, a large-scale de-identified chest x-ray dataset containing radiologist-labeled reports. LLM: large language model

Training Details

We trained our LLM, which has a total of 463,987,712 parameters, using an instruction dataset. During the training process, we maintained a batch size of 2, which allows for effective gradient estimation while minimizing memory usage. This choice of batch size is particularly beneficial given the substantial size of our model and the complexity of the task. The training was conducted over 5 epochs, providing sufficient iterations for the model to learn the intricate relationships

XSL•FO
RenderX

between the radiology reports and their corresponding pathology labels.

To optimize the training process, we used the ADAM optimizer [30] which facilitated faster convergence and improved performance. In addition, we implemented a gradient accumulation strategy with a value of 2. This approach effectively simulates a larger batch size by accumulating gradients over two iterations before performing a weight update, allowing us to maximize the use of available GPU memory while still benefiting from the stability of a larger batch size.

The learning rate was set at 1×10^{-4}, a value that strikes a balance between training speed and stability. An appropriate learning rate is crucial in preventing the model from oscillating around the optimal solution, ensuring gradual and consistent improvements in performance. For the instruction tuning of our LLM, we used the SFTTrainer from the TRL library [31]. This specialized trainer is designed for supervised fine-tuning, providing an efficient and effective framework for adapting pretrained models to specific tasks. It offers a range of features that streamline the training process, including automated handling of training loops, logging, and monitoring of performance metrics. We leveraged 4 NVIDIA RTX A6000 GPUs. This powerful hardware setup enables parallel processing, significantly reducing training time while accommodating the memory requirements of our large model.

Ablation Studies

Medical Contrastive Language-Image Pretraining Based Similar Reports Retrieval

To evaluate the effectiveness of our LLM based solution in its longer context we augment the LLM with similar retrieved reports which have been retrieved based on the cosine similarity, Medical Contrastive Language-Image Pretraining (MedCLIP) [32] is a Contrastive Language-Image Pretraining (CLIP)-based [33] model which is trained on medical images. It is trained in a constrastive manner and based on the cosine similarity between radiology images and texts it placed them closer or farther in its projection space. This helps in tasks such as image-image text-text or image-text and text-image based retrieval. To augment the input radiology report to the LLM, CheXbert, and CheXpert alike, we retrieve similar radiology reports from a datastore similar to [34]. MedCLIP has a limitation of 77 tokens as its context length and therefore text-text based retrieval is not possible. To overcome this, we use the radiology image associated with the radiology report of 687 radiologist annotated reports from MIMIC-CXR dataset and retrieve similar radiology images from the train set of MIMIC-CXR, this avoids any data leakage. Then the radiology reports corresponding to these top-k similar retrieved images is taken as the retrieved similar reports which are augmented to the test reports to increase the length of radiological text and test the abilities of labeling methods when longer context input is given. Retrieval is based on MedCLIP representations of input images and reports in the datastore, the datastore is precomputed offline and indexed with FAISS [35] for efficient nearest neighbor searching.

However, the performance of LLM dropped because the retrieved reports are not representative of the accurate information which can be used. Even though our model was able to process the additional information provided, it was unable to perform better because of the quality of those retrieved reports. In future with the advent of chat-bot style LLM solutions, longer bio-medical text in the form of patient-doctor conversation will be available and can be provided to our model as conversation history and this is where our model can be helpful.

Ethical Considerations

To fully use the capabilities of our pretrained LLM, we fine-tune it using a specialized instruction dataset.

Human Subject Research Ethics Review

This study did not involve direct human subject research. Instead, it used the MIMIC-CXR dataset, a publicly available, large-scale radiology dataset. The creation and distribution of the dataset adhere to ethical standards, with data anonymized to protect patient privacy. Therefore, specific ethics review and approval for this secondary analysis were not required.

Informed Consent

The MIMIC-CXR dataset is derived from hospital records collected during routine clinical care. Informed consent for the use of this data was waived by the Institutional Review Board (IRB) of the Beth Israel Deaconess Medical Center (BIDMC), as the dataset underwent rigorous deidentification processes to ensure compliance with Health Insurance Portability and Accountability Act standards.

Privacy and Confidentiality

The dataset has been thoroughly deidentified to ensure anonymity. This includes removing all protected health information from radiology reports, applying optical character recognition and masking techniques to redact protected health information from images, and assigning random identifiers to patients, studies, and images. This guarantees that patient confidentiality is maintained in all analyses.

Compensation

No compensation was involved in the collection or use of the MIMIC-CXR dataset, as it is a retrospective collection of clinical records for research purposes.

Identification of Participants

There is no risk of identification of individual participants, as all data in the MIMIC-CXR dataset is fully anonymized. The deidentification process for radiology reports, images, and associated metadata adheres to strict privacy protocols to ensure that no identifying information is present in the dataset or the results of this study

Evaluation

In this study, we evaluate the performance of our model, CheXbert and the CheXpert labeler, across a suite of retrieval tasks designed to assess their capabilities in clinical information extraction. Specifically, we focus on 3 main retrieval tasks, namely positive extraction, negative extraction, and uncertainty extraction. For each task, we designate the relevant class as the “positive” class for classification purposes, meaning, for

XSL•FO
RenderX

example, that the "negative" class is treated as the positive class in the negative extraction task, while other classes (such as positive or uncertain) are treated as negatives. This approach allows us to directly measure the model's ability to distinguish between the specified class and all others, thereby assessing its precision and recall within clinically relevant categories.

We compute the weighted average of the *F*1 scores for each of the 14 clinical findings or observations present in the CheXpert dataset across these tasks. *F*1 score is a harmonic mean of precision and recall which provides a balanced measure of a model's classification performance, particularly in settings where data is imbalanced. We calculate a weighted average of the *F*1 scores for each of the 14 observations across these tasks. By this we can mitigate the impact of class imbalance and obtain an *F*1 metric that accurately reflects the model's performance across both common and rare observations in the dataset.

This weighted metric, referred to as weighted-*F*1, is denoted simply as *F*1 in our results. Finally, we calculate and report the average *F*1 score across all 14 clinical observations, offering insight into the model's general extraction capability. This average *F*1 score serves as a key performance metric, allowing for a direct comparison between CheXbert and the CheXpert labeler on clinical information extraction tasks relevant to medical imaging applications in radiology .

Results

Table 1 and Table 2 present a quantitative assessment of our model's performance relative to prvious BERT-based approaches for the task of radiology report labeling. Table 1 reports the *F*1 scores obtained by our model on the MIMIC-CXR dataset, specifically on a radiologist-labeled test set comprising 687 radiology reports. These scores encompass all certainty levels, positive, negative, and uncertain, across each of the 14 pathology categories. The results indicate that our model demonstrates superior performance over previous methods, particularly in the Enlarged Cardiomediastinum and Support Devices categories, while maintaining competitive F1 scores across the other pathology labels.

Table . F_1 scores for predictions made by the proposed large language model-based model (ours) compared with CheXbert and CheXpert for all certainty levels (positive, negative, and uncertain). The evaluation was conducted on the MIMIC-CXR test set of 687 radiologist-labeled chest X-ray reports, covering 14 thoracic pathologies.

Pathologies	Ours, F_1 score	CheXbert, F_1 score	CheXpert, F_1 score
Enlarged cardiomediastinum	0.9022	0.8753	0.8644
Cardiomegaly	0.8555	0.8604	0.8143
Lung Opacity	0.8653	0.8820	0.8459

Support devices	0.7911	0.7603	0.7069
No finding	0.7704	0.7835	0.7836
Average	0.8708	0.8733	0.8525

Table 2 further delineates our model's performance by isolating only positive and negative certainty levels for each of the 14 pathology labels, thereby excluding uncertain cases to facilitate direct comparison. In this subset, our model yields notable improvements in *F*1 scores for Enlarged cardiomediastinum, cardiomegaly, and support devices.

The *P* values presented in Table 3 provide the results of statistical comparisons between the 3 models (ours, CheXbert, and CheXpert) based on their *F*1 scores. We performed both a paired *t* test and a Wilcoxon test to assess the statistical significance of the differences between the models. The paired *t* test *P* value for the comparison between ours and CheXbert is .35, which indicates that there is no statistically significant difference between the 2 models ($P>.05$). However, the comparison between ours and CheXpert yields a paired *t* test *P* value of .01, suggesting that ours performs significantly better than CheXpert at the 5% significance level ($P<.05$). Similarly, the Wilcoxon test confirms this finding with a *P* value of .005. The comparison between CheXbert and CheXpert shows highly significant differences with both a paired *t* test *P* value of .0005 and a Wilcoxon test *P* value of .002, indicating that these 2 models also differ significantly in performance. Overall, the statistical tests reveal that while ours and CheXbert are statistically similar, ours outperforms CheXpert, and there is a significant performance difference between CheXbert and CheXpert.

Table . *P* values from statistical tests (paired *t* test and Wilcoxon test) comparing the performance of the proposed LLM-based model (ours) with CheXbert and CheXpert across 14 thoracic pathologies. The evaluation was conducted on the MIMIC-CXR test set of 687 radiologist-labeled chest X-ray reports, assessing the significance of the differences in F_1 scores for all certainty levels.

Comparison	Paired *t* test *P* value	Wilcoxon test *P* value
Ours versus CheXbert	.35	.14
Ours versus CheXpert	.01	.005
Chexbert versus CheXpert	.0005	.002

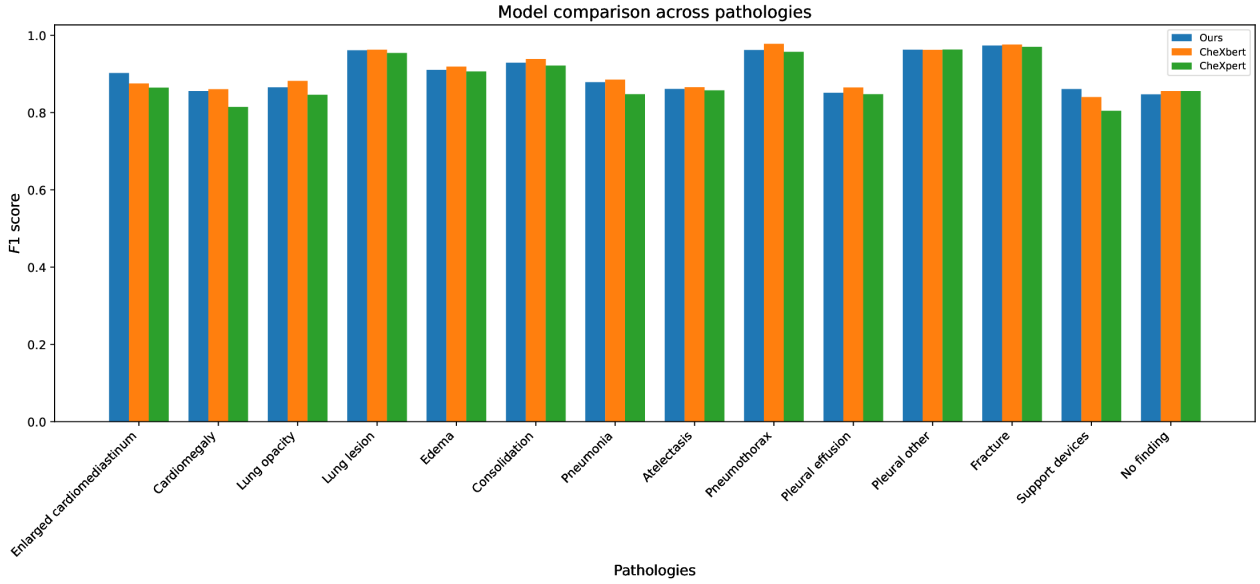
Compared with the rule-based CheXpert labeler [8], our model achieves substantial performance gains across all pathology labels, marking a significant advancement over both traditional rule-based systems and BERT-based models. These results demonstrate the ability of our large language model (LLM)-based approach in handling the task of radiology report labeling with greater precision with large context length as compared with the small context length of BERT based models.

Figure 2 presents the performance of the proposed model (ours) compared with the baseline models (CheXbert and CheXpert) across 14 chest pathologies, using *F*1 scores as the evaluation metric. The grouped bar chart enables a direct comparison, where each group corresponds to a specific pathology, and individual bars represent the scores for each model. The results reveal that all three models achieve consistently high *F*1 scores across most pathologies, indicating robust performance. While the differences are marginal, notable trends can be observed, the proposed model demonstrates an advantage in pathologies such as support devices and enlarged cardiomediastinum, whereas the baseline models perform slightly better in cases

XSL•FO
RenderX

like consolidation and pneumothorax. This chart highlights the subtle strengths and weaknesses of each model, providing a clear visual overview of their performance.

Figure 2. Performance comparison of the proposed large language model-based model (ours), CheXbert, and CheXpert across 14 thoracic pathologies. The F_1 scores for each pathology label were calculated using the MIMIC-CXR test set, comprising 687 radiologist-labeled reports. While all models show similar performance, the proposed model demonstrates competitive or superior results in cases such as "support devices" and "no finding."



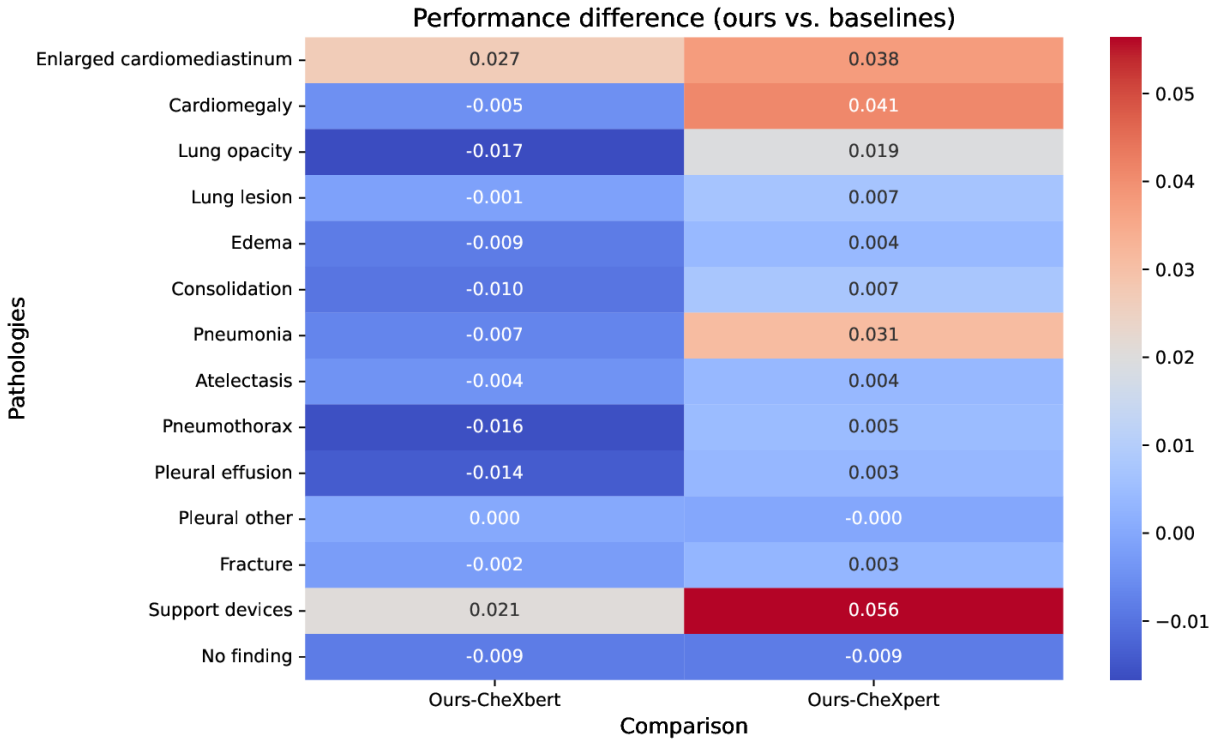


Figure 3 further explores the differences by visualizing the absolute performance gaps between the proposed model (ours) and the 2 baseline models using a heatmap. Rows correspond to the pathologies, and columns display the comparisons of ours against CheXbert and CheXpert. The heatmap emphasizes that the differences are minor, with most pathologies showing a difference of less than 0.02 in $F1$ scores. However, it also highlights key instances where ours performs notably better, such as in support devices and enlarged cardiomediastinum, while the baselines excel slightly in consolidation and pneumothorax. By focusing on performance differences, the heatmap provides a nuanced perspective, making it easy to identify pathologies where the models vary.

Figure 3. Heatmap showing the absolute differences in F_1 scores between the proposed arge language model-based model (ours) and the baseline models (CheXbert and CheXpert) across 14 thoracic pathologies. The analysis is based on predictions for the MIMIC-CXR test set of 687 radiologist-labeled reports. The heatmap highlights areas where ours excels, such as "support devices," and where baseline models perform better, such as "consolidation."

Discussion

Limitations

Currently, our work is limited to 14 pathology labels prevalent in radiology. However, our method can be extended to other medical fields and can accommodate many more pathology labels and can provide a reliable labeling solution. The lack of long form radiology text limits the demonstration of the longer contextual abilities of our model. In future with the advent of long form bio-medical text in the form of patient-doctor conversations, our model can provide better solutions as opposed to previous models. Furthermore, there is a need of more publicly available radiologist annotated datasets for additional evaluation of trained models. Furthermore, like other LLM-based approaches, our model is susceptible to biases present in the training data, which may inadvertently propagate into its predictions. This is particularly important in the medical domain, where biases can have significant ethical and clinical implications. Additional mechanisms for bias detection and mitigation are necessary to ensure fair and equitable outcomes across diverse patient populations.

The computational demands of LLMs are another limitation, as training and inference require substantial computational resources. This may limit the accessibility and scalability of the approach, especially in resource-constrained clinical settings. Exploring techniques such as model distillation or low-rank adaptation could help reduce these requirements while maintaining performance.

Interpretability remains a challenge with LLMs due to their complex architecture. The lack of transparency in how decisions are made can hinder trust and adoption in clinical workflows, where clear justification of predictions is often required. Future work should explore ways to improve the explainability of LLM predictions, such as attention visualization or feature attribution methods tailored to medical tasks.

While our method demonstrates promising results in radiology, further validation is needed in real-world clinical settings and across diverse medical contexts. The scalability of our approach to other modalities, such as MRI or CT reports, and its adaptability to different healthcare systems must also be explored to ensure generalizability.

Principal Findings and Conclusions

In our work, we propose a novel solution using LLMs for the challenging task of radiology report labeling. Our approach leverages the advanced capabilities of LLMs to accurately interpret and label various pathologies within radiology reports, which are crucial for supporting clinical decision-making and improving patient care. We demonstrate that LLMs achieve superior performance over previous BERT-based models, especially in accurately identifying specific pathology labels. This is a significant advancement, as certain pathologies that were previously challenging to label accurately can now be identified with greater precision using our LLM-based approach. In addition, our model achieves competitive scores across a broad range of pathology labels, confirming its robustness and versatility in handling complex medical language.

One of the key improvements introduced by our model is its ability to process longer radiology reports, overcoming the context length limitations often encountered in previous models. This capability is essential in clinical settings where comprehensive radiology reports often contain detailed descriptions spanning multiple paragraphs, which traditional models struggle to handle effectively. By accommodating extended context, our model ensures that no critical information is overlooked, thereby enhancing labeling accuracy and reliability in real-world applications.

Furthermore, the instruction-tuning methodology allows our approach to be extended to other biomedical text labeling tasks beyond radiology. This generalizability of our method makes it highly applicable across a wide range of biomedical domains, opening doors for enhanced automation in various clinical documentation and reporting tasks.

As LLM-based solutions are increasingly adopted in clinical settings, our model is designed to integrate seamlessly into existing workflows, promoting efficiency, and facilitating clinical automation. The potential for real-time, accurate labeling provided by our model not only reduces the manual workload on health care professionals but also contributes to more timely and precise diagnostic insights, ultimately benefiting patient outcomes.

Future research should explore integrating LLMs with other medical technologies, such as multimodal imaging systems that combine radiology reports with visual data from x-rays, CT scans, or magnetic resonance images. This integration could enable a more comprehensive analysis and further enhance the clinical utility of LLM-based models. In addition, extending the application of LLMs to different medical imaging modalities and nonradiology domains, such as pathology or cardiology, presents a promising avenue for expanding their impact across health care.

Developing scalable and efficient LLM solutions tailored to specific clinical needs, including resource-constrained environments, is another critical area for further exploration. This includes investigating lightweight alternatives or model compression techniques to reduce computational demands while maintaining performance.

Finally, the clinical adoption of LLMs will require continued efforts in improving model interpretability and building trust among health care professionals. Future work should focus on developing user-friendly interfaces and explainability mechanisms to facilitate the seamless integration of LLMs into routine clinical workflows. By addressing these challenges, LLM-based models like ours have the potential to revolutionize clinical practice, enabling more accurate, efficient, and scalable solutions for medical documentation, decision-making, and patient care.

This work was supported in part by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT; no.RS-2024-00334321) and by the Institute of Information and Communications Technology Planning and Evaluation (IITP) Grant funded by the Korea Government (MSIT) under Grant (IITP-2022-0-00078; Explainable Logical Reasoning for Medical Knowledge Generation), Grant (IITP-2025-RS-2023-00258649; Information Technology Research Center).

Data Availability

The dataset used in this study, MIMIC-CXR, is a publicly available dataset containing chest X-ray images and associated radiology reports. As the MIMIC-CXR dataset is a publicly available dataset, no restrictions are placed on the access to this dataset. The code used for instruction tuning is not currently available, but the authors are happy to discuss and share details upon request

Abstract

Background: The use of patient-reported outcome measures (PROMs) is an expected component of high-quality, measurement-based chiropractic care. The largest health care system offering integrated chiropractic care is the Veterans Health Administration (VHA). Challenges limit monitoring PROM use as a care quality metric at a national scale in the VHA. Structured data are unavailable, with PROMs often embedded within clinic text notes as unstructured data requiring time-intensive, peer-conducted chart review for evaluation. Natural language processing (NLP) of clinic text notes is one promising solution to extracting care quality data from unstructured text.

Objective: This study aims to test NLP approaches to identify PROMs documented in VHA chiropractic text notes.

Methods: VHA chiropractic notes from October 1, 2017, to September 30, 2020, were obtained from the VHA Musculoskeletal Diagnosis/Complementary and Integrative Health Cohort. A rule-based NLP model built using medspaCy and spaCy was evaluated on text matching and note categorization tasks. SpaCy was used to build bag-of-words, convoluted neural networks, and ensemble models for note categorization. Performance metrics for each model and task included precision, recall, and F-measure. Cross-validation was used to validate performance metric estimates for the statistical and machine-learning models.

Results: Our sample included 377,213 visit notes from 56,628 patients. The rule-based model performance was good for soft-boundary text-matching (precision=81.1%, recall=96.7%, and F-measure=88.2%) and excellent for note categorization (precision=90.3%, recall=99.5%, and F-measure=94.7%). Cross-validation performance of the statistical and machine learning models for the note categorization task was very good overall, but lower than rule-based model performance. The overall prevalence of PROM documentation was low (17.0%).

Conclusions: We evaluated multiple NLP methods across a series of tasks, with optimal performance achieved using a rule-based method. By leveraging NLP approaches, we can overcome the challenges posed by unstructured clinical text notes to track documented PROM use. Overall documented use of PROMs in chiropractic notes was low and highlights a potential for quality improvement. This work represents a methodological advancement in the identification and monitoring of documented use of PROMs to ensure consistent, high-quality chiropractic care for veterans.

Introduction

Patient-reported outcome measures (PROMs) are standardized, validated questionnaires completed by patients to identify and quantify their perceptions of their health status [1]. These measures are often of interest to clinicians to assess condition severity and response to treatment as a component of a measurement-based care approach. Measurement-based care is a recommended practice in the management of musculoskeletal pain conditions [2], where biomarkers of disease severity are lacking and baseline and serial reassessment for progress may influence clinical decision-making. Using PROMs can improve communication and shared decision-making between patients and clinicians, enable contextualization of pain within a patient's life, and may positively influence health and pain status [3].

In the Veterans Health Administration (VHA), patients with musculoskeletal pain may receive chiropractic care, where the use of PROMs is an expected component of high-quality care [4,5]. The VHA Office of Specialty Care Ongoing Professional Practice Evaluation quality program for chiropractors includes a quality metric stating "appropriate pain, functional, and/or other measures are documented and used to inform clinical decision making." However, substantial challenges limit monitoring this important metric of high-quality care at a national scale. Digital data systems integration is limited for both remote and point-of-care data collection that may otherwise facilitate structured data collection, thus any PROM documentation often occurs in unstructured clinic notes. Quality evaluation of these notes typically requires time-intensive, peer-conducted chart review, with substantial human effort limiting ongoing monitoring [6].

The VHA Chiropractic Program has expanded rapidly in recent years driven by policy change and natural growth [7,8], with 299 facilities now offering on-site chiropractic care in fiscal year (FY) 2024, up 344% from 87 facilities in FY2017. Scalable solutions are needed to monitor established care quality metrics, such as PROM use, and ensure high-quality chiropractic care delivery across the enterprise. Further, such solutions could also be widely applicable to other disciplines managing musculoskeletal pain, which is highly prevalent and burdensome in the VHA system and beyond.

Natural language processing (NLP) of clinic text notes is one promising solution to extracting care quality data from unstructured text [9], with previous studies focusing on pain care quality in primary care and chiropractic care settings [10,11]. Use cases for NLP across other clinical domains highlight its potential utility in information extraction and analysis tasks. NLP methods have been used to accurately identify functional status impairment for patients with dementia based on electronic health record (EHR) clinic notes [12]. Additionally, NLP techniques have shown utility in information extraction, classification, and risk prediction tasks for patient-reported outcomes among cancer patients [13]. Relevant to pain management, NLP has been used to identify opioid use and misuse in clinic notes [14] and support decision support systems to impact clinical care [15]. More recently, the use of large-language models in data mining of EHR data, including clinical text data, has demonstrated promise and efficiency in information extraction and content analysis [16].

The objective of this study was to develop an NLP approach to identify PROMs documented in VHA chiropractic clinic text notes. We aimed to iteratively develop a rule-based pipeline and evaluated performance for a text span pattern matching task and a note categorization task. We also aimed to compare the performance of the rule-based method to statistical and machine learning methods for the note categorization task and estimate the overall prevalence of documented PROM use in the corpus. We hypothesize a rule-based NLP approach, when iteratively developed and refined, will demonstrate comparable performance to statistical and machine learning methods in identifying and categorizing PROM documentation within VHA chiropractic clinic text notes.

Methods

Study Setting, Data Sources, and Cohort

We conducted a secondary, retrospective analysis of the Musculoskeletal Diagnosis/Complementary and Integrative Health (MSD/CIH) Cohort [17]—an EHR data cohort of VHA patients receiving VHA health care for musculoskeletal conditions, with updated cohort entry through September 30, 2020. Study reporting was informed by published recommendations for reporting machine learning and NLP studies [18,19].

We identified patients in the MSD/CIH Cohort who received VHA chiropractic care at a VHA facility between October 1, 2017, and September 30, 2020. All chiropractic clinic visits were identified using an administrative clinic identifier denoting "Chiropractic Care." Initiating chiropractic care in the VHA most often requires the placement of a referral order for consultation, with the consultation visit linked to this order in the EHR. We included only patients with an initial consultation visit during the study period and included all visits occurring within 1 year of their first consultation visit date. Population demographic and clinical characteristics were extracted from the EHR for each patient included in the sample, including age at first chiropractic consultation, sex of record, race/ethnicity, marital status, smoking status, service-connected disability percentage, and BMI. *International Classification of Diseases, 10th Revision* (*ICD-10*) codes were also extracted for each visit, and flags were used to denote whether a visit included a low back pain diagnosis, neck pain diagnosis, other spinal pain diagnosis, or any other diagnosis.

We obtained all clinic text notes linked to the identified visits to build a corpus of clinic visit notes. We excluded note types related to telecommunications and administrative events (eg, appointment scheduling, secure messaging), including only notes describing chiropractic care in the ambulatory, in-hospital, or telehealth setting.

Data Preparation

Multiple notes can be written to describe the same identified chiropractic visit; for example, a resident chiropractor note and an attending chiropractor note may each contain data relevant to a single visit. We concatenated all notes linked to the same

XSL•FO
RenderX

unique visit identifier on the same date of service (regardless of note author) to create a 1-to-1 relationship between visits and clinic notes. A unique character set was used as a delimiter to separate individual notes. To evaluate the amount of text present across notes in the corpus, we quantified each note length using tokenization based on whitespace splitting and visualized the data using a histogram of token lengths. We compared tokenized lengths across different types of visits and across FYs through visual comparison, Kruskal-Wallis tests across all groups, and Dunn tests across group pairs with a significance level α of 0.05 and a Bonferroni correction for multiple comparisons.

Additional metadata about each chiropractic care visit was extracted from the EHR and written into a header for each note, offset from the rest of the note using a unique character series delimiter. This included a patient identifier, visit identifier, visit date, VHA facility identifier code, the date of the first consultation visit, and the visit number with the total number of visits within the year after consultation (eg, "visit 3 of 6"), the number of days since the previous visit (if applicable), and the number of days to the next visit (if applicable).

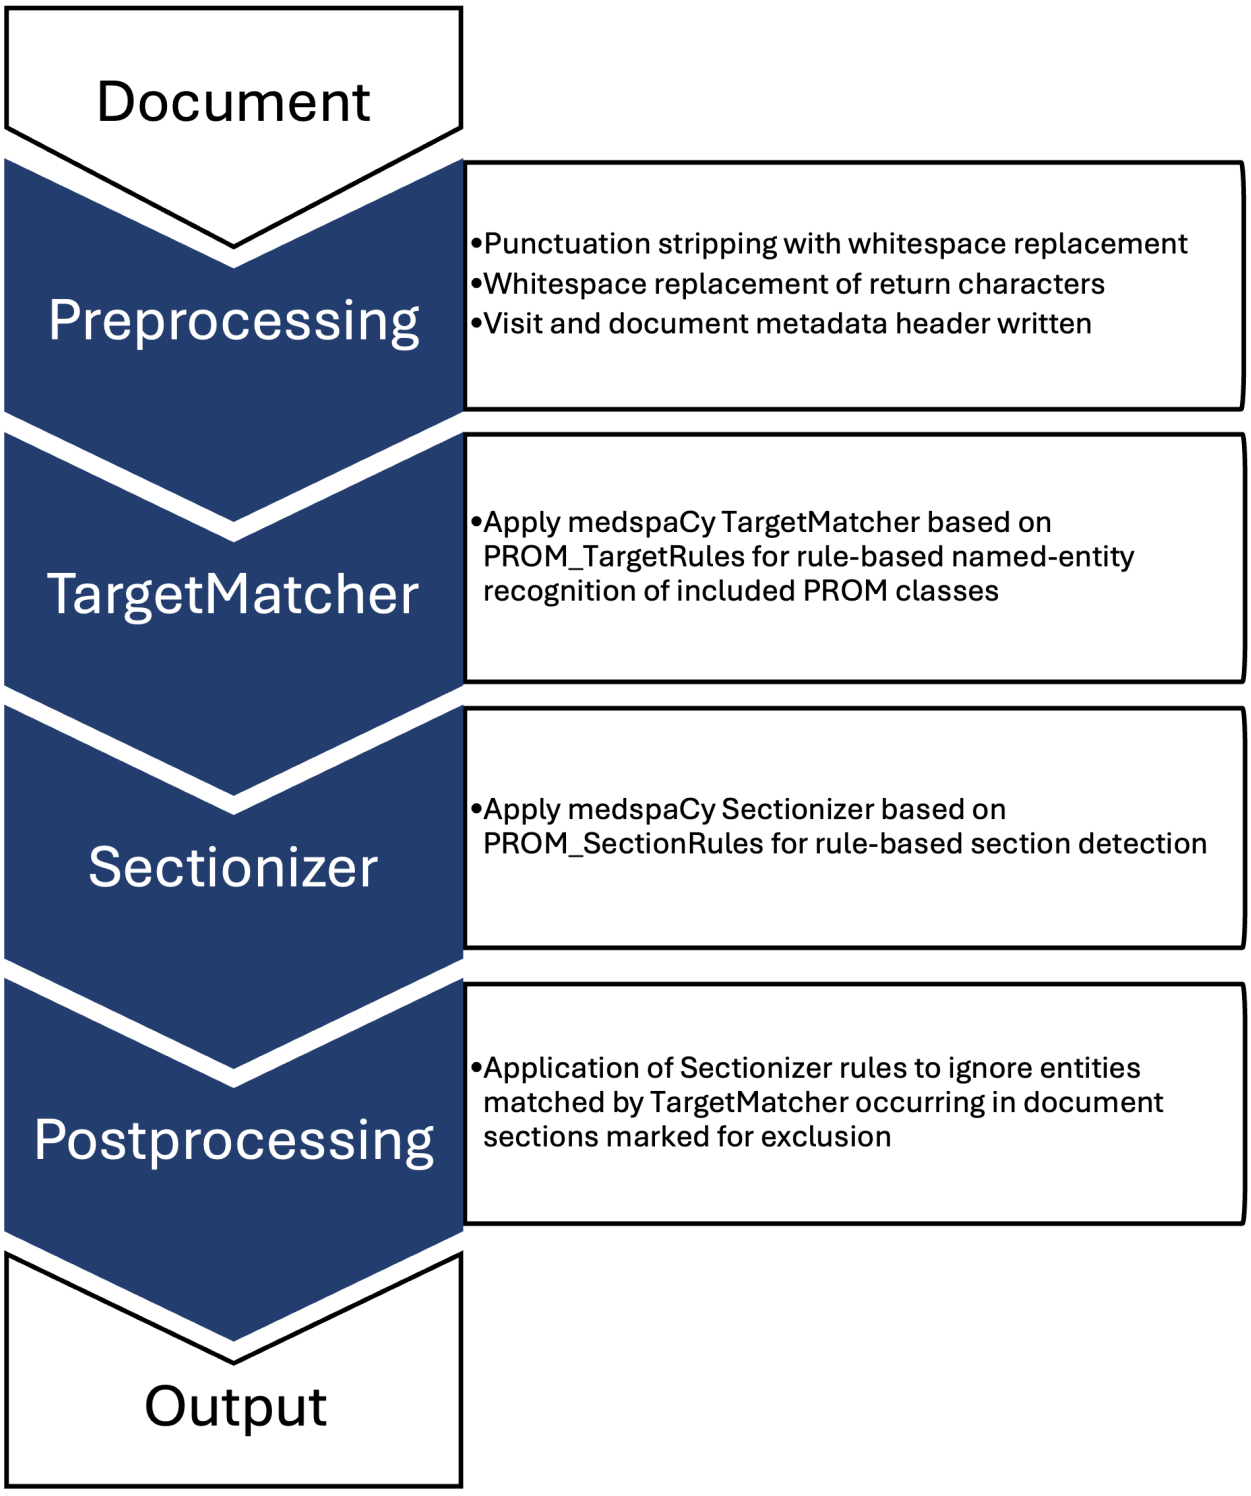
Visits were tagged into the following five exclusive categories using conditional logic: (1) first consultation visit, (2) final visit within 1 year, (3) visit immediately preceding a 60-day gap in care, (4) visit immediately following a 60-day gap in care, and (5) other intermediate visit. These categories were identified to stratify visits on having a higher likelihood of potential use of PROMs at the beginning or end of an episode of chiropractic care or before or after a gap in chiropractic care.

A nationally representative, random stratified sample of 300 notes was selected for human annotation to be used as an initial training set. The stratification approach was designed to select an approximately equal number of notes for each visit category and was randomly repeated until a maximum number of facilities was included in the training set (78 of 79, with 1 facility excluded due to very few notes included in the corpus).

Corpus Annotation

Two study investigators (BCC and KLC) with VHA chiropractic care subject-matter expertise annotated the training corpus using eHost, a Java-based annotation tool [20]. Annotators identified and tagged spans of text referencing documented use of PROMs and assigned a span attribute for the specific type of PROM based on an a priori list (Multimedia Appendix 1). The initial seed list of PROMs was a sample of validated PROMs potentially used by chiropractors addressing pain and function, particularly for spinal conditions. An additional attribute class was included for tagging an unspecified PROM that was not included in the list, which was reviewed for inclusion during subsequent iterations. We excluded all versions of the Numerical Rating Scale and Visual Analog Scales as unidimensional measures that have been criticized as potentially limited clinical importance [21], especially when trying to measure a complex, multifaceted condition like musculoskeletal pain [22,23]. An annotation guide was developed and iteratively revised/validated using a preparatory random note sample from a separate corpus during an annotation pilot. Interannotator agreement (IAA) was high across 3 samples of pilot notes (n_1=50 notes, IAA_1=78.8%; n_2=100 notes, IAA_2=84.5%; and n_3=100 notes, IAA_3=86.1%).

Annotation of the initial training set (n=300 notes) was iteratively completed in 100-note batches. IAA remained high across the 3 iterations of annotating the initial training set (IAA_1=71.7%, IAA_2=81.2%, and IAA_3=87.1%). Adjudication of disagreement was achieved through review and discussion between the annotators. A third-person adjudicator was available to provide a final adjudication decision in the event of unresolved disagreement, though this did not become necessary.



Initial NLP Model Development

A rule-based NLP pipeline (Figure 1) was built using medspaCy [24] (v1.0.0) and spaCy [25] (v3.6.0; Explosion) in Python (v3.8.5; Python Software Foundation). The initial pipeline used the medspaCy TargetMatcher and TargetRule functions to match spans of text in a spaCy Doc object. Matches were based on an initial set of rules to define text pattern rules for 15 predetermined PROMs, with an associated attribute referencing a specific measure assigned for each identified span.

For all iterations of NLP model development, evaluation statistics (precision, recall, and F-measure) were calculated based on true positives, false positives, and false negatives for three defined matching tasks: (1) strict-boundary matching, (2) soft-boundary matching, and (3) note categorization. Strict-boundary matching considered only the perfect overlap of the human annotation and NLP target matching methods to be a match in performance metric calculation. Soft-boundary matching was a fuzzy matching approach that allowed for flexibility in the overlap between the span start and span end positions of the human annotation and NLP target matching methods to define a match. Note categorization cast the results of the human annotation and NLP target matching to a binary document classification question, defining documented PROM use at the note level. All matching methods required matching on the assigned attribute for a specified PROM to be considered a match.

XSL•FO
RenderX

Figure 1. Rule-based natural language processing (NLP) medspaCy pipeline overview. PROM: patient-reported outcome measure.

NLP Model Refinement

The initial pipeline was run on the annotated first training set and false positives and false negatives were manually reviewed to revise the TargetMatcher rules and the overall NLP pipeline. Pipeline modifications were attentively designed to address only generalizable false positives and negatives and avoid overfitting the training data. During this review, false negatives were addressed by modifying TargetMatcher rules to better represent broader matching patterns (eg, abbreviations), supporting fuzzy matching (eg, typographic errors), and by adding TargetMatcher rules for 3 additional measures identified during annotation. False positives were addressed by adding sectionizer and postprocesser steps to the NLP pipeline. A medspaCy sectionizer component was added to define sections of the clinical note, with a Postprocessor component added to set rules for sections to ignore in defining PROM spans. This allowed the exclusion of inappropriate matches that were being identified in abbreviation lists, medication lists, goals of care,

XSL•FO
RenderX

and other irrelevant sections of the note. The final rule-based model is available on GitHub [26].

After the development of an initial NLP rule-based model to identify PROM documentation, a second high-probability training set (n=200) was identified based on a preliminary model NLP output as programmatic labeling and annotated by a single investigator (BCC). This created a full annotation set of 500 notes and increased the prevalence of positive notes in the training set to balance the prediction problem.

Using the full training set, we trained an initial set of statistical and machine learning models to complete the note categorization task prediction and compared their performance to the rule-based model. The full annotated training set was randomly partitioned with 75% allocated to the model training set, 15% to the development set to tune hyperparameters, and 10% to the test set to evaluate performance. We tested 3 model architecture configurations built in spaCy: (1) a bag-of-words (BOW) model, (2) a convoluted neural network model, and (3) an ensemble model combining a linear BOW model and Tok2Vec model. Architecture configurations for each model are detailed in Multimedia Appendix 2 with source code available on GitHub [26]. All computational analysis was conducted using a secure virtual machine with a Windows 10 operating system, 8 virtual processors (x86-64, 2.60 GHz), and 16 GB memory, with variable overall runtime based on competing user demands.

NLP Model Evaluation and Validation

For the initial evaluation of the rule-based model performance on the text matching and note categorization tasks, we evaluated performance based on precision, recall, and F-measure. To compare the performance of the rule-based model to the initial statistical and machine learning models for the note categorization task, precision, recall, F-measure, and accuracy were calculated. The area under the receiver operator characteristic curve (AUC-ROC) was calculated for the statistical and machine learning models. AUC-ROC was not calculated for the rule-based model as it is a deterministic model generating a binary decision output rather than a probability score output.

We used Monte Carlo and k-folds cross-validation (stratified and unstratified) to validate the calculated performance metrics for the initial statistical and machine learning models across multiple simulations. Monte Carlo cross-validation consisted of 100 simulation cycles randomly partitioning the annotated data set into 75% training/15% development/10% testing splits. k-folds cross-validation was performed using 10 cycles of 10-fold repeated cross-validation (100 total cycles), with and without stratification, and sampled 8 training folds, 1 development fold, and 1 test fold during each cycle. Precision, recall, F-measure, and AUC-ROC were calculated for each cycle across both cross-validation methods.

Ethical Considerations

This study received exemption approval from the institutional review boards of the VA Connecticut Healthcare System (1690344-1) and Yale University (2000032830).

Results

We identified 56,628 patients for inclusion in this study, with a total of 377,213 visits across the study period. Patient and visit characteristics are presented in Table 1. The patient population was consistent with those usually receiving VHA chiropractic care. Patients had a median of 5 (IQR 3-6) chiropractic care visits, with most visits occurring for low back pain. There were 14,198 patients (25.1%) who had at least one 60-day care gap. The tokenized text across the entire corpus had a mean length of 565 tokens (SD 434), with 4617 notes (1.2%) greater than 2000 tokens in length.

Assessing the tokenized text lengths by visit type for the entire corpus split by whitespaces (Figure 2) showed a greater number of tokens in the first (consult) visits compared with the other visit types. The distribution of tokenized length of first (consult) visits was right-shifted compared with all other visit types, with a mean length of 1069 tokens (SD 565) and 3198 notes (5.6%) greater than 2000 tokens in length. The mean token length was 464 (SD 316) for other intermediate visits, 514 (SD 404) for visits preceding a 60-day care gap, 587 (SD 427) for visits following a 60-day care gap, and 490 (SD 358) for final visits within 1 year. A Kruskal-Wallis test demonstrated statistically significant differences across the 5 visit types (P<.001), with all corrected pairwise comparisons significant at P<.001 except visits preceding a 60-day care gap compared with final visits within 1 year (P=.008). Tokenized text lengths by FY (Figure 3) showed a mean length of 579 (SD 456) tokens in FY2018, 571 (SD 435) tokens in FY2019, and 496 (SD 348) tokens in FY2020. A Kruskal-Wallis test showed a statistically significant difference across the FY groups (P<.001), with corrected pairwise comparisons demonstrating significant differences between FY2020 and each of FY2018 and FY2019 (P<.001), but not between FY2018 and FY2019 (P≥.99).

For each included PROM, the text span match frequency and note categorization frequency between human annotation and the rule-based model output on the full training set and in the full-text corpus are presented in Multimedia Appendix 1. When the rule-based model was run on the full note corpus, there were 112,131 PROM text spans identified across 64,027 notes (17.0% of the full corpus), a prevalence consistent with that of human annotation in the initial annotation training set (53 of 300 notes, 17.7%). PROM documentation was identified in 13.8% (n=32,341) of other intermediate visits, 32.7% (n=18,519) of first (consult) visits, 13.2% (n=2365) of visits preceding a 60-day gap in care, 13.9% (n=1733) of visits following a 60-day gap in care, and 16.0% (n=9069) final visits within 1 year. The prevalence of documented PROM use, by visit, decreased over time (19.1% in FY2018, 16.5% in FY2019, and 13.2% in FY2020) (Multimedia Appendix 3). The most documented PROMs were the Bournemouth Questionnaire (back and neck versions) and the Oswestry Disability Index.

Rule-based model performance across the strict- and soft-boundary matching and note categorization tasks are shown in Table 2. Performance for the strict-boundary matching task was low across all metrics. When relaxing the matching criteria to allow for soft-boundary overlap, the model performance

XSL•FO
RenderX

improved substantially with good to excellent model performance that was balanced across precision and recall with few false positives and very few false negatives. Rule-based model performance in the note categorization task was excellent, with high precision and near-perfect recall.

The comparison between the rule-based model and the initial statistical and machine learning model performance on the note categorization task is shown in Table 3. Using the rule-based model output as a binary text categorization yielded better performance across all metrics and high accuracy (95.8%) compared with the spaCy models. Performance metric distributions (Figure 4) and the mean metric with 95% CI (Table 4) were consistent across each cross-validation method, with acceptable to good model performance across all metrics for all spaCy models. The model consistently outperformed both the BOW and convoluted neural network models across all metrics, with a good balance between precision and recall and a high AUC-ROC.

Discussion

Principal Findings

In this study, we tested NLP approaches to identify PROM use documented in VHA chiropractic clinic notes as a method to monitor an important marker of high-quality chiropractic care. Our iterative process targeting a series of prediction tasks showed overall strong performance across rule-based, statistical, and machine-learning approaches, affirmed by multiple approaches to cross-validation. The rule-based NLP model had good to excellent performance in identifying text spans referencing PROMs when flexible span boundaries were used but not when span boundaries were strict. When using the rule-based model output as a note categorization prediction, overall performance was excellent, with high precision and near-perfect recall. While our initial hypothesis predicted comparable performance between the rule-based approach and the statistical and machine learning methods, our findings demonstrate that the rule-based approach achieved superior performance in identifying and categorizing PROM documentation within this sample of VHA chiropractic clinic text notes. We suspect improved performance may be attributable to data volume and sparsity of text indicators of PROMs relative to the remaining document content describing the rest of the chiropractic care encounter. Rule-based models are generally less susceptible to data volume issues given their methodical approach, whereas machine learning approaches thrive on large data sets where more complex patterns and relationships can be trained on and identified in the text. Important benefits of the rule-based approach include simplicity, interpretability, and efficiency—all of which provide added value alongside slightly superior performance.

Overall model performance was sufficient to have clinical utility for quality metric monitoring, especially given the low prevalence of false negatives. The error analysis process used during model development identified that remaining false positives were frequently due to unique circumstances difficult to address by creating exclusion rules without overfitting the training data. For example, the text “Goals of Care: Improve outcome measures, reduce ODI by 20%” would identify a section span to exclude (“Goals of Care”) followed by a section span to include (“outcome measures”) and a PROM span (“ODI”), therefore marking the PROM span for inclusion.

Consistent findings across multiple methods of cross-validation, with and without stratification accounting for baseline PROM use prevalence, showed acceptable performance for each of the statistical and machine learning models tested on the note categorization task. Of note, several performance metrics in the initial model evaluation fell outside the cross-validation estimated 95% CI, attesting to the benefit of cross-validation in generating a more appropriate representation of performance.

Clinical Implications and Future Work

While all models performed adequately for note categorization, we used the rule-based model, having the best performance, on the full corpus to estimate the overall prevalence of PROM

XSL•FO
RenderX

documentation. The overall prevalence was low and consistent with estimates from the annotation data, highlighting the potential limited documented use of PROMs by VHA chiropractors despite being an identified quality care metric. This is in contrast with data from surveys of US chiropractors in which 60% of respondents reported using PROMs several times per day [27]. Qualitative evaluation in a non-VHA setting has highlighted multiple barriers and facilitators to implementing PROMs in chiropractic care [28]. These included clinician knowledge and training, engagement and purpose of collecting PROM data, perceived utility versus burden for clinicians and patients, and organizational and administrative factors (such as in-visit time availability and ability to use electronic data collection systems). Evidence of external determinants influencing PROM use can be hypothesized from our results showing a decreasing trend in documented PROM use across each year of the study period. The VHA Chiropractic Program rapidly expanded nationally during this time, with an increase in the number of employed VHA chiropractors [29] and increasing service penetration across the national VHA system [30]. Thus it is possible that our results reflect an increasing number of new chiropractors not using PROMs, not documenting PROM use in clinic notes, or a combined effect of the 2, highlighting a potential opportunity for quality improvement and education.

Given our findings, we hypothesize there is a relationship between documentation quantity as a proxy for comprehensiveness of evaluation, including the use of PROMs. PROM use was most prevalent in first (consult) visits at more than double the rate found in other visit types. Paired with significantly longer text lengths compared with other visit types, this suggests that the increased complexity and information gathering inherent in initial consultations necessitate more thorough documentation, including the application of outcome measures. Additionally, the decrease in documented PROM use during FY2020, paired with shorter text length in FY2020, is potentially attributable to the onset of the COVID-19 pandemic with changes in the quantity and mode of delivery of chiropractic care [31] and challenges in administration due to impacted face-to-face care with limited availability of remote data collection information systems.

Future work should consider patient, visit, facility, clinician, and system factors, including qualitative perspectives of VHA chiropractors, that may influence the use of specific PROMs and their documentation by VHA chiropractors. These determinants can inform intervention development and implementation strategies related to improving PROM use and documentation. However, these potential external influences do not affect our confidence in the performance of the developed NLP models to evaluate documented PROM use by VHA chiropractors on a national scale as a quality metric.

The implications of tracking PROM use by VHA chiropractors using this approach include enhanced patient outcomes, improved clinical decision-making, and ensuring consistent, high-quality chiropractic care for veterans. These are consistent with core practical considerations for the development of NLP systems to address pragmatic clinical needs and improve patient outcomes, including offering an organization incentive for use and supporting ongoing monitoring with implementation feasibility [32]. Within the VHA chiropractic care setting, our approach allows for the monitoring of an important quality metric at a national scale using centralized resources. Additionally, this approach standardizes and enhances the objectivity and rigor of assessment of documentation content, while minimizing the individual burden of chart review by practicing VHA chiropractors. Further, our methods may have application in other clinical settings providing musculoskeletal pain care, in the VHA and beyond, given the high prevalence of musculoskeletal pain in both veteran and nonveteran populations. Future research should focus on refining these NLP models to enhance their applicability across diverse clinical settings, including other pain care clinics, and explore the integration of additional data sources to further enrich patient care insights. Additionally, future research can evaluate the efficiency of our approach in terms of financial, human, computational, and other resource costs compared with traditional manual review methods to best understand the potential value and system resource use implications of this work.

Limitations

There are several limitations to our study that are inherent to any observational research or studies using NLP. The text notes used in this study were originally intended for clinical care purposes. Thus, their secondary use for research is subject to limitations in the quality of the notes and the content documented for that purpose, which may not always fully reflect what was done during the patient encounter. Observing the variation in the quantity of text (ie, number of tokens) present in each note across the corpus showed an expectedly right-skewed distribution and highlighted heterogeneity in the quantity of text content included in VHA chiropractic clinic notes. Similar findings were evident in tokenized length differences between visit types and the year during which a visit occurred. We suspect this correlates with heterogeneity in comprehensiveness of documentation, and by proxy of care delivered, highlighting a future opportunity for VHA chiropractor education or other quality improvement interventions to ensure consistent quality on a national scale. Templated material in clinic notes, while difficult to quantify across the corpus, may limit the richness and variability of the text data, potentially affecting the capture of patient- and note-specific details. It was evident during annotation that templates were, at times, shared across VHA facilities, which may affect our intention to capture variability across the VHA by stratifying our random sampling of notes by the facility. Further, our sampling by facility may not account for variations between individual chiropractors at a given facility. Stratifying our random sampling by a chiropractor was an alternative strategy but risked increasing the heterogeneity of the sample.

Our strategy to capture clinic notes is consistent with previous practices to identify VHA chiropractic clinic visits and associated notes. However, facility variation in clinic workflow may also influence the use and the documentation of PROMs separately. While expected that these would be documented in the EHR, clinics may use alternative strategies for the collection and recording of PROMs from patients and limiting our findings

XSL•FO
RenderX

to representing "documented PROM use." Further, the initial seed list of PROMs suspected to potentially be used by VHA chiropractors was established a priori without empirical validation. We allowed flexible expansion of the initial list during the annotation process to include PROMs that had use, but were not considered in advance, yet it is possible we still failed to include PROMs that may have been used more rarely than our random sampling could capture. As future PROMs are developed and adopted, maintenance of the proposed NLP approach to incorporate these has not been assessed in this study. While this would require some degree of manual effort, we do not suspect that incorporating additional PROMs into the model is particularly challenging given our experience in expanding the initial seed list during this study. We also did not incorporate pretrained or large-language models into this analysis due to restricted use in our computing environment at the time of this study. If, in future research, these types of models are successfully able to be validated with adequate performance and implemented, their adoption may mitigate the requirement of ongoing manual efforts. We also did not conduct a formal text feature analysis on the output from the tested machine learning models, which could provide insight into the contributions of specific text to the model prediction. This may be an important contribution in future work to compare the explainability of the machine learning approaches to the generally interpretable rule-based approach and potentially optimize machine learning model parameters to enhance prediction performance.

Our sample of patients receiving VHA chiropractic care from the MSD/CIH Cohort allowed overlapping entry into the parent cohort and our study sample through the end of the study period, ideally representing all chiropractic care occurring during this time. However, by limiting our follow-up period for an individual patient to 1 year after their initial chiropractic visit, we may have excluded chiropractic care received later in the study period. This, along with the onset of the COVID-19 pandemic, may account for the rapid reduction in patients and visits during the final year of the cohort with unknown potential impact on our findings.

As all notes in this study originated during VHA chiropractic care, there is unknown utility of the developed NLP models in non-VHA chiropractic documentation. Variations in the documentation requirements between the VHA and non-VHA settings for administrative purposes (eg, billing) may influence the use and documentation of PROMs. Nonetheless, our sample originates from the largest collection of chiropractic care EHR data in an integrated medical setting, with evidence from VHA studies of chiropractic care having the potential to influence chiropractic care in the non-VHA setting.

Conclusions

Our study demonstrates the effective use of NLP to accurately identify documented PROM use from VHA chiropractic clinic notes, highlighting the potential for improved data use in quality monitoring of patient care. By leveraging an NLP approach, we can overcome the challenges posed by unstructured clinical text notes to track an identified quality care metric for chiropractic care. Overall documented use of PROMs was low and highlights the need for quality improvement. Future work should evaluate determinants influencing PROM use and develop intervention and implementation strategies to improve their use and documentation in VHA chiropractic care to ensure consistent, high-quality chiropractic care for veterans.

This material is based upon work supported by the National Center for Complementary & Integrative Health of the National Institutes of Health under award number K08AT011570. Successful completion of this study also builds on the support of previous work by the Department of Veterans Affairs, Veterans Health Administration, Office of Research and Development, Health Services Research and Development IIR-12-118, and the NCMIC Foundation, with resources and the use of facilities at the VA Connecticut Healthcare System.

Data Availability

The code developed in this research has been made publicly available on GitHub (bccolemanva/outcomemeasure-nlp). The datasets generated and analyzed during this study are not publicly available. To maximize the protection and security of veterans' data while making these data available to researchers, the US Department of Veterans Affairs (VA) developed the VA Informatics and Computing Infrastructure (VINCI). VA researchers must log onto VINCI via a secure gateway or virtual private network connection (VPN) and use a virtual workspace on VINCI to access and analyze VA data. As per the VA Office of Research and Development Policy, VINCI does not allow the transfer of any patient-level data out of its secure environment without special permission. Researchers who are not VA employees must be vetted and receive "without compensation" (WOC) employee status to gain access to VINCI. All analyses performed for this study took place on the VINCI platform. For questions about data access, contact study lead, BCC (Brian.Coleman2@va.gov) or the VA Office of Research and Development (VHACOORDRegulatory@va.gov).

Abstract

Background: Patients' oral expressions serve as valuable sources of clinical information to improve pharmacotherapy. Natural language processing (NLP) is a useful approach for analyzing unstructured text data, such as patient narratives. However, few studies have focused on using NLP for narratives in the Japanese language.

Objective: We aimed to develop a high-performance NLP system for extracting clinical information from patient narratives by examining the performance progression with a gradual increase in the amount of training data.

Methods: We used subjective texts from the pharmaceutical care records of Keio University Hospital from April 1, 2018, to March 31, 2019, comprising 12,004 records from 6559 cases. After preprocessing, we annotated diseases and symptoms within the texts. We then trained and evaluated a deep learning model (bidirectional encoder representations from transformers combined with a conditional random field [BERT-CRF]) through 10-fold cross-validation. The annotated data were divided into 10 subsets, and the amount of training data was progressively increased over 10 steps. We also analyzed the causes of errors. Finally, we applied the developed system to the analysis of case report texts to evaluate its usability for texts from other sources.

Results: The F_1-score of the system improved from 0.67 to 0.82 as the amount of training data increased from 1200 to 12,004 records. The F_1-score reached 0.78 with 3600 records and was largely similar thereafter. As performance improved, errors from incorrect extractions decreased significantly, which resulted in an increase in precision. For case reports, the F_1-score also increased from 0.34 to 0.41 as the training dataset expanded from 1200 to 12,004 records. Performance was lower for extracting symptoms from case report texts compared with pharmaceutical care records, suggesting that this system is more specialized for analyzing subjective data from pharmaceutical care records.

XSL•FO
RenderX

Conclusions: We successfully developed a high-performance system specialized in analyzing subjective data from pharmaceutical care records by training a large dataset, with near-complete saturation of system performance with about 3600 training records. This system will be useful for monitoring symptoms, offering benefits for both clinical practice and research.

Introduction

In clinical settings, information, such as changes in a patient's condition and the occurrence of adverse events, is essential for providing optimal pharmaceutical care. However, physicians commonly underestimate or underreport symptoms expressed by patients themselves [1,2]. For example, a clinical study involving patients with advanced non–small cell lung cancer showed that physicians underreported grade 2 skin toxicity and fatigue and all grades of diarrhea compared with patients, with only a few grade 3 and grade 4 adverse events reported [2]. In contrast, patient self-reports, including patient questionnaires and the PRO-CTCAE (patient-reported outcomes version of the Common Terminology Criteria for Adverse Events) Measurement System, are considered useful and are increasingly used in cross-sectional surveys of adverse events [3-5]. Therefore, the clinical information contained in a patient's self-report can be used, when appropriately identified, to prevent an underestimation of patient symptoms.

Unlike structured databases, such as the Japanese Adverse Drug Reaction Report Database, text data, such as patient narratives, comprising natural language, are often unstructured and ambiguous in meaning. To enable computers to handle and analyze natural languages, appropriate natural language processing (NLP) technology is necessary. For example, named entity recognition (NER) technology can be used to extract disease and symptom names from natural language text and determine whether the extracted terms are positively or negatively expressed (positive-negative classification). NER is expected to be useful for analyzing symptoms, as in adverse event monitoring. NER has been applied to data from social media platforms to investigate patient outcomes related to post–COVID-19 conditions [6] and to assess the frequency of adverse drug reactions [7].

Patient narratives are accumulated in pharmacist records as well as posts on social media platforms. Because pharmacists routinely assess the efficacy and safety of pharmacotherapy, their records contain a large amount of patient information regarding adverse drug events. Pharmacist records are often structured using the SOAP format: subjective data (S), objective data (O), assessment (A), and plan (P). The subjective data in the SOAP format contain the patients' raw words. Therefore, the subjective data in pharmacist records could serve as a rich source of patient narratives related to adverse events.

As mentioned above, some investigations have been conducted to extract information, such as diseases and symptoms, from text data. For example, Nikfarjam et al [7] developed a neural network–based system to extract adverse drug events from patient postings on social health networks in English. Similarly, Batbaatar et al [8] employed deep learning methods to extract not only diseases and symptoms but also pharmacological substances and other health-related information from social media service posts in English. However, most NER research has focused on physician records [9-11] or data in English [6-8,12-18], with few studies targeting Japanese pharmacist records.

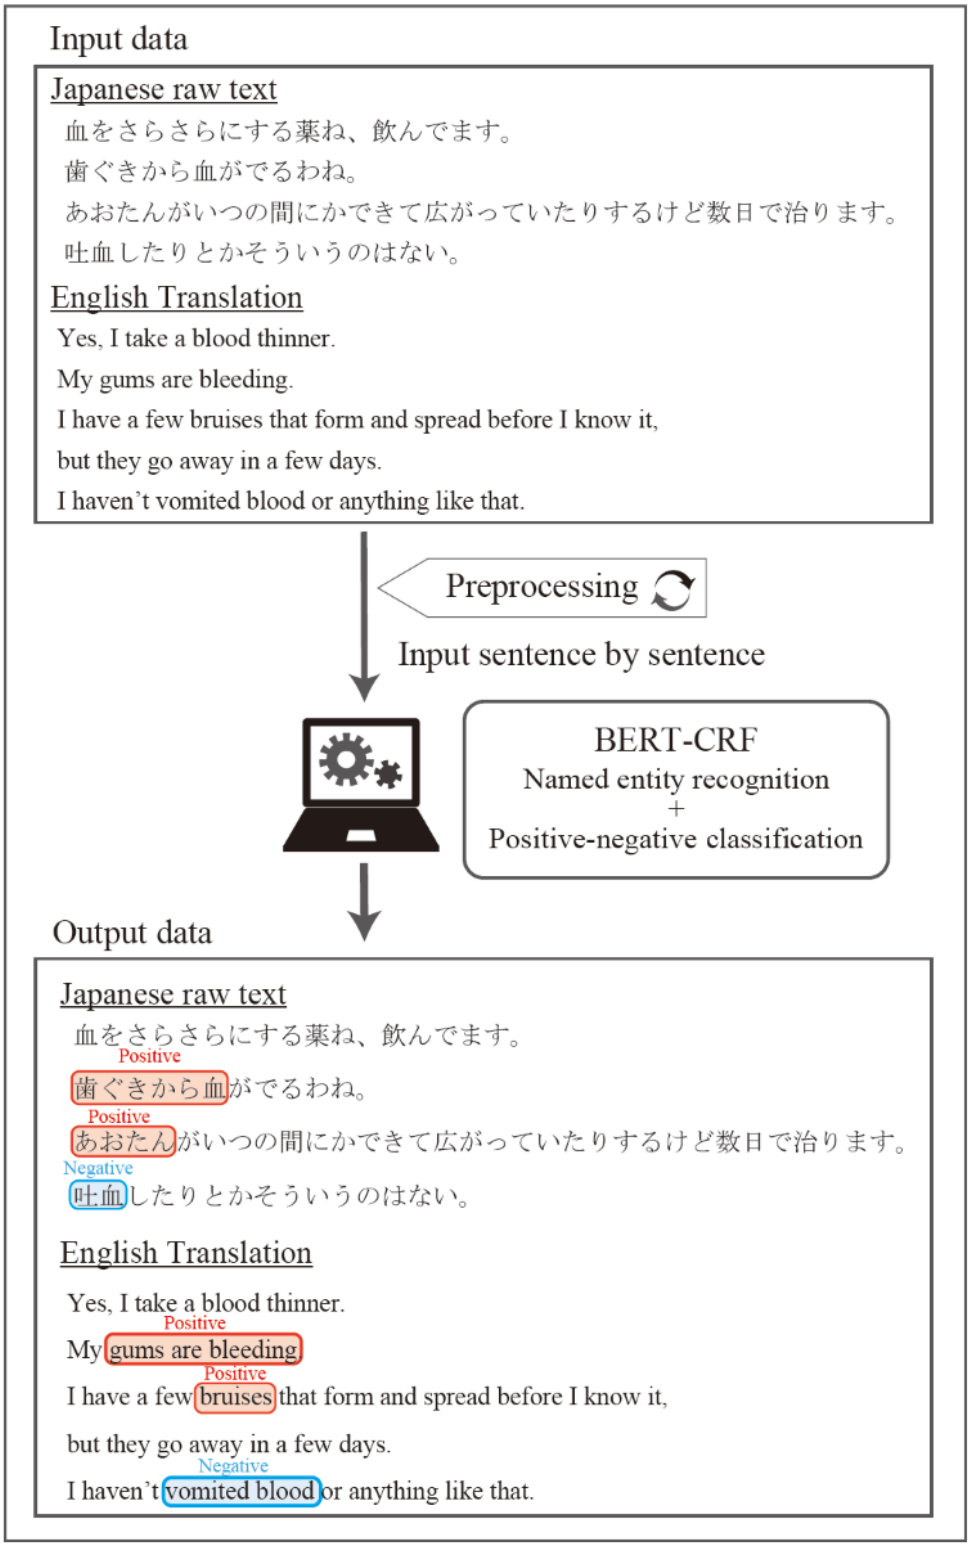
In a study focusing on Japanese pharmacist records, Usui et al [19] developed a rule-based system to extract patient complaints from the electronic medication records of Japanese community pharmacies and standardize them using International Statistical Classification of Diseases and Related Health Problems 10th Revision (ICD-10) codes. However, the rule-based system could not handle patient words not appearing in its predefined list of rules. Therefore, we hypothesized that a deep learning model could extract diseases and symptoms from the text more accurately than the rule-based system of Usui et al [19].

A system has already been developed to target physician records based on a deep learning model, bidirectional encoder representations from transformers (BERT)–conditional random field (CRF). BERT is an effective NLP model that can be fine-tuned for a variety of tasks [20]. In addition, several studies have reported that BERT-CRF [21,22], which adds a CRF layer to the output, performs well in the NER task. We previously examined whether the current system could be adapted to pharmaceutical care records without modification [23]. The system showed relatively high performance for the assessment data from pharmaceutical care records written in SOAP format. However, the performance of the system was inadequate for subjective data, objective data, and the plan. Furthermore, taking into account the importance of subjective data in adverse event analysis, it was determined that the system needed to be trained using subjective data.

In this study, we aimed to develop a new NLP system to accurately extract disease and symptom names (disease name extraction) from patients' subjective data and determine whether these conditions are affirmed or denied (ie, present or absent). In addition, it is generally accepted that system performance improves with the amount of training data used. However, case reports and physician summaries, in which more research has been conducted than patient narratives, are organized in physicians' own words. On the other hand, patients' narratives are freely worded and nonorganized. Therefore, it is important to know how the system's performance changes as the training amount increases when targeting such unorganized data. Furthermore, from an annotation cost perspective, annotation

XSL•FO
RenderX

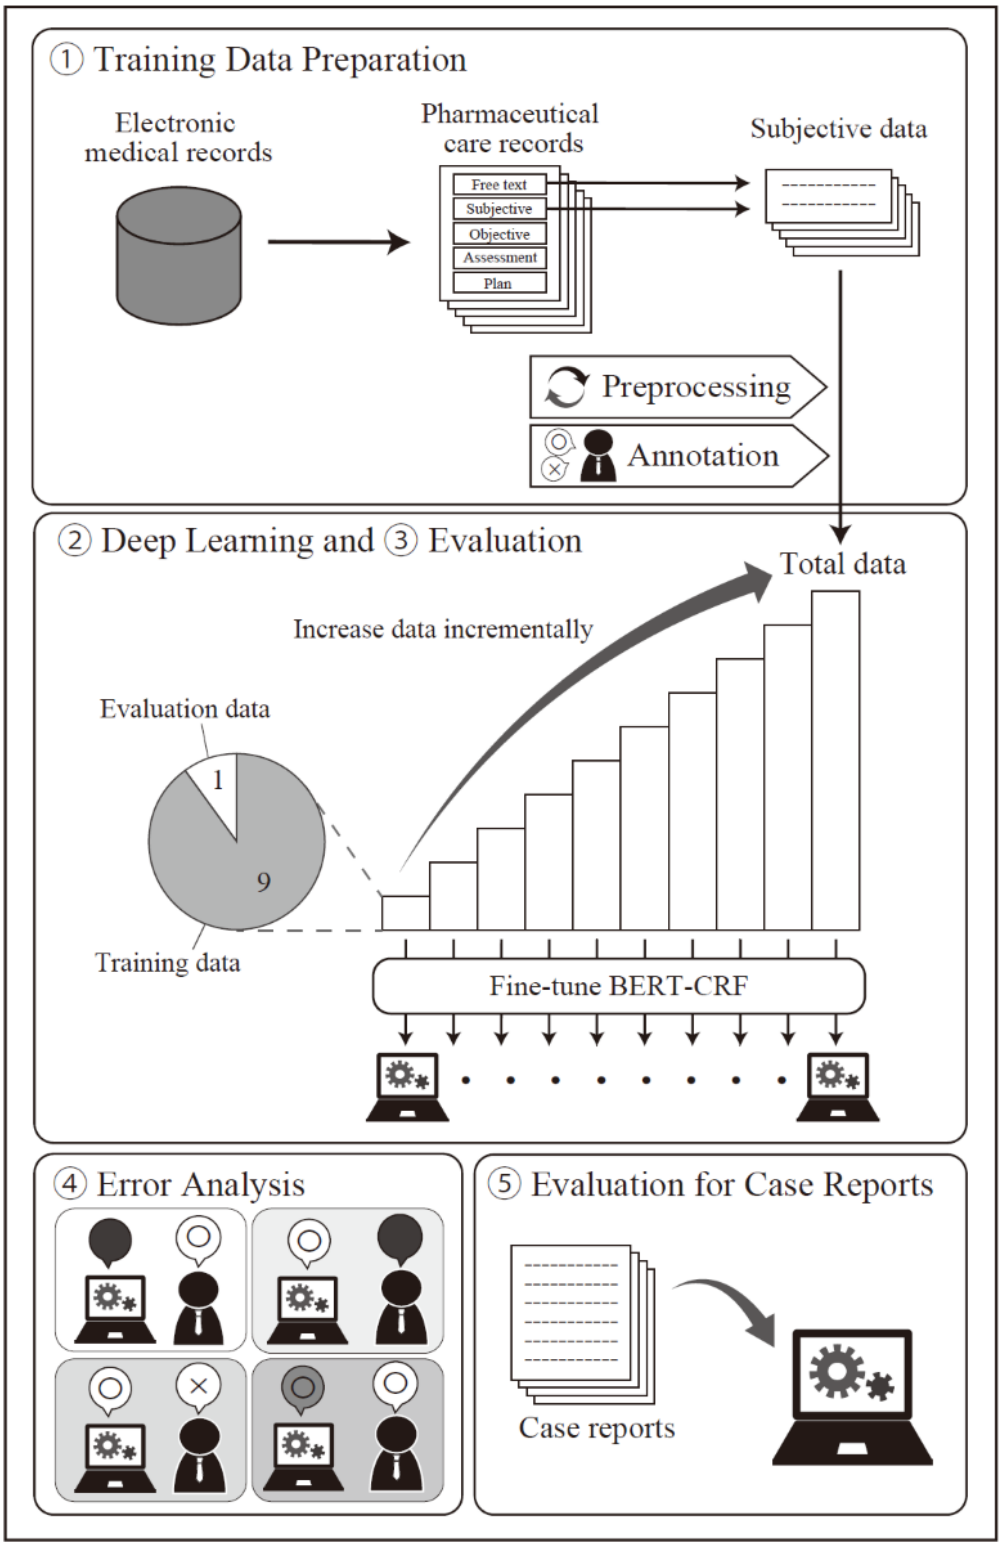
of medical documents requires more cost and effort due to its highly specialized and complicated nature. Therefore, resources can be distributed efficiently by predicting the approximate amount of annotation with a high learning effect. Thus, we also investigated how the system performance changed as the amount of training data increased.



Methods

Overview

We aimed to develop a system that extracts disease names from patients' subjective texts and determines whether the conditions are affirmed or denied in the sentence (Figure 1). The input was processed sentence by sentence. To develop and evaluate the system, this study included 5 parts: training data preparation, model training, evaluation, error analysis, and evaluation of the usability of the system for case reports (Figure 2).



XSL•FO
RenderX

Figure 1. Conceptual diagram of the disease-name extraction system operation. After inputting preprocessed text data into the system sentence by sentence, the system extracts diseases and symptoms as outputs and predicts the presence or absence of each finding. BERT: bidirectional encoder representations from transformers; CRF: conditional random field.

XSL•FO
RenderX

Figure 2. Overview of this study. Subjective data were collected from pharmaceutical care records in the electronic medical record system. Data were preprocessed, and diseases and symptoms in the data were annotated to prepare the training data. A disease-name extraction system was developed, and its performance was evaluated through 10-fold cross-validation with progressive increases in the amount of training data over 10 steps. Errors that occurred during the performance evaluation were sampled, and the causes of the errors were analyzed. The developed system was applied to case reports, and its performance for case reports was investigated. BERT: bidirectional encoder representations from transformers; CRF: conditional random field.

In the training data preparation, subjective texts were preprocessed and annotated. In the deep learning part, a disease-name extraction system was constructed based on a deep learning model by increasing the amount of training data in 10 steps. In the evaluation part, cross-validation was used to evaluate performance at the same time as training. We sampled the evaluation results and classified the causes of errors in the error analysis part. In the evaluation of the usability of the system for case reports, we evaluated the performance of the developed system when applied to case reports. Each step has been described in the following sections.

XSL•FO
RenderX

Training Data Preparation

The pharmaceutical care records in the electronic medical record system of Keio University Hospital, written by pharmacists in Japanese, were used as the source of training data. These records comprise 5 columns: subjective, objective, assessment, plan, and free text. In some cases, SOAP-formatted sentences are included in the free-text column. In this study, we collected 12,004 subjective data records from 6559 cases in the subjective and free-text columns described from April 1, 2018, to March 31, 2019.

All text data in the pharmaceutical care records were converted to full-width (2-byte) characters. Line breaks or periods were used as sentence separators, and spaces at the beginning and end of sentences, as well as blank lines, were deleted. Additionally, the string "_X000D_," indicating a line break, was removed. Two researchers independently annotated 400 records based on the annotation criteria described in the following paragraph. A comparison between their annotations obtained a high κ coefficient (κ coefficient=0.92), indicating almost perfect agreement. Therefore, the remaining data were annotated by a single researcher.

The annotation criteria were originally developed by our group to collect information for adverse event monitoring in clinical practice and epidemiological studies. Patient expressions related to diseases or symptoms, including nouns, verbs, adjectives, and adverbs, were extracted. The time of onset, site, severity, and triggers of symptoms were also extracted when they were described near the clinical findings. Numerical information was excluded because such data should be obtained from the structured electronic medical record database rather than text data. However, if the text verbally referred to changes in laboratory values, such as "increase in blood pressure," it was extracted as a target. Texts referring to normal renal function, liver function, blood electrolyte levels, appetite, sleep, and bowel movements were interpreted as negative references to abnormalities (ie, denial of symptoms) and were included in the extraction.

Deep Learning Method

In this study, we used BERT-CRF as a deep learning method. Several pretrained Japanese BERT models have been developed and published. In this study, we used the character-based BERT of Tohoku University, which is the most commonly used pretrained BERT model for Japanese. BERTJapaneseTokenizer [24], which uses MeCab as a morphological analyzer, was used as a tokenizer. Fine-tuning was performed with a batch size of 32 and with 10-fold cross-validation. In the 10-fold cross-validation, data were shuffled by sentence and then split into 10 groups (folds). The amount of training data was increased in 10 steps from 1200 to 12,004 records.

Evaluation

Precision, recall, and F_1-score were used as indices for performance evaluation. Precision was calculated as follows: number of true positives/number of true positives and false positives. Recall was calculated as follows: number of true positives/number of true positives and false negatives. F_1-score was calculated as follows: 2 × precision × recall/(precision + recall).

The final accuracy was calculated with the cross-validation method. The number of epochs was determined based on the F_1-scores obtained during cross-validation. We also investigated the performance by taking partial matches into consideration, as partially matched terms can still convey valuable clinical information. The Levenshtein distance [25] was used as the criterion for partial matches. The Levenshtein distance measures the resemblance between 2 strings (W1 and W2) and is defined as the minimum number of character deletion, insertion, and replacement operations required to convert one string into the other. Similarity was calculated using the following formula: similarity (W1, W2) = {max (|W1|, |W2|) − Levenshtein distance}/max (|W1|, |W2|), where |Wn| represents the number of characters (length) of Wn. Similarity values ranged from 0 to 1. We sampled the results of the cross-validation to list the partial matches and investigated any failures to extract essential terms that were correctly detected by researchers due to partial matches. Detailed results of this survey are provided in Multimedia Appendix 1. In this survey, the number of incomplete extractions without essential terms increased rapidly when the similarity was below 0.667. Of the 63 extracted terms with a similarity of 0.667 or higher, 4 terms had partially or entirely missing essential terms. However, at the next lowest similarity levels of 0.636 and 0.625, 5 of 9 extracted terms had partially or entirely missing essential terms. Therefore, in this study, "the number of matches, including partial matches" was defined as the sum of the number of complete matches and partial matches with a similarity of 0.66 or greater. In the error analysis, "partial matches with a lower similarity," described in the next section, were defined as partial matches with a similarity of less than 0.66. During the process of information processing in BERT, infrequent characters were converted to unknown keys ([UNK]). Because the data that we used to evaluate partial matches contained [UNK], we converted all [UNK] into full-width asterisks to calculate the similarity of the Levenshtein distances by regarding them as single characters.

Error Analysis

For 5 steps of the amount of training data, the results of the system were compared with the annotated diseases and symptoms in the validation data, and the causes of mismatches were classified into 4 categories (Table 1): error 1, failure of the system to extract; error 2, incorrect extraction by the system; error 3, difference in positive-negative classification; and error 4, partial matches with low similarity. Because the amount of data contained in 1 fold was different for each training amount, we used the number of folds that contained close to 1200 records: 10 folds, 3 folds, 2 folds, 1 fold, and 1 fold in the training data of 1200, 3600, 6002, 8402, and 12,004 records, respectively. The choice of which fold of the validation data to use for this analysis was based on the proximity of the F_1-score to the average rates when they were used in the evaluation. In this study, we defined the total number of extractions by the following formula: total number of extractions = number of researchers' extractions + number of system extractions − (number of exact matches + number of partial matches with a

XSL•FO
RenderX

similarity of 0.66 or greater). The error rate was given as the ratio of the number of errors to the total number of extractions: error rate (%) = number of errors × 100/total number of extractions.

Table 1. Definitions of error cause categories.

P-N[a] classification	Named entity recognition			
	Exact match	Partial match		Unmatch
		1>similarity>0.66	0.66>similarity>0	
Match	Exact match	Partial match	Error 4[b]	Error 1[c]/2[d]
Unmatch	Error 3[e]	Error 3[e]	Error 1[c]/2[d]	Error 1[c]/2[d]

[a]P-N: positive-negative.

[b]Error 4: partial matches with low similarity.

[c]Error 1: system extraction failure.

[d]Error 2: incorrect extraction by the system.

[e]Error 3: difference in the P-N classification.

In cases where the number of extracted terms differed between the researchers and the system, the number of errors was counted for the larger number. For example, when one extracted 2 symptoms and the other extracted them as a single (long-named) symptom, we counted them as 2 errors. Therefore, the sum of the error rate and the correct answer rate could exceed 100%. We further investigated changes in the error rates of the 4 categories with an increase in the amount of training data. For error categories with a greater increase in variation of the error rate obtained by the following formula, a detailed descriptive error analysis was performed: variation of error rates (%) = error rates after increasing training amount/error rates before increasing training amount × 100.

When the error rate before increasing the training amount was 0% and the error rate after increasing the training amount was greater than 0%, the variation of error rates was regarded as 100%.

Evaluation for Case Reports

To evaluate whether the developed system can be applied to other types of texts, we assessed the system performance using Japanese case report data. A series of 148 case reports was collected as validation data from the Real-MedNLP Test Collection. These data were distributed in the Real-MedNLP Test Collection and permitted for redistribution by the respective journal publisher [10]. These reports are available as open access through the "Japan Science and Technology Information Aggregator, Electronic," an electronic journal platform operated by the Japan Science and Technology Agency.

Case report validation data were also preprocessed and annotated in the same manner as the training data. Two researchers independently annotated 15 cases, approximately 10% of the total cases. Because the agreement between their annotations was almost perfect, with a κ coefficient of 0.93, the remainder was annotated by a single researcher. The validation data were applied to the 10 systems that were developed in the 10-fold cross-validation of each training amount to evaluate performance. The individual performances of the 10 systems were averaged and regarded as the performance of the system for each training amount.

Ethical Considerations

This study was conducted with the approval of the Keio University School of Medicine Ethics Committee (approval number: 20200067).

An opt-out method was used to ensure that study subjects had the opportunity to refuse the use of their information, since obtaining informed consent was difficult due to the large number of subjects and the fact that many of them had already been discharged from the hospital and had no direct contact with the hospital. Information on the research has been disclosed on the website of the Clinical Translational Research Center, Keio University Hospital.

Each subject's electronic medical record information was assigned a dummy ID at the time of registration, and information was managed through pseudonymization using dummy IDs.

Results

Training Data Features

12,004 subjective data in the pharmaceutical care records used as training data contained 43,553 sentences. These records included 12,287 affirmed diseases and symptoms and 8822 denied diseases and symptoms.

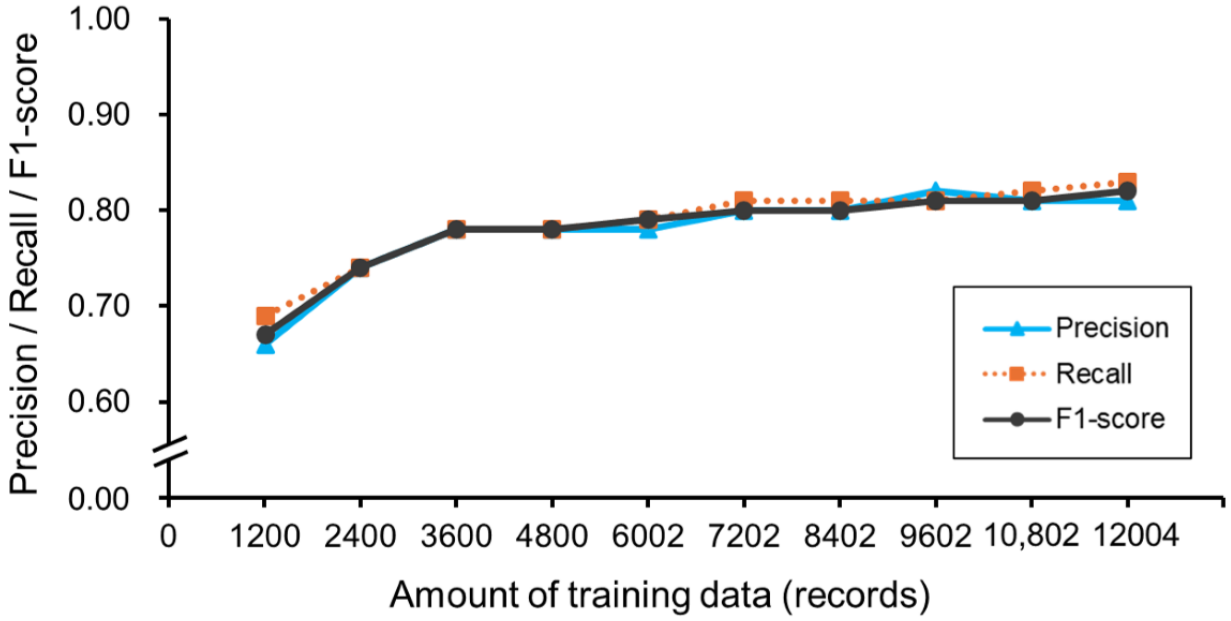
Evaluation

The training curves for precision, recall, and F_1-score values for exact matches are shown in Figure 3. As the training data increased from 1200 to 12,004 records, precision, recall, and F_1-score improved from 0.66 to 0.81, from 0.69 to 0.83, and from 0.67 to 0.82, respectively. A power approximation expression for the F_1-score of exact matches yielded the equation: $y = 0.40x^{0.08}$, predicting an F_1-score of 0.90 with 25,251 training records. Performance improvement saturated after training with 3600 records, indicating that a large amount of training data is needed to improve the F_1-score beyond 0.78. Comparing the F_1-scores for exact matches and those including partial matches, the performance gap tended to diminish as the amount of training data increased (Figure 4). The system trained

XSL•FO
RenderX

with 12,004 records achieved an F_1-score of 0.82 for exact matches and 0.84 when partial matches were included.

Figure 3. Training curve during cross-validation (only exact matches). Trends in the mean precision, recall, and F1-score values are shown from 1200- to 12,004-record trainings.



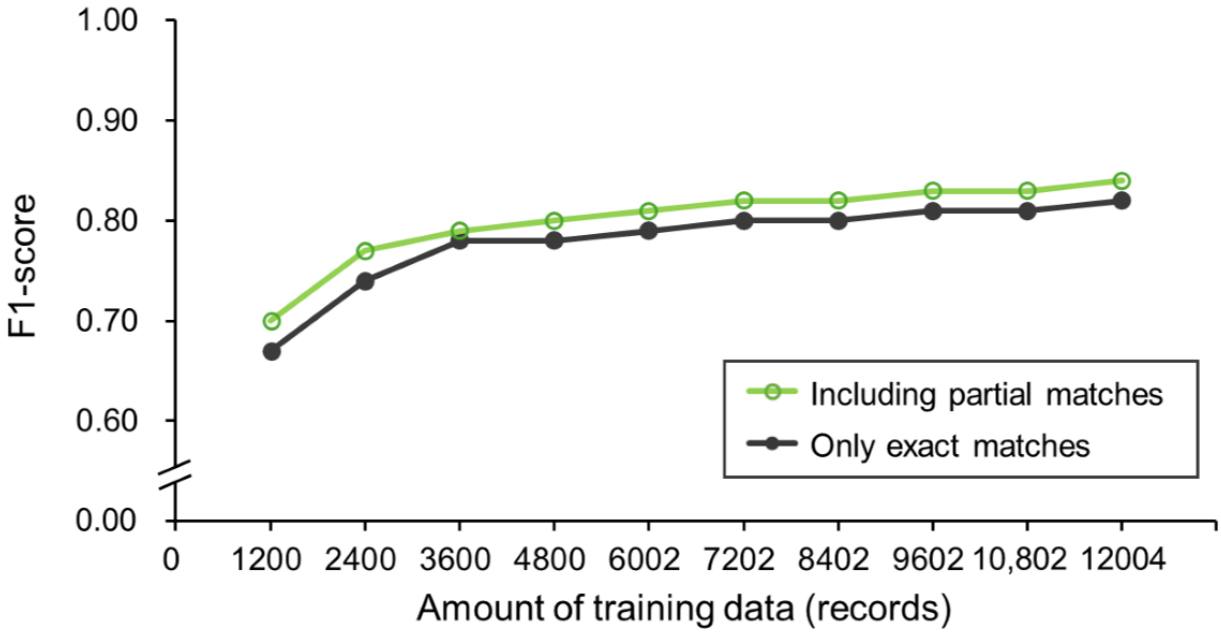


Figure 4. Training curve of the F1-scores during cross-validation (only exact matches/including partial matches). Trends in the mean F1-scores in which only exact matches were considered matches and in the mean F1-scores in which partial matches were included as matches are shown from 1200- to 12,004-record trainings.

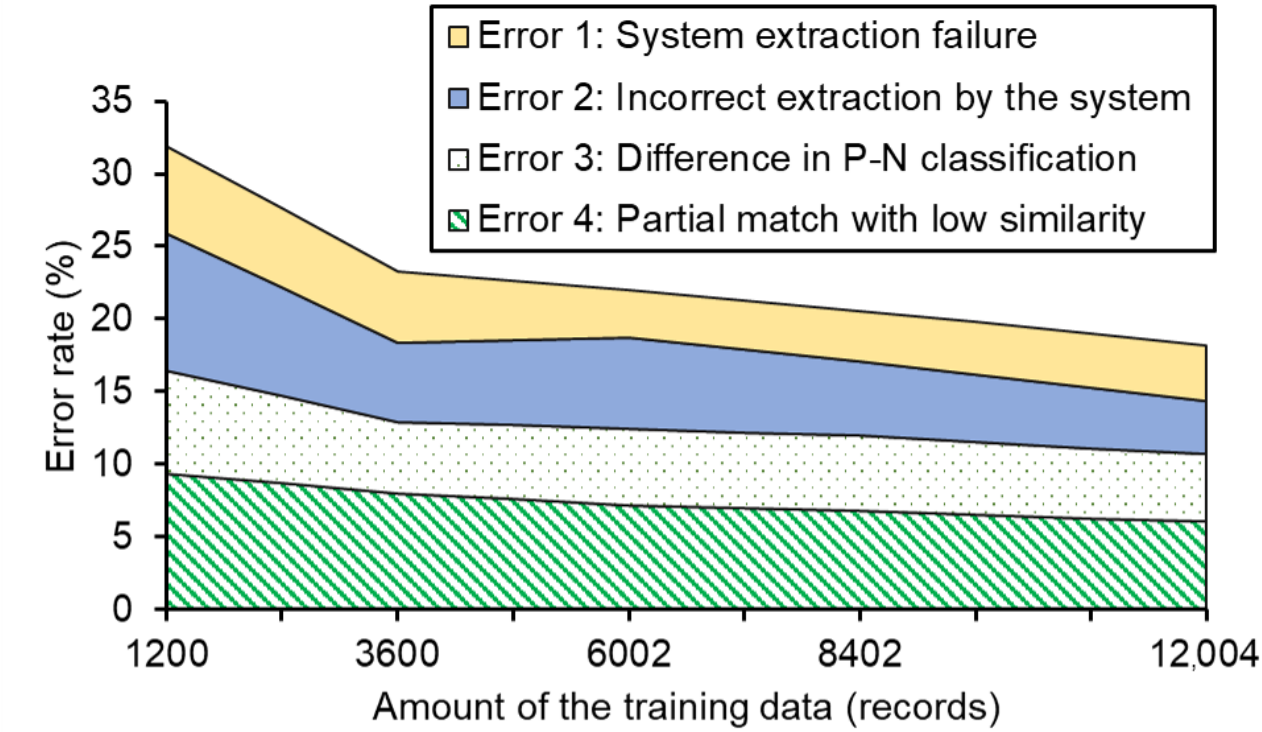


Error Analysis

Error analysis was carried out for 4395, 3924, 4396, 3071, and 4356 sentences from the validation data during cross-validation using 1200, 3600, 6002, 8402, and 12,004 records, respectively. The causes of errors were classified, and Figure 5 shows the transition of error rates for each cause. The overall error rate decreased from 31.9% (945/2963) to 18.2% (444/2446). The rate of error 2 (incorrect extraction by the system) showed the most significant decrease with an increase in the training records, followed by errors 4, 3, and 1. Error 2 decreased from 9.4% (280/2963) to 3.7% (90/2446) (–5.7 percentage points). Errors 4, 3, and 1 decreased from 9.4% (278/2963) to 6.1% (148/2446) (–3.3 percentage points), from 7.1% (209/2963) to 4.7% (114/2446) (–2.4 percentage points), and from 6.0% (178/2963) to 3.8% (92/2446) (–2.2 percentage points), respectively. Error 4 was the primary cause of error for the system trained with 12,004 records, followed by errors 3, 1, and

XSL•FO
RenderX

2. The 3600-record training when performance reached a plateau was used as a reference point. Comparing the variation in the error rates associated with the increase in the training amount from 1200 to 3600 records to the variation in the error rates associated with the increase in the training amount from 3600 to 12,004 records, the variation for errors 1 and 4 decreased by 9 percentage points and 5 percentage points, respectively, while the variation for errors 2 and 3 increased by 24 percentage points and 10 percentage points, respectively, indicating that improvement was stagnant. Therefore, we categorized errors 2 and 3 into subcategories and investigated the difference in the variation in error rates before and after the 3600-record training.

Figure 5. Trends in error rates for each error cause category. A sample study of performance evaluation results was conducted from 1200- to 12,004-record trainings. The errors are classified into 4 cause categories, and trends in error rates for each category are shown. P-N: positive-negative.

Error 2 was further classified into 7 subgroups (Table 2). The most common errors in the 1200-record training involved error 2a (the extraction of information that was neither symptoms nor supplemental information related to symptoms). This subcategory encompassed a wide variety of patient expressions, including behaviors, such as “strained in the bathroom,” indications of healthiness, such as “my blood pressure has been quite good,” and medication-related issues unrelated to patient symptoms, such as “the remaining number (of medications) became limited.” The second most common subcategory, error 2b (incomplete extraction without essential terms), involved errors in extracting terms that were not considered symptoms due to the absence of a subject, such as “loose” or “didn’t go well with me.” It also included cases where only supplemental words were extracted, such as “at night” or “very much.” The third most common subcategory, error 2c, involved errors related to the extraction of conditional terms that were annotated or not annotated by researchers depending on the context or were not finally annotated after the researcher was faced with a difficult decision. For example, researchers would annotate the patient expression “I couldn’t eat” as it indicates a symptom of the loss of appetite, while the expression “I couldn’t eat because I was too sleepy” would not be attributed to appetite. In addition, the expression “my stomach went like this” may have been regarded as a symptom because it represented an abnormal condition. However, the researchers finally decided not to annotate it. The next most common error subcategories were errors 2d and 2e (partial matches with low similarity and an incorrect positive-negative classification), which involved either entire or partial extraction of essential terms.

XSL•FO
RenderX

Table 2. Number of errors and the ratio of errors to total extraction in the subcategories of error 2.

Subgroup	Number of errors in 1200-record training (n=2963), n (%)	Number of errors in 3600-record training (n=2387), n (%)	Number of errors in 12,004-record training (n=2446), n (%)
Total errors of category 2	280 (9.4)	130 (5.4)	90 (3.7)
Error 2a: Extraction of information that was neither symptoms nor supplemental information	86 (2.9)	32 (1.3)	12 (0.5)
Error 2b: Incomplete extraction without essential terms	76 (2.6)	27 (1.1)	16 (0.7)
Error 2c: Extraction of conditional terms that were annotated or not by researchers depending on the context or were not finally annotated after the researcher was faced with a difficult decision	55 (1.9)	47 (2.0)	32 (1.3)
Error 2d: Partial matches with low similarity and incorrect P-N[a] classifications that involved entire extractions of essential terms	35 (1.2)	15 (0.6)	12 (0.5)
Error 2e: Partial matches with low similarity and incorrect P-N classifications that involved partial extractions of essential terms or incomplete extractions without essential terms	19 (0.6)	2 (0.08)	3 (0.1)
Error 2f: Symptoms that the researchers forgot to extract	7 (0.2)	6 (0.3)	12 (0.5)
Error 2g: Partial matches with low similarity involving entire extractions of symptoms for which the researchers made incorrect P-N classifications	2 (0.1)	1 (0.04)	3 (0.1)

[a]P-N: positive-negative.

From 1200- to 12,004-record trainings, significant improvements were observed in the following order: “extraction of information that was neither symptoms nor supplemental information (error 2a),” “incomplete extraction without essential terms (error 2b),” and “partial matches with low similarity and incorrect positive-negative classifications that involved entire extractions of essential terms (error 2d).” In contrast, “symptoms that the researchers forgot to extract (error 2f)” and “partial matches with low similarity involving entire extractions of symptoms for which the researchers made incorrect positive-negative classifications (error 2g)” increased from 0.2% (7/2963) to 0.5% (12/2446) and from 0.1% (2/2963) to 0.1% (3/2446), respectively. However, other subgroups showed overall improvements.

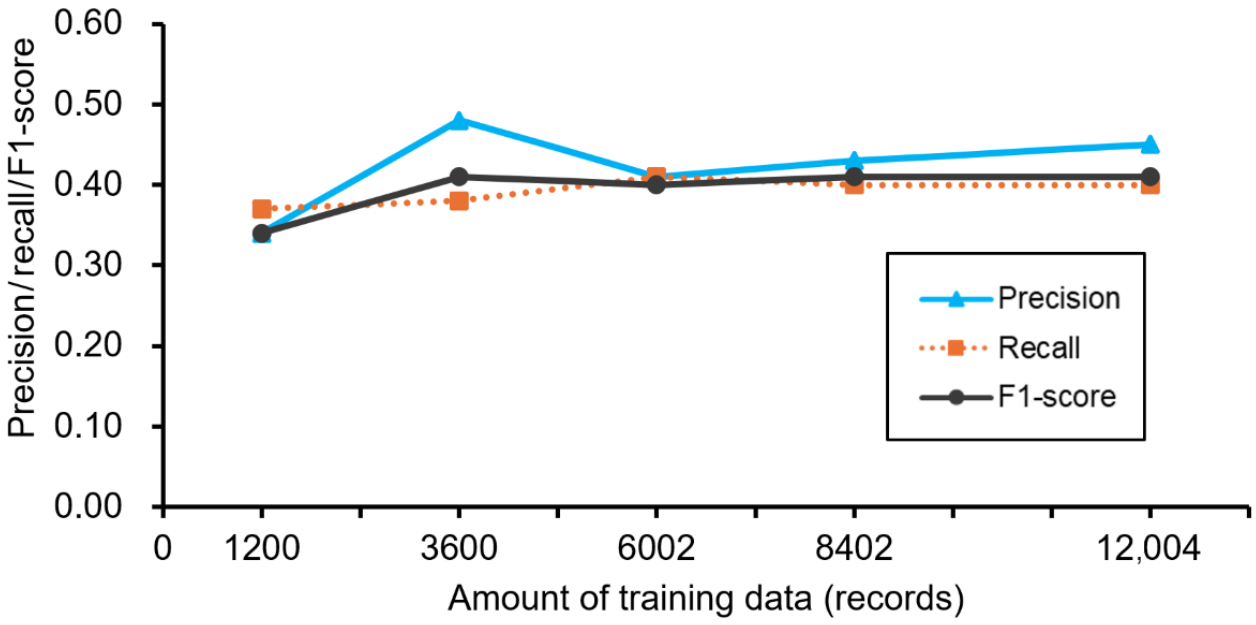
The differences in the variation of each subcategory before and after the 3600 cases were large in the following order: “partial matches with low similarity involving entire extractions of symptoms for which the researchers made incorrect positive-negative classifications (error 2g)” (231 percentage points), “partial matches with low similarity and incorrect positive-negative classifications that involved partial extractions of essential terms or incomplete extractions without essential terms (error 2e)” (133 percentage points), “symptoms that the researchers forgot to extract (error 2f)” (89 percentage points), “partial matches with low similarity and incorrect positive-negative classifications that involved entire extractions of essential terms (error 2d)” (25 percentage points), “incomplete extraction without essential terms (error 2b)” (14 percentage points), “extraction of information that was neither symptoms nor supplemental information (error 2a)” (–10 percentage points), and “extraction of conditional terms that were annotated or not by researchers depending on the context or were not finally annotated after the researcher was faced with a difficult decision (error 2c)” (–40 percentage points). A larger difference in the variation indicates a relative stagnation in the improvement of errors on increasing the training amount beyond 3600 records.

Error 3 was classified into 5 subcategories (Multimedia Appendix 2). The top 3 subcategories with the largest differences in variation before and after the 3600-record training in each subcategory were as follows: “determined from positive expressions (error 3b)” (125 percentage points), “determined from negative expressions (error 3c)” (64 percentage points), and “determined from other information (error 3a)” (–8.4 percentage points).

The contents of errors 3b and 3c, which showed particularly large differences in variation rates, were classified into further subcategories based on 2 points: the position of the positive-negative expression and the way in which the positive-negative expression was stated (Multimedia Appendix 3 and 4). Based on the method focusing on the position and the way of positive-negative expressions, we classified them into 5 and 6 subcategories, respectively. The differences in the variation before and after the 3600-record training in the subcategories focusing on the position of positive-negative expressions were large in this order: “more than three words are in between from the extracted terms (error 3bc-1-4)” (369 percentage points), “determination with reference to the positive-negative classification of another extracted term in the same sentence (error 3bc-1-5)” (200 percentage points), “included within the extracted terms (error 3bc-1-2)” (195 percentage points), “one or two words are in between from the

XSL•FO
RenderX

extracted terms (error 3bc-1-3)" (90 percentage points), and "immediately before or/and after the symptom (error 3bc-1-1)" (60 percentage points).



The differences in the variation before and after the 3600-record training in the subcategories focusing on the way of positive-negative expressions were large in this order: "determination with reference to the positive-negative classification of another extracted term in the same sentence (error 3bc-2-5)" (200 percentage points), "reversal of positive-negative classification by partial match (error 3bc-2-6)" (200 percentage points), "included within the extracted terms (error 3bc-2-2)" (157 percentage points), "mild negative expressions (error 3bc-2-3)" (119 percentage points), "simple positive or negative expressions (error 3bc-2-1)" (76 percentage points), and "negated positive or negative expressions (error 3bc-2-4)" (–15 percentage points).

"Error 3bc-1-5 (3bc-2-5): determination with reference to the positive-negative classification of another extracted term in the same sentence" and "error 3bc-2-6: reversal of positive-negative classification by partial match" had an error rate of 0% at the 3600-record training. Therefore, the difference in variability was large, as only one or two errors at the 12,004-record training resulted in 100% variation.

Evaluation of Case Reports

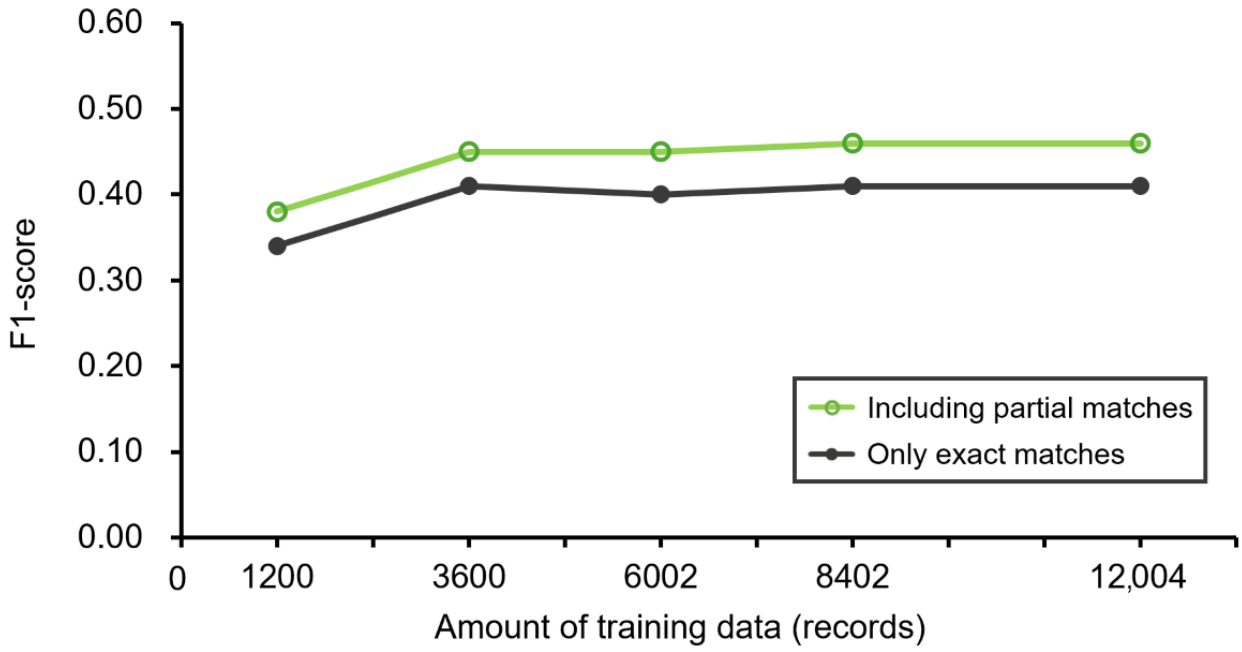


Figure 6 shows the improvement in system performance for the handling of the text data of case reports with an increase in the number of training datasets. The F_1-score increased from 0.34 to 0.41 with an increase in the training dataset and saturated at 3600 records of the training dataset. The differences between the F_1-scores for case reports and those for pharmaceutical care records were 0.33 and 0.41 at 1200 and 12,004 training dataset records, respectively. The differences between the F_1-scores for exact matches and those including partial matches were larger than those at cross-validation. In the performance evaluation for case reports, the F_1-scores for partial matches were always 0.04-0.05 higher than those for exact matches (Figure 7).

Figure 6. Performance of the case report analysis (only exact matches). Case reports were analyzed using systems trained with between 1200 and 12,004 pharmaceutical care records. Trends in the mean precision, recall, and F1-score values, which included only exact matches as matches, are shown.

XSL•FO
RenderX

Figure 7. F1-scores of the case report analysis (only exact matches/including partial matches). Case reports were analyzed using systems trained with between 1200 and 12,004 pharmaceutical care records. Trends in the mean F1-scores in which only exact matches were considered matches and in the mean F1-scores in which partial matches were included as matches are shown.

Discussion

Principal Findings

We developed a disease-name extraction system targeting subjective data in Japanese pharmaceutical care records by fine-tuning BERT-CRF. The performance of the system, evaluated by exact matches with a correct positive-negative classification, improved as the amount of training data increased, even though the system targeted subjective data, which has not been adequately addressed before. A similar trend was observed when evaluated by matches including partial matches, with a similarity score of 0.66 or higher. Although there was a certain number of partial match extractions, the extraction performance with partial matches was close to that for exact matches. This could be attributed to the strict criterion for similarity used in this study. The system performance increased slowly and reached a plateau at the 3600-record training. The results were presumably influenced by a combination of factors, including the deep learning model used (BERT-CRF), the complex annotation criteria, and human error in the annotation, which cannot be determined from this study. To resolve this point and further improve system performance, the use of deep learning models other than BERT-CRF should be considered. In addition, system performance will vary depending on the content of the training data. Therefore, when other training data are used to develop the system, it is difficult to say whether the system performance will reach a plateau with the same training amount in this study. However, by utilizing the characteristics of a gradual curve in performance transition, efficient training can be achieved by increasing the amount of training data step by step from a small amount and using an approximate formula to predict the training amount when performance reaches a plateau.

The analytical performance of the system was lower for case reports than for pharmaceutical care records. When records from different sources were used as training data, the improvement in system performance with increasing training data was inferior to that observed when training with records from the same source type. In addition, the analytical performance gap between text from the same type of training data and that from different types of data persisted, regardless of the amount of training data. In other words, the developed system was not well-suited for analyzing case reports but proved especially useful for analyzing patient narratives when trained on subjective data from pharmaceutical care records. This indicates that separate system development is necessary to analyze different types of records. The difference in performance between the case report analysis and the pharmaceutical care record analysis is assumed to be largely due to the existence of raw patient statements. However, another important feature is the different occupations of the health care professionals who create the records. Physicians create case reports covering the patients' conditions comprehensively and summarizing the patients' backgrounds and disease processes in their own words, while pharmacists mainly monitor drug efficacy and side effects and create pharmaceutical care records. Therefore, pharmacists naturally create SOAP format records that contain a lot of information about adverse events. We would like to emphasize again that our system is likely to be suitable for the collection of adverse event information since the system learned from the subjective data in pharmaceutical care records. Furthermore, since the pharmaceutical care records were written in SOAP format, we were able to selectively collect subjective data and use them for the training data in this study. As a result, a system specialized for subjective data was efficiently developed. This suggests that SOAP-format data may be a useful source for deep learning.

XSL•FO
RenderX

Error analysis revealed that the reduction in error 2 with increased training data was 5.7 percentage points (from 9.4% to 3.7%), a larger decrease than that observed for any other error type. This reduction in false-positive extractions significantly contributed to the improvement in precision. Although we prioritized recall over precision during system development to avoid missing symptoms, the increase in training data led to higher precision without compromising recall. Therefore, we believe that increasing the training data helped to develop a more user-friendly system with fewer false extractions.

Error Analysis

While errors in most subgroups of error 2 decreased, there were increases in error 2f (symptoms that the researchers forgot to extract) and error 2g (partial matches with low similarity involving entire extractions of symptoms for which the researchers made incorrect positive-negative classifications). Researchers may be more prone to making annotation mistakes as the amount of data to be prepared increases and as they encounter a wider variety of expressions. However, the percentage of these errors in total extractions was only 0.3% (9/2963) for the 1200-record training and 0.6% (15/2446) for the 12,004-record training, and thus, their impacts on overall system performance were small. Additionally, the system showed improvements in other types of false positives, indicating that increasing the training data can help to reduce a wide variety of false-positive errors.

Next, we looked at the variation in error rates for error 2. Among errors 2g, 2e, 2f, and 2d, which showed large differences in error rate variation, “partial matches with low similarity involving entire extractions of symptoms for which the researchers made incorrect positive-negative classifications (error 2g)” and “partial matches with low similarity and incorrect positive-negative classifications that involved partial extractions of essential terms or incomplete extractions without essential terms (error 2e)” were almost eliminated at the 3600-record training. Errors related to “symptoms that the researchers forgot to extract (error 2f)” and “partial matches with low similarity and incorrect positive-negative classifications that involved entire extractions of essential terms (error 2d)” were caused by researchers’ mistakes or errors in the extraction range or positive-negative classification, but the system was able to partially recognize the information to be extracted. Therefore, these errors may have been difficult to resolve.

Among errors 2b, 2a, and 2c, which showed limited differences in error rate variation, the extracted terms or pre/post descriptions of “extraction of information that was neither symptoms nor supplemental information (error 2a)” and “incomplete extraction without essential terms (error 2b)” were different from the real extraction target. Concerning the system’s context-readable specification, the system appears to have learned that the contexts before and after the incorrect extractions were not symptom-related contexts, reducing errors 2a and 2b, as it learned from large amounts of training data. “Error 2c” error rates increased at the 3600-record training. This finding indicates that error 2c improved less than error 2a and 2b when comparing the 1200 and 12,004-record trainings, although the difference in variation was small. Error 2c is more difficult to improve than errors 2a and 2b, presumably because error 2c contains expressions that researchers are also unsure about and that may be extracted depending on the situation.

Among the subcategories of error 3 focusing on the position of positive-negative expressions, “included within the extracted terms (error 3bc-1-2)” (195 percentage points) had a larger difference in error rate variation than “one or two words are in between from the extracted terms (error 3bc-1-3)” (90 percentage points) and “immediately before or/and after the symptom (error 3bc-1-1)” (60 percentage points). This suggests that the system may be able to perform correct positive-negative classification when the extracted terms and the positive-negative expressions are close to each other but not contained within the extracted terms.

Among the subcategories of error 3 focusing on the way of positive-negative expressions, simple sentences were considered easy to judge: “simple positive or negative expressions (error 3bc-2-1)” (76 percentage points) and “negated positive or negative expressions (error 3bc-2-4)” (–15 percentage points). In “mild negative expressions (error 3bc-2-3)” (119 percentage points), on the other hand, the researchers focused on the description of the degree of denial to determine whether the symptoms were completely denied. However, due to the variety of degree descriptions, this annotation criteria could have been cumbersome for the system.

Through this error analysis, it was inferred that while the system can easily improve the extraction results with reference to the context near the extracted terms due to increased learning, the system cannot handle cases where the researchers are unsure of the decision or complex annotation criteria in which the extraction results change depending on the situation.

Evaluation

The system developed in this study performed better than the systems in previous studies focused on the Japanese language. In a previous study of Japanese patient narratives, Usui et al [19] aimed to thoroughly extract patient complaints from subjective data using a rule-based system. The high performance achieved by our deep learning–based system suggests that our system had considerable flexibility in handling data where symptoms could not be extracted through rules alone. As a result, the performance of our system, with an F_1-score of 0.82, surpassed that of the system by Usui et al [19] (F_1-score of 0.65), although it should be noted that the output functions of the 2 systems were not exactly the same, complicating a direct comparison. Similarly, Aramaki et al [26] used Japanese case reports as training data to develop a system for extracting a variety of symptoms. The F_1-scores of their system were 0.87 for NER and 0.63 for NER with positive-negative classification [26], both of which were lower than the scores achieved by our system. Although many previous studies of NER have focused on specific symptoms or patient populations, our system has the advantage of covering a broader range of patients and extracting a wider variety of symptoms. This makes it particularly useful for comprehensively collecting information on patient narratives.

XSL•FO
RenderX

The performance of the developed system is the same or even higher than that of similar systems in English, which aimed to extract a variety of symptomatic adverse drug events from patient narratives. For example, the neural network–based system developed by Nikfarjam et al [7] achieved a micro-average F_1-score of 0.74 in NER for drug adverse events in patient posts on social health networks. Another system by Batbaatar et al [8] achieved an F_1-score of 0.82 for NER of diseases or syndromes and an F_1-score of 0.88 for signs and symptoms from social media posts. Of these 2 systems, one extracted only the adverse events experienced by the patient, while the other did not involve positive-negative classification. Therefore, our system, despite its added complexity with positive-negative classification, appears to have comparable or even superior performance compared with the aforementioned systems.

Future Applications

The developed system is expected to be applied to monitor adverse events based on patient reports and narratives. Among previous studies using NER systems, the study by Ujiie et al [27] aimed to reduce the screening burden of drug safety information for pharmaceutical companies by identifying medical articles that contained descriptions of adverse drug events. Similarly, the system developed by Nishioka et al [28] sought to detect a specific adverse reaction—hand-foot syndrome—by identifying blog posts from patients with breast cancer, analyzing each text and post to determine whether it involved the adverse reaction. However, they did not use an NER approach. Given that our system has the advantage of extracting a wide variety of symptoms from diverse patient expressions, it is better positioned for broader use in monitoring adverse events across a wider range of conditions.

Although we focused on patient narratives, assessments recorded by health care professionals are undoubtedly another important source of patient information. Specifically, patient summaries, such as discharge and transfer summaries, contain information that has been reviewed, selected, and organized by health care professionals. However, evaluations by health care professionals carry the risk of underestimation and underreporting [1,2]. When using any medical records for research, including pharmaceutical care records, there is a concern about the filtering of information by health care professionals. However, we succeeded in establishing a system for analyzing patient narratives. The next step is to target patient narratives automatically transcribed by voice input so that the analysis of patient narratives can be achieved with fewer omissions in the recordings. By comparing patient narratives collected by either method with professional assessments using a system, such as ours, the gap between patients and health professionals can be identified. The developed system could contribute to achieving gap-free assessment and care between patients and health care professionals through the identification and analysis of the gap.

Limitations of This Study

One limitation of this study is that we used data from a single facility. Therefore, further verification is needed to determine whether this system can be used for subjective data from other facilities. Since subjective data include raw patient speech, differences in dialect and the patient's disease and treatment are assumed to be factors that cause differences in the content of the descriptions between facilities. Therefore, while this study used data from an acute care hospital in Tokyo, the system may perform differently for data from chronic care hospitals, community pharmacies, and medical facilities in areas where dialects are spoken. Validation is expected to be conducted in the future using data from medical facilities with the same features and different features to reveal the versatility of the system.

Another issue is the evaluation of the validity of the system in clinical settings. For example, F_1-score, the evaluation index used in this study, provides a relative evaluation and can be used to compare systems under the same conditions. Since there is no standard value for judging practicality, the results cannot be used to judge the applicability in actual clinical settings. However, since different applications require different performances, the system is potentially usable in a real clinical setting even if it does not have 100% performance. For example, signal detection is more important to capture overall trends than to overlook individual cases, so the system is useful for processing large amounts of data. Another limitation is the lack of standardization for extracted terms, which could be addressed by developing additional databases or systems.

Conclusions

This is the first study to develop an NER system to extract disease and symptom names from subjective data in Japanese hospital pharmaceutical care records and to investigate how its performance improves with increasing training data. The developed system demonstrated high performance in extracting disease and symptom names when trained on a large dataset, although performance improved gradually as the training amount increased, reaching a plateau after training on approximately 3600 records.

The system enables the monitoring of various symptoms using patient narratives as a source and is expected to be a valuable tool for supporting both clinical practice and research.

Abstract

Background: A challenge in updating systematic reviews is the workload in screening the articles. Many screening models using natural language processing technology have been implemented to scrutinize articles based on titles and abstracts. While these approaches show promise, traditional models typically treat abstracts as uniform text. We hypothesize that selective training on specific abstract components could enhance model performance for systematic review screening.

Objective: We evaluated the efficacy of a novel screening model that selects specific components from abstracts to improve performance and developed an automatic systematic review update model using an abstract component classifier to categorize abstracts based on their components.

Methods: A screening model was created based on the included and excluded articles in the existing systematic review and used as the scheme for the automatic update of the systematic review. A prior publication was selected for the systematic review, and articles included or excluded in the articles screening process were used as training data. The titles and abstracts were classified into 5 categories (Title, Introduction, Methods, Results, and Conclusion). Thirty-one component-composition datasets were created by combining 5 component datasets. We implemented 31 screening models using the component-composition datasets and compared their performances. Comparisons were conducted using 3 pretrained models: Bidirectional Encoder Representations from Transformer (BERT), BioLinkBERT, and BioM- Efficiently Learning an Encoder that Classifies Token Replacements Accurately (ELECTRA). Moreover, to automate the component selection of abstracts, we developed the Abstract Component Classifier Model and created component datasets using this classifier model classification. Using the component datasets classified using the Abstract Component Classifier Model, we created 10 component-composition datasets used by the top 10 screening models with the highest performance when implementing screening models using the component datasets that were classified manually. Ten screening models were implemented using these datasets, and their performances were compared with those of models developed using manually classified component-composition datasets. The primary evaluation metric was the F10-Score weighted by the recall.

Results: A total of 256 included articles and 1261 excluded articles were extracted from the selected systematic review. In the screening models implemented using manually classified datasets, the performance of some surpassed that of models trained on all components (BERT: 9 models, BioLinkBERT: 6 models, and BioM-ELECTRA: 21 models). In models implemented using datasets classified by the Abstract Component Classifier Model, the performances of some models (BERT: 7 models and BioM-ELECTRA: 9 models) surpassed that of the models trained on all components. These models achieved an 88.6% reduction in manual screening workload while maintaining high recall (0.93).

XSL•FO
RenderX

Conclusions: Component selection from the title and abstract can improve the performance of screening models and substantially reduce the manual screening workload in systematic review updates. Future research should focus on validating this approach across different systematic review domains.

Introduction

Systematic reviews are based on evidence-based medicine and constitute crucial sources of information for health care professionals and policy makers to access the latest information in their fields and thereby aid decision-making [1,2]. Systematic reviews of randomized controlled trials are highly valued and frequently referenced in the development of clinical practice guidelines by authoritative organizations, such as the World Health Organization (WHO), representing a crucial foundation for evidence-based health care decision-making. When systematic reviews are outdated or fail to encompass all the available evidence, they risk misinforming decision makers and other stakeholders [3]. Therefore, systematic reviews should be regularly updated. Shojania et al [4] analyzed 100 quantitative systematic reviews that were registered with the ACP Journal Club and reported a median survival time of 5.5 years for systematic reviews [4]. However, most systematic reviews remain outdated, and Hoffmeyer et al [2] reported that 88% of reviews in the Cochrane Database of Systematic Reviews had not been updated for 5.5 years.

A significant challenge in updating systematic reviews is the workload associated with article screening that, for systematic review research and updates, is usually performed using the following 5 steps [5,6]: (1) identifying databases relevant to the topic, (2) finding potentially relevant articles through a tailored search strategy, (3) screening articles based on titles and abstracts, (4) selecting articles for detailed analysis from the screened texts, and (5) extracting and synthesizing data from the selected articles. The significant effort required for these steps as well as the stringent requirement that these tasks be performed independently by 2 or more individuals [7], seems to contribute to the low rate of systematic review updates.

Recent advancements in natural language processing (NLP) technology have led to numerous attempts to automate these screening tasks. Qin et al [8] used an ensemble learning model that integrated multiple Bidirectional Encoder Representations from Transformer (BERT) models that were trained on the titles or abstracts and results of articles screened before an update of a systematic review on the treatment of type 2 diabetes with sodium-glucose cotransporter-2 inhibitors. Their model achieved a sensitivity of 96%, a specificity of 78%, and a 64.1% reduction in workload. While these models, like any NLP applications, require careful consideration of potential challenges such as overfitting and validation across different domains, these promising, along with other studies, have established the viability of NLP-based screening automation.

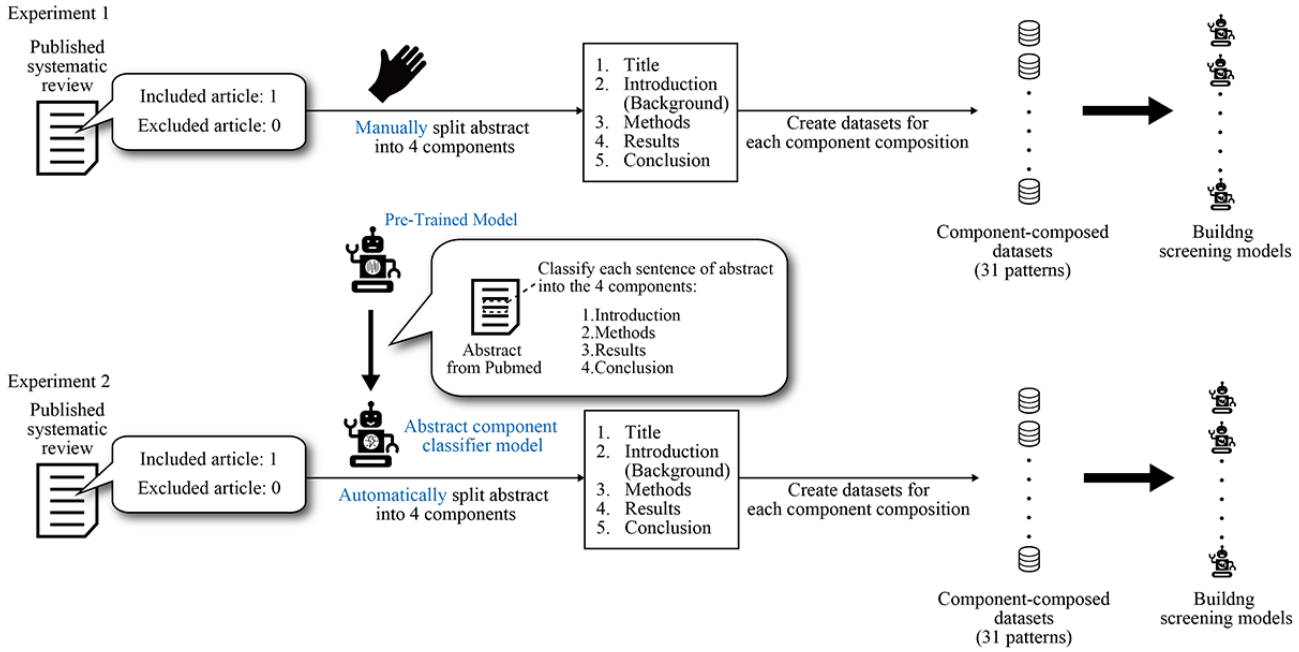
Building upon these achievements, we explored a novel approach focusing on how models process and learn from abstract information. Scientific abstracts contain distinct components (eg, introduction, methods, results, and conclusions) that serve different rhetorical functions and potentially contribute differently to determining article relevance for systematic reviews. While current approaches typically treat abstracts as uniform text, we hypothesized that selective training on specific abstract components might help address common challenges in NLP-based screening models, including the risk of overfitting large volumes of text data. By focusing on the most relevant information for the systematic review's inclusion criteria, this approach could potentially enhance model performance compared to traditional methods that process entire abstracts as uniform text.

This component-based approach potentially offers several advantages. For example, methods sections often contain crucial information about study design and participant characteristics, while results sections present outcome measures—both critical factors when selecting articles for inclusion in systematic reviews. By selectively focusing on these key components, models might learn more effectively from smaller, more targeted training data.

Scientific journals have widely adopted structured abstracts with clearly labeled components (eg, Introduction, Methods, Results, and Conclusion) since the early 1990s [9]. However, systematic reviews often need to process both structured and unstructured abstracts. To implement our component-based screening approach effectively across all articles, we needed to develop an NLP-based automatic abstract component classifier that could systematically identify and process abstract components regardless of their original format (structured or unstructured).

In this study, we demonstrate the usefulness of a screening model that learns by selecting abstract components as a novel method for improving the performance of screening models. In addition, we construct a screening model with an NLP-based automatic abstract classifier that classifies abstracts by component.

Methods



Overview

Our study consisted of 2 experiments (Figure 1). First, to evaluate the impact of selecting titles and abstract components of articles on the development of the screening model, we constructed datasets with different combinations of titles and 4 abstract components and built a screening model using these

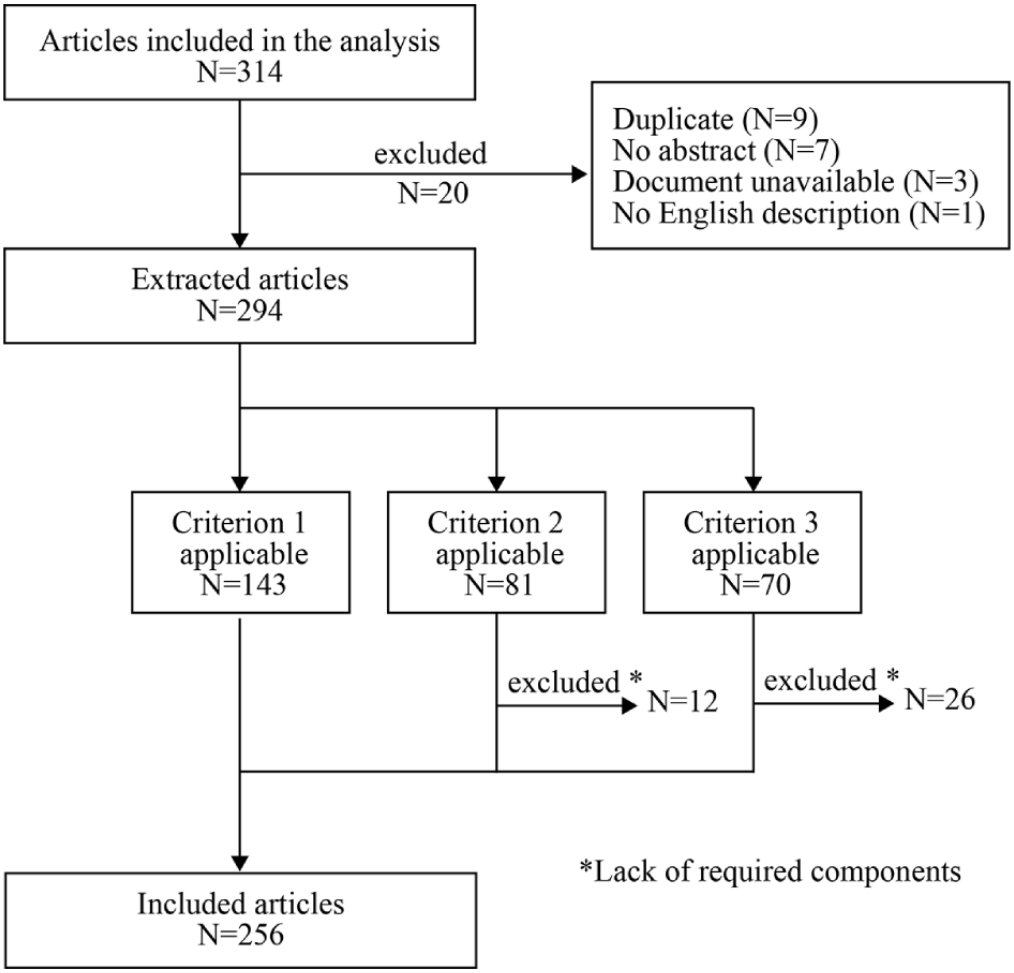
XSL•FO
RenderX

datasets (under subheading Experiment 1). Second, to automate the process from dataset creation to classifier development, we developed a model for classifying abstract components of articles (Abstract Component Classifier Models) and built a screening model using the abstract components identified by the Abstract Component Classifier Model (under subheading Experiment 2).

Figure 1. Overview of this study experiments.

For identifying both included and excluded articles, our study followed a systematic process: first, articles were identified and curated based on our selection criteria, then their abstracts were systematically subdivided into components for analysis. This component classification process was performed manually in Experiment 1 and automatically using our classifier in Experiment 2. The details of each step are described in the following sections.

Experiment 1: Evaluation of the Impact of Selecting Titles and Abstract Components of Articles on the Development of the Screening Model



Data Sources

We scrutinized the study "Adverse events in people taking macrolide antibiotics versus placebo for any indication," published by Hansen et al [10] in the Cochrane Database of Systematic Reviews on January 18, 2019 as the data source. The data source was a systematic review that assessed adverse events in randomized controlled trials of patients treated with antibiotics compared with a placebo. This review was selected for 2 reasons. First, the number of studies included in the analysis was substantial, with 184 unique studies (reported across 314 publications), providing sufficient data for implementing the screening model. Second, the systematic review included randomized controlled trials, consistent with other systematic reviews analyzing treatment effects.

To identify the included articles, we analyzed the 184 studies (314 articles) in the inclusion list for the systematic review. The screening process for included articles is shown in Figure 2. We selected articles that met any of the criteria with both the title and abstract written in English, the criteria are mentioned in Textbox 1.

XSL•FO
RenderX

Figure 2. Screening process for included articles in this study.

Textbox 1. Inclusion criteria for included articles.

Criterion 1:

- The abstract was structured into 4 components, introduction (background), methods, results, and conclusion, or equivalent, from which the title and the aforementioned 4 components could be extracted.

Criterion 2:

- The abstract was not divided into exactly four components but followed a structured format (eg, 3 or 5 components) and could be reclassified by researchers into 4 components—introduction (background), methods, results, and conclusion, or equivalent—from which the title and the aforementioned four components could be extracted.

Criterion 3:

- The abstract did not follow a structured abstract, but the text could be classified into four components—introduction (background), methods, results, and conclusion, or equivalent—from which the title and the aforementioned four components could be extracted.

The criteria for the 4 components equivalent to introduction (background), methods, results, and conclusion, as well as for excluding text, are shown in Table S1 in Multimedia Appendix 1. For the classification of criteria 2 and 3, two researchers (TH and YY) independently classified each sentence in the abstract into 4 components. Disagreements, if any, were resolved through discussion. In our study, all abstracts were assumed to be written in the following order: introduction (background), methods, results, and conclusion. Therefore, according to the criteria listed in Table S1 in Multimedia Appendix 1, if the sentences before and after a sentence classified as results were related to methods, the sentence was classified as methods. In total, 256 articles were included.

To identify the excluded articles, we did not contact the original review authors but instead searched MEDLINE (Ovid) and the Cochrane Central Register of Controlled Trials using the same search terms and search periods as those used in the systematic review. The search terms and formulas used are listed in Table S2 of Multimedia Appendix 1. Articles that met the above criteria 1 or 2 with both the title and abstract written in English were then extracted, and the “included articles” in our study and any articles similar to those were excluded. The following

XSL•FO
RenderX

exclusion criteria were applied: (1) articles without English abstracts, as they would not be suitable for our model training, (2) articles without abstracts, particularly older publications or those with only titles, and (3) articles with unstructured abstracts lacking clear background, methods, results, and conclusion sections, as they would not be appropriate for our component classification task. We did not include articles that only met criterion 3 (articles with title and abstract written in English but not meeting criterion 1 or 2) as negative instances, as we had already obtained a sufficient number of excluded articles from articles meeting criteria 1 and 2. The classification of the 4 components was conducted with reference to the criteria listed in Table S1 in Multimedia Appendix 1. For the classification of criterion 2, we evaluated the agreement rate between 2 researchers. The simple agreement rate was 98.76% (5752/5824; 95% CI 98.47%-99.05%). It was considered sufficiently high; therefore, one researcher (TH) performed the classification.

In addition, the decision regarding duplicates in the "included articles" in our study was made using the SequenceMatcher object from the difflib library. The similarity ratio of the text of each component in the excluded articles to the text of the same components in all the "included articles" and extracted the highest value was calculated. Articles with a combined similarity ratio value of 4.0 or more, or with a similarity ratio of the title of more than 0.8, were excluded. Through manual verification of the flagged cases, we confirmed 1 complete text duplication and 2 cases of substantial text similarity above our thresholds. These 3 cases were excluded from the analysis, confirming the appropriateness of our automated duplicate detection criteria. A similar assessment using the title was also performed for the studies excluded from the article dataset. Duplicates among the excluded articles were not excluded because duplicates might exist in the articles to be scrutinized for practical use. Ultimately, 1261 articles were extracted.

We created 31 different component-composed datasets from 5 components in the extracted articles. These included datasets containing only the title, introduction, methods, results, or conclusions; datasets containing all 5 components; and datasets containing any combination of 2, 3, or 4 of these components. All variations are shown in Table S3 in Multimedia Appendix 1.

Development of Screening Models

From each component-composed dataset, we created training, validation, and test sets. Included and excluded articles were treated as positive and negative data, respectively. For positive data, 40 articles were randomly extracted as the test set, and the remaining 216 articles were randomly divided into training and validation sets in a 9:1 ratio. Negative data were randomly assigned to the training and validation sets to ensure 1:1 positive-to-negative data. In the test set, 960 articles were assigned randomly. For articles exceeding the maximum sequence length of 512 tokens, the text was truncated during the model training phase. All shorter inputs were padded to ensure uniform input length. This means that for articles exceeding the token limit, information from the latter portions of the text was not used during model training.

We developed screening models that predicted binary labels for the test set using the transformer library. During model development, different learning rates (Lr; 6e-7, 2e-6, and 6e-6) were evaluated using the validation set. Screening models were developed using 3 pretrained language models: Bidirectional Encoder Representations from Transformers (BERT; bert-large-uncased [11]), BioLinkBERT (BioLinkBERT-Large) [12], and BioM- Efficiently Learning an Encoder that Classifies Token Replacements Accurately (ELECTRA) (BioM-ELECTRA-Large-SQuAD2) [13]. BERT, introduced by Google in 2018, is pretrained on 2.5 billion words from the English Wikipedia and 800 million words from BookCorpus [14]. It uses a Transformer Encoder using a method known as attention, which can effectively incorporate information from distant positions within a text.

We used this as the baseline pretrained model. BioLinkBERT is a pretrained model developed by Yasunaga et al [15] at Stanford University. Traditional BERT models cannot learn from the text of hyperlinks and citation links used in pretraining documents. The base model, LinkBERT, can capture these document links. BioLinkBERT [12] was pretrained on 3.1 billion words from PubMed abstracts and documents from their hyperlinks and citation links. BioM-ELECTRA-Large-SQuAD2 is a model developed by Alrowili and Shanker [16] from the University of Delaware that trains BioM-ELECTRA-Large on the SQuAD2.0 dataset to enhance question-answering capabilities. BioM-ELECTRA is based on the ELECTRA model, introduced by Clark et al [17] in 2020, which improves the pretraining methods of BERT to achieve comparable or superior performance with fewer computational resources. BioM-ELECTRA was pretrained on 29,000 domain-specific PubMed abstracts, following the same domain-specific approach as PubMedBERT [16]. Among the pretrained models implemented in this study, BioLinkBERT and BioM-ELECTRA were the highest-performing models in the BLURB benchmark [18], which evaluates the performance of pretrained models in the biomedical literature.

Task and Metrics

For each pretrained model, we fine-tuned 31 screening models corresponding to all possible combinations of the 5 components (Title, Introduction, Methods, Results, and Conclusion) and compared their performances. In systematic review screening, minimizing false negatives (missed relevant articles) is critically important, as failing to include relevant articles could significantly impact review conclusions. While Recall would be an appropriate metric for this purpose, using it alone would favor models that simply classify all articles as positive, achieving perfect recall but poor practical utility.

To address this, we designated the Fβ-score as our primary evaluation metric. This score is the harmonic mean of recall and precision, where β determines their relative importance. During our preliminary analysis, we tested several values of β to determine the optimal balance between recall and precision for our specific use case. Compared to other potential metrics, such as maximizing specificity at fixed recall thresholds, the Fβ-score provides a single, interpretable measure that enables explicit control over the balance between false positives and

XSL•FO
RenderX

false negatives. We set β=10 to strongly prioritize recall while maintaining some consideration for precision, reflecting the practical trade-off in systematic review screening where missing relevant studies is more problematic than including irrelevant ones for subsequent manual screening. This value was chosen based on both empirical testing and principles of systematic review methodology where comprehensiveness in literature identification is critical. While this strong prioritization through β=10 results in increased false positives, this trade-off is considered acceptable in the context of systematic reviews, where missing relevant studies could significantly impact review conclusions. This approach also ensures that a model simply classifying everything as positive would be penalized through its low precision component, despite achieving perfect recall.

We calculated the average F10-Score evaluated 5 times using 5 datasets with different assignments for each component composition and compared these averages between the screening models. To elaborate, for each of the 31 possible component combinations, we created 5 distinct datasets using different random samples of included and excluded articles for training, validation, and test sets. This process of splitting the data into training, validation, and test sets was repeated 5 times, ensuring that each of the 5 datasets was distinct, and allowing us to evaluate the model performance with more reliability and less influence from any specific split. Specifically, from the 256 included articles, we randomly selected 40 articles to form the test set. The remaining 216 articles were randomly divided into training and validation sets using a 9:1 ratio. The excluded articles were assigned randomly to the training and validation sets, and 960 were randomly assigned to the test set. By averaging the F10-scores across these 5 datasets, we aimed to evaluate model performance across multiple splits, providing more stable evaluation metrics by mitigating variations due to randomness in data sampling.

The number of epochs for training the screening models was set to 32, patience for early stopping to 3, and weight decay to 0.01. In addition, we compared the screening model with the highest average F10-Score with those of other component compositions among the 3 Lr: 6e-6, 2e-6, and 6e-7.

Experiment 2: Development of a Screening Model Using Article Components as Determined by the Abstract Component Classifier Model

In Experiment 2, we aimed to construct a screening model by automating the division of abstract components, which was done manually in Experiment 1. To achieve this, we first developed an Abstract Component Classifier Model to automate the partitioning of abstract components.

Development of the Abstract Component Classifier Model

We obtained 25,584 articles with abstracts registered in PubMed from May 2 to 8, 2018, and from August 16 to 19, 2022, using the "fha[Filter]" search term, which is a PubMed filter tag that helps identify articles with structured abstracts. From the article base, we extracted 5331 articles that met the criteria of having abstracts structured into 4 components (introduction or background, methods, results, and conclusion) with both the title and abstract written in English, allowing the extraction of these components along with the title. Each component was classified according to the criteria listed in Table S1 in Multimedia Appendix 1. Using the tokenized object from the Natural Language Toolkit library for initial sentence splitting, we divided the abstracts into individual sentences. Each sentence was then manually labeled with exactly one mutually exclusive component tag "Introduction [I], Methods [M], Result [R], Conclusion [C]". Ultimately, we extracted 62,798 sentences, comprising 11,961; 17,154; 23,204; and 10,479 sentences for the introduction, methods, results, and conclusion, respectively (PubMed dataset). In addition, abstracts of the articles extracted from the systematic review in Experiment 1 were divided into sentences and labeled (Systematic Review Dataset). The dataset included 3477, 6265, 7091, and 3038 sentences for the introduction, methods, results, and conclusion, respectively, with a total of 19,871 sentences.

From the labeled sentences of the PubMed Dataset, we created training, validation, and test sets. We randomly allocated 4000 sentences (8:1:1) to the training, validation, and test sets. These datasets comprised equal proportions of samples for each label to prevent performance deterioration owing to unbalanced samples.

Abstract Component Classifier models were implemented to predict the sentence labels using the transformer library. We developed them from 4 pretrained models: (BERT; bert-large-uncased [11]), BioLinkBERT (BioLinkBERT-Large) [12], 2 types of BioM-ELECTRA, BioM-ELECTRA-Large-SQuAD2 [13] and BioM-ELECTRA-Large-Discriminator [19]. BioM-ELECTRA-Large-Discriminator is a model that, unlike the BioM-ELECTRA-Large-SQuAD2, does not undergo fine-tuning with SQuAD2; it uses the same pretraining corpus as BioM-ELECTRA-Large-SQuAD2.

We trained the classifier models on the training and validation sets and evaluated the model performance using the test set. For the Abstract Component Classifier Model, we limited our parameter tuning to Lr, as our primary objective was to confirm the basic capability of the component classification model rather than maximizing performance through extensive parameter optimization. This focused approach was supported by the strong baseline performance achieved with basic parameter settings.

Then, we classified the sentences in the PubMed dataset and evaluated their performance. The primary evaluation metric was the macro–F_1-score (F_1-score). The number of epochs for training the screening models was set to 32, patience for early stopping to 3, and weight decay to 0.01.

Similarly, we conducted the same analysis for the Systematic Review Dataset, and the model with the highest F_1-score was also selected as the Abstract Component Classifier Model, which was used for subsequent analysis.

Development of a Screening Model Using Article Components as Determined by the Abstract Component Classifier Model

As described in Experiment 1, we developed screening models using the same data sources and methods. However, we used

XSL•FO
RenderX

the Abstract Component Classifier Model, which we developed to automatically classify abstract components of articles that were previously classified manually in Experiment 1. These abstracts were reclassified into 4 components based on the results of classification using the Abstract Component Classifier Model. If no sentence was allocated to any of the components in the classifier model, the component was treated as a document with 0 words. From the title data and reclassified component data, we created component-composed datasets. To focus on the most promising approaches while maintaining computational efficiency, we selected 10 datasets corresponding to the top 10 performing models from Experiment 1. This focused approach was selected to specifically examine whether the advantages observed with manual classification could be maintained when transitioning to an automated system; a key consideration for practical implementation. This selection allowed us to evaluate how well these high-performing component combinations performed when using automated classification instead of manual classification. Table S3 in Multimedia Appendix 1 lists the component composition used in the screening models, which were implemented using training datasets created from the selected 10 component-composed datasets. The primary endpoint was the F10-score, which was compared to the performance of 10 classifiers with the same component composition constructed in Experiment 1.

Ethical Considerations

All analyses were conducted using previously published studies, and therefore, ethics approval and patient consent were unnecessary. This study does not include human subject information, primary data collection, or any form of experimentation involving individuals.

Results

Overview

All results reported in this section were obtained using the test set, which was completely separate from the training and validation sets used for model development.

Experiment 1: Evaluation of the Impact of Selecting Article Titles and Abstract Components on the Development of the Screening Model

Characteristics of the Number of Words in the Extracted Articles

The word count of the 1517 articles had a median of 276 (range 103-1099) words. After tokenization, 50 articles (including 2 included articles) exceeded the maximum sequence length of 512 tokens that our pretrained models could process in one iteration.

Performance of Screening Models

A detailed description of all datasets, including class proportions, is provided in Table S4 in Multimedia Appendix 1. Details of the final evaluation results on the held-out test set for the screening models with different Lr (6e-7, 2e-6, and 6e-6) are shown in Table S5-S7 in Multimedia Appendix 1. For the screening model using BERT (Table S4 in Multimedia Appendix 1), the model trained on the 4 components "Title + Methods + Results + Conclusion" demonstrated the highest average F10-Score (precision=0.35; recall=0.93; F10-Score=0.91). Conversely, the model with the lowest F10-Score was trained solely on the conclusion (precision=0.48; recall=0.77; F10-Score=0.75). The model trained on all 5 components ranked tenth in the average F10-Score of all 31 screening models. For BioLinkBERT (Table S5 in Multimedia Appendix 1), similar to BERT, the model trained on "Title + Methods + Results + Conclusion" recorded the highest F10-Score (precision=0.28; recall=0.95; F10-Score=0.93). The lowest F10-Score, as with BERT, was observed in the model trained only on the Conclusion (precision=0.58, recall=0.77; F10-Score=0.76). The model trained on all 5 components had the seventh highest average F10-Score of all 31 screening models. For the BioM-ELECTRA (Table S6 in Multimedia Appendix 1), the model trained on Methods + Conclusion achieved the highest F10-Score (precision=0.37; recall=0.89; F10-Score=0.88). The lowest F10-Score was obtained for the model trained on Title + Introduction + Methods (precision=0.32; recall=0.74; F10-Score=0.73). The model trained on all 5 components ranked 20 seconds in the average F10-Score among all the 31 screening models.

Experiment 2: Development of a Screening Model Using Article Components as Determined by the Abstract Component Classifier Model

Development of the Abstract Component Classifier Model

Table 1 lists the average results of 5 evaluations of the classifier models using the PubMed Dataset. The main evaluation metric, the F_1-score was 0.89 for BERT; Lr:6e-6, 0.92 for BioLinkBERT; Lr:2e-6, and 0.91 for both BioM-ELECTRA-Large-SQuAD2; Lr:6e-6 and BioM-ELECTRA-Large-Discriminator; Lr:6e-6.

Table 1. Performance of the Abstract Component Classifier using PubMed dataset.

Model	Learning rate	Epochs	Accuracy	Precision	Recall	F_1-score
BERT[a]	6e-6	4.6	0.89	0.90	0.89	0.89
BioLinkBERT	2e-6	5.8	0.92	0.92	0.92	0.92

RenderX

The performance results by label using the dataset composed of sentences from the abstracts of the articles in the targeted systematic review (Systematic Review Dataset) are shown in Table 2. Implemented classifiers showed the average F_1-scores of 0.88-0.93, 0.93-0.95, 0.92-0.92, and 0.83-0.85 for Introduction, Methods, Results, and Conclusions, respectively. In this study, the BioM-ELECTRA-Large-Discriminator, which achieved a macro–F_1-score of 0.94 in one instance, was selected as the Abstract Component Classifier Model.

Table 2. Performance of classifiers implemented by each label using the Systematic Review Dataset.

Development of a Screening Model Using Article Components as Determined by the Abstract Component Classifier Model

Table 3 shows the average results of 5 evaluations of 10 screening models created from the component-composed datasets classified by the developed Abstract Component Classifier Model, along with the results of models created from the same 10 component-composed datasets and all 5 components in Experiment 1. In the tables, among the screening models with the same component composition, those with higher average F10-Scores are highlighted in bold. The results of the screening models using Lr not included in these tables are shown in Table S6-S7 in Multimedia Appendix 1. For the screening model using BERT (Table 3), the model trained on the 4 components Title + Methods + Results + Conclusion recorded the highest F10-Score (precision=0.35; recall=0.93; F10-Score=0.91). The model with the lowest F10-Score that was trained on Title + Methods + Conclusion showed precision=0.40; recall=0.86; and F10-Score=0.85. For BioLinkBERT (Table 4), the model trained on Title + Methods + Results + Conclusion recorded the highest F10-Score (precision=0.42; recall=0.90; F10-Score=0.88). The lowest F10-Score was observed in the model trained on Introduction + Methods (precision=0.63; recall=0.78; F10-Score=0.78). For BioM-ELECTRA (Table 5), the model trained on Methods + Results + Conclusion achieved the highest F10-Score (precision=0.38; recall=0.86; F10-Score=0.85). The lowest F10-Score was obtained for the model trained on Title + Results + Conclusion (precision=0.25; recall=0.69; F10-Score=0.68).

Discussion

Principal Results

In this study, we evaluated the significance of selecting components from article titles or abstracts on the performance of screening models for systematic review updates. Our results demonstrated that for all pretrained models, we were able to implement screening models that outperformed those trained on all 5 components. This indicates that the selection of components from the article title or abstracts is beneficial for improving the performance of the screening models. The performance differences between models trained on all components versus selected components may be attributed to the interaction between token limitations and information priority. When using all 5 components, the inclusion of introduction or background sections might have resulted in the loss of crucial information from results or conclusion sections due to the 512-token limit. Furthermore, domain-specific models can show varying performance depending on the input information structure [20]. The 3 pretrained models used in this study showed different component compositions, leading to higher average F10-Scores, despite using the same training datasets. Through our comprehensive exploration of all 31 component combinations, we identified certain combinations that consistently showed superior performance. Specifically, the Title+Method+Result+Conclusion combination demonstrated strong performance across different models, and combinations including Methods and Results components generally performed well. For practical implementations where computational resources are limited, focusing on these high-performing combinations, rather than exhaustively testing all possible combinations, could provide a more efficient path to developing effective screening models while maintaining high performance.

Furthermore, we implemented screening models by using the dataset for each component classified using the developed Abstract Component Classifier Model, which analyzes the semantic content of individual sentences to determine their rhetorical roles, enabling the classification of both structured and unstructured abstracts. Consequently, for the large-uncased model, 7 out of the 10 models outperformed the model trained on all 5 components. For BioM-ELECTRA, 9 out of 10 screening models showed higher performance than the model trained on all 5 components. These results demonstrate that a screening model implemented by combining component classification using a classifier model and component selection can surpass the performance of traditional screening models. However, when using the Abstract Component Classifier in Experiment 2, all 10 screening models using BioLinkBERT demonstrated lower performance than BioLinkBERT's model trained on all 5 components. This behavior, which differs from our observations in Experiment 1, suggests that BioLinkBERT

XSL•FO
RenderX

may be more sensitive to the quality and structure of the component classification. The automatic classification process might disrupt certain patterns or contextual relationships that BioLinkBERT relies on, making it perform better with manually classified components in Experiment 1 but not as well with automatically classified components in Experiment 2. This suggests that the effectiveness of component selection strategies may depend not only on the model's characteristics but also on how the components are identified and structured. This finding highlights the complex interaction between model architecture, component classification method, and overall performance.

Comparison With Previous Work

Among the screening models using datasets classified by the developed Abstract Component Classifier, the model trained on Title+Method+Result+Conclusion using BERT achieved the highest average F10-Score (precision=0.35, recall=0.93; F10-Score=0.91). The test set included 40 of the 1000 articles. Therefore, this model reduced 1000 studies that had to be scrutinized manually to an average of 106.3, while extracting an average of 37.2 included articles. Following Cohen (2006) formula for work-saved oversampling, which accounts for both the number of articles to be screened and the model's recall of 0.93, this represents an 88.6% reduction in screening workload. In a previous study by Qin et al [8], the implemented screening model achieved a sensitivity of 96%, a specificity of 78%, and a 64.1% reduction in workload, thereby demonstrating the rationality and feasibility of using a screening model. The F10-Score of the screening model in Qin's study exceeded that of the model implemented in this study precision=0.50; recall=0.96; F10-Score=0.95). However, it is important to note that Qin's study used an ensemble model that integrated 4 different screening models, and the F10-Scores of each individual screening model used to implement the ensemble model were lower than the average F10-Score of the screening model in this study (F10-Scores=0.79, 0.81, 0.91, and 0.81).

In screening models that used the article abstract component classifier, 7 out of 10 models for BERT and 8 models for BioM-ELECTRA underperformed compared to the average F10-Score of models with the same component compositions that were created through manual component classification. For BioLinkBERT, all screening models showed lower average F10-Scores than those of the screening models with manually classified component datasets. These results indicate a tendency for screening models with the classifier model's classification to underperform when compared with those using manually classified component datasets. This performance gap suggests that our Abstract Component Classifier does not achieve the same level of accuracy as manual labeling, possibly due to limitations in maintaining the contextual integrity of the text during the automatic classification process.

Jiang et al [21] implemented a classifier using the BERT model to classify text into 5 components: background, objective, methods, results, and conclusion and achieved an F1-Score of 0.98 [21]. This F1-Score surpasses that of the classifier implemented in our study. This result may contribute to the differences in the classification methods from previous studies conducted as Machine Reading Comprehension tasks and the scale of the dataset, which used PubMed 200k and comprised approximately 200,000 RCT trial abstracts [22]. However, previous studies used BERTbase13 without a medical literature corpus for pretraining. In our study, the classifiers that used BioLinkBERT, BioM-ELECTRA-Large-SQuAD2, and BioM-ELECTRA-Large-Discriminator achieved higher F_1-scores than the one using BERT. Therefore, it is important to construct a classifier using these pretrained models, and the same method that was used in previous studies could implement a superior classifier.

Analysis of Model Performance Metrics

In this study, the F10-Score was the primary evaluation metric for the screening model. This choice was made for 2 reasons: to prioritize recall and apply an appropriate penalty to screening models that classify everything as positive. As expected, our results showed that the screening model could be evaluated based on the F10-Score. Moreover, we implemented screening models that had a higher F10-Score than one that classified everything as positive (F10-Score=0.81). This suggests that adopting the F10-Score as the main evaluation metric in our study was appropriate. However, the F10-Score of the screening model classifying everything as positive varied depending on the ratio of the included and excluded articles in the test set. Therefore, it is inferred that when creating test sets with different ratios from those used in our study and conducting similar evaluations, it will be necessary to set a new appropriate β.

Alternative approaches to evaluation metrics, such as maximizing specificity at 99% recall, could also be considered for systematic review screening tasks. While our F10-score approach prioritizes recall while maintaining some consideration for precision, the specificity-focused approach would explicitly maximize the number of excluded articles while maintaining a fixed, very high recall. Both approaches have merit for systematic review updating, though they are optimized for slightly different practical outcomes. Furthermore, F10-scores can be influenced by class prevalence in the test set. In our study, we maintained the class distributions of the test set similar to those of the original systematic review to ensure realistic performance evaluation, reflecting the naturally imbalanced distribution of relevant versus irrelevant articles. Future research might explore how different evaluation metrics and varying class distributions affect model selection and practical utility in systematic review updating, particularly in the context of identifying a small number of relevant articles from a large corpus.

In comparing different models' performances, we observed that small improvements in the F10-Score often reflected different trade-offs between precision and recall. For example, the BioLinkBERT model trained on Title+Method+Result+Conclusion achieved a higher F10-Score (0.93) compared to BERT (0.91), primarily due to higher recall (0.95 vs 0.93) despite lower precision (0.28 vs 0.35). While this trade-off resulted in a numerically higher F10-Score, it is important to note that in practical applications, significantly lower precision means more irrelevant articles requiring manual screening. However, in the context of systematic reviews, this trade-off might be acceptable given the critical importance of

XSL•FO
RenderX

not missing relevant studies, though it suggests the need for careful consideration of the balance between comprehensive coverage and screening efficiency in different systematic review contexts.

Limitations

One limitation of this study pertains to the generalizability of our results. We implemented and compared the performances of the screening models using the screening results of a single systematic review focusing on adverse events of macrolide antibiotics. While this dataset provided a solid foundation for model development and evaluation, comprehensive validation across multiple systematic reviews in different medical specialties, such as oncology, cardiology, infectious diseases, and pediatrics, is essential to confirm the broad applicability of our approach. Without such validation, the model's performance may vary significantly across different medical domains due to variations in terminology, study designs, and reporting patterns. For instance, the language and structure used in oncology trial reports may differ substantially from those in used cardiovascular studies, potentially affecting the model's component classification accuracy and overall screening performance. Our results may not fully represent the model's performance in systematic reviews of other medical areas (such as cardiovascular disease, and oncology) or different types of studies (such as observational studies or cohort studies). Furthermore, regarding the criteria for classification by component used in this study, it is possible that not all criteria are comprehensively applicable for classifying components in articles from other fields. Another limitation is that our study did not include comparisons with recent large language models (LLMs). Computational resource constraints and reproducibility concerns primarily drove the decision to exclude LLM comparisons, as many current LLMs are not open-source and require significant computational infrastructure for fine-tuning. In addition, the rapid evolution of LLMs poses challenges for establishing stable benchmarks. While we focused on established BERT-based models that are widely validated for classification tasks, recent research has shown that the relative performance of different models can vary significantly based on data availability. For instance, Jahan et al. demonstrated that while LLMs can outperform fine-tuned models on biomedical tasks with limited training data, BERT-based models often maintain advantages when substantial training data is available for fine-tuning [23]. Our current approach using BERT-based models, with access to sufficient training data, provides a solid benchmark for evaluating the effectiveness of component-based classification in systematic review updating.

Future Work

In this study, we classified each piece of article into 5 components: title and 4 abstract components (introduction, methods, results, and conclusion). Article abstracts can be further subdivided. By refining the component classification, we can improve the performance of the screening model. Therefore, future research that implements screening models using further subdivided articles is required. The dataset used in this study comprised 256 studies. This number is relatively high for the articles analyzed in a systematic review. Our screening model intended to use the included and excluded articles from a preupdated systematic review as the training dataset. Therefore, implementing a screening model for a systematic review that analyzes a small number of studies may result in decreased performance. Therefore, it is necessary to estimate the number of studies required to achieve a performance level comparable to that of the screening model that was developed in this study. Finally, the performance of the screening model was evaluated individually. Therefore, combining the technique of article title or abstract component selection with methods, such as implementing ensemble models, could potentially implement even high-performance screening models.

Future research should also explore strategies to address the few limitations observed in our study. This may include investigating models designed for handling longer sequences, such as Longformer [24] or Big Bird [25], or developing methods to process each abstract component separately before combining their vector representations. While these approaches could improve screening performance, they are likely to increase computational complexity compared to our current method. Therefore, future work will need to explore ways to balance these advanced techniques with computational efficiency requirements.

Investigating the integration of LLMs into systematic review screening presents a promising direction for future research. Consequently, future studies should examine the cost-effectiveness and computational efficiency of various LLM integration strategies, particularly in resource-constrained settings. Research into fine-tuning smaller, more efficient LLMs specifically for systematic review tasks could provide a practical balance between model performance and computational requirements.

Conclusions

Our study revealed that implementing a screening model trained on selected components of the title or abstract articles could enable better performance than a traditionally implemented model that was trained on all 5 components in some cases. Furthermore, we developed an Abstract Component Classifier that classifies each sentence of the abstract into different components and implements screening models through the component classification of target article abstracts using this classifier and the selection of article title/abstract components. Thus, we were able to implement screening models with a higher performance than the traditional model trained on all 5 components in the 2 pretrained models. This approach could reduce the workload of the systematic review update process.

Abstract

Background: Valuable insights gathered by clinicians during their inquiries and documented in textual reports are often unavailable in the structured data recorded in electronic health records (EHRs).

Objective: This study aimed to highlight that mining unstructured textual data with natural language processing techniques complements the available structured data and enables more comprehensive patient phenotyping. A proof-of-concept for patients diagnosed with specific autoimmune diseases is presented, in which the extraction of information on laboratory tests and drug treatments is performed.

Methods: We collected EHRs available in the clinical data warehouse of the Greater Paris University Hospitals from 2012 to 2021 for patients hospitalized and diagnosed with 1 of 4 immune-mediated inflammatory diseases: systemic lupus erythematosus, systemic sclerosis, antiphospholipid syndrome, and Takayasu arteritis. Then, we built, trained, and validated natural language processing algorithms on 103 discharge summaries selected from the cohort and annotated by a clinician. Finally, all discharge summaries in the cohort were processed with the algorithms, and the extracted data on laboratory tests and drug treatments were compared with the structured data.

Results: Named entity recognition followed by normalization yielded F_1-scores of 71.1 (95% CI 63.6-77.8) for the laboratory tests and 89.3 (95% CI 85.9-91.6) for the drugs. Application of the algorithms to 18,604 EHRs increased the detection of antibody results and drug treatments. For instance, among patients in the systemic lupus erythematosus cohort with positive antinuclear antibodies, the rate increased from 18.34% (752/4102) to 71.87% (2949/4102), making the results more consistent with the literature.

Conclusions: While challenges remain in standardizing laboratory tests, particularly with abbreviations, this work, based on secondary use of clinical data, demonstrates that automated processing of discharge summaries enriched the information available in structured data and facilitated more comprehensive patient profiling.

Introduction

Background

Since the 2010s, the widespread adoption of electronic health records (EHRs) and health data warehouses has enabled the development and application of new algorithms for patient phenotyping, which corresponds to the extraction of a set of observable patient characteristics, including laboratory test results, symptoms, diseases, and past or current treatments [1]. The automated extraction of these characteristics from large-scale databases supports predictive risk assessments, preselection for therapeutic trials, and pharmacovigilance analyses [2-4].

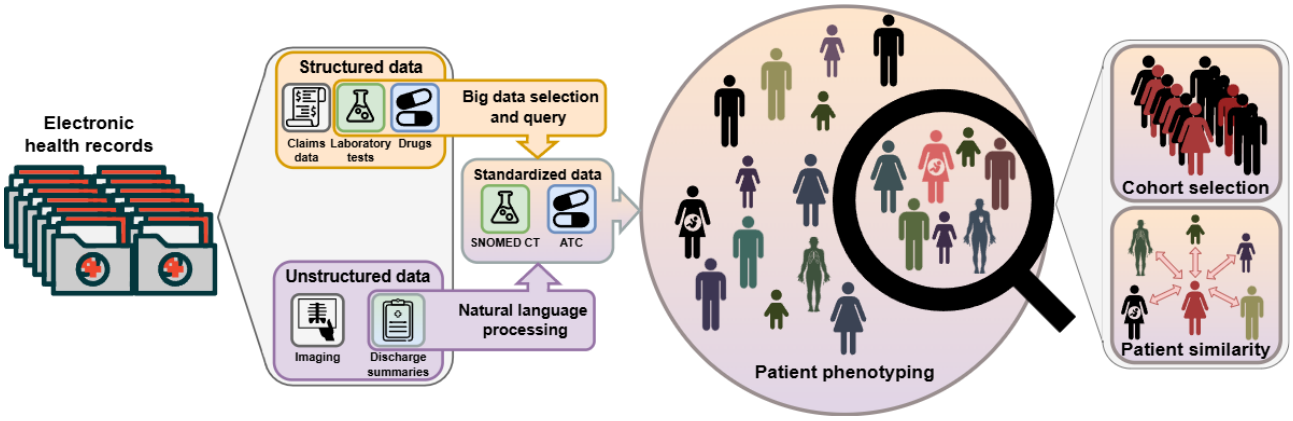
EHR data is typically categorized into 2 types: structured data and unstructured data. Structured data refers to directly queryable numerical values, such as laboratory test results or *International Classification of Diseases, Tenth Revision* (*ICD-10*) codes, while unstructured data encompasses raw clinical texts and medical imaging. Structured data from clinical warehouses is often incomplete, capturing only intrahospital records and excluding extrahospital information. For instance, a patient's blood test conducted at an external laboratory before hospitalization might not be included. In addition, historical biological results in clinical databases are often limited to a few years. This is particularly problematic for conditions like autoimmune diseases, where historical immunologic results critical to the initial diagnosis are often documented only in clinical text rather than in structured data. Similarly, details about prior treatments are usually found only in textual records. Valuable information that is not present in structured data is often found in observations recorded in the discharge summaries [5]. The application of automated text analysis to this unstructured text, in conjunction with structured data, has already demonstrated increased effectiveness in predicting patients' clinical courses [6-11].

Transforming unstructured data into structured formats involves multiple natural language processing (NLP) tasks. In this research, we primarily concentrate on named entity recognition (NER) and normalization, which are fundamental for extracting meaningful information from large volumes of unstructured clinical text.

NER refers to locating and classifying terms into predefined categories, such as drug name, laboratory test, or medical disorder. Traditional NER methods often depend on dictionary-based term-matching techniques, which require meticulously maintained lexical resources [12]. However, maintaining these resources can be both labor-intensive and error-prone. A more effective method treats NER as a sequence-labeling task using tagging systems like the beginning, inside, outside, unit, and last scheme, which is widely recognized in biomedical NER for its ease of implementation and efficiency [13,14]. Sequence labeling models, particularly conditional random fields [15], have been extensively used for NER. When combined with transformer-based architectures like bidirectional encoder representations from transformer (BERT), these models have set state-of-the-art performance benchmarks for NER in clinical and biomedical text analyses [16-19].

Following NER, the normalization process assigns standard codes (unique identifiers that correspond to concepts within established medical terminologies) to the detected terms. For example, standard codes, such as concept unique identifiers (CUIs) from the Unified Medical Language System (UMLS) [20], can be used to map detected entities like drug or laboratory tests to their corresponding concepts. Common normalization strategies often rely on exact or approximate string matching against predefined dictionaries. Tools, such as KnowledgeMap Concept Identifier [21], MetaMap [22], MedLEE [23], MedEx [24], HITEx [25], and cTAKES [26] have been widely adopted in phenotyping models [27-29]. The emergence of deep contextual embeddings, notably BERT [30], has revolutionized NLP methodologies, including normalization tasks. Current state-of-the-art approaches heavily use transformer-based encoders pretrained on domain-specific corpora, demonstrating substantial improvements in normalization [31-33].

Although large language models like GPT-4 [34] hold promise for biomedical applications, their current performance in tasks like NER and normalization remains limited [35]. Moreover, implementing these models at scale to extract phenotypes from large volumes of clinical documents poses considerable cost challenges.



Goal of the Study

The aim of the study was to provide a proof-of-concept for end-to-end patient phenotyping from their EHRs. Patient phenotyping refers to the process of characterizing patients based on their clinical features, such as clinical diagnoses, laboratory results, or drug treatments. Secondary uses of EHRs require the application of various processes to transform the data into meaningful variables. In this research, we focused specifically on leveraging discharge summaries (written in French) through NLP techniques to enrich the information contained in the structured data. We restricted our study to patients hospitalized for one of the following immune-mediated inflammatory diseases: systemic lupus erythematosus (SLE), systemic sclerosis, antiphospholipid syndrome (APS), and Takayasu arteritis (TA). As we analyzed autoimmune diseases, we also restricted phenotyping to the analysis of autoantibodies (laboratory tests) and immunosuppressive therapies (drugs), which are central to the management of these diseases. As shown in Figure 1, laboratory tests and drug therapies were extracted from both structured and unstructured data. Then, to analyze the data jointly, a standard concept code was assigned to each laboratory test using the Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT; US edition) [36] and drug using the Anatomical Therapeutic Chemical (ATC)

XSL•FO
RenderX

classification [37]. Our hypothesis was that incorporating the results of laboratory tests and drug treatments recorded in patients' discharge summaries would complement the information available in structured data and enable more in-depth, interoperable phenotyping of patients, while remaining reliable.

Figure 1. Overview of the end-to-end patient phenotyping pipeline. Structured and unstructured data are extracted from electronic health records, enabling large information retrieval, refining cohort selection, and facilitating more robust patient comparisons. ATC: Anatomical Therapeutic Chemical; SNOMED: Systematized Nomenclature of Medicine Clinical Terms.

Methods

Selected Diseases

As a proof of concept, we focused on 4 immune-mediated inflammatory diseases: SLE, systemic sclerosis, APS, and TA.

SLE is an autoimmune disease that mainly affects the skin, joints, and kidneys [38,39]. According to the revised 2019 EULAR/ACR classification criteria for SLE, patients are eligible for SLE criteria only if they have a positive antinuclear antibody ≥1/80 at least once. Anti-dsDNA and anti-Smith autoantibodies with high specificity for SLE are also included in the classification criteria for SLE. Therefore, we have chosen these 3 antibodies to identify SLE patients. Hydroxychloroquine, glucocorticoids, mycophenolate mofetil, cyclophosphamide, and belimumab are key treatments of SLE [40] and have been chosen to identify patients with SLE.

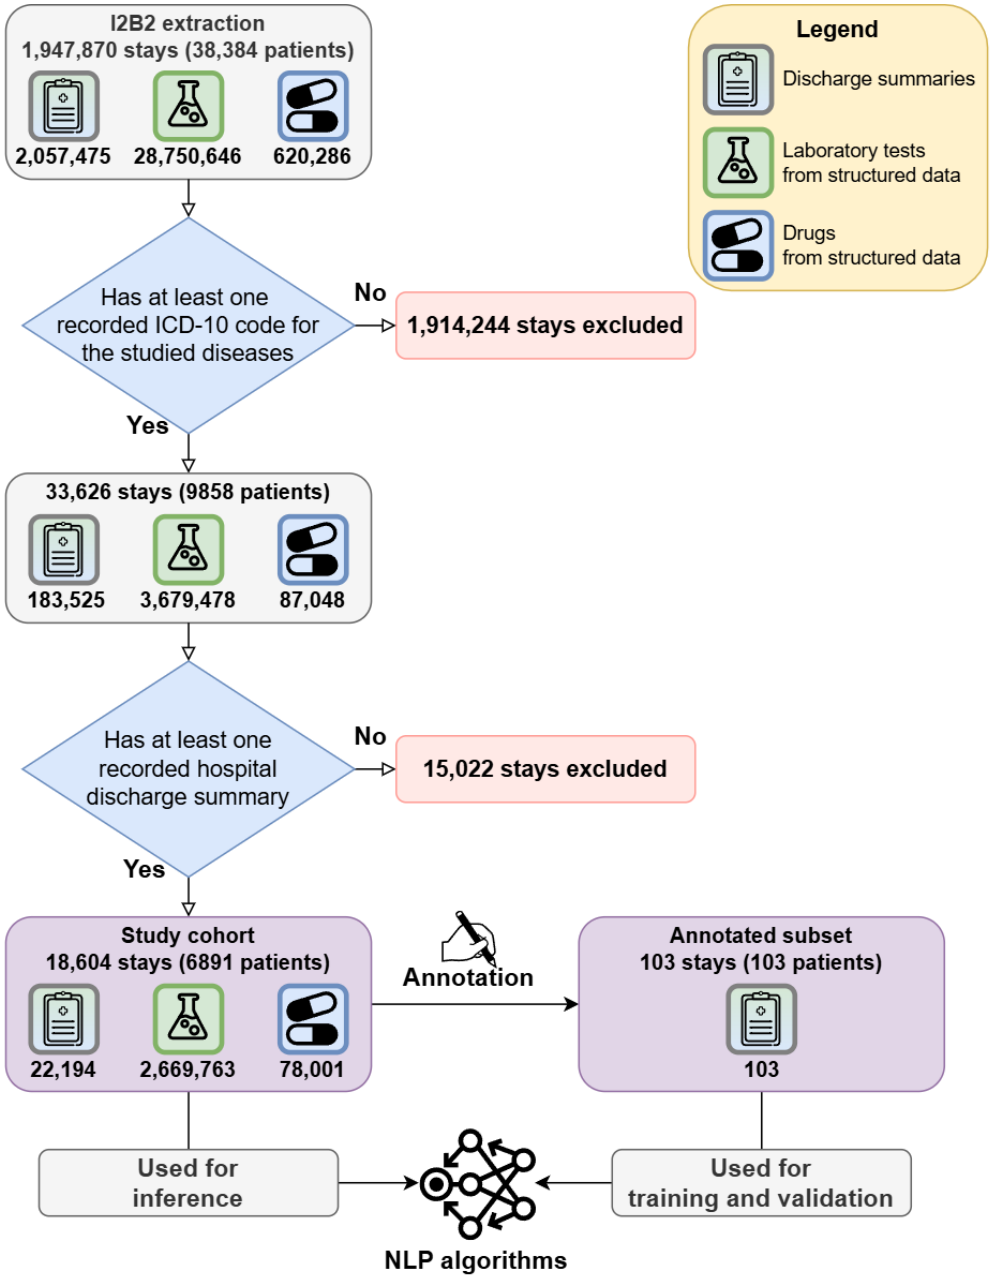
Systemic sclerosis is a rare autoimmune disease, inducing skin fibrosis, digestive disorders, such as gastroesophageal reflux disease and chronic pseudoocclusive syndrome, interstitial lung involvement, and sometimes inaugural renal crisis. Classification criteria are also based on specific autoantibodies, including anti-Scl-70, anticentromere, and anti-RNA polymerase III, which we have chosen to analyze here [41]. Therapeutic management is also based on glucocorticoids and immunosuppressive drugs, such as mycophenolate mofetil.

APS is a systemic autoimmune disease defined by the thrombosis or pregnancy morbidity in the presence of persistent antiphospholipid autoantibodies, lupus anticoagulant, IgG or IgM anticardiolipin, IgG or IgM anti-β2glycoprotein-1 antibodies. Treatment is based on curative anticoagulation with heparin, low-molecular-weight heparin, and antivitamin K [42].

TA is an inflammatory disease of the large arteries, leading to arterial stenosis in young people. C-reactive protein is used as an indicator of inflammation and disease activity in TA. Treatment is based on immunosuppressive therapies, such as glucocorticoids, and biologic, such as methotrexate or tocilizumab. Therefore, we have chosen to focus our analysis on these treatments.

Finally, in the context of the immunosuppressive treatments proposed, patients are at greater risk of infection; therefore, vaccination, particularly against pneumococcal and influenza infections, is recommended. Hence, we also looked for this information in the texts.

Dataset Selection



The dataset used in this study comes from the clinical data warehouse (CDW) of the University Hospitals of Greater Paris (Assistance publique-hôpitaux de Paris; AP-HP). The CDW brings together information on all patients followed in the 39 teaching hospitals in the Paris region (>22,000 beds and 1.5 million hospitalizations per year) that use a common EHR software, ORBIS Dedalus Health care. This software has been gradually implemented in the 39 hospitals since 2012.

The dataset was extracted from the CDW research database, in the integrating biology and the bedside format [43]. The inclusion criteria for the study were as follows: all patients aged >15 years with SLE, systemic sclerosis, APS, or TA who had at least one stay at AP-HP hospitals initially from July 1, 2017, to December, 31, 2020. Patients in the database were selected in 2 ways: by the *ICD-10* codes of these 4 pathologies and by keywords present in the medical reports (using regular expression matching), as summarized in Table S1 in Multimedia Appendix 1 [20,32,33,36,37,44-51]. For these patients, the data available were demographic data; textual data, including all full-text medical reports, laboratory tests performed during patients' stay, drug prescription, and administration when available; and medico-administrative coding data (*ICD-10*). The extraction covered all medical departments that could potentially manage patients with the 4 pathologies of interest: internal medicine and clinical immunology, nephrology, rheumatology, dermatology, pneumology, neurology, gastroenterology, oncology, hematology, infectious diseases, and emergency and intensive care.

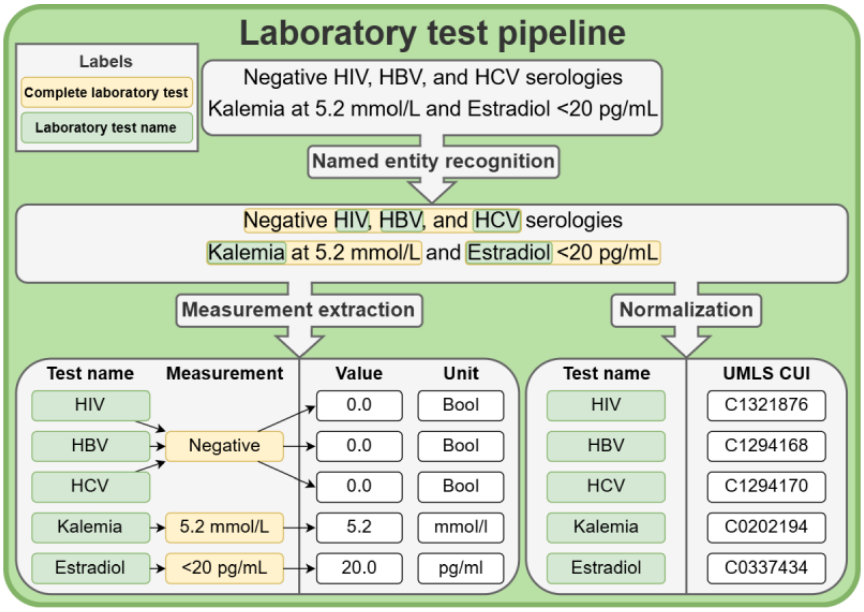
XSL•FO
RenderX

As this study involves the secondary use of real-life health data, from this large integrating biology and bedside extraction, we limited the study to EHRs with at least one *ICD-10* code corresponding to the diseases studied (SLE, systemic sclerosis, APS, or TA) and at least one recorded hospital discharge summary, as these are validated by a senior clinician. Subsequently, a subset of this study cohort of 103 hospital discharge summaries, each corresponding to a different patient, was randomly selected and annotated by a clinician (CG), following the same annotation rules as proposed by the national NLP clinical challenges 2022 [44]. Details regarding this annotation process are provided in the Annotation Guidelines section of Multimedia Appendix 1. The global approach of this work was to build, train, and validate NLP algorithms on the annotated subset before applying it to the full study cohort. Figure 2 presents the cohort selection process.

Figure 2. Cohort selection flowchart. Starting with integrating biology and bedside extraction of 1,947,870 stays (38,384 patients), the cohort was filtered to include stays with at least 1 International Classification of Diseases, 10th Revision (ICD-10) code corresponding to the studied diseases and at least 1 recorded hospital discharge summary. A final study cohort of 18,604 stays (6891 patients) was created, with 103 randomly selected discharge summaries annotated for training and validation purposes. NLP: natural language processing.

End-to-End Pipeline

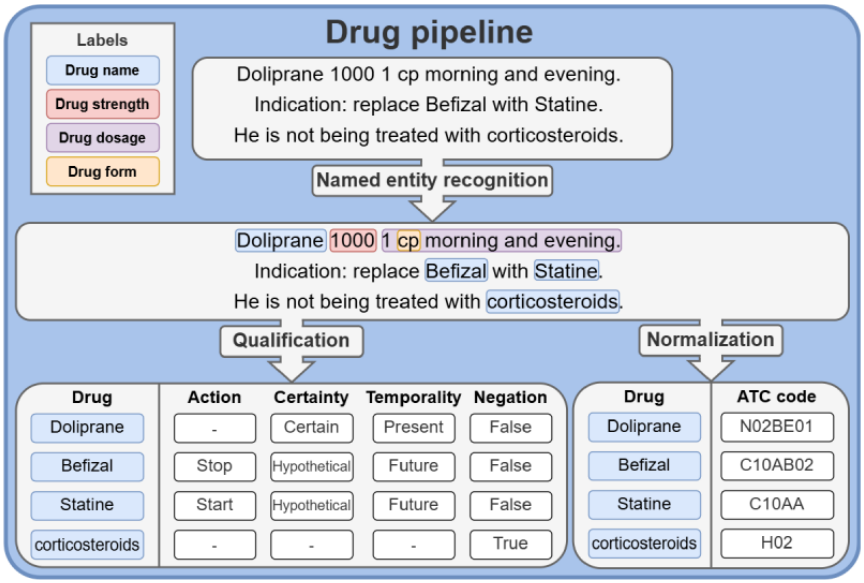
Overview



The system presented in this work required 4 NLP tasks: (1) NER: this task identified and classified entities of interest mentioned in the text into predefined categories. The possible categories included drug name, drug strength, drug dosage, drug form, laboratory test name, and complete laboratory test. (2) Qualification: this task involved assigning predefined qualifiers to the recognized named entities. Only entities classified as "drug name" by the NER algorithm were qualified There were 4 qualifiers [52]: action (start, stop, increase, decrease, unique

XSL•FO
RenderX

dose, and unknown), temporality (present, past, and future), certainty (certain, hypothetical, and conditional), as well as negation (true and false). (3) Measurement extraction: this task extracted and standardized the value and unit contained in the "complete laboratory test" entities detected by the NER algorithm. (4) Normalization: this task assigned predefined standard concepts to the recognized named entities. Each entity classified as "drug name" by the NER algorithm was assigned a code from the ATC classification system [37]. Each entity classified as "laboratory test name" by the NER algorithm was assigned a CUI of the UMLS [20] restricted to the laboratory procedure semantic type and the SNOMED CT US edition vocabulary [36]. As described in Figures 3 and Figure 4, the laboratory test pipeline and the drug pipeline involved both NER and normalization, while measurement extraction only concerned the laboratory test pipeline and qualification only concerned the drug pipeline.

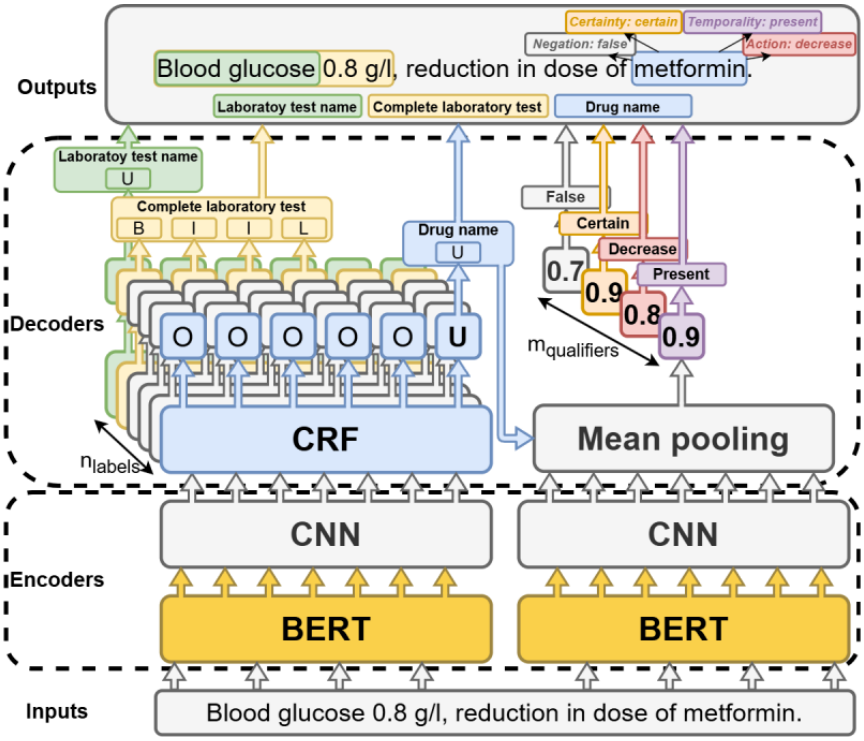


All the work presented in this paper was programmed in Python. Tabular data were processed with Spark (version 2.4.8) and distributed over 160 central processing units in parallel. This computing process is scalable over a large amount of data. Then, the cohorts were analyzed using Pandas (version 1.3.5). Inference and training of the NLP algorithms have been achieved on a V100 graphics processing unit. The code developed to run the experiments is freely available in a GitHub repository: Aremaki/BioMedics [53]. The code makes extensive use of EDS-NLP (version 0.13.0) [54], a collaborative NLP framework that aims primarily at building hybrid multitask NLP pipelines and extracting information from French clinical notes. It has also been made publicly available under an open-source license (BSD 3-clause): aphp/edsnlp.

Figure 3. Diagram of the laboratory test pipeline. It takes raw text as input, which is processed by 3 algorithms in total. It starts with the extraction and classification of relevant terms into 2 categories: laboratory test name and complete laboratory test. Then, the measurements associated with the complete laboratory tests are extracted and standardized into 2 components: value and unit. Finally, the extracted laboratory test names are normalized to the concept unique identifiers (CUIs) of the Unified Medical Language System (UMLS). HBV: hepatitis B virus; HCV: hepatitis C virus.

XSL•FO
RenderX

Figure 4. Diagram of the drug pipeline. It takes raw text as input, which is processed by 3 algorithms in total. It starts with the extraction and classification of relevant terms into 4 categories: name, strength, dosage, and form. At the same time, drugs are also qualified with several possible values: action (start, stop, increase, decrease, unique dose, and unknown), temporality (present, past, and future), certainty (certain, hypothetical, and conditional), and negation (true and false). Then, the extracted drugs are normalized according to the Anatomical Therapeutic Chemical (ATC) classification system. Cp: capsule.



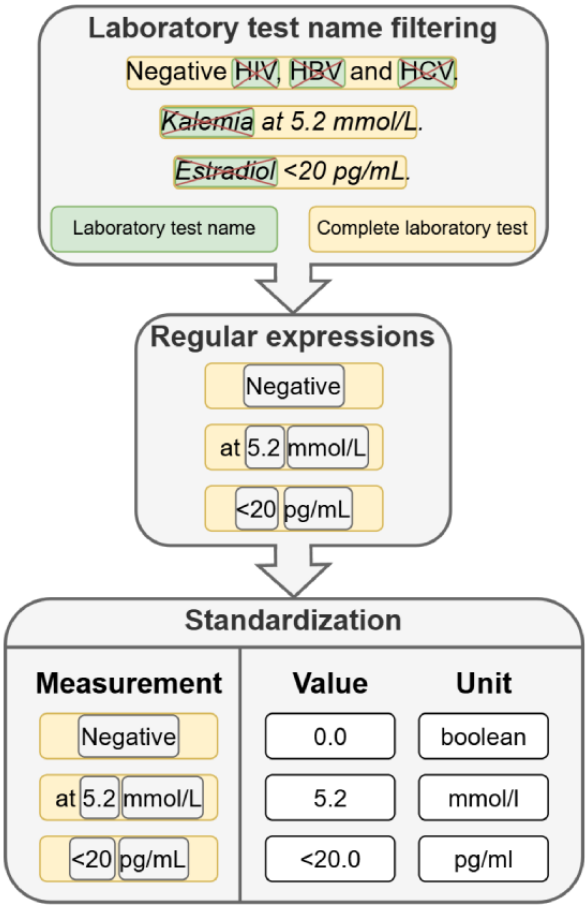
NER and Qualification Tasks

In the NER and qualification step, we experimented with different methods: a rule-based method as a preliminary approach, using the terms provided by the standard terminologies directly for exact matching. The ATC classification system [37] was used for drugs, and the SNOMED CT US edition vocabulary [36] was used for laboratory tests. A detailed description of the dictionaries is provided in Table S2 in Multimedia Appendix 1.

As a second approach, we experimented with a deep neural network architecture, described in Figure 5. The model consists of 2 BERTs encoders [30,55] followed by 2 convolution neural networks [56]. The first one is followed by a conditional random fields decoder [15] and a softmax block, which outputs probability vectors based on the beginning, inside, outside, unit, and last tagging scheme [14] to perform NER. The second is followed by a mean pooling layer and a softmax block to perform entity qualification. Several pretrained language models such as CamemBERT-EDS [45], CamemBERT-base [46], CamemBERT-bio [47], and DrBERT [48] have been compared.

XSL•FO
RenderX

Figure 5. Diagram of the named entity recognition and qualification architecture for laboratory tests and drugs entities. BERT: bidirectional encoder representations from transformer; CNN: convolution neural network; CRF: conditional random field.



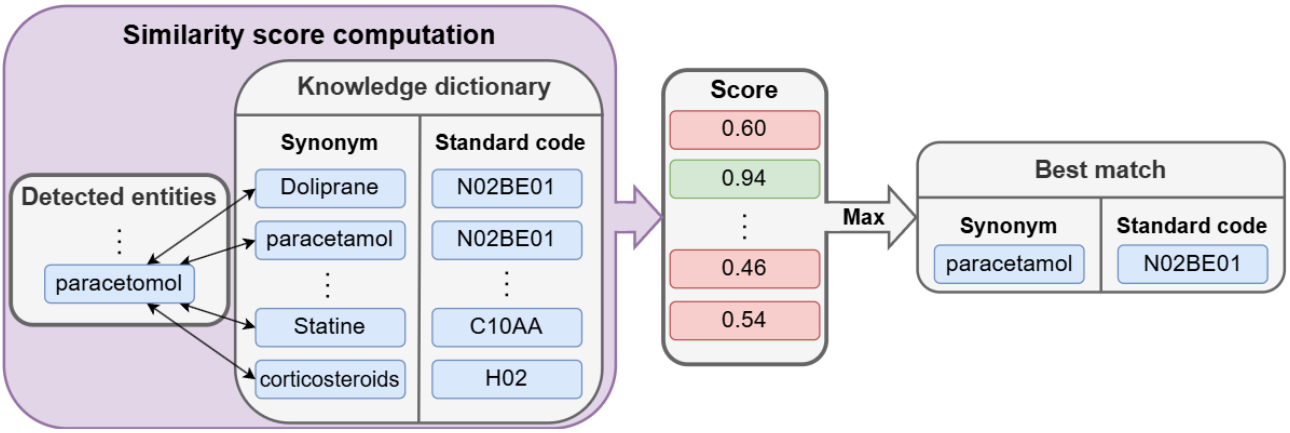
To select the best approach, precision, recall, and F_1-score were evaluated on 20 AP-HP discharge summaries. The performance of the rule-based method is presented in Table S3 in Multimedia Appendix 1, and the performance of the neural network method of each pretrained language model is presented in Tables S4 and S5 in Multimedia Appendix 1. The neural network approach using CamemBERT-EDS [45] was selected as the final model because it demonstrated superior performance compared to the other methods. Parameters of the architecture and fine-tuning are outlined in Table S6 in Multimedia Appendix 1.

Measurement Extraction Task

Extraction and standardization of the numerical value and unit were carried on the outputs of the NER step, which extracts the complete laboratory test entity from the text in a single block (laboratory test name, numerical value, and unit). The extraction and standardization were achieved with a rule-based algorithm using regular expressions. The algorithm steps are described in Figure 6: (1) the laboratory test names were removed from the complete laboratory test entity, (2) regular expressions were designed to extract the numerical or qualitative value and the unit, and (3) qualitative values (eg, “positive,” “negative,” or “normal”) were standardized into graded numbers (1.0, 0.0, or 0.5), while units were converted to conventional standards.

XSL•FO
RenderX

Figure 6. Diagram of the laboratory test measurement extraction process. HBV: hepatitis B virus; HCV: hepatitis C virus.



Normalization Task

The aim of the normalization step was to determine the standard code for each detected entity classified as "laboratory test name" and "drug name." As described in Figure 7, for a given detected term, similarity scores were computed for all terms of a knowledge dictionary. The resulting standard code corresponded to the term with the highest similarity score. For drugs, the knowledge dictionary is an aggregation of 2 open-source dictionaries of drug names with their corresponding ATC codes: the UMLS [20], restricted to the French ATC vocabulary [37], and the Unique Drug Interoperability Repository created by the French National Agency for Medicines and Health Products Safety [57]. For laboratory tests, the knowledge dictionary consists of all the French and English synonyms of the UMLS [20] restricted to the laboratory procedure semantic type and the SNOMED CT US edition vocabulary [36]. We experimented with 2 types of score computation: (1) fuzzy matching methods that directly compared word characters: Jaro-Winkler Distance [49] and Levenshtein distance [50], as well as (2) neural network–based methods that compute cosine similarity scores between the embeddings of the words: CODER-all [33] and SapBERT-all [32]. Table S7 in Multimedia Appendix 1 presents the performance of each method. The neural-based method with CODER-all seems to be significantly better for laboratory tests. However, for drugs, there is no significantly better solution, so we used the Jaro-Winkler Distance [49] method because it is less computationally expensive.

XSL•FO
RenderX

Figure 7. Diagram of the normalization process. In this example, the best match of "paracetomol," written with a typo, is "paracetamol," which provides the correct Anatomical Therapeutic Chemical (ATC) code.

Ethical Considerations

The research protocol for this project was approved in 2020 by the institutional review board of Assistance Publique – Hôpitaux de Paris (AP-HP) (20-93). All data used in this study were collected as part of routine medical care, and their use for research purposes falls under the ethical guidelines of the institutional review board. All patient data were pseudonymized to ensure privacy and comply with data protection regulations. No financial compensation was provided, as the study relied solely on retrospective data from electronic health records.

Results

Dataset Description

The number of patients, hospitalizations, and discharge summaries for each disease of the study cohort are given in Table 1. The age distribution and the distribution of admission start dates for each disease are presented in Figure S1 in Multimedia Appendix 1.

Table 1. Data description of the study cohort. Number of patients, hospitalizations, and discharge summaries for each studied disease. The number of discharge summaries is higher than the number of hospitalizations, as patients may change departments several times during the same stay (eg, be transferred to an intensive care unit, etc).

Disease	Number of patients	Number of hospitalizations	Number of discharge summaries
Antiphospholipid syndrome	1059	1818	2380
Lupus	4102	10,445	12,500
Systemic sclerosis	2031	6455	7585
Takayasu arteritis	252	833	965

We performed various analyses on the extracted data combined with the structured data from the cohort. The results are reported in 2 sections. The first section presents the performance of the NLP algorithms on the annotated subset of 103 discharge summaries. The second section is about the application of these algorithms to the 22,194 discharge summaries included in the study cohort. It described the contribution of unstructured data to structured data.

NLP Performance

Overview

The performance of the model was evaluated on 4 main tasks: NER, qualification, measurement extraction, and normalization. This evaluation was conducted using 2 datasets: 103 manually annotated discharge summaries from the study cohort and the publicly available Quaero FrenchMed corpus [51]. Performance metrics, including precision, recall, and F_1-score, were calculated and reported along with 95% CIs derived using the empirical bootstrap method at the discharge summary level [58]. It is important to note that while NER and qualification required annotated data for both training and testing, measurement extraction and normalization only required annotated data for testing. Therefore, all 103 discharge summaries were annotated for NER and qualification, with 83 (80.6%) randomly selected for training and the remaining 20 (19.4%) used for testing. These 20 (19.4%) test documents were further annotated for measurement extraction. Of these 20 documents, 11 (10.7%) were additionally annotated for normalization, resulting in 668 annotated entities, which was a more time-consuming process.

NER Task

Our model was evaluated for the NER task on both the AP-HP annotated discharge summaries and the Quaero FrenchMed corpus [51]. The results of our annotated dataset containing 103 discharge summaries from AP-HP are presented in Table 2. Precision, recall, and F_1-score were measured in a "strict" way, that is, a true positive result was obtained when a predicted entity and a gold entity had the exact same boundaries and label. The model achieved an overall F_1-score of 88.8. The results on the Quaero FrenchMed corpus [51] are presented in Tables S8 and S9 in Multimedia Appendix 1. The model achieved an

XSL•FO
RenderX

overall F_1-score of 66.2 for MEDLINE corpus and 71.71 for the European medicines agency corpus.

Table 2. Performance of the model for named entity recognition on University Hospitals of Greater Paris (Assistance Publique-Hôpitaux de Paris) discharge summaries. The model was trained on 83 annotated discharge summaries and tested on 20 discharge summaries. Each result was bootstrapped by discharge summary to provide a 95% CI given inside the brackets.

Label	Number of entities (95% CI)	Precision (95% CI)	Recall (95% CI)	F_1-score (95% CI)
Laboratory test name	1292 (1603-1010)	90.6 (88.5-92.7)	89.9 (87.5-92.2)	90.3 (88.2-92.3)
Complete laboratory test	1041 (1323-793)	86.2 (84.3-88.3)	83.6 (79.1-87.5)	84.9 (82.1-87.5)
Drug name	585 (731-454)	90.8 (85.8-95.4)	92.5 (88.4-95.7)	91.6 (87.5-95.1)
Drug dosage	276 (368-194)	89.1 (85.4-94.1)	86.2 (81.7-90.8)	87.7 (84.0-92.1)
Drug form	170 (247-106)	86.5 (78.8-93.4)	94.1 (91.5-97.6)	90.1 (85.6-94.0)
Drug strength	130 (196-77)	93.1 (87.7-97.0)	93.8 (89.2-97.6)	93.5 (89.3-96.6)
Overall	3494 (4194-2885)	89.1 (87.5-90.8)	88.5 (86.4-90.5)	88.8 (87.1-90.5)

Qualification Task

The model was evaluated for the qualification task and achieved an F_1-score of 78.8 on our annotated dataset containing 103 discharge summaries from AP-HP. The results are presented in Table S10 in Multimedia Appendix 1. On the test set, the model achieved an overall F_1-score of 78.8.

Measurement Extraction Task

The model was evaluated for the measurement extraction task on 20 annotated discharge summaries from AP-HP. Precision, recall, and F_1-score are presented in Table S11 in Multimedia Appendix 1 and were measured in a "strict" way: a true positive result was obtained when a predicted measurement and a gold measurement had the same value and unit. The algorithm obtained an F_1-score of 96.7.

Normalization Task

The rule-based algorithm for drug name normalization and the deep learning algorithm for the laboratory test name normalization were both evaluated on 11 annotated discharge summaries from AP-HP, 3 documents from European medicines agency, and 833 titles from MEDLINE [51]. For the evaluation, a true positive result was obtained when the predicted code of an entity was part of the list of annotated gold standard codes. Precision, recall, and F_1-score are presented in Table S12 in Multimedia Appendix 1. On our dataset of discharge summaries, the rule-based method for drug names achieved an F_1-score of 92.9 and the neural network–based method used for laboratory tests achieved an F_1-score of 82.2.

End-to-End Pipeline

The model was evaluated on the NER and normalization task using 11 annotated discharge summaries from AP-HP. Precision, recall, and F_1-score were measured in a "strict" way: a true positive result was obtained when a predicted entity and a gold entity had exactly the same boundaries and label and the predicted standard code of the entity was part of the list of annotated gold standard codes. Precision, recall, and F_1-score are presented in Table 3. We obtained an F_1-score of 71.1 for laboratory tests and 89.3 for drug names.

Table 3. Performance of the models for named entity recognition and normalization tasks on University Hospitals of Greater Paris (Assistance Publique-Hôpitaux de Paris) discharge summaries. The model was tested on 11 discharge summaries. Each result was bootstrapped by discharge summary to provide a 95% CI given inside the brackets.

Label	Number of entities (95% CI)	Precision (95% CI)	Recall (95% CI)	F_1-score (95% CI)
Laboratory test name	356 (204-548)	72.0 (65.3-79.1)	70.2 (59.7-77.9)	71.1 (63.6-77.8)
Drug name	312 (206-424)	91.9 (88.9-93.5)	86.9 (82.9-90.0)	89.3 (85.9-91.6)

Clinical Application

For each studied disease (SLE, systemic sclerosis, APS, and TA), each studied antibody, and each studied drug treatment, we reported the number of patients for whom we extracted a positive antibody or a prescribed drug treatment from both the structured and unstructured data of the study cohort. Lists of CUI codes for the studied antibodies and ATC codes for drug treatments are available in Tables S9 and S10 in Multimedia Appendix 1. We were particularly interested in the number of patients for whom we extracted positive antibodies or drug treatments from the unstructured data of their EHRs that were not available in the structured data. In the analysis of the unstructured data, only entities explicitly qualified as "certain" and not negated were retained.

Laboratory Test Results

Table 4 describes the number of antibody-positive patients for each disease, where positivity was determined either by test values exceeding reference ranges or by explicit interpretation of the test as positive. The first column shows the number of patients for whom we extracted at least 1 positive test from the structured data of their EHR. The second column shows the number of patients for whom we extracted at least 1 positive test from both the structured and unstructured data. The third column shows the number of patients for whom we extracted

XSL•FO
RenderX

at least 1 positive test from the unstructured data, but only among patients without positive tests extracted from the structured data.

To ensure the reliability of the detected autoantibodies across the entire study cohort, we conducted a second evaluation focused specifically on the studied autoantibodies. While the precision was reported in Table 3 as 72% in the general case for all laboratory tests, this additional analysis aimed to ensure comparable performance for the autoantibodies studied. For this evaluation, we randomly selected 10 positively detected entities for each studied autoantibody, yielding a total of 110 entities. These entities, identified through NER, measurement extraction, and normalization, were reviewed by a clinician. The review identified 3 errors, resulting in a precision of 97.3%.

Finally, to identify potential errors made by the algorithm, we examined EHR cases in which a positive autoantibody appeared in the structured data but was not detected in the unstructured data. For each antibody, we randomly selected 10 EHRs (for some antibodies, fewer than 10 documents met this criterion, so we included all available cases). A clinician reviewed 63 discharge summaries from the EHRs and identified 2 types of algorithmic errors: (1) in 23 (26.5%) summaries, the algorithm either failed to detect the relevant antibody or did not normalize it correctly; and (2) in the remaining 40 (63.5%) summaries, either the antibody was not mentioned in the text, or the mention was interpreted as a negative result by the clinician.

Table 4. Number of patients with positive antibodies mentioned in the text and in structured data.

Disease and laboratory test	Number of patients with positive tests (ratio)		
	Structured data only, n (%)	Structured and unstructured data, n (%)	Benefits of the unstructured data, n (%)
Antiphospholipid syndrome (1059 patients)			
Anticardiolipin antibody	184 (17.37)	478 (45.14)	294 (27.76)
Anti-B2GP1 antibody	103 (9.73)	334 (31.54)	231 (21.81)
Lupus anticoagulant	277 (26.16)	423 (39.94)	146 (13.79)
Systemic lupus erythematosus (4102 patients)			
Antinuclear antibody	752 (18.33)	2949 (71.89)	2197 (53.56)
Anti-DNA antibodies	541 (13.19)	2174 (53)	1633 (39.81)
Anti-Smith antibodies	255 (6.22)	858 (20.92)	603 (14.7)
Systemic sclerosis (2031 patients)			
Anti-RNA polymerase III antibody	39 (1.92)	156 (7.68)	117 (5.76)
Anti-Scl-70 antibodies	97 (4.78)	568 (27.97)	471 (23.19)
Anticentromere antibody	144 (7.09)	609 (29.99)	465 (22.9)

Drug Treatments

Table 5 describes the number of patients with drug treatments for each of the studied drugs related to the respective disease. The first column presents the number of patients for whom we extracted at least 1 drug treatment from the structured data of their EHR. The second column presents the number of patients for whom we extracted at least 1 drug treatment from both the structured and the unstructured data. The third column provides the number of patients for whom we extracted at least 1 drug treatment from the unstructured data but only among the patients without drug treatment extracted from the structured data.

XSL•FO
RenderX

Table 5. Number of patients with drug treatments. It describes the number of patients with drug treatments for each of the studied drugs related to the respective disease, extracted from structured and unstructured data. The proportions in percentage of the total number of patients diagnosed with the respective disease are given inside parenthesis.

Diseases and drugs	Number of patients with drug treatments (ratio)		
	Structured data only, n (%)	Structured and unstructured data, n (%)	Benefits of the unstructured data, n (%)
Antiphospholipid syndrome (1059 patients)			
VKA	186 (17.56)	628 (59.3)	442 (41.74)
Heparin	238 (22.47)	677 (63.94)	439 (41.46)
Oral anticoagulant	47 (4.44)	177 (16.72)	130 (12.28)
Systemic lupus erythematosus (4102 patients)			
Systemic glucocorticoids	950 (23.16)	3308 (80.64)	2358 (57.49)
Cyclophosphamide	64 (1.56)	894 (21.79)	830 (20.23)
Mycophenolate mofetil	301 (7.34)	1263 (30.78)	962 (23.46)
Rituximab	75 (1.83)	709 (17.28)	634 (15.46)
Belimumab	43 (1.05)	247 (6.02)	204 (4.97)
Methotrexate	112 (2.73)	963 (23.48)	851 (20.75)
Hydroxychloroquine	920 (22.43)	3520 (85.83)	2600 (63.4)
Prevenar 13 vaccine	122 (2.97)	984 (23.99)	862 (21.02)
Pneumovax vaccine	43 (1.05)	436 (10.63)	393 (9.58)
Influenza vaccine	96 (2.34)	577 (14.07)	481 (11.73)
Systemic sclerosis (2031 patients)			
Systemic glucocorticoids	258 (12.71)	1260 (62.06)	1002 (49.33)
Cyclophosphamide	6 (0.3)	390 (19.2)	384 (18.91)
Mycophenolate mofetil	88 (4.33)	463 (22.81)	375 (18.47)
Rituximab	13 (0.64)	258 (12.71)	245 (12.07)
Methotrexate	66 (3.25)	541 (26.63)	475 (23.39)
Prevenar 13 vaccine	59 (2.9)	545 (26.84)	486 (23.93)
Pneumovax vaccine	13 (0.64)	285 (14.03)	272 (13.4)
Influenza vaccine	42 (2.07)	425 (20.93)	383 (18.87)
Takayasu arteritis (252 patients)			
Systemic glucocorticoids	68 (27)	223 (88.49)	155 (61.51)
Cyclophosphamide	0 (0)	18 (7.14)	18 (7.14)
Tocilizumab	15 (5.95)	47 (18.65)	32 (12.7)

Rituximab	0 (0)	6 (2.38)	6 (2.38)
Methotrexate	20 (7.94)	135 (53.57)	115 (45.63)
Prevenar 13 vaccine	9 (3.57)	83 (32.94)	74 (29.37)
Pneumovax vaccine	3 (1.19)	48 (19.05)	45 (17.86)
Influenza vaccine	6 (2.38)	41 (16.27)	35 (13.89)

To ensure the precision of the drug treatments identified by the algorithm, we conducted a second evaluation specifically focused on the studied drugs. Although the general precision for all drugs had previously been reported as 91.9% in Table 3, this additional analysis aimed to confirm comparable performance for the specific drug treatments studied. For this evaluation, we randomly selected 10 positively detected entities per studied drug (spanning NER and normalization), resulting in a total of 130 entities. A clinician reviewed these entities individually and found no errors, corresponding to a precision of 100%.

Inference Time and Carbon Footprint

When considering scaling these methods to a CDW that may process hundreds of thousands of documents daily, it is critical to evaluate both processing speed and environmental impact. The entire NLP process on the 22,194 documents took 145 minutes on a graphics processing unit (Tesla V100-SXM2-32GB) and resulted in a total emission of 0.39 kg equivalent of CO_2.

Discussion

Principal Findings

In this paper, we proposed a novel block-based algorithm for extracting and normalizing medical data from text, enabling fine-grained phenotyping of patients with autoimmune or autoinflammatory diseases. We demonstrated that these cascading algorithms significantly improve patient characterization compared to relying only on structured data. In addition, we provided detailed results for every step of the algorithm (NER, qualification, measurement extraction, and normalization), evaluated our method using a publicly available dataset, Quaero [51], and provided a comprehensive performance comparison between models.

Our work offers several strengths. Notably, we leveraged state-of-the-art language models, particularly the BERT model, for named entity extraction. Indeed, when compared with recent large language models, such as GPT, BERT models remain the most effective for the NER task [58]. We evaluated and compared several language models and various methods for each step, demonstrating strong performance outcomes. The model evaluated for the NER task on 20 annotated discharge summaries achieved high F_1-scores: 90.3 for laboratory test names and 91.6 for drug names. Similarly, the model achieved high F_1-scores for the qualification task, the measurement extraction task, and the overall end-to-end task. A posteriori precision analysis also showed very good results (97.3% for laboratory tests and 100% for drugs). Finally, as shown in Tables 4 and Table 5, our study highlights significant improvements in information availability by enriching structured data with information extracted from unstructured data.

Beyond these results, our findings are consistent with those of previous studies. For instance, 71.87% (2949/4102) of patients in the lupus cohort exhibited positive antinuclear antibodies (≥1/80), a finding that aligns with the clinical criteria for the disease [40]. Similarly, when compared with previous data [38,40], 85.81% (3520/4102) of patients with SLE were treated with hydroxychloroquine, and 80.64% (3308/4102) received corticosteroids during hospitalization. For comparison, a recent conference abstract by Eviatar et al [59] reported that 81% of patients were treated with hydroxychloroquine, 65% with systemic corticosteroids, and 55% with immunosuppressants (2259/4102, 55.07% in our study). In addition, 64.4% (682/1059) of patients with APS had at least one positive antibody assay. For patients with TA, the treatments were consistent with national recommendations [60], with 88.5% (223/252) of patients receiving systemic corticosteroids and 18.7% (47/252) treated with tocilizumab.

The clinical implications of algorithms that enable accurate patient phenotyping are substantial. They facilitate more precise recruitment of patients for studies, particularly therapeutic trials, and support clinical practice by addressing key questions, such as, “What happened to a patient like mine?” Prototypes are currently under development to construct cohorts of patients with similar characteristics to a specific individual under care, using information extracted from hospital reports. The algorithm we present can identify patients with comparable immune profiles (eg, matching positive antibodies) and analyze the treatments they received, offering valuable insights for personalized care.

Limitations

However, there are several limitations to our study. A significant limitation lies in the complexity of standardizing laboratory tests, especially for tests with abbreviated terms. For instance, the glomerular filtration rate (or “DFG” in French) is not directly classified as a biological test in the SNOMED CT US edition [36], making it challenging to standardize. Similarly, the abbreviation “ACC” for lupus circulating anticoagulant is missing in the UMLS [20], which makes normalization difficult and partially explains the lower contribution of text-based analysis for this assay. In general, drug names are often written in a relatively standardized format in texts (using either trade names or generics), whereas the terminology for describing biological data tends to be more varied. For example, a clinician might describe “hemoglobin” using variations, such as “anemia at 9g/dL,” “Hb=9g/dL,” or “hemoglobin at 9,” among others. This variability complicates the normalization process for laboratory tests, leading to poorer performance compared with that of drug treatments. Another limitation is the relatively small evaluation sample size. Our NLP end-to-end system was evaluated on only 11 annotated clinical documents, comprising 668 annotated entities. This limited dataset is a consequence of the labor-intensive process involved in manually annotating CUIs and ATC codes, which constrained the number of documents we could feasibly annotate. Also, interannotator agreement could not be computed due to having a single annotator involved in the annotation process. To minimize potential biases, several precautions were taken. First, an expert clinician performed the annotations following strict guidelines, while the model was independently designed by a separate researcher. Second, the training and test datasets were created using distinct discharge summaries from different patients. These precautions reduce the risk of information leakage during model evaluation.

Finally, it is important to note that this study relies on the secondary use of “real-life” health care data. While clinical texts are central to characterizing patients, as demonstrated, they do not comprehensively capture all patient characteristics. Our error analysis revealed that for patients with both textual information and biological test results from the same hospitalization, 63% (40/63) of the biological tests were either not mentioned in the text or were interpreted by the clinician as negative results. To enhance the accuracy of patient phenotyping, we believe it is essential to incorporate both structured and textual data.

RenderX

Future Works

Moreover, we acknowledge that the analyses presented here are preliminary for each pathology, and we anticipate more detailed future work in this area. Particularly, it will be necessary to establish a precise relationship between target organ damage and antibody positivity, some of which are known to be more specific for certain types of damage. For example, anti-RNA polymerase III antibodies are more often associated with sclerodermic renal crisis [61], and triple positivity of APS antibodies is also a poor prognostic marker. The type and severity of organ damage should also be considered in conjunction with treatment options. These analyses will also be based on our current patient phenotyping work [62]. Analysis of the dosages associated with each treatment is not currently explored either, but work is in progress for this future step. Another direction is adapting our methodology to other languages. While the current implementation is tailored for French, the approach can be generalized by substituting the pretrained clinical BERT model with other language-specific alternatives, such as models pretrained for Spanish [63] or English [64]. However, successful adaptation would require annotated datasets specific to the new language, as well as adjustments to the terminology and clinical standards used in the target CDW. Beyond linguistic adaptability, the methods described could also be extended to unstructured data in different formats, such as imaging. Addressing these directions could advance this research toward a more comprehensive, multilingual, and multiformat phenotyping framework.

Conclusions

To the best of our knowledge, this is the first study to automatically analyze such a large volume of patients with autoimmune diseases using data derived directly from text. It seems to us that this finer, text-based characterization of patients in the context of rare diseases could enable researchers to target them more effectively, and clinicians to bring synthesis to their management.

Acknowledgments

The authors thank the clinical data warehouse of the Greater Paris University Hospitals for its support and the realization of data management and data curation tasks. The authors express sincere thanks to Dr Arthur Mageau, Prof Karim Sacré, and Prof Olivier Steichen for their careful review of this manuscript.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to their classification as sensitive data under the General Data Protection Regulation and the National Data Protection Commission. Access to the data requires prior approval from the local institutional review board and must follow the process outlined on its website [65]. In the case of non-University Hospitals of Greater Paris (Assistance Publique-Hôpitaux de Paris) researchers, the signature of a collaboration contract is mandatory.

Abstract

Background: The American Medical Association recommends that electronic health record (EHR) notes, often dense and written in nuanced language, be made readable for patients and laypeople, a practice we refer to as the simplification of discharge notes. Our approach to achieving the simplification of discharge notes involves a process of incremental simplification steps to achieve the ideal note. In this paper, we present the first step of this process. Large language models (LLMs) have demonstrated considerable success in text summarization. Such LLM summaries represent the content of EHR notes in an easier-to-read language. However, LLM summaries can also introduce inaccuracies.

Objective: This study aims to test the hypothesis that summaries generated by LLMs from highlighted discharge notes will achieve increased accuracy compared to those generated from the original notes. For this purpose, we aim to prove a hypothesis that summaries generated by LLMs of discharge notes in which detailed information is highlighted are likely to be more accurate than summaries of the original notes.

Methods: To test our hypothesis, we randomly sampled 15 discharge notes from the MIMIC III database and highlighted their detailed information using an interface terminology we previously developed with machine learning. This interface terminology was curated to encompass detailed information from the discharge notes. The highlighted discharge notes distinguished detailed information, specifically the concepts present in the aforementioned interface terminology, by applying a blue background. To calibrate the LLMs' summaries for our simplification goal, we chose GPT-4o and used prompt engineering to ensure high-quality prompts and address issues of output inconsistency and prompt sensitivity. We provided both highlighted and unhighlighted versions of each EHR note along with their corresponding prompts to GPT-4o. Each generated summary was manually evaluated to assess its quality using the following evaluation metrics: completeness, correctness, and structural integrity.

Results: We used the study sample of 15 discharge notes. On average, summaries from highlighted notes (H-summaries) achieved 96% completeness, 8% higher than the summaries from unhighlighted notes (U-summaries). H-summaries had higher completeness in 13 notes, and U-summaries had higher or equal completeness in 2 notes, resulting in P=.01, which implied statistical significance. Moreover, H-summaries demonstrated better correctness than U-summaries, with fewer instances of erroneous information (2 vs 3 errors, respectively). The number of improper headers was smaller for H-summaries for 11 notes and U-summaries for 4 notes (P=.03; implying statistical significance). Moreover, we identified 8 instances of misplaced

XSL•FO
RenderX

information in the U-summaries and only 2 in the H-summaries. We showed that our findings supported the hypothesis that summarizing highlighted discharge notes improves the accuracy of the summaries.

Conclusions: Feeding LLMs with highlighted discharge notes, combined with prompt engineering, results in higher-quality summaries in terms of correctness, completeness, and structural integrity compared to unhighlighted discharge notes.

Introduction

Background

Electronic health records (EHRs) [1] are digital versions of a patient's medical records that were originally intended for communication among health care professionals, such as clinicians and nurses, to facilitate quick comprehension and efficient interoperability. These notes are typically written in highly technical language, filled with abbreviations, complex sentence structures, and medical jargon that may be unfamiliar to individuals without a medical background [2].

According to the 21st Century Cures Act and the Open Notes Rule [3], it is required to make these notes available to patients through patient portals, and because of this, a significant challenge has emerged. Patients with limited health literacy may struggle to understand written medical information, communicate health concerns with health care providers, and navigate EHR systems [2]. Research shows that patients often use different vocabulary than clinicians when searching for health information [4], indicating that the language clinicians use in discharge notes is potentially unfamiliar and difficult for patients to understand. To increase the comprehension of EHR notes, the American Medical Association recommends a grade 6 reading level, whereas the National Institutes of Health (NIH) recommends a grade 7 to 8 reading level for EHR notes [5,6]. The National Cancer Institute recommends an grade 6 reading level, reflecting the average reading level for a US citizen [7-9].

Large language models (LLMs) [10-13] have demonstrated success in text summarization and simplification tasks [14-16]. ChatGPT (OpenAI) [17], in particular, has shown promise in generating summaries that are comparable to those created by human experts [18]. Prompt engineering [19,20] has gained significant popularity in recent years due to its potential to improve the performance of LLMs. By carefully crafting prompts, we can instruct LLMs on how to extract key information, maintain coherence, and structure summaries according to specific needs. Well-designed prompts help control the level of detail, tone, and style, thereby improving both accuracy and readability [19,21]. Because LLMs rely on input instructions [22], prompt engineering is essential for aligning model behavior with the desired summarization outcome, reducing ambiguity and enhancing reliability.

Despite the advantages, several concerns remain regarding the use of LLMs in the medical field, particularly for summarizing medical texts [23,24]. These include issues of reliability, inconsistency in output quality, the potential for false information, and prompt sensitivity. Without addressing these concerns, LLMs might not realize their full potential for summarizing discharge notes. As mentioned earlier, the presence of inadequate sentence structure, a lack of punctuation, the presence of fragmented expressions, and an abundance of abbreviations within discharge notes make summarization relatively more difficult compared to general domain text summarization. Therefore, LLM-generated summaries may sometimes omit crucial information or lack proper structure.

In this paper, we present the first step in the process of simplifying discharge notes by harnessing the summarization capabilities of LLMs. In this study, we aim to generate more accurate, structured summaries from discharge notes where headers provide clear orientation and make the content easier to understand [25]. These summaries are then converted into accurate, simplified notes that are understandable for patients with a grade 6 reading level [26].

To address and evaluate the loss of crucial information in the summaries of discharge notes, our approach involves modifying the input by providing LLMs with highlighted discharge notes, where detailed information is emphasized. We then compare these summaries with those generated from unhighlighted notes. Our previous research [27,28] developed an innovative method for automatically highlighting detailed information in discharge notes. In this study, we automatically highlighted discharge notes using that technique (which is described in the Methods section). Our technique also uses prompt engineering to enhance the structural integrity of the generated summaries and address prompt sensitivity. We hypothesize that feeding LLMs with the highlighted notes aids in summarizing them more accurately. The rationale for this prediction is that, with a prompt to focus on the highlighted detailed information in a text, the summary will be more accurate and better structured than one obtained without highlighting.

We conducted this study to test the following hypothesis: Summaries generated by LLMs from highlighted discharge notes will achieve increased accuracy compared to those generated from the original notes. This is done by generating summaries from both unhighlighted and highlighted discharge notes using LLMs and then comparing both versions of the summaries for each discharge note to see which method yields better results. We evaluated different dimensions of the accuracy of summaries with proper metrics, including completeness, correctness, and structural integrity. Our findings support the

XSL•FO
RenderX

hypothesis that summarizing highlighted discharge notes improves the accuracy of the summaries as measured by these metrics. Thus, it is advantageous to generate summaries of discharge notes after highlighting them. Structured summaries of highlighted discharge notes provide a valuable starting point for future efforts to enhance the simplification of these notes while maintaining their accuracy.

Related Work

The goal of text summarization is to condense text while keeping its key information and important content intact [29,30]. Before the advent of LLMs, text summarization was primarily performed by automatic text summarization (ATS) [31-33]. ATS involves a trainable summarizer that considers various features, such as sentence position, keywords, sentence centrality, resemblance to the title, inclusion of named entities and numerical data, relative length, bushy path, and aggregated similarity to generate summaries [34].

While traditional ATS methods are still in use, LLMs are increasingly adopted for summarization tasks as they have shown great performance in this area. Therefore, there has been a significant shift from ATS to LLMs, with methods evolving from pretraining and fine-tuning to prompt-based approaches [31]. Besides, when summarizing discharge notes, mainly replete with medical abbreviations, LLMs typically spell out most of the abbreviations, yielding more readable clinical notes.

In a recent study [35], 8 LLMs (Flan-T5, Flan-UL2, Alpaca, MedAlpaca, Vicuna, Llama-2, GPT-3.5, and GPT-4) were evaluated for various clinical text summarization tasks. The study identified GPT-4 as the best-performing model, particularly when using in-context learning [36] for adaptation. GPT-4 demonstrated superior completeness, correctness, and conciseness in summaries compared to other models and even human experts. Therefore, in this study, we have used the latest version of ChatGPT, GPT-4o, for summarization.

In the study by Kanwal and Rizzo [37], they developed an extractive summarization method tailored for discharge notes using a bidirectional encoder representations from transformers–based model fine-tuned on the MIMIC-III dataset. Their approach uses attention scores from the final transformer layer to identify clinically important sentences without relying on reference summaries. The model dynamically selects sentences with above-average attention scores, aiming to preserve essential clinical content. Their method outperformed 3 baseline approaches, namely frequency-based, graph-based, and K-means centroid-based extractive summarization, demonstrating better content preservation and semantic alignment with the original notes.

In the study by Alsentzer and Kim [38], they explored extractive summarization of discharge notes from the MIMIC-III database. They estimated an upper bound on extractive summarization by measuring how much of the information in a discharge summary can be found elsewhere in the patient's EHR notes using concept unique identifiers. To support future summarization tasks, they also developed a long short-term memory model to label word-level topics in the "history of present illness" sections. This classifier achieved an F_1-score of 0.876 on a manually annotated test set, demonstrating its potential for generating topic-specific evaluation datasets for extractive summarization models.

In the study by Ma et al [39], the researchers developed a method called ImpressionGPT to summarize the "impression" section of radiology reports using ChatGPT. They used a dynamic prompt generation and iterative optimization approach to improve the performance of ChatGPT in this task. The results showed that ImpressionGPT achieved better performance in generating correct and concise summaries compared to existing methods, demonstrating its potential to enhance clinical workflows and reduce the workload of health care professionals.

The challenges faced by clinicians with limited time to remain abreast of the rapidly expanding medical literature have been documented in the study by Hake et al [40]. The authors evaluated the performance of ChatGPT in summarizing 140 peer-reviewed medical abstracts from 14 different journals. Their methodology involved prompting ChatGPT to create summaries and then having physicians assess the quality, accuracy, and bias of these summaries, where bias refers to the phenomenon where artificial intelligence (AI) systems are trained on data that lack sufficient reflection of the diversity within the population. The results showed that ChatGPT-produced summaries were 70% shorter than the original abstracts but maintained an accuracy of 92.5%. The study concluded that while ChatGPT can aid in summarizing medical literature, full-text evaluation remains crucial for critical medical decisions. Although they conducted the study on scientific paper abstracts, which are well structured and have much simpler language than discharge notes, they reported several occurrences of serious inaccuracies in ChatGPT summaries that could materially impact the major interpretation of the text.

Methods

Overview

Existing research on summarization using ChatGPT [35] has primarily focused on prompt engineering to achieve optimal results. These studies have not explored the potential benefits of modifying the input format and providing customized context tailored to the specific text. In contrast, our study goes beyond prompt engineering by incorporating important information directly into the input text. This approach ensures that ChatGPT pays attention to key details, enhancing the completeness, correctness, and structural integrity of the generated summaries.

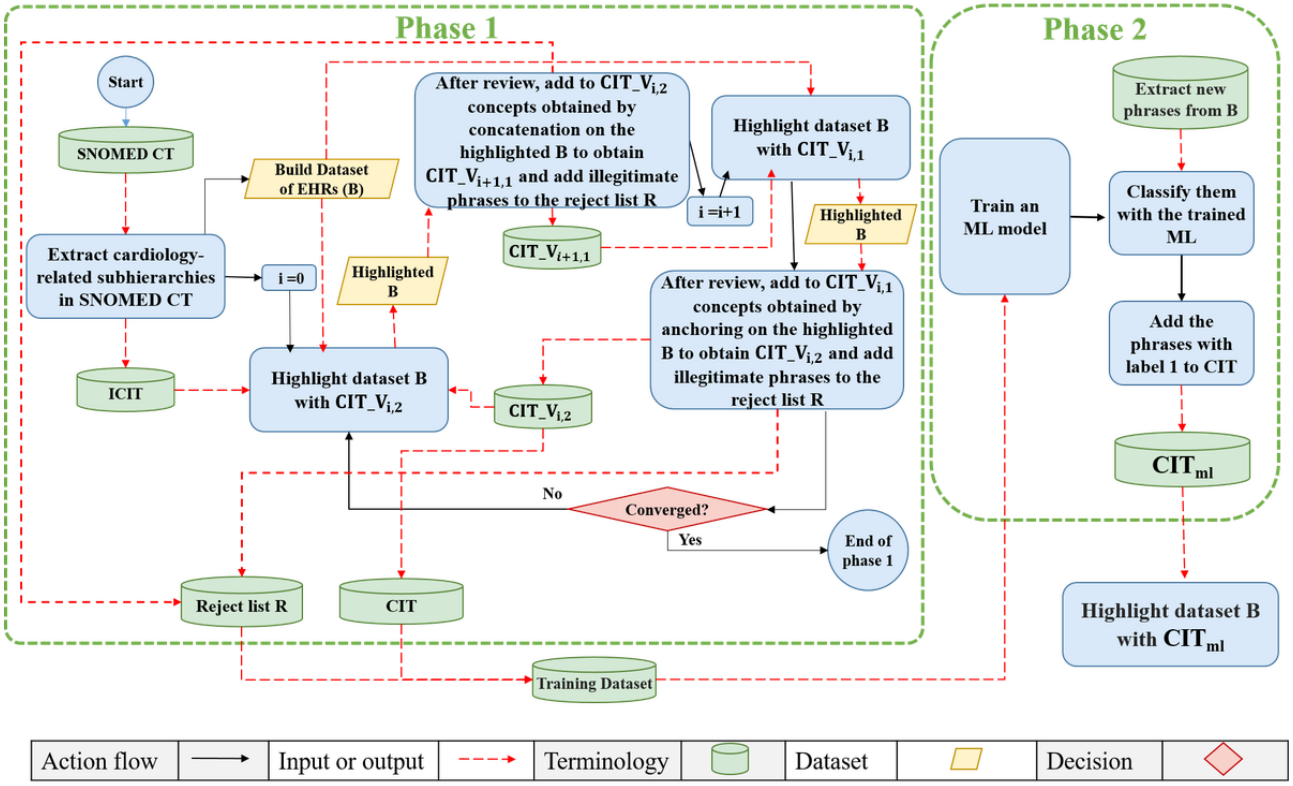
In the Methods section, we first explain the automatic EHR highlighting technique, followed by the summarization method used in this study.

Automatic EHR Highlighting

In our previous studies [27,28], we developed a cardiology interface terminology (CIT) to facilitate efficient highlighting of detailed content in cardiology-related discharge notes. The process is composed of 2 phases. In the first phase [27], we created an initial version of CIT (ICIT), which contains the cardiology-related subhierarchies of Systematized Nomenclature of Medicine–Clinical Terms [41,42]. However, ICIT did not

XSL•FO
RenderX

capture all the important information from the discharge notes of cardiology patients. Therefore, we added concepts by extracting fine-granularity phrases from discharge notes that contained ICIT concepts. This was done using a semiautomatic iterative process, resulting in the formation of CIT. In each iteration, we highlighted the build dataset with the last version of the CIT and calculated the coverage and breadth of the highlighted dataset. Coverage is the percentage of the total number of words that are highlighted in one note, and breadth is the average length of each highlighted concept.



We defined 2 operations for mining more complex, higher-granularity phrases from the build dataset: concatenation and anchoring. Concatenation combined adjacent highlighted concepts, potentially separated by stop words, to form a meaningful phrase. Anchoring expanded existing highlighted concepts by attaching surrounding words on the left, right, or both sides. We applied an iterative process in which the application of the concatenation operation was followed by the application of the anchoring operation.

Because CIT is an interface terminology, its concepts should follow the requirements for being considered concepts of a terminology. According to the desiderata of Cimino et al [43], a concept is an embodiment of a particular meaning. Concept orientation means that terms must correspond to at least one meaning ("nonvagueness") and no more than one meaning ("nonambiguity") and that meanings correspond to no more than one term ("nonredundancy") [43,44].

After each application of either concatenation or anchoring, the newly mined phrases, as potential CIT concepts, were manually and automatically reviewed. Phrases that were deemed legitimate during the review, both structurally and semantically, such as "normal ejection fraction," were accepted and added to the CIT. All illegitimate phrases, whether identified automatically or manually, were added to a rejection list. For example, "step down unit for further" was rejected because it is a truncated phrase with an incomplete meaning. After each application of either the concatenation or anchoring operation, we highlighted the build dataset with the updated version of the CIT. This iterative process continued until the increase in coverage became negligible (<2% increase). The results of this phase served as training data for the second phase, where all the concepts in the resulting CIT were considered positive samples (labeled 1), and all the illegitimate phrases in the rejection list were considered negative samples (labeled 0). More detailed descriptions, including examples, are given in the study by Dehkordi et al [27].

In the second phase [28], we first trained a feedforward neural network model using the training data obtained from the first phase. Next, we extracted more phrases from discharge notes and applied predefined rules to filter out structurally illegitimate ones. The remaining phrases were labeled using the neural network model. The accepted phrases were then added to the CIT, forming CIT_{ml}. CIT_{ml} significantly improved the evaluation metrics of highlighted discharge notes. More detailed descriptions, including examples, are given in the study by Dehkordi et al [28]. Figure 1 shows the diagram of constructing CIT_{ml}.

Figure 1. Diagram of constructing CITml. Cardiology interface terminology (CIT) has versions with 2 indices. The first indicates the iteration number, and the second is binary, with 1 following concatenation and 2 following anchoring. CIT_V: updated version of the CIT; EHR: electronic health record; ICIT: initial version of the CIT; ML: machine learning; SNOMED CT: Systematized Nomenclature of Medicine–Clinical Terms.

XSL•FO
RenderX

In another study [45], we created and assessed interface terminologies designed to extract pertinent details from the clinical records of patients with COVID-19, underscoring the generalizability of our methodologies.

Data

We randomly selected 15 discharge notes from the MIMIC-III database from 2 intensive care units related to cardiology patients: the coronary care unit and the cardiac surgery recovery unit. Only the "discharge summary" category was extracted from the discharge notes. We chose 15 notes to enable a careful manual comparison of 2 summaries per note, with and without highlighting, versus the original text.

For each note, we created 2 HTML files: one containing the original discharge note without highlights and the other containing the highlighted discharge note, which is the output of the highlighting technique from our previous work.

As described in the Methods section, our previous work involved curating an interface terminology leveraging machine learning techniques. This terminology encompasses fine-granular, detailed concepts found in discharge notes. In this study, we applied this curated interface terminology to highlight the 15 discharge notes, such that all concepts from the terminology that were present in these notes were highlighted. The highlighted information was marked using span tags with a blue background color with the color code of #ADD8E6. Moreover, we created plain text in HTML format to ensure both inputs have a uniform format to be provided to ChatGPT. The plain text HTML file was created by enclosing the entire text within a tag.

To provide insights into the 15 discharge notes we were summarizing, Table 1 presents the text volume, overall themes, word frequency, and the repetition count of each word within a single document.

Table 1. Text volume, overall themes, and word frequency of 15 discharge notes.

Prompt Engineering

Prompt engineering [19,20,46] is used to craft and refine input prompts to achieve the best possible results from LLMs, such as ChatGPT. However, it is a challenging task because even a minor change can significantly impact performance, leading to different results [39].

XSL•FO
RenderX

We proposed a protocol to incrementally generate effective prompts for both types of summaries from highlighted and unhighlighted notes.

In prompt engineering, we need to use static input and simply refine the prompt to find an appropriate prompt, which leads us to the best possible result. Therefore, we chose a random note that was not used in the evaluations to develop and test the prompt engineering design. We needed 2 prompts because 2 summaries are required for each note, the summary from unhighlighted notes (U-summary) and the summary from highlighted notes (H-summary).

We began the prompt engineering process with the unhighlighted text. To generate summaries, we initially used a simple prompt, "Give me a summary of this note." We evaluated the completeness, correctness, word count, and structure of the generated summaries. If the summaries were too long, erroneous, or incomplete, we adjusted the prompt accordingly. For instance, the first prompt, "Give me a summary of this note," resulted in a summary longer than the original text, so we revised it to "Give me a short summary of this note." In another example, we determined that the output was not structured, so we added "structured" to the prompt, forming the prompt "Give me a short structured summary of this note," so the summary would include headers and bullets for better orientation. This iterative process continued until the results were satisfactory to us after measuring the relevant metrics. Once we finalized the prompt for the unhighlighted text, we adapted it for the highlighted text by adding information about the format of the highlighted information.

Finally, to ensure that the prompts were generalizable to other clinical notes, we applied the final prompts to 3 more randomly selected notes that were not used in the evaluation of this study. Because we obtained satisfactory summaries, after measuring the relevant metrics for both U-summaries and H-summaries, we concluded that the final prompts were suitable for our study.

The final prompts were as follows:

- The prompt for the unhighlighted note was "Give me a short structured summary of this EHR note"
- The prompt for the highlighted note was "Give me a short structured summary of this EHR note, focusing on the highlighted information [whose tags are "style="'background-color: #ADD8E6']"

Generating Summaries

For each of the 15 randomly selected notes, we provided both the prompts to GPT-4o, along with the corresponding HTML files. To measure the evaluation metrics, we extracted all important information items from the original notes. Consequently, we manually inspected both summaries for each such item. For each summary, we counted the number of words, the number of important information items included by comparing them to the list of all important information items, and the number of possible erroneous statements generated by ChatGPT. We also counted the structural elements, misplaced information items, and false information items. We used this information to calculate the evaluation metrics.

Evaluation Metrics

Overview

Assessing the quality of a summary is challenging, and currently, no automatic proxy exists for this task. Therefore, similar to related studies [35], extensive manual effort is required to measure various aspects and compare which summary is more accurate. The evaluation was done by MKHD, a third-year PhD candidate in computer science with 3 years of research experience in processing EHR notes who has published studies [26-28,47,48] on this subject under the supervision of YP, who has more than 30 years of experience in medical informatics research. We used existing metrics and proposed new metrics for evaluating several aspects of the structured summaries generated. Our purpose was to test the following hypothesis: The H-summaries of discharge notes are likely to be more accurate than the U-summaries of those notes.

To assess the plausibility of the hypothesis, we needed to consider several metrics. The following 4 aspects should be evaluated in a summary: completeness, correctness, succinctness, and structural integrity. First, the completeness and correctness of the summary must be assessed. We followed the study by Van Veen et al [35] in using the metrics for completeness and correctness, which, respectively, measured the extent to which important information was covered and how accurate the covered information was. Second, the structure of the summary should be assessed by examining all the headers to identify proper and improper headers as well as bullets, which contribute to secondary structuring. In addition, because correct information might be placed under inappropriate headers within the text, we proposed a metric called the misplaced information to evaluate this aspect of each summary. Furthermore, the succinctness of the summary could be evaluated by the percentage reduction in size compared to the original text, which we referred to as the length reduction metric. This metric, although interesting, was not related to the quality of the summary.

Completeness

The completeness metric measures how well the summary has captured the important information from the original text. It is calculated as the percentage of the important information items included in the generated summary compared to all the important information items in the original text. This metric has also been used in other studies [35,49,50] to evaluate summaries based on the original text. Completeness can be calculated using the following equation:

Examples of important information items in Figure 2A are "known aortic stenosis," "worsening DOE," and "extubated without incident."

XSL•FO
RenderX

Figure 2. (A) An original highlighted note with 128 words, (B) the summary from unhighlighted notes of the note with 91 words and 84% (31/37 items of information) completeness, (C) and the summary from highlighted notes of the same note with 111 words and 100% completeness. The pink highlight in (B) indicates misplaced information. The orange highlight in (B) indicates repetitive information, the first of which is redundant and misplaced. The yellow highlights in (C) indicate information items from the original text that do not appear in (B).

Mrs. is a 75 year old female with known aortic stenosis who has had worsening DOE. A recent echo showed her aortic valve area to be 0.57 cm2, moderate MR and a normal ejection fraction. She underwent a cardiac catheterization which revealed one vessel coronary artery disease. She is now transferred for surgical management Hyperlipidemia HTN Type 2 Diabetes, Ms. neurologically intact and was extubated without incident. On postoperative day two, she was transferred to the step down unit for further care and recovery. She tolerated beta blockade and remained in a normal sinus rhythm. Over several days, she continued to make clinical improvements with diuresis and made steady progress with physical therapy. Medical therapy was optimized and she was eventually discharged to home on postoperative day five

(a)

Patient Information: 75-year-old female with known aortic stenosis.
Condition: Worsening dyspnea on exertion (DOE), aortic valve area measured at 0.57 cm^2, moderate mitral regurgitation (MR), normal ejection fraction, and one vessel coronary artery disease.
Procedures:
- **Cardiac Catheterization:** Revealed one vessel coronary artery disease.
- **Surgical Management:** Patient was transferred for surgical intervention.

Postoperative Course:
- **Extubation**: Performed without incident
- **Day 2:** Transferred to step-down unit
- **Medications:** Tolerated beta blockade; remained in normal sinus rhythm
- **Recovery:** Continued clinical improvements with diuresis and steady progress in physical therapy

Discharge: Discharged home on postoperative day five

(b)

Patient Information:
- **Age/Gender:** 75-year-old female
- **Medical History:** Known aortic stenosis, hyperlipidemia, hypertension (HTN), Type 2 Diabetes

Clinical Presentation:
- **Symptoms:** Worsening dyspnea on exertion (DOE)

Recent Diagnostics:
- **Echocardiogram:**
  - Aortic valve area: 0.57 cm^2
  - Moderate mitral regurgitation (MR)
  - Normal ejection fraction
- **Cardiac Catheterization:**
  - One vessel coronary artery disease

Treatment and Hospital Course:
- **Initial Management:** Transferred for surgical management
- **Postoperative Course:**
  - Neurologically intact and extubated without incident.
  - Transferred to step-down unit on postoperative day two
  - Tolerated beta blockade; remained in normal sinus rhythm
  - Showed clinical improvement with diuresis and made steady progress with physical therapy

Discharge: Discharged home on postoperative day five after optimized medical therapy

(c)

To calculate completeness, we first extracted and listed all information items from the original notes. We examined each summary, identifying how many of these items were present in the summary. We calculated the completeness of each note using equation 1. We calculated the average completeness scores for the 15 H-summaries and the 15 U-summaries separately.

Correctness

A summary is considered correct if it does not contain erroneous information. If it contains at least one instance of inaccurate information, it is then considered incorrect. The correctness of the summaries for a group of notes is the percentage of correct summaries. To evaluate correctness, we manually scanned the

XSL•FO
RenderX

15 U-summaries and the 15 H-summaries to identify all false information items based on the original text. This metric has also been used in similar studies [35,50,51].

Structural Elements Count

Overview

This metric quantifies the total number of structural elements, including the headers and bullet points, used to organize and structure the summaries. The structural elements count (SEC) is calculated by simply counting all the headers and bullet points in each summary.

ChatGPT added headers and subheaders to both the H-summaries and U-summaries based on the given prompt. Upon manual review of the headers, we found that most of them accurately captured the information that followed, and we referred to these as "proper headers." However, some headers were found to be redundant or misleading. Redundant headers are unnecessary and do not provide additional orientation for the reader, while misleading headers do not accurately represent the content that follows. Overall, having more proper headers and subheaders enhances the orientation of the note. In contrast, improper headers, whether redundant or misleading, may confuse the reader. Naturally, our goal was to maximize the number of proper headers to improve reader orientation and minimize the number of improper headers to avoid confusion and redundancy.

Proper Headers

Proper headers are those that correctly and effectively organize the text, accurately capturing the information that follows, leading to a clearer summary. The number of proper headers for each summary is determined by subtracting the improper headers from the total number of headers. For example, Figure 3A shows a portion of a summary where all the information is included in a single block of text, while Figure 3B shows the same portion of the summary with proper headers. In Figure 3B, information regarding status, medications, imaging, and physical examination is correctly categorized under separate sections with appropriate labels, thereby improving the orientation of the note.

Figure 3. (A) A portion of a summary lacking proper headers and (B) the same portion of the summary with proper headers.

Post-Operative Day (POD) 1: Recovering well, Swan-Ganz catheter removed, started on diuretics and beta-blockers per protocol, chest X-ray (CXR) showed bibasilar atelectasis and small right pleural effusion, matched with bibasilar rales and diminished breath sounds on exam **(a)**	**Post-Operative Day (POD) 1:** • **Status:** Recovering well, Swan Ganz catheter removed. • **Medications:** Diuretics and Beta-blockers started. • **Imaging:** Chest X-ray showed bibasilar atelectasis and small right pleural effusion. • **Physical Exam:** Bibasilar rales and diminished breath sounds. **(b)**

Improper Headers

Figure 4 shows an example of improper headers. Figure 4A shows a portion of a U-summary, and Figure 4B is the corresponding H-summary. As shown, Figure 4A contains numerous redundant subtitles, which significantly interfere with the orientation because they may overwhelm and confuse the reader.

Figure 4. (A) A portion of a summary having improper headers and (B) the same portion of the summary without improper headers.

Discharge:
• **Date of Discharge:** POD 4
• **Condition at Discharge:**
  • **Wounds:** Clean, dry, and intact
  • **Vital Signs:** Stable
Additional Note:
• **Follow-Up:**
  • **Cardiologist:** Dr. (Name not provided)
  • **Primary Care Physician:** (Name not provided)
(a)
	Discharge:
	Discharged home on postoperative day four
	• Wounds were clean, dry, and intact
	• All vital signs were stable
	• Follow-up with cardiologist and primary care physician as an outpatient
	(b)

XSL•FO
RenderX

To assess the improper headers metric, we manually reviewed all the summaries to identify the number of additional structural headers in each summary to compare the corresponding summaries with regard to their structural integrity.

Misplaced Information

Sometimes, a summary incorrectly categorizes information under the wrong section, resulting in misplaced information, confusing the reader. For example, in Figure 2B, "known aortic stenosis" is placed under the "patient information" category, whereas it should be under a header titled "medical history." This structure is correctly applied in the highlighted summary shown in Figure 2C. We counted the number of cases of misplaced information in both types of summaries to compare their structural information integrity.

Length Reduction

To evaluate the succinctness of the generated summaries, we used the length reduction metric, which is calculated using equation 2 with a Python (Python Software Foundation) program:

We used the Fisher exact test [52,53] twice; once to compare the completeness metric between the H-summaries and the U-summaries and the second time to compare the number of improper header metrics between the H-summaries and the U-summaries.

Power Analysis

In our methodology, power analysis [54] was conducted using the Fisher exact test to determine the necessary sample size for detecting significant effects, particularly valuable when dealing with categorical data in scenarios of small sample sizes or sparse data. We started our analysis with the 2 metrics that were dominant for the accuracy of the discharge notes.

Completeness Metric Analysis

For assessing the completeness of summaries, we had 2 equal-sized groups, each comprising 15 paired discharge notes. In this evaluation, summaries generated by method 1 (H-summaries) were superior in 13 instances, while method 2 (U-summaries) led in 2 cases. Consequently, the probability of a favorable outcome in group 1 (H-summaries) was 86.7%, and in group 2 (U-summaries), it was 13.3%. Given the consistent performance advantage of H-summaries, a 1-sided Fisher exact test was appropriate, with a significance level (α) set at .025. The resulting power analysis yielded a high power of 0.98, indicating robust confidence in these findings.

Improper Header Metric Analysis

For the improper header metric, power analysis using the Fisher exact test was conducted, taking into account unequal sample sizes. The total count of structural elements (SECs), which include headers and bullet points, was 463 for H-summaries, of which 4 (0.9%) were improper, and 516 for U-summaries, of which 30 (5.8%) were improper This metric necessitated a 2-sided test with an α of .05, achieving a perfect power of 1, suggesting that the test reliably confirmed substantially more improper headers for method 2 when compared to method 1.

Correctness Metric Analysis

Regarding the correctness metric, all H-summaries contained 870 items of information, 2 (0.2%) of which were false, while the U-summaries contained 795 items, 3 (0.38) of which were false. This resulted in probabilities of 0.2% (2/870) for H-summaries and 0.3% (3/795) for U-summaries. Given the substantial total sample size exceeding 1000 items (1665 items of information in total), a Pearson chi-square test [55] for unequal sample sizes was deemed suitable. However, the resulting power was low at 0.06. Further analysis revealed that to achieve a minimum power of 0.8 with a 2-sided test, the required sample sizes would need to increase to 41,146 items for H-summaries and 37,032 items for U-summaries, which is not practical for manual comparison.

Misplaced Information Metric Analysis

Finally, for the misplaced information metric, considering that there are 2 instances of misplaced information in 463 SECs for H-summaries and 8 in 516 SECs for U-summaries, the probabilities are 0.4% (2/463) and 1.6% (8/516), respectively. Conducting a 2-sided Fisher exact test power analysis with α of .05 and considering unequal sample sizes, we found that the resulting power was 0.41, which was low. To achieve a desired power of 0.8, recalculations suggested that sample sizes of 1272 for H-summaries (almost 3 times the current size) and 1145 for U-summaries (almost twice the current size) were needed.

Ethical Considerations

This study used discharge notes from the MIMIC-III dataset [56], a large, freely available database containing deidentified health-related data from >40,000 patients who were admitted to the Beth Israel Deaconess Medical Center between 2001 and 2012. The database includes information, such as vital signs, laboratory test results, procedures, medications, etc. The MIMIC-III database was approved by the institutional review boards [57] of the Beth Israel Deaconess Medical Center and the Massachusetts Institute of Technology. The requirement for individual patient consent was waived, as the dataset is fully deidentified and does not impact clinical care [58]. Before inclusion in MIMIC-III, all data underwent a rigorous deidentification process in compliance with Health Insurance Portability and Accountability Act (HIPAA) [59] standards [58]. Structured data were deidentified by removing all 18 HIPAA-defined protected health information elements, such as names, addresses, phone numbers, and exact dates [58]. To further ensure privacy, dates were randomly shifted while preserving relative intervals, and patients aged >89 years had their ages masked. Free-text fields, including physician notes and diagnostic reports, were processed using an extensively evaluated deidentification system that used dictionary lookups and pattern-matching algorithms to remove protected health information [58]. Because all data are deidentified and do not contain any identifiable patient information, the requirement for informed consent was waived by the overseeing institutional review boards [58].

RenderX

Results

Overview

Figure 2A shows an example of a discharge note (note 15) with 128 words, accompanied by its U-summary (Figure 2B) and H-summary (Figure 2C), containing 91 and 111 words, respectively. We noted that this discharge note was missing, describing the actual surgery that obviously happened during hospitalization of the patient. We assumed that this omission was based on the fact that the surgery was described in the surgical note section of the discharge note. We chose this note because it enabled us to demonstrate several efficiencies in 1 short note. As shown in Figure 2C, 6 important information items from the original text, marked by yellow color, appeared in the H-summary but did not appear in the U-summary. In contrast, H-summary did not miss any items. Consequently, the calculated completeness for the H-summary was 100% (35/35), while the completeness of the U-summary was 84% (31/37 items of information), as shown also for note 15 in Table 2.

Table 2. Values of 2 metrics for 15 notes.

Notes	Word count of the original text[a]	Length reduction		Completeness	
		H- summaries[b] (%)	U-summaries[c] (%)	H-summaries, n/N (%)	U- summaries, n/N (%)
1	164	2	–10	35/35 (100)	29/35 (83)

[a]Mean 320, SD 139 words.

[b]H-summary: summary from highlighted notes (length reduction: mean 22, SD 15; completeness: mean 96, SD 4).

[c]U-summary: summary from unhighlighted notes (length reduction: mean 23, SD 15; completeness: mean 88, SD 6).

Completeness

As shown in Table 2, on average, the completeness of the U-summaries was 88% (SD 6%), while the completeness of the H-summaries was 96% (SD 4%), which was 8% higher. All percentages in Table 2 are rounded to the nearest whole number. It is worth mentioning that for 13 notes, the completeness of the H-summary was higher than that of the U-summary, and for 2 notes, the completeness was equal. Using the Fisher exact test [52,53], we compared the number of notes with higher completeness in the H-summary group (13 notes) versus the number of notes with higher or equal completeness in the U-summary group (2 notes). The Fisher exact test yielded P=.01, indicating a statistically significant difference.

Length Reduction

As shown in Table 2, the average word count of the original notes was 320 words, and the average length reduction of the H-summaries and U-summaries was 22% (SD 15%) and 23% (SD 15%) words, respectively. A negative number for length reduction in Table 2 indicates that the summary generated had more words than the original text.

Correctness

In our analysis, we identified 3 instances of false information in U-summaries. In contrast, H-summaries contained only 2 false information items. However, this did not provide a statistically significant result, implying improvement. As an example of erroneous information, the original note contained the phrase “consistent either with aspiration pneumonia or increased apical interstitial edema,” whereas the U-summary incorrectly contained “consistent either with aspiration pneumonia and increased apical interstitial edema.” Replacing “or” with “and” changed the meaning of the phrase. Another example was a U-summary that mistakenly referred to Troponin T, a protein, as an enzyme.

XSL•FO
RenderX

Structural Evaluation

The total number of SECs, which were either headers or bullet points, for the U-summaries was 516, while for H-summaries, it was 463. In terms of improper headers, there were 30 instances in the U-summaries compared to only 4 in the H-summaries. Table 3 presents the distribution of improper headers and misplaced information for the U-summaries and H-summaries for each of the 15 notes. For 11 (73%) of the notes, according to Table 3, the number of improper headers in the U-summaries was larger than the number for the H-summaries. For the other 4 (27%) notes, the numbers were equal. Hence, the number of improper headers in U-summaries was larger than those for H-summaries with statistical significance according to the Fisher exact test [52,53]. We compared the number of notes with a higher number of improper headers in the U-summary group (11 notes) and the number of notes with a higher number of improper headers in the H-summary group (4 notes). The Fisher exact test yielded P=.03, indicating a statistically significant result.

Table 3. Distribution of improper headers and misplaced information for the summaries from unhighlighted notes (U-summaries) and summaries from highlighted notes (H-summaries).

Notes	Improper headers		Misplaced information	
	U-summaries (n=30), n (%)	H-summaries, (n=4), n (%)	U-summaries, (n=8), n (%)	H-summaries, (n=2), n (%)
1	1 (3)	0 (0)	0 (0)	1 (50)
2	1 (3)	0 (0)	1 (12)	0 (0)
3	1 (3)	0 (0)	1 (12)	0 (0)
4	5 (17)	0 (0)	0 (0)	0 (0)
5	4 (13)	0 (0)	0 (0)	0 (0)
6	1 (3)	1 (25)	0 (0)	0 (0)
7	1 (3)	0 (0)	1 (12)	1 (50)
8	1 (3)	0 (0)	1 (12)	0 (0)
9	0 (0)	0 (0)	0 (0)	0 (0)
10	1 (3)	0 (0)	0 (0)	0 (0)
11	2 (7)	1 (25)	0 (0)	0 (0)
12	2 (7)	2 (50)	0 (0)	0 (0)
13	6 (20)	0 (0)	0 (0)	0 (0)
14	3 (10)	0 (0)	2 (25)	0 (0)
15	1 (3)	0 (0)	2 (25)	0 (0)

In other words, 5.8% (30/516) of the SECs in U-summaries were improper headers, whereas this percentage was only 0.1% (4/463) in the H-summaries. On the other hand, the number of proper SECs, after deducting the improper headers, was 94.2% (486/516) for the U-summaries and 99.1% (459/463) for the H-summaries. Hence, the structure of U-summaries was slightly more detailed than that of the H-summaries. However, the high percentage of improper headers rendered this advantage irrelevant because the structure was meaningfully less reliable. Moreover, we identified 8 instances of misplaced information in the U-summaries and only 2 in the H-summaries.

Discussion

Principal Findings

In this study, we evaluated summaries generated by LLMs from 2 versions of discharge notes, H-summaries and U-summaries, to test the hypothesis that highlighting discharge notes improves the accuracy of the generated summaries. Our results show that feeding LLMs with H-summaries, combined with prompt engineering, results in higher-quality summaries in terms of correctness, completeness, and structural integrity compared to U-summaries.

This study serves as the first step toward meeting the NIH challenge, which is facilitating the conversion of text in discharge notes into language that is comprehensible to a patient with a grade 6 reading level [6,60]. In a previous work [26], we conducted a study to simplify discharge notes using 2 simplification approaches.

In the first approach, we first summarized the discharge notes and then, in a second step, converted them into language understandable by a grade 6 reader. In the second approach, we directly generated, in a single step, a simplified summary understandable by a grade 6 reader from the discharge note. Our results showed that the first approach, simplifying notes in 2 steps, led to higher-quality and more understandable notes for grade 6 readers. Our interpretation is that, given discharge notes are inherently dense and complex, breaking the task into 2 steps reduces the cognitive load on the LLM, allowing it to generate more accurate and comprehensible results. Hence, cascading the findings of the previous study [26] to the findings of this paper provides a pipeline responding to the NIH challenge of summarizing discharge notes into a language that

XSL•FO
RenderX

is comprehensible to a patient with a grade 6 reading level with high accuracy. Because the findings of both studies satisfy statistical significance, their combined impact is reliable, although this study is based on a sample of only 15 discharge notes.

Usually, summaries are shorter than the original text and thus enable the reader to review the content of a document faster. LLMs can actually generate summaries of various lengths according to the prompt provided to them. Because our final goal is the simplification of discharge notes, we are not necessarily interested in short summaries for the sake of brevity but in succinct summaries that capture all detailed information of a note in a simpler language.

When evaluating the summary of a discharge note, if the summary lacks key information from the original note (ie, low completeness), it cannot be considered accurate. Similarly, if the summary contains erroneous information (lacking correctness), its accuracy is also compromised. Furthermore, if relevant information is placed under incorrect categories (referred to as "misplaced information"), the summary's accuracy is further affected. Therefore, in this paper, when we state that H-summaries have higher accuracy than U-summaries, we mean that H-summaries exhibit greater completeness, correctness, and structural integrity compared to U-summaries.

The scientific contribution of this research is the improvement in the accuracy of LLM summaries of discharge notes by feeding the LLMs with discharge notes in which the detailed information is highlighted. Automatic highlighting of discharge notes is provided by techniques from our previous research [28]. A sample of a discharge note highlighted automatically by this technique is shown in Figure 2A. Our hypothesis was that providing such highlighting would better direct the LLMs to capture the detailed information of the note and would better structure its summary. Our study has proven the plausibility of this hypothesis by the evaluation of several metrics.

Although highlighting is used in this paper, it is not the primary focus of our study. However, we wish to clarify an observation regarding the highlighting in Figure 2A. This example is rich in information but with some stop words not highlighted. While there are other notes in our sample where several words and phrases are not highlighted, we note that "discharge notes" from MIMIC-III EHRs have contributed to this richness of information as they summarize the hospital course of the patient. Our highlighting method is based on mining phrases from clinical notes and determining which ones should be incorporated into the interface terminology. Only concepts present in the interface terminology are subsequently highlighted within the clinical note. Indeed, the density of the highlighting depends on the type of clinical notes and will be higher in discharge notes due to the richness of information they contain. Full details can be found in the studies by Dehkordi et al [27,28].

Out of the 4 metrics we used to compare the H-summaries to the U-summaries, results from 2 metrics have shown statistical significance for better quality of the H-summaries. For the other 2 metrics, instances of erroneous information were low, but still, the results are better for H-summaries. The reason for having fewer improper headers in H-summaries compared to U-summaries may be attributed to the fact that by identifying the detailed information in the text, ChatGPT achieves better orientation in the note, allowing it to focus on the essential content and structure it more effectively. Despite the higher completeness in H-summaries compared to U-summaries, the inclusion of redundant information in U-summaries resulted in a similar length reduction for both H-summaries and U-summaries. For instance, the orange color in Figure 2B indicates that there is repetitive information in the U-summary, such as the phrase "one vessel coronary artery disease," which appears twice.

We define SEC as the total number of headers and bullets. In general, a larger number of proper headers and bullets is desirable, as such categorization of information enhances the clarity of the notes, making them more understandable for the reader. Because this study represents the first step toward simplifying the texts, having information categorized in different sections to increase clarity is preferable, unless the headers are improper. Our study demonstrated that the ratio of improper headers is substantially lower in H-summaries compared to U-summaries.

Traditionally, for summarization, evaluation metrics such as recall-oriented understudy for gisting evaluation [61] are used. We have not used these metrics since (1) our hypothesis is comparing highlighted versus nonhighlighted notes with a focus on completeness, correctness, and structural integrity; and (2) there is a lack of human-generated summaries used by these metrics for computing the respective scores. Similarly, simplification of text is measured using metrics, such as the Flesch-Kincaid Grade Level [62], Simple Measure of Gobbledygook [63], and Gunning-Fog Index [64]. Because this study's focus was not on the readability of the notes, these metrics were not applicable.

Limitations

In our study, we considered only the discharge note part of the clinical notes, which are the most relevant parts of the clinical notes for the patients. Due to their summarizing nature, discharge notes have aspects from all other parts of clinical notes. Thus, we have chosen to concentrate only on the discharge note, while we expect a similar result for a study that would summarize the complete clinical note.

To minimize the amount of tedious manual review required for the evaluation of the various metrics, we have chosen a study of 15 notes, and this number was sufficient to yield the statistical significance for 2 dominant metrics of the 4 metrics for accuracy. For the other 2 metrics, the number of erroneous information items and misplaced information cases was infrequent, and a much larger sample would be needed to display statistical significance. Altogether, the results have proven our hypothesis that providing highlighted notes as input for ChatGPT will likely yield more accurate summaries.

Moreover, the reliance on extensive manual review for evaluating the summaries may introduce subjectivity into the assessment process. Future studies could benefit from developing more automated methods to assess summary quality to reduce potential bias and labor intensity. In addition, although

XSL•FO
RenderX

highlighting is used to enhance the input for LLMs, the technique itself may have limitations, such as the potential for overhighlighting or missing critical information not recognized by the underlying algorithm. This could affect the quality of the input and, consequently, the accuracy of the summaries produced. However, we are continuously working in parallel on different automated methods to improve the highlighting techniques and algorithms [47,48]. Finally, this study's results are based on the state of a specific LLM at a point in time. Continuous updates to LLMs could alter their performance characteristics, necessitating ongoing validation of the findings.

Future Work

In future work, we will use the LLM H-summaries as a starting point for further simplification of the notes to meet NIH's readability target for patients with grade 6 reading skills using various techniques. Some patients may be interested in just the big picture without many details, while others, based on their health literacy, may require detailed information. As mentioned previously, in the future, we intend to explore the capabilities of LLMs alongside the vast wealth of curated knowledge embedded in biomedical ontologies and terminologies in catering to the varied requirements of patient populations by offering summaries and simplifications of clinical notes tailored to individual needs and comprehension levels. While this study demonstrated statistical significance in the completeness and improper headers metrics, the limited sample size of 15 discharge notes was insufficient for the other 2 metrics. In future studies, we plan to use a larger sample to test statistical significance for the correctness and misplaced information metrics as well.

Ethical Concerns

The integration of LLMs into clinical data summarization introduces several ethical considerations that warrant careful attention. A primary concern is the potential for these models to generate inaccurate or fabricated information, commonly referred to as hallucinations [65], which could adversely affect patient care.

Bias within training data presents another ethical challenge. If LLMs are trained on unrepresentative datasets, they may perpetuate existing health disparities by providing less accurate summaries for certain populations [66]. Addressing these biases is critical to ensure equitable health care delivery.

Moreover, the lack of transparency in how LLMs generate outputs [67] can lead to challenges in clinical settings. Clinicians may find it difficult to trust or validate AI-generated summaries without a clear understanding of the underlying processes, potentially hindering the integration of these tools into health care practice.

To mitigate these ethical concerns, it is imperative to implement robust validation processes, ensure compliance with privacy regulations, actively address biases in training data, and maintain transparency in AI operations.

Conclusions

In this paper, we propose the use of highlighted discharge notes, emphasizing detailed information, to enhance the completeness and correctness of the summaries generated by LLMs. We have also developed and applied prompt engineering techniques to improve the structural integrity of these summaries, effectively addressing issues related to prompt sensitivity and reliability. Our study includes empirical validation with a random sample of 15 highlighted discharge notes from the MIMIC-III database, demonstrating that the input with the highlighted notes leads to more accurate LLM summaries of clinical notes. The final goal is to simplify discharge notes to be readable by a patient with grade 6 reading skills. To achieve this goal, we will use the summaries obtained in this research as input for the future simplification process.

Abstract

Background: Extracting genetic phenotype mentions from clinical reports and normalizing them to standardized concepts within the human phenotype ontology are essential for consistent interpretation and representation of genetic conditions. This is particularly important in fields such as dysmorphology and plays a key role in advancing personalized health care. However, modern clinical named entity recognition methods face challenges in accurately identifying discontinuous mentions (ie, entity spans that are interrupted by unrelated words), which can be found in these clinical reports.

Objective: This study aims to develop a system that can accurately extract and normalize genetic phenotypes, specifically from physical examination reports related to dysmorphology assessment. These mentions appear in both continuous and discontinuous lexical forms, with a focus on addressing challenging discontinuous entity spans.

Methods: We introduce DiscHPO, a 2-phase pipeline consisting of a sequence-to-sequence named entity recognition model for span extraction, and an entity normalizer that uses a sentence transformer biencoder for candidate generation and a cross-encoder reranker for selecting the best candidate as the normalized concept. This system was tested as part of our participation in Track 3 of the BioCreative VIII shared task.

Results: For overall performance on the test set, the top-performing model for entity normalization achieved an F_1-score of 0.723, while the best span extraction model reached an F_1-score of 0.665. Both scores surpassed those of 2 baseline models using the same dataset, indicating superior efficacy in handling both continuous and discontinuous spans. On the validation set, we were able to demonstrate our system's ability to recognize these mentions, with the model achieving an F_1-score of 0.631 for exact match on discontinuous spans only.

Conclusions: The findings suggest that exact extraction of entity spans may not always be necessary for successful normalization. Partial mention matches can be sufficient as long as they capture the essential concept information, supporting the system's utility in clinical downstream tasks.

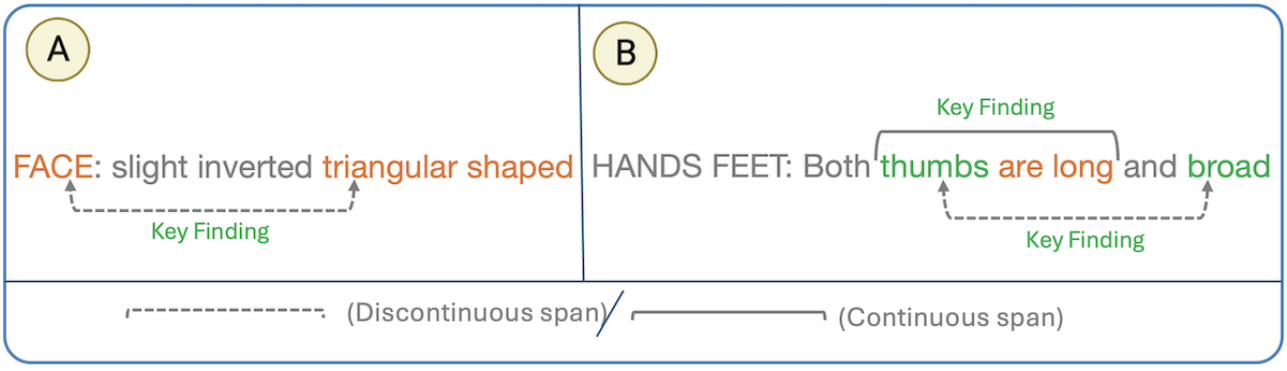
Introduction

Overview

Information extraction (IE) from unstructured text is a crucial task in natural language processing (NLP) and plays a key role in structuring text efficiently [1,2]. The recent advances in generative large language models (LLMs) have proven highly beneficial across various IE tasks in several domains [3]. Within the health care sector, both researchers and clinicians are actively seeking to extract valuable insights from unstructured clinical documents [4]. Leveraging LLMs for addressing IE tasks in this specific domain promises to expedite and enhance clinical operations, thereby improving clinical decision-making and documentation quality, which results in better patient care [5,6].



Named entity recognition and named entity normalization (NER and NEN) serve as crucial IE tasks within the medical domain [7]. NER focuses on accurately identifying entities of interest, such as findings, diseases, medications, and procedures. Subsequently, NEN performs the standardization of these entities using referencing standards such as concept ontology or knowledge bases. These tasks play a fundamental role in various health care applications, facilitating interoperability between different medical systems.

State-of-the-art approaches often frame the NER task as a sequence labeling problem, which is well-suited for continuous named entities (NEs). However, NE words may sometimes appear nonconsecutively, forming what is known as Discontinuous Named Entities (DiscNEs) [8]. These entities may also be referred to as "disjoint spans" or "disjoint mentions." Conventional sequence labeling schemes are insufficient to handle DiscNEs, and specialized schemes, although tailored, often lack generalizability [9]. Therefore, this study aims to explore the effectiveness of generative LLM-based models as a unified solution for identifying both continuous and discontinuous NEs within a newly introduced benchmark dataset, as part of the BioCreative VIII shared task [10,11].

Until recently, the ongoing series of BioCreative challenges contributed significantly to advancing the clinical NLP community by providing benchmark datasets to evaluate the effectiveness of IE models. The eighth edition of the BioCreative challenge, organized into 4 tracks, includes our participation in the third track. This track focuses on the extraction and normalization of genetic phenotypes in clinical reports [10]. As part of this track, participants were provided with patient physical examination reports comprising both normal and key findings. Normal findings (NORMFs) typically denote the absence of phenotypic abnormalities in the observation (eg, "intact palate"), while key findings (KEYFs) indicate the presence of phenotypic abnormalities (eg, "high-arched palate"). The tasks involve extracting KEYFs while excluding NORMFs, as they are not represented in the human phenotype ontology (HPO), and then mapping these KEYFs to their corresponding HPO identifiers [12].

A significant challenge revolves around the presence of DiscNEs in the text. Approximately 14% of mentions in the training and validation sets can be considered as discontinuous (465 DiscNEs out of 3247 NEs). We observed 2 forms of DiscNEs in the dataset: either one entity is interrupted by nonentity tokens (nonoverlapping disjoint mentions), or multiple entities share a common head, with one or more entities interrupting the other (overlapping disjoint spans). Figure 1 demonstrates examples of the 2 forms of discontinuity found in the clinical entries, where example (A) presents a nonoverlapping case. The gold standard annotations mark the span "FACE triangular shaped," as a KEYF. As we can see, the nonentity tokens, "slightly inverted," interrupt the original span. This example is considered to be nonoverlapping as none of its tokens are shared with another mention. As for Example B, an instance of overlapping disjoint spans is demonstrated. Here, the token "thumbs" acts as a shared head between the 2 KEYFs, "thumbs are long" and "thumbs are broad." The task organizers encouraged addressing this challenge, urging solutions that go beyond traditional sequence labeling methods, effective only in identifying entity spans with consecutive tokens, and falling short in extracting DiscNEs [10].

Figure 1. Examples of discontinuous named entities: (A) nonoverlapping and (B) overlapping disjoint mentions.

To accomplish this task, we introduce DiscHPO, a 2-component pipeline. The first component involves a sequence-to-sequence approach for detecting continuous and DiscNE spans, while the second component focuses on normalizing the extracted spans to their associated HPO identifiers using the Sentence Transformers framework. The DiscHPO pipeline can enhance downstream tasks such as diagnostic decision support. For instance, integrating our system into electronic health record (EHR) platforms could enable real-time identification of phenotypic patterns relevant to rare diseases, potentially accelerating diagnosis. Furthermore, normalization to standardized vocabularies like HPO facilitates interoperability

XSL•FO
RenderX

and large-scale phenotypic analyses, ultimately supporting more personalized and data-driven health care delivery.

The HPO

The HPO was introduced in 2008 as a comprehensive logical framework intended to describe and analyze phenotypic abnormalities in patients with a particular disease [12]. It offers a standardized representation of phenotype concepts. The use of HPO not only enhances clinical care and education but also serves as a valuable resource for EHR analysis and structuring, facilitating accurate diagnosis of diseases. Thus, the automatic extraction of a thorough and precise set of HPO terms directly from the EHR data is highly desirable to reduce the burden of manual annotation and save time and resources [13].

In this study, we use a version of the HPO dictionary provided by the shared task organizers. This version encompasses around 17,000 terms, which include both the preferred term for the phenotypic abnormality and the corresponding HPO identifier. In addition to this, the organizers provided a supplementary list of 5000 terms that were not observed in the corpus, which has been helpful in refining the original list of terms.

Prior Work

We first explore the existing work in biomedical NER and normalization. Conventionally, NER is followed by an NEN step (2-stage pipeline), where identified mentions are mapped to standardized concepts within controlled vocabularies. For instance, Peng et al [14] introduced a standalone normalizer that receives input mentions from an external NER component. Their method uses an interaction-based synonym marginalization technique that effectively captures the relationships between a given NE and its candidate matches. Similarly, Ji et al [15] proposed a BERT (bidirectional encoder representation from transformers)-based ranking method for biomedical entity normalization, showing the power of contextualized embeddings in disambiguating similar terms.

Beyond these 2-stage methods, several studies have explored joint or end-to-end frameworks that integrate NER and normalization tasks to reduce error propagation and exploit shared contextual representations. Xiong et al [16] proposed a joint model that treats NER as a machine reading comprehension task and NEN as a multilabel sequence tagging problem. Zhao et al [17] further advanced this line of work with a multitask learning framework that jointly models both NER and normalization, incorporating explicit feedback strategies to enhance performance.

We now review studies dedicated to NER and normalization to the HPO. Increasing attention has been given to the automated identification of HPO concepts from clinical narratives. For example, Son et al [18] introduced EHR-Phenolyzer to extract phenotypes from EHR narratives. Their approach involves the use of 2 clinical IE tools, namely MedLEE [19] and MetaMap [20]. They found that both systems performed comparably to expert annotation. Since the earlier approach relies on general NLP tools, a more tailored phenotypes extraction approach, ClinPhen is introduced by Deisseroth et al [21], which uses the natural language toolkit and a hash table for the extraction and normalization. ClinPhen showed superior performance compared with general IE tools: MetaMap and cTAKES [22]. A comparative evaluation study conducted by Liu et al [23] included comparing the following HPO extraction models: MetaMapLite, MedLEE, ClinPhen, cTAKES, as well as 4 ensemble techniques. Their findings show that ensemble methods consistently surpass individual models in recognizing both generic and patient-specific phenotypic concepts.

Other approaches have developed interactive platforms for extracting HPO terms. For instance, Doc2HPO [24] provides a web interface for real-time extraction and normalization of HPO terms. Another platform, Monarch Initiative [25], serves as a comprehensive platform for integrating phenotypes and genotypes data and analytics. However, these dictionary-based approaches (MetaMapLite, cTAKES, ClinPhen, and Doc2HPO) use dictionary matching as their primary method, depending exclusively on exact matches with dictionary terms. This approach proves challenging in capturing semantic and syntactic variations within terms [26].

Alternatively, machine-learning approaches have shown efficacy in understanding textual semantics. For instance, the PhenoTagger system [26] is a hybrid approach merging dictionary-based matching and machine-learning classification to identify HPO concepts. Inspired by PhenoTagger, Feng et al [27] introduced PhenoBERT. While both methods use BERT [28] as their core model, PhenoBERT distinguishes itself by incorporating 2-level hierarchical CNNs. This integration serves to narrow down the BERT search space, which results in a reduction in computational time.

For identifying overlapping mentions, PhenoTagger has incorporated several heuristic rules to handle nested mentions and those sharing common tokens. Additionally, PhenoBERT has introduced a phrase recovery step to handle simple coordination ellipses. However, both models still encounter difficulties in resolving overlapping DiscNEs with gaps longer than one token, as in the example in Figure 1B. Moreover, they struggle to recognize nonoverlapping DiscNEs (Figure 1A).

Goal of This Study

Although sequence labeling and deep learning methods have been widely used to recognize both continuous and discontinuous NEs, our study aims to incorporate a generative model as the NER component within our DiscHPO pipeline. We explore the capabilities of these models in detecting both continuous and discontinuous genetic phenotype mentions in physical examination reports. Our goal is to deliver an integrated solution that recognizes and normalizes these mentions within a consistent framework.

The main contributions of our work are as follows:

1. An investigation into the effectiveness of open-source generative pretrained language models (PLMs) for extracting both continuous and discontinuous spans.
2. The integration of a Sentence-Transformers model with the NER component to effectively normalize the extracted mentions to the HPO.

Methods

Dataset

The BioCreative VIII shared task dataset [11] comprises deidentified reports documenting clinical observations from dysmorphology physical examinations. It consists of 3136 observations, distributed among a training set (1716 observations), a validation set (n=454), and a test set (966 + 2427 decoy observations). Each observation may encompass one or more entity spans categorized as either key or NORMF entities.

Table 1 displays a snippet featuring 2 entries from the provided gold standard annotations. The dataset includes 5 columns: an observation ID assigning a unique identifier to each observation, raw observation text, an HPO column containing an HPO ontology identifier associated with the mention, a Polarity column indicating "X" for NORMFs and "NA" for KEYFs, and a Spans column encompassing the character offsets of the entity mention.

Table 1. Example snippet of the gold standard annotations from the training set.

Observation ID	Text	HPO[a]	Polarity	Spans
F8D319161DE176F2	FACE: No facial abnormalities noted within the limitations of examination.	HP:0000271	X[b]	6-35
DC00B8A9EDA2C78	HANDS FEET: Both thumbs are long and broad	HP:0011304	N/A[c]	17-27 and 37-42
DC00B8A9EDA2C78	HANDS FEET: Both thumbs are long and broad	HP:0032524	N/A	17-32

[a]HPO: human phenotype ontology.

[b]Normal findings

[c]N/A: not applicable.

As shown in Table 1, discontinuous spans are presented with 2 offset ranges separated by a comma. In the case of overlapping spans, each span is represented in a separate row with its assigned HPO identifier, ensuring the preservation of all HPOs associated with the observation. Furthermore, there are 2 levels of segmentation, where disjoint mentions can be divided into 2 or 3 constituent parts. Table 2 provides a numerical analysis of the corpus.

Table 2. Analysis of the BioCreative VIII task 3 corpus, including the training and validation sets.

Analysis	Training set	Validation set
Number sentences, n	1716	454
Number entities, n	2562	685
Number disjoint mentions, n	369	96
Percent of disjoint mentions, %	14.4	14
Disjoint (2-constituent parts), n	358	91
Disjoint (3-constituent parts), n	11	5
Normal findings, n	329	78
Key findings, n	2233	607

During the competition evaluation period, the test set was provided, comprising solely observation IDs and raw text entries. It consists of 966 deidentified observations, along with 2427 decoy observations. However, the gold-standard annotations were not provided to participants to ensure a level playing field.

In addition to this dataset, we aimed to assess the generalizability of our model under different conditions using the GCS+ dataset [29], a widely adopted benchmark that has been used by several models for HPO term extraction and normalization. The dataset contains annotated HPO terms along with their corresponding HPO IDs. Its structure often includes nested named entities, but DiscNEs are not explicitly annotated, despite their presence in the text. We followed the data splits provided by Yang et al [30] and further fine-tuned our DiscHPO checkpoint on the GCS+ dataset.

Data Preprocessing

We approach the NER task by framing it as a sequence-to-sequence NER problem [31]. In this setup, the system takes a sequence of tokens as input and generates a target sequence containing recognized spans categorized as either NORMF, KEYF, or not applicable entities. Unlike sequence labeling, where models assign tags to individual tokens, sequence-to-sequence models learn to produce a new sequence of tokens that transforms the input sequence. To align with this approach, preprocessing of NER system inputs and targets is necessary before model training. Both datasets underwent the same preprocessing steps.

First, we convert the numerical offsets of entity spans into word spans. Each span is then prefixed with its corresponding entity type. Subsequently, all entity spans related to a single

XSL•FO
RenderX

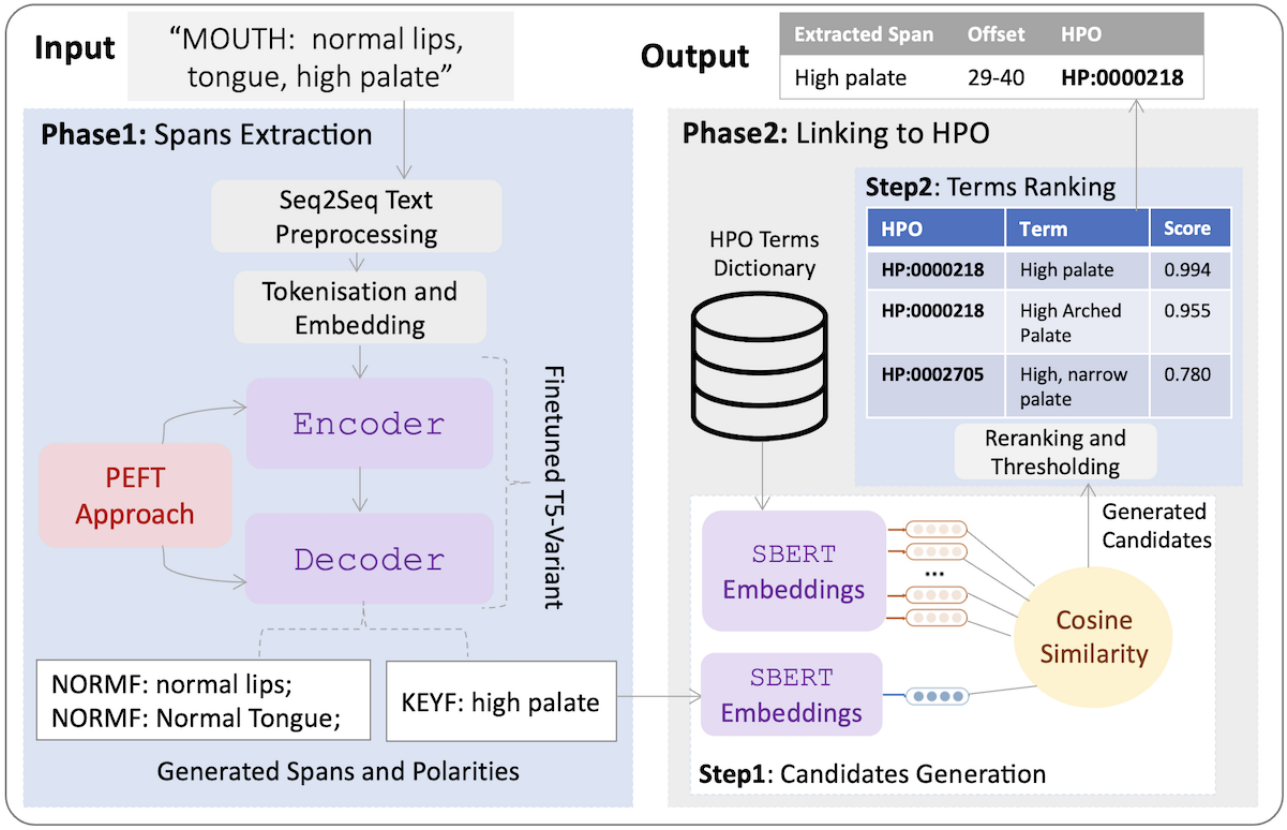
observation are consolidated into one sequence, separated by a semicolon. Both the training and validation sets undergo the same preprocessing steps. An example of a preprocessed target is illustrated in Table 3. By using this scheme, DiscNEs can be represented more effectively since no special labels are used to distinguish the disjoint entities. After preprocessing the BioCreative dataset, we reviewed the dataset and identified minor inconsistencies in the textual spans, primarily caused by inaccurate numerical offsets. We manually corrected these issues and provided the complete list of revised entity spans in Table S1 in Multimedia Appendix 1.

Table 3. Preprocessed named entity recognition inputs.

Input	Target
EYES: Sparse eyebrow hair. Normal lids and lashes.	KEYF[a]: Sparse eyebrow; NORMF[b]: Normal lashes; NORMF: Normal lids
NECK: Excess nuchal skin noted with no webbing, cysts.	KEYF: Excess nuchal skin; NORMF: NECK: no webbing; NORMF: NECK: no cysts

[a]KEYF: key finding.

[b]NORMF: normal finding.



For the training phase, the model input consists of the context, including the input sentence, followed by the corresponding predictions, which include all textual named entities and their types. During inference, the model is given just the sentence and is tasked with generating the NE predictions.

After the model predicts the spans, a postprocessing step is performed to convert the spans back into numerical offsets by locating the offset positions of a given span within the observation text using regular expressions. This step is essential to ensure compatibility with the format specified in the evaluation script provided by the task organizers when calculating the validation set prediction results.

DiscHPO Pipeline

We designed DiscHPO as a pipeline of 2 components: a sequence-to-sequence NER model that can recognize both continuous and discontinuous mentions at the sentence level, and an entity normalizer underpinned by a sentence transformer bidirectional encoder (biencoder) for candidate generation and a cross-encoder reranker. The DiscHPO pipeline is illustrated in Figure 2.

Figure 2. DiscHPO pipeline architecture. HPO: human phenotype ontology.

The NER Model

We implemented a sentence-level NER system by fine-tuning a pretrained sequence-to-sequence encoder-decoder language model based on the transformers architecture [32]. Our approach involved leveraging different versions of the text-to-text transfer transformer (T5) [33]. The T5 model adopts a unified approach to transfer learning, transforming various text processing tasks (eg, question answering, language modeling, or span extraction) into a "text-to-text" problem. The model underwent pretraining

XSL•FO
RenderX

through a consecutive span denoising objective and uses the standard maximum likelihood training method, incorporating teacher forcing. The generative capability of T5 enables seamless fine-tuning for the extraction of the span and prediction of their target class simultaneously. Consequently, the NER component will be capable of distinguishing both types of mentions. (ie, normal and KEYFs).

Each observation and its corresponding spans undergo tokenization using the T5 tokenizer, which is built upon SentencePiece [34]. The tokenizer breaks down the sequences into tokens, translates these tokens into IDs, pads them to achieve the maximum sequence length, and appends the end-of-sequence token (</s>). As we are not engaging in multitask training, there is no need for a task prefix at the beginning of the text (eg, “NER:”).

For the model fine-tuning, we examined the following T5 architectures:

- The original T5 [33], which is based on the transformers’ encoder-decoder architecture and pretrained with the Colossal Clean Crawled Corpus.
- FLAN-T5 [35], or (Fine-tuned LAnguage Net-T5), which is an improved version of T5, instruction-finetuned across a variety of tasks, including NER.

We also considered experimenting with a domain-specific (ie, biomedical) variant of T5, which is the following:

- SciFive [36], which differs by pre-training a T5-architecture model on biomedical articles from the PMC and abstracts from PubMed.

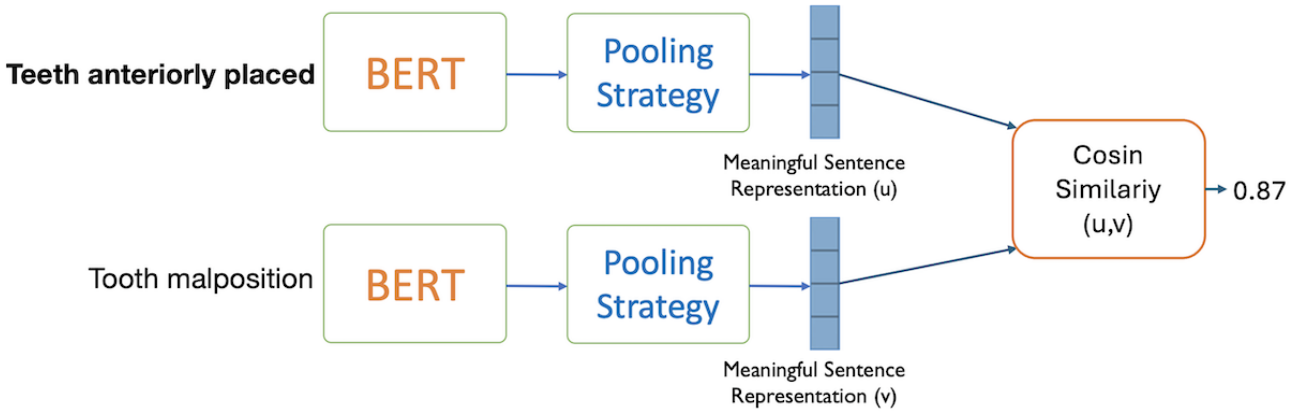
Table S2 in Multimedia Appendix 1 outlines the optimal hyperparameter settings used in all T5 architectures throughout our NER experiments.

To optimize the NER model, a parameter-efficient fine-tuning method such as low-rank adaptation (LoRA) [37] is used, eliminating the hardware costs associated with fine-tuning LLMs by using a small portion of the pretrained parameters (around 1.1%). To do this, LoRA reparametrize (or decomposes) the required weight updates (ΔW) based on the original pretrained weight matrix $W_0 \in \ d \times k$, where d and k are the dimensions of the weight matrix. The low-ranked decomposed matrix is the result of the multiplication of LoRa matrices A and B:

$$\Delta W = BA \quad (1)$$

where $B \in \ d \times r$, $A \in \ r \times k$, and the rank $r \ll \min(d,k)$.

Hence, the sizes of the A and B matrices are adjusted using LoRa rank (r). However, for the initial scaling of the update weights, 2 hyperparameters of LoRa: the rank (r) and a constant alpha (α) are used as in the equation:



$$\Delta W = \alpha / r \quad (2)$$

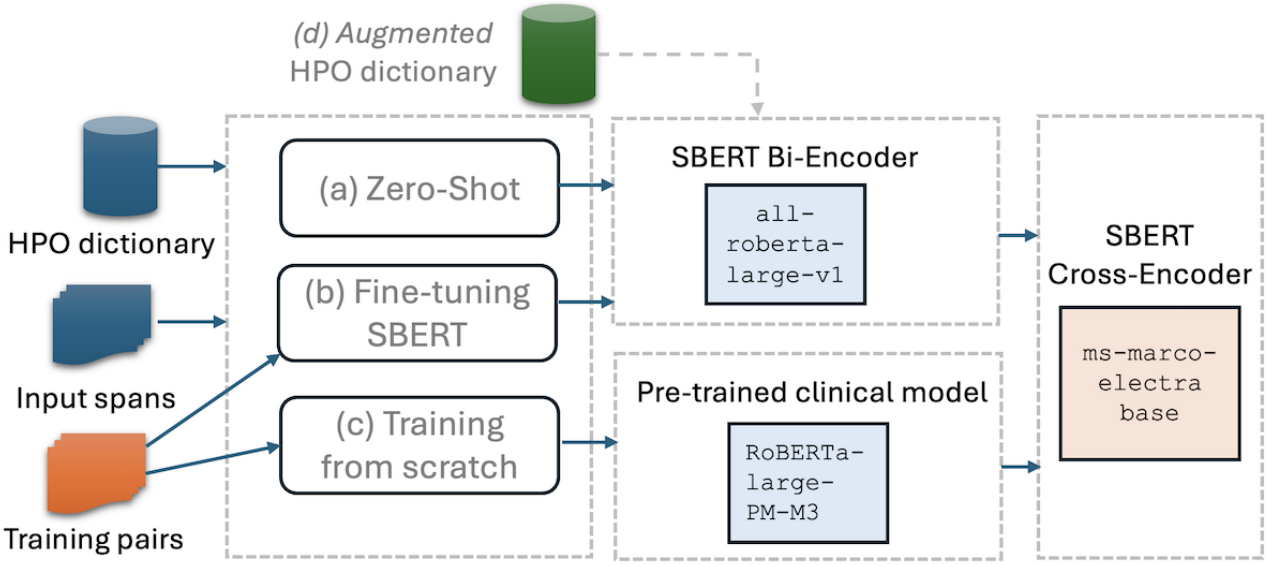
We used the Python package loralib, to implement LoRa. Specifically, we chose the extra-large version of Flan-T5 (Flan-T5-XL). After exploring various combinations of r and α values, we achieved optimal results when setting r to 16, and α set to values of both 512 and 1024.

Normalization to HPO

The second task of this challenge involves normalizing the identified KEYFs to their HPO identifiers. We use Sentence-transformers (or SBERT [sentence bidirectional encoder representation from transformers]), a Python framework, that excels in embedding sentences, text, and images, demonstrating state-of-the-art performance in sentence-pair regression tasks [38,39]. Figure 3 illustrates the main design aspects of SBERT. Specifically, it is a modified version of BERT that uses Siamese networks to generate sentence embeddings with semantic similarity. These embeddings can be compared efficiently using cosine similarity, resulting in a significant reduction in computational overhead [40]. A crucial aspect of SBERT’s design involves the pooling operation, used to aggregate the output embeddings of BERT into a fixed-sized sentence embedding. Commonly used pooling strategies include (1) using the (CLS) token embedding of BERT, (2) mean pooling (averaging all token embeddings), and (3) max pooling (taking the maximum value across embeddings). In our experiments, we opted for mean pooling as it offers a favorable balance between computational efficiency and representational effectiveness, being less resource-intensive compared with other aggregation strategies. For a detailed comparative analysis of these pooling methods and their impact on performance, we refer readers to the study by Xing et al [41].

Figure 3. SBERT general Siamese network architecture. SBERT: sentence bidirectional encoder representation from transformers.

In our study, we leverage this framework to conduct a semantic textual similarity task between pairs of extracted mentions and



XSL•FO
RenderX

HPO concepts sourced from the provided dictionary. This framework involves two steps: (1) candidate generation and (2) reranking.

The candidate generation step includes identifying candidate terms from the HPO dictionary. In this step, the mention and each candidate HPO term are jointly encoded to compute a semantic similarity score, which reflects how closely related the 2 texts are in meaning. This score typically ranges from 0 to 1, where 1 indicates perfect semantic equivalence and 0 denotes complete dissimilarity. The higher the score, the more semantically aligned the candidate is with the input mention.

Using the 734 gold standard spans from the validation set, we conducted a preliminary investigation using different sentence transformer biencoders and exploring 3 training paradigms within the framework (Figure 4). These paradigms include (1) using an existing sentence transformer biencoder without training (zero-shot setting), (2) continuing training (fine-tuning) the Sentence Transformer biencoder, or (3) training a non-Sentence Transformer PLM from scratch by defining the SBERT individual layers.

Figure 4. Preliminary exploration of different settings for 3 training paradigms of Sentence Transformers. Configurations in (A) and (B) employ an existing SBERT biencoder, whereas (C) involves training a non-SBERT pretrained language model from the clinical domain. In (D), we investigate a setting where an augmented HPO dictionary with synonyms is used for both (A) and (B). HPO: human phenotype ontology; SBERT: sentence bidirectional encoder representation from transformers.

For the latter 2 scenarios, we used pairs of spans from the training set and their corresponding HPO terms to fine-tune SBERT-biencoder and train a clinical PLM from scratch on a semantic similarity objective. We used MegaBatchMarginLoss as the training loss function, which is tailored to our training paradigm involving 2 pairs: an anchor and a positive example demonstrating semantic similarity to the anchor. Moreover, as illustrated in Figure 4D, we sought to enhance the generated candidates' accuracy by using an augmented HPO dictionary with synonymous terms sourced from the training dataset.

Based on the insights gained from this investigation, we select the optimal setting for our DiscHPO normalization component. We found that fine-tuning an existing SBERT biencoder (all-roberta-large-v1) with an augmented HPO dictionary, which incorporated synonyms from the training set, proved to be the most effective approach to create embeddings for both HPO terms and the extracted entity spans.

The reranking step is when the candidate results are reranked using a cross-encoder, which reorders the candidates using their similarity score, ensuring that the most semantically relevant HPO concepts are prioritized at the top of the list. Specifically, the top 30 candidates obtained by semantic matching are then passed on to a sentence transformer cross-encoder model. After experimenting with several cross-encoders, we found that ms-marco-electra-base yielded the highest results. It reranks the generated candidates by calculating the scores for each span-candidate term combination. Its results are sorted to produce the final reordered HPO terms. Among these results, only the top score is considered for submission.

Evaluation Metrics

For evaluation, we adhered to the official evaluation script provided by the task organizers. It incorporates the Precision (P), Recall (R), and F_1-score (F_1) metrics. The equations for these 3 metrics are as follows:

Precision = True Positive / (True Positive + False Positive)

Recall = True Positive / (True Positive+False Negative)

F_1-score = (Precision * Recall) / (Precision + Recall)

There are 2 evaluation scenarios implemented in the provided evaluation script:

- Evaluation of normalization task: which is calculated solely from the normalized output (the HPO term ID) of the extracted span. Here, the span extraction result is not part of the calculation.

XSL•FO
RenderX

- Evaluation of a combined span extraction and normalization: which measures the performance of both steps taken together.

To evaluate the latter, metrics for span extraction were reported based on exact matching (where the character offsets of the KEYF must be identical with the gold standard annotations) and partial matching (which considered an extracted span to be correct if it overlaps with the gold standard span with at least one correct token). In all evaluation experiments, we maintain consistent settings for the normalization component while experimenting with different NER models that are based on T5.

Baselines

To assess the effectiveness of our proposed approach, we benchmark it against 2 baseline models:

- PhenoTagger [26]: A hybrid approach that combines an HPO dictionary with machine learning techniques, leveraging several PLMs such as Bioformer, BioBERT, and PubMedBERT. In our work, we adopt the evaluation by Weissenbacher et al [42] where BioBERT served as the base model.
- PhenoID [42]: This system follows a 2-phase architecture, comprising an extractor and a normalizer. The extractor is a sequence labeling approach that leverages a transformer-based model, specifically the Bio-ClinicalBERT. For normalization, the task is treated as a classification problem by fine-tuning Bio-ClinicalBERT.

For the GCS+ dataset, we benchmarked our model against PhenoTagger and 2 SOTA models:

- PhenoRerank [43]: This model builds on a BlueBERT backbone pretrained on a weakly supervised dataset that includes HPO concepts, synonyms, definitions, and comments from the HPO database. The model is trained using a contrastive loss and reranks its predictions using external HPO extraction tools.
- PhenoGPT [30]: Based on GPT-3 and pretrained on a dataset derived from EHRs, literature, and phenotypic databases. The final PhenoGPT model is further fine-tuned on the GCS+ dataset to optimize its performance.

Ethical Considerations

This study makes use of the BioCreative VIII shared task dataset, which is publicly available. The original shared task paper provides details on the data collection process and sources [11]. As this work does not involve any primary data collection or experimentation with human participants, no ethics approval is required.

Results

We start by presenting our DiscHPO validation results: the extracted findings and their normalized HPO IDs (Table 4).

Table 4. DiscHPO results on the validation set.

Model	Normalization			Exact extraction and normalization			Partial extraction and normalization		
	Precision	Recall	F_1-score	Precision	Recall	F_1-score	Precision	Recall	F_1-score
SciFive-Large	0.722	0.726	0.724	0.695	0.637	0.665	0.719	0.719	0.719
T5-Large	0.725	0.743	0.734	0.696	0.644	0.669	0.724	0.739	0.732
FlanT5-Large	0.708	0.731	0.719	0.678	0.637	0.658	0.708	0.729	0.718
FlanT5-XL LoRa 512	0.735	0.739	0.737	0.710	0.654	0.681[a]	0.734	0.738	0.736
FlanT5-XL LoRa 1024	0.743	0.739	0.742[a]	0.716	0.642	0.677	0.742	0.735	0.738[a]

[a]Best-performing values.

Since FlanT5-XL showed the best performance in the evaluation stage, in the testing phase, we submitted 3 runs based on this model. Same as the evaluation, we applied the same normalization component in all runs while using different NER settings:

- Run1: FlanT5-XL and LoRa, α=1024 trained on the training set only.
- Run2: FlanT5-XL and LoRa, α=1024 trained on both the training and validation sets.
- Run3: FlanT5-XL and LoRa with α=512 trained on the training set only.

As shown in Table 5, the best normalization score of 0.723 F_1-score is achieved by using FlanT5-XL with LoRa α of 512.

XSL•FO
RenderX

Table 5. DiscHPO results on the test set submitted to the competition.

Runs	Normalization			Exact extraction and normalization			Partial extraction and normalization		
	Precision	Recall	F_1-score	Precision	Recall	F_1-score	Precision	Recall	F_1-score
1	0.721	0.723	0.722	0.694	0.638	0.665[a]	0.72	0.721	0.72
2	0.707	0.731	0.719	0.674	0.625	0.648	0.706	0.727	0.716
3	0.718	0.728	0.723[a]	0.69	0.637	0.662	0.717	0.726	0.721[a]

[a]Best-performing values.

The test set results are comparable to the validation set, which indicates that the model's performance is consistent across different sets. Overall, the highest normalization improvement was obtained by using FlanT5-XL with LoRa α=512.

In Table 6, we compare our highest-performing submission with the baselines on the same dataset, demonstrating the superiority of DiscHPO in terms of Recall and F_1-score. We also compare with the best-performing participants in the shared task. PheNormGPT [44] achieves the best performance by leveraging few-shot learning with GPT-4. This model generates 2 outputs for each span: the extracted span from the text and a preferred term generated by GPT-4. While the results are robust, this model has not been validated in a multiclass setting, where only KEYFs were extracted. In addition, although the BioCreative dataset is deidentified, the nonlocal deployment of GPT-4 raises privacy concerns when used with nondeidentified clinical data due to the potential disclosure of protected health information [45]. In contrast, open-source models such as the T5 family offer full local deployment on authorized machines, ensuring better control over data privacy, while also providing a more cost-effective alternative to proprietary models like GPT-4. W2NER+PhenoTagger [46] comes in second place. The model uses the W2NER framework for NER [47], which formulates NER as a grid-tagging problem. It uses a grid structure to capture all word relationships. However, this approach depends on a predefined tagging scheme. In contrast, our model does not rely on custom tagging structures, offering flexibility in handling diverse entity types.

Table 6. Best DiscHPO results on test set, compared against baseline methods [1,5] and the top 2 performing models from the BioCreative VIII Track 3 shared task.

System	Normalization			Partial extraction and normalization		
	Precision	Recall	F_1-score	Precision	Recall	F_1-score
PhenoTagger	0.587	0.687	0.633	0.586	0.685	0.632
PhenoID	0.736	0.699	0.717	0.735	0.696	0.715
W2NER+PhenoTagger	0.831	0.706	0.763	0.830	0.704	0.762
PheNormGPT	0.842	0.799	0.820[a]	0.841	0.794	0.817[a]
DiscHPO (Ours)	0.718	0.728	0.723	0.717	0.726	0.721

[a]Best-performing values.

To assess model performance in differentiating between normal and KEYFs, we calculated class-wise F_1-scores. The model demonstrates a stronger ability to recognize KEYFs (77.2% F_1-score; 471 true positives, 142 false positives, and 135 false negatives) compared with NORMFs (56.4% F_1-score; 44 true positives, 34 false positives, and 34 false negatives), reflecting a recognition bias. This bias is expected and can be attributed to the notable class imbalance in the dataset, where NORMFs constitute only 12% of the total entity spans across the combined training and validation sets (Table 2). Given that the primary goal of the shared task is the detection and normalization of KEYFs, where NORMFs are excluded from the final evaluation, this class imbalance has minimal impact on overall task performance. Consequently, our model was optimized to prioritize KEYFs, as they are the only entities passed to the normalization phase.

To evaluate the models' proficiency in specifically identifying disjoint spans, we computed the NER results for the top 4 DiscHPO models by incorporating only the extracted disjoint mentions from the validation set. We computed both the exact and partial extraction scores for each model. As shown in Table 7, our NER models can identify discontinuous spans. As can be seen, FlanT5-XL with LoRa α 512 is superior in detecting disjoint mentions of findings with an F_1-score of 63.1%. In terms of overlapping extraction, FlanT5-XL with LoRa α=1024 has the best performance when it comes to extracting some of the parts of the disjoint mentions.

XSL•FO
RenderX

Table 7. Results for discontinuous span extraction on the validation set.

Model	Exact extraction			Partial extraction		
	Precision	Recall	F_1-score	Precision	Recall	F_1-score
T5-Large	0.546	0.575	0.57	0.873	0.937	0.904
SciFive-Large	0.6	0.578	0.589	0.911	0.868	0.889
FlanT5 LoRa 512	0.699	0.569	0.631	0.79	0.823	0.806
FlanT5 LoRa 1024	0.658	0.578	0.615	0.927	0.881	0.904

In Table 8, we further analyzed the model's behavior across structural variations in discontinuous entities, including spans without interrupting tokens and those with shared heads (ie, overlapping tokens) with varying head locations and structural complexity. The F_1-score was highest for left-overlapping spans and spans with no overlap. Right and multiple overlaps also showed reasonable performance, with some variation that correlates with the number of instances in each category (eg, 19 and 12 spans respectively, compared with 40 for left overlaps).

Table 8. Model's performance across different discontinuous structures.

DiscNE[a] category	Precision	Recall	F_1-score
No overlap	0.69	0.67	0.68
Left overlap	0.71	0.62	0.67
Right overlap	0.50	0.46	0.48
Multiple overlaps	0.83	0.45	0.59

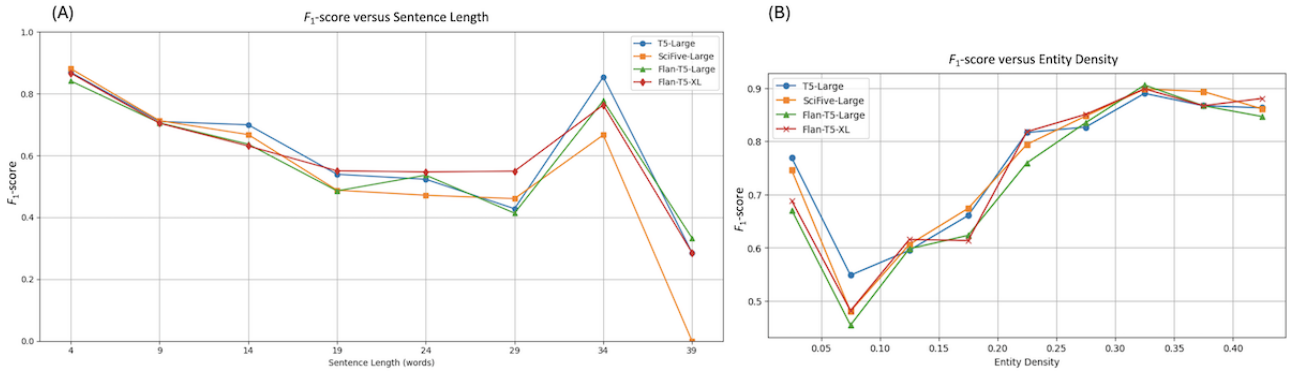
[a]DiscNE: discontinuous named entity.

To assess the generalizability of the model, we show the performance results of DiscHPO on the GCS+ dataset in Table S3 in Multimedia Appendix 1. We have also included a discussion of these results in comparison with the baseline models.

Discussion

Principal Findings

It is noteworthy that, in both our system and the compared ones, the scores for partial extraction and normalization are very close to those of normalization, which suggests that normalization performance is not substantially degraded by partially extracted spans. This implies that exact span extraction is not always a condition for accurate normalization. This can be observed in cases where partially extracted spans did not negatively affect the normalization outcome.



In around 15 normalization output examples from the validation set, we found that partial extraction of continuous and discontinuous NEs can be sufficient for normalization. This is especially true when a disjoint span is interrupted by nonentity tokens and does not share a head. If we consider the following example: "EYES: normal brows, mild hooding." While all our models accurately extracted the exact disjoint span "EYES: hooding," we further examined this by inputting the normalizer with the partial span "hooding." This also resulted in correct normalization, as the term "hooding" is commonly associated with an eye condition.

Quantitative Error Analysis

Figure 5 presents a comparative analysis of the F_1-scores achieved by T5-Large, SciFive-Large, Flan-T5-Large, and Flan-T5-XL-LoRa1024, which we used as a backbone PLMs for DiscHPO, across different sentence lengths (Figure 5A) and varying levels of entity density (Figure 5B).

XSL•FO
RenderX

Figure 5. Quantitative error analysis of DiscHPO. It compares the F1-score performance of 4 backbone pretrained language models (T5-Large, SciFive-Large, Flan-T5-Large, and Flan-T5-XL) under two factors: (A) the impact of sentence length and (B) the impact of entity density. HPO: human phenotype ontology.

We first examine the impact of sentence length on F_1-score. In Figure 5A, we observe a general decline in F_1-score as sentence length increases across all 4 models. This trend is expected, as longer sentences contain more complex syntactic structures. However, T5-Large shows increased performance, particularly in longer sentence ranges, suggesting robustness to increased sequence complexity. SciFive-Large and Flan-T5-Large show relatively parallel performance, though SciFive-Large shows a sharper drop at the longest sentence bin. Flan-T5-XL demonstrates a stable performance across medium-length sentences. We can observe a spike in performance in the 34-word bin for all models, suggesting a concentration of entity-rich sentences in that length category.

Next, we explore the impact of entity density, defined as the percentage of annotated NEs within a sentence. Figure 5B shows that model performance improves with increasing NE density, peaking around the 0.3-0.35 density range. This trend indicates that models benefit from contexts rich in NEs, which may provide clearer clues for learning entity boundaries and relationships. Flan-T5-XL achieves the highest performance at higher density levels, suggesting strong capabilities in recognizing entities in dense annotations, due to its larger parameter capacity and better instruction tuning. Other models perform comparably with each other, but Flan-T5-Large performs slightly lower, suggesting potential limitations in handling low-entity sentences.

Qualitative Error Analysis

From our analysis of the gold DiscNEs, we found that certain tokens are deemed nonessential for normalization. For example, in the instance “EYES: Mild epicanthus, mild up-slant,” the gold standard span “EYES - mild up-slant” is disjoint. However, none of our models incorporated the severity level “mild” into the extracted span; this omission did not adversely impact the normalization outcome.

On the other hand, in certain examples, specific tokens in disjoint mentions are crucial for achieving exact normalization. For example, in the case of “HANDS FEET: L clinodactyly,” the gold annotation is the disjoint span “hand L clinodactyly,” whereas all our models extracted only “clinodactyly.” This led to normalization as “clinodactyly” encompassing both fingers and toes, instead of the more specific concept “Finger clinodactyly.”

The case is different when disjoint spans share a common head, in which each span must be resolved to its own head and its constituent tokens to avoid missing normalizations. We also observed that the models easily identified simple coordinated ellipses, such as “NOSE: broad nasal bridge and tip.” However, challenges arise in scenarios where 2 spans share 2 heads, as in the example “Deep palmar and plantar creases,” where the tokens “deep” and “creases” are common to both “palmar” and “plantar.” Scifive struggled with this complexity, failing to accurately resolve the second span and consequently missing its normalization. In contrast, the other 3 models effectively handled this complexity and successfully addressed the shared elements.

Shifting to normalization errors, some can be attributed to the lack of descriptions or synonyms for the HPO concepts. These additional details provide the normalizer with additional information for accurate concept identification. For instance, in the first example from Table 9, the extracted span “white plaque under the tongue” led the normalizer to mistakenly assign the concept “Erythematous plaque” instead of “Oral leukoplakia” due to lexical similarity. This type of error occurred 28 times out of 155 total normalization errors in the validation set. While we have already enhanced the normalizer’s training data with synonyms from the original training set, they might be inadequate for unseen examples in the validation set. Therefore, we assume that adding more HPO synonyms or descriptions may have the potential to improve the normalization process.

XSL•FO
RenderX

Table 9. Examples of human phenotype ontology (HPO) terms incorrectly predicted by the normalizer on the validation set.

Gold and predicted span	Gold Standard HPO		Predicted HPO	
	Concept	HPO ID	Concept	HPO ID
White plaque under the tongue	Oral leukoplakia	HP:0002745	Erythematous plaque	HP:0025474
Hypotonia	Hypotonia	HP:0001252	Generalized hypotonia	HP:0001290
Abdominal wall hernia	Hernia	HP:0100790	Hernia of the abdominal wall	HP:0004299
Flat-nasal bridge	Depressed nasal ridge	HP:0000457	Depressed nasal bridge	HP:0005280

Another example of error arises when our model selects the term “Generalized hypotonia,” instead of the more specific term “Hypotonia” as provided by the gold standard. Conversely, another error arises when our model selects the highly precise concept “Hernia of the abdominal wall,” while the gold standard prefers the broader term “Hernia.” This type of error was observed in 5 instances among all normalization errors. In addition, we observed only 8 inconsistencies among the gold standard annotations, as illustrated in the final example of Table 9. In this case, the term “Depressed nasal bridge” was mistakenly recorded as “Depressed nasal ridge,” and has been assigned the wrong HPO ID.

More complex coordinations expectedly posed challenges to all evaluated NER models. For example, in the sentence “Contractures of 3rd and 4th digits,” the expected resolution is the doubly-disconnected named entities “Contractures of 3rd digit” and “Contractures of 4th digit.” The models encountered difficulty, likely due to the presence of the word “digit” in its plural form, which caused confusion in determining whether to resolve it as 2 separate entities or not. To provide a clearer overview of the types of normalization errors, we summarized their distribution in Table S4 in Multimedia Appendix 1. This table presents the proportion of each error category observed in the validation set, offering insights that may support future improvements in sentence-transformer–based normalizers.

Limitations

Although the dataset used in this study was granted a waiver of HIPAA authorization for access to identifiable medical record information [42], our approach prioritizes privacy by enabling local deployment of open-source PLMs to ensure sensitive data remains secure. Unlike systems that rely on closed-source models such as GPT-4, our method leverages the open-source T5 family of PLMs. This makes the approach well-suited for use with confidential clinical datasets that are only accessible under restricted licenses. Additionally, it offers a cost-effective alternative to proprietary models.

Despite its reasonable performance, the model shows a tendency to favor the recognition of KEYFs, which were the primary focus of the shared task. This bias is likely caused by the class imbalance in the dataset and has not yet been explicitly addressed. Future work could explore strategies such as data augmentation or balanced sampling to mitigate this bias.

Although DiscHPO is specifically fine-tuned and evaluated on genetic phenotype findings, we hypothesize that the underlying generative and transformer-based framework is well-suited for clinical findings in other medical domains. The model architecture can be adapted to recognize NEs in diverse specialties like oncology, cardiology, or general medical NER. However, this study does not evaluate the system’s generalizability beyond datasets related to HPO, which remains a direction for future work. Furthermore, although the official competition evaluation was conducted using a gold-standard annotated corpus, evaluating the full system under more challenging conditions -such as noisy or unlabeled input- remains an important avenue for future work and would provide an indication of real-world applicability.

Conclusions

This paper presents an overview of our DiscHPO, which is an NER and NEN pipeline capable of processing both continuous and discontinuous spans. We evaluated our model within the context of the BioCreative VIII - Track 3 challenge, focusing on extracting KEYF mentions of genetic phenotypes and normalizing them to the HPO. In the NER component, various T5 model variants were explored for KEYF extraction, and an additional experiment incorporated LoRA with extra-large models. From the extraction results, we found that optimizing Flan-T5-XL’s parameters using LoRA resulted in improved extraction outcomes for both continuous and discontinuous findings, leading to enhanced normalization performance.

Furthermore, improving normalization results can be achieved by resolving all disjoint mentions that share a common head, thereby avoiding the omission of relevant mentions. On the other hand, there may be cases in which extracting the exact mention, continuous or discontinuous, is not crucial for successful normalization. This is apparent in our observations of the normalization results, where several examples with partially extracted mentions still led to accurate normalization.

In future research, and inspired by Peng et al [14], there is a potential to enhance the accuracy of the NEN task by incorporating auxiliary components alongside the SBERT framework. For instance, combining semantic or lexical similarity measures (eg, TF-IDF or Cosine Similarity) with SBERT. Specifically, candidate generation could be performed in parallel using both SBERT and the similarity measure, with the aggregated set of candidates subsequently passed through a cross-encoder for final ranking. Moreover, we intend to conduct a comparative analysis between our DiscHPO model and an end-to-end NER and normalization model that shares contextualized embeddings for both tasks. This joint approach may improve performance by reducing error propagation across pipeline stages and enabling end-to-end optimization. Additionally, we aim to investigate the efficacy of autoregressive

XSL•FO
RenderX

entity normalizers, as suggested in the work of De Cao et al [48].

Abstract

Background: Predicting serious hematological adverse events (SHAEs) from poly (adenosine diphosphate ribose) polymerase inhibitors (PARPis) would allow us to prioritize patients with ovarian cancer at higher risk for more intensive care, ultimately lowering morbidity and preventing them from premature termination of medication.

Objective: This study aimed to explore the risk factors for SHAEs in patients with ovarian cancer receiving PARPi treatment and develop a risk prediction model for such events.

Methods: Prospective clinical data were collected on patients with ovarian cancer who received PARPi treatment at the Guangxi Medical University Affiliated Tumor Hospital from December 2018 to August 2024. They were divided into a SHAE group and a no-SHAE group based on the occurrence of SHAEs. Variable differences were screened using the chi-square test or Fisher exact test. Multivariate logistic regression was used to determine independent factors influencing SHAEs in patients with ovarian cancer. A predictive model for serious blood-related complications in ovarian cancer treatment was developed from identified independent risk factors using the R software. The model's clinical utility was assessed through decision curve analysis (net benefit), calibration (calibration curve), and discrimination (receiver operating characteristic curve).

Results: A total of 70 patients with ovarian cancer receiving PARPi treatment were included in this study. Of these 70 patients, 16 (23%) experienced SHAEs, with decreases in red blood cell (RBC) count and hemoglobin levels being the most common. Multiple logistic regression analysis identified 4 independent predictors of PARPi-associated SHAEs in patients with ovarian cancer: lymph node metastasis (odds ratio [OR] 6.733, 95% CI 1.197-37.873; *P*=.03), creatinine clearance rate of ≤60 mL per minute (OR 23.722, 95% CI 3.121-180.303; *P*=.002), RBC count of $\leq 3.3\times10^{12}$ per liter (OR 4.847, 95% CI 1.020-23.041; *P*=.047), and combination therapy with vascular endothelial growth factor inhibitors (OR 6.749, 95% CI 1.313-34.689; *P*=.02). The internal validation yielded an area under the curve of 0.874 (95% CI 0.793-0.955), indicating moderate clinical utility and accuracy for the risk prediction model incorporating these predictors.

Conclusions: Lymph node metastasis, creatinine clearance rate of ≤60 mL per minute, RBC count of $\leq 3.3\times10^{12}$ per liter, and combination therapy with vascular endothelial growth factor inhibitors are independent risk factors for PARPi SHAEs in patients with ovarian cancer. The risk prediction model established based on these factors demonstrated moderate predictive value.

Introduction

Background

Ovarian cancer is the most aggressive gynecologic malignancy. Most patients with ovarian cancer are diagnosed in later stages due to unclear early symptoms and its anatomical location deep in the pelvis. Even after surgery, it is still prone to recurrence and metastasis, which has a serious impact on women's lives and health. Approximately 70% of patients still experience recurrence and develop chemotherapy resistance within 3 years after initial treatment despite showing sensitivity in the early stages of chemotherapy [1,2]. Given the frequent and rapid development of chemotherapy resistance in ovarian cancer, there is an urgent clinical need to identify new treatment options. High-level medical evidence shows that poly (adenosine diphosphate ribose) polymerase inhibitors (PARPis) can interfere with the base excision repair pathway, block the DNA single-strand break repair of tumor cells, form a "synthetic lethal" effect in tumor tissues that cannot undergo DNA double-strand repair due to homologous recombination repair deficiency (HRRD), promote tumor cell apoptosis, effectively prolong the platinum-free interval of patients with ovarian cancer, and provide a new treatment option for patients who cannot tolerate chemotherapy in the late stage [3]. Germline mutations in the *BRCA1* and *BRCA2* genes, which are ovarian cancer susceptibility genes, are common causes of HRRD. Therapeutic benefits of PARPis have been observed in patients with cancer carrying germline mutations in the *BRCA1* and *BRCA2* genes, particularly for ovarian cancer cases [4]. In terms of safety, serious adverse reactions to PARPis are mainly manifested in hematological toxicity and are most likely to lead to drug reduction, interruption, or even discontinuation, seriously hindering the normal treatment process of patients with ovarian cancer and causing adverse effects on their long-term prognosis [5,6]. Therefore, identifying serious hematological adverse events (SHAEs) related to PARPis in advance is particularly important in clinical diagnosis and treatment practice.

Objectives

This study aimed to explore the risk factors for SHAEs in patients with ovarian cancer receiving PARPi treatment and develop a risk prediction model to guide personalized treatment and care for patients with ovarian cancer to achieve the best survival benefits.

Methods

Study Design

This open-label, prospective cohort study was designed to evaluate the incidence of SHAEs in patients with ovarian cancer receiving PARPi treatment in routine clinical situations and determine the variables linked to the emergence of these reactions. This study included patients aged ≥18 years with histologically proven ovarian, fallopian tube, or primary peritoneal cancer who received care at the Guangxi Medical University Affiliated Tumor Hospital from December 2018 to August 2024. All participants (or their legal representatives) provided informed consent, and all had been treated with PARPis for a minimum duration of 6 weeks in any treatment line. The exclusion criteria were the participants' or the responsible family members' withdrawal of permission to take part in the research at any time or PARPi discontinuation due to disease progression or death.

Study Procedures and Assessments

Participants were followed up on on-site or contacted via telephone calls at least once a month to inquire about the incidence of any untoward effect from PARPis from initiation until they completed their treatment, were lost to follow-up, or died between December 2018 and August 2024. Patients were evaluated for treatment-related hematological indicators and imaging of tumor lesions every 2 to 3 treatment cycles. Any hematological adverse event (including time of occurrence, severity, and prognosis) was also included in the data recording. When to stop treatment in case of an adverse event was decided by the attending physician.

The safety data were collected using the National Cancer Institute Common Terminology Criteria for Adverse Events version 5.0. Depending on whether there were SHAEs during the follow-up period, the patients were split into 2 groups: the SHAE group and the no-SHAE group. SHAEs are defined as hematological adverse events of a grade of ≥3, including thrombocytopenia, leucopenia, neutropenia, erythropenia, decreased hemoglobin, anemia, myelodysplastic syndrome, and acute myeloid leukemias. If none of the aforementioned SHAEs occurred, patients were included in the no-SHAE group. In addition, when a single report contained multiple adverse events, if any of the aforementioned serious adverse events occurred, patients were included in the SHAE group.

The outcomes of each patient were assessed by combining the Response Evaluation Criteria in Solid Tumors version 1.1 and the Gynecologic Cancer Intergroup criteria, including disease control rate (DCR), partial response, stable disease, and progressive disease.

Establishment of the Nomogram Model

General clinical characteristics of patients before PARPi treatment, including age, BMI, marital status, pathology type, previous antitumor therapies, lymph node metastasis, distant metastasis, and number of distant metastases, were collected. Univariate analyses were conducted for each parameter using the chi-square test or Fisher exact test, as appropriate. Variables with a significance level of $P<.20$ in the univariate analysis were included in the subsequent multivariate logistic regression analysis using a backward elimination approach (removal criterion: $P>.05$ based on the Wald statistic) to identify independent risk factors for SHAEs during PARPi treatment in patients with ovarian cancer. For all binary categorical variables (eg, lymph node metastasis), the reference category was explicitly set to the negative group (coded as 0) to ensure clinically intuitive interpretation of odds ratios. Statistical analyses were conducted using SPSS (version 23.0; IBM Corp). Subsequently, the final multivariate model was imported into the R software (version 4.2.2; R Foundation for Statistical Computing), and the *rms* software package was used to construct a nomogram for predicting the risk of SHAEs.

XSL•FO
RenderX

Validation of the Nomogram Model

By charting the receiver operating characteristic (ROC) curve and computing the area under the curve (AUC), the differentiation of the model was assessed. To confirm the model's consistency, a calibration curve was created by contrasting the projected and actual probabilities of SHAEs. The clinical usefulness of the prediction model was assessed using decision curve analysis. To quantify the net benefit at various threshold probabilities, decision curve analysis compares the model's performance to 2 reference lines: one that assumes that all patients experience SHAEs and receive the intervention (which represents the highest clinical cost) and one that assumes that no patients receive the intervention (which represents no clinical benefit).

Statistical Analysis

Data were analyzed using SPSS (version 23.0). Categorical variables are presented as frequencies and percentages and were compared using the chi-square test or Fisher exact test, as appropriate. Cases categorized as "unknown" were excluded from the analysis to ensure validity and minimize potential bias. In the tables, variables with missing data are marked with a footnote symbol, indicating that these cases were excluded. For variables with a high proportion of missing values (≥50%), no statistical comparisons were conducted, and *P* values are denoted using an em dash (ie, not applicable).

Survival outcomes were assessed using the Kaplan-Meier method. To evaluate the association between the occurrence of serious hematological toxicity and clinical efficacy, a comparative analysis of progression-free survival (PFS) was conducted between participants who experienced any hematological adverse events of a grade of ≥3 during the treatment period and those who did not. The 2 groups were compared using the log rank test. Time-to-event end points specific to hematological adverse event occurrence were analyzed using survival analysis. The primary end point was time to first onset of hematological adverse events of a grade of ≥3, and secondary end points included time to first onset of any-grade hematological adverse events. The event was defined as the first documented occurrence of a hematological adverse event (including anemia, neutropenia, and thrombocytopenia) meeting the specified severity grade. Data from patients who did not experience an event were censored at the date of their last follow-up. The cumulative probability of each end point was estimated using the Kaplan-Meier method and visualized via Kaplan-Meier curves.

The associated factors influencing SHAEs following PARPi medication were examined using a multivariate logistic regression model, and a prediction model was created. The ROC curve was used to verify the model's prediction ability, and the AUC was calculated. The degree to which the prediction model fit the data was assessed using the Hosmer-Lemeshow test. The difference was considered statistically significant if $P<.05$.

Ethical Considerations

The protocol for this study was approved by the Ethics Review Board of Guangxi Medical University Affiliated Tumor Hospital (KY2023772). All procedures were conducted in accordance with the ethical standards of the Declaration of Helsinki and local regulations. Written or verbal informed consent was obtained from all participants (or their legal guardians) before their inclusion in the study.

To ensure participant privacy and confidentiality, all personal information was handled with strict adherence to our ethical protocols. Data collection forms were anonymized and stored separately from any personal identifiers. Access to the original dataset was restricted to authorized research personnel only. Throughout the data analysis and publication process, all participant data were de-identified to prevent any possibility of tracing back to individuals. Specifically, all direct personal identifiers (such as names, patient ID numbers, and detailed contact information) were removed from the research dataset.

Results

Overview

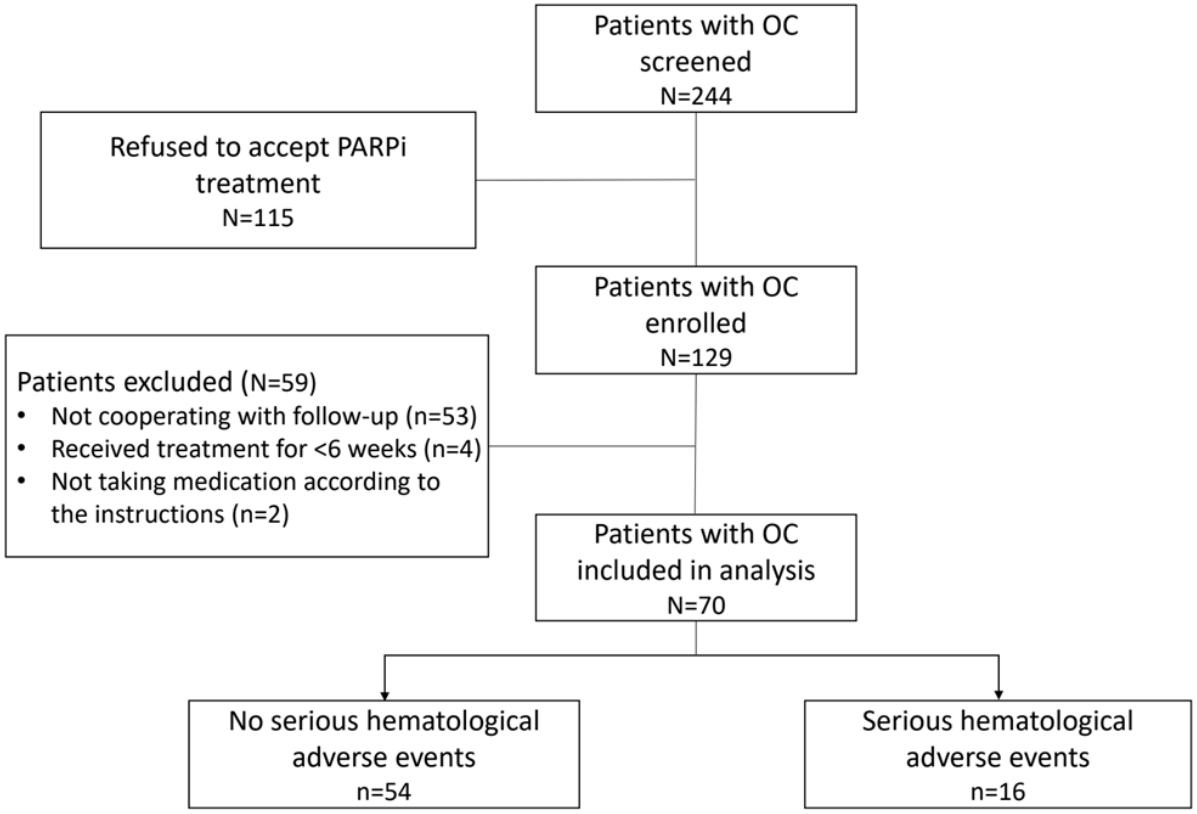

Figure 1 shows the study sample recruitment. Of the 244 patients with ovarian cancer surveyed at baseline, 115 (47.1%) were not eligible for follow-up due to refusal. Of the 129 participants receiving PARPi treatment, we excluded 59 (45.7%) for the following reasons: 53 (90%) did not return for any follow-up visit and could not be reached for the entire study duration, 4 (7%) received treatment for <6 weeks, and 2 (3%) did not take their medications according to the instructions. As a result, the total sample size for the analysis was 70 patients.

The follow-up period lasted a median of 12 (IQR 7-24) months.

Of the 70 patients with ovarian cancer treated with PARPis, 16 (23%) experienced hematological adverse events of a grade of ≥3 and were classified as the SHAE group, and the 54 (77%) remaining individuals were categorized as the no-SHAE group. After the clinical characteristics of the individuals in the 2 groups were analyzed, the findings (Multimedia Appendix 1) demonstrated that there were statistically significant differences in creatinine clearance rate (Ccr), red blood cell (RBC) count, and response to 6-week treatment among the groups ($P<.05$).

Figure 1. Flow diagram of this study. OC: ovarian cancer; PARPi: poly (adenosine diphosphate ribose) polymerase inhibitor.

Assessment of Effectiveness and Prognosis

Treatment response was assessed in all study patients through combined application of the Response Evaluation Criteria in Solid Tumors version 1.1 and the Gynecologic Cancer Intergroup criteria. The results showed that progressive disease developed in 56% (39/70) of the patients, stable disease developed in 44% (31/70) of the patients, and partial response developed in 0% of the patients. A DCR was present in 44% (31/70) of the entire population. A significant difference was not found in PFS between the SHAE group and the no-SHAE group according to the results of a Kaplan-Meier survival analysis conducted for PFS in the 2 groups (P=.82), and the median PFS was 13.0 (IQR 0.0-38.4) months and 24.0 (IQR 19.2-28.8) months, respectively (Figure 2).

Further analysis of the relationship between SHAEs in patients with ovarian cancer and the efficacy of PARPis did not reveal any association between the early occurrence of SHAEs related to PARPi hematological toxicity and antitumor efficacy (Table 1).

XSL•FO

Figure 2. Progression-free survival (PFS) compared between participants who experienced serious hematological adverse events (SHAEs) and those who did not.

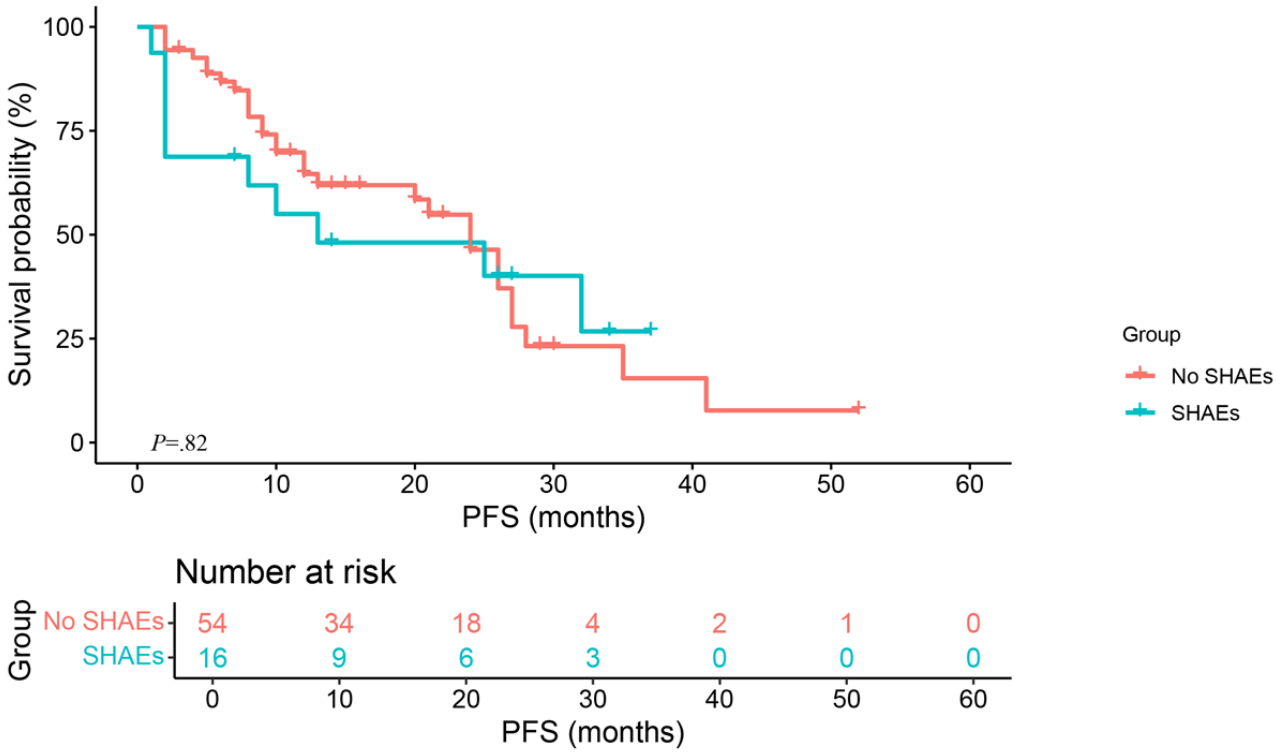

Table 1. Disease control rates (DCRs) and absolute frequencies by adverse event experiences.

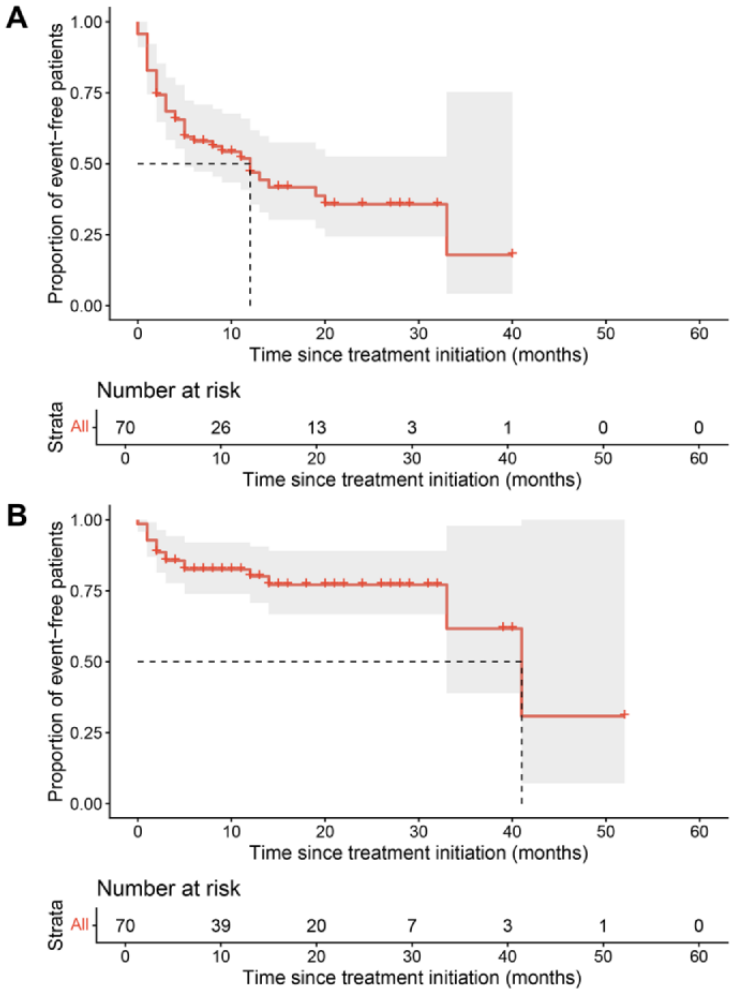
Time before initial event (mo)	Total, n	Disease control, n (%)	*P* value
Adverse events			.43
≤1	8	5 (62.5)	
>1	32	13 (40.6)	
Serious hematological adverse events			.30
≤1	5	3 (60.0)	
>1	11	3 (27.3)	

Presentation of Hematological Adverse Events in Patients



The spectrum and classification of hematological adverse events are shown in Table 2. Erythropenia and decreased hemoglobin showed the highest incidence regardless of severity. Figure 3 illustrates the onset time of hematological adverse events during PARPi treatment. All-grade hematological adverse events had a median onset time of 12.0 (IQR 6.5-17.468) months, whereas hematological adverse events of a grade of ≥3 manifested later (median onset time 41.0, IQR 29.3-52.7 months).

Multifactor Logistic Regression Analysis of Factors Affecting SHAEs

To further investigate the pertinent factors influencing the occurrence of SHAEs, variables with $P<.20$ in Multimedia Appendix 1. were included in the multivariate logistic regression analysis, and the results (Table 3) showed that lymph node metastasis, Ccr of ≤60 mL per minute, RBC count of $\leq 3.3\times10^{12}$ per liter, and combined therapy with vascular endothelial growth factor inhibitors (VEGFis) were risk factors influencing the occurrence of SHAEs ($P<.05$).

[d]VEGFi: vascular endothelial growth factor inhibitor.

Development and Assessment of the Nomogram Model

A nomogram model was developed using the R software to forecast SHAEs after receiving PARPi medication based on the findings of the multifactor analysis (Figure 4). The ROC curve was developed to evaluate this model's predictive ability. With an AUC of 0.874, the nomogram model showed great predictive ability and consistency (Figure 5A). The ROC curve derived from bootstrap resampling maintained consistent stability in its positional trajectory (Figure 5B), suggesting that this phenomenon is more likely attributable to sample distribution and class imbalance issues common in small datasets rather than overfitting. The Hosmer-Lemeshow test was used to assess the model's goodness of fit. According to the findings, the nomogram model developed in this study had a goodness of fit with a *P* value of .36. The model demonstrated moderate calibration (mean absolute error=0.061), with observed versus predicted risks aligning closely across deciles (Figure 5C). Decision curve analysis (Figure 5D) was conducted to evaluate the clinical utility of our risk prediction model. The curve demonstrates that the model yielded a positive net benefit at threshold probabilities ranging from 0% to 70%, suggesting that it can be safely applied to guide clinical interventions within this range. However, when the threshold probability exceeds 70%, the net benefit turns negative, indicating that the model-based decision strategy underperforms the "treat none" strategy (reference line net benefit=0) in this high-threshold range. This limitation may stem from either (1) an insufficient number of high-risk patients in the training dataset, leading to distributional bias and unreliable predictions in high-probability intervals; or (2) inherent inaccuracies in the model's predictions for extreme-risk subgroups. Therefore, for patients within the high-threshold range (threshold probability>70%), additional confirmatory screening (eg, imaging examinations) or closer clinical monitoring should be prioritized to enhance decision accuracy rather than relying solely on this model to justify high-risk interventions.

Discussion

Principal Findings

During the treatment process with PARPis, most patients will experience varying degrees of adverse reactions, mainly mild or moderate, most commonly manifested as hematological adverse events, gastrointestinal adverse events, and fatigue. Most of the adverse events of a grade of ≥3 are hematological adverse events, which are the main reasons for adjusting drug dosage and interrupting and terminating medication, with a discontinuation rate of 27% [7-9]. SHAEs may also be associated with life-threatening declines in organ function and quality of life and even fatal outcomes. This study found that patients who experienced SHAEs showed a trend toward worse PFS than those without SHAEs (median 13.0, IQR 0.0-38.4 months vs median 24.0, IQR 19.2-28.8 months; *P*=.82); although no statistically significant difference was found, these toxicities still require early detection and proper management.

However, a previous study found that patients who experienced hematological adverse events while receiving PARPi treatment had much higher survival and response rates than those who did not experience toxicity. This finding may be connected to PARPis' extensive cell dispersion [10]. Early adverse events related to PARPi hematological toxicity have been linked to antitumor activity, which may be a reliable and readily quantifiable clinical indicator in patients with ovarian cancer. In this study, although patients who developed hematological adverse events of a grade of ≥3 within the first month of PARPi treatment appeared to exhibit a higher DCR, this difference did not reach statistical significance. Conversely, the early efficacy of PARPis showed an inverse relationship with their associated hematological toxicities. Compared with patients who experienced SHAEs during treatment, patients who did not experience SHAEs showed higher DCR (94.4% vs 68.8%; *P*=.02) in the early stages of treatment (within 6 weeks), which may be due to the longer median time to onset of hematological adverse reactions of a grade of ≥3 reported in this study (median 41.0, IQR 29.3-52.7 months). Furthermore, it cannot be ruled out that the small-sample bias may have an impact on the research results. Although logistic regression analysis did not show that early efficacy could predict SHAEs related to PARPis, we still recommend closely monitoring relevant indicators for patients with poor early treatment response (within 6 weeks) to identify and intervene in adverse events early.

Of the 70 patients in this analysis, 16 (23%) experienced SHAEs, with a median time to onset of 41.0 months (IQR 29.3-52.7 months). In addition, 57% (40/70) experienced all-grade hematological adverse events, with the main onset time window falling between 7.4 and 26.6 months. The hematological adverse events of the patients in this study were mostly erythropenia and decreased hemoglobin regardless of severity, which was comparable to those found in previous research. Therefore, it is recommended that routine blood testing, especially RBC count and hemoglobin, be strengthened from the second year of patient medication. If necessary, preventive medication should be administered.

Lymph node metastasis was found to be an independent factor influencing the incidence of hematological adverse events using multivariate logistic regression analysis. Previous studies have demonstrated that patients with advanced solid tumors experience less tolerance to treatment. Lymph node status is not only a part of the International Federation of Gynecology and Obstetrics staging system for ovarian cancer but also an established prognostic factor in ovarian cancer [10-13]. A 13-year retrospective analysis suggests that, when it comes to patients with ovarian cancer, the lymph node ratio (calculated as the number of positive lymph nodes divided by the total number removed) is a more reliable prognostic indicator than the standard lymph node status [14]. As a result, PARPi users with lymph node metastasis in any pathological stage should be considered for further evaluation.

Previous studies have identified an association between PARPi dose and adverse events [9]. PARPis are predominantly eliminated via the kidneys. In clinical practice, creatinine and Ccr are used as markers to determine the glomerular filtration rate and functional parameters to assess renal function in patients. Patients with renal dysfunction are more likely to experience excessive accumulation of the drug or its active metabolites, which could result in severe adverse events. In general, low Ccr consistently appears to be a risk for drug adverse events, especially for drugs primarily excreted through the kidneys, and from the results of our study, this remains true for SHAEs related to PARPis. It is worth noting that elevated serum creatinine is a frequent adverse reaction to PARPis reported in previous studies [15-17], although most studies have shown that elevated serum creatinine may be caused by the inhibition of renal transporters but not accurately reflect a decline in glomerular filtration rate or renal failure [15,18]. Given the findings of this study, it is still advised that PARPi users with a Ccr of ≤60 mL per minute be routinely monitored.

This study found that an RBC count of $\leq 3.3\times10^{12}$ per liter was a risk factor for SHAEs related to PARPis. The most plausible explanation for the association between erythrocyte reduction and hematological toxicity is impaired bone marrow reserve. Immature platelet fraction serves as an accurate hematological marker for assessing bone marrow function. However, as baseline immature platelet fraction testing is not routinely conducted in patients with ovarian cancer receiving PARPis at our institution, this study conducted a comprehensive evaluation of bone marrow reserve using indicators including RBC count, platelet count, hemoglobin, platelet-large cell ratio, mean corpuscular volume, and lactate dehydrogenase. Chi-square tests and multivariate logistic regression analysis revealed that none of the aforementioned parameters—except for RBC count—demonstrated a significant correlation with PARPi-related hematological adverse events. Insufficient evidence was found to support the hypothesis that SHAEs related to PARPis are primarily mediated by impaired bone marrow function. Instead, our findings may be better explained by the research by Molina et al [19] and Mehibel et al [20], which explores the association between the tumor microenvironment (TME) and the antitumor activity of PARPis. The RBCs are the efficient carriers of oxygen and other essential nutrients that are linked to aberrant metabolism in the TME,

XSL•FO
RenderX

such as hypoxia. Hypoxia is a common characteristic of the TME in solid tumors and is caused by the rapid growth and proliferation of malignant solid tumors and the underdevelopment of vascular system tissues, resulting in local hypoxic tension in tissues; hypoxia, in turn, regulates the angiogenesis and growth of tumor tissue, promoting tumor invasion and metastasis, to adapt to hypoxic and nutrient-limited environments [19,21]. This causal transformation results in most solid tumors being in a state of moderate (1%-2% oxygen) to severe (<0.01% oxygen) hypoxia internally [22]. In the female population, the normal RBC count is 4.0 to 5.0×10^{12} per liter. When it is below the lower limit of the normal range, the ability of blood to transport oxygen is weakened, which may further exacerbate the hypoxic condition of the TME. It has been found that hypoxia can induce the overexpression of breast cancer resistance protein and multiple drug resistance protein [23] and the activation of the transforming growth factor beta, transforming growth factor alpha and epidermal growth factor receptor, and cyclooxygenase-2 pathways [24-26] by regulating the hypoxia-inducible factor α and cancer-associated fibroblasts, thus inducing therapeutic resistance. The study by Mehibel et al [20] revealed that cancer cells exhibited increased resistance to PARPis under moderate hypoxia (2% oxygen) when compared to their normoxic counterparts, suggesting a hypoxia-induced protective mechanism. However, under severe hypoxia (0.5% oxygen), cancer cells showed the same significant increase in sensitivity to PARPis regardless of whether HRRD was negative or positive. Notably, the interpretation of our results based on those of these previous studies remains limited by the sample size, cross-sectional design, and suboptimal sensitivity of bone marrow evaluation methods, necessitating future validation in prospective cohorts with dynamic bone marrow function monitoring.

In addition, this study found that PARPi combination with VEGFis was one of the risk factors for SHAEs during PARPi treatment. The VEGFis used in patients undergoing combination therapy in this study included bevacizumab, apatinib, and lenvatinib. Previous literature has reported a significant proportion of hematological adverse events of a grade of ≥3 during the use of VEGFi monotherapy [27-29]. Notably, neutropenia and thrombocytopenia have been reported to occur more frequently with VEGFis monotherapy than with PARPis monotherapy, although the proportion of grade ≥ 3 anemia accounts for less than 4% of cases. The hematological toxicity of VEGFis may arise from their suppression of vascular endothelial growth factor (VEGF) signaling, which disrupts the bone marrow microenvironment, leading to vascular regression, hypoxia, and impaired stromal cell function, thereby compromising hematopoietic stem cell survival and differentiation. Concurrently, blockade of VEGF receptors (eg, VEGF receptors 1 and 2) on hematopoietic progenitor cells can interfere with erythroid, myeloid, and megakaryocytic maturation, resulting in anemia, neutropenia, and thrombocytopenia. Furthermore, VEGF inhibition may upregulate proinflammatory cytokines (eg, tumor necrosis factor and interleukin-6) and hepcidin, further suppressing hematopoiesis or inducing iron-restricted anemia. These mechanisms collectively contribute to the potential hematological adverse effects associated with VEGFis [30]. PARPis cause anemia by binding to poly (adenosine diphosphate ribose) polymerase 2 in the RBCs, leading to shortened life span and increased absorption of RBCs [31]. The possible mechanism of PARPi-mediated bone marrow suppression also includes inhibiting poly (adenosine diphosphate ribose) polymerase 1 in hematopoietic stem cells, interfering with neutrophil, platelet, and RBC formation [32]. Thus, it is hypothesized that the 2 together could worsen overall hematological toxicity via distinct mechanisms, increasing the risk of hematological adverse events of a grade of ≥3 in patients. This phenomenon can also be observed in the PAOLA-1 (PArp inhibitor OLaparib in Advanced ovarian cancer 1) clinical study of olaparib combined with bevacizumab in ovarian cancer treatment [33].

Other than the previously discussed factors, further parameters may modulate the development of SHAEs from PARPi therapy. Previous studies have found that *BRCA1* and *BRCA2* mutation or HRRD positivity is a risk factor for hematological adverse events related to PARPis [34-36]. Moreover, the Spanish Society of Medical Oncology clinical guidelines [37] for ovarian cancer indicate that PARPis induce cell death in HRRD-positive tumor cells through a “synthetic lethality” mechanism, with *BRCA1* and *BRCA2* mutations being one of the established causes of HRRD in tumors. Therefore, the guidelines recommend *BRCA* mutation testing in patients before PARPi therapy. However, due to the high cost of testing, this study found that the willingness of most patients with cancer to undergo *BRCA* and HRRD testing was low, with a detection rate of less than 55%. Therefore, it is difficult to verify the impact of *BRCA* and HRRD status on PARPi SHAEs. A network meta-analysis indicated that there was a significant difference in the risk of any adverse events of a grade of ≥3 across PARPi treatments, and based on the surface under the cumulative ranking curve rankings, olaparib was the safest PARPi in terms of risk of hematological adverse events [6]. Some studies have also found that hypertension, low baseline hemoglobin level, and low baseline hematocrit level are related to the occurrence of hematological adverse events induced by PARPi monotherapy [35]. Due to data limitations in this study, definitive comparative analyses could not be conducted, warranting future studies to address this gap.

On the basis of the identified predictive factors, this study developed a nomogram model to provide a user-friendly method for early prediction of SHAEs associated with PARPis in clinical practice. Internal validation demonstrated that this risk assessment model exhibited moderate accuracy and predictive capability, with an ROC curve AUC of 0.874 and Hosmer-Lemeshow test of P=.36. These findings provide evidence for developing personalized treatment strategies in clinical practice and suggest potential clinical utility.

This study also has several limitations. First, although repeated cross-validation showed no strong signs of overfitting, the small sample size limited our ability to fully address associated challenges such as data distribution biases and class imbalance. Furthermore, external validation, which is essential for confirming generalizability, could not be conducted due to the unavailability of an independent external cohort. This is a common constraint in single-center studies of rare conditions.

XSL•FO
RenderX

Future multi-institutional studies are warranted to externally validate our findings. The analysis was further limited by missing data for several key prognostic indicators (eg, *BRCA* and HRRD status), which precluded their inclusion in the model. Finally, as the model was developed and validated exclusively on a Chinese population, its generalizability to other ethnic groups requires further investigation.

Conclusions

This study used objective data widely used in clinical settings to create and internally test a basic predictive model of SHAEs for PARPi users with ovarian cancer. The clinical nomogram included the 4 best predictors of PARPi SHAEs: lymph node metastasis, Ccr, RBC count, and therapeutic schedule. This should help identify patients who need closer monitoring for SHAEs and more rigorous treatment.

Acknowledgments

This work was supported by the Scientific Research and Technology Development Project of the Guangxi Zhuang Autonomous Region Medical Products Administration (Contract No.: Gui Yao Ke [2022] Zixuan 23). The authors extend their sincere appreciation to the Affiliated Tumor Hospital of Guangxi Medical University for its invaluable support throughout this research. We are also deeply grateful to all the physicians, nurses, and healthcare professionals for their dedicated efforts and contributions. Above all, we wish to express our profound gratitude to the patients and their families for their trust, cooperation, and unwavering support.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

XL designed the study, collected and analyzed the data, and wrote the manuscript. YL supervised the research, critically revised the manuscript, and provided final approval. Both authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Publicly accessible critical care–related databases contain enormous clinical data, but their utilization often requires advanced programming skills. The growing complexity of large databases and unstructured data presents challenges for clinicians who need programming or data analysis expertise to utilize these systems directly.

Objective: This study aims to simplify critical care–related database deployment and extraction via large language models.

Methods: The development of this platform was a 2-step process. First, we enabled automated database deployment using Docker container technology, with incorporated web-based analytics interfaces Metabase and Superset. Second, we developed the intensive care unit–generative pretrained transformer (ICU-GPT), a large language model fine-tuned on intensive care unit (ICU) data that integrated LangChain and Microsoft AutoGen.

Results: The automated deployment platform was designed with user-friendliness in mind, enabling clinicians to deploy 1 or multiple databases in local, cloud, or remote environments without the need for manual setup. After successfully overcoming GPT's token limit and supporting multischema data, ICU-GPT could generate Structured Query Language (SQL) queries and extract insights from ICU datasets based on request input. A front-end user interface was developed for clinicians to achieve code-free SQL generation on the web-based client.

Conclusions: By harnessing the power of our automated deployment platform and ICU-GPT model, clinicians are empowered to easily visualize, extract, and arrange critical care–related databases more efficiently and flexibly than manual methods. Our research could decrease the time and effort spent on complex bioinformatics methods and advance clinical research.

KEYWORDS

big data; critical care–related databases; database deployment; large language model; database extraction; intensive care unit; ICU; GPT; artificial intelligence; AI; LLM

Introduction

Critical care medicine has experienced an explosion of complex, heterogeneous data from various sources, such as electronic medical records, monitoring systems, imaging, registries, and omics platforms. This massive amount of multimodal data, often referred to as "big data," offers enormous potential for improving patient outcomes in intensive care units (ICUs) through studies and analytics.

There are many high-quality medical databases that excel in the dimensions of volume, velocity, veracity, variety, and value. Examples include the Medical Information Mart for Intensive Care (MIMIC; MIMIC-III, MIMIC-IV, MIMIC-IV-Note, etc) at the Beth Israel Deaconess Medical Center in Boston [1-3], the Electronic Intensive Care Unit Collaborative Research Database (eICU-CRD) from 208 hospitals in the United States, and the Amsterdam University Medical Center Database (Amsterdam UMCdb) [4-6]. By integrating demographic, monitoring, laboratory, imaging, pharmacy, and waveform data, these databases provide a wealth of valuable information that

XSL•FO
RenderX

has facilitated clinical research [7] and expanded the evidence base for clinical practice [8]. Many studies have demonstrated the potential of leveraging ICU big data for applications such as risk stratification, predictive models, treatment recommendations, and cohort phenotyping [9-12].

However, there are significant barriers to translating big data resources into clinical insights and decision support for frontline critical care teams. The complexity of ICU data requires specialized skills in data wrangling, mining, visualization, and interpretation, which most clinicians need to acquire. The gap between data science and clinical science hinders harnessing big data to improve ICU care [13,14]. Despite the promise of rich data and analytics, the adoption of actionable insights depends on accessible interfaces and informative data presentations [15].

Recent advances in medical natural language processing using artificial intelligence (AI) and large language models (LLMs) like GPTs have demonstrated the potential for intuitive human-computer interaction with health care data. Clinicians do not have to learn complex programming languages, and interfaces based on natural language and clinical logic can make big data analysis more accessible. An increasing body of research demonstrates that AI applications significantly enhance the efficiency and accuracy of disease diagnosis and treatment. Farič et al [16] developed an AI-based imaging software tool for detecting pulmonary nodules in chest computed tomography scans. Through qualitative semistructured interviews, they demonstrated the tool's usability and effectiveness as both a decision-support system and a "second reader" for clinical users. Sjoding et al [17] employed a deep convolutional neural network to identify acute respiratory distress syndrome findings on chest radiographs. The convolutional neural network demonstrated expert physician-level accuracy in acute respiratory distress syndrome radiograph detection, as validated through comprehensive quantitative assessments using both internal and external test sets. However, general domain language models still face great challenges in handling niche biomedical data and require customization and continuous iterative improvement.

Therefore, we seek to empower clinicians by simplifying database deployment and developing the intensive care unit–generative pretrained transformer (ICU-GPT). This tool aims to simplify data extraction via LLMs, liberating clinicians from complex bioinformatics methods to focus on clinical research and data analysis. With ICU-GPT, clinicians can focus on clinical research advancement and feel more capable and in control of their data analysis.

Methods

Overview

To achieve the availability and visualization of critical care–related databases and simplify the process of data extraction, we developed this platform in 2 steps. Step 1 was database deployment based on Docker container technology through the web-based client rather than by installing other applications. Step 2 was the development of ICU-GPT based on LLMs to generate Structured Query Language (SQL) queries for data extraction after request input.

Technologies of the Database Deployment and Visualization

Docker is an open-source platform that, by utilizing containerization technology, enables users to package the applications together with all their dependencies into an isolated container to achieve portability, consistency, and high segregation [18]. Database deployment involves the installation and configuration of health care databases onto PostgreSQL. This process ensures proper data storage and operational functionality. Based on Docker technology and customized PostgreSQL database initialization scripts [19], we aimed for a cross-platform automated deployment of critical care–related databases on different operating systems.

Database visualization leverages business intelligence tools to graphically represent the structure, content, and relationships within a database. This approach not only facilitates simple plotting but also provides a comprehensive and intuitive understanding of the database's table structure and overall architecture. We provide 2 web-based clients with business intelligence tools to achieve database visualization: Metabase and Superset. Metabase and Superset are open-source data analytics and visualization tools for easy data exploration [20,21]. With simple and convenient working interfaces, they allow users to extract data from various sources without writing SQL statements, including relational databases (MySQL, PostgreSQL, SQL Server, etc) and NoSQL databases. They also enable users to add plugins and visualization components to meet specific requests with high extensibility and customizability.

Technologies of ICU-GPT

With the appearance of the OpenAI GPT-3.5 in 2023, we decided to use LLMs to participate in the SQL query generation process [22]. An LLM is a natural language processing tool driven by AI technology and has recently emerged as a powerful tool across many areas of biomedicine. It can generate answers based on patterns observed during the pretraining stage, summarize large amounts of text, generate high-quality text from a short description, create code that can help support data analysis, produce images based on a verbal description, and much more.

ICU-GPT does not develop new LLM models but utilizes and is compatible with all OpenAI application programming interface (API) models. We chose OpenAI API-compatible models for ICU-GPT development for several reasons. First, our research team is more familiar with OpenAI. There is also a large number of models compatible with the OpenAI API, including GPT-3.5, GPT-4o, and GPT-4o mini, offering wide applications and cost-effectiveness. Users can select the appropriate OpenAI API model based on their specific requirements. Moreover, OpenAI encompasses knowledge bases from the MIMIC databases, which other models lack, including *International Classification of Diseases* (*ICD*) codes and itemid data.

XSL•FO
RenderX

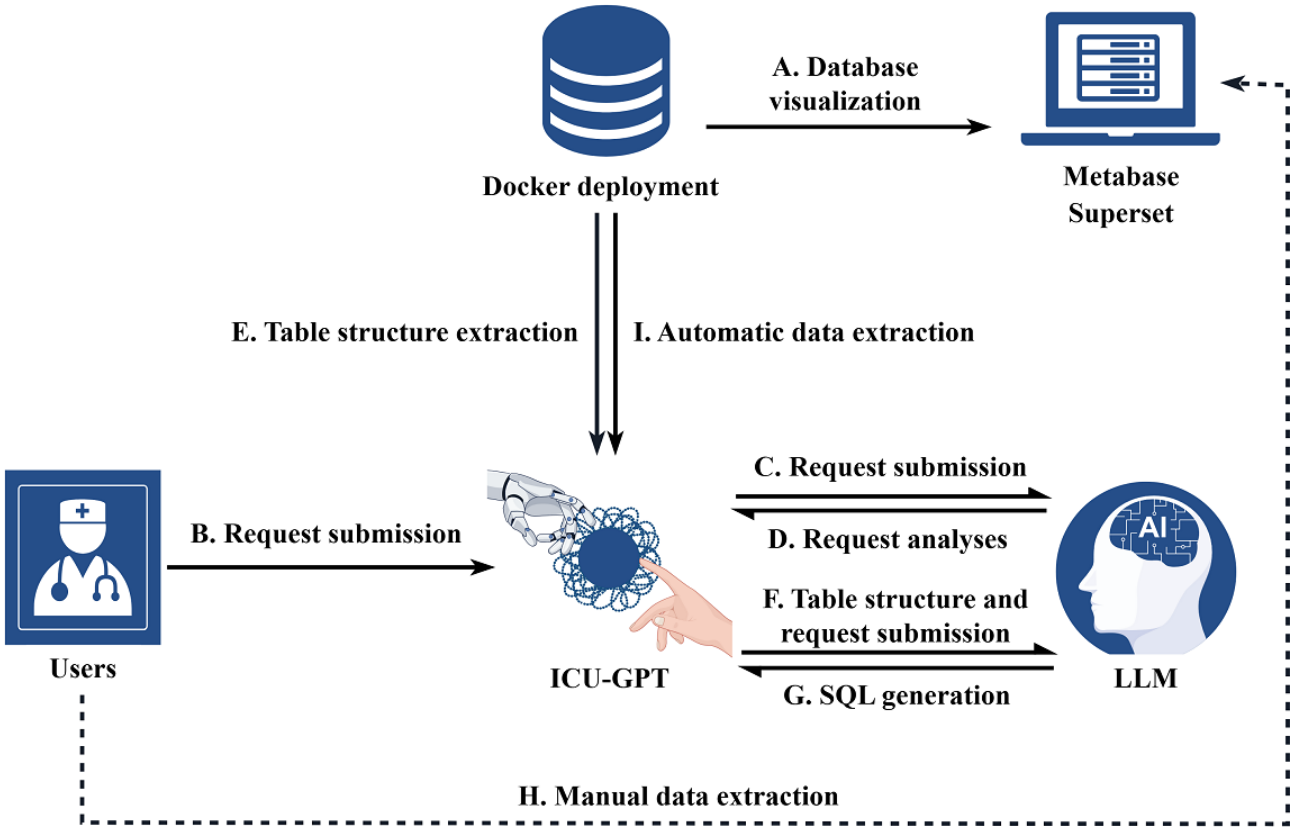
Using the BIRD and Spider, 2 extensive cross-domain datasets designed to evaluate the impact of comprehensive database content on text-to-SQL parsing, we conducted a comparative analysis of OpenAI API models with other models [23,24]. The OpenAI API models demonstrated consistently high performance in execution accuracy and reward-based valid efficiency within the BIRD dataset [25]. Furthermore, these models exhibited stable and superior performance in execution with values within the Spider dataset [26]. Although reports suggest that certain models may surpass OpenAI's performance, we were unable to include them in our comparison due to limitations in accessibility [27-30]. Moreover, due to the absence of a benchmark dataset specifically tailored for critical care–related databases, it remains challenging to directly compare ICU-GPT's performance with other models on such databases.

Ollama is a lightweight framework with high extensibility for building and running LLMs on local and cloud environments [31]. It provides an API for model creation, execution, and management as well as a prebuilt model library. It is compatible with the OpenAI API for dialogue creation. The development of ICU-GPT also involved 4 technologies: LangChain, Microsoft AutoGen, Pandas, and Gradio.

LangChain is an open-source Python library that provides the modules and tools to build AI applications based on LLMs [32]. It can easily integrate with LLMs to achieve text generation, question-answering, and translation. The LangChain SQL database object was adopted and adjusted in our platform to support databases with multiple schemas, such as MIMIC and eICU-CRD.

Microsoft AutoGen is a framework that can be customized and conversed with, facilitating the development of LLM applications and seamlessly allowing for human participation [33]. Userproxy is a specialized agent within Microsoft AutoGen that receives users' requests and generates appropriate prompts. GroupChat comprises 2 agents and Userproxy, working in tandem to facilitate the contemplation, execution, and refinement of users' requests.

Pandas is a powerful Python-based library. It could provide accessible data structures to make data cleaning, transformation, and analysis more convenient [34]. Current data extraction functions are developed based on Pandas to achieve data processing.



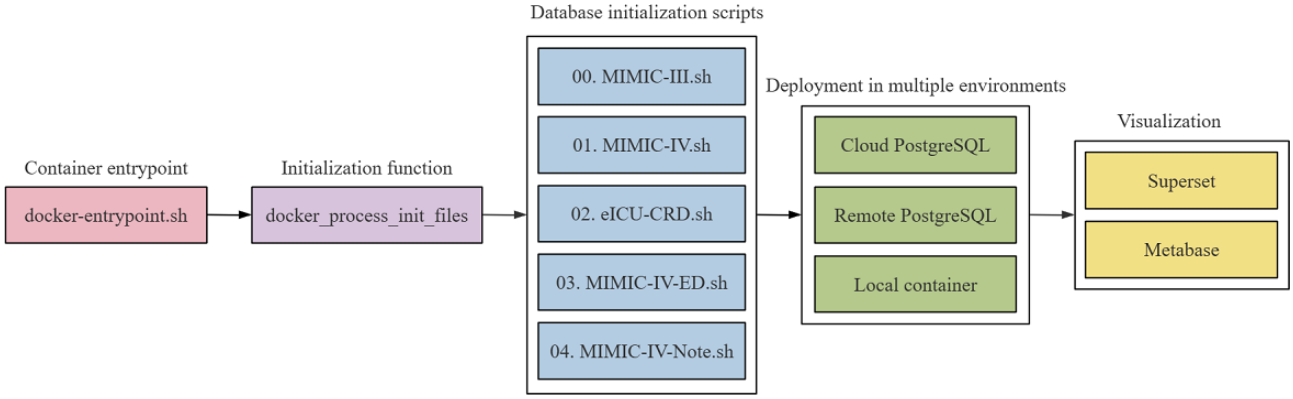
Gradio is an open-source Python library. It enables developers to transform machine learning models and various functions into shareable web applications, facilitating a quick and easy showcasing of their work through intuitive and accessible interfaces [35].

Results

We summarized the workflow of database deployment, visualization, SQL generation, and data extraction in Figure 1.

XSL•FO
RenderX

Figure 1. The procedures for the platform construction. The platform construction workflow encompasses several key components: database deployment based on Docker container technology; visualization powered by Metabase and Superset (A); SQL generation involving multiple rounds of interaction between users, LLMs, and ICU-GPT, including request submission, analysis, table structure extraction, and SQL generation (B to G); and data extraction (H and I). (A) Critical care–related database visualization based on Metabase and Superset. (B) Users send data extraction requests to ICU-GPT. (C) ICU-GPT sends requests to the LLM. (D) The LLM splits and analyzes the requests and sends them back to ICU-GPT. (E) ICU-GPT extracts table structure information from databases. (F) ICU-GPT sends requests and table structure information to the LLM. (G) The LLM generates SQL queries and sends them to ICU-GPT. (H) Users can choose to manually verify the SQL queries in Metabase and Superset. (I) ICU-GPT runs the SQL automatically for data extraction. ICU-GPT: intensive care unit–generative pretrained transformer; LLM: large language model; SQL: Structured Query Language. Figure created using Figdraw.



Database Deployment and Visualization

We adopted Docker technology to achieve the simplicity and flexibility of the cross-platform automated deployment of critical care–related databases. Functions of docker_process_init_files in docker-entrypoint.sh possess the mechanism of scanning shell files automatically in specific directories during the initial PostgreSQL container startup. The corresponding database initialization scripts are placed in the scanning path. Based on the mechanism, we named the files according to specific numbers to ensure the initialization process ran in the intended order and initialized the databases accordingly.

Our deployment platform supports several public critical care–related databases through PostgreSQL database initialization scripts, including MIMIC-III, MIMIC-IV, MIMIC-IV-ED (Medical Information Mart for Intensive Care IV – Emergency Department), MIMIC-IV-Note, eICU-CRD, etc. Clinicians can select the corresponding database initialization scripts or combine multiple scripts according to their specific requests. This design also allows clinicians to initialize the database with multiple phases in local, cloud, or remote environments and support database upgrades with great flexibility. Through 2 business intelligence solutions, Metabase and Superset, data querying, extraction, and charting can be easily performed by the web-based client without the installation of any other applications (Figure 2).

XSL•FO
RenderX

Figure 2. Deployment and visualization of critical care–related databases. eICU-CRD: Electronic Intensive Care Unit Collaborative Research Database; MIMIC: Medical Information Mart for Intensive Care; MIMIC-IV-ED: Medical Information Mart for Intensive Care IV – Emergency Department.

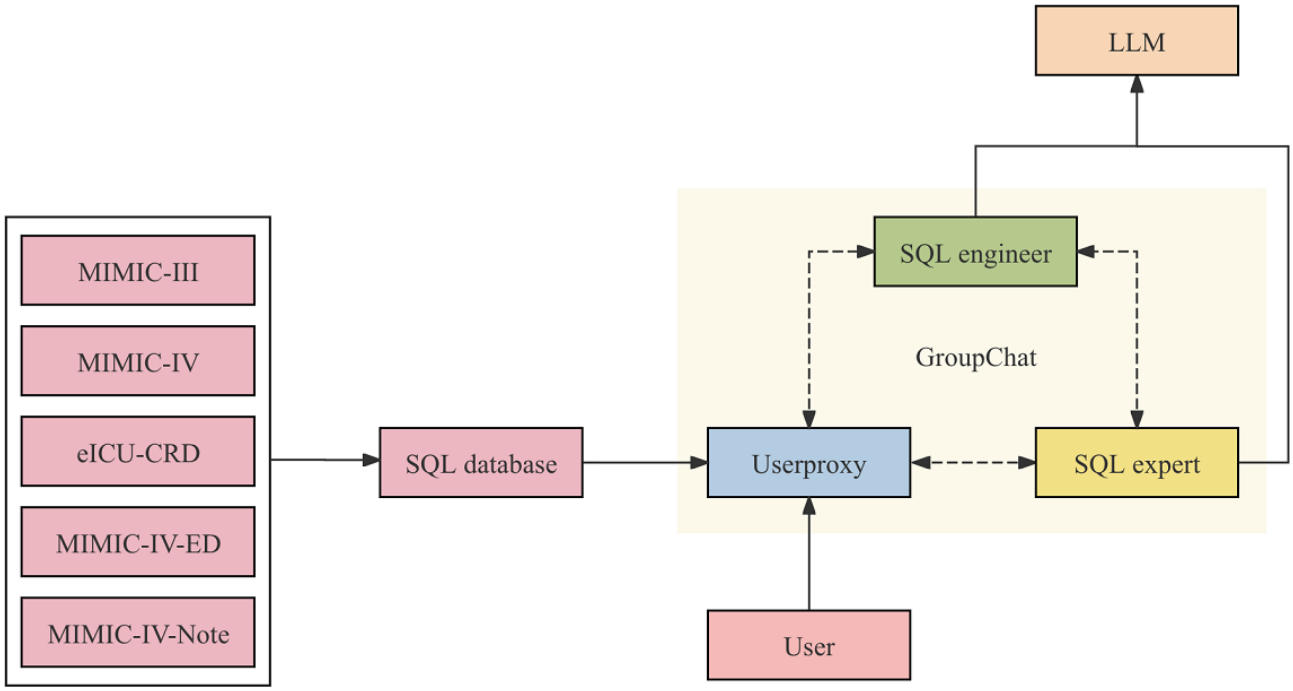
SQL Query Generation and Data Extraction

We developed ICU-GPT to accurately assist in SQL query writing and provide a more intelligent and efficient approach to simplify data extraction.

Extensive research was conducted on SQL query generation. We found that most SQL query generation tools were only practical for tables under a single schema or merely supported a single table. The handling of databases with multiple schemas, such as MIMIC, was found to be poor. By thoroughly studying the source code of table information retrieval based on the LangChain SQL database object, we successfully overcame this deficiency and achieved multischema support.

Given the massive number of MIMIC tables, the actual tokens used to generate prompts exceed the upper limit of 16,000 tokens in OpenAI GPT-3.5. To address this issue, the table selection function was introduced to allow clinicians to generate SQL queries within a specific table range. This innovation not only solved the problem of the token limit but further improved the accuracy of SQL query generation. On the basis of this innovation, our platform is now highly flexible and available for more complex database structures.

Two agents and a Userproxy were established as a GroupChat using Microsoft AutoGen. One agent serves as the SQL engineer, responsible for SQL generation, while the other agent acts as the SQL expert, verifying and optimizing the SQL generated by the SQL engineer. A manager was also created to supervise the GroupChat and facilitate information interaction and agent selection within the group.



The Userproxy generates prompts based on clinicians' requests and tables specified by users, then sends them to the manager. The manager transmits these prompts to agents and selects an appropriate agent to process the prompt using a relevant algorithm. This selected agent then sends the prompts to the LLM. The LLM generates SQL based on prompts and requests and then sends it back to the manager. The manager repeats this process, sending messages to agents and selecting the appropriate agent using the algorithm. The LLM receives prompts from the selected agent and interacts with the requests. The SQL expert evaluates the performance and accuracy of the generated SQL. If the SQL expert determines that the SQL accuracy is suboptimal, an iterative dialogue process is initiated to refine and improve the SQL as much as possible.

As AI cannot fully replace human intelligence, there are limitations when users input prompts based on their research objectives. This is particularly evident when the entered keywords are not comprehensive, synonyms or similar prompts are used, or even when typos occur. In such cases, ICU-GPT may struggle to fully comprehend the user's intent, potentially leading to incorrect or incomplete responses. To address this, SQL is not automatically executed after generation. Instead, users are given the opportunity to review and inspect the generated SQL themselves. If the results are unsatisfactory, users can further refine and optimize their prompts. This approach fosters a dynamic human-AI collaboration, maximizing SQL accuracy and user satisfaction (Figure 3) [36,37].

The code of the platform development is available online [38]. We warmly welcome and greatly appreciate any user feedback or new ideas, which can be submitted to us via GitHub. We will update ICU-GPT versions when the MIMIC and eICU-CRD databases are updated or when improved models become available. Some examples of how to achieve database deployment and SQL generation based on Python are presented in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 3. SQL query generation process. The GroupChat consists of the Userproxy, the SQL engineer, and the SQL expert. The manager is created to facilitate communication and information synchronization within the group. The SQL engineer is responsible for SQL generation and interaction with the LLM while the SQL expert is responsible for SQL optimization. The Userproxy generates prompts based on clinicians' requests and user-specified tables. The manager then selects appropriate agents to process these prompts using the LLM. The LLM generates SQL queries, which are subsequently evaluated by the SQL expert. If necessary, an iterative dialogue ensues to refine the SQL for optimal accuracy and effectiveness. eICU-CRD: Electronic Intensive Care Unit Collaborative Research Database; LLM: large language model; MIMIC: Medical Information Mart for Intensive Care; MIMIC-IV-ED: Medical Information Mart for Intensive Care IV – Emergency Department; SQL: Structured Query Language.

User Interface of ICU-GPT

We developed a front-end user interface using Gradio and ICU-GPT to simplify the SQL generation process. Users can download our prebuilt Docker mirroring in the Dockerfile and follow the instructions to achieve code-free SQL generation on the web-based client [39]. First, users select a database: MIMIC-III, MIMIC-IV, MIMIC-CareVue, or eICU-CRD (Figure 4). The platform displays all table names under all schemas of the selected database. Users select the corresponding tables based on their requests (Figure 5). Users then input requests in the "Prompt" section and press "Submit" (Figure 6). Our platform supports prompts both in Chinese and English. Finally, the SQL bot outputs the SQL queries (Figure 7).

Discussion

Principal Results

In order to conduct the critical care–related database mining as efficiently and thoroughly as possible, we developed a platform in two steps: (1) we first implemented critical care–related database deployment by applying Docker container technology with 2 visualization tools, Metabase and Superset; (2) ICU-GPT was then developed based on LLMs to achieve SQL query generation and data extraction. By fully utilizing the advantages of open-source technology and being highly replicable and scalable, this platform provides great convenience for clinicians.

The critical care–related public databases cover a large sample size with various aspects during hospitalization, including demographic, physiologic, laboratory measurements, diagnoses, and medication administration data, which represents a certain degree of universality. While bringing tremendous clinical value, it is accompanied by the increasing complexity of database size and table structures. Even professional database administrators find it challenging to explore the table structures. Much time and effort would be spent on clinicians understanding the table

XSL•FO
RenderX

structure and performing data extraction. Therefore, we simplified the complex and time-consuming process into 2 steps.

With Docker container technology, we first provided an efficient and reliable deployment solution to support the widespread application of critical care–related databases. With high repeatability and consistency, the automated deployment solution provides a professional and convenient database management and visualization tool for clinicians to arrange massive amounts of data.

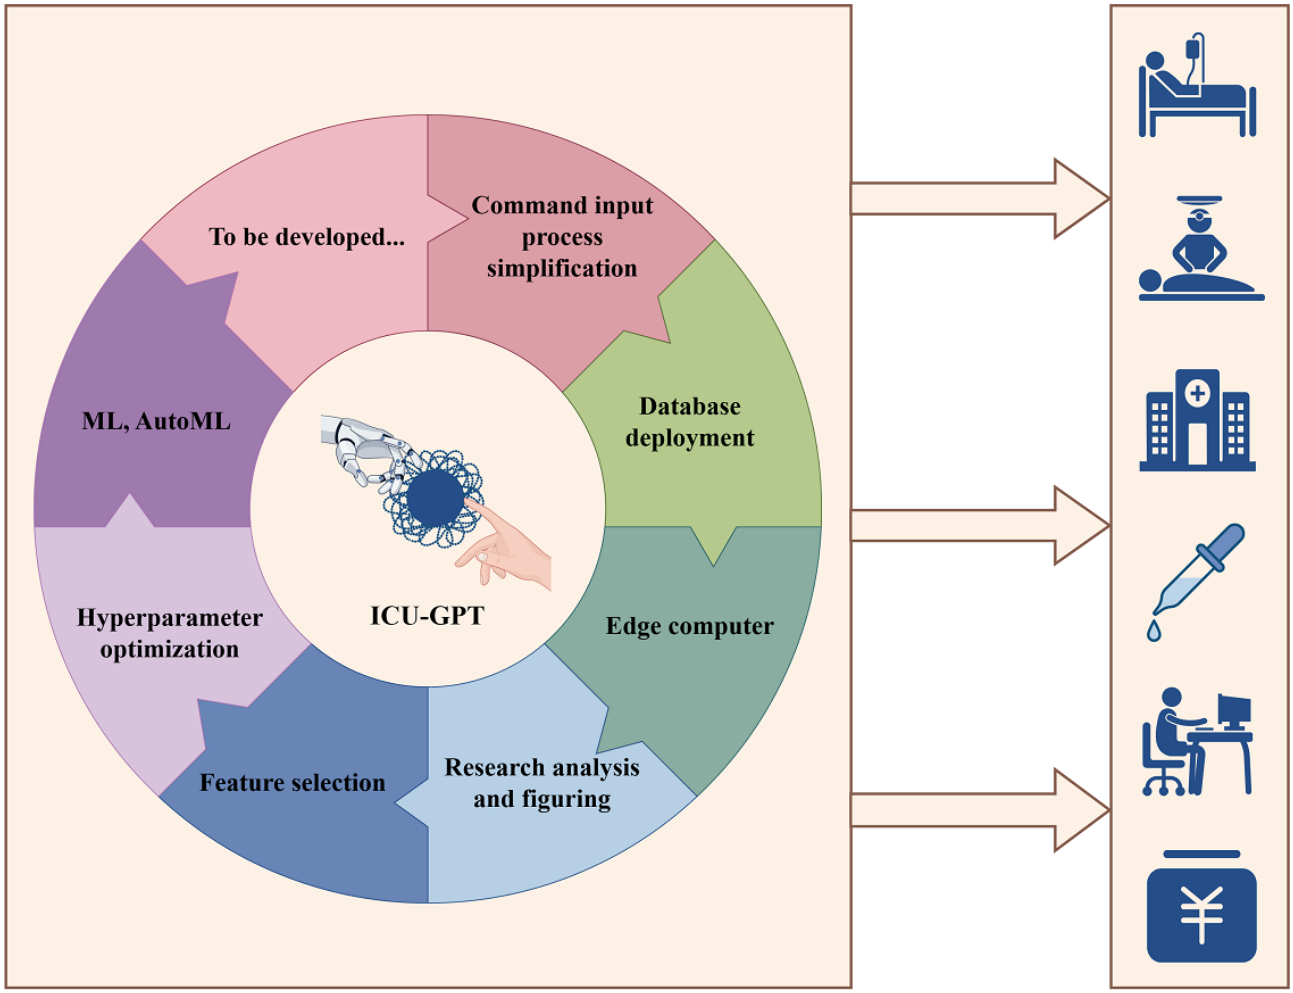
After database deployment, we aimed to simplify the data extraction process. The Python peewee Object Relational Mapper library was considered for analyzing the database table structures automatically, binding them to peewee objects, and encapsulating the corresponding data extraction functions [40]. After multiple tests, although this approach could save the learning cost of SQL and database structures, programming foundation and data analysis experience in personalized extraction and data processing were still required. Despite extensive consideration of potential solutions for this problem, we could not achieve satisfactory outcomes, which led to a stagnation of the development process.

LLMs have recently emerged as powerful tools across many areas of biomedicine. As mentioned, they can rapidly summarize large amounts of text, generate high-quality text from a short description, create code that can help support data analysis, produce images based on a verbal description, and much more. Therefore, based on LLMs, we integrated LangChain and Microsoft AutoGen to develop the ICU-GPT. It not only overcame the token limit of GPT and supported multischema data, but it also achieved the seamless integration of SQL query generation and data extraction.

ICU-GPT empowers users with clinical expertise without data extraction proficiency to extract information from professional databases, significantly reducing the time spent on self-directed learning. However, quantifying the time saved and the efficiency gains from this learning process is complex, making it difficult to compare pre- and postimplementation efficiency improvements.

We agree that a comprehensive evaluation is crucial to demonstrate the system's effectiveness and reliability. While this study focuses on design and implementation, we are actively implementing a thorough evaluation of ICU-GPT's performance metrics. These include SQL query accuracy, system speed, user satisfaction, and the handling of large-scale datasets.

Limitations and Implications



Our study has several limitations. First, our platform only involved MIMIC-III, MIMIC-IV, and eICU-CRD to demonstrate the methodological feasibility and clinical applicability of ICU-GPT in database deployment and data extraction in critical care–related databases. We will expand the research achievements to other databases and enrich the prompt templates of ICU-GPT, such as the Amsterdam UMCdb and high time–resolution intensive care unit dataset (HiRID) [6,41]. Issues of data security and ethical procedures require further improvement. The MIMIC and eICU-CRD databases were deidentified prior to their release, replacing identifiers with random integers while preserving data integrity to maximize data privacy to the fullest extent possible. However, more private databases may be developed in the future. Special attention should be paid particularly to these databases. Adherence to health care regulations, such as the Health Insurance Portability and Accountability Act (HIPAA) in the United States or the General Data Protection Regulation (GDPR) in Europe, is crucial. Second, multiple tests were conducted to verify the reliability and stability of the platform. Systematic evaluation and validation of this platform are warmly welcomed to facilitate further exploration of critical care–related databases. Third, ICU-GPT mainly focuses on structured data SQL generation and analysis. We plan to leverage function calls and the Medical Concept Annotation Toolkit (MedCAT) to achieve unstructured data extraction and analysis like clinical notes from electronic health records in the future [42]. This will enable us to link the unstructured data to biomedical models, facilitating more comprehensive database mining. We will continue to enhance ICU-GPT and strive to achieve automated data processing through Pandas. Fourth, ICU-GPT, as a system built on existing LLMs, may inherit certain biases or limitations from the underlying models. These biases are a known challenge with LLMs due to the nature of their training on large-scale datasets, which may contain imbalances or inaccuracies. To mitigate these risks, we have implemented several measures. We chose OpenAI API compatible models for ICU-GPT development for its incorporation of knowledge bases from the MIMIC database, which includes crucial *ICD* codes and itemid data that other models lack. The system is designed to be used as a human-in-the-loop tool rather than an autonomous system, with users reviewing and validating the generated outputs. We also actively monitor the system's performance in real-world applications and incorporate user feedback to iteratively improve accuracy and reliability. Moreover, periodic audits are conducted to identify and address potential biases in the system's responses. Fifth, it is indispensable to note that AI cannot replace human intelligence and judgment. Cautious inspection and correction are required for platform improvement.

Despite the aforementioned limitations, this study addresses the development of ICU-GPT to simplify critical care–related database deployment and extraction via LLMs. Further work may focus on enhancing the intelligence level of ICU-GPT, such as achieving autonomous SQL generation based on complex requests, rather than relying solely on fixed templates. It is also anticipated that researchers and developers will create advanced tools for the auxiliary diagnosis and treatment of critical illnesses, as well as sophisticated diagnostic decision support systems based on ICU-GPT.

The massive expansion of critical care–related databases and functions in ICU-GPT will offer enormous potential to uncover patterns, derive predictive models, tailor interventions, and enable precision medicine through data science [43]. This will further hold immense potential and promising broad prospects for patient care, clinical work, hospital development, academic progress, administrative management, and business improvement (Figure 8). This area of research is ripe for exploration and could lead to groundbreaking advancements in the field.

Conclusions

Leveraging our automated deployment platform and ICU-GPT model, clinicians can now easily visualize, extract, and organize public critical care–related datasets with greater efficiency and flexibility compared to manual methods. By reducing the time and complexity of bioinformatics analysis, our platform and customized LLM enable clinicians without programming expertise to harness large ICU databases for clinical research advancements. The end-to-end solution from deployment to analysis makes complex data more accessible to frontline ICU staff, unlocking the potential of big data to enhance evidence-based care and outcomes for critically ill patients. Overall, this work demonstrates the promise of thoughtful human-AI collaboration in transforming critical care delivery through data-driven insights.

Data Availability

The code of the developed platform is available online [38].

Authors' Contributions

ZY, SSX, and XL designed this study. ZY, XL, NX, YC, and SW completed the coding for the database deployment. ZY, SSX, MYM, MH, SL, and YMZ completed the coding for intensive care unit–generative pretrained transformer (ICU-GPT) development. SSX, XL, and LZ drafted the manuscript. LZ and JXZ revised the manuscript. All authors read and approved the final manuscript. JXZ and LZ contribute equally as corresponding authors.

Abstract

Background: Asthma is a common chronic respiratory disease with increasing prevalence among children over the past few decades. It can cause significant respiratory symptoms and acute exacerbations, often requiring emergency care or hospitalization. Moreover, exposure to respiratory viral infections, such as COVID-19 and influenza, can trigger severe complications in children with asthma. Despite these concerns, few studies have directly compared the in-hospital outcomes of children with asthma experiencing these infections.

Objective: This study aimed to compare the in-hospital outcomes of these infections in children with asthma from a population-based perspective.

Methods: We conducted a population-based retrospective cohort study using data from the 2020 US Nationwide Readmissions Database. Children aged 1 to 19 years with asthma who were admitted for COVID-19 or influenza were eligible for inclusion. Outcomes evaluated included in-hospital mortality, major complications, and 90-day readmission rate. Survey-weighted logistic regression models were used to compare clinical outcomes between the two infection groups, adjusting for demographic and clinical characteristics.

Results: A total of 1472 hospitalized children with asthma were included, of whom 405 (27.5%) were admitted for COVID-19 and 1067 (72.5%) for influenza. After adjustment, the multivariate analysis revealed that children admitted for COVID-19 had a significantly higher risk of sepsis or shock (adjusted odds ratio [aOR] 4.30, 95% CI 1.79-10.32) but a lower risk of bacterial or fungal pneumonia (aOR 0.37, 95% CI 0.23-0.61) compared with those admitted for influenza. Stratified analyses by age revealed that among children aged 1 to 5 years, the risk of 90-day readmission was significantly higher for those with COVID-19 than for

XSL•FO
RenderX

those with influenza (aOR 3.02, 95% CI 1.09-8.35). No significant difference in in-hospital mortality was detected between the two infection groups in either the multivariable model or any of the age-stratified analyses.

Conclusions: US children with asthma hospitalized for COVID-19 had higher risks of sepsis or shock compared to those admitted for influenza. In contrast, children admitted for influenza had a higher risk for bacterial or fungal pneumonia. After stratifying by age, children aged 1 to 5 years with COVID-19 had a significantly higher risk of 90-day readmission than those with influenza. Our findings suggest that different clinical approaches may be needed for children with asthma, depending on infection etiology and patient age.

KEYWORDS

asthma; children; influenza; COVID-19; National Readmission Database; NRD

Introduction

Background

Asthma prevalence has risen steadily worldwide over the past 4 decades [1]. The incidence of childhood asthma has markedly increased over the past 40 years. Despite therapeutic advances, underdiagnosis and undertreatment remain common in children with asthma [2,3].

Respiratory viral infections such as COVID-19 and influenza often precipitate severe asthma exacerbations in children. Recent research indicates that asthma increases the risk of hospitalization in children with COVID-19 [4,5]. In addition, individuals with uncontrolled asthma are more likely to experience severe illness from COVID-19 that requires hospitalization [6]. Similarly, influenza can also lead to a worsening of asthma symptoms and may require hospitalization [7].

Although children with asthma who contract COVID-19 or influenza often experience more severe disease than their peers without asthma, there is a lack of studies examining the in-hospital outcomes of children with asthma who develop COVID-19 or influenza. Lee et al [8] analyzed the Korean Childhood Asthma Study cohort and showed that health care use among children with asthma significantly decreased during the COVID-19 pandemic, suggesting that only more severe cases reached hospital care. Furthermore, longitudinal work by Yoon et al [9] identified distinct phenotypic trajectories of childhood asthma with allergic comorbidities, underscoring the importance of age-specific risk estimates. However, no national study has directly compared the in-hospital outcomes of children with asthma admitted with COVID-19 versus those admitted with seasonal influenza.

Objectives

The purpose of this study was to compare in-hospital mortality, major complication rates, and 90-day readmission rates between children with asthma admitted for COVID-19 and those admitted for influenza using a national US database.

Methods

Data Source

The Nationwide Readmissions Database (NRD) is a database of all-payer hospital inpatient stays that can be used to generate national estimates of readmissions [10]. The NRD is a 100% sample from the Health Care Cost and Utilization Project (HCUP) State Inpatient Databases with discharge-level and hospital-level exclusions. The database contains verified patient linkage numbers that can be used to track a person across hospitals within a state while adhering to strict privacy guidelines. Researchers can identify diagnoses and procedures in the NRD using the *ICD-10-CM* (*International Classification of Diseases, 10th Revision, Clinical Modification*) and the *ICD-10-PCS* (*International Classification of Diseases, 10th Revision, Procedure Coding System*) codes. We used deidentified patient records from hospital discharges across multiple states, which allowed researchers to track readmissions nationally. Our research team obtained access to the NRD through the HCUP central distributor as per a data use agreement. The database is not open access in the sense of being freely downloadable; however, it is accessible to researchers worldwide who complete the requisite training and agree to the terms of the HCUP.

Study Design and Population

This population-based retrospective cohort study used NRD data from the year 2020. Inclusion criteria for this study were (1) children aged 1 to 19 years; (2) first admission for COVID-19 or influenza between January 1 and September 30, 2020, identified by the relevant *ICD-10-CM* codes documented as the principal diagnosis; and (3) asthma as a secondary diagnosis. Children with missing information on the main end points, sex, and sample weights were excluded. Following the index admission, patients were considered *at risk* for hospitalization and were followed until December 31 of the admission year or until death. Detailed *ICD-10-CM* codes used are provided in Multimedia Appendix 1.

Ethical Considerations

This study is a secondary analysis and adheres to the terms of the HCUP data use agreement. Specifically, the data were acquired from the online HCUP central distributor and were anonymized and publicly available. According to 45 CFR §46.104(d)(4) of the US Common Rule, secondary research on publicly available, fully deidentified data is exempt from institutional review board (IRB) review [11]. Hence, this study was exempt from IRB approval as per our institutional guidelines. Therefore, no informed consent or further IRB approval was required.

XSL•FO
RenderX

Variables and Outcome Measures

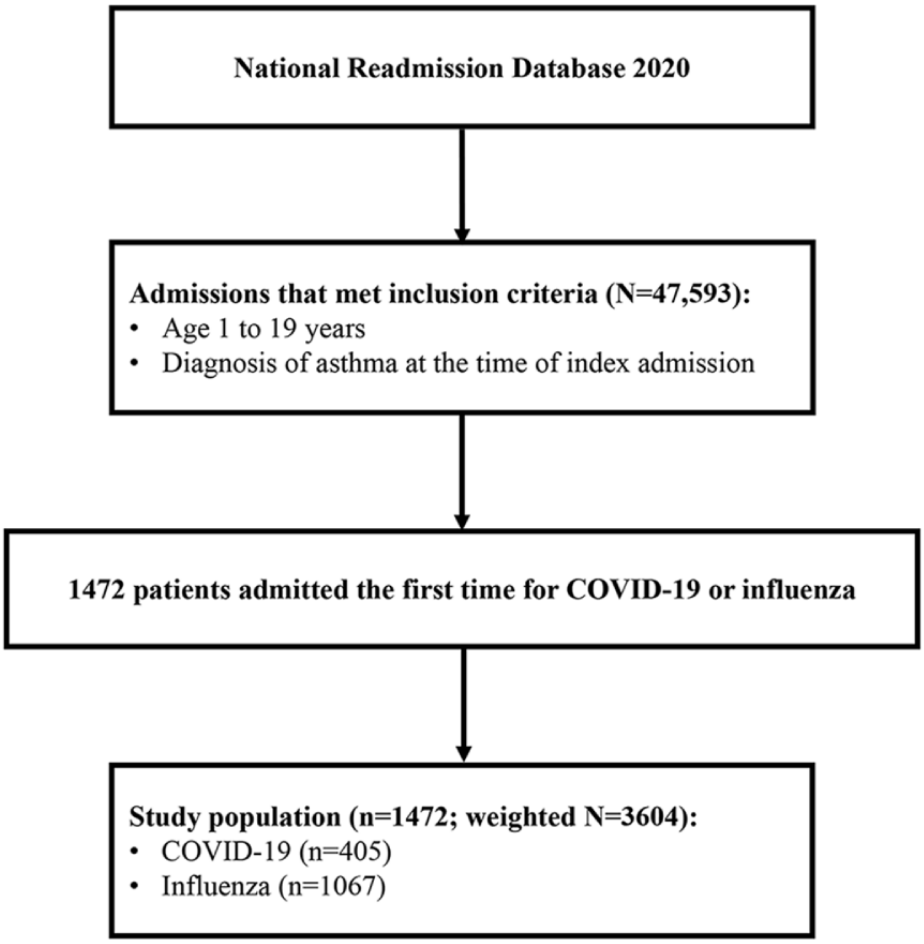
Data collected included patient age, sex, insurance status, and household income. Asthma was defined exclusively by *ICD-10-CM* code J45, which is assigned by trained coders only when a treating clinician documents a definite diagnosis of asthma. Furthermore, data relating to hospital characteristics such as weekend admission, admission type (emergent or elective), hospital bed size, and location or teaching status were collected. Major comorbidities extracted from the medical records and included in the analysis were hypertension, diabetes mellitus, obesity or overweight, neurological diseases, Down syndrome or chromosomal anomalies, metabolic diseases, cystic fibrosis, sickle cell disease, congenital heart conditions, congenital lung conditions, autoimmune disease, and mental or physical disabilities. These are comorbidities frequently considered in hospital admissions of children.

The outcomes evaluated included in-hospital mortality and complications, including sepsis or shock, secondary bacterial or fungal pneumonia, respiratory failure or mechanical ventilation, and acute kidney injury. In addition, 90-day readmission rates were assessed.

Statistical Analysis

The NRD includes discharge-level weights, stratum variables, and cluster Hospital identifier variable in the Nationwide Readmissions Database variables, which were used to estimate discharges from community hospitals in the United States, excluding rehabilitation and long-term acute care facilities. These variables were also used to calculate SEs and produce national estimates for all analyses in this study. In SAS statistical software (SAS Institute), the survey procedure is available for the analysis of sample survey data. Descriptive statistics of patients at the time of index admission were presented as either number and weighted percentage or mean and SE, and patients were categorized into the COVID-19 or influenza group. Categorical data were examined using the PROC SURVEYFREQ (survey frequency procedure) statement, while continuous data were assessed using the PROC SURVEYREG (procedure for survey regression analysis) statement. The SURVEYFREQ procedure includes the Rao-Scott chi-square test to assess the significance between weighted proportions. The SURVEYREG procedure fits linear models for survey data and provides significance tests for the model effects. For univariate analyses, no correction was applied for multiple comparisons, as these were considered exploratory. This approach is supported by methodological literature, which suggests that adjustment for multiplicity is not always necessary in such contexts [12].

Logistic regressions were performed using the PROC SURVEYLOGISTIC (procedure for survey logistic regression analysis) statement to compare the risk of adverse outcomes between children admitted for COVID-19 or influenza, including in-hospital mortality, major complications, and 90-day readmission, adjusting for covariates with significance in the univariate analysis in a multivariable model. Data were reported as odds ratios and 95% CI. All *P* values were 2-sided, and the value of $P<.05$ was considered statistically significant. Statistical analyses were performed using SAS software (version 9.4; SAS Institute).



Results

Patient Selection

The selection process for the study population is illustrated in Figure 1. A total of 1472 patients aged 1 to 19 years with asthma who were admitted for the first time with COVID-19 or influenza were identified in the 2020 NRD. Of the 1472 patients, 405 (27.5%) were admitted for COVID-19 and 1067 (72.5%) for influenza. This sample represented 3604 individuals who were hospitalized in the entire United States after applying the sample weights provided by the NRD.

XSL•FO
RenderX

Figure 1. Flow diagram of patient selection for a nationwide retrospective cohort study of US children aged 1–19 years with asthma who were hospitalized for a first diagnosis of COVID-19 or seasonal influenza between Jan 1 and Dec 31, 2020, in the Nationwide Readmissions Database (NRD); final analytic sample: n=1472 (weighted N=3604).

Patient Characteristics

Patient characteristics are summarized in Table 1. The mean age of all patients was 8.5 (SD 0.2 years), and 59% (862/1472) were male individuals. Significant differences were observed in age, household income, insurance status or primary payer, hospital bed size, and location or teaching status between patients with COVID-19 and those with influenza. In addition, the proportions of patients with diabetes mellitus, hypertension, obesity or overweight, metabolic diseases, sickle cell disease, and congenital heart conditions were significantly different between patients with COVID-19 and those with influenza.

[b]AKI: acute kidney injury.

[c]Data excluding patients who died in the hospital.

[d]HMO: Health Maintenance Organization.

[e]DM: diabetes mellitus.

Patients admitted for COVID-19 had higher frequencies of in-hospital mortality (2.5% vs 0.4%; *P*=.003), sepsis or shock (8.4% vs 1%; *P*<.001), respiratory failure or mechanical ventilation (9.1% vs 4.3%; *P*<.001), and acute kidney injury (9% vs 2.2%; *P*<.001) compared to those admitted for influenza. On the other hand, the proportion of patients with secondary bacterial or fungal pneumonia was significantly higher in the group admitted for influenza compared to the group admitted for COVID-19 (18% vs 8%; *P*<.001).

Comparison of Adverse Outcomes Between Children Admitted for COVID-19 and Those Admitted for Influenza

A comparison of outcomes between children admitted for COVID-19 and influenza is provided in Table 2. After adjustment in the multivariable analysis, patients admitted for COVID-19 had a significantly higher risk of sepsis or shock (adjusted odds ratio [aOR] 4.30, 95% CI 1.79-10.32; *P*=.001) but a lower risk of secondary bacterial or fungal pneumonia (aOR 0.37, 95% CI 0.23-0.61; *P*<.001) compared to those admitted for influenza (Table 2).

Comparison of Adverse Outcomes Between Children Admitted for COVID-19 and Those Admitted for Influenza, Stratified by Age

The results of the stratified analysis are shown in Table 3. Among patients aged 1 to 5 years, those admitted for COVID-19 had a significantly higher 90-day readmission rate (aOR 3.02, 95% CI 1.09-8.35; *P*=.03) and a significantly lower risk of secondary bacterial or fungal pneumonia (aOR 0.13, 95% CI 0.02-0.96; *P*=.046) compared to those admitted for influenza. In those aged 6 to 10 years, children with asthma who were admitted for COVID-19 had a significantly higher risk of sepsis or shock (aOR 6.64, 95% CI 1.23-35.91; *P*=.03). Among adolescents aged 11 to 19 years, patients admitted for COVID-19 had a significantly higher risk of sepsis or shock (aOR 4.79, 95% CI 1.79-12.84; *P*=.002) but a significantly lower risk of secondary bacterial or fungal pneumonia (aOR 0.42, 95% CI 0.24-0.73; *P*=.002; Table 3).

Discussion

Principal Findings

In this study, we compared the outcomes of children with asthma who were hospitalized with COVID-19 or influenza using the US NRD. Our analysis showed that children with asthma hospitalized for COVID-19 had a higher risk of sepsis or shock, whereas those hospitalized for influenza had a higher risk of secondary bacterial or fungal pneumonia. There was no significant difference in in-hospital mortality between the two groups. Furthermore, age-stratified analysis indicated that children aged 1 to 5 years with COVID-19 had a 3-fold higher risk of 90-day readmission compared to those with influenza. In adolescents (aged 11 to 19 years), the COVID-19 group faced a higher sepsis or shock risk but a lower risk of secondary bacterial or fungal pneumonia. These findings highlight the different clinical challenges in managing influenza and COVID-19 in children with asthma.

Comparison With Prior Work

Both influenza and COVID-19 are serious infections, and comorbidities such as asthma can worsen their clinical outcomes. While there have been studies comparing the outcomes of these infections in adults, there is limited research on children, especially those with asthma. Xie et al [13] found that hospitalization for COVID-19 was associated with a higher risk of death compared to that for influenza (6% for COVID-19 vs 3.7% for influenza; hazard ratio 1.16). The risk of death decreased with "with increasing numbers of COVID-19 vaccinations (*P*=.009). An earlier study comparing patients diagnosed with influenza during the 2017 to 2018 season to those diagnosed with COVID-19 between February and June 2020 found that, despite being younger and having fewer comorbidities, patients with COVID-19 had a higher risk of severe illness [14]. Dupont et al [15] found worse outcomes in adults with asthma who had COVID-19 compared to those with asthma who had influenza. However, these studies did not focus on pediatric or asthma populations.

Most studies on COVID-19 in children with asthma indicate that coexisting asthma is linked to a poorer prognosis. For example, Robbins et al [16] reported that children with asthma seen in the emergency department for COVID-19 were more likely to have severe infections compared to those without asthma. Another study of 5510 patients with asthma, including 414 patients with COVID-19, found a positive correlation between COVID-19 severity and asthma symptoms [17]. Similarly, Lara et al [18] showed that asthma significantly increased the risk of hospitalization in children with COVID-19.

While many studies report that asthma worsens COVID-19 outcomes, some studies present conflicting results. Notably, Oliveira et al [19] observed that children with asthma hospitalized for COVID-19 had a significantly lower risk of death compared to children without asthma. Similarly, Dolby et al [20] reported in a large cohort study that individuals with mild or well-controlled asthma were not at increased risk of severe COVID-19 outcomes. In line with these findings, 1 study of 107 pediatric patients with COVID-19 found that asthma and allergic diseases were not risk factors for hospitalization [21]. Yilmaz et al [22] suggested that COVID-19 may have a milder course than influenza in children (not specifically those with asthma).

Mechanisms

Both COVID-19 and influenza can exacerbate asthma symptoms, but our findings show that children with asthma admitted for COVID-19 had a higher risk of developing sepsis or shock compared to those admitted for influenza. COVID-19 is known to trigger a severe immune response or cytokine storm, leading to high systemic inflammation, rapid respiratory deterioration, and increased risk of sepsis and shock [23]. The SARS-CoV-2, compared to the influenza virus, can induce deeper immune dysregulation [24], which may amplify the underlying airway inflammation in asthma. Consistent with this heightened virulence, Brehm et al [14] observed a markedly higher mortality in immunocompromised adults with COVID-19 than with influenza (33% vs 11.6%; *P*=.01).

Conversely, we found that children with asthma admitted for influenza had a higher risk of secondary bacterial infections than those admitted for COVID-19. Influenza can directly damage the respiratory epithelium, impair mucociliary clearance, and allow bacterial pathogens to invade, leading to secondary infections such as bacterial pneumonia [25]. COVID-19, although capable of severe pneumonitis, generally causes less direct epithelial destruction than influenza [25,26]. Poorly controlled asthma may exacerbate these risks, as noted by Lansbury et al [26], who reported that bacterial coinfection rates in patients with COVID-19 were much lower than during influenza pandemics. This finding suggests that the routine use of antibiotics in patients with COVID-19 may not be necessary. Early in the pandemic, despite low rates of bacterial coinfections (<10%), antibiotics were widely prescribed to patients with COVID-19 (75%) [27]. Such practices might have reduced secondary bacterial infection rates, making patients with influenza more susceptible to secondary infections.

Clinical Implications

Despite these differences in complications, we observed no significant difference in in-hospital mortality rates between the two groups. This could be due to effective clinical management or the resilience of the pediatric population. However, younger children (aged 1 to 5 years) with COVID-19 had a higher 90-day readmission rate than those with influenza, indicating a need for targeted follow-up care after discharge.

Studies have shown that COVID-19 vaccines are safe and effective for children, including those with asthma [6]. Ongoing research continues to support vaccination, particularly for those with uncontrolled asthma, who are at increased risk of severe disease and complications [6].

These findings can guide health care providers in optimizing care during respiratory viral outbreaks. The study underscores the need for different management strategies for children with asthma hospitalized with COVID-19 or influenza. Specifically, the higher risk of sepsis or shock in the COVID-19 cohort warrants proactive hemodynamic monitoring and early escalation of care. Vaccination and close follow-up, particularly

XSL•FO
RenderX

for younger children with COVID-19, are crucial to prevent hospitalizations and manage complications.

Strengths and Limitations

A strength of this study is its use of a large, nationally representative dataset, providing a comprehensive overview of hospitalizations across the United States. This broad scope enhances the generalizability of the findings and allows a detailed understanding of the differential impact of COVID-19 and influenza on children with asthma. In addition, the analysis included in-hospital data and readmission data, which are informative in assessing health care use for these patients.

However, this study still had several limitations. First, the retrospective, observational design limited causal inference and may have introduced selection bias. The absence of a healthy (noninfected) comparison group further constrained interpretation, and the single-year study period (2020) limited generalizability to later phases of the pandemic. Moreover, reliance on *ICD-10-CM* codes could underestimate milder comorbidities, and variations in coding accuracy may have affected our results.

Second, several key clinical parameters were unavailable in the NRD, such as vaccination history of patients, COVID-19 viral load, laboratory measures, influenza subtypes, detailed treatment regimens, asthma medication regimens (particularly inhaled corticosteroids), and asthma severity. These factors could significantly influence patient outcomes and limit the ability to fully understand the nuances of disease interactions in this population. Emerging evidence suggests that impaired fetal growth, rather than prematurity, influences childhood lung function; such perinatal data were similarly not captured [28].

Third, the COVID-19 and influenza groups differed markedly in age (mean 13.3 vs 6.8 years, respectively), raising the possibility of residual confounding. Although age-stratified analyses yielded trends but these results were not statistically significant (P=.12) consistent with the primary results, small subgroup sample sizes reduce statistical power—particularly for rare outcomes such as mortality.

Finally, clinical management of COVID-19 evolved rapidly during 2020, and pandemic-related changes in health care–seeking behavior may have biased our sample toward more severe cases. A nationwide Korean survey reported a transient decline in pediatric asthma prevalence from 2020 to 2021, potentially reflecting underdiagnosis or reduced health care use [29]; similar dynamics could have influenced the US data.

Future Directions

Future work should couple national hospital data with electronic health records to add missing variables—vaccination status, asthma-control metrics, and viral subtype—across multiple post-2020 seasons. Including a group of noninfected children with asthma would clarify the absolute risk estimates, while extended follow-up may reveal longer-term monitoring.

Conclusions

In conclusion, children with asthma in the United States hospitalized for COVID-19 have a higher risk of sepsis or shock compared to those admitted for influenza. Conversely, those admitted for influenza are at increased risk of secondary bacterial or fungal pneumonia. These findings underscore the need for targeted clinical management strategies for children with asthma, tailored to the specific risks posed by COVID-19 and influenza.

Abstract

Background: Psoriasis is a chronic inflammatory skin disorder that has been increasingly linked to metabolic imbalances, particularly obesity. Conventional anthropometric indicators such as BMI and waist circumference (WC) may not sufficiently capture body fat distribution or reflect metabolic risk. The body roundness index (BRI), which integrates both height and waist measurements, has emerged as a potentially superior metric, though its relevance to psoriasis risk remains underexplored.

Objective: This study aimed to investigate the use of BRI as a digital biomarker for assessing psoriasis risk and to compare its predictive strength against BMI and WC across various demographic and metabolic subgroups using data from a nationally representative sample.

Methods: A cross-sectional analysis was conducted using data from 13,798 adults aged 20 to 59 years who participated in the National Health and Nutrition Examination Survey between 2003 and 2006 as well as between 2009 and 2014. Psoriasis status was self-reported. Anthropometric measures (BRI, BMI, and WC) were calculated from standardized physical assessments. Weighted multivariable logistic regression models and restricted cubic spline analyses were used to examine associations while adjusting for demographic, metabolic, and lifestyle variables. A nomogram was constructed to quantify the relative predictive contributions of each metric.

Results: BRI exhibited a strong linear association with psoriasis risk (odds ratio [OR] 1.11 per unit increase, 95% CI 1.05 - 1.17; *P*<.001), outperforming BMI (OR 1.03) and WC (OR 1.01). Tertile analysis revealed a 1.73-fold increased risk of psoriasis in the highest BRI group (*P*=.003). Subgroup analyses confirmed consistent associations across age, sex, race or ethnicity, and metabolic status (*P* for interaction >.05). The nomogram highlighted BRI as the most influential predictor, indicated by its broad scoring range.

Conclusions: BRI shows stronger and more consistent associations with psoriasis risk than BMI or WC, supporting its potential role as a digital biomarker for early risk stratification. Incorporating BRI into clinical decision-making tools may enhance personalized approaches to psoriasis prevention and management.

KEYWORDS

psoriasis; body roundness index; obesity; digital biomarker; risk prediction

Introduction

Psoriasis is a widespread, long-term inflammatory skin condition affecting approximately 2% to 3% of the global population [1,2]. Clinically, it is characterized by erythematous plaques, scaling, epidermal hyperplasia, and other symptoms, typically affecting the scalp, elbows, knees, and lower back [3,4]. The disease often follows a prolonged, relapsing course with considerable interindividual variation. Beyond its dermatologic manifestations, psoriasis is increasingly recognized as a systemic condition associated with several metabolic comorbidities, including obesity, diabetes, and cardiovascular disease (CVD) [1,5-7]. Chronic systemic inflammation may be a key mechanism linking psoriasis to metabolic disorders. The inflammatory milieu in psoriasis can disrupt insulin sensitivity and lipid metabolism, thereby promoting the development of metabolic diseases [2,8,9]. Understanding the interplay between psoriasis, obesity, and metabolic syndrome is thus crucial for improving early diagnosis and developing integrated intervention strategies.

Recent evidence underscores the strong association between psoriasis and metabolic diseases [10,11], particularly obesity. Obesity is considered a significant risk factor for psoriasis onset [12,13] and may also worsen disease severity [14]. In individuals with obesity, adipose tissue functions as an active endocrine organ, releasing proinflammatory cytokines, which induce

XSL•FO
RenderX

chronic low-grade systemic inflammation [13,15,16]. These cytokines can trigger or exacerbate psoriatic inflammation [12,17]. Moreover, individuals with both obesity and metabolic syndrome tend to have a longer disease duration and more refractory clinical course, highlighting the potential value of weight management in psoriasis care [10,18].

Although BMI and waist circumference (WC) are commonly applied in clinical practice to assess obesity, they have notable limitations. BMI estimates general obesity based solely on weight-to-height ratio and cannot distinguish between fat and lean mass or identify fat distribution patterns [19]. Consequently, its application may result in inaccurate risk assessment in patients with psoriasis [20]. WC, while reflective of abdominal fat, lacks the precision to capture total or visceral fat distribution [21]. The body roundness index (BRI) is a recently developed anthropometric measure that combines WC and height, offering a potentially valuable alternative to traditional obesity metrics [22]. BRI more accurately estimates visceral and abdominal fat distribution and has demonstrated stronger associations with metabolic syndrome and obesity-related disorders [23,24]. Its potential application in predicting risk of psoriasis, however, remains underexplored.

While previous research has documented a linkage between BRI and risk of psoriasis [25], its comparative predictive performance against traditional measures such as BMI and WC across different population subgroups requires further validation. This study probes into the predictive use of BRI for psoriasis and to determine whether it offers superior risk stratification in comparison with conventional anthropometric indices. By leveraging large-scale national health data, we seek to support the development of more individualized screening and prevention strategies for psoriasis, thereby advancing both theoretical understanding and clinical management.

Methods

Data Source

This study is based on data from the National Health and Nutrition Examination Survey (NHANES) [26], conducted by the National Center for Health Statistics of the Centers for Disease Control and Prevention. NHANES is a nationally representative, ongoing cross-sectional survey aimed at evaluating the nutritional and health conditions of the US civilian population not living in institutions. It integrates in-home interviews with standardized health assessments conducted in mobile examination centers (MECs), offering comprehensive demographic, clinical, and laboratory data.

We analyzed data from the 2003 to 2006 and 2009 to 2014 NHANES cycles. The 2003 - 2006 datasets included self-reported psoriasis information for adults aged 20 to 59 years, while the 2009 - 2014 cycles provided relevant health and anthropometric data for participants aged 16 to 80 years. For consistency and comparability, our analysis focused on adults aged 20 to 59 years across all cycles.

Study Population

This cross-sectional analysis included data from the 5 NHANES cycles: 2003 - 2004, 2005 - 2006, 2009 - 2010, 2011 - 2012, and 2013 - 2014. Participants were included if they were aged 20 to 59 years and had complete data on psoriasis status and relevant anthropometric and clinical variables. The exclusion criteria were as follows: (1) missing data on psoriasis diagnosis; (2) missing height, WC, or weight data, which prevented BRI calculation; (3) missing key demographic or clinical variables, including poverty-income ratio (PIR), education, marital status, smoking status, alcohol consumption, BMI, CVD, diabetes, or metabolic syndrome.

Definition and Measurement of Psoriasis and BRI

Psoriasis status was determined based on participants' responses in the "Medical Conditions" section of the NHANES questionnaire. Respondents were considered to have psoriasis if they answered "yes" to the question: "Has a healthcare provider ever told you that you have psoriasis?" The validity of self-reported psoriasis has been previously established [27,28].

WC and height were collected by trained personnel at MECs following established measurement procedures. Participants were examined while barefoot and dressed in light clothing. Height was recorded at the anatomical point between the lower margin of the last palpable rib and the top of the iliac crest. The BRI was calculated as: $BRI=364.2 - 365.5\times(1 - [WC(m)/2\pi]^2/[0.5\times height(m)]^2)^{½}$ [29]. BRI was then grouped into tertiles based on its distribution in the sample: tertile 1 (<3.87, corresponding to < 33rd percentile), tertile 2 (≥3.87 to <5.61, corresponding to the 33rd-67th percentiles), and tertile 3 (≥5.61, corresponding to ≥ 67th percentile; Figure S1 in Multimedia Appendix 1). This standardized approach to psoriasis classification and BRI calculation ensures high reproducibility and provides a robust framework for subsequent analyses.

Covariate Data Source

Based on prior literature, the following covariates were included in this study: age, sex, race or ethnicity, education level, marital status, PIR, smoking status, alcohol consumption, BMI, body fat percentage (BFP), CVD, metabolic syndrome, and diabetes.

Demographic Variables

Race or ethnicity was self-reported and classified into 4 categories: Mexican American, non-Hispanic Black, non-Hispanic White, and other Hispanic and other races. Marital status was classified as married, unmarried, cohabiting, or other [30]. Education level was categorized as: (1) high school or less, (2) some college education, and (3) college graduate or above. Age was treated as a continuous variable in the main analysis and dichotomized into 2 age brackets (20 - 39 y and 40 - 59 y) for subgroup analysis to explore age-related heterogeneity.

Lifestyle Factors

Smoking status was categorized into 3 groups: never smokers (individuals who had smoked fewer than 100 cigarettes in their lifetime), former smokers (those who had smoked at least 100 cigarettes but were not currently smoking), and current smokers (participants who had smoked over 100 cigarettes and continued smoking at the time of the survey) [30]. Alcohol consumption

XSL•FO
RenderX

was stratified into 5 levels based on self-reported consumption over the previous year: never (lifetime consumption of fewer than 12 occasions), former (no alcohol intake in the past year but at least 12 past occasions), light (women drinking ≤1 time per day and men ≤2 times per day in the past year), moderate (women drinking ≤2 times per day and men ≤3 times per day), and heavy (women drinking ≥3 times per day and men ≥4 times per day) [31].

Anthropometric and Clinical Measures

BMI was determined as weight in kilograms divided by height in meters squared (kg m^{-2}) [32]. BFP was tested using bioelectrical impedance analysis, conducted at the NHANES MEC using standardized equipment. BFP reflects the proportion of an individual's body weight that is composed of fat and is calculated based on parameters such as height, weight, age, and sex, following the algorithm outlined in the official NHANES technical manual [32]. For statistical analysis, BFP was analyzed both as a continuous measure and by tertiles, aligning with the BRI grouping structure to explore its association with psoriasis risk across fat distribution levels.

Clinical Conditions

Diabetes was determined based on any of the following criteria: receipt of antidiabetic treatment, HbA_{1c}≥6.5%, use of antidiabetic medications, oral glucose tolerance test results ≥11.1 mmol L^{-1}, fasting blood glucose ≥ 7.0 mmol L^{-1}, or random blood glucose ≥ 11.1 mmol L^{-1} [33, 34]. CVD was identified based on self-reported medical history of coronary artery disease, myocardial infarction, heart failure, stroke, or angina [35,36]. Metabolic syndrome was defined according to the Adult Treatment Panel III (2005) and International Diabetes Federation (2009) criteria [37,38].

Statistical Analysis

This study used the fasting subsample from the NHANES dataset to ensure the reliability of metabolic indicator measurements. The fasting subsample includes participants who underwent blood sampling under standardized fasting conditions. According to NHANES analytic guidelines, the appropriate sampling weight for combined 10-year analyses was calculated using the formula: 10-year MEC weight=2-year MEC weight/5 [28].

We used weighted multivariable logistic regression models to estimate odds ratios (ORs) and 95% CIs, evaluating the association between the BRI and the risk of psoriasis. Three sequential models were sequentially applied: model 1 (unadjusted), model 2 (adjusted for demographic variables including race or ethnicity, age, sex, education level, PIR, and marital status), model 3 (further adjusted for smoking status, alcohol consumption, metabolic syndrome, diabetes, CVD, and NHANES survey cycle, as differences in sampling strategy, measurement methods, or public health trends across survey cycles could introduce systematic bias and act as potential confounders). Trend tests were performed to assess the robustness of its association with psoriasis. In Model 3, we also conducted a weighted restricted cubic spline (RCS) analysis to test the nonlinear relationship between BRI and psoriasis.

To comprehensively assess body size indicators in relation to psoriasis, we performed subgroup analyses and interaction tests to evaluate the role of BRI across different populations (by age, sex, race or ethnicity, CVD, metabolic syndrome, and diabetes), and further conducted logistic regression analyses on WC and BMI to examine their independent effects.

Descriptive statistics were computed by applying NHANES sampling weights. For continuous variables, we reported weighted averages along with their corresponding SDs. Categorical variables were described using unweighted frequencies and weighted proportions. Group comparisons were made using survey-weighted 2-tailed *t* tests for continuous measures and the Rao-Scott adjusted chi-square tests for categorical data. To evaluate the relationship between BRI and psoriasis, we fitted weighted multivariable logistic regression models, treating BRI both as a continuous variable and as categorical tertiles.

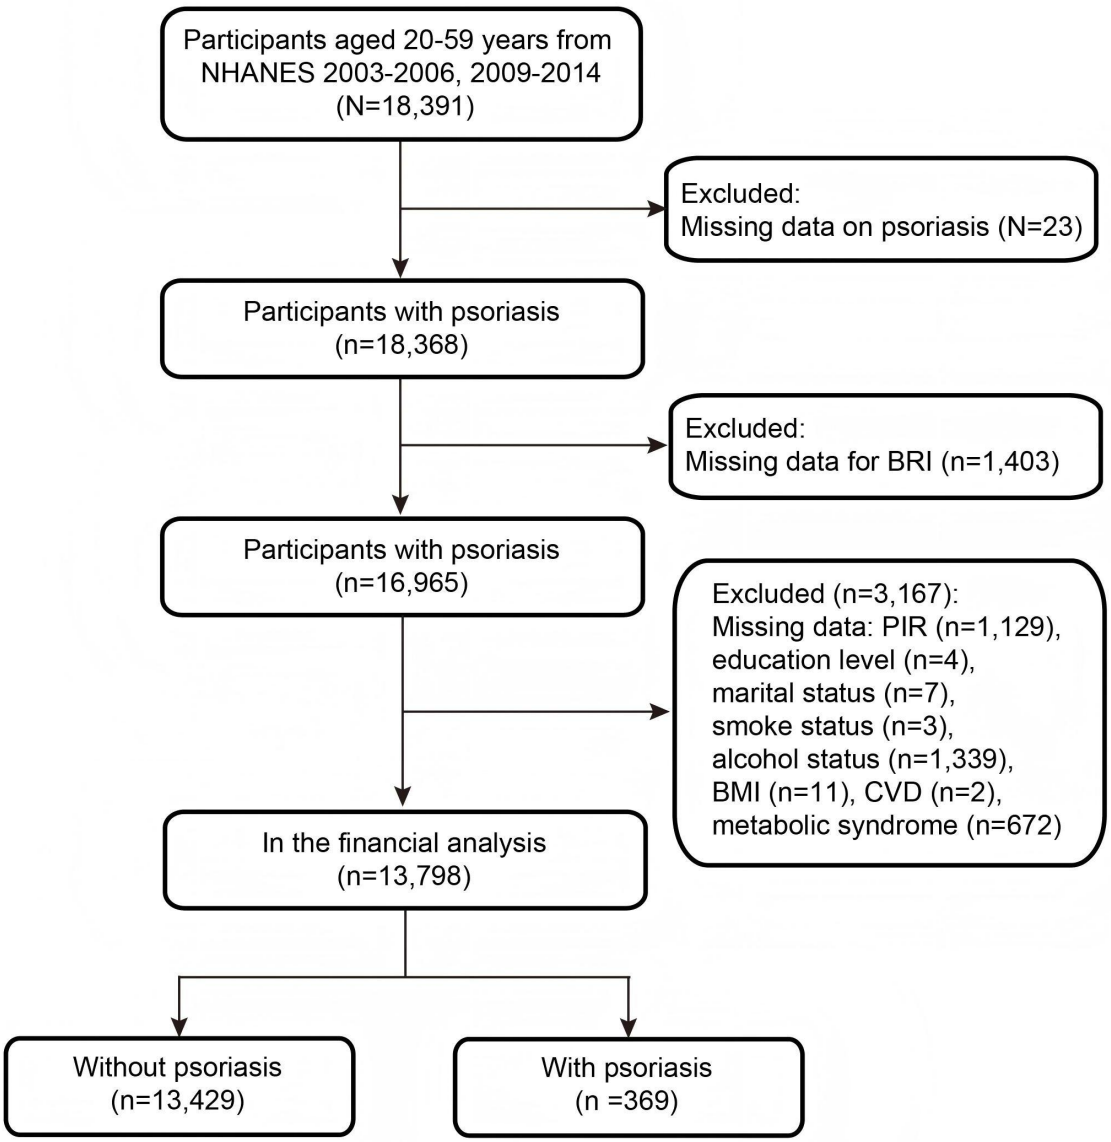
All statistical procedures were executed using R software (version 4.4.1; R Foundation for Statistical Computing), supplemented with Free Statistics software (version 1.9.2). NHANES-recommended survey weights were incorporated throughout to reflect the survey's complex multistage design and to yield estimates generalizable to the US civilian population. A 2-sided *P*-value <.05 was deemed statistically significant.

Ethical Considerations

This study followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines [39] to maintain high standards of methodological clarity and transparency. The NHANES study protocol received approval from the National Center for Health Statistics institutional review board, and all participants provided informed written consent. Since the dataset is anonymized and publicly accessible, no additional ethical review was necessary for this secondary analysis.

Results

Baseline Characteristics



The final analytic sample is detailed in the study flowchart (Figure 1). A total of 13,798 participants aged 20 to 59 years from the NHANES dataset were included in this study. Among them, 369 (3%) self-reported a diagnosis of psoriasis. The mean age of participants was 39.62 (SD 11.43) years. A total of 7037 (51%) participants were male and 6761 (49%) were female (Table 1). Participants were stratified into tertiles based on BRI, with tertile 1 (<3.87, n=4599), tertile 2 (3.87 - 5.61, n=4599), and tertile 3 (≥5.61, n=4600). Significant differences in demographic, socioeconomic, and health-related characteristics were observed across tertiles.

In terms of demographic characteristics, individuals in tertile 3 (highest BRI ≥5.61) were older (mean 42.51, SD 10.79 y versus mean 35.57, SD 11.38 y in tertile 1). Female participants accounted for 2682 of 4600 (55.4%) participants in tertile 3, compared with 2104 of 4599 (49.4%) in tertile 1. In terms of race or ethnicity, non-Hispanic Whites were most common in tertile 3, with 1942 of 4600 (64.3%) participants, while Mexican

XSL•FO
RenderX

Americans were least common, with 908 of 4600 (11.3%) participants. Regarding socioeconomic status, participants in tertile 3 had the lowest PIR and the highest proportion of individuals with low education levels, with 2307 of 4600 (44.1%) having only high school or less education. The proportion of married participants was also highest in tertile 3, with 2383 (56.8%).

[a]BRI: body roundness index.

[b]PIR: family poverty income ratio.

[c]CVD: cardiovascular disease.

BMI and WC levels increased significantly with higher BRI levels (*P*<.001). Regarding health status, the prevalence of psoriasis also rose, with 152 of 4600 (3.7%) participants in tertile 3 compared to 89 of 4599 (2.1%) in tertile 1 (*P*<.001). In addition, comorbidities were more frequent in tertile 3, including CVD in 321 of 4600 (6.4%) participants, metabolic syndrome in 2378 (53.2%), and diabetes in 910 (17.8%; all *P*<.001).

In terms of lifestyle factors, participants in tertile 3 were more likely to report never smoking (2597/4600, 55.1%) and light alcohol consumption (1229/4600, 29.2%) compared with tertile 1 (lowest BRI*; P*<.001).

Association Between BRI and Risk of Psoriasis

As shown in Table 2, the BRI was distinctly linked to an increased risk of psoriasis across all models. Model 1 (unadjusted): each 1-unit increase in BRI was associated with a 10% increase in the odds of psoriasis (OR 1.10, 95% CI 1.05 - 1.14; *P*<.001). Model 2 (adjusted for demographic variables such as age, sex, race or ethnicity, education level, PIR, and marital status): the association slightly attenuated but remained statistically significant (OR 1.09, 95% CI 1.04 - 1.14; *P*<.001). Model 3 (fully adjusted model: further controlling for NHANES survey cycle, metabolic syndrome, diabetes, CVD, smoking status, and alcohol consumption): the positive association remained robust and significant, with each unit increase in BRI corresponding to an 11% increased risk of psoriasis (OR 1.11, 95% CI 1.05 - 1.17; *P*<.001).

When BRI was divided into tertiles, the risk of psoriasis increased with BRI levels (*P*=.04). Compared to the lowest BRI tertile (<3.87, as the reference group), the second tertile (3.87≤BRI<5.613) showed linkage with a significantly higher risk of psoriasis (model 3: OR 1.49, 95% CI 1.03 - 2.15*; P*=.04). The highest BRI tertile (≥5.61) showed an even greater increase in risk of psoriasis (model 3: OR 1.73, 95% CI 1.22 - 2.45; *P*=.003; Table 2).

RCS analysis (Figure 2) demonstrated a significant linear association between BRI and risk of psoriasis, with no evidence of nonlinearity (*P* for nonlinearity=.23). Furthermore, this study conducted an in-depth analysis of the association between BFP and the risk of psoriasis. The results validated a notable positive correlation between BFP and risk of psoriasis, independent of confounding factors. In the unadjusted model, each 1% increase in BFP showed linkage with a 6% increase in risk of psoriasis (OR 1.06, 95% CI 1.04 - 1.08; *P*<.001). After adjusting for demographic variables, the odds ratio decreased slightly to 1.05 (95% CI 1.03 - 1.07; *P*<.001), and in the fully adjusted model—which included metabolic syndrome, diabetes, and other covariates—the association remained significant (OR 1.04, 95% CI 1.02 - 1.06; *P*<.001). When analyzed in conjunction with BRI tertiles, participants in the middle and highest BRI tertiles had a 38% (OR 1.38, 95% CI 1.15 - 1.66; *P*<.001) and 82% (OR 1.82, 95% CI 1.43 - 2.32; *P*<.001) increased risk of psoriasis, respectively, relative to those in tertile 1 (lowest BRI)—suggesting that BRI may outperform BFP in predicting risk of psoriasis. Subgroup analyses further revealed that the association between BRI and psoriasis was stronger among individuals over the age of 40 years (OR 1.07, 95% CI 1.05 - 1.09; *P*<.001). The risk was slightly higher in men (OR_male=1.06) than in women (OR_female=1.04; Table 3).

Association Between BRI and Risk of Psoriasis Across Subgroups

Subgroup analyses were implemented to assess the consistency of the association between BRI and risk of psoriasis across different population groups (Figure 3). Stratification was applied by age, sex, race or ethnicity, CVD, metabolic syndrome, and diabetes status, to explore potential effect modification. Across all subgroups, BRI remained significantly and positively associated with risk of psoriasis, with no statistically significant interactions noted (*P* for interaction >.05), indicating a stable association across population strata.

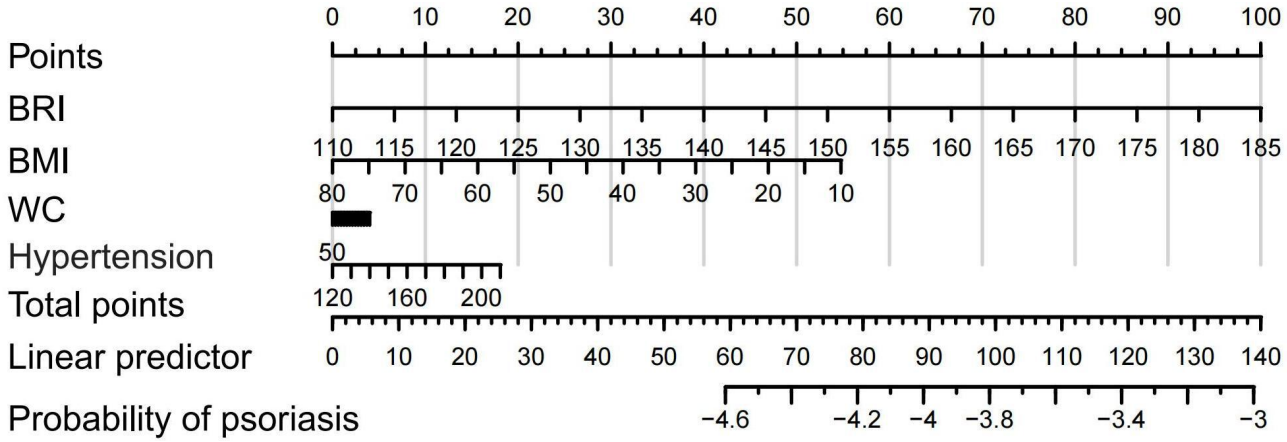
XSL•FO
RenderX

Figure 3. Forest plot analysis of the association between the body roundness index (BRI) and risk of psoriasis across different subgroups. CVD: cardiovascular disease; DM: diabetes mellitus; OR: odds ratio.

In the 40 - 59 years age group, the OR was 1.14 (95% CI 1.04 - 1.24), slightly higher than the OR of 1.08 (95% CI 1.00 - 1.15) observed in the 20 - 39 years age group (*P* for interaction=.22). For sex-based subgroups, the ORs were 1.15 (95% CI 1.08 - 1.24) in males and 1.07 (95% CI 0.99 - 1.15) in females (*P*=.78), indicating no significant sex-specific differences. Among participants with metabolic syndrome, the OR was 1.13 (95% CI 1.03 - 1.23), compared to 1.09 (95% CI 1.02 - 1.17) in those without metabolic syndrome (*P* for interaction=.39), suggesting consistent associations across metabolic health status.

Comparison of BRI With Traditional Body Measurement Indicators (BMI and WC)

To further evaluate the predictive value of BRI and compare it with traditional anthropometric measures—BMI and WC—we conducted multivariable logistic regression using the fully adjusted model 3. For each 1-unit increase in BRI, the risk of psoriasis increased by 11% (OR 1.11, 95% CI 1.05 - 1.17; *P*<.001). In comparison, each 1-unit increase in BMI was associated with a 3% increased risk (OR 1.03, 95% CI 1.02 - 1.05; *P*<.001). Each 1-unit increase in WC conferred only a 1% increased risk (OR 1.01, 95% CI 1.01 - 1.02; *P*<.001; Table 4).



To visualize and quantify the relative contributions of these indicators, we constructed a nomogram model based on multivariable logistic regression. The nomogram illustrated that the BRI score axis had the widest range, indicating that BRI contributed the most to risk of psoriasis prediction. In contrast, BMI and WC had shorter score axes, reflecting their smaller relative contributions (Figure 4).

Discussion

Principal Findings

Psoriasis is a long-standing inflammatory skin condition that has been closely linked to metabolic disorders such as obesity, diabetes, and CVD [1,2,5,6]. Prior research has demonstrated significant links between risk of psoriasis and a range of anthropometric indicators such as BMI, WC, waist-to-hip ratio (WHR), and BRI [25,40]. However, most of this research has focused on individual obesity indicators in isolation, lacking a comprehensive comparison of their predictive value. Furthermore, many analyses did not sufficiently adjust for confounding factors that could influence observed associations. Using large-scale data from the NHANES, this study is the first to systematically compare the predictive performance of BRI, BMI, and WC in relation to the risk of psoriasis. The results suggest that BRI demonstrates higher sensitivity and greater clinical use than the other indices examined.

Prior research has consistently reported a positive correlation between BMI and risk of psoriasis. Obesity is thought to influence both the onset and severity of psoriasis through mechanisms such as chronic low-grade inflammation, elevated levels of proinflammatory cytokines, insulin resistance, and broader metabolic disturbances [41,42]. Despite its widespread use, BMI reflects only overall body mass without distinguishing between fat distribution types—particularly visceral versus subcutaneous fat—potentially limiting its ability to capture obesity-related metabolic risk [25]. Although WC is a better indicator of abdominal fat accumulation, it does not adjust for individual height differences. In contrast, BRI integrates both WC and height, enabling a more accurate estimation of total body fat distribution and metabolic burden [43]. Some studies have also suggested a J-shaped or U-shaped association between BMI and risk of psoriasis [44]. Our study used weighted RCS analysis and identified a stable linear association between BRI and risk of psoriasis (*P*=.23), reinforcing the potential of BRI as a reliable risk predictor. These findings are consistent with recent evidence [25].

The BRI, as an integrated measure of WC and height, is not only influenced by genetic and metabolic factors but also modifiable lifestyle factors, such as smoking, alcohol consumption, and physical activity [22]. In this analysis, participants in the highest BRI tertile were more frequently identified as light drinkers and never smokers, suggesting behavioral patterns may modulate body shape and fat distribution. Notably, prior studies have documented that smoking is linked to an increased visceral adiposity despite lower overall BMI, potentially elevating BRI scores through central fat accumulation [45]. Similarly, moderate to heavy alcohol consumption has been linked to higher WC and increased abdominal fat [46], which directly contributes to elevated BRI. Moreover, few studies have examined the distribution patterns of BRI across different population subgroups or its association with psoriasis. In this study, BRI demonstrated more stable trends than BMI and WC across demographic subgroups defined by age, sex, educational level, and marital status. Importantly, BRI showed a consistent positive association with psoriasis risk across all subgroups. Previous research has shown that higher BMI and WC are more prevalent among women, individuals with lower socioeconomic status, and those with limited educational backgrounds [2]. Our findings indicate that the distribution trends of BRI in these populations mirror those of BMI and WC. However, BRI may be more sensitive in capturing obesity-related metabolic risk [25]. Unlike prior studies that have largely focused on BMI and WC, this study uses NHANES data to systematically evaluate BRI distribution across diverse populations and its association with both psoriasis and metabolic disorders. These findings not only provide new insights into the complex interplay between obesity

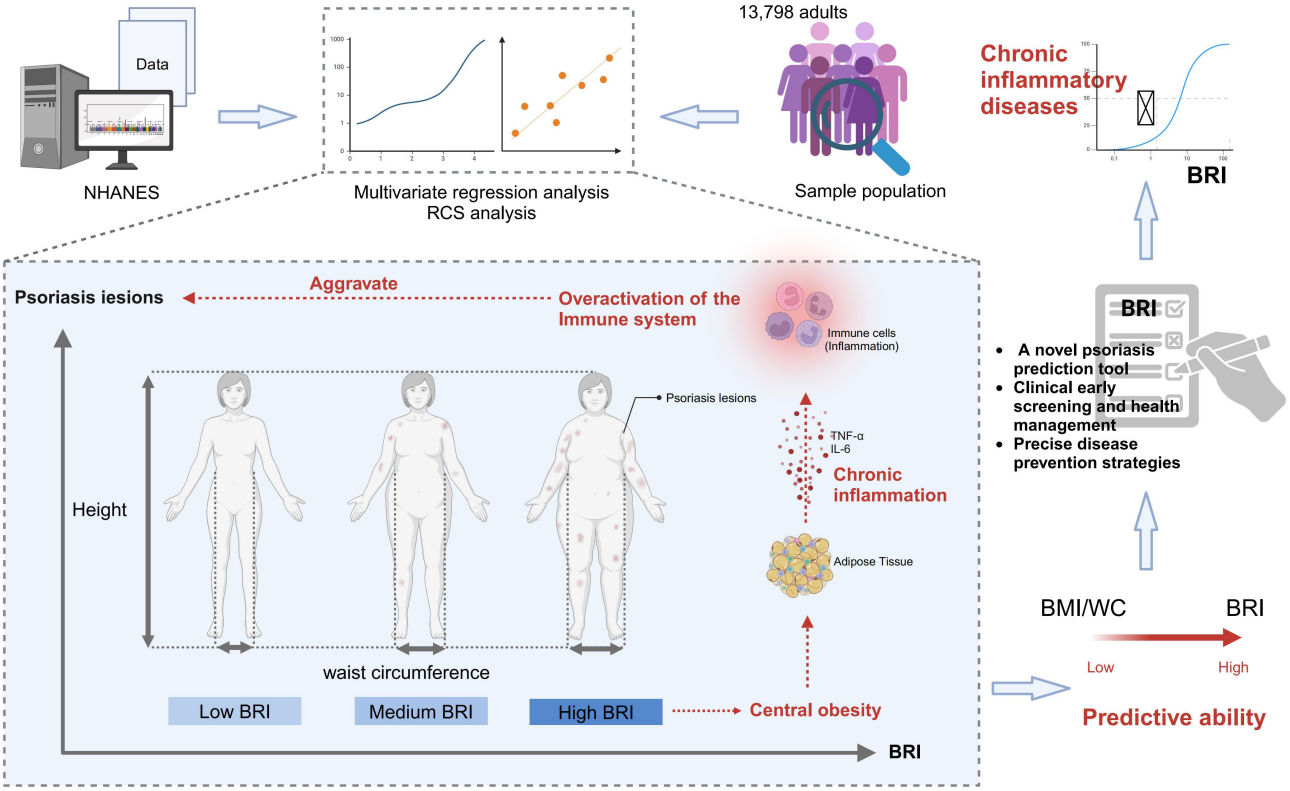
XSL•FO
RenderX

and inflammatory diseases such as psoriasis, but also underscore the significance of BRI as a practical clinical tool for metabolic health surveillance. In subgroup analyses, the association between BRI and psoriasis remained significant across various strata, including age, sex, race or ethnicity, diabetes, CVD, and metabolic syndrome. Education level, smoking status, and alcohol consumption were not included in the subgroup analyses due to potential multicollinearity with socioeconomic and lifestyle factors, as well as concerns about statistical power related to over-stratification. Although WHR and waist-to-height ratio (WHtR) are also widely adopted indicators of central obesity, they were not included in our analysis due to data limitations and a desire to minimize multicollinearity among closely related anthropometric indices. Moreover, BRI already incorporates WC and height into its calculation, thereby partially accounting for the components used in WHtR. Future studies could explore the predictive value of WHR and WHtR in combination with BRI to further refine obesity-related risk assessment models. In this analysis, lifestyle behaviors—including smoking and alcohol use—showed significant associations with BRI. Participants in the highest BRI tertile were more frequently identified as light alcohol consumers and individuals who had never smoked. These findings suggest that lifestyle factors may influence body shape and fat distribution, thereby indirectly impacting BRI values. This underscores the need to consider behavioral determinants when interpreting BRI in clinical and epidemiological contexts.

Although this study provides compelling evidence for the link between BRI and risk of psoriasis, the underlying biological mechanisms remain to be fully clarified. Prior research has suggested that obesity contributes to the pathogenesis of psoriasis through mechanisms such as chronic low-grade inflammation, elevated levels of proinflammatory cytokines, insulin resistance, and broader metabolic dysregulation [47-49]. As a novel anthropometric index, BRI may more accurately capture fat distribution, metabolic abnormalities, and systemic inflammatory burden relative to traditional measures such as BMI or WC, potentially making it more relevant to the pathophysiology of psoriasis. In this study, BRI remained a notable independent predictor of risk of psoriasis even after adjusting for multiple confounding factors, including metabolic syndrome, diabetes, and CVD. This reinforces its potential clinical value in identifying individuals at elevated risk for inflammation-related conditions. Future research should aim to elucidate the biological pathways underlying this association by integrating multiomics approaches—such as metabolomics, inflammatory biomarker profiling, and gut microbiome analysis—which may offer deeper insight into the mechanistic links between BRI and psoriasis.

This study highlights a strong and consistent association between elevated BRI and an increased likelihood of psoriasis. This association remained stable under various model adjustments and statistical frameworks, suggesting it is not merely attributable to confounding influences. Importantly, the risk of psoriasis rose progressively with increasing BRI, indicating a clear linear trend. These observations support the potential of BRI as a meaningful indicator for identifying individuals with heightened susceptibility to psoriasis. Given its capacity to reflect both fat distribution and metabolic status, BRI may serve as a useful addition to existing risk assessment tools. Future studies should delve deeper into the mechanistic pathways linking BRI and psoriatic disease and evaluate its relevance in clinical prediction models and preventive strategies.

Despite offering compelling evidence for the use of BRI in assessing psoriasis risk, this study contains several limitations. First, as it is based on cross-sectional data from NHANES, causality cannot be inferred; thus, longitudinal cohort studies are necessary to confirm the long-term impact of BRI on psoriasis development and progression. Second, while BRI is a useful surrogate for fat distribution, it does not directly measure visceral adiposity or the muscle-to-fat ratio. Future research incorporating advanced imaging modalities such as dual-energy X-ray absorptiometry or magnetic resonance imaging could yield more precise assessments of body composition and further clarify the biological relevance of BRI in the context of psoriasis. Finally, as this study is based on US NHANES data, the findings may not be directly generalizable to populations in other countries with different ethnic, dietary, and health care backgrounds. Although subgroup analysis within the US population revealed consistent associations across various demographic groups, future studies should validate these results using international datasets. Cross-country comparisons could help evaluate the universality of BRI as a biomarker for psoriasis risk.



Conclusions

Using large-scale NHANES population data, this study systematically evaluated the association between the BRI and psoriasis risk, and, for the first time, directly compared the predictive performance of BRI, BMI, and WC within a unified analytical framework. The results indicate that BRI may offer greater sensitivity in predicting psoriasis risk. Unlike traditional anthropometric measures, BRI integrates both height and WC, providing a more accurate representation of fat distribution and metabolic burden. Furthermore, weighted RCS analysis confirmed a stable linear association between BRI and psoriasis risk, and BRI consistently showed strong predictive value across diverse demographic subgroups. These findings highlight the potential clinical use of BRI as an early risk assessment tool for psoriasis.

To advance this line of research, future investigations should delve into unraveling the biological pathways linking BRI to psoriatic pathophysiology—particularly in the context of chronic inflammation, metabolic dysregulation, and fat distribution. Given the cross-sectional nature here, prospective cohort studies are essential to validate the predictive value of BRI for psoriasis onset and progression across different populations. In addition, integrating multiomics data—including metabolomics, inflammatory markers, and microbiome profiles—may further enhance the use of BRI in personalized health monitoring and disease prevention, offering new strategies for early diagnosis and targeted intervention in psoriasis (Figure 5).

Abstract

Background: Clinical trial eligibility screening using electronic medical records (EMRs) is challenging due to the complexity of patient data and the varied clinical terminologies. Manual screening is time-consuming, requires specialized knowledge, and can lead to inconsistent participant selection, potentially compromising patient safety and research outcomes. This is critical in time-sensitive conditions like acute ischemic stroke. While computerized clinical decision support tools offer solutions, most require software engineering expertise to update, limiting their practical utility when eligibility criteria change.

Objective: We developed and evaluated the intelligent trial eligibility screening tool (iTEST), which combines natural language processing with a block-based visual programming interface designed to enable clinicians to create and modify eligibility screening rules independently. In this study, we assessed iTEST's rule evaluation module using pre-configured rules and compared its effectiveness with that of standard EMR interfaces.

Methods: We conducted an experiment at a tertiary teaching hospital in Taiwan with 12 clinicians using a 2-period crossover design. The clinicians assessed the eligibility of 4 patients with stroke for 2 clinical trials using both standard EMR and iTEST in a counterbalanced order, resulting in 48 evaluation scenarios. The iTEST comprised a rule authoring module using Google Blockly and a rule evaluation module utilizing MetaMap Lite for extracting medical concepts from unstructured EMR documents and structured laboratory data. Primary outcomes included accuracy in determining eligibility. Secondary outcomes measured task completion time, cognitive workload using the National Aeronautics and Space Administration Task Load Index scale (range 0 - 100, with lower scores indicating a lower cognitive workload), and system usability through the system usability scale (range: 0 - 100, with higher scores indicating higher system usability).

Results: The iTEST significantly improved accuracy scores (from 0.91 to 1.00, $P<.001$) and reduced completion time (from 3.18 to 2.44 min, $P=.004$) compared to the standard EMR interface. Users reported lower cognitive workload (National Aeronautics and Space Administration Task Load Index scale, 39.7 vs 62.8, $P=.02$) and higher system usability scale scores (71.3 vs 46.3, $P=.01$) with the iTEST. Particularly notable improvements in perceived cognitive workload were observed in temporal demand, effort, and frustration levels.

Conclusions: The iTEST demonstrated superior performance in clinical trial eligibility screening, delivering improved accuracy, reduced completion time, lower cognitive workload, and better usability when evaluating preconfigured eligibility rules. The improved accuracy is critical for patient safety, as the misidentification of eligibility criteria could expose patients to inappropriate treatments or exclude them from beneficial trials. The adaptability and ability of the iTEST to process both structured and unstructured data make it valuable for time-sensitive scenarios and evolving research protocols. Future research should evaluate clinicians' ability to create and modify eligibility rules using the block-based authoring interface, as well as assess the iTEST across diverse types of clinical trials and health care settings.

Introduction

Clinical trials follow strict criteria for participant selection, using documented medical records as essential information sources. Over time, electronic medical records (EMRs) have evolved into comprehensive data repositories, enabling health care providers to track information systematically [1-3]. However, the increased volume and complexity of EMRs offer a detailed view of patient histories while posing challenges for researchers analyzing this wealth of data.

The complexity of EMRs demands extensive time and effort from researchers to analyze documents. Addressing EMR-related cognitive overload and burnout is now critical [4]. Researchers face tight deadlines, especially in clinical trials for time-sensitive conditions like stroke or brain injury. The phrase “time is brain” underscores the urgency for immediate therapy post-onset [5,6]. Therefore, researchers must rapidly verify inclusion and exclusion criteria [7,8]. Accurately extracting relevant information from EMRs is also essential for participant eligibility; violations could compromise trial validity and harm participants. This heavy workload increases mental stress and risks judgment errors among clinical researchers.

To address these challenges, using computerized clinical decision support tools in trial eligibility screening offers a promising solution [9]. These systems can efficiently process EMRs, enabling rapid candidate screening. However, EMRs contain a significant amount of unstructured narrative text, with about 80% being narrative—a format clinicians prefer for patient information [10]. These unstructured data complicate medical concept extraction automation. The widespread use of synonyms, acronyms, and abbreviations in clinical documentation further complicates matters, making conventional natural language processing (NLP) techniques often inadequate and necessitating specialized medical NLP tools.

Our previous study developed an NLP-enhanced task-specific EMR interface that presented relevant medical concepts to clinicians through highlighted documents for determining intravenous thrombolysis eligibility criteria [11]. The results showed that this EMR interface improved decision-making in stroke therapy. However, creating entirely new systems with specific rules for each clinical problem remains challenging. Clinical trial or therapy eligibility criteria often evolve as new evidence emerges [12]. Current approaches require software engineers to update rules or build new systems whenever clinical guidelines or criteria change, raising costs [13]. Therefore, there is considerable room for improving the design of such tools.

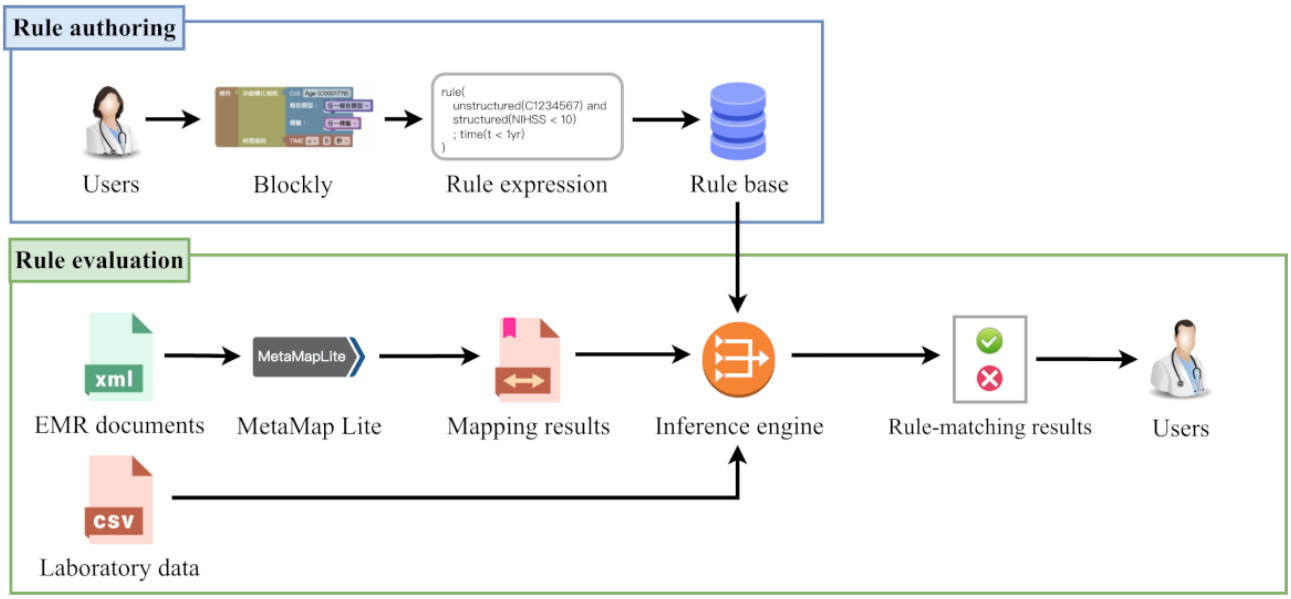
This study aimed to develop an intelligent trial eligibility screening tool (iTEST) adaptable to various medical scenarios, particularly where eligibility criteria frequently change. By identifying common patterns in eligibility criteria and using a block-based visual programming interface, our tool enables clinicians to create computerized eligibility rules independently, without requiring software engineering expertise. We conducted experiments to evaluate the tool’s impact on users’ accuracy, efficiency, and cognitive workload during eligibility determination.

Methods

Study Setting

This study was conducted at Ditmanson Medical Foundation Chia-Yi Christian Hospital, a 1000-bed tertiary teaching hospital in southern Taiwan, which has a certified comprehensive stroke center managing approximately 650 stroke admissions annually. We evaluated 2 sets of eligibility criteria: the first set for intravenous thrombolysis, adapted from the National Institute of Neurological Disorders and Stroke (NINDS) recombinant tissue-plasminogen activator (rt-PA) trial [14], which examined the efficacy of tissue plasminogen activator for acute ischemic stroke, and the second set from the Librexia STROKE trial [15], examining milvexian’s safety and efficacy in preventing recurrent cerebrovascular events post-acute ischemic stroke or high-risk transient ischemic attack.

Ethical Considerations



The study protocol received formal approval from the Institutional Review Board of Ditmanson Medical Foundation Chia-Yi Christian Hospital (2022102). A unique study identification number replaced patient identifiers to ensure confidentiality. Informed consent was thus exempted. Participants were compensated NTD 3000 (≈USD 96) for their time and participation.

Intelligent Trial Eligibility Screening Tool

Figure 1 illustrates the overview of the iTEST, which has 2 main components: the rule authoring and evaluation modules. In the rule authoring module, users convert narrative eligibility criteria into Blockly blocks [16], which are parsed into customized rule expressions and stored in the rule base. The rule evaluation module extracts structured laboratory data from EMRs and maps medical concepts from unstructured EMR documents using MetaMap Lite [17]. The inference engine then determines eligibility for each criterion by matching the extracted information to the rule base, and the tool presents users with rule-matching results.

XSL•FO
RenderX

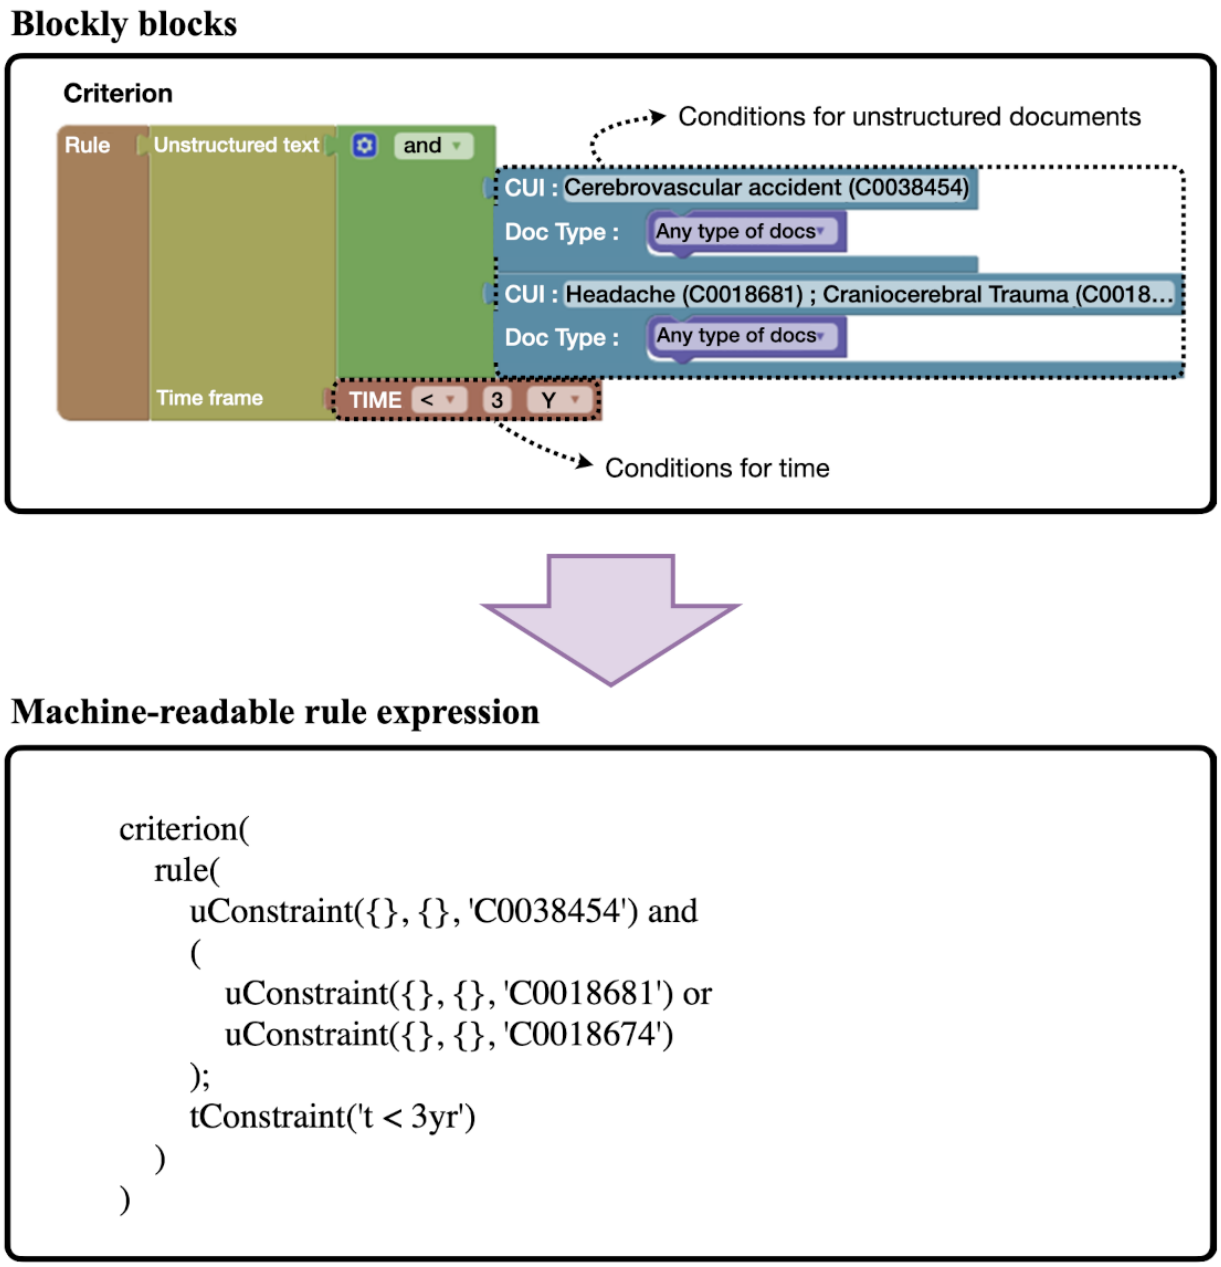


Figure 1. Overview of the intelligent trial eligibility screening tool (iTEST), which comprises a rule authoring module (upper part) and a rule evaluation module (lower part). EMR: electronic medical record.

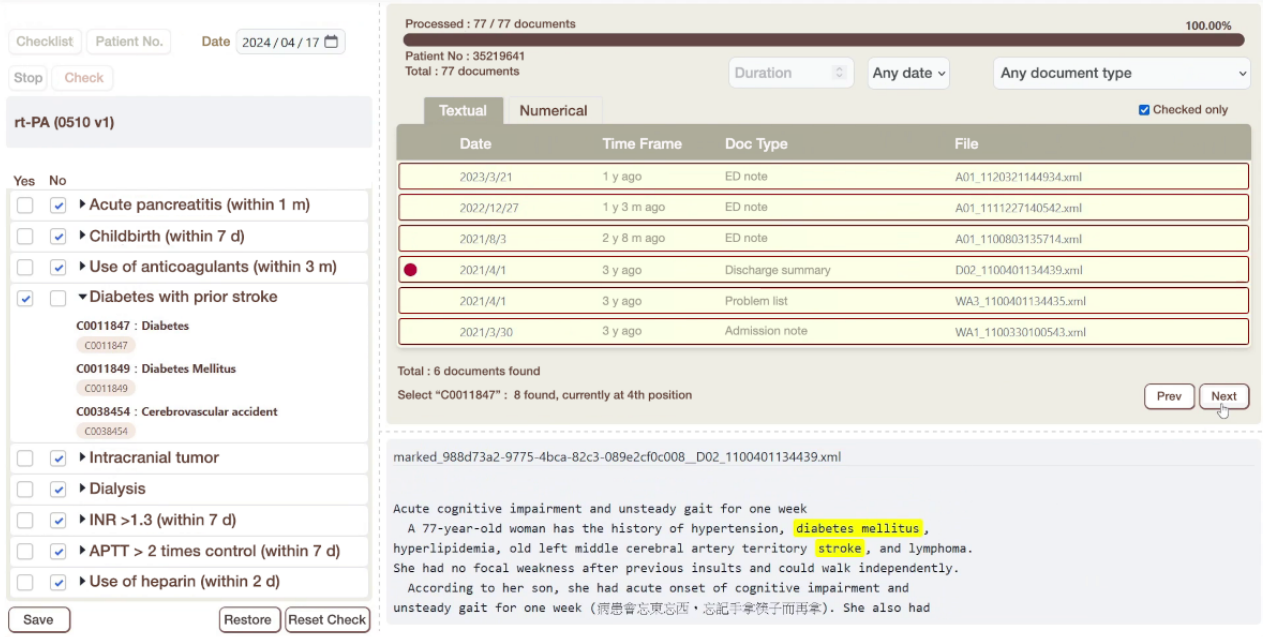
The rule authoring module (upper part of Figure 1) creates, edits, and versions the eligibility criteria checklist using a block-based visual programming interface powered by Blockly (version 10.4.3; Google) [16]. This method, commonly used in programming education, provides visual cues and drag-and-drop functionality while avoiding invalid block combinations. Our study developed customized rule expressions that represent medical concepts and laboratory items in a machine-readable format. Users can easily convert human-written checklist criteria into rule expressions by creating criterion blocks. For numerical laboratory data, criterion blocks allow users to input laboratory items to define conditions (eg, “Platelets <100,000”). For unstructured documents, criterion blocks enable users to specify multiple medical concepts and select EMR document types. Time conditions can be added by using temporal blocks that perform date calculations on EMR timestamp fields (Figure 2), while logical operators such as AND can combine blocks, which execute separate queries across EMR documents, to express complex criteria like “Having a headache or head injury within three years” or “diabetes with prior stroke in the past.” The module translates these blocks into machine-readable rule expressions, enhancing the readability of eligibility criteria and making it easier for nonprogrammers to understand. This module thus enables clinicians to develop complex eligibility rules without requiring programming skills.

XSL•FO
RenderX

Figure 2. An example showing how Blockly blocks are converted into machine-readable rule expressions.

The rule evaluation module (lower part of Figure 1) processes 2 data types. It reads numerical laboratory data in tabular format and uses MetaMap Lite (3.6.2rc8 binary only version; U.S. National Library of Medicine) to extract medical concepts from unstructured EMR documents. MetaMap Lite [17], a faster version of MetaMap [18], maps concepts using the Unified Medical Language System Metathesaurus and assigns Unified Medical Language System concept unique identifiers to annotated concepts [17]. It generates a list of concepts from EMR documents, discarding irrelevant ones based on semantic type settings. Additionally, it addresses challenges like complex concepts with multiple synonyms and potential misinterpretation of word context variations.



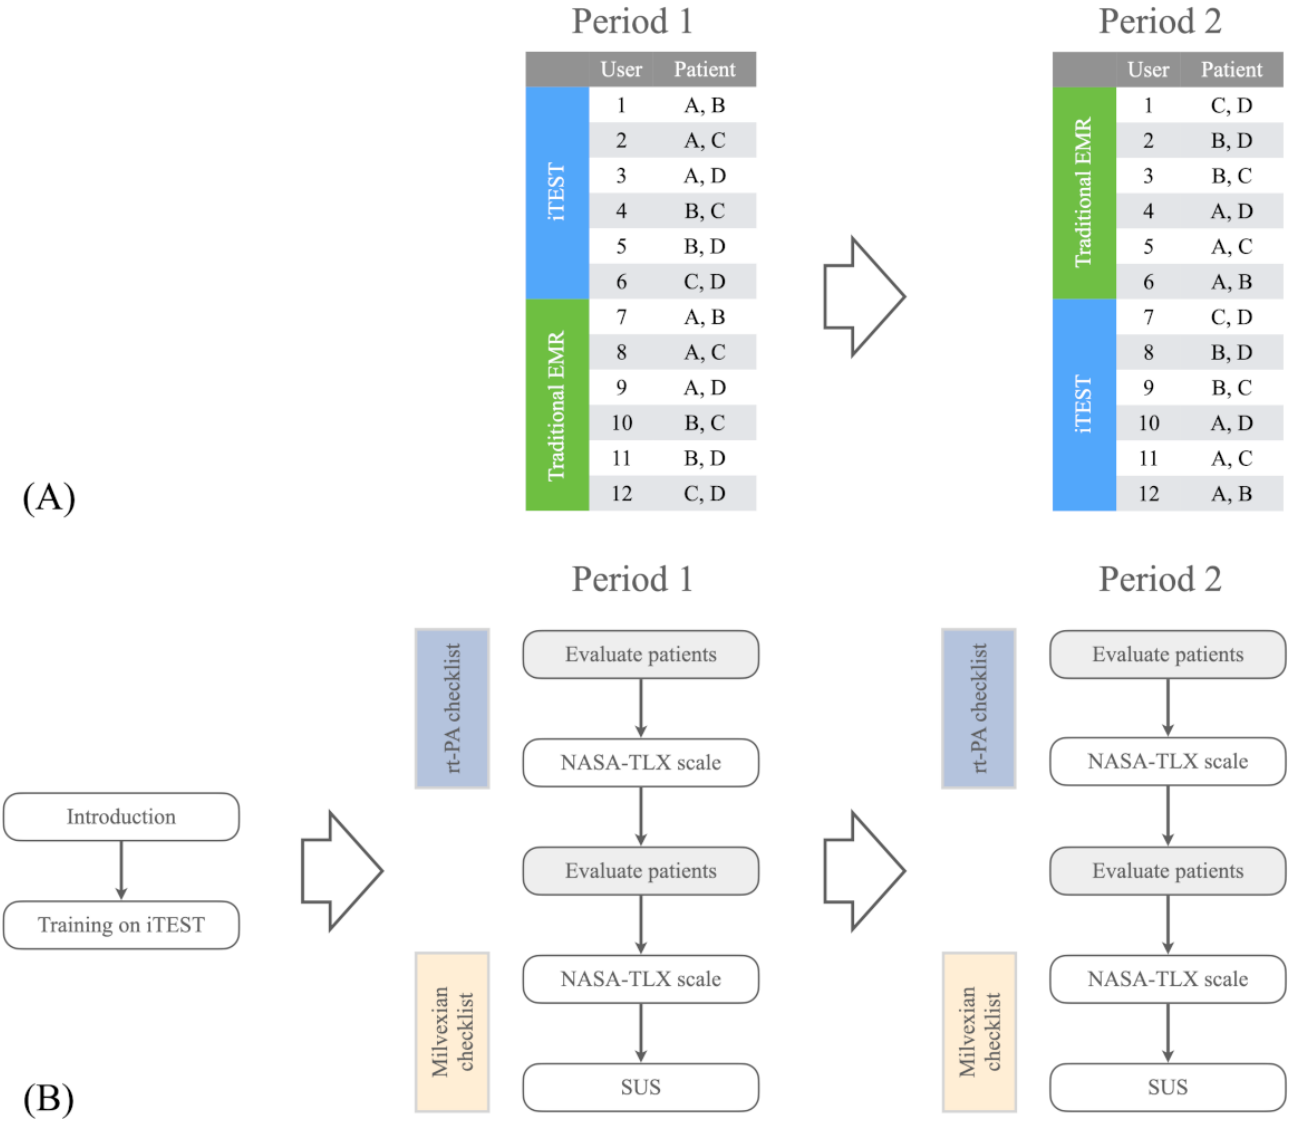
As an internal validation, we evaluated MetaMap Lite's ability to identify medical concepts related to the eligibility criteria examined in this study. We randomly selected 61 documents from 20 patients in a validation dataset separate from the one used for rule development. Two independent expert clinicians manually reviewed and annotated each document to establish a gold-standard reference, resolving disagreements through discussion and consensus. Precision and recall were calculated by comparing MetaMap Lite's automated extractions with the gold-standard annotations for each eligibility concept. Table S1 in Multimedia Appendix 1 displays the results, showing high precision and recall for most of the related concepts.

The inference engine analyzes the extracted information against the rule base to evaluate eligibility for each criterion. A web-based interface displays the rule-matching results, allowing users to review the eligibility criteria checklist with links to

XSL•FO
RenderX

annotated EMR documents, highlighting key concepts for review (Figure 3).

Figure 3. The intelligent trial eligibility screening tool (iTEST) interface. The left panel displays a trial eligibility criteria checklist, with each criterion marked yes or no based on the patient's data. The upper right panel features 2 tabs: one for clinical documents and one for numerical laboratory data. A red dot marks documents with relevant information. The lower right panel shows the content of the selected clinical document, highlighting key medical concepts for easy reference.



User Experiment

We conducted a user experiment to assess users' accuracy, efficiency, and perceived workload in determining eligibility. A total of 12 clinicians participated in the study, using either a standard EMR interface or the iTEST on a desktop computer to complete eligibility criteria checklists for the NINDS rt-PA and Librexia STROKE trials. Participation was voluntary and compensated.

The experiment used a 2-period crossover design to compare the effectiveness of the iTEST with a standard EMR interface. Each user evaluated 4 patients—2 with the iTEST and 2 with the standard EMR—resulting in 48 scenarios (Figure 4A). We set the participant count at 12 to ensure each patient appeared 6 times in both testing scenarios.

XSL•FO
RenderX

Figure 4. A 2-period crossover design for the user experiment (A). Procedures of the user experiment (B). EMR: electronic medical record; NASA-TLX: National Aeronautics and Space Administration Task Load Index; rt-PA: recombinant tissue-plasminogen activator; SUS: system usability scale.

The 4 cases chosen for this study are actual patients with stroke from our hospital. They have complex histories, detailed records across multiple departments, and several treatment contraindications. Some critical contraindications are only documented in less prominent sections, like outpatient notes, making them harder to identify quickly during assessment. To prevent overfitting and ensure an unbiased evaluation, the 4 cases were held out from the datasets used for the development or internal validation of the eligibility extraction rules.

At the experiment's start, each user received a detailed introduction to procedures (Figure 4B) and 10 minutes of iTEST training. A study coordinator managed the process and recorded time points. In period 1, users utilized either the standard EMR interface or the iTEST, switching to the other in period 2. During each period, users evaluated eligibility for 2 patients, first for the rt-PA checklist and then for the milvexian checklist. After evaluations, they assessed cognitive workload using the National Aeronautics and Space Administration Task Load Index (NASA-TLX) scale [19]. At the end of each period, they provided overall usability feedback through the system usability scale (SUS) questionnaire [20].

Outcomes

The primary outcome measured response accuracy to the eligibility checklist. For each patient, users completed checklists for 2 trials (Tables S2 and S3 in Multimedia Appendix 1). At least 2 senior neurologists (YHS and SFS) with extensive stroke care experience established reference answers by consensus, against which user responses were marked as correct or incorrect. Each correct response earned 1 point, and the final accuracy score (maximum=1) for each checklist was the average of the points of all criteria in that checklist.

Secondary outcomes included checklist completion time, cognitive workload (measured by the NASA-TLX scale), and tool usability (measured by the SUS). The NASA-TLX assesses 2 dimensions of subjective workload: mental demand, physical demand, temporal demand, performance, effort, and frustration [19], rated from 0 to 20, with higher scores indicating greater cognitive workload. Ratings are weighted to produce a total score from 0 to 100. The SUS evaluates interface usability via a 10-item Likert scale questionnaire (from strongly agree to strongly disagree), assessing factors including support needs, training requirements, complexity, integration, ease of learning,

XSL•FO
RenderX

and user confidence [20]. SUS scores range from 0 to 100, with higher scores indicating better usability. A prior study showed that adjective ratings of "poor," "OK," and "good" corresponded to average SUS scores of 35.7, 50.9, and 71.4, respectively [21].

In addition to the above planned analyses comparing overall performance between the standard EMR interface and the iTEST, we conducted exploratory subgroup analyses examining each treatment protocol (rt-PA and milvexian) separately to provide more detailed insights into system performance across different clinical scenarios.

Statistical Analysis

Given the small sample size in the user experiment and the non-normal distribution of the outcome measures, we reported the outcome measures as medians with interquartile ranges and conducted nonparametric analyses. The iTEST and the standard EMR interface were compared using the Wilcoxon signed-rank test for repeated user measurements. Two-tailed *P* values <.05 were considered statistically significant. Analyses were performed using R version 4.4.0 (R Foundation for Statistical Computing).

Results

User Statistics

Table 1 summarizes participant characteristics. The study included 6 physicians and 6 nurse practitioners. The participants, who were evenly split between male and female participants, had a mean age of 41 years and varied widely in experience levels across clinical practice, EMR use, personal computer use, and stroke care. The median clinical experience was 14.5 years, and they used the standard EMR interface for a median of 7 years.

Table . User characteristics.

User	Age (y)	Gender	Profession	Experience (y)			
				Clinical practice	EMR[a] use	PC[b] use	Stroke care
#1	34	Male	Physician	7	5	7	1
#2	46	Female	NP[c]	25	15	30	5
#3	51	Female	NP	27	9	30	16
#4	39	Female	NP	10	10	20	16
#5	40	Female	NP	20	8	20	3

#9	41	Male	Physician	15	1	22	15
#10	43	Male	Physician	16	12	20	16
#11	40	Female	NP	18	7	22	2
#12	48	Female	NP	7	7	7	3

[a]EMR: electronic medical record.

[b]PC: personal computer.

[c]NP: nurse practitioner.

Computational Performance

To evaluate the iTEST's computational performance, we measured processing time using EMRs from 15 patients with different documentation volumes. The number of clinical notes per patient ranged from 417 to 7299. System processing time (measured from patient selection to the full display of MetaMap Lite-analyzed clinical notes) varied from 6 to 345 seconds (average: 39 ms per note). This processing represents an initial computational overhead when a patient is first loaded; the subsequent evaluation of multiple eligibility criteria requires no extra processing time. In our clinical workflow, iTEST processing begins at patient triage in the emergency department, ensuring that all EMR analyses are completed before clinicians assess trial eligibility.

Evaluation Outcomes

Table 2 compares the outcomes of the standard EMR interface with the iTEST. Users attained a median accuracy score of 0.91 for the primary outcome using the standard EMR interface. In contrast, the iTEST produced a higher median accuracy score of 1.00, representing a 9.9% improvement with strong statistical significance (*P*<.001).

XSL•FO
RenderX

Table . Comparisons of outcomes between scenarios using the standard EMR[a] interface and the iTEST.

Outcome	Standard EMR interface, median (IQR)	iTEST[b], median (IQR)	*P* value
Accuracy score	0.91 (0.84 - 0.96)	1.00 (0.95 - 1.00)	<.001
Time (min)	3.18 (2.34 - 4.52)	2.44 (1.67 - 3.17)	.004
NASA-TLX[c] score	62.8 (36.7 - 75.8)	39.7 (26.8 - 52.0)	.02
SUS[d] score	46.3 (36.9 - 55.0)	71.3 (56.9 - 75.6)	.01

[a]EMR: electronic medical record.

[b]iTEST: intelligent trial eligibility screening tool.

[c]NASA-TLX: National Aeronautics and Space Administration Task Load Index.

[d]SUS: system usability scale.

Tables S2 and S3 in Multimedia Appendix 1 display the average accuracy scores of all 12 users for each eligibility criterion. With the standard EMR interface, accuracy scores ranged from 0.54 to 1.00, while the iTEST improved this range to 0.75 to 1.00. Users particularly struggled with certain criteria while using the standard interface, including identifying a diabetes history along with a prior stroke, internal bleeding within the last 3 months, and an activated prothrombin time of ≤1.4 times the control value within 7 days. For these challenging criteria, accuracy scores dropped below 0.60 with the standard interface but improved to at least 0.75 with the iTEST.

For secondary outcomes, the iTEST reduced task completion time by 0.74 minutes (23.3% reduction; from 3.18 to 2.44 min; *P*=.004) compared with the standard EMR interface. Users reported a 23.1-point reduction in NASA-TLX scores (36.8% decrease; from 62.8 to 39.7; *P*=.02), indicating substantial improvement in perceived cognitive demand. The SUS scores improved by 25 points (54% increase; from 46.3 to 71.3; *P*=.01), moving the system from the “POOR to OK” category to the “OK to GOOD” category and exceeding the acceptability threshold [21].

Table 3 presents the scores for each NASA-TLX subscale. Among the 6 dimensions of cognitive workload, mental demand, temporal demand, and effort received higher scores than physical demand, performance, and frustration. Participants reported significant reductions in temporal demand, effort, and frustration when using the iTEST as opposed to the standard EMR interface.

Table . Comparisons of NASA-TLX[a] subscales between scenarios using the standard EMR[b] interface and the iTEST[c].

NASA-TLX subscale	Standard EMR interface, median (IQR)	iTEST, median (IQR)	*P* value
Mental demand	13.5 (10.0 - 16.6)	10.0 (6.8 - 14.3)	.13
Physical demand	10.0 (6.8 - 13.0)	7.0 (4.4 - 10.0)	.18
Temporal demand	14.0 (10.0 - 17.6)	9.0 (4.9 - 11.5)	.007
Performance	7.0 (2.0 - 10.5)	3.8 (2.0 - 5.3)	.10
Effort	14.0 (10.0 - 17.6)	9.0 (4.4 - 14.0)	.02
Frustration	7.5 (3.5 - 10.0)	4.3 (1.0 - 8.0)	.02

[a]NASA-TLX: National Aeronautics and Space Administration Task Load Index.

[b]EMR: electronic medical record.

[c]iTEST: intelligent trial eligibility screening tool.

The results of the exploratory subgroup analysis, which compares the outcomes for each checklist individually, are listed in Table S4 in Multimedia Appendix 1. For the rt-PA checklist, the accuracy score significantly improved from 0.91 to 1.00 (*P*=.001) using the iTEST. However, no significant differences were observed in task completion time or NASA-TLX scores. In contrast, the iTEST significantly improved all outcomes for the milvexian checklist.

Discussion

Principal Results

This study demonstrated that the iTEST outperformed the standard EMR interface in multiple ways. It improved the accuracy of determining trial eligibility criteria while enhancing efficiency through shorter task completion time. The iTEST also significantly reduced users’ cognitive workload and offered better usability than the standard interface.

Accuracy of Eligibility Screening

The iTEST showed significant improvements over the standard EMR interface. It enhanced accuracy in identifying both

XSL•FO
RenderX

numerical laboratory data and textual information in clinical documents. For instance, for the milvexian checklist, the accuracy score for "APTT≤1.4 times control" increased markedly from 0.54 to 0.92 (Table S3 in Multimedia Appendix 1). This improvement likely occurred because the standard EMR lacks automated rule checking, requiring users to perform mental or manual calculations of numerical values.

The iTEST also improved accuracy when determining eligibility criteria using textual information. For instance, for the rt-PA checklist, users often misidentified patients with "diabetes with prior stroke," achieving only a 0.54 accuracy score. This low score likely arose from the complexity of the assessments needing both laboratory data and clinical narratives. Extensive medical histories can obscure crucial diagnostic evidence, leading to medical errors [22]. This is a common challenge for clinical researchers working with large, complex medical records—even in electronic form, the human brain struggles to identify key concepts quickly [23,24]. The iTEST addressed this challenge by extracting and highlighting essential information in clinical documents, thereby improving eligibility screening accuracy from 0.54 to 0.75 (Table S2 in Multimedia Appendix 1). However, the suboptimal accuracy (0.75) underscores the challenge of linking temporal relationships between conditions documented across multiple clinical notes. This limitation affects both automated systems and human reviewers due to cognitive load and fragmented information in medical records.

While the iTEST performed well overall in clinical trial screening, our NLP validation (Table S1 in Multimedia Appendix 1) revealed issues with key concept extraction. Notably, "Anticoagulant" detection (F_1-score=0.33) was poor, mainly due to nonstandard negation expressions that caused false positives and incomplete concept mapping, leading to missing specific anticoagulants. We refined the process by adding 5 anticoagulants (warfarin, apixaban, dabigatran, edoxaban, rivaroxaban), greatly improving accuracy. This workaround, however, highlights a significant limitation of MetaMap Lite's concept generalization and ontology depth for broad drug classes; the tool failed to effectively handle a critical, broad safety concept without explicit enumeration of individual drugs. This highlights the need for concept validation and iterative refinement in NLP tools for critical criteria.

Furthermore, using MetaMap Lite instead of the full MetaMap may result in less effective concept extraction. While faster and lighter, MetaMap Lite implements only a subset of MetaMap's extensive options and lacks sophisticated word-sense disambiguation modules, which can result in mapping all available senses of a term and generating false positives [17]. The failure to generalize the anticoagulant concept exemplifies this limitation. Specifically, MetaMap Lite's shallower ontology proved inadequate for managing hierarchical drug class relationships essential for safety screening. Although suitable for resource-limited or real-time applications, high-accuracy tasks are better served by the full MetaMap, emphasizing the trade-off between speed and depth.

Therefore, we recommend that clinical implementations of the iTEST include a validation phase where each new eligibility criterion is tested against a small set of annotated medical records before deployment. This quality assurance step can identify concept-mapping issues and help refine the process, especially for critical safety−related criteria such as anticoagulant use. Furthermore, despite the iTEST achieving a median accuracy of 1.00, the relatively lower accuracy on critical, complex criteria such as "diabetes with prior stroke" still indicates a high-risk failure mode that the iTEST did not fully address.

Efficiency and Usability

Even though users were trying the iTEST for the first time, they completed eligibility screening significantly faster after just a 10-minute training session. Users took a median of 2.44 minutes with the iTEST compared to 3.18 minutes with the standard EMR interface (Table 2) despite having years of experience with the latter. Notably, when analyzing individual checklists, the rt-PA checklist showed no significant improvement in completion time. This likely occurred because users were already highly familiar with checking eligibility criteria for intravenous thrombolysis (similar to those of the NINDS rt-PA trial) in their daily clinical practice before the study. Additionally, our study might have been underpowered to detect these smaller effects on familiar tasks, unlike the significant improvements seen across all metrics for the unfamiliar milvexian checklist.

With users achieving higher accuracy in less time during eligibility screening, it is unsurprising that the iTEST demonstrated better system usability than the standard EMR interface. The SUS score of 71.3 represents acceptable usability in the "OK to GOOD" range, indicating meaningful improvement over the standard EMR (46.3) but also suggesting room for further optimization. Despite being new to users and having received only 10 minutes of training, the iTEST demonstrated reasonable ease of use for this specific task. Research has shown that EMR systems should incorporate ongoing physician feedback to enhance usability, as poor EMR design can negatively impact physicians' well-being and increase their perceived workload [25]. Consistent with these findings, the iTEST not only improved system usability but also reduced the perceived cognitive workload.

Cognitive Workload

The iTEST significantly outperformed the standard EMR interface in overall NASA-TLX scores. While some researchers question the mathematical validity of combining the 6 NASA-TLX dimensions into a single workload score [26], we analyzed both the overall and individual dimensions (Table 3). The most substantial improvements were observed in temporal demand (from 14.0 to 9.0, P=.007) and effort (from 14.0 to 9.0, P=.02), with frustration levels also showing a significant reduction (from 7.5 to 4.3, P=.02). The marked reduction in temporal demand aligned with the decreased task completion time, which is crucial since the effectiveness of stroke therapy depends heavily on timing [27] and creates substantial pressure for clinicians [28,29]. While we observed significant improvements in temporal demand, effort, and frustration subscales, reductions in mental demand, physical demand, and

XSL•FO
RenderX

performance subscales did not reach statistical significance, possibly due to a limited sample size.

Few studies have assessed trial eligibility screening workload [30,31], primarily measuring work volume instead of cognitive burden. To our knowledge, no research has specifically analyzed the cognitive workload of this task. However, studies have compared perceived cognitive workload across different EMR interfaces and visualization tools for various clinical tasks [32-34], indicating that renovations to the EMR interface can enhance efficiency and reduce cognitive demands.

Clinical Implications

The iTEST improves upon the standard EMR interface with better accuracy and efficiency in eligibility screening, reduced cognitive workload, and enhanced usability, leading to several clinical benefits. Researchers can enroll suitable trial participants more effectively, ensuring scientific validity and data quality while protecting ineligible patients. Additionally, the iTEST enhances patient safety by avoiding unnecessary risks. For instance, the NINDS-rt-PA trial, which examined rt-PA in patients with acute ischemic stroke, highlights the importance of careful patient selection to mitigate serious intracranial bleeding risks [35]. The eligibility criteria established by this trial have become the standard for intravenous thrombolysis [36]. Consequently, the iTEST can assist clinicians in selecting appropriate patients for therapies, improving routine clinical practice.

While the iTEST's computational overhead can reach up to 345 seconds for patients with extensive EMR histories, this does not affect time-sensitive clinical decision-making in our workflow. By starting EMR processing at emergency department triage, all computational work is completed before clinicians evaluate trial eligibility. This integration ensures that the iTEST's processing time does not cause delays during the critical acute stroke assessment window. Future implementations in other clinical settings should consider similar workflow integration strategies, and improving MetaMap Lite's performance may further reduce processing times for real-time use.

This study examined 2 checklists. Users were already familiar with the rt-PA checklist before the study. They still made occasional mistakes, achieving a median accuracy score of 0.91. The iTEST improved this score to 1.00. The milvexian checklist, being new to users, yielded a lower median accuracy score (0.84) than the rt-PA checklist (0.91), highlighting how unfamiliarity with eligibility criteria can lead to more errors. With the iTEST, users achieved nearly perfect accuracy (median score 1.00) for both the familiar rt-PA and unfamiliar milvexian checklist, demonstrating its value over the standard EMR interface, especially for new eligibility checklists. However, the separate analyses of the rt-PA and milvexian checklists were exploratory. While these findings provide valuable insights into protocol-specific performance, they should be interpreted cautiously and confirmed in future prospective studies with predefined hypotheses.

Cognitive overload is a leading cause of burnout among clinicians [4]. When facing burnout, clinicians favor patients with straightforward medical histories, as fewer clinical documents are needed for eligibility determination. They may overlook patients with complex, lengthy medical histories requiring thorough review. This selection bias can compromise clinical trial validity by causing the trial population to deviate from the intended target population. The iTEST addresses this issue by reducing cognitive workload, thus streamlining patient recruitment and minimizing selection bias. This benefit becomes even more pronounced as EMR documentation grows over time.

Prior research on trial eligibility screening has primarily focused on enhancing recruitment efficiency through the application of NLP and machine learning to EMR data. The foundational work by Ni et al [30,31] demonstrated substantial workload reductions, with over 90% in pediatric emergency department settings and 85% in pediatric oncology, by leveraging both structured data and unstructured clinical notes. The subsequent development of the Automated Clinical Trial Eligibility Screener [9] advanced this work into real-time, prospective screening, achieving a 34% reduction in screening time and an SUS score of 80.0.

The iTEST extends this foundation by addressing clinician empowerment and cognitive burden through 2 key innovations. First, its block-based visual programming interface enables clinicians to independently author and update screening rules without software engineering support, enhancing adaptability to evolving eligibility criteria. Second, the iTEST demonstrated significant improvements not only in efficiency but also in accuracy and cognitive workload, quantitatively validating its ability to reduce mental burden while maintaining acceptable usability. This positions the iTEST as a clinician-centric solution that enhances both the efficiency and reliability of eligibility screening while reducing clinician burnout.

Future Direction

Clinical notes at our hospital are primarily in English, with very few in Chinese. Therefore, we disregarded the Chinese portions when developing the iTEST. Besides, extracting medical concepts from non-English clinical documents presents significant challenges [37]. However, advancements in large language models (LLMs) may help address the challenge of multilingual clinical notes. They could potentially process multilingual clinical notes without explicit translation, reducing information loss. Moreover, LLMs provide promising capabilities that could overcome several limitations of rule-based approaches, such as those used in our study. Their natural language understanding could improve the handling of variations in clinical documentation, context-dependent interpretations, and complex eligibility criteria that require reasoning across multiple data points.

However, several issues must be addressed before widespread clinical use. First, reliability and consistency remain major challenges [38,39]. LLMs can produce inconsistent outputs for the same inputs and may generate plausible but incorrect information ("hallucinations"), which is unacceptable in clinical decisions. Second, computing costs and infrastructure requirements could limit scalability compared to rule-based systems. Third, regulatory compliance presents significant obstacles, as current frameworks require explainable, auditable

XSL•FO
RenderX

decision-making processes, but LLM reasoning often lacks transparency. Finally, concerns about data privacy and the need for specialized medical training data require careful consideration [40].

Future hybrid approaches that combine rule-based reliability with LLM flexibility may offer the best solutions [41], where LLMs handle complex language understanding and concept extraction [42]. Conversely, rule-based systems guarantee consistent application of explicit eligibility criteria. Importantly, such hybrid frameworks can improve explainability by maintaining transparent decision pathways: the rule-based component offers clear, traceable logic for eligibility determinations, while LLM outputs can be limited to produce interpretable explanations for their reasoning processes. In this way, LLMs, with their strong reasoning and summarization abilities, could be useful in various clinical and research scenarios [43].

Limitations

This study has several limitations. First, with only 12 clinicians evaluating 4 patients' eligibility, the study findings may not reflect real-world scenarios. Furthermore, the small number of participants may lack enough statistical power to detect differences between the groups. Although our study design, with 12 clinicians, was appropriate for identifying medium-to-large differences, we acknowledge that it may have been underpowered to detect smaller, yet potentially clinically important, effects. Despite this limitation, all 4 outcomes achieved statistical significance. Second, the 4 patients chosen for this study may not accurately represent a typical patient population. However, these cases truly demonstrate the difficulties clinicians encounter when trying to retrieve crucial information from traditional EMR systems. In real-world clinical settings, these patients represent a specific group that not only risks misjudgment and possible harm but also presents challenges for clinical trials.

Third, while our crossover design enhances internal validity through within-subject comparisons, its applicability to real-world recruitment is limited due to the small number of participants and patient scenarios. These may not accurately reflect the diversity of clinical experience, patient complexity, practice patterns, or technological skills across different settings. Real-world implementation involves a wider range of patient presentations, comorbidities, and situations that could impact system performance differently. Future research should test the iTEST in diverse clinical environments with larger samples to better determine its effectiveness for large-scale trial recruitment. Fourth, the controlled experimental setting may not fully capture the time pressures, interruptions, and multitasking demands of actual emergency care that could influence accuracy and efficiency.

Fifth, the brief 10-minute training and the crossover design could theoretically lead to learning effects [44] that may influence our results. Although we counterbalanced the task order to minimize these effects, the crossover design means participants' second interface evaluation might have been affected by familiarity with the eligibility screening task itself. However, the counterbalancing of task order should have evenly distributed any such learning effects across conditions [45]. Additionally, the short 10-minute training period for the iTEST actually serves as a conservative test of the system's usability. The fact that the iTEST showed superiority despite minimal training strengthens rather than weakens our findings.

Sixth, we acknowledge that our user study focused exclusively on the rule evaluation module and did not assess clinicians' ability to author rules using the block-based interface. Our study design prioritized evaluating whether the system could effectively support the eligibility screening workflow with preconfigured rules, as this represents the most common use case in our target clinical settings. However, we recognize that this does not validate the authoring capabilities.

Finally, while participants had extensive experience with the standard EMR interface compared to minimal training with the iTEST, we cannot rule out the influence of the novelty effect [46] or the Hawthorne [47] effect on our results. Participants' awareness of being observed and evaluated, along with the novelty of the iTEST interface, may have led to increased attention and improved performance. Future studies with longer training periods, repeated testing, and naturalistic observation could help determine whether the observed benefits persist beyond initial exposure, revealing learning curves for both systems.

Conclusions

In this study, we introduced the iTEST, an innovative NLP-powered clinical decision support tool that uses MetaMap Lite to extract relevant concepts from EMRs. The system design includes a block-based visual programming interface intended to enable clinicians to author and modify eligibility rules independently; however, the usability and effectiveness of this authoring capability were not evaluated in this study and remain objectives for future research. Our user evaluation focused exclusively on the rule evaluation module using preconfigured rules, where the iTEST demonstrated superior accuracy and usability compared to the standard EMR interface, while reducing both task completion time and perceived cognitive workload. The tool's applications can extend beyond clinical trial screening to include the verification of indications and contraindications for specific therapies or interventions. Through these capabilities, the iTEST has the potential to enhance patient safety while easing clinicians' cognitive burden. Future research should evaluate clinicians' ability to create and modify eligibility rules using the block-based authoring interface to fully validate the system's empowerment objectives and finalize the assessment of the iTEST's intended functionality.

Abstract

Background: In hospitals, Code Blue is an emergency that refers to a patient requiring immediate resuscitation. Over 85% of patients with cardiopulmonary arrest exhibit abnormal vital sign trends prior to the event. Continuous monitoring and accurate interpretation of clinical data through artificial intelligence (AI) models can contribute to preventing critical events.

Objective: This study aims to evaluate changes in clinical outcomes following the use of VitalCare (Major Adverse Event Score and Mortality Score), which is an AI-based early warning system, and to validate the performance of the algorithm.

Methods: A retrospective analysis was conducted by extracting electronic health record data, using a total of 30,785 inpatient cases from general wards and intensive care units. A comparative analysis was performed by setting a 3-month period before and after the system implementation. For clinical evaluation, we measured the incidence rates of Code Blue and adverse events, the proportion of prolonged hospitalization, and the frequency of early interventions. The area under the receiver operating characteristic curve (AUROC) was calculated to assess the performance of the algorithm.

Results: This study demonstrated that, following the implementation of VitalCare, there was a 24.97% reduction in major events such as Code Blue (P=.004) and the proportion of prolonged hospitalization in general wards (P<.05), along with a significant increase in the rate of early interventions. The model performance exhibited superior outcomes compared with traditional scoring systems, with a Major Adverse Event Score AUROC of 0.865 (95% CI 0.857 - 0.873) and Mortality Score AUROC of 0.937 (95% CI 0.931 - 0.944).

Conclusions: A well-developed AI-based model that provides high predictive power can contribute to the prevention of major in-hospital events by providing early predictive information to clinicians. Additionally, it plays a crucial role in effectively addressing unmet needs and challenges in terms of human resources and practical procedures.

KEYWORDS

adverse event; artificial intelligence; Code Blue; early warning system; rapid response system; VitalCare; hospitalization

Introduction

Code Blue is an emergency code used in hospital settings to indicate a patient experiencing cardiopulmonary arrest (CA), necessitating immediate resuscitative intervention [1]. This represents a critical and resource-intensive process in which health care providers must respond promptly and initiate action as soon as Code Blue is activated. Despite intensive and concerted efforts by medical staff, the survival rate of patients who experience a Code Blue event remains below 20% [1,2]. It is not only directly associated with a poor prognosis and high mortality rate of patients, but also contributes significantly to their economic burden.

Nevertheless, the early identification and prediction of CA or clinical deterioration can be achieved through a comprehensive analysis of patients' vital signs and blood test results. A previous

XSL•FO
RenderX

study demonstrated that over 85% of patients who experience in-hospital CA exhibit abnormal vital signs 6 to 24 hours before adverse events (AEs) [3]. Implementing timely interventions based on these predictions may help delay or prevent mortality. The effective management of Code Blue events depends on the timeliness and quality of interventions [4]. In this context, artificial intelligence (AI)–based early warning systems (EWSs) can facilitate preparedness and support timely intervention by providing advanced alerts. The ability to predict the risk of critical AEs in advance enables hospitals to allocate the necessary resources and establish timely medical treatment plans proactively [1,5].

Numerous studies have demonstrated the positive outcomes of using AI-EWS, underscoring the value of continuous patient monitoring for the early detection of critical events [6-9]. However, most AI-EWS studies have predominantly focused on developing models that predict individual clinical events, such as CA or death, thereby providing limited information. To enhance the early detection of patient deterioration, training algorithms with broadly defined indications are essential. Accordingly, we developed a multilabel algorithm that is designed to recognize the deterioration of patient conditions, including unplanned ward-to-intensive care unit (ICU) transfer (UIT), cardiopulmonary resuscitation, and mortality.

Despite advancements in AI-EWSs, insufficient evidence is available regarding their clinical utility when they are implemented in real-world hospital settings, particularly in terms of reducing in-hospital Code Blue events. Comprehensive validation across multiple domains is essential for the successful implementation and integration of AI-EWS technologies in clinical practice. Therefore, the primary objective of this study was to evaluate the effectiveness of applying an AI-EWS on clinical outcomes, including Code Blue events in hospitals, prolonged length of stay (pLOS), and the frequency of ordering new codes, such as early interventions or assessments for AEs, compared with a silent period using real-world electronic medical record (EMR) data. The secondary objective was to assess the performance in a hospital environment with different characteristics from those of the development data to verify the generalization of the model.

Methods

Study Design and Participants

This retrospective study was conducted at the Presbyterian Medical Center in the Republic of Korea, where a rapid response system (RRS) had not yet been established. Instead, the condition of each patient was monitored by an assigned registered nurse for potential clinical deterioration. In March 2023, the hospital introduced an AI solution named VitalCare (VC) for continuous patient monitoring in the general ward (GW) and ICU to predict patient deterioration. The study population consisted of patients aged 19 years and older who were admitted to the GW or ICU over a 17-month period from December 2022 to May 2024. A “silent period” was designated from December 2022 to February 2023 to establish control settings, during which health care providers did not use VC. Excluding the first 1-month adaptation period following the introduction of the system, data from April 2023 to May 2024 were set as the “entire alert period.” We classified and analyzed the intervention period into two categories. To control for seasonal bias, the alert period was defined as the winter months between December 2023 and February 2024 to match the control period, which was also confined to the winter months. Winter was associated with a higher incidence of AEs and mortality. Therefore, this study was designed to focus on comparative analyses specific to winter. To evaluate the overall trend in Code Blue occurrences, a comparative analysis was conducted using 5 years of event data. This analysis compared the 4-year average before the implementation of VC with data from the first year after implementation.

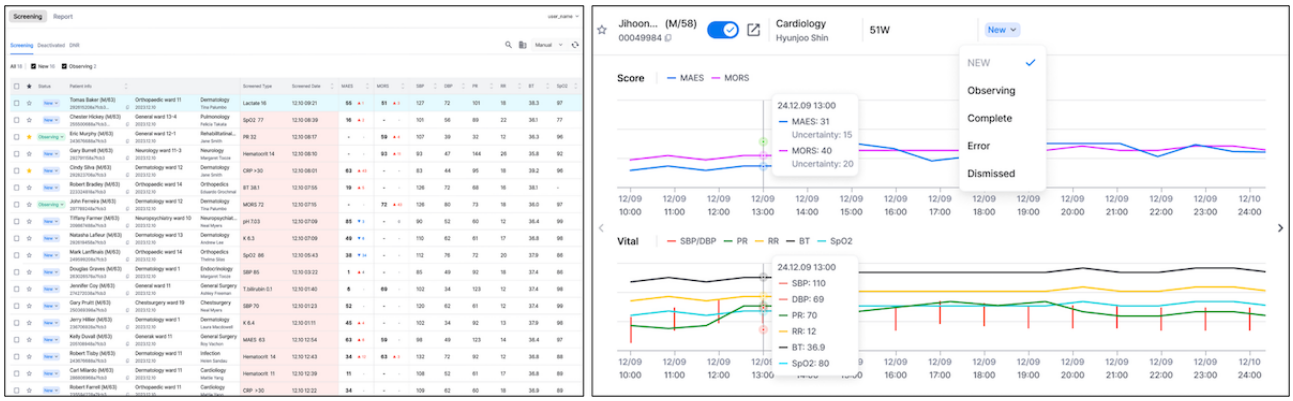
Ethical Considerations

The Institutional Review Board of the Presbyterian Medical Center approved this study on December 12, 2023, and waived the requirement for informed consent given the specific nature of the retrospective study (2023-12-051). This study was conducted in accordance with the principles of the 1975 Declaration of Helsinki. To protect the privacy of participants, all data were anonymized during extraction from the hospital’s EMR system and used solely for analysis purposes. As this was a retrospective study, no compensation was provided to participants.

Algorithm Description

The VC algorithm is a deep-learning-based model that uses a bidirectional long short-term memory architecture as a binary classifier to predict the occurrence of major AEs (positive or negative) in GW inpatients. It comprises VC-Major Adverse Event Score (MAES) and VC-Mortality Score (MORS), both of which have been approved by the Korean Ministry of Food and Drug Safety. The VC-MAES is designed to comprehensively predict 3 key events, namely, UIT, death, or cardiopulmonary resuscitation, within the GW. In contrast, the VC-MORS is designed to provide a score that could predict death in patients who are admitted to the ICU. ICU transfers within 3 hours of surgery completion or 12 hours of procedure initiation were considered as planned ICU transfers and were excluded from the outcome analyses. The VC-MAES was trained using data from 334,185 hospitalizations of 209,825 adult patients between 2013 and 2017 at Yonsei Severance Hospital, which is a 2454-bed tertiary academic medical center in Seoul, Republic of Korea. The VC-MORS was trained using data from 21,186 hospitalizations of 19,570 adult patients who were admitted to the ICU between 2013 and 2017 at the same hospital. The dataset encompasses more than 35 surgical and medical specialties. The details of the model architecture were the same as those described in a previous study, with slight modifications [10].

The model primarily uses 5 vital signs—systolic and diastolic blood pressure, heart rate, respiratory rate, and body temperature—along with age to generate risk scores ranging from 0 to 100. Higher scores indicate an increased risk of target events occurring within the next 6 hours. When available, the model also incorporates optional variables, including oxygen saturation (SpO_2), mental status (Glasgow Coma Scale), total bilirubin, lactate, creatinine, platelet count, pH, sodium,



XSL•FO
RenderX

potassium, hematocrit, white blood cell count, bicarbonate, and C-reactive protein. These inputs are updated whenever new data are recorded in the EMR system to ensure that the score reflects the patient's most recent condition. Given that these optional parameters are infrequently measured, missing values are imputed using the last observation carried forward method, where the most recent available value is used. If no prior values are available, normal reference values are assigned for score computation [11].

Practical Setting

We integrated the hospital network's EMR system with the pretrained VC algorithm, which was deployed to another institution without any retraining or recalibration, thereby enabling validation using real-world data from hospitalized patients. The system was configured to allow VC access across all GWs and ICUs. Health care providers reviewed single parameters, such as vital signs, laboratory data, and VC prediction scores, for all hospitalized patients via the VC web platform. The VC web platform presents a trend graph of score changes over time, alarm history, and single-parameter history (Figure 1). It was displayed continuously, allowing the health care providers to access it at any time, and clinicians used the information provided by the VC as a reference during clinical decision-making.

Figure 1. Web interface of VitalCare.

Clinical Evaluation

We analyzed clinical variables such as the in-hospital Code Blue incidence rate, AE (death and UIT cases) incidence rate, proportion of long-term hospitalization during each period, and frequency of early interventions to evaluate the clinical effectiveness following the implementation of VC.

We investigated the annual number of Code Blue events from 2019 to 2023 and calculated the incidence rate relative to the total number of hospitalized patients, excluding those with documented "Do Not Resuscitate" status. The silent period was represented by the average values from 2019 to 2022. The pLOS was defined as the 75th percentile of the total length of stay in the study population [12,13]. Based on this criterion, patients who were admitted to the GW for 9 days or more and those who were admitted to the ICU for 4 days or more were classified as having a prolonged hospital stay. The proportion of patients meeting these criteria was subsequently calculated to evaluate the prevalence of prolonged hospital stay within the cohort.

Given the varying total number of hospital admissions across different periods, the incidence rate of AEs was calculated per 1000 admissions. The number of interventions or evaluations performed within 2 hours of the first alarm activation was calculated to analyze the frequency of early interventions. For this analysis, intervention and evaluation items were compared using prescription codes, such as new oxygenation or change orders, laboratory tests, and any new code orders.

Performance Evaluation

The overall accuracy of the scores was determined by calculating the area under the receiver operating characteristic curve (AUROC) and area under the precision-recall curve (AUPRC) based on whether a target event occurred within 6 hours of the predicted scores. The bootstrap method was used to compare the AUROC and AUPRC with the National Early Warning Score (NEWS), Modified Early Warning Score (MEWS), Sequential Organ Failure Assessment (SOFA), and Acute Physiology and Chronic Health Evaluation II (APACHE II). Given the extensive use of NEWS, MEWS, and SOFA in studies worldwide to predict cardiac arrest or clinical deterioration, these scores were also used as comparators in this study [1,2,14,15]. NEWS and MEWS were calculated using current values of systolic blood pressure, heart rate, respiratory rate, body temperature, mental status, SpO_2, and the fraction of inspired oxygen (FiO_2) recorded in the EMR within 1 hour before the prediction point. The SOFA score was calculated using the worst recorded values in the EMR within 24 hours following ICU admission. As the APACHE II score is specifically used to predict the mortality risk of acutely ill patients within 24 hours of ICU admission [16], the AUROC and AUPRC were calculated based on whether death occurred during the ICU stay.

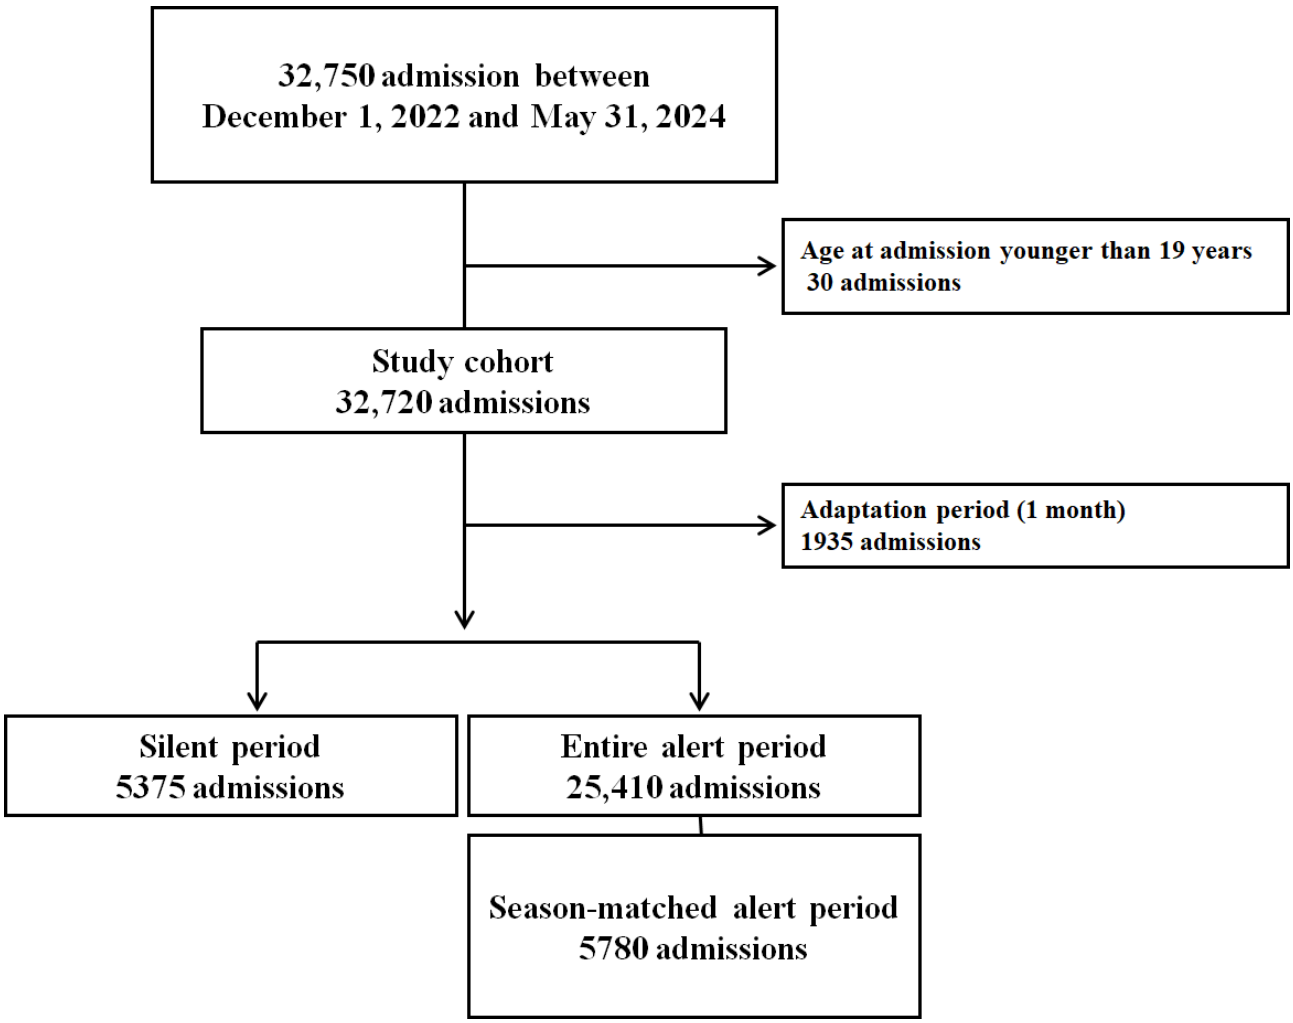
Statistical Analysis

Demographic characteristics during the silent and alert periods were compared using chi-square tests for categorical variables. For continuous variables, normality was assessed using the Shapiro-Wilk test and histogram inspection, which noted that large sample sizes may cause the test to reject normality due to high sensitivity. Normally distributed variables were compared using independent 2-tailed *t* tests, and nonnormally distributed variables were compared using the Mann-Whitney *U* test (2-tailed).

XSL•FO
RenderX

To evaluate predictive performance, 95% CIs for the AUROC were estimated using the bootstrap method with 1000 resamples. DeLong's test was used for statistical comparison of AUROC values, while a bootstrap-based test with 1000 resamples was applied for AUPRC.

Sensitivity, specificity, positive predictive value, and negative predictive value were calculated to evaluate the performance of the scores, using predefined thresholds corresponding to moderate and high alarm levels. Proportions were compared using the 2-sample proportion test, applying either 1- or 2-tailed approaches as appropriate. One-tailed tests were used to compare AE rates when a directional effect was prespecified, whereas 2-tailed tests were applied when no prior direction was assumed.



All statistical analyses were performed using Python (version 3.12.9; Python Software Foundation), with statistical significance defined as $P<.05$, applied uniformly across 1- and 2-tailed tests. The analyses used the MLstatkit and scikit-learn libraries.

Results

Overview

This study initially included 32,750 admissions from 24,187 patients. After applying the exclusion criteria, 30 admissions involving patients aged younger than 19 years of age were excluded, resulting in 32,720 admissions being included in the study dataset, which was used for performance evaluation. Considering the adaptation period, 1935 admissions were excluded from the study. The final dataset consisted of 5375 admissions during the silent period, 25,410 admissions during the alert period, and 5780 admissions during the seasonally matched alert period. There were 3576 ICU admissions, of which 2 were younger than 19 years of age and were excluded, leaving 3574 admissions for the VC-MORS performance evaluation. After excluding 214 admissions during the adaptation period, 3360 admissions remained, including 647 admissions during the silent period, 2713 admissions during the entire alert period, and 597 admissions during the seasonally matched alert period (Figure 2).

Figure 2. Flowchart of admission selection.

Baseline Characteristics

We compared baseline characteristics of patients admitted during the silent and alert periods, including vital signs, laboratory values, and the Charlson comorbidity index, which was calculated according to previously published methods [17,18]. While statistically significant differences were observed in pulse rate, respiratory rate, SpO_2, bilirubin, sodium, NEWS, MEWS, Charlson Comorbidity Index, and other baseline characteristics

XSL•FO
RenderX

were similar (Table 1). These findings indicate that patient baseline characteristics were largely similar between the 2 periods.

Reduction in Code Blue and AEs

The incidence of Code Blue was expected to decrease in 2023 compared to the 4-year average between 2019 and 2022. Since the implementation of the VC system in 2023, the hospital's Code Blue incidence rate (per 1000) has decreased by 24.97%, from 10.57 to 7.93 (*P*=.004). As shown in Table 2, even year-by-year comparisons during the pre-VC period show that the incidence was lower after the introduction of VC.

Table . Code blue trends before and after VC[a] implementation.

Year	Number of hospitalized patients[b]	Number of Code Blue events	Code Blue period incidence rate (per 1000)
Before VC implementation			
2019	22,262	262	11.69
2020	21,726	229	10.34
2021	22,087	210	9.32
2022	21,381	223	10.19
Average	21,864	231	10.57
After VC implementation			
2023	21,061	167	7.93

[a]VC: VitalCare

[b]Excluding DNR (Do Not Resuscitate) patients.

Moreover, we compared the rates of UIT and in-hospital mortality across three intervals: the silent (pre-VC) period, the season-matched period, and the entire study period. The baseline UIT event rate during the silent period was 69.40 events per 1000 admissions, which significantly decreased to 60.73 (*P*=.03) in the season-matched period and 62.37 (*P*=.03) in the entire study period. For in-hospital mortality, the baseline rate was 19.72 deaths per 1000 admissions, decreasing to 16.78 (*P*=.12) during the season-matched period and further to 15.87 (*P*=.02) during the entire period (Table 3).

Table . Number of adverse events by period.

	UIT[a]	*P* value	Mortality	*P* value
Silent period	69.40	—[b]	19.72	—
Season-matched alert period	60.73	.03	16.78	.12
Entire alert period	62.37	.03	15.87	.02

[a]UIT: unplanned ward-to-intensive care unit transfer.

[b]Not applicable.

Clinical Outcomes

The pLOS rate in the GW decreased significantly following VC implementation. No significant difference in the pLOS rate was observed before and after the implementation of the VC system in the ICU (Table 4).

Table . Comparison of length of stay between periods.

	General wards (n=30,785 admissions)		Intensive care units (n=4013 transfers)	
	Proportion of pLOS[a] (LOS ≥9 days), %	*P* value	Proportion of pLOS (LOS ≥4 days), %	*P* value
Silent period	26.85	—[b]	28.91	—
Season-matched alert period	24.65	.01	30.96	.39
Entire alert period	25.46	.03	28.54	.84

[a]pLOS: prolonged length of stay

[b]Not applicable.

As shown in Tables 5 and 6, significantly more early interventions such as oxygenation, laboratory tests, and new code orders occurred following the activation of both moderate (VC-MAES=30) and high (VC-MAES=50) alarms. However, in the ICU, significant earlier interventions were observed only following a moderate VC-MORS alarm (VC-MORS=20), particularly with the ordering of laboratory tests, such as that for lactate.

Model Performance Compared With Traditional Scoring System

VC-MAES and VC-MORS outperformed conventional EWS in both AUROC and AUPRC. VC-MAES achieved an AUROC of 0.865 (95% CI 0.857-0.873) and an AUPRC of 0.088 (95% CI 0.080 - 0.098), which were significantly higher than those of NEWS (AUROC=0.804; AUPRC = 0.018) and MEWS (AUROC=0.772; AUPRC=0.020).

Similarly, VC-MORS showed strong predictive performance for 6-hour mortality, with an AUROC of 0.937 (95% CI 0.931 - 0.944) and an AUPRC of 0.098 (95% CI 0.087-0.109), which outperformed SOFA (AUROC=0.754; AUPRC=0.011). APACHE II, calculated once within 24 hours of ICU admission, showed an AUROC of 0.814 and an AUPRC of 0.259 for predicting ICU mortality (Table 7).

Discussion

Principal Findings

We retrospectively collected the EMR data of hospitalized patients and compared the pre- and postintervention clinical outcomes to evaluate the effectiveness of VC. The results demonstrated that VC use was associated with high predictive performance and a significant reduction in Code Blue events. Specifically, VC-MAES exhibited a reduced pLOS and a lower number of AEs compared with the silent period, along with an increased frequency of early interventions.

Bridging the Afferent Limb With AI-EWS

Globally, the importance of RRS as a means of preventing AEs has been increasingly emphasized. However, rescue failures may occur even in environments where RRSs are implemented owing to challenges in the afferent limb [19]. The afferent limb refers to the “recognition” phase, encompassing processes such as monitoring, identification, and triggering a response [20]. VC supports automated monitoring, aids in the detection of early high-risk patients, and offers potential solutions for delaying and preventing Code Blue events [1]. In this regard, it can be used systematically and efficiently in environments where an RRS is already established. Conversely, it can maximize the potential impact by addressing unmet needs, even in hospitals where the RRS is not organized or is understaffed.

Optimizing Care With Predictive Monitoring

In practical settings, the initial assessment and recognition of a patient’s condition are typically performed by nursing staff. Subsequently, the attending physician is notified of the patient’s condition to facilitate decision-making regarding diagnosis and treatment. Vital signs and laboratory tests are also intermittently monitored, making the automatic interpretation and screening of time-series data a critical clinical requirement. As AEs often occur abruptly, such sequential processes can serve as barriers to timely intervention. VC can address this challenge by providing predictive alerts before the occurrence of AEs. This study confirmed a short-term decrease in UIT and death cases, which was found to have led to a significant long-term reduction in Code Blue events.

VC provides the opportunity to assess a patient’s condition (eg, laboratory tests, blood culture, and imaging) proactively or report it to the attending physician early, enabling the preparation of the necessary resources in advance. Accordingly, our findings suggest that VC implementation leads to notable clinical improvements, including increased early intervention and reduced AEs. Prior studies have indicated that several patients who ultimately experience CA remain in the GW for extended periods before being transferred to the ICU (or are never transferred at all), which negatively affects their survival rates. Consequently, these studies asserted that AI-based EWSs have the potential to reduce in-hospital mortality [15,21-23].

We conducted a subgroup analysis of the frequency of early interventions and observed a more significant increase in the GW following VC use (Table 5). It is well established that early intervention improves patient outcomes [24-26]. The occurrence of any intervention or evaluation within 2 hours of the initial risk prediction of VC can be interpreted as an indication that the clinician agreed with this information and suspected patient deterioration. VC can detect AEs more quickly than traditional

XSL•FO
RenderX

scoring systems, thereby offering the benefit of securing opportunities for early recognition and treatment, and potentially preventing AEs in the GW, where closed observation may not be as rigorous. Conversely, as patients in the ICU were already under real-time close observation by medical staff, there was no change in the intervention rate within 2 hours of the first elevation. Similarly, a trend was observed in which the difference in intervention rates diminished as the patient severity increased. These results were predictable and reasonable. Based on these findings, we propose that the use of VC-MORS in the ICU is more beneficial for real-time patient monitoring, enabling the early prediction of critical events with high predictive power, rather than offering new information that could lead to additional prescriptions.

In conclusion, VC serves as a clinical decision-supporting system that provides supplementary information for health care providers rather than functioning as an independent diagnostic tool. Ultimately, the clinical judgment of health care professionals remains the final determinant in decision-making. The successful integration and adaptation of AI-EWS into clinical practice suggest the potential for clinical decision-supporting systems to be used more extensively. Various research will be needed to achieve this. We believe that the synergy between the enhancement of health care professionals' ability to use predictive information and the advancement of AI-EWS could yield significant outcomes for patients and clinical settings.

This study demonstrates the effectiveness of AI-based EWS in a community hospital without an RRS; however, its applicability to institutions in resource-limited settings requires further consideration. The adoption and integration of health AI can vary significantly across countries, depending on geopolitical and socioeconomic development [27,28]. Consequently, several challenges may arise in rural hospitals or institutions with limited digital infrastructure [29]. These include the absence of real-time EMR systems, poor clinical data quality, limited clinician training in AI tools, and variability in clinical workflows and institutional acceptance. While simplified models may offer a feasible alternative, future research should explore implementation strategies for lightweight AI-EWS systems and scalable integration approaches in community-based and resource-limited settings.

Limitations

This study has several limitations. First, the control period was relatively short owing to constraints in data extraction following the computerized system upgrade period at our institution. A comparative analysis was conducted within a given period using the same computerized system. Second, the effect of VC on patient prognosis following discharge was not investigated. Third, although this was a real-time EWS validation study, it did not evaluate interaction variables between AI-based EWS and the clinician, such as alarm fatigue. Given that real-time EWS operates as a continuous monitoring system, some degree of alert fatigue may perhaps be unavoidable. While adjusting thresholds—such as lowering sensitivity—may mitigate excessive alerts, it may also increase the risk of missing critical events. Future research will focus on assessing the effectiveness of clinician-AI interactions through the AI-based EWS and their influence on discharge outcomes and postdischarge prognosis.

Conclusions

A well-designed and validated AI-based EWS, such as VC, can effectively reduce major in-hospital AEs by enabling early detection and intervention. By supporting clinical decision-making without replacing professional judgment, this study demonstrates the potential of AI-EWS to enhance patient outcomes and optimize resource utilization in hospital settings.

Data Availability

The datasets analyzed during this study comprise deidentified data stored in the cloud-based storage system of the Presbyterian Medical Center and are not publicly available as they contain protected patient medical information and are restricted for disclosure outside the hospital.

Abstract

Background: Total knee and hip arthroplasty (TKA and THA) are among the most performed elective procedures. Rising demand and the resource-intensive nature of these procedures have contributed to longer wait times despite significant health care investment. Current scheduling methods often rely on average surgical durations, overlooking patient-specific variability.

Objective: To determine the potential for improving elective surgery scheduling for TKA and THA, respectively, by using a 2-stage approach that incorporates machine learning (ML) prediction of the duration of surgery (DOS) with scheduling optimization.

Methods: In total, 2 ML models (one each for TKA and THA) were trained to predict DOS using patient factors based on 302,490 and 196,942 patients, respectively, from a large international database. In total, 3 optimization formulations based on varying surgeon flexibility were compared: Any (surgeons could operate in any operating room at any time), Split (limitation of 2 surgeons per operating room per day), and multiple subset sum problem (MSSP; limit of 1 surgeon per operating room per day). Two years of daily scheduling simulations were performed for each optimization problem using ML prediction or mean DOS over a range of schedule parameters. Constraints and resources were based on a high-volume arthroplasty hospital in Canada.

Results: The TKA and THA prediction models achieved test accuracy (with a 30 min buffer) of 78.1% (mean squared error 0.898) and 75.4% (mean squared error 0.916), respectively. Any scheduling formulation performed significantly worse than the Split and MSSP formulations with respect to overtime and underutilization (P<.001). The latter 2 problems performed similarly (P>.05) over most schedule parameters. The ML prediction schedules outperformed those generated using a mean DOS for most scheduling parameters, with overtime reduced on average by 300-500 minutes per week (12 - 20 min per operating room per day; P<.001). However, there was more operating room underutilization with the ML prediction schedules, with it ranging from 70 - 192 minutes more underutilization (P<.001). Using a 15-minute schedule granularity with a waitlist pool of a minimum of 1 month generated the ML schedule that outperformed the mean schedule 97.1% of times.

Conclusions: Assuming a full waiting list, optimizing an individual surgeon's elective operating room time using an ML-assisted predict-then-optimize scheduling system improves overall operating room efficiency, significantly decreasing overtime. This has significant potential implications for health care systems struggling with pressures of rising costs and growing operative waitlists.

Introduction

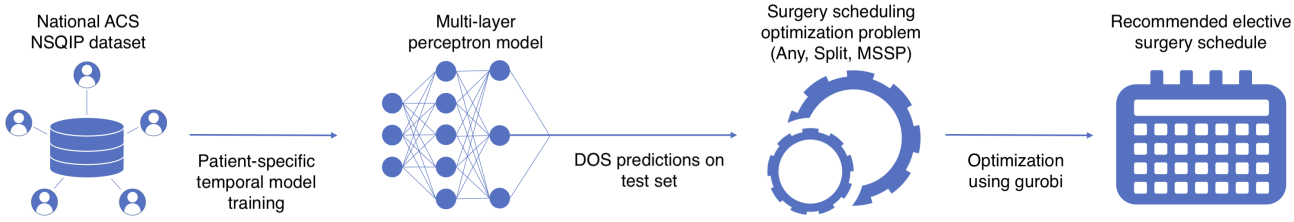
Total knee and hip arthroplasty (TKA and THA, respectively) are the gold-standard treatment for end-stage arthritis of the hip and knee joints. These procedures are the first and second most frequently performed in the United States, excluding maternal and neonatal procedures [1]. In 2018, 1.3 million of these procedures were performed in the United States, a 21.9% increase from 2008 [1]. This number will continue to increase globally due to an aging population and the ongoing obesity pandemic [2,3]. The ubiquity of these procedures correlates strongly with their burden on health care systems globally. In the United States, approximately 5% of the gross domestic product is to care for musculoskeletal conditions [4,5]. Despite this spending, wait times for elective surgical procedures in OECD countries continue to increase, conferring extended periods of time with poor quality of life for TKA and THA patients [6,7]. For these reasons, there is a growing interest and research into improving the efficiency and cost-effectiveness of arthritis care [8,9].

Most research has focused purely on the prediction of duration of surgery (DOS) or the optimization of operating room scheduling, ignoring their inherent interrelation [10-14]. More recently, these approaches have been combined to plan post-surgical beds and plan emergency surgeries based on predicted priority with varying results [15,16]. DOS prediction models typically represent a large volume of varying procedures, spanning multiple surgical specialties with limited practical applications. Classic regression modeling in orthopedics has identified age, BMI, surgical procedure, primary or revision, and gender as important variables affecting DOS predictions [17,18]. Machine learning (ML) models have been applied to predict DOS for various surgeries [10,12,19-24]. However, in practice, mean time or surgeon-specific rolling mean time is typically used to generate schedules at the operational level.

Research evaluating the optimization of surgery scheduling has been performed using an average or a randomly sampled (typically from a lognormal distribution) DOS value prior to optimizing a schedule through integer linear programming based on either the multiple knapsack or job-shop scheduling problem [25-27]. Stochastic programming and distributionally robust optimization have also been attempted to mitigate the effects of an uncertain DOS, but these approaches assume a distribution of DOS rather than using specific features to aid in prediction [28].

To our knowledge, no prior work has combined patient-level DOS predictions with schedule optimization to create an optimized surgical schedule at the operational level. It is known that neural networks are strong predictors of DOS; however, their realizable improvements when implemented over various surgical schedule optimization problems, while performing simulations accounting for real-world constraints, remain unclear [23,24]. The primary aim of this paper was to determine if a 2-stage approach using an ML model for prediction of DOS paired with schedule optimization improves operating room overutilization or underutilization compared to using the mean DOS. Secondary objectives were to determine the effect of schedule granularity and length of surgeon waitlist on scheduling accuracy.

Methods



Ethical Considerations

This retrospective study analyzed deidentified American College of Surgeons National Surgical Quality Improvement (ACS NSQIP) data. The study was approved by the Institutional Research Ethics Board (Sunnybrook Health Sciences Center, Project REB ID #4899). Informed consent was waived due to the secondary, minimal-risk nature of the analysis. No local institutional patient data were used. Privacy and confidentiality were protected in accordance with institutional and journal policies. Data use complied with NSQIP data-use agreements. The study adhered to the Declaration of Helsinki.

Setting

Population-level data from the ACS NSQIP database were used to generate prediction models. This database compiles patient and outcome data following surgery from over 700 hospitals in North America, capturing over 1 million surgeries per year, with a high level of accuracy [29]. The database was queried for all TKA and THA surgical procedures performed between 2014 and 2019. The actual DOS times as reported in the ACS NSQIP dataset were used to inform simulated daily operating room schedules. A flowchart that helps visualize the overall 2-stage approach is shown in Figure 1.

Figure 1. High-level overview of the predict-then-optimize approach. ACS NSQIP: American College of Surgeons National Surgical Quality Improvement Program; DOS: duration of surgery; MSSP: multiple subset sum problem.

Duration of Surgery Prediction

Data pertaining to 302,490 TKA and 196,942 THA procedures performed during this period as identified from the ACS NSQIP database were used to train models to predict DOS. DOS predictions were done as per Abbas et al [23,24]. They identified a PyTorch multilayer perceptron model that outperformed 10 alternative ML models for predicting DOS for TKA and THA [23,24]. Both models were trained on procedures from 2014 to 2017, hyperparameters tuned with Ray on procedures from 2018, and evaluated on procedures from 2019 [23,24,30,31]. These models were generated using the Niagara supercomputer

XSL•FO
RenderX

at the SciNet HPC Consortium [32]. Predictions of DOS from the test subsets of data were used in the optimization model. Refer to the study by Abbas et al [23,24] for further details regarding the DOS prediction, model development, hyperparameter tuning, and feature importance.

Schedule Optimization Formulations

Assumptions

The generated scheduling model considered elective case scheduling, in which surgeries are planned for in advance. The constraints and available resources for the model were generated using real-world constraints from the authors' institution, the highest-volume elective arthroplasty hospital in Canada. This included cleaning time (30 min), number of operating rooms (n=5), number of surgeons (n=11), and days a surgeon was unavailable in a week. The planning horizon of 1 week (5 workdays) was also based on these constraints. The penalty for an individual operating room running overtime (after 5 pm), λ, was chosen to be double the value of daytime operating room underutilization. This was due to the approximate additional costs associated with operating room staff working after hours. The following assumptions regarding scheduling were made: surgeons are available to operate any day anytime except for 0 - 2 randomly selected days per week per surgeon, and once a surgery is assigned to a surgeon, they must perform it (ie, no sharing patients). These assumptions were made as the study did not have access to historical data on surgeon availability from the authors' institution. There were no constraints placed on the schedule based on staffing or patient beds in the recovery unit or ward.

Optimization Formulations

In total, 3 scheduling optimization problems were formulated. All formulations were based on an integer linear programming framework that has been used for many different scheduling problems, including but not limited to surgery scheduling [27,33]. The first, "Any," was adapted from Marques et al [27] with notable modifications including the addition of an overtime penalty and only considering 1 surgery specialty. "Any" allows any surgery to be scheduled at any time of day in any room subject to the constraints that no surgeries in a room overlap, and that no surgeon is operating in 2 rooms simultaneously. The second formulation, "Split," is the same as "Any" but enforces a maximum of 2 surgeons per operating room on a given day and a maximum of 1 room per surgeon per day. This was chosen as it is common when there are rooms that may be split between 2 surgeons if 1 surgeon cannot fill the room for that particular day. Finally, the third formulation is akin to a max-sum multiple subset sum problem and is thus referred to as "MSSP." It enforces 1 surgeon per operating room on a given day, simplified into multiple optimization problems for each surgeon, following a fair distribution of rooms among surgeons. This is the most common configuration used on a clinical basis, where one surgeon has one operative room dedicated to their cases per day. "Any" is the most flexible optimization formulation, ie, the least constrained of the 3. "Split" and "Any" impose additional constraints on feasible schedules and reflect realistic logistical restrictions that a hospital may want to impose, eg, having a surgeon use the same room on any given day. Details of these formulations are found in Multimedia Appendix 1.

Simulated Schedule Generation

Using the ACS NSQIP data, simulated schedules were generated using each optimization formulation, with schedule parameters as follows. Schedule granularity of 10- and 15-minute block times was considered. These sizes were chosen to ensure interpretable schedule generation. Surgery completion times were rounded up to the nearest block. The effect of surgeon waitlist size on schedule accuracy was also evaluated. Waitlist sizes representing 2 weeks (n=250), 4 weeks (n=500), 8 weeks (n=1000), and 12 weeks (n=1500) were considered. The cases within the waitlist were all given the same priority to be booked (no rank by time), unless randomly considered to be of high priority.

Three different versions of each model with the above schedule parameters were created. The first model used the ML-predicted DOS values for THA and TKA; this is the novel 2-stage approach of predicting then optimizing that we are proposing in this work. The second model used the mean DOS for each different type of surgery (THA and TKA) in order to obtain a schedule that mimics the current operating room schedule. Finally, a hindsight model was created that used the true DOS values to provide an upper bound on the best possible schedule that could be generated with perfect information (100% accurate to the minute). Each of these 3 simulations was performed 104 times (to represent 2 y) using a random sample of surgeries from the testing set.

Scheduling Comparisons

To compare the 3 schedule optimization formulations (Any, Split, and MSSP), the results of the 2-stage predict-then-optimize simulation results across all schedule parameter combinations were assessed. To evaluate the efficacy of the 2-stage schedule generation technique, it was compared to the results of scheduling by 2 other techniques: the mean DOS for each surgery (the current gold standard at most institutions) and the hindsight schedule. Each of these 3 schedules was constructed for each week of the simulation, and metrics consisting of overtime, underutilization, and the objective function value were calculated for each schedule. Student's t-test was used to compare the effect between scheduling formulations. Overtime and underutilization for 2-stage and mean DOS schedules over the simulated weeks were compared using the paired Wilcoxon signed-rank test, as the same surgical cases were randomly selected for each generated schedule. The effect of schedule granularity and considered waitlist size was evaluated using unpaired Student's *t*-test and analysis of variance as these were grouped over multiple selections of random cases. *P* values of <.05 were considered statistically significant.

Results

Prediction Model Accuracy

Demographic details of patients included are found in Multimedia Appendix 2. A summary of the DOS prediction models is found in Multimedia Appendix 3. The TKA prediction

XSL•FO
RenderX

model obtained a training accuracy (with a 30 min buffer) of 76.9% and a training mean squared error (MSE) of 0.904. The validation accuracy was 77.7% with an MSE of 0.904. The test accuracy was 78.1% with an MSE of 0.898. The THA prediction model obtained a training accuracy of 74.0% and a training MSE of 0.888. The validation accuracy was 75.0% with an MSE of 0.910, and the test accuracy was 75.4% with an MSE of 0.916.

Schedule Optimization Formulation Comparison

Overall, the Any scheduling optimization formulation exhibited the poorest performance across all different schedule parameter combinations (Table 1). There was no significant difference in overtime across all schedule parameters between the Split and MSSP formulations. For 2 combinations of schedule parameters (10 min granularity, 1500 waitlist size and 15 min granularity, 1500 waitlist size), there was significantly less operating room underutilization with the MSSP formulation; however, this was only 10.9 minutes and 15.4 minutes, respectively, on average over an entire week (Table 1). In contrast, for 15-minute granularity and a 250-waitlist size, there was significantly more operating room underutilization with MSSP compared to the Split formulation, 42.3 minutes over an entire week (Table 1). Figures 2 and 3 display this comparison for overtime and underutilization across all 3 optimization problems, respectively.

Simulated Schedule Comparison

As the MSSP scheduling formulation performed best across all schedule parameters, it was used in all further analyses. The 2-stage predict-then-optimize approach performed better than using mean DOS for over 80% of weekly schedules in terms of objective optimization problem value across all schedule parameter combinations. This difference was more consistent across the schedules generated using 15-minute schedule granularity size, where 2-stage was superior to mean in over 90% of simulated schedules (Table 2). There was less overtime across all schedule parameters when using the 2-stage approach (P<.001), equating to an average decrease in overtime of 300-500 minutes per week at the simulated hospital (or 12-20 min per operating room per day). However, there was more operating room underutilization with the 2-stage approach across all schedule parameters (Table 3; P<.001). As expected, the hindsight schedule was nearly perfect for all generated schedules and was significantly better than the 2-stage or mean approach with respect to objective value, overtime, and underutilization (Table 3). Despite a statistically significant difference, there was no clinically realizable difference in the number of cases performed between the 2-stage and mean groups; however, the hindsight formulation scheduled less cases than both the mean and the 2-stage approach (mean of approximately 12 fewer cases per wk). Details regarding the Any and Split scheduling formulation results are found in Multimedia Appendices 4 and 5, respectively.

The changes to schedule granularity and considered waitlist size did not influence the amount of overtime. However, there was significantly less operating room underutilization with the 15-minute granularity schedules (P=.02) and with waitlist sizes greater than 500, or 1 month considered (P<.001) (Table 4).

Discussion

This paper compared 3 different scheduling optimization problems and evaluated a novel approach to surgical scheduling for TKAs and THAs using a combined 2-stage ML DOS prediction and optimization. There was no significant difference in operating room underutilization or overtime between the MSSP (one surgeon designated to one operating room per day) or Split (maximum of 2 surgeons designated for 1 operating room per day) optimization formulations. However, both performed significantly better than the Any (no limit on surgeons per operating room per day) formulation.

We believe this is due to the limitations of the predictions: underestimating the DOS of 1 case c being performed by surgeon h in room r can have cascading effects on another room r' in which the same surgeon h is due to perform another surgery c' at a later time. This causes additional overtime penalties for "Any," something that the more restrictive "Split" and "MSSP" do not encounter. This is why, despite optimal solutions to "Any" being theoretically better than those of "Split," they performed worse when simulated with the actual DOS.

Overall, the combined 2-stage approach significantly outperformed the current standard for scheduling cases, which is a case-specific mean surgery duration. This performance improvement was maintained across all schedule parameter combinations, including different schedule block granularity and different patient waitlist sizes considered. Despite this improvement, the 2-stage approach performed considerably worse than the hindsight schedule, highlighting the limitations of the current predictions that are based solely on preoperative patient data. Interestingly, there was no impact on overtime by varying schedule granularity or waitlist size; however, both of these impacted the amount of underutilization. The smaller waitlist size of 2 weeks of considered cases had a greater amount of underutilization, which was likely due to surgeons not having enough cases to fill their operating room time. Once a threshold was met at a 4-week pool of cases, there was no difference between groups. Also notable was the fact that when only considering a 2-week pool of cases, the Split optimization formulation outperformed MSSP, likely due to some surgeons not having enough cases to fill their time. Therefore, as the MSSP formulation is most practically implementable, it must be ensured that either the considered case pool is large enough or surgeons are allocated time when they have enough cases to fill an entire operating room day to avoid underutilization.

Errors in procedure length estimation by clinicians occur in approximately 75% of cases, with 32% - 50% of daily operating room schedules being underbooked and 37% - 42% overbooked [34,35]. This is compounded by the fact that less than 50% of operating time is spent doing surgery [34]. Booking based on a historical mean is more accurate than when estimated by the surgical team, though less accurate than traditional ML approaches [10,36-38]. Previous approaches using computing to improve surgical scheduling have included schedule optimization or ML to predict DOS in isolation [13,21,27,37,39,40]. Other approaches to scheduling operating room utilization include the use of surgeon-specific mean DOS or a surgeon case-specific rolling average time. To our knowledge, these have not been compared to an ML prediction-based approach. Due to the lack of surgeon-specific details included in the ACS NSQIP dataset, we could not assess the efficacy of these approaches in the present study.

The implementation of this predict-then-optimize scheduling approach would face several challenges in the real world. The MSSP optimization model is in line with current surgical scheduling practices at most hospitals. This formulation optimizes a specific surgeon's waiting list, increasing their ability to accurately plan their day while ensuring a fair distribution of time (by operating room days) for each surgeon. However, attempting to implement the other optimization formulations (Split and Any) may be faced with resistance by end-users. Particularly, using the Any formulation, surgeons may have cases at the beginning and end of the day spread out across more days in a week. ML-predicted DOS has been trialed previously in operating room planning by one group that found a reduction in wait time between cases [41]. However, they generated the predicted DOS and evaluated the implications of that information over a single day, not considering other cases from the waitlist or optimizing the schedule based on the predicted DOS.

In addition to improving operating room utilization at the systems level, the present study has implications for surgeon-level daily planning. Accurate patient-specific DOS prediction and scheduling allow for more effective personal

XSL•FO
RenderX

scheduling, including preoperative preparation, intraoperative workflow, and postoperative responsibilities. Accurate DOS predictions can assist surgeons in anticipating the need for ancillary support (eg, anesthesia, nursing, imaging) and have the potential to help decrease fatigue associated with unplanned overruns. When integrated into scheduling systems that allocate block time based on surgeon-specific waitlists (as in the MSSP formulation), this can enhance both surgeon efficiency and case throughput, aligning institutional resource allocation with the surgeon's realistic operative capacity.

The generated models and optimization formulations have the ability to transform how elective operating room scheduling is performed. By developing models specific to each operation, this increases the accuracy of each model. Most previous research evaluating the effect of ML for DOS prediction has grouped multiple different procedures [21,37]. Using such models, the procedure performed would generally be the most important feature, diluting the effect of other important patient factors without using appropriate ML techniques. The potential for cost savings for hospitals, related to reduction in overtime costs and valuable underused operating room time, is high, but the main limitation lies in the accuracy of the DOS prediction. The predictive models for TKA and THA included 33 individual patient features. Improving the model with the use of operational factors from a specific institution would likely have a corresponding effect on the schedule results but would reduce the generalizability of the approach. Further improvements may also be made by directly integrating the downstream scheduling optimization problem into training the predictive ML model [42].

This work presents some limitations. First, the DOS prediction was restricted to preoperative patient factors, based on the availability of data elements in the ACS NSQIP database, limiting the prediction accuracy. This was evidenced by the large difference in schedule performance between the 2-stage method and the perfect, hindsight, schedule. Nevertheless, this approach to predicting DOS still yielded improved schedules as compared to using a surgery-specific mean time estimate. Second, the goal of our optimization problem was to maximize the utilization of the operating room; however, this may not be directly in line with the goals of all hospitals, as some institutions may have other priorities, such as maximizing the number of cases completed. This project only developed predictive models for primary TKA and THA procedures, which may have artificially lowered the potential effect size of using this approach, as these are relatively routine procedures with lower DOS variability. By generating more surgery-specific predictive models within orthopedic surgery or other specialties, the potential for this approach may be even larger. However, these results are more directly applicable to high-volume arthroplasty surgical centers. Additionally, this scheduling approach was a simplified proof-of-concept model that may not be applicable to more complex, real-world scheduling scenarios. For example, it did not consider downstream constraints, such as the number of recovery beds, ward beds, or available staff. This was not a concern at our local institution due to its relative efficiency as a high-volume arthroplasty center. However, this would need to be expanded upon in future work if this is to be practically implemented in less specialized centers. Finally, the Split and Any optimization problems were computationally intensive when considering a waiting list size of 2 - 3 months of patients. This may be a consideration depending on institutional computational resources, which is worth noting when implementing a similar solution.

In conclusion, using ML patient-specific DOS predictions coupled with optimization was superior to elective scheduling based on a mean DOS metric over 3 different optimization problems with varying constraints and combinations of waitlist size and granularity. This generalizable approach suggests that improvements in hospital resource utilization are possible with the application of new computational methods, but the inclusion of institution-specific operational data may be considered to further improve predictions and scheduling. This has significant potential implications for health care systems struggling with pressures of rising costs and growing operative waitlists.

Abstract

Background: Offline reinforcement learning (RL) has been increasingly applied to clinical decision-making problems. However, due to the lack of a standardized pipeline, prior work often relied on strategies that may lead to overfitted policies and inaccurate evaluations.

Objective: In this work, we present a practical pipeline—Pipeline for Learning Robust Policies in Reinforcement Learning (PROP-RL)—designed to improve robustness and minimize disruption to clinical workflow. We demonstrate its efficacy in the context of learning treatment policies for administering loop diuretics in hospitalized patients.

Methods: Our cohort included adult inpatients admitted to the emergency department at Michigan Medicine between 2015 and 2019 who required supplemental oxygen. We modeled the management of loop diuretics as an offline RL problem using a discrete state space based on features extracted from electronic health records, a binary action space corresponding to the daily use of loop diuretics, and a reward function based on in-hospital mortality. The policy was trained on data from 2015 to 2018 and evaluated on a held-out set of hospitalizations from 2019, in terms of estimated reduction in mortality compared to clinician behavior.

Results: The final study cohort included 36,570 hospitalizations. The learned treatment policy was based on 60 states: the policy deferred to clinicians in 36 states, recommended the majority action in 22 states, and diverged significantly from clinician behavior in 2 of the states. Among the cases where the policy meaningfully diverged from the behavior policy, the learned policy was estimated to significantly reduce the mortality rate from 3.8% to 2.2% by 1.6% (95% CI 0.4 - 2.7; *P*=.006).

Conclusions: We applied our pipeline to the clinical problem of loop diuretic treatment, highlighting the importance of robust state representation and thoughtful policy selection and evaluation. Our work reveals areas of potential improvement in current clinical care for loop diuretics and serves as a blueprint for using offline RL for sequential treatment selection in clinical settings.

KEYWORDS

reinforcement learning; artificial intelligence; loop diuretic; treatment recommendation; treatment selection; clinical decision support; dynamic treatment regime

Introduction

Reinforcement learning (RL) is a branch of artificial intelligence that, through interactions with an environment, learns the optimal sequence of actions that will maximize a desired outcome [1]. RL methods are especially well suited to tackle problems that require sequential decision-making where the rewards are delayed. This makes it an attractive solution for learning dynamic treatment policies in health care problems (eg, sepsis [2], diabetes [3], and hypotension [4]) where decisions are made sequentially over a prolonged period of time and the outcome (eg, in-hospital mortality) is observed at a later time point. Due to safety and ethical concerns, training and evaluation of RL policies in this domain often rely on a fixed set of historical data and require the use of offline RL algorithms [5].

XSL•FO
RenderX

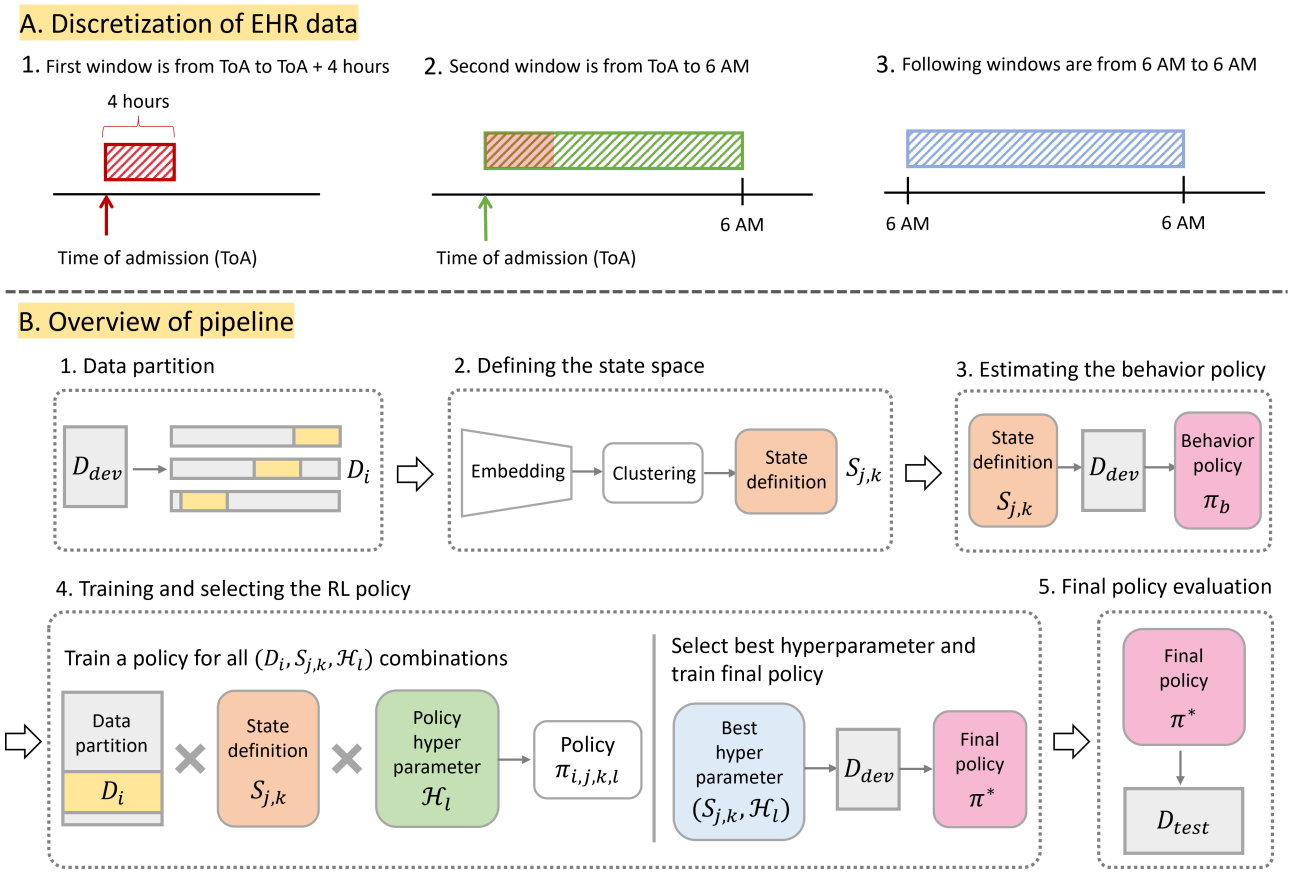
However, effectively applying offline RL poses several challenges. First, deriving a robust and informative state representation from high-dimensional health features can be challenging, especially with limited data. Second, the performance of offline RL algorithms is sensitive to hyperparameters [6-8], often leading to policies that perform well during development but fail once deployed. Yet a standardized approach for hyperparameter selection has not been established for offline RL. Third, the learned policy may differ substantially from current clinician behavior, resulting in low confidence in evaluation results and potential disruption to clinical workflows [9]. While some of these issues have been solved in isolation [10-12], there is a notable absence of a standard pipeline for applying offline RL, comparable to the training-validation framework in supervised learning, that integrates these individual solutions. We address this gap by presenting a pipeline (Pipeline for Learning Robust Policies in Reinforcement Learning; PROP-RL) along with a codebase for applying offline RL to health care settings, and demonstrate its efficacy by applying it to the problem of learning treatment policies for loop diuretics.

Loop diuretics are one of the most commonly prescribed medications in hospitals and are used to control volume and edema in the body by increasing urinary sodium and water excretion [13]. They are used to treat patients with acute shortness of breath from fluid accumulation in their lungs, typically associated with conditions such as congestive heart failure or acute pulmonary edema [14]. There remains substantial uncertainty and variability regarding when to start and stop loop diuretics [15,16]. This uncertainty leads to inadequate use of loop diuretics, which has been associated with worse clinical outcomes, including higher rates of acute kidney injury and electrolyte disturbances [17,18].

In this paper, we apply offline RL to learn a loop diuretics treatment policy—designed to aid health care professionals—from electronic health records (EHRs) of hospitalized patients at a large academic hospital. In doing so, we establish a pipeline—PROP-RL—for applying offline RL in health care settings that incorporates state representation learning, hyperparameter selection, and modification of the learned policy to minimize disruption to existing workflows. We demonstrate the effectiveness of PROP-RL through off-policy evaluation (OPE) and ablation studies [19].

Methods

Study Cohort



We included adult patients (≥18 years) admitted to the hospital through the emergency department at Michigan Medicine during the years 2015‐2019, who required any amount of supplemental oxygen support during the first 24 hours of admission. Patients who underwent surgery within 24 hours of admission were excluded as the supplemental oxygen support provided may not be due to a primary respiratory condition (Section A1 in Multimedia Appendix 1). The cohort was split into a development set and a held-out test set consisting of data from patients admitted in 2015‐2018 and 2019, respectively.

Data Preprocessing

To formulate the management of loop diuretics as an RL problem with discrete time steps, we split the hospitalization data into chronological windows. With the exception of the first and second windows, all windows were 24 hours long, starting and ending at 6 AM (Figure 1A; Section A2 in Multimedia Appendix 1). In each window, medication records were analyzed to determine whether an oral or intravenous loop diuretic was administered. We assumed all treatment decisions made within a window were based on the patient's state in the previous window. A 6 AM cutoff time was chosen as most clinical rounds (where decisions are made) occur immediately after this point. Analysis was constrained to the first 8 days of hospitalization.

Figure 1. (A) Diagram of the windowing rule for hospitalizations. (B) Overview of pipeline. (1) Data partition: the development data D_{dev} are partitioned in multiple ways to create the data partitions D_i, $i \in \{1...10\}$. (2) Defining the state space: a set of candidate discrete state definitions, characterized by the data partition D_j used to derive the state definition and the number of states k, is generated by learning a lower-dimensional representation of the features and clustering them. (3) Estimating the behavior policy: the behavior policy π_b is estimated from the development state using each state definition $S_{j,k}$. While π_b is dependent on $S_{j,k}$, for simplicity, we refer to the behavior policy as π_b in general. (4) Training and selecting the RL policy: a policy $\pi_{i, j, k, l}$ is trained for each possible hyperparameter combination across all data partitions. The best hyperparameter is used to train the final policy π^* on the entire development set. (5) Final policy evaluation: π^* is evaluated on the test set D_{test}. EHR: electronic health record; RL: reinforcement learning.

For each window, EHR features including age, vital sign measurements, laboratory test results, medications, fluid input and output, and Sequential Organ Failure Assessment (SOFA) scores were extracted (Section A3 in Multimedia Appendix 1). These features capture the patient's most recent health state as well as past treatments, which are necessary for determining future treatments. We used the Flexible Data-Driven Pipeline (FIDDLE) software to convert these into 243-dimensional feature vectors (Section A2, A3, and A16 in Multimedia Appendix 1) [20].

Model Development and Evaluation

Overview

We modeled the patient environment as a Markov decision process (MDP) defined by (S, A, P, R, γ). S and A represent the state and action spaces. Given a hospitalization, $s_t \in S$ represents the patient's health on day t and $a_t \in A$ is the treatment decision made based on st. $P(s_{t+1}|s_t, a_t)$ is the transition function, $R(s_t) = r_t$ is the reward function, and $\gamma \in [0, 1]$ is the discount factor. The discrete state space S was defined by clustering the EHR features in a learned embedding space. The action space $A = \{0, 1\}$ was defined to encode binary treatment decisions, corresponding to whether the patient received loop diuretics (Section A4 in Multimedia Appendix 1). All intermediate rewards were set to 0, and a terminal reward was given when the patient's hospitalization ended or reached 8 days (whichever is earlier). The terminal reward was 100 if the patient was discharged alive and –100 if the patient died. Our objective was to learn a policy π: $S \times A \rightarrow [0, 1]$ which maps s_t to a probability distribution over a_t, in order to maximize the expected cumulative reward $J(\pi)=E\pi\sum t=09\gamma tR(st)$ where $\gamma=0.99$. This roughly corresponds to an objective that focuses on minimizing the overall mortality rate.

PROP-RL consists of the following 5 steps (Figure 1B): (1) data partition, (2) defining the state space, (3) estimating the behavior policy, (4) training and selecting the RL policy, and (5) final policy evaluation.

Step 1. Data Partition

We created 10 partitions of the development set by randomly assigning each hospitalization to either the training or validation split. These partitions were used for steps (2) and (4).

XSL•FO
RenderX

Step 2. Defining the State Space

We used a data-driven approach to establish state definitions. For each data partition, a function mapping the 243-dimensional feature space to a discrete state space was learned by training a neural network embedding model and applying ensemble *k*-means clustering in the embedding space (Section A5 in Multimedia Appendix 1) [21,22]. *k*, the size of the discrete state space, was a hyperparameter that varied from {20,40,...,160} (Section A6 in Multimedia Appendix 1). The state definition itself was treated as a hyperparameter.

Prior to policy learning, the state definitions were evaluated for generalizability and informativeness. We verified that each hospitalization transitioned across multiple different states and that the state distribution was not heavily skewed toward a few specific states. Failing to meet both criteria implies an overfitted state definition unlikely to generalize to new patients. Second, to ensure the embeddings captured important information, we conducted a principal component analysis of the cluster centers. We visualized the distribution of the cluster centers using the average and SD of the mortality rates, SOFA scores, and clinicians' previous and next actions among the windows belonging to each state.

Step 3. Estimating the Behavior Policy

We estimated the behavior policy by computing the average observed action for each state within the development set. This is a stochastic policy that maps each state to a probability over the binary actions. To further validate the state definitions, we performed 2 evaluations using the estimated behavior policy. First, we compared the estimated mortality rate of the behavior policy on the held-out test set to the true mortality rate. Significant differences in these values would either indicate a significant change in clinicians' behavior between the 2 datasets, or the state definitions' inability to encode the behavior policy. Second, we investigated whether the estimated behavior policy aligns with clinical understanding by visualizing trends in the behavior policy with respect to key features of the states (Section A7 in Multimedia Appendix 1).

Step 4. Training and Selecting the RL Policy

After learning the transition matrix from the training data, we learned the optimal policy using a modified version of value iteration with 2 offline RL constraints: batch-constrained Q-learning (BCQ) and pessimistic Markov decision process (pMDP) [1,23,24]. These constraints mitigate extrapolation error, which refers to inaccurate value estimations for state-action pairs that were rarely or never observed during training [23]. In brief, BCQ constrains the policy to avoid actions unlikely to be selected by the behavior policy, and pMDP encourages the policy to avoid areas in the state-action space with high uncertainty (Section A8 in Multimedia Appendix 1). Both BCQ and pMDP have additional hyperparameters.

Recent work found hyperparameter selection in offline RL to be sensitive to the partitioning of the dataset [7]. To mitigate this, we use the Split-Select-Retrain (SSR) pipeline that selects the optimal hyperparameters by aggregating validation performance over multiple partitions of the development set [7]. The final policy is then learned from the entire development set using the selected optimal hyperparameters. We leveraged the same 10 partitions (train and validation split) described in step (1) (Section A9 in Multimedia Appendix 1).

Performance was measured using the OPE method weighted importance sampling (WIS), known for its simplicity and reliance on relatively few assumptions [25]. WIS is a biased but consistent estimator, with estimates converging to the true value as sample size increases. WIS estimates both the performance and effective sample size (ESS) of the policy, which is a measure of confidence in the performance estimate [26]. ESS values closer to the size of the dataset used for evaluation (ie, validation set) indicate higher confidence in the performance estimate. For the main analysis, we focus on WIS, but for robustness, we also consider 3 additional OPE methods: fitted Q evaluation, approximate model, and weighted doubly robust estimates (Section A10 in Multimedia Appendix 1 for methodological details). *P* values are estimated by a one-sided bootstrap resampling test [27].

In order to minimize disruption to clinical workflow without sacrificing policy performance, we modified the learned policy prior to evaluation by identifying "unimportant states," inspired by Shen et al [28]. In unimportant states, no action can significantly impact the outcome. Our policies deferred to clinicians' decisions in unimportant states, thus minimizing the amount of potential deviation from clinician behavior. The threshold used to determine unimportance was considered a hyperparameter (Section A11 and A12 in Multimedia Appendix 1).

Step 5. Final Policy Evaluation

The final policy was evaluated on the held-out test set using WIS. Improvement in performance compared to the behavior policy was measured across 1000 bootstrapped samples in terms of expected cumulative reward and mortality. The level of disagreement between the average clinician and the final learned policy was compared to the level of disagreement among clinicians (Section A13 in Multimedia Appendix 1).

To understand how the learned policy differs from the behavior policy, we focused on "divergent" states where the action recommended by the learned policy diverged from the majority action of the behavior policy. The learned policy was then evaluated on a subset of the cohort where the patient's hospitalization included divergent states. We further characterized these states by comparing the average values of their key features to those of the general population (Section A14 in Multimedia Appendix 1).

Ablation Studies of Pipeline

Our pipeline included 3 key elements designed to improve the robustness of the learned policy: (1) using unimportant states to "relax" the learned policy, (2) evaluation across multiple data partitions (SSR), and (3) treating state definitions as a hyperparameter. To demonstrate the effect of each element on the robustness of the learned policy, we conducted an ablation study by selectively removing each component from the pipeline. As a proxy for measuring robustness, we looked at the worst-case OPE performance of the learned policies to establish an empirical lower bound.

Ethical Considerations

This study was approved by the Institutional Review Board at the University of Michigan Medical School (HUM00141899) with a waiver of informed consent among study patients. All data collected were deidentified and were accessed via a secure cloud storage platform and a secured, Health Insurance Portability and Accountability Act (HIPAA)–compliant server. Participants were not compensated for the use of their data in this study. The study followed the TRIPOD+AI (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis+Artificial Intelligence) reporting guideline [29] (Checklist 1). As this study was retrospective in nature, no formal study protocol was developed and the study was not registered. No patients or the public were involved in any aspect of this study.

Results

Study Cohort and Patient Characteristics

The initial cohort consisted of 57,907 hospitalizations. We removed cases where supplemental oxygen was not given within 24 hours (n=14,902), patients were moved to surgery within 24 hours (n=6283), and hospitalizations lasting shorter than 2 windows (n=152). The final study population contained 23,945 unique patients and 36,570 unique hospitalizations divided temporally by admission year into the development (n=29,765; 2015 - 2018) and test set (n=6805; 2019) (Table 1; Section A1 in Multimedia Appendix 1). The mortality rate of the entire cohort was 5.4% (1978/36,570), and 5.2% (1555/29,765) and 6.2% (423/6805) for the development and test set, respectively.

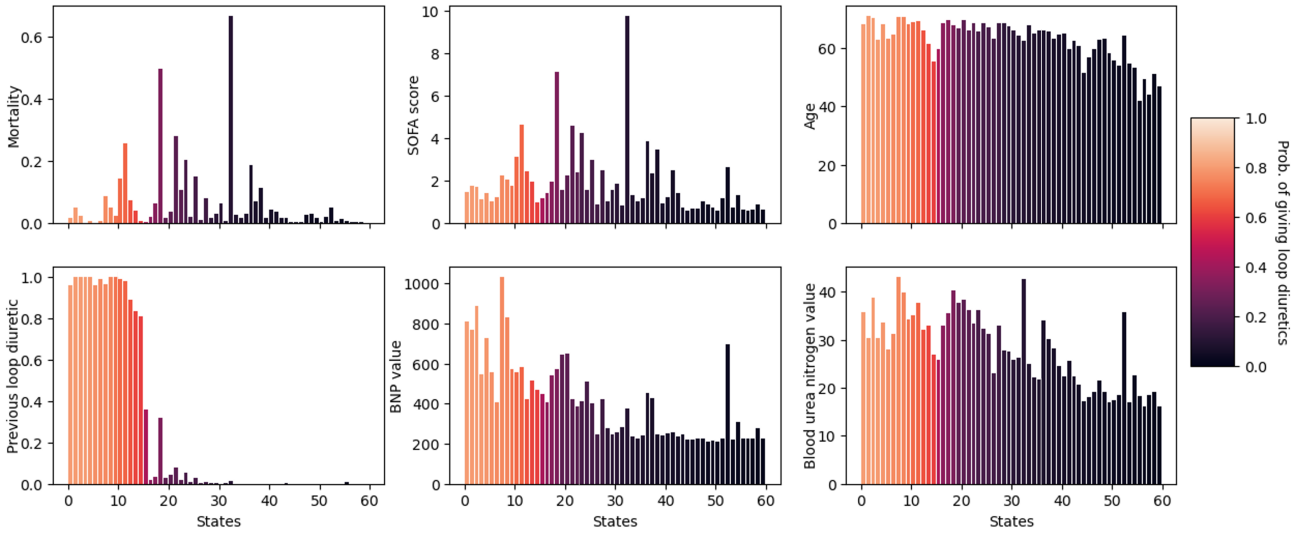
Evaluation of State Definitions

The final state definition $S_{j,k}$ (j=7, k=60) was selected from the hyperparameter search. Overall, 98.3% (29,270/29,765) of hospitalizations in the development set and 98.9% (6730/6805) in the test set contained at least 2 distinct states, indicating at least one transition between different states within these hospitalizations (Figure 2A). All states appeared relatively uniformly in the data with each state constituting 1.7% (SD 0.5%) of all windows on average in both the development set (3769, SD 1187; 226,178 total windows) and test set (893, SD 268; 53,591 total windows) (Figure 2B; Section B2 in Multimedia Appendix 1 for test set results).

XSL•FO
RenderX

Figure 2. Sanity checks for the state definitions on the development set. The first row shows histograms depicting (A) number of states in each trajectory and (B) the number of windows in each state. The second and third rows show principal component analysis of the representations of the cluster centers that define each state. The hue and size of each dot represent the average and SD of the feature value of all samples in that state. The features are (C) mortality rate, (D) SOFA score, (E) whether loop diuretics were administered in the past 24 hours, and (F) whether clinicians chose to administer loop diuretics. SOFA: Sequential Organ Failure Assessment.

Plots of the cluster centers show that information regarding mortality and clinicians' actions is encoded in the states. Figure 2C and 2D indicate that a visible gradient exists in the state representation space with respect to both average mortality and average SOFA score. Figure 2E and 2F show a distinct separation in the state representation space in terms of both the clinician's previous and next actions. Note that even without being explicitly trained for it, the state representation space captures information about the previous action.



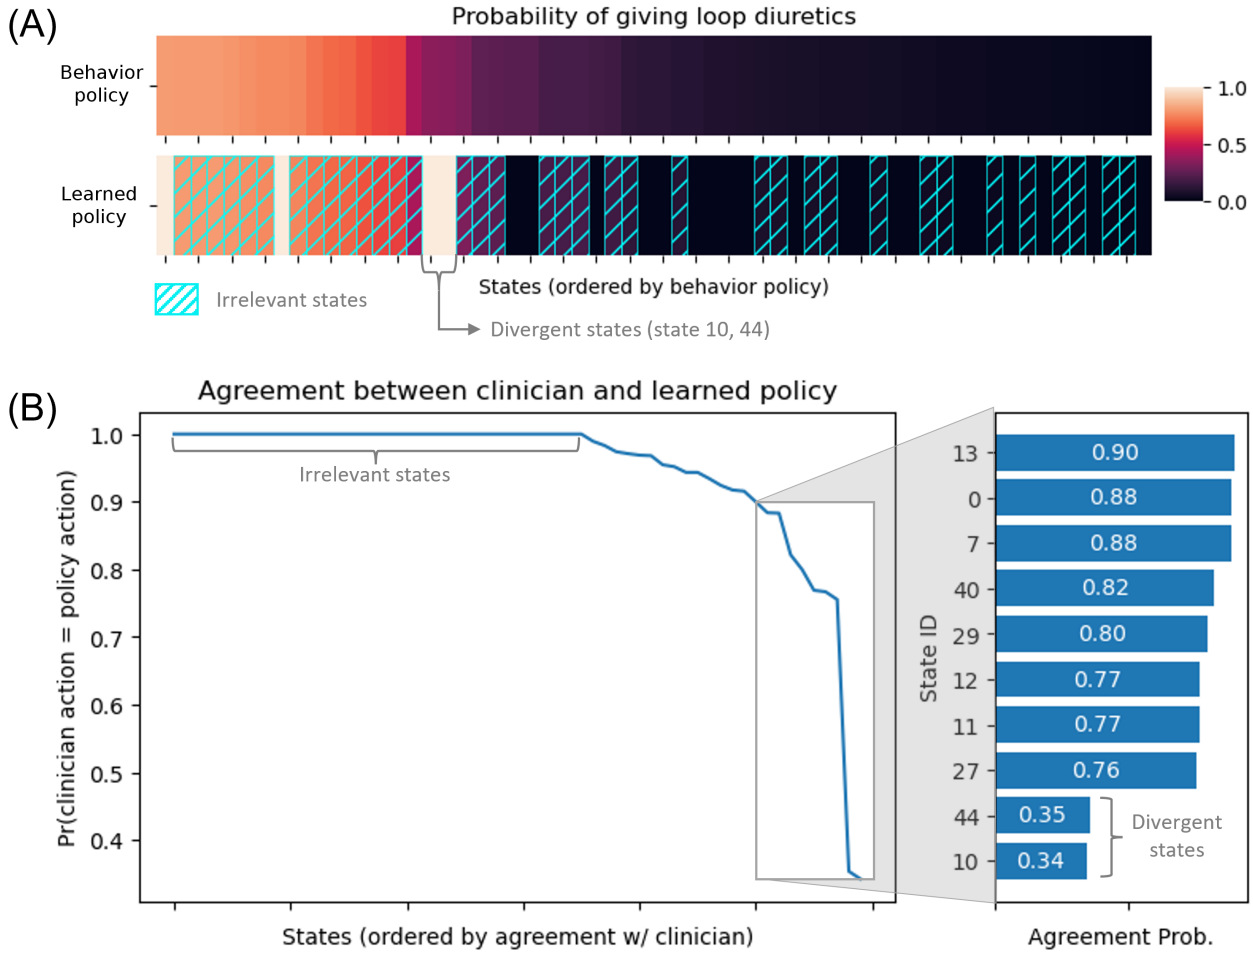
Evaluation of the Estimated Behavior Policy

The estimated mortality rate of the clinician behavior policy across 1000 bootstrapped samples was 6.2% (95% CI 5.6 - 6.8) (Section B9 in Multimedia Appendix 1). This was comparable to the true mortality rate of 6.2% (95% CI 5.6% - 6.8%) observed in the held-out test set, suggesting the state definitions

XSL•FO
RenderX

have accurately captured clinicians' behavior. Qualitatively, we found the estimated behavior policy to recommend loop diuretics if the patient is older, given loop diuretics the previous day, has higher brain natriuretic peptide (BNP) values, and has higher blood urea nitrogen values (Figure 3). We report trends for additional features in Section B3 in Multimedia Appendix 1.

Figure 3. The relationship between the clinician's likelihood of administering loop diuretics and key features. Features shown are (from left to right, top to bottom): mortality, SOFA score, age, whether loop diuretics were administered in the past 24 hours, BNP value, and blood urea nitrogen value. The height of the bars represents the average value of each feature within the state, and the color represents the clinician's likelihood of administering loop diuretics. BNP: brain natriuretic peptide; SOFA: Sequential Organ Failure Assessment.



Evaluation of the Final Learned Policy

Of the 60 states, 36 were unimportant and the learned policy deferred to clinicians (Figure 4A). For the remaining 24 states, the learned policy tended to recommend the majority action: among 21,759 windows belonging to these states in the test set, only 3858 (17.7%) windows were assigned a different action under the learned policy. Yet in 2 divergent states (states 10 and 44), the learned policy did not follow the majority action. While the learned policy always recommended loop diuretics to be administered for both states, clinicians only took this action 34% (454/1326) and 35% (568/1614) of the time, respectively (Figure 4B).

XSL•FO
RenderX

Figure 4. (A) Comparison of the actions recommended by the clinician behavior policy and the learned policy for each state. The color of the boxes indicates the probability of giving loop diuretics. States are ordered by decreasing likelihood of clinicians prescribing loop diuretics. Hatched boxes indicate "unimportant" states where the learned policy recommends the same actions as the behavior policy. (B) Likelihood of agreement between the clinician behavior policy and the learned policy for each state. On the left graph, states are ordered by decreasing likelihood of agreement with the clinicians. The right bar graph focuses on the 10 states where the clinicians disagree the most with the learned policy. States 10 and 44, where the likelihood of agreement is less than 0.5 (learned policy does not follow majority action), are defined as "divergent" states.

On the entire held-out test set, the learned policy outperformed the behavior policy 967 times across 1000 bootstraps (96.7%) and was estimated to reduce mortality from 6.2% to 5.7%, by 0.5 (95% CI 0.0−1.1; *P*=.03) percentage points on average (Table 2). The ESS of the learned policy was 3168.45 (95% CI 3090.91-3256.65), nearly half the size of the dataset (n=6805) indicating a high confidence in the WIS estimate (Section B7 in Multimedia Appendix 1 for validation set results). On the subset of hospitalizations with divergent states, the learned policy outperformed the behavior policy 994 times across 1000 bootstraps (99.4%) and significantly decreased the estimated overall mortality from 3.8% to 2.2% by 1.6 (95% CI 0.4 - 2.8; *P*=.006) percentage points on average (Table 2). The ESS of the learned policy was 550.39 (95% CI 511.49 - 588.70), approximately 25% of the sample size (n=2152) and indicated a high confidence in the performance estimate. Similar improvements were observed with other OPE methods (Section B10 in Multimedia Appendix 1).

XSL•FO
RenderX

Table . Quantitative evaluation of behavior and learned policy on the held-out test set and a subset of the test set where the patient trajectories included the 2 divergent states. Values in parentheses indicate the 95% CI across 1000 bootstraps.

Dataset	Held-out test set (n=6805)		Subset with divergent states (n=2152)	
Policy	Behavior policy	Learned policy	Behavior policy	Learned policy
Estimated $J(\pi)$ (95% CI)	87.56 (86.42 to 88.74)	88.59[a] (87.10 to 90.01)	92.40 (90.89 to 93.96)	95.57[b] (93.10 to 97.89)
Estimated improvement in $J(\pi)$ (95% CI)	—[c]	1.03 (−0.05 to 2.10)	—	3.17 (0.77 to 5.46)
Estimated mortality (%) (95% CI)	6.22 (5.63 to 6.79)	5.70 (4.99 to 6.45)	3.80 (3.02 to 4.56)	2.22 (1.06 to 3.45)
Estimated decrease in mortality (%) (95% CI)	—	0.52 (−0.03 to 1.05)	—	1.58 (0.38 to 2.75)
Effective sample size (95% CI)	6805	3168.46 (3090.91 to 3256.65)	2152	550.39 (511.49 to 588.70)
% of time outperformed behavior policy	—	96.70	—	99.40
Disagreement with clinician (%) (95% CI)	22.91 (22.61 to 23.18)	21.19 (20.86 to 21.49)	30.80 (30.63 to 30.96)	32.38 (32.19 to 32.57)

[a]P=.03.

[b]P=.006.

[c]Not applicable.

State visualization (Section B4 in Multimedia Appendix 1) found that states 10 and 44 are close in the embedding space. Feature importance analysis of classifiers for each state showed a large overlap in key features (Section B5 in Multimedia Appendix 1), including age, previous loop diuretic, BNP value, and blood urea nitrogen value. Both states consisted of slightly older patients with an average age of 69.8 (SD 13.9) (state 10) and 68.7 (SD 13.5) (state 44) compared to the population mean of 63.4 (SD 16.2). Patients in both groups had higher BNP values (539.7, SD 960.8 vs 405.5, SD 781.8 vs 397.1, SD 687.0 for state 10, state 44, and the population, respectively) and mild kidney impairment as characterized by higher blood urea nitrogen values (35.6, SD 25.2 vs 32.9, SD 21.6 vs 28.2, SD 21.3 for state 10, state 44, and the population, respectively; Section B6 in Multimedia Appendix 1).

Ablation Study of Pipeline

In all cases, the worst-case performance of the learned policy when one or more components were removed from the pipeline was significantly lower than the worst-case performance of the policy derived from the full pipeline (Table 3). We focus on the 2 novel aspects of the pipeline here: relaxing the unimportant states and tuning the state definitions.

Table . Worst-case performance of the learned policy when one or more of the 3 key elements in the pipeline were removed. The 3 elements are: (1) use of unimportant state relaxation (no vs yes), (2) number of data splits (single vs multiple), and (3) number of state definitions (single vs multiple). Values in parentheses indicate the 95% CI across 1000 bootstraps.[a]

Unimportant state relaxation	Number of data splits	Number of state definitions	Estimated improvement in $J(\pi)$ (95% CI) (↑)	Estimated mortality % (95% CI) (↓)	% Time outperformed behavior policy (↑)
No	Single	Single	No viable policy	—[b]	—
No	Single	Multiple	No viable policy	—	—
No	Multiple	Single	No viable policy	—	—
No	Multiple	Multiple	No viable policy	—	—
Yes	Single	Single	−2.48 (−8.80 to 2.09)	7.46 (4.93 to 10.76)	20.20
Yes	Single	Multiple	−0.04 (−0.63 to 0.55)	6.24 (5.59 to 6.90)	44.90
Yes	Multiple	Single	0.45 (−1.48 to 2.22)	6.00 (4.93 to 7.18)	70.70
Yes	Multiple	Multiple	1.03 (−0.05 to 2.10)	5.70 (4.99 to 6.45)	96.70

[a]The estimated improvement in $J(\pi)$ (↑) and estimated mortality % (↓) for the behavior policy is 0.00 (95% CI −1.14 to 1.18) and 6.22 (95% CI 5.63 to 6.79), respectively.

[b]Not applicable.

Removing the unimportant state relaxation led to a catastrophic failure, as no policy obtained an ESS of at least 10% the validation dataset size. This indicates overfitting, and we were unable to get a reliable estimate of the policies' performance

XSL•FO
RenderX

on the test set. Using a fixed state definition instead of tuning the state definitions led to significant variation in the performance of the learned policy depending on the data split used to learn the fixed state definition (Section B8 in Multimedia Appendix 1). In the worst-case scenario, the improvement in value of the learned policy compared to the behavior policy was −0.04 (95% CI −0.63 to 0.55), which was significantly lower than the improvement in value of 1.03 (95% CI −0.05 to 2.10; *P*=.01) of the policy derived from the full pipeline.

Discussion

Principal Findings

Offline RL has been applied to various health care domains [2-4]. However, a clear guide that practitioners can refer to has not been established. We present a blueprint based on previous literature to streamline the development of offline RL policies and further facilitate this through a public code base. We demonstrated the utility of our rigorous pipeline in the context of learning treatment decision policies for loop diuretics in hospitalized patients. Overall, in retrospective analysis, the learned policy was estimated to lead to significant improvement in outcome for the general patient population, especially for a subset of patients where the learned policy differed the most from clinician behavior. Though it will require prospective validation, our results reveal areas of potential improvement in current clinical care.

A key challenge in offline RL is ensuring the robustness of the learned policy. Two elements in our pipeline contributed to the improvement in robustness and performance. The first element—tuning state definitions—addresses the issue of hyperparameter sensitivity in offline RL. To select the optimal hyperparameters, prior work often relied on the hold-out method which partitioned the development dataset into training and validation sets [3,30,31]. Recently, Nie et al [7] found policy performance to be sensitive to this partitioning itself and proposed the SSR pipeline which uses multiple dataset partitions during evaluation. Building upon this insight, we show that while common practice has been to use a fixed state definition derived from a single train-validation split [3,30,31], the partitioning used to learn the state definitions can also result in significant variability of the final policy's performance, and thus jointly tuning state definitions and policy learning over multiple data partitions is important for robustness of the learned policy.

The second element—relaxing the learned policy via unimportant states—is a form of policy constraint that mitigates the impact of extrapolation error by reducing the deviation of the learned policy from the behavior policy [5]. Using unimportant states to constrain the policy post hoc also helps reduce disruptions to the current workflow, an important consideration in health care settings. During deployment, the policy acts as an alert system to notify providers of the appropriate treatment [32]. Yet a well-known consequence in alert systems is "alert fatigue," where providers ignore alerts due to the high frequency of irrelevant or unhelpful alerts [32,33]. By generating recommendations only when the action will meaningfully impact the outcome, unimportant state relaxation presents a simple solution to reduce disruptions to existing workflows while minimally compromising the policy's performance.

In analyzing our learned policy, we found that loop diuretics had a limited effect on patient outcome for a sizable portion of the cohort. Our pipeline could thus be used to identify patient groups that are likely responsive to treatments. In these treatment-responsive cases, the learned policy tended to agree with the majority of clinicians, indicating that our policy could help reduce heterogeneity in treatment decisions. Patients in the 2 divergent states were slightly older and had mild kidney impairment, which could explain clinicians' hesitancy in prescribing loop diuretics. However, the high BNP values indicate that the patients are fluid overloaded and may still benefit from diuretic treatment.

Our study is not without limitations. The pipeline used a single OPE method (WIS) during hyperparameter selection and a single dataset. While designed to be agnostic to both, future studies using external datasets and different OPE methods during hyperparameter tuning will further validate the generalizability of PROP-RL. Our problem formulation enforced decisions to be binary and to occur every 24 hours at fixed time points (Section B1 in Multimedia Appendix 1 for results across different decision points). A finer-grained problem formulation—such as specifying the exact dosage, incorporating additional actions (ie, other medications), and using shorter or more flexible time intervals for actions—along with additional data will be required to learn a policy that can be deployed in clinical settings. A promising direction for future work is incorporating clinician feedback after deployment to further refine the alert threshold and better understand when recommendations are most useful to clinicians, beyond our current approach of using unimportant states (Section A15 in Multimedia Appendix 1).

Another important limitation is our reliance on retrospective evaluation. In the absence of a reliable simulator and safety concerns associated with real-world evaluation, we relied on OPE methods which may not reflect the policy's true performance during deployment. We mitigate this by imposing a large cutoff on the ESS during hyperparameter selection and by confirming our findings across multiple OPE methods. Nonetheless, retrospective evaluation should only be viewed as a preliminary step for identifying promising policies prior to investing in prospective studies. Future work must include robust prospective validation in accordance with guidelines such as the DECIDE-AI reporting framework [34]. The potential for unmeasured confounding is also a fundamental limitation of OPE methods. To mitigate this, we derived our state space using a comprehensive set of EHR features, selected in close consultation with a clinical collaborator with deep domain expertise. However, residual confounding may remain. Since these challenges are present in any realistic problem setting, our approach serves as a guide for other researchers to follow when learning offline RL policies.

Conclusion

In summary, we present a standardized pipeline to streamline the development of offline RL policies in health care settings.

XSL•FO
RenderX

We demonstrate the utility of this pipeline in the context of learning treatment decision policies for loop diuretics in hospitalized patients and show that the learned RL policy could potentially lead to a significant improvement in a key subset of the patient population. Our work highlights important considerations for applying RL to observational data to learn treatment decision policies, and our open-sourced code base can facilitate future development of offline RL policies on other clinical problems.

Abstract

Background: Early diagnosis of hepatocellular carcinoma (HCC) in patients with chronic hepatitis B virus (HBV) is challenging. Models that combine novel biomarkers with clinical features may improve both early diagnosis and risk stratification, but few have been systematically validated.

Objective: This study aimed to develop and validate an extra spindle pole bodies–like 1 (ESPL1)–based model for diagnostic discrimination of HBV-related HCC and longitudinal risk stratification in patients with chronic HBV infection.

Methods: Patients with chronic HBV were consecutively recruited from the First Affiliated Hospital of Guangxi Medical University (a single-center, tertiary hospital) between January 2012 and November 2023. Patients were divided into a training set and an independent hold-out testing set. A LASSO logistic regression model was constructed to identify independent predictors and then used to develop a risk score discriminating patients with HBV-related HCC from those with chronic hepatitis B or cirrhosis. Model performance was evaluated using discrimination (C-index), calibration, and decision curve analysis. Internal validation was performed with bootstrap resampling, and independent hold-out validation was conducted with the independent hold-out testing set. Longitudinal follow-up of patients with chronic hepatitis B or cirrhosis was subsequently used to examine cumulative incidence across risk groups, thereby assessing the model's ability to stratify future HBV-related HCC risk. A web-based calculator was developed to facilitate clinical application.

Results: The study involved a cohort of 621 patients diagnosed with chronic HBV infection, divided into a training set of 373 (60.1%) patients and an independent hold-out testing set of 248 (39.9%) patients. Age (odds ratio [OR] 1.08, 95% CI 1.05 - 1.12), ESPL1 expression (OR 1.01, 95% CI 1.00 - 1.01), and log (alpha-fetoprotein) levels (OR 2.55, 95% CI 1.95 - 3.33) were identified as independent predictors of HBV-related HCC. The model demonstrated excellent diagnostic discrimination, with a C-index of 0.922 in the training set and 0.958 in the independent hold-out testing set, coupled with strong calibration. Decision curve analysis revealed that the model consistently provided a higher net benefit across clinically relevant threshold probabilities. Subgroup analyses further validated the model's high discriminative power, with C-index values ranging from 0.86 to 0.98, and no significant interactions were detected (all interaction *P* values > .10). Furthermore, the model demonstrated superior discriminatory power relative to 5 established HBV-related HCC risk scores, including REACH-B, GAG-HCC, CU-HCC, PAGE-B, mPAGE-B, and alpha-fetoprotein alone, with all pairwise comparisons yielding statistical significance (*P*<.001). For prognostic stratification, patients categorized as low risk, medium risk, and high risk had distinct 5-year cumulative HCC incidences of 5.1%, 21.1%, and 31.3%, respectively (*P*<.001).

Conclusions: The ESPL1-based model may serve as both a diagnostic tool for differentiating patients with HCC from those with non-HCC and as a preliminary approach for risk stratification during follow-up. This dual role has the potential to support earlier detection and personalized monitoring. The web-based calculator improves accessibility and may facilitate future clinical integration.

Introduction

Global Burden and Clinical Challenges of Hepatitis B Virus–Related Hepatocellular Carcinoma

Hepatitis B virus (HBV), mainly spread through blood and bodily fluids, is a major global health concern and a leading cause of hepatocellular carcinoma (HCC), accounting for more than 50% of cases worldwide [1,2]. More than 200 million people have chronic HBV, of whom 15% to 25% at risk of developing liver cirrhosis or HCC. The prevalence and mortality of HBV-related HCC are projected to continue rising over the next two decades [3]. HCC increases public health challenges and places significant economic and emotional strain on patients and families [4]. Surgical resection is the best cure for early-stage HCC, but most patients are diagnosed at advanced stages because of the asymptomatic nature of early disease, rendering curative treatment infeasible. Thus, early diagnosis and risk stratification of high-risk patients are essential for improving HCC outcomes.

Limitations of Current Risk Prediction Models

Current guidelines advocate for patients with chronic hepatitis B (CHB) to undergo a series of diagnostic tests every 3 to 6 months during antiviral therapy. However, challenges such as limited patient compliance, the low sensitivity of individual biomarkers, high costs, and inconsistent implementation across different health care settings impede the early detection of HCC [5-8]. A cost-effective approach to facilitate early HCC diagnosis and treatment involves the identification of high-risk individuals with chronic HBV infection and their regular monitoring. Risk prediction models provide personalized assessments of HCC risk for patients with CHB, thereby aiding physicians in improving patient adherence and optimizing screening and monitoring strategies [9,10]. Several models, including REACH-B, GAG-HCC, and PAGE-B, have been developed to assess HCC risk in patients with chronic HBV [11-16]. Nevertheless, these models primarily rely on conventional clinical parameters, limiting their generalizability, and they often fail to incorporate novel biomarkers or undergo validation for both diagnostic accuracy and longitudinal applicability.

Objectives

Among the various potential biomarkers, the extra spindle pole bodies-like 1 (ESPL1) gene has garnered significant attention because of its involvement in genomic instability and tumor progression. Alterations in ESPL1, potentially induced by chronic viral infections or environmental carcinogens, may play a role in malignant transformation [17]. Our previous research identified frequent HBV S–ESPL1 fusion events in HBV-related HCC tissues and demonstrated that circulating ESPL1 protein levels can effectively differentiate early HCC from cirrhotic nodules [17,18]. Building upon these findings, this study pursued 2 primary objectives: first, to construct an ESPL1-based model capable of accurately distinguishing patients with HBV-related HCC from those with non-HCC, thereby demonstrating its diagnostic utility; and second, to substantiate its prognostic significance through longitudinal follow-up, stratifying patients with non-HCC according to their prospective risk of developing HCC. By integrating a biologically pertinent biomarker with real-world patient data, our model seeks to address the limitations of conventional methodologies and offer a clinically significant framework for both the early diagnosis and longitudinal risk stratification of HBV-related HCC.

Methods

Ethical Considerations

This study was approved by the Ethics Committee of the First Affiliated Hospital of Guangxi Medical University (2024-E614-01). The Ethics Committee of the First Affiliated Hospital of Guangxi Medical University waived written or oral informed consent of participants because there was no personally identifiable information in the article. The study followed the ethical standards outlined in the Declaration of Helsinki (World Medical Association Declaration of Helsinki 2013). All data were anonymized before analysis to protect patient privacy and confidentiality. No individual-level identifiers were included in the dataset, and all results are presented in aggregate form. No financial or other compensation was provided to participants in this study. Finally, no images or other materials that could potentially identify individual participants are presented in this manuscript or supplementary files.

Study Design and Patients

This study was designed in 2 parts: (1) development of a diagnostic model to distinguish patients with HBV-related HCC from those with non-HCC (CHB and cirrhosis) and (2) longitudinal validation of its prognostic utility using follow-up data in patients with non-HCC.

This study is reported following the Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis reporting guideline checklist for developing and validating prediction models [19]. To minimize selection bias, all eligible patients with chronic HBV infection who were managed by our team from January 2012 to November 2023 were enrolled consecutively, adhering to stringent inclusion and exclusion criteria. Standardized follow-up protocols were implemented to accurately represent the natural clinical spectrum of HBV patients in our region. These protocols included assessments every 3 months during the first year of antiviral therapy, which comprised evaluations of HBV serological markers, HBV DNA levels, liver function tests, and alpha-fetoprotein (AFP) levels. Subsequently, follow-ups were conducted every 6 months, incorporating abdominal ultrasound. Patients diagnosed with cirrhosis or hepatic nodules were monitored every 3 months, with additional imaging modalities such as contrast-enhanced ultrasound, computed tomography,

XSL•FO
RenderX

or magnetic resonance imaging recommended if nodules increased in size by more than 1.0 cm or if AFP levels rose.

To further reduce center-related bias, patients who met the inclusion criteria were divided based on their enrollment period into a training set and a temporally distinct testing set, rather than being allocated randomly. This approach provided an independent hold-out validation that more accurately simulates real-world application compared to random resampling. In addition, a subset of patients from the follow-up cohort, who had stored paired serum samples (1 at baseline and another after more than 5 years of follow-up), was included in a longitudinal analysis. These patients were managed under the same standardized protocol as the main cohort. Their paired samples were used to calculate predicted HCC risk values at both time points, thereby enabling an evaluation of the model's capacity to capture dynamic changes in risk over time.

Inclusion Criteria

The inclusion criteria have been described below.

Patients with Chronic HBV

These included individuals aged >18 years with CHB or HBV-related liver cirrhosis. CHB was defined as persistent HBsAg positivity for more than 6 months, detectable HBV DNA, and evidence of active liver disease, characterized by either persistently or intermittently elevated alanine aminotransferase (ALT) levels, histological findings of significant necroinflammation, or histological/noninvasive evidence of significant fibrosis (≥F2) [8]. HBV-related cirrhosis was diagnosed either histologically, based on liver biopsy consistent with cirrhotic changes, or clinically [8]. Clinical diagnosis required documented chronic HBV infection (current HBsAg positivity or HBsAg negativity with anti-HBc positivity and a history of HBsAg positivity >6 mo, with other causes excluded), together with at least two of the following 5 features: (1) imaging findings of cirrhosis and/or portal hypertension; (2) endoscopic evidence of esophageal or gastric varices; (3) liver stiffness measurement (LSM) consistent with cirrhosis, defined as ≥12.0 kPa when ALT <1×ULN or ≥17.0 kPa when ALT is 1 - 5×ULN; (4) serum albumin <35 g/L or prothrombin time prolonged >3 seconds compared with controls; and (5) platelet count <100×10 /L.

Patients with HBV-related HCC

These included patients with pathologically confirmed HCC following partial hepatectomy. All HCC cases had chronic HBV infection as defined earlier, with no evidence of other etiologies such as hepatitis C, alcohol, or autoimmune liver disease.

Patients with Untreated HCC

These included patients with newly diagnosed HBV-related HCC who had not undergone prior curative or palliative therapies, including liver resection, transarterial chemoembolization, radiofrequency ablation, systemic therapy, or chemotherapy.

Adequate Frozen Serum Samples

There should have been the availability of at least 0.5 mL of stored serum per patient, collected before HCC treatment or during routine follow-up, and preserved at −40°C or lower in our serum biobank.

Exclusion Criteria

The exclusion criteria were as follows: (1) patients co-infected with HBV and other infections such as hepatitis D, E, C, or HIV/AIDS; (2) patients with non-HBV-related cancers, including non-HBV-related HCC; (3) patients with liver disease from other causes, such as autoimmune liver disease; and (4) patients with decompensated liver cirrhosis or liver failure.

Peripheral venous blood samples (5 mL) were collected from patients in the CHB and cirrhosis of liver (LC) groups during outpatient visits and from the HBV-HCC group before surgical resection. Samples were centrifuged at 4000 rpm for 5 minutes, and the serum supernatant was stored at −40°C for subsequent analysis.

Serum ESPL1 Levels Detection

Serum ESPL1 levels were measured using an Enzyme-Linked Immunosorbent Assay (ELISA) kit (Nova Lifetech Inc, Catalog No.: ELI-48263h) according to the manufacturer's instructions. The procedure included standard and sample preparation, incubation, washing, addition of reagents, and optical density measurement. The absorbance (optical density value) of each sample was quantified using a microplate reader (BioRad, Co, Ltd, USA) at a wavelength of 450 nm. Three replicate wells were used for each sample, and the mean value was determined. The concentration of serum ESPL1 in the unknown samples was calculated based on the standard curve [20].

Data Collection

Collected patient follow-up data included name, diagnosis, sex, family history of HCC or LC, age details (age at ESPL1 testing, antiviral treatment duration), antiviral drugs, HBV DNA levels, HBeAg status, liver nodules, and ALT, albumin (ALB), and AFP levels at ESPL1 testing.

A total of 16 variables were collected: 9 continuous (ESPL1, age at ESPL1 testing, antiviral treatment duration, HBV DNA, AFP, ALT, aspartate aminotransferase [AST], ALB, and liver stiffness) and 7 categorical (diagnosis, sex, family history of HCC/LC, treatment status, antiviral medication, HBeAg status, and liver nodules). To enhance data robustness and reduce outlier effects, a log transformation was applied to the HBV DNA and AFP data because of their wide range and extreme values.

Missing Data

Missing data rates were 1.6% for AFP, 0.5% for ALB, and 18.7% for liver stiffness. Missingness was addressed using multiple imputation via the mice package in R (version 3.6.2, Institute for Statistics and Mathematics, Vienna, Austria) [21]. The missing data pattern was inspected, and imputations were generated under the assumption of missing at random using predictive mean matching, which preserves the observed data distribution. Five imputed datasets were created, pooled according to Rubin's rules, and used for the primary analyses. To assess robustness, sensitivity analyses were conducted by comparing results from the pooled imputed dataset with those from the complete-case dataset, and each of the 5 individual

XSL•FO
RenderX

imputed datasets. The retained predictors and their effect sizes were consistent across all analyses, indicating that missing data had minimal influence on the final model in Multimedia Appendix 1.

Comparison With Established HCC Risk Models

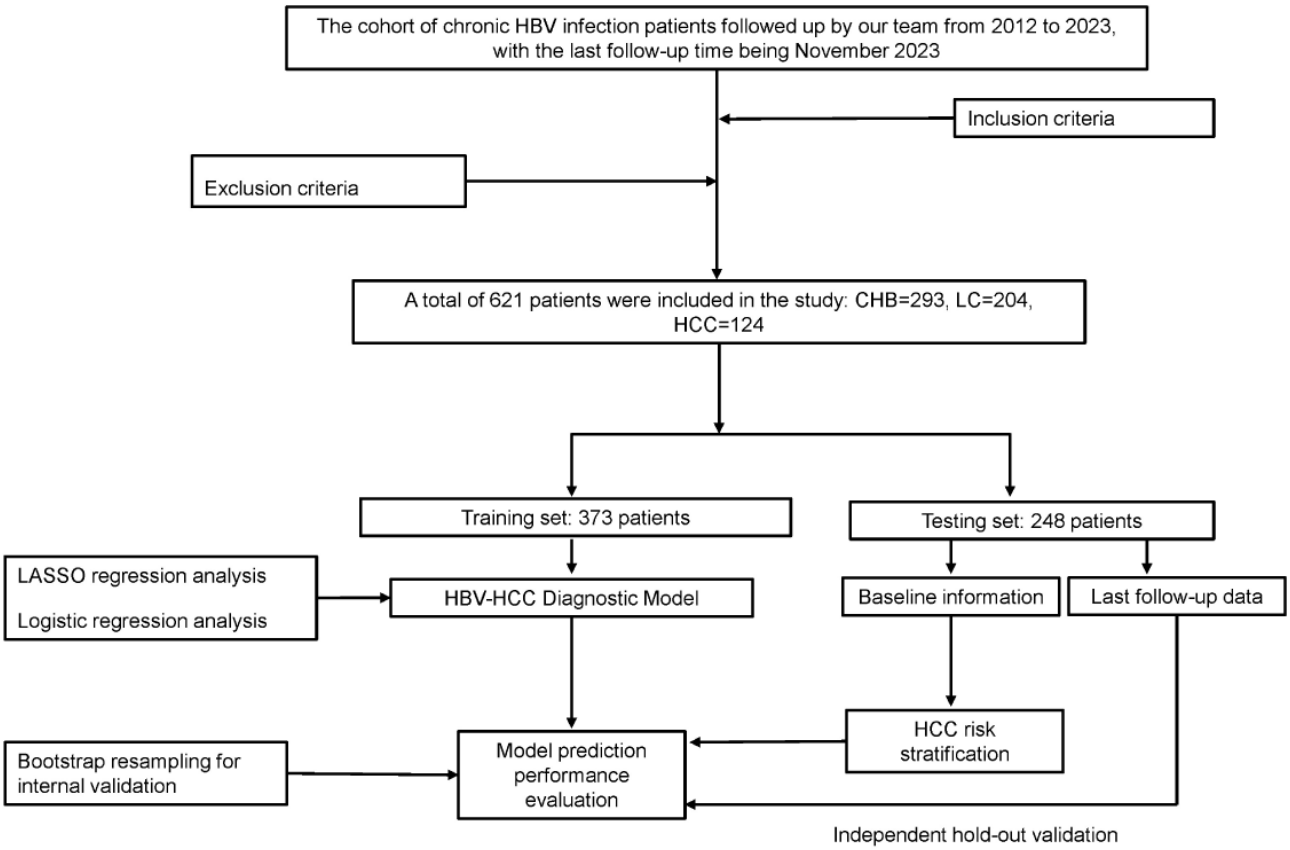
To assess the comparative performance of the ESPL1-based Age-ESPL1-AFP (AEA) score, we conducted an evaluation against 5 established HBV-related HCC risk models (ie, REACH-B, GAG-HCC, CU-HCC, PAGE-B, and mPAGE-B [22]) using an independent hold-out testing cohort. These models were chosen due to the consistent availability of their requisite predictors within our dataset, facilitating direct implementation and ensuring a fair comparison. Each score was computed in accordance with its original published definition, with comprehensive details of the scoring algorithms provided in the Supplementary Materials in Multimedia Appendix 2. Subsequently, the predictive performance of these models was evaluated and juxtaposed with that of our model.

Statistical Analysis

Statistical analysis was conducted using SPSS 26.0 and R 4.3.2 with rms and DynNom packages. Two-sided *P* values <0.05 were deemed significant. Normally distributed data are shown as "mean (SD)" and compared with *t* tests, whereas nonnormally distributed data are presented as [median (P25, P75)] and analyzed using the Wilcoxon rank-sum test. Categorical data are shown as n (%), and group differences were assessed with the χ^2 test.

LASSO regression, a data mining technique, adds a penalty to traditional linear regression to simplify the model by reducing coefficient values, addressing multicollinearity, and preventing overfitting. It was used by the modeling group to initially select predictors for HBV-related HCC [23]. Variables with nonzero coefficients from the LASSO regression were refined using stepwise backward selection in multivariate logistic regression to determine the final predictors for HBV-related HCC risk. The primary objective was to establish a diagnostic tool that differentiates patients with HBV-related HCC from those with CHB/LC. Subsequently, to examine prognostic relevance, we applied the model to the non-HCC subgroup with longitudinal follow-up, assessing cumulative HCC incidence across risk strata. We then developed a clinical prediction model and an interactive web-based risk calculator using Shinyapps, designed exclusively for patients with chronic HBV infection or HBV-related cirrhosis, and not intended for use in the general population without HBV.

We assessed the model's predictive performance by calculating discrimination and plotting calibration curves for both training and independent hold-out testing sets [24]. The C-index, ranging from 0.5 (no discrimination) to 1.0 (perfect prediction), was used to evaluate discrimination. Calibration was further evaluated using the Hosmer–Lemeshow goodness-of-fit test, which compares observed and predicted event rates across deciles of risk [25]. Calibration was also assessed using calibration curves and the Brier score, where lower scores indicate higher accuracy. We conducted 1000 bootstrap resampling iterations for internal validation of the model's predictive performance. Optimal cutoff values for HBV-related HCC risk stratification were determined using X-tile software, a validated tool for biomarker assessment and outcome-based cutoff optimization [26]. These cutoffs were first applied to baseline predicted risk values in the longitudinal cohort, categorizing patients into low risk, medium risk, and high risk groups. The cumulative incidence of HCC within each risk group was then estimated using the Kaplan–Meier method, with differences between groups assessed by the log-rank test [27]. Clinical decision curves were used to evaluate the model's clinical applicability. The main metric in the clinical decision curve was the net benefit, determined by the model's true and false positive rates in predicting outcomes for the target population. The formula applied was as follows: net benefit=(true positives/N)−(false positives/N)×(Pt/(1−Pt)), with N as the total sample size and Pt as the model's event probability threshold. By linking net benefits across various probabilities, we created a decision curve, where a higher net benefit signifies greater model value in clinical use [28].



Results

Patient Characteristics

A total of 621 patients with chronic HBV were included, comprising 373 in the training set (median follow-up: 2.6 years) and 248 in the independent hold-out testing set (median follow-up: 5.0 years), as shown in Figure 1. The overall median age was 46 years, with 467 males (75.2%) and 154 females (24.8%). At baseline, 293 patients (47.2%) had CHB, 204 (32.9%) had LC, and 124 (20.0%) had HCC. Clinical characteristics of the two cohorts are summarized in Table 1.

[i]LC: liver cirrhosis.

[j]HCC: hepatocellular carcinoma.

During follow-up in the independent hold-out testing set, 38 patients (15.3%) developed HCC, with cumulative incidence rates of 2.4%, 9.3%, and 15.3% at 1, 3, and 5 years, respectively. Compared with the training set, patients in the independent hold-out testing set were older, had longer antiviral treatment duration, and exhibited higher ALT levels. They also showed

XSL•FO
RenderX

lower HBV DNA, AFP, AST, and ESPL1 levels, fewer liver nodules, a lower prevalence of family history of HCC/LC, and different distributions of antiviral medication use.

Construction of a Risk Prediction Model for HBV-Related HCC

Using LASSO regression, 9 predictors with non-zero coefficients were identified from an initial set of 16 variables, including gender, age, ESPL1, antiviral drugs, log (HBV DNA), Alb, AST, log (AFP), and liver nodules (Multimedia Appendix 3). Detailed information on these HCC-related predictors is provided in Table 2 (lambda.min=0.04091). Subsequently, a predictive model for predicting HBV-related HCC risk was developed using multivariable logistic regression, incorporating both the LASSO-selected variables and those identified through univariable logistic regression variables, as presented in Table 2. The final prediction model included age, ESPL1, and log (AFP) as independent predictors, and the regression coefficients are provided in Table 2. The estimated probability of HCC was calculated using the logistic regression equation: logit(P)=−8.9764+0.0802×age+0.0059×ESPL1+0.9365×log (AFP).

Table . Univariate and multivariate logistic regression analyses variables relating to HCC in the training set. Note: In multivariate logistic regression, variables such as first-line nucleotides and liver nodules produced extremely high odds ratios with confidence intervals of (0, Inf), consistent with quasi-complete separation. Under such conditions, maximum likelihood estimation becomes unstable, and the coefficients are not reliable; therefore, these variables were excluded from the final model.

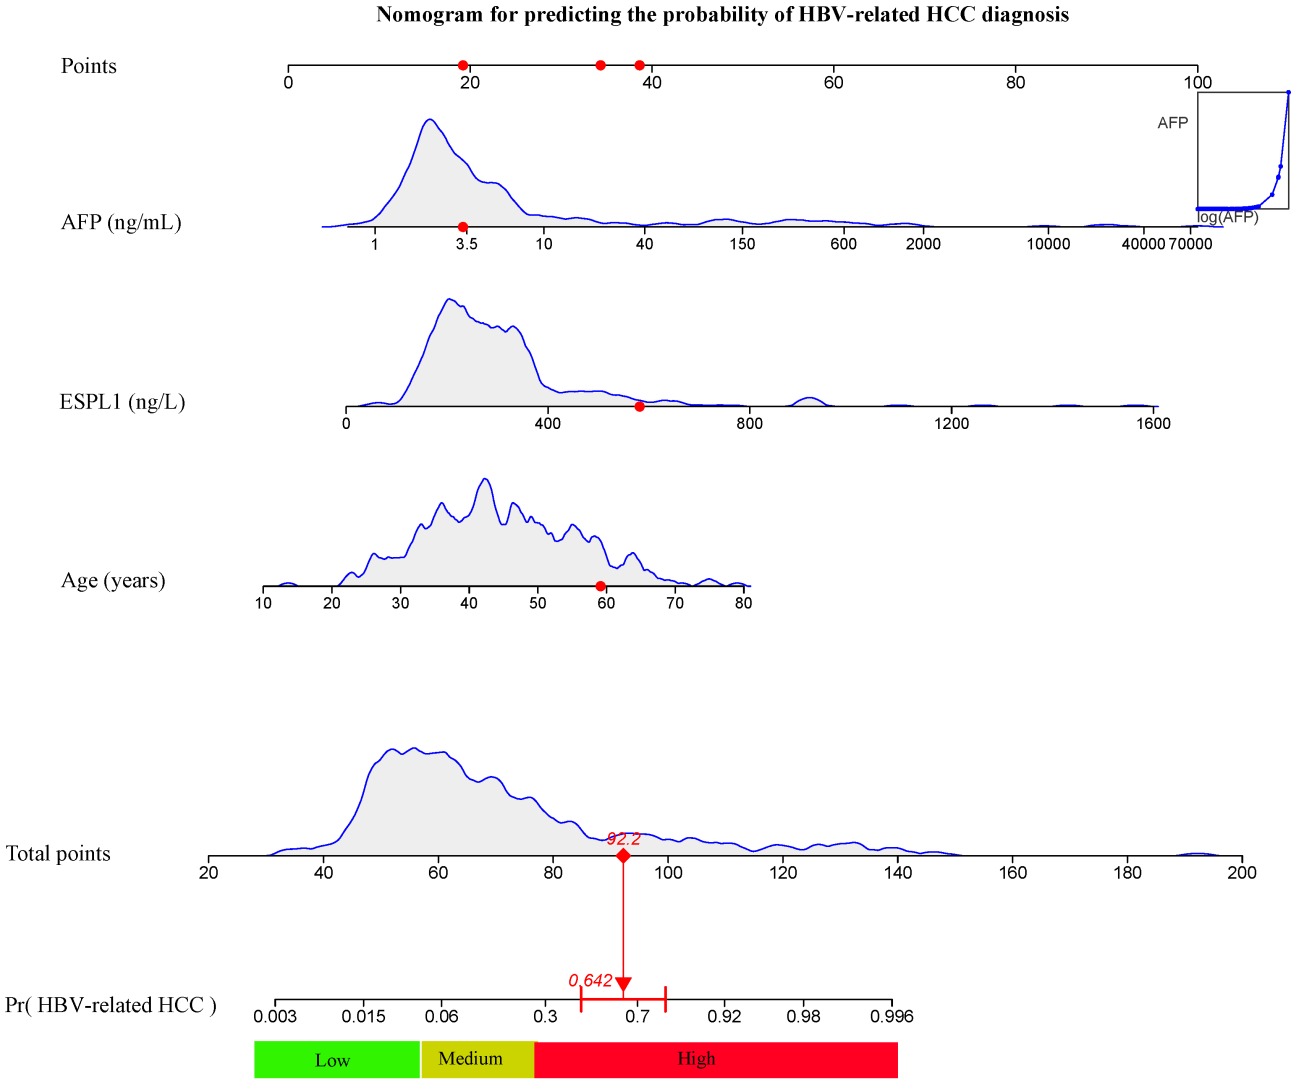
[a] ESPL1: extra spindle poles like 1.

[b]HBV: hepatitis B virus.

[c]ALB: albumin.

[d]AST: aspartate aminotransferase.

[e]AFP: alpha-fetoprotein.



A risk model for predicting HBV-related HCC was developed using age, ESPL1, and AFP (AEA score) from multivariable logistic regression analysis, as depicted in Figure 2. Each variable has a score, and their sum estimates HCC risk. For example, in a 59-year-old male patient with pathologically confirmed HBV-related HCC who had an AFP level of 3.32 ng/mL and an ESPL1 level of 581.60 ng/L, the calculated total score corresponded to a predicted HCC risk probability of 64.2%. Conversely, in a 45-year-old male patient with chronic HBV infection and imaging evidence of cirrhotic nodules but no HCC diagnosis, with an ESPL1 level of 252.50 ng/L and an AFP level of 3.09 ng/mL, the calculated score indicated a predicted HCC risk probability of 7.47%. These contrasting examples illustrate how the AEA score can distinguish between patients at markedly different levels of HCC risk within the HBV population. For easier clinical use, we developed a web calculator [29]. In this, we can access the URL, input the necessary data, and click “Predict” to view the patient’s current HCC risk, as shown in Figure 3.

Sensitivity analyses, which compared the pooled imputed dataset, the 5 individual imputed datasets, and the complete-case dataset, yielded highly consistent results. The same independent predictors were retained, and similar effect sizes were observed

XSL•FO
RenderX

across all methodologies, as detailed in Multimedia Appendix 1.

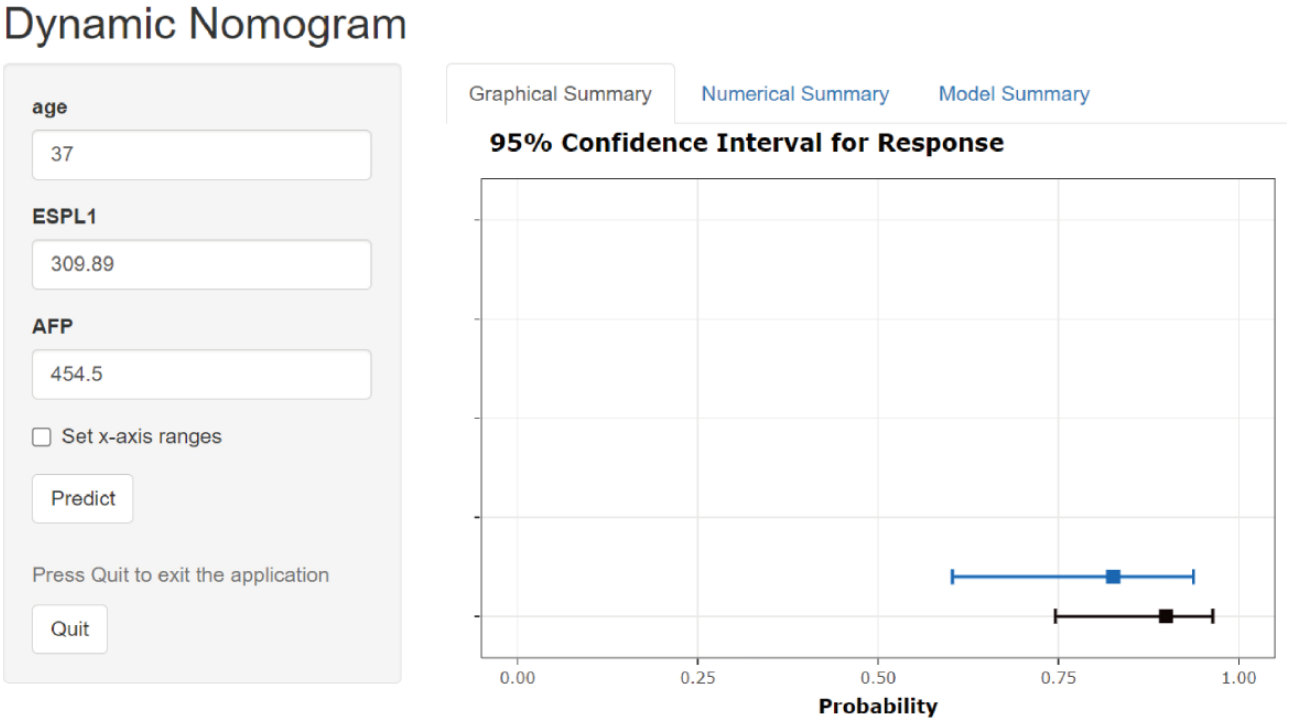


Figure 2. AEA score for predicting HBV-associated HCC risk was constructed based on the results of multivariate logistic regression analysis. Risk stratification thresholds were determined using X-tile: low risk (<4%), medium risk (4% - 24%), and high risk (>24%), as illustrated by the colored bar at the bottom of the figure. This is an example of calculating the probability of HBV-related HCC risk in patients. The irregular curves corresponding to each variable in the figure represent the distribution of variable values in the modeling group. On the basis of the corresponding variable, a score can be obtained, and the scores are added to get a total score. Finally, the total score can be used to calculate the corresponding HCC risk probability. In this illustrative case of a patient with pathologically confirmed HBV-related HCC, the red dots for AFP, ESPL1, and age indicate the patient's respective values: AFP=3.32 ng/mL, ESPL1=581.60 ng/L, and age=59 years. The corresponding scores (19+39+34.2) yield a total of 92.2, which translates into a predicted HCC risk probability of 64.2%. AFP: alpha-fetoprotein; ESPL1: extra spindle poles like 1; HBV: hepatitis B virus; HCC: hepatocellular carcinoma.

Risk stratification thresholds : Low risk (<4%), Medium risk (4%-24%), and High risk (>24%)

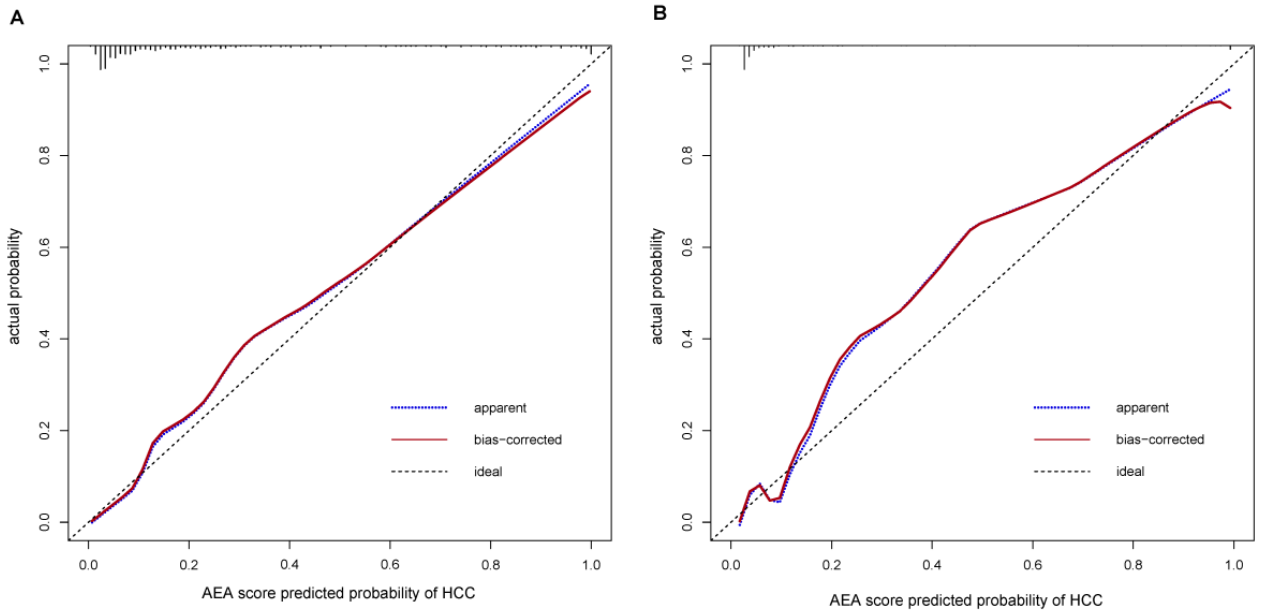
Figure 3. Example of HBV-related HCC risk probability web calculator. Age is in years, AFP in ng/mL, and ESPL1 in ng/L. AFP: alpha-fetoprotein; ESPL1: extra spindle poles like 1; HBV: hepatitis B virus; HCC: hepatocellular carcinoma.



Evaluation of HBV-Related HCC Diagnostic Model Performance

Internal Validation

In the training set, the Hosmer–Lemeshow test yielded a *P* value of .596, suggesting an absence of evidence for model overfitting. The model demonstrated a C-index of 0.922 (95% CI 0.890–0.954), with an internally validated C-index of 0.923 (95% CI 0.890–0.950). It exhibited a consistency of 0.83, sensitivity of 0.89, specificity of 0.82, a positive predictive value of 0.606, a negative predictive value of 0.959, and a Youden Index of 0.71, indicating excellent discriminatory power. Furthermore, the model surpassed the performance of AFP alone (C-index 0.605) and ESPL1 alone (C-index 0.773) in predicting HCC risk. The calibration curve (Figure 4A) demonstrated a strong concordance between predicted and observed HCC incidence, with a slope of 0.93, a mean squared error of 0.023, and a Brier score of 0.08. Collectively, these findings suggest that the model provides both precise and dependable risk estimation, which is crucial for early clinical decision-making.

Figure 4. Calibration curves of the AEA score in the training set (A) and independent hold-out testing set (B). The dashed line indicates perfect calibration, the dotted line represents the apparent performance, and the solid line shows the bias-corrected performance after 1000 bootstrap resamples. Short vertical ticks at the top of each panel denote the distribution of patients according to predicted HCC risk (rug plot). HCC: hepatocellular carcinoma.

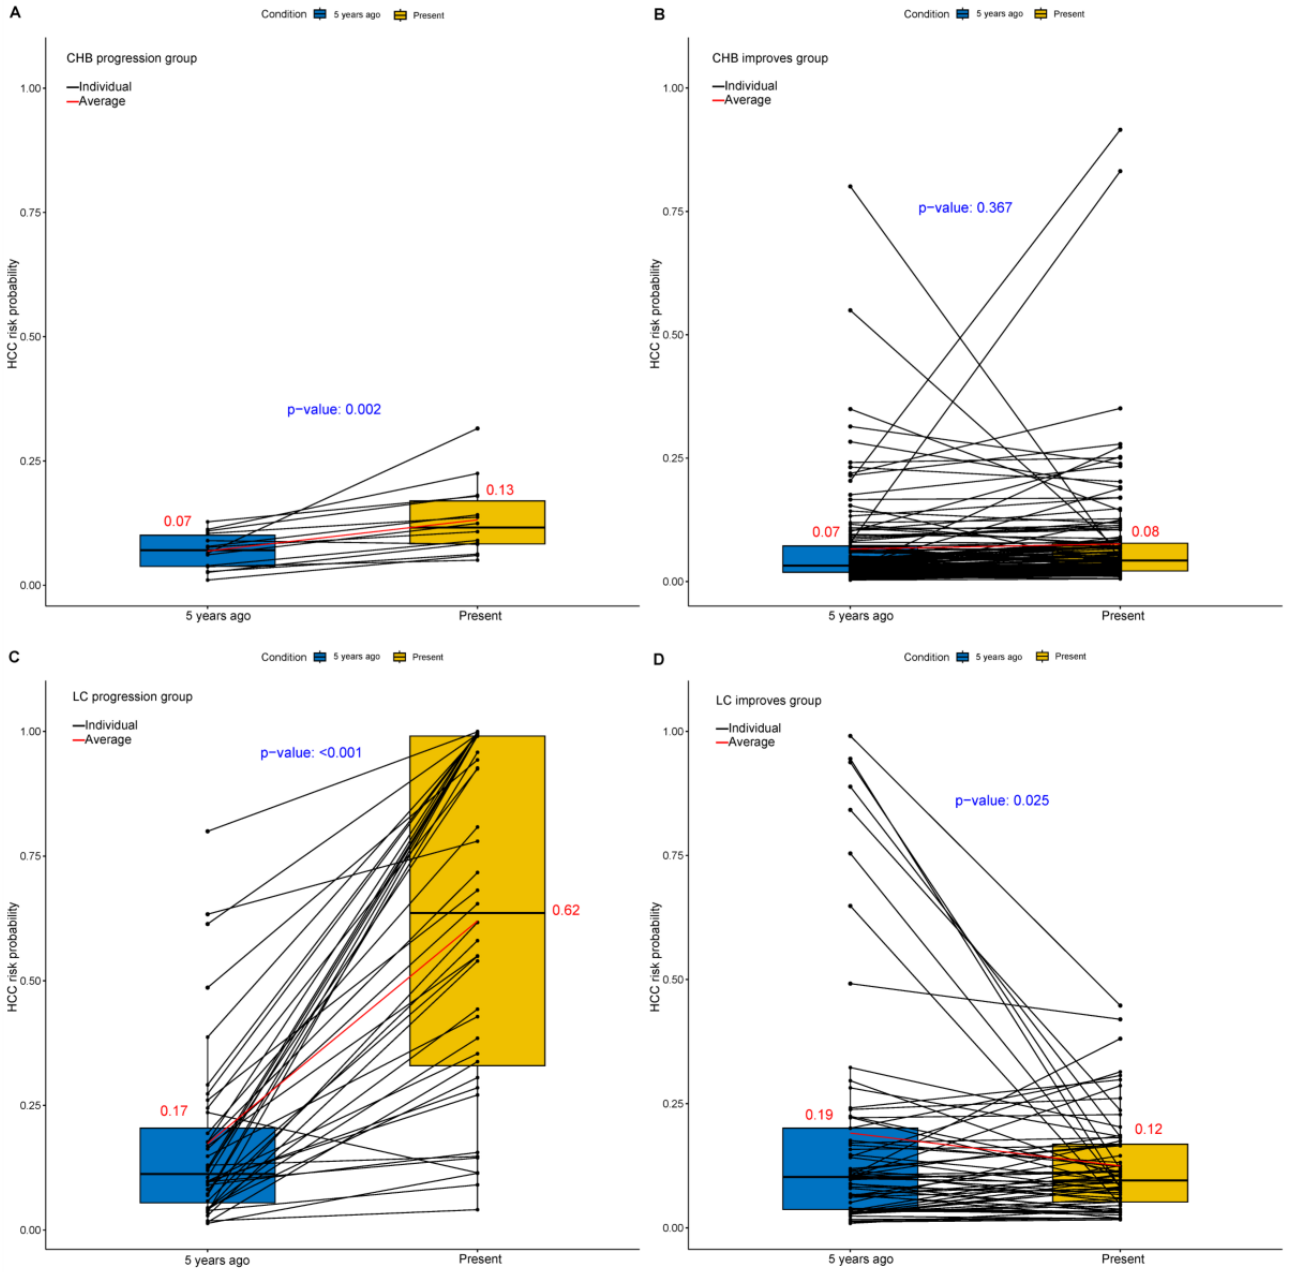
XSL•FO
RenderX

To further evaluate robustness, subgroup analyses were conducted across clinically pertinent categories, including sex, antiviral drug usage, treatment history, family history of LC/HCC, and HBeAg status in Multimedia Appendix 4. The model consistently exhibited high discriminatory performance, with C-index values ranging from 0.86 to 0.98, and no significant interactions were detected (all *P* values for interaction >.10). Owing to the absence of HCC events among noncirrhotic patients during the follow-up period, subgroup analysis stratified by cirrhosis status was not feasible. Collectively, these findings affirm that the ESPL1-based model maintains stable predictive accuracy across diverse patient subgroups, underscoring its reliability for broad clinical application.

Independent Hold-Out Validation

In the independent hold-out testing set, the model demonstrated robust performance, evidenced by a C-index of 0.958 (95% CI 0.929–0.988) and an adjusted C-index of 0.958 (95% CI 0.926–0.986). Additionally, the model exhibited a consistency of 0.92, a sensitivity of 0.87, a specificity of 0.94, a positive predictive value of 0.696, a negative predictive value of 0.976, and a Youden Index of 0.81. The calibration curve (Figure 4B) confirmed consistency between predicted and observed outcomes, with a slope of 0.91, mean squared error of 0.027, and a Brier score of 0.05. These findings support the robustness and clinical applicability of the model, suggesting that its predictions remain reliable when applied to independent patient data.

Comparison of AEA Score With Other HBV-Related HCC Risk Scores



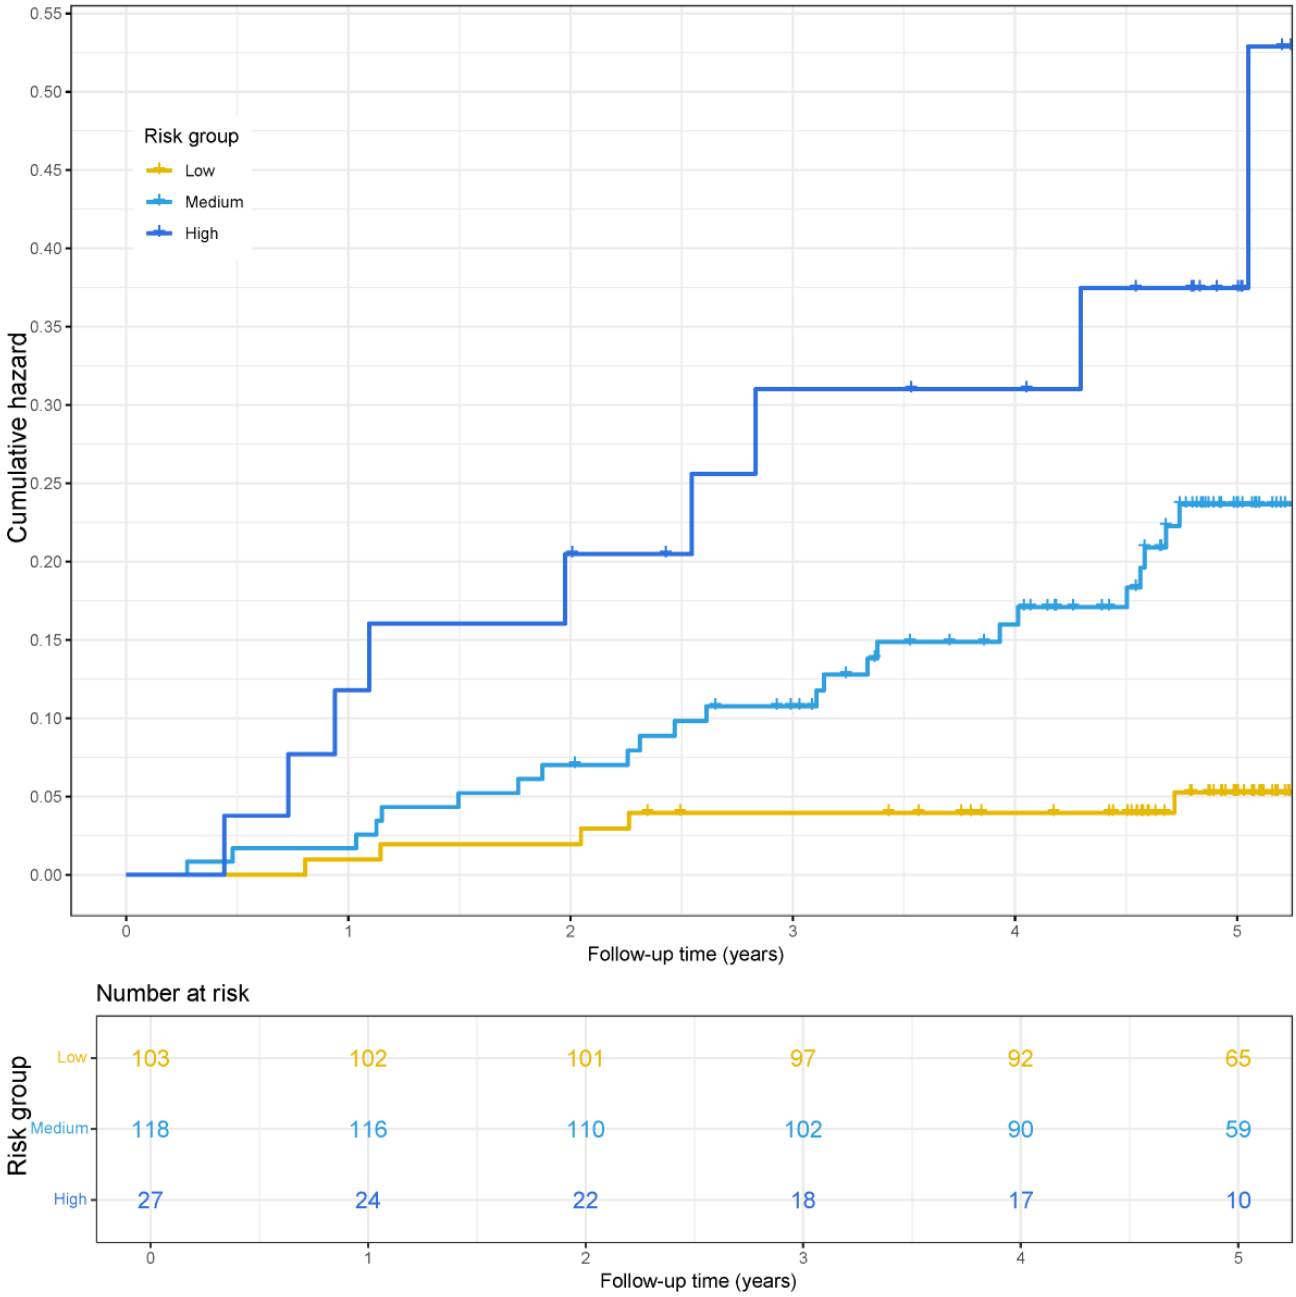
The AEA score consistently exhibited superior discriminatory power compared to the 5 established HBV-related HCC risk models (REACH-B, GAG-HCC, CU-HCC, PAGE-B, and mPAGE-B). Within our cohort, the C-index of the AEA score was significantly greater than that of each comparator model, with all pairwise comparisons achieving statistical significance (*P*<.001, Multimedia Appendix 5). In addition, the discriminative ability of AFP alone was limited (C-index=0.61, 95% CI 0.56 - 0.65), further highlighting the incremental value of incorporating ESPL1 into the AEA score. These results underscore the enhanced predictive value of integrating ESPL1 into risk assessment, surpassing traditional demographic and clinical variables.

Validation of AEA Score for HBV-Related HCC in a Longitudinal Cohort

The longitudinal analysis confirmed that the ESPL1-based AEA score dynamically reflected disease trajectories: predicted HCC risk remained stable or significantly decreased in patients with clinical improvement, whereas it rose markedly in those with disease progression. Patients with CHB who exhibited clinical improvement (n=129) maintained stable risk values over a 3-year period (0.07 vs 0.08, *P*=0.367). In contrast, those who experienced disease progression (n=14) showed a significant increase in risk values (0.07 vs 0.13, *P*=.002; Figure 5A–B). Similarly, among patients with cirrhosis, those demonstrating clinical improvement (n=65) experienced a significant reduction in predicted risk (0.19 vs 0.12, *P*=.025), whereas patients who developed HCC during follow-up (n=40) exhibited a substantial increase in risk probability, rising from 0.17 to 0.62 (*P*<.001; Figure 5C–D). These results underscore the model's capability not only to estimate baseline risk but also to detect significant changes corresponding with clinical outcomes, thereby affirming its utility for dynamic risk monitoring.

XSL•FO
RenderX

Figure 5. Trend chart of AEA score predicting HCC risk changes with the condition of patients with chronic HBV infection. HBV: hepatitis B virus; HCC: hepatocellular carcinoma.



Using the X-tile tool, 3 optimal cutoff points (4% and 24%) were identified for stratifying HBV-related HCC risk. Application of these thresholds in the independent hold-out validation cohort (n=248) categorized patients into low risk (45.6%), medium risk (47.5%), and high risk (10.9%) groups (Figure 6). Kaplan–Meier analysis revealed significant differences in cumulative HCC incidence among groups, with 5-year rates of 5.1% in the low-risk group, 21.1% in the medium-risk group, and 31.3% in the high-risk group (P<.001). This separation highlights the ability of the model to statistically distinguish relative risk levels among patients, which may support risk-adapted surveillance strategies in future studies.

As shown in Multimedia Appendix 6, the distribution of clinical outcomes at the end of follow-up varied markedly across the 3 risk strata in the independent hold-out testing set. In the high-risk group, most patients had progressed to HBV-related HCC by the end point (88%), whereas the medium-risk group comprised a mixture of CHB, LC, and HCC cases. In contrast, the low-risk group at follow-up was composed predominantly of patients with CHB, and no HCC events were observed in this category. This clear gradient in outcome distribution demonstrates the model's ability to stratify patients according to their likelihood of HBV-related HCC development and underscores its potential to inform surveillance strategies.

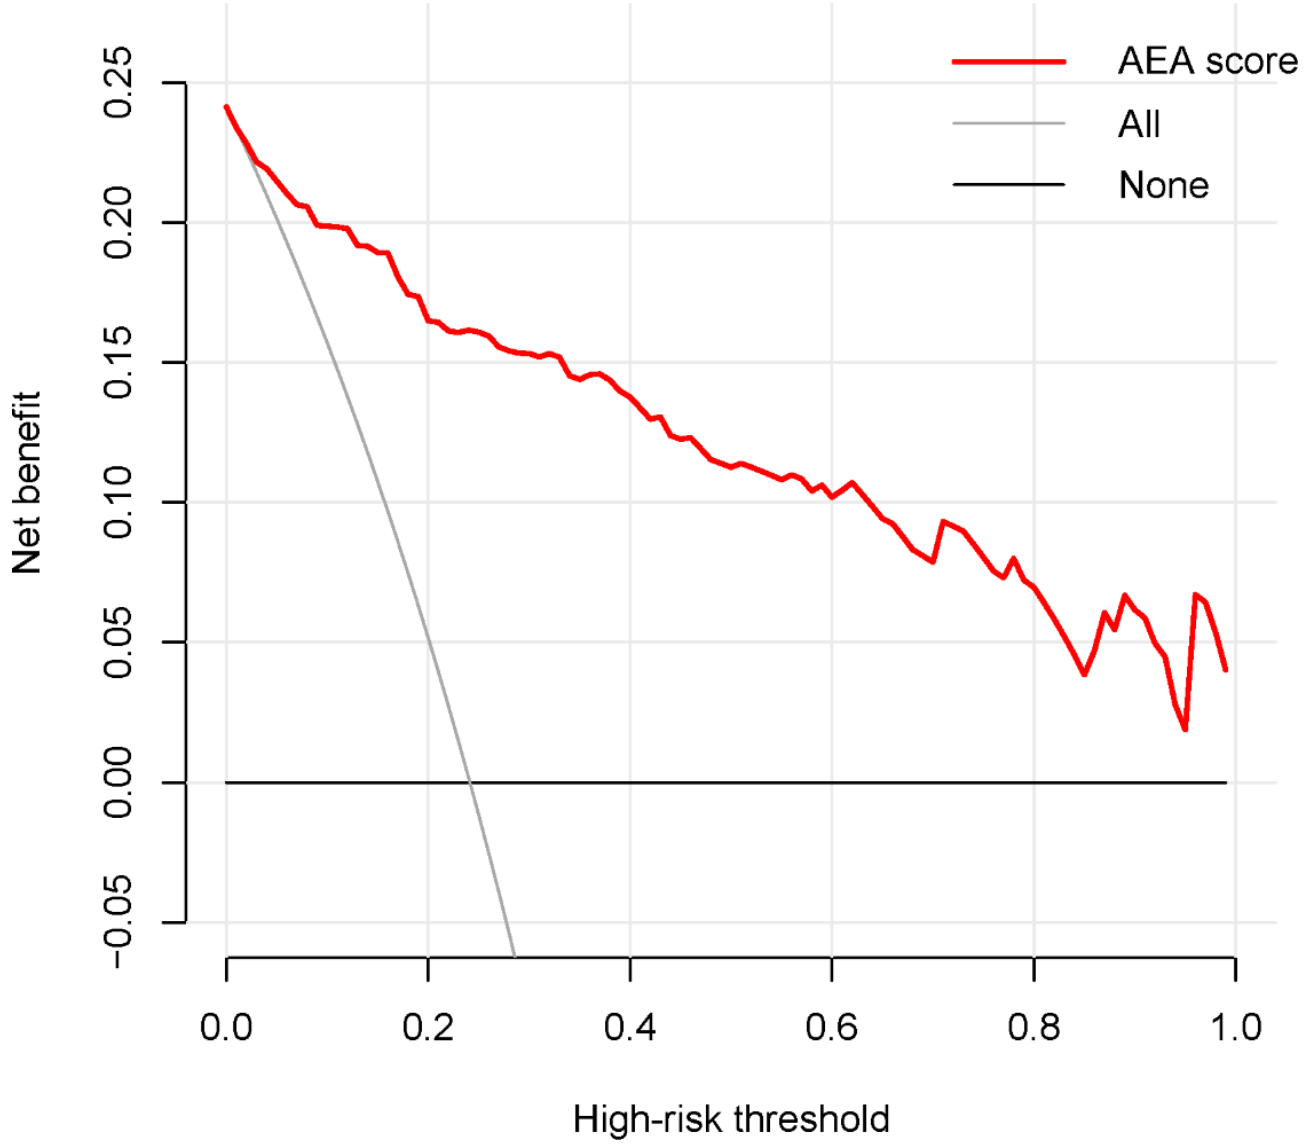
RenderX

Figure 6. Cumulative incidence curve of HBV-related HCC in longitudinal cohort. HBV: hepatitis B virus; HCC: hepatocellular carcinoma.



The Clinical Application Value of HBV-Related HCC Prediction Model

As shown in Figure 7, decision curve analysis indicated that our AEA score consistently provided greater net benefit than either the “All” and “None” strategies when the risk threshold is above 0.01. This finding implies that the model has the potential to enhance surveillance efficiency by improving case detection across clinically relevant thresholds. Nevertheless, all risk groups continue to face nonnegligible risks, necessitating ongoing monitoring in alignment with current guidelines.

XSL•FO
RenderX

Figure 7. Clinical decision curve of the AEA score in HCC diagnosis. Net benefit is the primary outcome observed in the clinical decision curve. It is calculated based on the true positive rate and false positive rate of the model's prediction for the outcome in the target population. The formula is as follows: net benefit=(true positives/N)–(false positives/N)×(Pt/(1−Pt)), where N is the total sample size and Pt is the probability threshold used by the model to distinguish between the occurrence and nonoccurrence of the event. Connecting the net benefit values at different probability thresholds forms the decision curve. A higher net benefit indicates greater practical value of the model in real-world applications.

Discussion

Principal Findings

Chronic HBV infection can lead to liver inflammation and fibrosis, which may progress to HCC. Early detection of HCC significantly enhances prognosis; however, the asymptomatic nature of its early stages poses challenges for timely diagnosis. Recent technological advancements [30] and the identification of novel biomarkers, in conjunction with clinical features, are expected to enhance the accuracy and feasibility of early HCC detection. Building on our previous research, we developed an AEA score that integrates the newly identified ESPL1 protein biomarker with long-term clinical data from patients with chronic HBV infection. The AEA score demonstrated superior performance in both accuracy and calibration compared to existing HCC risk models. In addition, subgroup analyses indicated that the ESPL1-based model maintained high discriminatory accuracy across various factors, including sex, antiviral regimen, treatment history, family history of LC or HCC, and HBeAg status, thereby affirming its robustness across diverse clinical contexts.

Comparison to Prior Work

In this study, the ESPL1-based AEA score demonstrated consistently superior predictive accuracy compared with 5 widely used HBV-related HCC risk models (ie, REACH-B, GAG-HCC, CU-HCC, PAGE-B, and mPAGE-B). As our study was conducted in Guangxi, a region with a particularly high incidence of HBV-related HCC, these findings emphasize that conventional models may not fully reflect risk profiles in this population. By integrating ESPL1, the AEA score provides additional discriminatory value beyond demographic and clinical variables, enabling more accurate risk stratification in high-burden settings. With respect to individual biomarkers, AFP and PIVKA-II remain widely used in clinical practice but have well-recognized limitations in sensitivity and specificity for early HCC detection. In our comparative analysis within the

XSL•FO
RenderX

same cohort, ESPL1 demonstrated significantly stronger discriminatory ability than both AFP and PIVKA-II (C-index: 0.923 vs 0.572 and 0.788, respectively), underscoring its potential to distinguish early HCC from cirrhotic nodules [17,18,31]. Although LSM reflects fibrosis and cirrhosis, it was not retained as an independent predictor in our multivariate analysis, suggesting limited incremental value when combined with ESPL1 and clinical factors in this population. Taken together, these findings highlight that while conventional models and biomarkers provide useful prognostic information, they remain insufficient for precise early HCC risk prediction in patients with chronic HBV, especially in high-incidence regions such as Guangxi. By incorporating ESPL1 with readily available clinical variables, the AEA score delivers both superior discrimination and appears to provide incremental value for risk stratification in populations with a high burden of HBV-related HCC. Nevertheless, these observations should be interpreted cautiously, as our study was based on a single-center cohort and requires external confirmation.

Our study used a cross-sectional design combined with LASSO regression to identify key predictors, thereby reducing redundancy and confounding relative to traditional Cox survival models. This methodology facilitated the selection of the most informative variables and the development of a parsimonious logistic regression model, ultimately enhancing both predictive accuracy and stability. The final model, which included age, serum ESPL1 levels, and log (AFP), exhibited strong discrimination and calibration in both the training and testing sets. In contrast, other variables commonly cited as predictors of HCC in previous studies, such as serum albumin [13,32,33], HBV DNA [11,12], ALT [11], and LSM [34], did not maintain independent significance in our multivariate analysis. A possible explanation for this finding is that early-stage HCC induces only subtle changes in biochemical markers, whereas the widespread use of antiviral therapy diminishes the predictive value of HBV DNA levels. Similarly, although LSM reflects fibrosis and cirrhosis, it may not offer additional discriminatory power once ESPL1 and AFP are accounted for.

Biological Rationale

Our prior study revealed that the expression of the HBV S–ESPL1 fusion gene persists despite long-term antiviral therapy, underscoring its specific role in hepatocarcinogenesis [17,35]. Mechanistically, ESPL1 encodes separase, a cysteine protease that plays a critical role in chromatid segregation during anaphase. Dysregulation of ESPL1 results in chromosomal instability, a well-established driver of malignant transformation. Under conditions of chronic viral infection and prolonged carcinogenic stress, integration of HBV into the ESPL1 locus can produce HBV S–ESPL1 fusion transcripts, potentially enhancing oncogenic signaling and compromising genomic integrity. Previous studies have demonstrated that mutations, overexpression, or viral fusion events involving ESPL1 contribute to uncontrolled cell proliferation, defective DNA repair, and the activation of tumor-promoting pathways, including p53 inhibition and Wnt/β-catenin signaling [36-38]. Beyond HCC, overexpression of ESPL1 has also been implicated in breast, prostate, osteosarcoma, and endometrial cancers, highlighting its role as a broadly relevant oncogenic driver [39-41]. From a clinical perspective, these biological mechanisms elucidate the enhanced efficacy of ESPL1 in comparison to traditional biomarkers. AFP, the most commonly used biomarker, demonstrates limited sensitivity in the early stages of HCC, frequently remaining below diagnostic thresholds and exhibiting a stronger correlation with tumor burden rather than the molecular initiation of malignancy [18,42]. Conversely, serum levels of ESPL1 protein may indicate early oncogenic events induced by HBV integration and genomic instability, thereby capturing risk signals before the overt formation of tumors. In our study, AFP alone did not reach conventional diagnostic thresholds; however, the log (AFP) maintained independent predictive significance. Notably, when combined with patient age and serum ESPL1 levels, the resultant AEA score demonstrated excellent discrimination (C-index 0.92) and was robustly validated in external cohorts. Collectively, these findings suggest that ESPL1 enhances predictive accuracy in a statistically significant manner and serves as a mechanistically substantiated biomarker that encapsulates the molecular mechanisms underlying HBV-induced hepatocarcinogenesis. This dual benefit—biological plausibility combined with robust clinical efficacy—advocates for its incorporation into risk prediction models to facilitate earlier and more precise identification of patients with high-risk HBV.

Clinical Implications

Cirrhotic nodules, a family history of liver cirrhosis or HCC, and the use of non–first-line antiviral agents are well-recognized clinical risk factors for HCC development, and their identification remains important for patient management. In our univariate analysis, all 3 factors were significantly associated with HCC risk. However, these associations lost statistical significance in the multivariate model. This phenomenon likely reflects that their predictive influence is relatively modest once stronger predictors, such as age, serum ESPL1, and AFP, are accounted for and may also be partly explained by correlations among variables (eg, cirrhotic nodules reflecting fibrosis already captured by ESPL1 or AFP). Our subgroup analyses further confirmed that the ESPL1-based model maintained robust discrimination across strata of sex, antiviral treatment regimen, prior treatment status, family history of LC/HCC, and HBeAg status, with no significant interactions detected. These findings suggest that the diminished significance of these factors in the multivariate model does not reflect instability, but rather their limited incremental predictive value beyond the key predictors. Nevertheless, given their established clinical relevance, these factors should not be disregarded in practice, and future studies with larger multicenter cohorts and nonlinear modeling approaches may help clarify their contribution to HCC risk prediction.

Accurate HCC risk prediction in patients with chronic HBV is essential during follow-up. Tumor heterogeneity and complex serum biomarkers pose challenges. Unlike models using AFP or PIVKA-II, our HBV-related HCC risk model based on ESPL1 integrates patient disease status and serological marker characteristics. This enables personalized HCC risk assessments to inform patient follow-up strategies. Our study shows that patients with an HCC risk probability over 24% are at high risk.

XSL•FO
RenderX

This was validated externally, where patients with chronic HBV who developed HCC had an average risk of 62%, much higher than the 17% baseline. This confirms our model's effectiveness in predicting HCC occurrence. The model's risk values allow patients to be categorized into low risk, medium risk, and high risk groups, with significant differences in 3-year and 5-year HCC incidence rates. These findings suggest that ESPL1 may improve early identification of patients at elevated risk; however, their implications for guiding follow-up strategies need to be validated in larger multicenter cohorts. In the internet age, online calculators enable quick risk assessments. Such tools may facilitate predicting HCC risk exclusively in patients with chronic HBV infection or HBV-related cirrhosis, supporting individualized follow-up strategies. However, their role in routine clinical decision-making remains exploratory and requires further validation.

Clinical prediction models are crucial for assessing HCC risk in patients with chronic HBV, aiding physicians in predicting risk and guiding treatment. However, traditional evaluation metrics such as discrimination and calibration often fall short in reflecting clinical benefits at varying risk thresholds [43-45]. Discrimination metrics such as AUC assess a model's predictive accuracy but do not confirm its clinical usefulness. To validate the clinical utility of the HBV-related HCC risk prediction model based on ESPL1, we used clinical decision curve analysis instead of multicenter, large-sample prospective studies, which are time-consuming and involve many uncertainties. Clinical decision curves reveal potential clinical benefits at various risk thresholds and calculate net benefits [28]. An ideal curve should show positive net benefits across clinically relevant thresholds. Our analysis indicates that when the threshold probability is over 1%, the model achieves a positive net benefit. In addition, the 4% and 24% thresholds used to categorize patients into low risk, medium risk, and high risk groups in our HBV-RELATED HCC model are within this range. These results provide insight into possible clinical relevance but cannot substitute for large-scale, multicenter prospective validation. Our findings suggest that the model may be clinically informative, yet confirmation in diverse populations is warranted before widespread adoption.

In addition to its predictive accuracy, the practical feasibility of ESPL1 testing is a critical consideration for clinical translation. Serum ESPL1 levels can be measured through a standard ELISA assay, which is cost-effective and comparable in price to AFP testing. Although this suggests potential feasibility, reproducibility across laboratories and consistency in different health care systems have not yet been established. Therefore, widespread clinical implementation should await further multicenter validation and assay standardization. Furthermore, we developed a web-based calculator that can be accessed on computers and mobile devices, allowing clinicians to easily input routinely available variables, including ESPL1, to obtain individualized risk estimates. At this stage, the calculator should be regarded as a prototype tool to illustrate the model's potential application rather than a ready-to-use clinical instrument.

Limitations

This study has several limitations. First, all patients were recruited from a single tertiary hospital in Guangxi, which may introduce selection bias and limit representativeness compared with broader, community-based populations. Second, as the study population was restricted to a high-incidence HBV region, the global generalizability of ESPL1 as a biomarker remains uncertain. Third, ESPL1 levels were quantified using a single ELISA kit under standardized laboratory conditions, and interlaboratory variability may affect reproducibility. Fourth, although major demographic, clinical, and virological factors were included, residual confounding from unmeasured variables (eg, lifestyle behaviors, alcohol consumption, aflatoxin exposure, or other environmental risks) cannot be excluded. We attempted to mitigate these limitations using strict inclusion criteria, internal and independent hold-out validation, and robust statistical modeling; however, multicenter prospective studies are needed to confirm these findings.

Future Directions

Future research should focus on multicenter, geographically diverse cohorts to validate the ESPL1-based model, standardize assays across laboratories, and evaluate integration into clinical practice. In addition, combining ESPL1 with other emerging biomarkers or imaging modalities may further enhance predictive accuracy. Although the model demonstrated prognostic value during longitudinal validation, it was primarily developed for diagnostic purposes. Therefore, larger multicenter prospective cohorts will be needed to confirm its long-term predictive performance and ensure generalizability. Further work should also aim to standardize ESPL1 assays, assess cost-effectiveness in different health care systems, and evaluate patient and clinician acceptance. Finally, mechanistic studies on ESPL1 in HBV-related hepatocarcinogenesis may reveal therapeutic targets and extend its utility beyond risk stratification.

Conclusions

The ESPL1-based AEA score exhibits enhanced predictive accuracy relative to existing HBV-related HCC risk models, indicating significant potential for individualized risk stratification. By incorporating both biomarker and clinical features, this model could facilitate earlier detection of HCC and enable personalized surveillance strategies. However, larger multicenter prospective studies across diverse populations are necessary to validate its broader applicability.

Abstract

Background: Severe tubular atrophy/interstitial fibrosis are critical pathological features associated with poor prognosis in IgA nephropathy (IgAN). The early identification of patients at high risk for severe tubular damage could guide clinical management and improve outcomes.

Objective: This study aimed to construct and validate a predictive model for assessing the risk of severe tubular atrophy and interstitial fibrosis in patients diagnosed with IgAN.

Methods: A total of 3276 patients from the Hankou branch of Tongji Hospital were retrospectively enrolled for model development. A predictive model for severe tubular atrophy/interstitial fibrosis was constructed based on independent predictors identified through univariate analysis, least absolute shrinkage and selection operator regression, and stepwise logistic regression. Furthermore, the model underwent internal and external validation using an independent dataset (n=1062), and performance evaluation using six machine learning algorithms: random forest, generalized linear model, decision tree, gradient boosting decision tree, extreme gradient boosting, and support vector machine.

Results: In this study, 8 variables were identified as independent predictors and used to construct a predictive model for severe tubular atrophy/interstitial fibrosis: Logit (P)=0.011×age (years)+0.324×hypertension history–0.302×education+.111×coefficient of variation of red cell distribution width–0.152×direct bilirubin (μmol/L)+0.003×uric acid (μmol/L)–0.021×estimated glomerular filtration rate (ml/min/1.73m²)+1.151×ln(24 h urine microalbumin) (mg/24h). The AUC for the predictive model was 0.860 (95% CI 0.847 - 0.873). The AUCs (95% CI) of the six machine learning algorithms ranged from 0.793 (0.765 - 0.822) to 0.880 (0.859 - 0.902) in internal validation and from 0.785 (0.756 - 0.814) to 0.862 (0.839 - 0.885) in external validation.

Conclusions: We developed a concise and clinically useful model for predicting severe tubular atrophy/interstitial fibrosis in IgA nephropathy. It offers a non-invasive tool for risk assessment when biopsy is not feasible, aiding personalized treatment decisions.

KEYWORDS

tubular atrophy/interstitial fibrosis; IgA nephropathy; predictive model; machine learning; internal and external validation

Introduction

Immunoglobulin A nephropathy (IgAN) is the most common form of primary glomerulonephritis worldwide, particularly in China [1,2]. As IgAN progresses, the glomerular filtration rate gradually declines, and approximately 30% - 40% of patients develop end-stage renal disease (ESRD) within 20 to 30 years after the onset of clinical symptoms, imposing a substantial burden on both individuals and health care systems [3,4].

The hallmark pathological feature of IgAN is the deposition of IgA in the glomerular mesangium, and renal biopsy remains the gold standard for diagnosis. According to the current Oxford classification guidelines [5], the pathological lesions in IgAN include mesangial hypercellularity (M), endocapillary hypercellularity (E), segmental glomerulosclerosis (S), tubular

XSL•FO
RenderX

atrophy/interstitial fibrosis (T), and cellular or fibrocellular crescents (C), that is, MEST-C. Among these, tubular atrophy and interstitial fibrosis (T lesions) are considered key prognostic indicators [6]. The Oxford derivation and North American validation studies, along with the VALIGA study, with a median follow-up of 5.6 years, demonstrated that severe tubular atrophy and interstitial fibrosis were significantly associated with an increased risk of renal function decline or progression to ESRD [7]. Similarly, a multicenter retrospective cohort study from China involving 2047 patients with IgAN confirmed that severe tubular atrophy and interstitial fibrosis markedly elevated the risk of renal function deterioration or ESRD [8]. These findings indicated that severe tubular atrophy and interstitial fibrosis might lead to poor prognosis over long-term follow-up. However, renal biopsy is an invasive procedure that requires technical expertise, is costly, and is poorly accepted by patients, making it difficult to perform repeatedly. These limitations hinder its broad application in the long-term management of chronic kidney disease (CKD).

Predictive models are increasingly recognized as valuable tools for early risk stratification, particularly when renal biopsy is infeasible or repeat biopsy is not practical due to clinical or ethical concerns. Such models can facilitate precision medicine by informing treatment decisions, follow-up scheduling, and lifestyle modifications, thereby improving disease management while reducing unnecessary hospitalizations and health care expenditures. However, existing predictive models [8-10] for tubular atrophy and interstitial fibrosis in IgAN are often limited by small sample sizes, lack of validation, and limited feasibility in clinical practice. Therefore, developing a simple, practical, and reliable model to predict tubular atrophy and interstitial fibrosis in patients with IgAN is of great clinical and social importance.

In this study, we aimed to construct a predictive model for tubular atrophy and interstitial fibrosis in IgAN by integrating multidimensional data from hospitalized patients who underwent renal biopsy at the Department of Nephrology, Tongji Hospital. The model was developed using least absolute shrinkage and selection operator (LASSO) regression and logistic regression, and was internally and externally validated using six different machine learning algorithms.

Methods

Study Population

Participants were recruited from three medical centers located in Wuhan, China, including Tongji Hospital Hankou branch (Qiaokou District), the Tongji Hospital Optics Valley branch (Donghu High-Tech Development Zone), and the Tongji Hospital Sino-French New City branch (Caidian District). Demographic characteristics, lifestyle factors, medical history, and laboratory test results were extracted from the electronic medical record system. Specifically, we retrospectively enrolled 3970 patients who were hospitalized in the Department of Nephrology at the Tongji Hospital Hankou branch between 2004 and 2023 and who underwent renal biopsy during hospitalization. The following exclusion criteria were applied: (1) age ≤18 years (n=98); (2) number of glomeruli <8 in the biopsy specimen (n=32); (3) history of tumor or transplantation (n=103); (4) variables with more than 20% missing values were excluded, that is, 66 variables were included; participants with more than 20% missing data among these 66 variables were further excluded (n=461). Finally, 3276 patients were included as the population for model development. The study design flowchart is presented in Figure S1 in Multimedia Appendix 1. An independent validation sample consisting of 1062 patients was enrolled from the Nephrology Divisions of Tongji Hospital's Sino-French New City and Optics Valley branches, who underwent renal biopsy between 2015 and 2023. Detailed exclusion criteria for the validation population are provided in Figure S2 in Multimedia Appendix 1.

Data Collection

With the support of the Big Data Center of Tongji Hospital, data on demographic characteristics (age, sex, education level, height, and weight), lifestyle factors (smoking and alcohol consumption), medical history (hypertension and diabetes), and laboratory test results (blood and urine tests) were extracted from the electronic medical record system. Educational attainment was categorized as "middle school or below" and "high school or above." The BMI was calculated as weight in kilograms divided by height in meters squared. Within 24 hours of hospital admission, fresh whole blood samples were collected from each patient for routine blood tests and assessments of liver function, renal function, lipid profile, and fasting blood glucose levels. In addition, morning urine and 24-hour urine samples were collected during hospitalization for routine urinalysis and 24-hour urine biochemical tests, including urinary protein and renal function markers. All blood and urine examinations were conducted by trained technicians in the clinical laboratory of Tongji Hospital, following uniform testing protocols. To reduce skewness, natural logarithmic transformation was applied to the following variables: urinary creatinine, urine albumin-to-creatinine ratio, urinary micro total protein, urinary microalbumin, 24-hour urine total microprotein, and 24-hour urine microalbumin.

Renal Biopsy Evaluation

All study participants underwent renal biopsy. Each biopsy specimen was subjected to light microscopy, immunofluorescence staining, and electron microscopy examination. For light microscopy analysis, slides were stained with hematoxylin and eosin, periodic acid–Schiff, Masson's trichrome, and silver staining, following standardized protocols. All renal pathology assessments were performed by experienced renal pathologists and classified according to the Oxford MEST-C scoring system for IgAN. Light microscopic findings of IgA nephropathy range from mild mesangial hypercellularity to diffuse mesangial proliferation, which may be accompanied by segmental sclerosis, glomerular adhesions, and/or crescent formation. Immunofluorescence predominantly showed mesangial staining of IgA. Electron microscopy revealed mesangial deposits along with mesangial matrix expansion (Figure S3 in Multimedia Appendix 1). In the MEST-C score, the T component refers to tubular atrophy and interstitial fibrosis: T0 corresponds to ≤25%, T1 to 26% - 50%, and T2 to >50%. In this study, renal biopsy specimens classified as T0

XSL•FO
RenderX

were defined as mild tubular atrophy/interstitial fibrosis, whereas T1 and T2 were grouped as severe tubular atrophy/interstitial fibrosis (Figure S4 in Multimedia Appendix 1).

Statistical Analysis

Data are presented as median (Q1–Q3) for continuous variables and number (%) for categorical variables. The Shapiro-Wilk test was used to assess the normality of all continuous variables. For variables that followed a normal distribution, between-group differences were assessed using the independent samples *t* test; for non-normally distributed variables, the Mann-Whitney *U* test was employed. Variables showing significant between-group differences were further analyzed using least absolute shrinkage and selection operator (LASSO) regression to identify predictors of severe tubular atrophy/interstitial fibrosis. To address multicollinearity and enhance model stability, variables with a variance inflation factor greater than 5 were excluded. Subsequently, stepwise backward logistic regression was performed on the LASSO-selected candidate predictors to determine independent influencing factor for the severity of tubular atrophy/interstitial fibrosis. Model parameters were estimated, and the prediction model was constructed as follows: Logit (P=β0+Variable1 × β1+Variable2 × β2 +…+VariableX×βX). The effects of the predictors on tubular atrophy/interstitial fibrosis severity were visualized using a forest plot. A nomogram was developed to provide a graphical representation of the IgAN tubular atrophy/interstitial fibrosis prediction model. The predictive performance and calibration of the model were evaluated by receiver operating characteristic (ROC) curves, calibration curves, and decision curve analysis (DCA). To evaluate the overall accuracy of the predictive model, we calculated the Brier score, which measures the mean squared difference between the predicted probabilities and the observed outcomes. In addition, the Youden index was used to determine the optimal cutoff value for classification by maximizing the sum of sensitivity and specificity. For internal validation, the development population was randomly split into training and testing sets at a ratio of 7:3. An external validation cohort consisting of 1062 patients hospitalized at the Sino-French New City and Optics Valley branches of Tongji Hospital between 2015 and 2023, who underwent renal biopsy, was used to validate the model's performance.

During both internal and external validations, five-fold cross-validation was conducted combined with six machine learning algorithms—random forest, generalized linear model, decision tree, gradient boosting decision tree, extreme gradient boosting, and support vector machine. Model performance and discriminative ability were assessed using accuracy, precision, recall, F_1-score, area under the ROC curve (AUC), and precision-recall curves. All statistical analyses were performed using R software (version 4.4.1; R Foundation for Statistical Computing). A two-sided *P* value <.05 was considered statistically significant.

Ethical Considerations

This study was approved by the Ethics Committee of Tongji Hospital (approval number: TJ-IRB202410023), and written informed consent was obtained from all participants. In addition, the patient information included in this study has been deidentified. No compensation was provided to any participants.

Results

A total of 3276 hospitalized patients with biopsy-confirmed IgA nephropathy were included in this study. The characteristics of individuals with mild and severe tubular atrophy/interstitial fibrosis are presented in Table 1. Among the 3276 participants, 2086 (63.7%) had mild tubular atrophy/interstitial fibrosis, whereas 1190 (36.3%) had severe tubular atrophy/interstitial fibrosis. Compared to those with mild tubular atrophy/interstitial fibrosis, individuals with severe tubular atrophy/interstitial fibrosis were older, more likely to be male, had lower educational attainment, and exhibited higher proportions of hypertension, diabetes, smoking, and alcohol consumption, as well as higher BMI (all *P*<.05). In addition, significant differences were observed between the two groups in terms of hematological parameters, liver function, renal function, lipid profiles, and glucose metabolism indicators (all *P*<.05).

[j]eGFR: Estimated glomerular filtration rate.

Univariate analysis revealed that 48 out of 66 analyzed variables showed statistically significant differences between the mild and severe tubular atrophy/interstitial fibrosis groups. These 48 variables were subsequently included in a LASSO regression model to reduce dimensionality and identify potential predictors. The LASSO analysis yielded 35 candidate predictors (Figure S5 in Multimedia Appendix 1). To further reduce multicollinearity and enhance model stability, variables with a variance inflation factor greater than 5 were excluded, resulting in 31 remaining candidate predictors (Figure S6 in Multimedia Appendix 1). Furthermore, these 31 predictors were then subjected to stepwise backward logistic regression analysis. Eight variables were ultimately identified as independent predictors of severe tubular atrophy/interstitial fibrosis: age (OR 1.011; 95% CI 1.002 - 1.020; *P*=.021), hypertension history (OR 1.383; 95% CI 1.144 - 1.672; *P*<.001), education (high school or above; OR 0.739; 95% CI 0.607 - 0.900; *P*=.003), coefficient of variation of red blood cell volume size (red cell distribution width-CV; OR 1.117; 95% CI 1.048 - 1.190; *P*<.001), direct bilirubin (OR 0.859; 95% CI 0.802 - 0.920; *P*<.001), uric acid (OR 1.003; 95% CI 1.002 - 1.004; *P*<.001), estimated glomerular filtration rate (eGFR; OR 0.979; 95% CI 0.976 - 0.982; *P*<.001), and ln(24-hour urine microalbumin) (OR 3.161; 95% CI 2.843 - 3.513; *P*<.001; Figure 1).

Based on these eight independent predictors, a logistic regression model was constructed to predict severe tubular atrophy/interstitial fibrosis. The final model equation was as follows: Logit (P)=0.011×age (years)+0.324×hypertension history –0.302×education+.111×red cell distribution width-CV –0.152×direct bilirubin (μmol/L)+0.003×uric acid (μmol/L) –0.021×eGFR (ml/min/1.73m²)+1.151×ln(24 h urine microalbumin) (mg/24h). In this equation, hypertension history was coded as 0=no, 1=yes; education level was coded as 0=junior high school or below, 1=high school or above. The predicted probability *P* ranges between 0 and 1. To facilitate clinical application, a nomogram was developed based on the final model (Figure 2). The nomogram included a point scale (0 - 100 points), the eight independent predictors, a total score axis (0 - 240 points), a linear predictor axis, and the predicted probability of severe tubular atrophy/interstitial fibrosis. This provided an intuitive and user-friendly visualization of the contribution of each predictor to the risk of severe tubular atrophy/interstitial fibrosis.

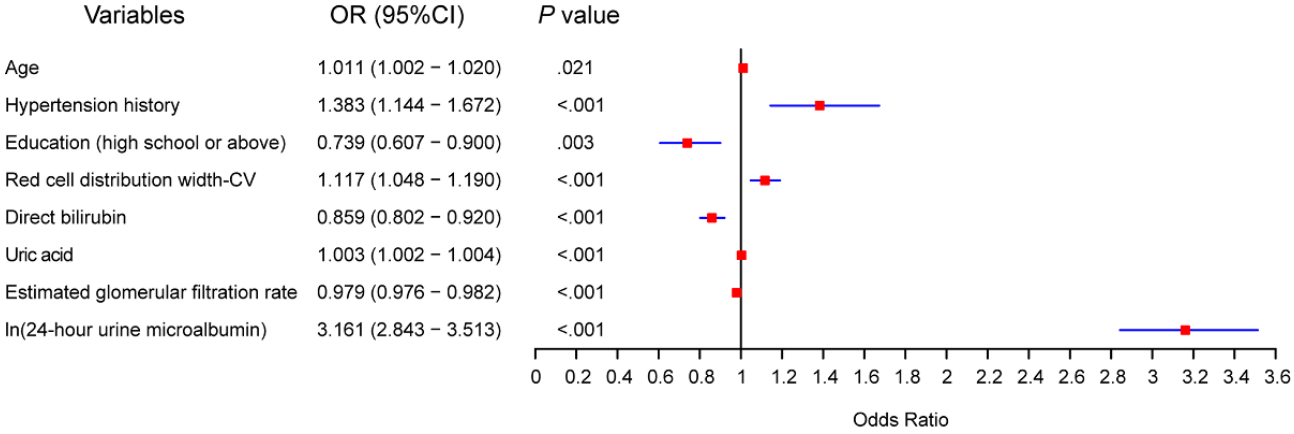
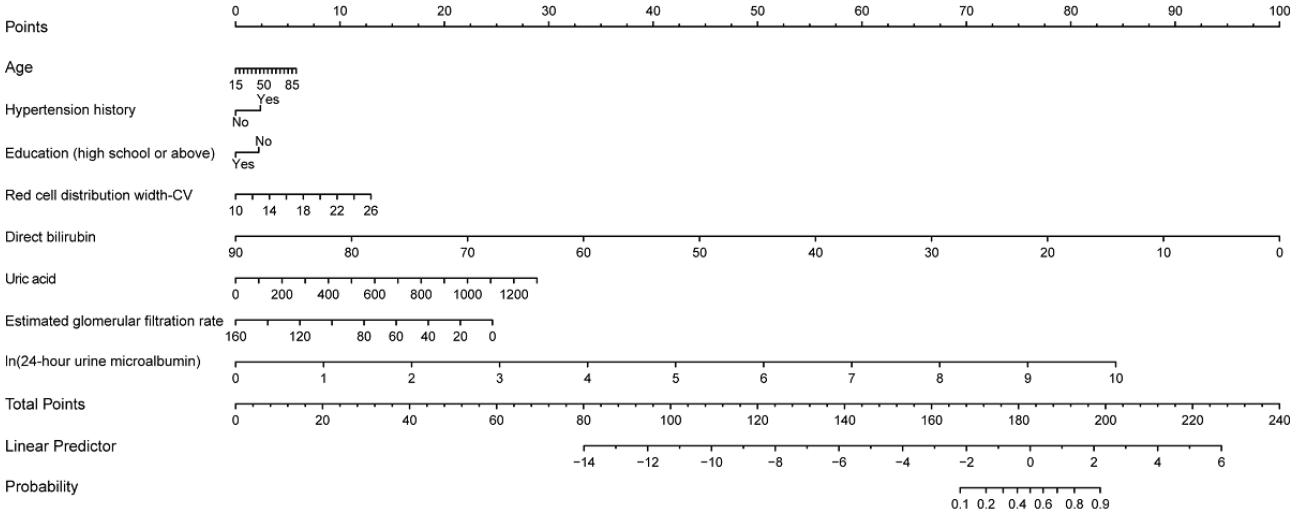
Figure 1. Forest plot of independent predictors for severe tubular atrophy/interstitial fibrosis identified on logistic regression analysis.





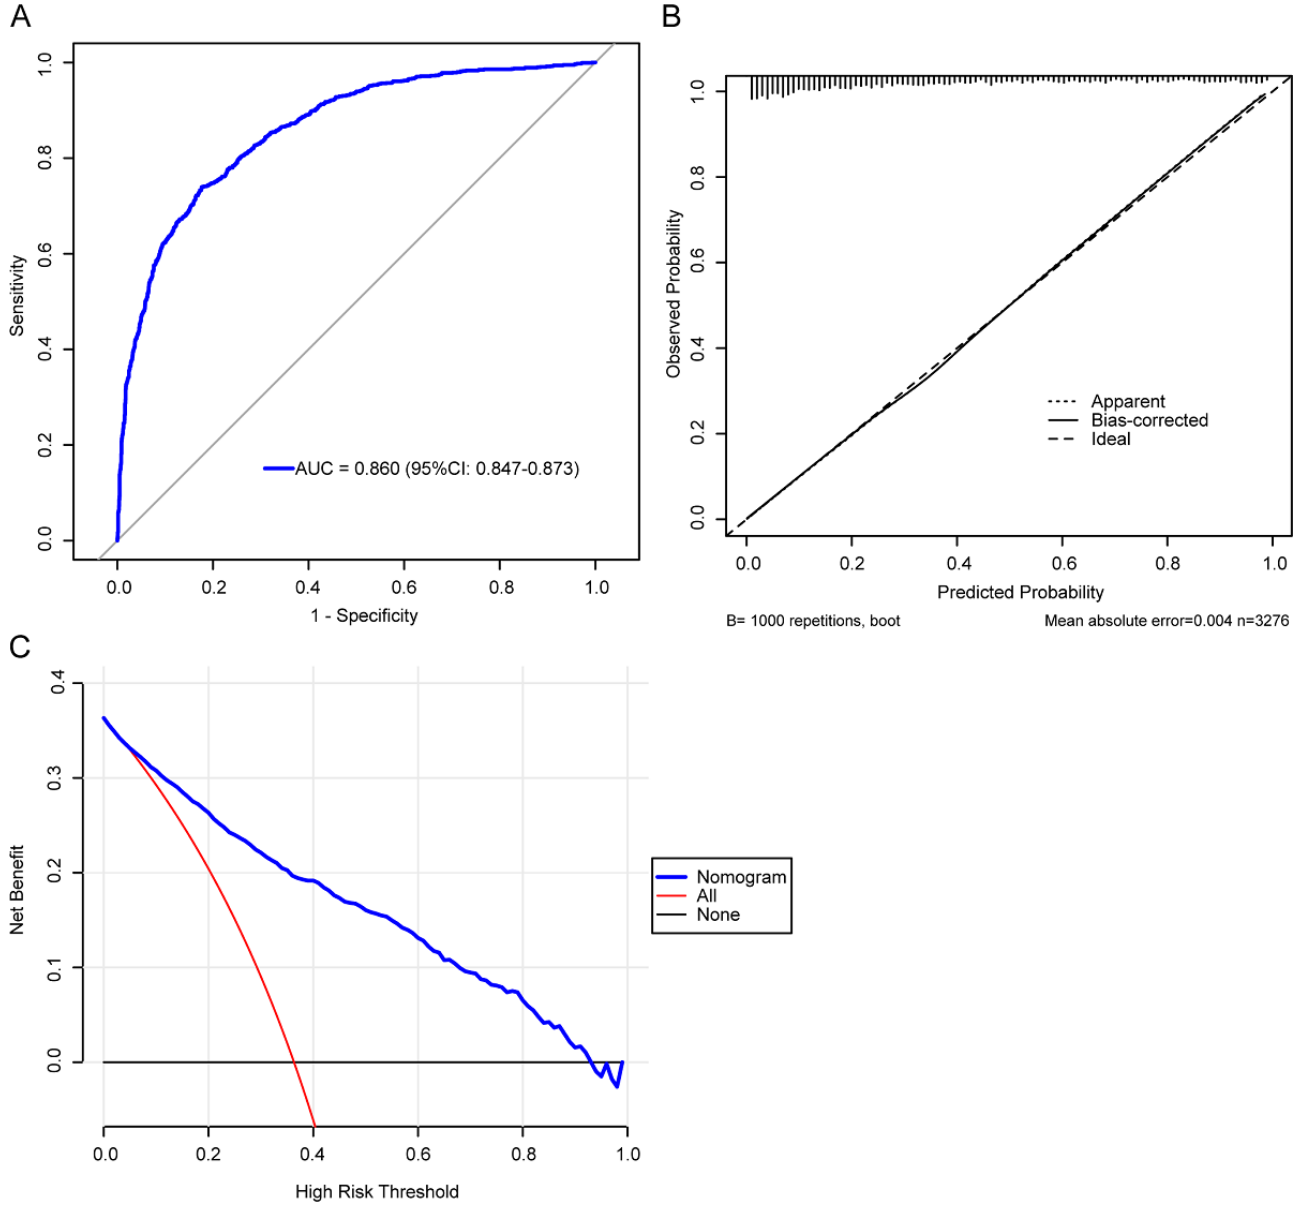


Figure 2. Nomogram for predicting the risk of severe tubular atrophy/interstitial fibrosis.

Model performance was evaluated using ROC, calibration plots, and DCA. The AUC for the logistic model was 0.860 (Figure 3A), indicating excellent discriminative ability. The calibration curve closely followed the diagonal line (y=x), with a mean absolute error of 0.004, suggesting a high agreement between predicted and observed risks (Figure 3B). DCA demonstrated favorable net benefits across a range of threshold probabilities from 0 to 1 (Figure 3C). The optimal cutoff value determined by the Youden index was 0.407, yielding a sensitivity of 73.9% and a specificity of 82.4%. Accordingly, patients with predicted probabilities ≥0.407 were classified as high risk for severe tubular atrophy and interstitial fibrosis. The Brier score was 0.143, indicating good calibration and probability prediction performance of the model. Internal and external validation of the prediction model was further performed using six machine learning algorithms. In internal validation, the AUCs (95% CI) of the ROC curves ranged from 0.793 (0.765 - 0.822) to 0.880 (0.859 - 0.902), while those of the precision-recall curves ranged from 0.748 (0.698 - 0.792) to 0.813 (0.776 - 0.845; Figure 4A and C). In external validation, ROC AUCs (95% CI) ranged from 0.785 (0.756 - 0.814) to 0.862 (0.839 - 0.885) and precision-recall AUCs from 0.655 (0.603 - 0.704) to 0.720 (0.664 - 0.776; Figure 4B and D). As summarized in Table 2, the logistic regression model demonstrated robust classification performance, with consistently high accuracy, precision, F_1-score, and recall across both internal and external validation datasets. All six machine learning models exhibited comparable performances. During internal validation, accuracy ranged from 0.758 to 0.783, with recall values consistently high (0.742 - 0.896). The model with the highest accuracy (0.783) also achieved the best F_1-score (0.747) and recall (0.896). In external validation, the model accuracy ranged from 0.721 to 0.757, and recall remained satisfactory (0.754 - 0.870). The top-performing model yielded an F_1-score of 0.698 and a recall of 0.862, indicating good generalizability. Despite minor variations across models, precision was generally lower than recall in both validation sets, suggesting a trade-off between false positives and sensitivity.

Discussion

Principal Findings and Comparison With Previous Work

This study developed and validated a predictive model for severe tubular atrophy/interstitial fibrosis in hospitalized patients with IgA nephropathy at Tongji Hospital, based on multidimensional clinical data. The model was successfully constructed using 8 independent predictors significantly associated with severe tubular atrophy/interstitial fibrosis: age, hypertension history, education, red cell distribution width-CV, direct bilirubin, uric acid, eGFR, and ln(24-hour urine microalbumin). This model holds substantial clinical value in early diagnosis and screening, clinical decision-making, personalized treatment planning, and pathological monitoring in renal transplant recipients.

In line with previous studies, age and hypertension were identified as independent risk factors for severe tubular atrophy/interstitial fibrosis, highlighting their pivotal roles in CKD progression [11-14]. Advancing age is typically associated with a decline in nephron number, increased glomerulosclerosis, and exacerbated interstitial fibrosis [11,12]. Moreover, age-related inflammatory processes may contribute to irreversible structural kidney damage. Hypertension, a major driver of CKD progression, may promote ischemic injury in renal microvasculature and activate pro-fibrotic pathways, thereby accelerating tubular atrophy/interstitial fibrosis [13,15]. Interestingly, a higher education level (high school or above) was inversely associated with severe tubular atrophy/interstitial fibrosis. Previous cohort and Mendelian randomization studies have demonstrated a causal relationship between lower educational attainment and both increased risk of chronic kidney disease and reduced eGFR [16-18]. These data indicated that higher educational attainment might indeed play a role in preserving kidney function, including structural injury such as tubular atrophy and interstitial fibrosis. It was unlikely that education level directly influences tubular damage or fibrosis. Rather, it might act as a proxy for a range of interconnected downstream factors. Individuals with a higher education might have better health literacy, medication adherence, and proactive engagement with health care systems, enabling the earlier identification and management of modifiable risk factors like hypertension, diabetes, and metabolic syndrome [19]. Furthermore, prior studies have suggested that a low educational attainment might amplify the genetic risk for reduced eGFR [17], offering a potential mechanistic link from a genetic–environmental interaction perspective. Together, these findings support the plausibility that the education level is indirectly associated with tubular atrophy/interstitial fibrosis severity through both environmental and genetic pathways.

In this study, we observed that higher levels of RDW-CV were positively associated with tubular atrophy and interstitial fibrosis. RDW-CV, an index reported in the routine complete blood count test, reflects the variation in red blood cell size and is an established marker of erythrocyte volume heterogeneity. It has been linked to systemic inflammation and oxidative stress

XSL•FO
RenderX

in various chronic diseases [20]. A large population-based cohort study revealed a strong graded association between RDW and C-reactive protein, which remained significant even after adjusting for multiple confounding factors [21]. Chronic inflammation and subsequent oxidative stress are thought to be key mediators linking elevated RDW to kidney injury [22]. In renal tissue, persistent inflammation and oxidative stress can activate NF-κB pathways, promoting fibroblast proliferation and extracellular matrix deposition [23,24]. Direct bilirubin, an endogenous antioxidant, has recently gained attention for its anti-inflammatory and anti-fibrotic properties. Mildly elevated bilirubin levels might confer protective effects against several chronic conditions, including diabetic nephropathy, metabolic syndrome, cardiovascular disease, and cancer [25-28]. For instance, a large cohort study demonstrated an inverse association between plasma bilirubin levels and all-cause mortality [29]. Mechanistically, bilirubin can modulate immune responses by influencing the expression of cell adhesion molecules and complement activity, as well as by inhibiting T cell differentiation [30]. It also suppresses the release of cytokines such as IL-2, IL-6, IL-10, and tumor necrosis factor-α, and reduces the expression of major histocompatibility complex class II in macrophages [25], thereby contributing to its immunomodulatory and anti-inflammatory effects. Additionally, bilirubin could alleviate renal inflammation and fibrosis through suppression of oxidative stress, inhibition of NADPH oxidase, and blockade of the TGF-β signaling pathway [25,31]. The inverse association observed in this study supports its potential nephroprotective role.

Elevated serum uric acid levels were known to exert pro-inflammatory effects and can induce tubular epithelial cell apoptosis and epithelial-to-mesenchymal transition [32,33]. In this study, we observed a positive association between serum uric acid levels and the severity of tubular atrophy and interstitial fibrosis. Consistent with our findings, previous studies have also reported that elevated serum uric acid contributes to the progression of renal dysfunction [34]. Several potential mechanisms might underlie this association. For instance, the accumulation of uric acid has been reported to induce mast cell degranulation and stimulate renin secretion, which subsequently enhances angiotensin II production and contributes to oxidative stress within renal tissue [35]. Animal studies have demonstrated that uric acid promotes interstitial damage and fibrosis through the activation of the NLRP3 inflammasome and ROS signaling pathways [36,37]. Clinically, hyperuricemia has been consistently associated with poor outcomes in IgAN [38]. Furthermore, both eGFR and 24-hour urinary microalbumin are established biomarkers reflecting glomerular and tubular damage [39,40]. Persistent microalbuminuria might indicate impaired tubular reabsorption and increased local inflammation. The predictive value of these markers for tubular atrophy/interstitial fibrosis was further corroborated in this study.

Limitations

Although the study benefits from a relatively large sample size, strong statistical foundations, and clinical relevance, several limitations should be acknowledged. First, data were derived from three medical centers affiliated with Tongji Hospital in Wuhan, and although both internal and external validations were conducted, further validation in multi-center cohorts is necessary to assess the model's generalizability. Second, the cross-sectional nature of the biopsy-based design limits the ability to predict the progression of tubular atrophy/interstitial fibrosis over time. Third, although our model included a comprehensive set of routinely available clinical and laboratory variables, key factors such as diabetes subtype, medication use (such as renin-angiotensin system inhibitors or immunosuppressants), and kidney imaging data were not captured in our dataset. The absence of these variables might have limited the model's predictive accuracy and clinical interpretability. Future studies integrating multicenter cohorts, longitudinal follow-up, and additional biomarkers, medication history, or imaging features are needed to improve the model's external validity and clinical applicability.

Conclusions

In summary, this study developed a concise, accurate, and clinically interpretable predictive model for severe tubular atrophy/interstitial fibrosis in patients with IgA nephropathy, integrating multi-center data and machine learning techniques. This tool offers a non-invasive alternative for risk stratification of patients in whom renal biopsy is contraindicated or impractical, providing valuable support for clinical decision-making and promoting individualized management strategies.

Abstract

Background: Generative artificial intelligence (AI) systems are increasingly deployed in clinical pharmacy; yet, systematic evaluation of their efficacy, limitations, and risks across diverse practice scenarios remains limited.

Objective: This study aims to quantitatively evaluate and compare the performance of 8 mainstream generative AI systems across 4 core clinical pharmacy scenarios—medication consultation, medication education, prescription review, and case analysis with pharmaceutical care—using a multidimensional framework.

Methods: Forty-eight clinically validated questions were selected via stratified sampling from real-world sources (eg, hospital consultations, clinical case banks, and national pharmacist training databases). Three researchers simultaneously tested 8 different generative AI systems (ERNIE Bot, Doubao, Kimi, Qwen, GPT-4o, Gemini-1.5-Pro, Claude-3.5-Sonnet, and DeepSeek-R1) using standardized prompts within a single day (February 20, 2025). A double-blind scoring design was used, with 6 experienced clinical pharmacists (≥5 years experience) evaluating the AI responses across 6 dimensions: accuracy, rigor, applicability, logical coherence, conciseness, and universality, scored 0 - 10 per predefined criteria (eg, −3 for inaccuracy and −2 for incomplete rigor). Statistical analysis used one-way ANOVA with Tukey Honestly Significant Difference (HSD) post hoc testing and intraclass correlation coefficients (ICC) for interrater reliability (2-way random model). Qualitative thematic analysis identified recurrent errors and limitations.

Results: DeepSeek-R1 (DeepSeek) achieved the highest overall performance (mean composite score: medication consultation 9.4, SD 1.0; case analysis 9.3, SD 1.0), significantly outperforming others in complex tasks (P<.05). Critical limitations were observed across models, including high-risk decision errors—75% omitted critical contraindications (eg, ethambutol in optic neuritis) and a lack of localization—90% erroneously recommended macrolides for drug-resistant *Mycoplasma pneumoniae* (China's high-resistance setting), while only DeepSeek-R1 aligned with updated American Academy of Pediatrics (AAP) guidelines for pediatric doxycycline. Complex reasoning deficits: only Claude-3.5-Sonnet detected a gender-diagnosis contradiction (prostatic hyperplasia in female); no model identified diazepam's 7-day prescription limit. Interrater consistency was lowest for conciseness in case analysis (ICC=0.70), reflecting evaluator disagreement on complex outputs. ERNIE Bot (Baidu) consistently underperformed (case analysis: 6.8, SD 1.5; P<.001 vs DeepSeek-R1).

Conclusions: While generative AI shows promise as a pharmacist assistance tool, significant limitations—including high-risk errors (eg, contraindication omissions), inadequate localization, and complex reasoning gaps—preclude autonomous clinical decision-making. Performance stratification highlights DeepSeek-R1's current advantage, but all systems require optimization in dynamic knowledge updating, complex scenario reasoning, and output interpretability. Future deployment must prioritize human oversight (human-AI co-review), ethical safeguards, and continuous evaluation frameworks.

(JMIR Med Inform 2025;13:e76128) doi:10.2196/76128

KEYWORDS

artificial intelligence; DeepSeek-R1; clinical pharmacy; comparative analysis; generative AI

Introduction

With the breakthrough development of generative artificial intelligence (AI) technology, the health care field is experiencing a significant transformation, with AI-driven pharmaceutical practice at the forefront of this evolution [1]. Pharmaceutical intelligence has the potential to transform pharmaceutical practice by addressing the complexity of drug data, evolving health care needs, and technological advancements. Global research indicates that AI demonstrates transregional universality in enhancing the efficiency of drug information

XSL•FO
RenderX

retrieval [2]. Clinical studies indicate that such systems demonstrate significant advantages in efficient drug information retrieval and exhibit a certain degree of accuracy and specificity in predicting drug interactions [3]. However, recent systematic reviews point out that current AI chatbots primarily face challenges of "generating inaccurate or fabricated content" and "lower accuracy in answering questions" [4,5]. This gap between technological potential and practical application [6,7] highlights the urgency of establishing scientific evaluation systems to identify high-quality generative AI systems.

Despite some existing research beginning to conduct clinical application assessments of generative AI dialogue systems, these efforts are largely limited to testing individual models on single tasks [8-10], lacking horizontal comparative analysis across multiple dialogue models and validation of continuous decision chains in real clinical scenarios.

This research innovatively constructs a 6-dimensional evaluation system, conducting systematic assessment and comparative analysis of 4 types of clinical pharmacy practice scenarios: medication consultation, medication education, prescription review, and case analysis with pharmaceutical care. The study sample encompasses 8 representative mainstream dialogue-based AI platforms from both domestic and international origins: ERNIE Bot (version 4.0; Baidu; Release Date: October 17, 2023), Doubao (version: Pro; ByteDance; Release Date: May 15, 2024), Kimi (version: V1.1; Beijing Moonshot Technology Co., Ltd.; Release Date: November 16, 2023), Qwen (version: long; Alibaba Cloud; Release Date: May 21, 2024), GPT (version: 4o; OpenAI; Release Date: May 14, 2024), Gemini (version: 1.5-Pro; Google DeepMind; Release Date: February 14, 2024), Claude (version: 3.5-Sonnet; Anthropic; Release Date: June 21, 202), and DeepSeek (version: R1; Hangzhou DeepSeek Artificial Intelligence Basic Technology Research Co, Ltd; Release Date: January 20, 2025). Through designing parallel tests in realistic clinical settings and using a modified Delphi method for double-blind evaluation, we quantitatively analyzed and descriptively evaluated the capabilities of these 8 generative AI dialogue systems in addressing clinical pharmacy problems across 6 dimensions: accuracy, rigor, applicability, logical coherence, conciseness, and universality. The research findings will provide empirical evidence for optimizing the application of generative AI systems in clinical pharmacy and offer valuable reference for constructing AI-assisted decision-making systems that conform to medical ethics.

Methods

Research Design

We collected 48 common questions from 4 categories of clinical pharmacy work scenarios:

1. Medication consultation questions (n=20) content covered 10 aspects, with 2 questions per aspect: drug indications (efficacy), administration methods, dosage, medication precautions, drug interactions, storage methods, identification and management of adverse drug reactions, special dosage form usage guidance, medication use in special populations, and disease prevention.
2. Medication education questions (n=10) content primarily covered medication use for patients with chronic diseases and special populations.
3. Prescription audit questions (n=10) content encompassed inappropriate treatment regimens, inappropriate usage and dosage, inappropriate combination therapy, inappropriate drug selection, inappropriate administration routes, contraindications, inappropriate treatment duration, and inappropriate clinical diagnosis. The task required assuming the role of a pharmacist to identify prescription errors using relevant pharmacotherapeutic knowledge and the latest clinical guidelines.
4. Case analysis and pharmaceutical care questions (n=8) content included common chronic disease cases such as coronary heart disease, hypertension, type 2 diabetes, asthma, chronic obstructive pulmonary disease, gout, lung cancer, and so on. The task required assuming the role of a pharmacist to analyze pharmacotherapy plans based on patient information (basic information, reason for visit, present illness history, past medical history, medication history, family history, allergy history, adverse reaction history, unhealthy habits, diagnosis, current medication records, and auxiliary examination results), and to develop a pharmaceutical care plan addressing 4 aspects: indications, effectiveness, safety, and adherence.

The study used a standardized experimental design, with 3 researchers using identical "inquiry prompts" to question 8 generative AI dialogue systems during the same time period. All models were tested using their publicly available versions as of February 20, 2025; the results reflect a performance snapshot restricted to this timepoint. Each chatbot received 48 inquiry prompts, generating a total of 384 independent response samples. The evaluation was conducted by 6 clinical pharmacists who had successfully obtained clinical pharmacist training certificates after standardized training and had more than 5 years of clinical pharmacy work experience. The evaluation encompassed six dimensions: (1) accuracy, (2) rigor, (3) applicability, (4) logical coherence, (5) conciseness, and (6) universality. These clinical pharmacists' professional domains covered all disease types relevant to the questions. A double-blind scoring mechanism was implemented for independent evaluation to avoid subjective bias and ensure objectivity and fairness in the assessment process.

Standardized prompting instructions: all questions were input to the model using a standardized format. The core instruction template was to act in the role of a clinical pharmacist. Based on the latest clinical guidelines and evidence-based principles, answer the following question (Specific question description). For prescription review tasks, the following emphasis was added: determine whether this prescription contains errors and provide your rationale. For case analysis and pharmaceutical care tasks, the following emphasis was added: analyze the pharmacotherapy plan for this case and develop a pharmaceutical care plan addressing the following 4 aspects "Indication, Efficacy, Safety, and Adherence." The complete list of all 48 standardized prompting instructions used in this study is provided in Multimedia Appendix 1.

XSL•FO
RenderX

Data Sources

Questions were collected using stratified sampling, drawing from the following sources: common medication inquiries at a medication consultation clinic in a large Grade A Class 3 hospital in China, real clinical cases, the theoretical assessment question banks for standardized clinical pharmacist training programs of the Chinese Medical Association (CMA) and the Chinese Hospital Association (CHA), the China Medication Therapy Management (MTM) pharmacist training program, and the China Pharmacist Skills Competition. Specific steps are as follows:

Question bank construction: questions from the 5 sources above were categorized into 4 scenarios: medication consultation, medication education, prescription review, and case analysis and pharmaceutical care.

Stratified sampling:

- Medication consultation (20 questions): ensured coverage of the 10 aspects mentioned in the Abstract (medication indications, administration methods, dosage, precautions, drug-drug interactions, storage methods, identification and management of adverse drug reactions, guidance on special dosage forms, medication use in special populations, and disease prevention). Two questions were randomly selected from each aspect.
- Medication education (10 questions): randomly selected from 2 subcategories, medication use for patients with chronic disease (6 questions), and medication use for special populations (4 questions).
- Prescription review (10 questions): ensured coverage of the 8 types of inappropriate prescriptions mentioned in the Abstract (inappropriate therapeutic regimen, inappropriate dosage and administration, inappropriate combination therapy, inappropriate drug selection, inappropriate route of administration, presence of contraindications, inappropriate duration of therapy, and inconsistency with clinical diagnosis). Prescription cases containing typical or high-risk errors were prioritized.
- Case analysis and pharmaceutical care (8 questions): 8 representative cases were randomly selected from the question bank covering common chronic diseases (eg, coronary heart disease, hypertension, type 2 diabetes, asthma, chronic obstructive pulmonary disease, gout, and lung cancer).

Question screening: the initially screened questions were independently reviewed by 2 senior clinical pharmacists. This process ensured the questions aligned with the assessment objectives, possessed clinical relevance, were clear and unambiguous, and excluded duplicate or outdated items. Ultimately, 48 questions were finalized for inclusion in the study.

Evaluation Methods

Scoring standards were constructed based on evidence-based medical references, including drug package inserts, the latest clinical guidelines, and the Micromedex database. Clinical pharmacists conducted quantitative assessments of response contents according to standard answers and scoring criteria, with accuracy levels represented on a 0 - to 10-point scale. Unified scoring rules were established, with each question having a maximum score of 10 points, with deductions as follows:

1. Accuracy: 3 points deducted for not directly addressing the question or not providing an accurate answer;
2. Rigor: 2 points deducted for incomplete answers;
3. Applicability: 2 points deducted for failing to provide individualized recommendations based on patient-specific conditions;
4. Logical coherence: 1 point deducted for unclear reasoning or disorganized logic;
5. Conciseness: 1 point deducted for verbose language;
6. Universality: 1 point deducted for overly technical terminology lacking general applicability;
7. Comprehensive answers without deduction criteria: 0 points deducted.

Evaluators were required to select at least one scoring option during the assessment process.

Statistical Analysis

One-way ANOVA was used to compare score differences among the 8 generative AI dialogue systems across 4 task categories (medication consultation, medication education, prescription review, and case analysis with pharmaceutical care). Data satisfied the assumptions of normality through Shapiro–Wilk tests (P>.05) and homogeneity of variance through Levene tests (P>.05), followed by Tukey Honestly Significant Difference (HSD) multiple comparison analysis to identify significant differences. Interrater consistency was calculated using the intraclass correlation coefficient (ICC) through a 2-way random effects model, with ICC>0.75 indicating good consistency.

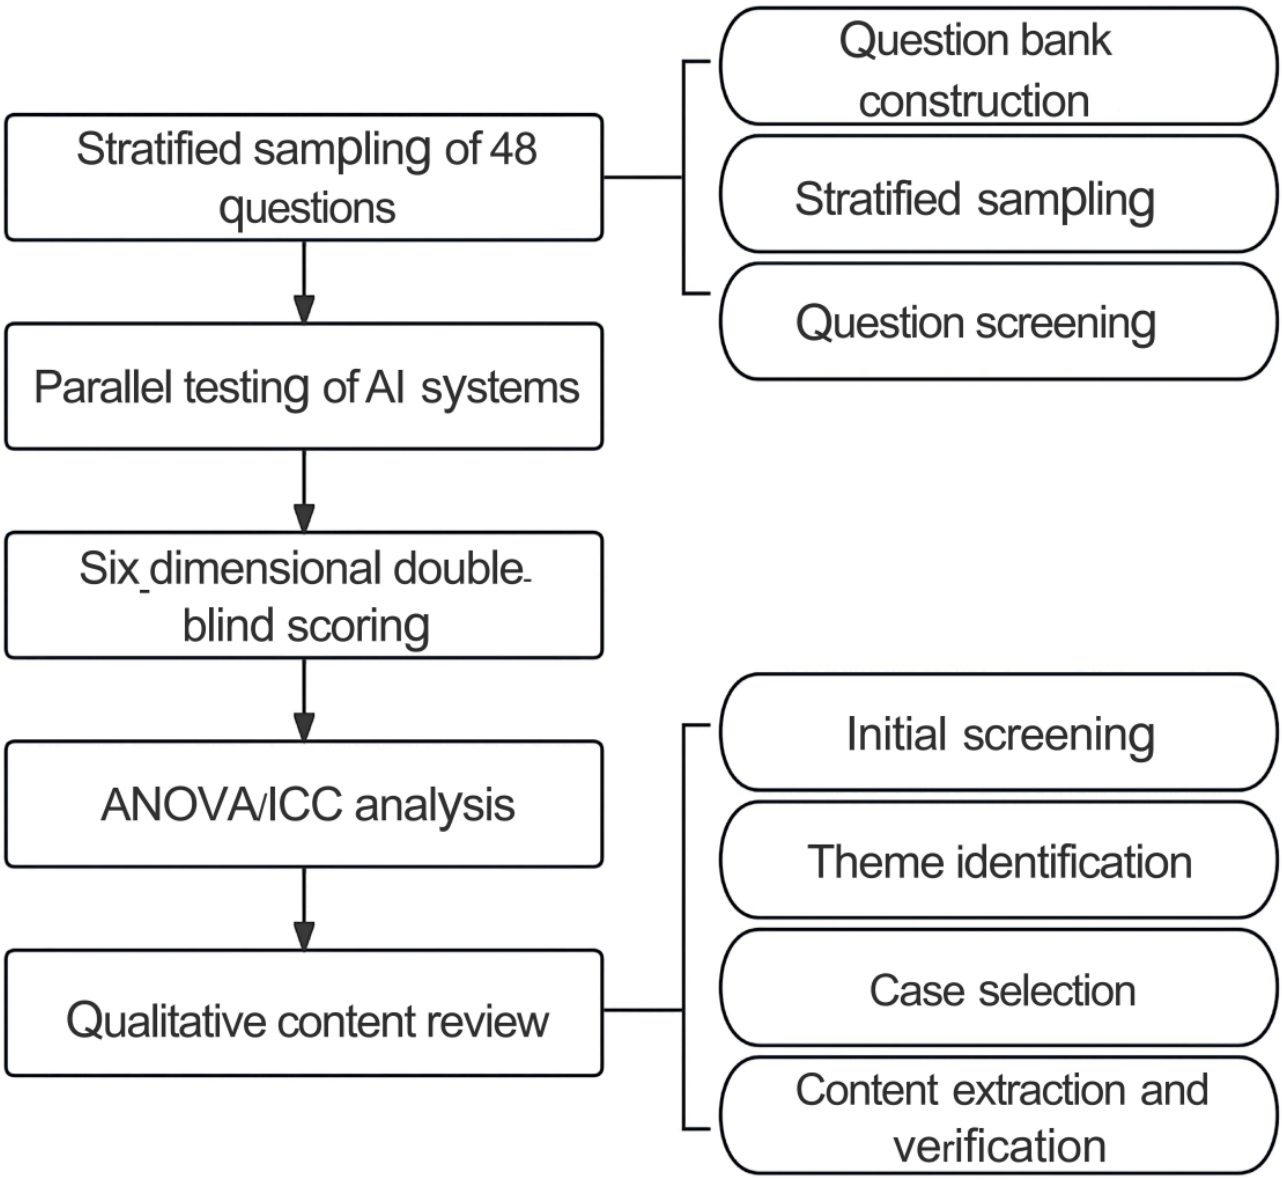
Qualitative Analysis Process

Following quantitative scoring, the research team (3 investigators) conducted a systematic content review of all 384 AI-generated responses to identify recurrent strengths, typical error patterns, critical limitations, and notable variations across models. The review process followed the steps mentioned below.

Initial screening: investigators independently reviewed all responses, documenting exemplar responses that demonstrated exceptional performance or significant deficiencies in accuracy, rigor, applicability, logical coherence, conciseness, or generalizability.

Theme identification: investigators consolidated preliminary observations and identified recurring themes through discussion (eg, “Errors in Special Device Instructions,” “Lack of Localized Medication Recommendations,” “Failure to Identify Critical Contraindications,” “Overly Technical or Jargon-Rich or Verbose Language,” and “Ignoring Conflicting Gender-Specific Diagnostic Criteria”).

Case selection: for each identified theme, representative response examples demonstrating the issue or strength were selected across different models. Priority was given to cases where quantitative assessment revealed performance variations



XSL•FO
RenderX

and where the response content clearly illustrated the qualitative concern.

Content extraction and verification: key content was abstracted from selected cases to ensure descriptions accurately reflected the original response meaning (with critical verbatim excerpts cited where necessary). Final qualitative cases and their analyses were confirmed by consensus within the research team.

These qualitative findings supplement the quantitative results, providing deeper insight into model performance variations and potential risks across different clinical scenarios. They are reported and analyzed in detail in the Discussion section. The methodology flowchart is shown in Figure 1.

Figure 1. Research methodology flow diagram. AI: artificial intelligence; ICC: intraclass correlation coefficient.

Ethical Considerations

This study constitutes a noninterventional evaluation of outputs from publicly accessible generative AI systems. It does not involve direct participation, intervention, or interaction with human participants (patients or healthy volunteers).

According to the policy of the Ethics Committee of Fuwai Central China Cardiovascular Hospital, this type of research (performance evaluation of publicly available AI systems using deidentified question banks and simulated scenarios) is qualified for exemption from formal ethics review application. The study design strictly followed the principles of the Declaration of Helsinki concerning nonbiomedical research.

This study exclusively used rigorously deidentified question texts as input stimuli for the AI systems. It did not involve the use, storage, or analysis of any raw patient data containing personally identifiable information. Therefore, additional informed consent for this secondary analysis was not required.

All question texts input into the AI systems were based on simulated scenarios or deidentified, generic inquiries, containing no real, personally identifiable patient information. The AI-generated output texts produced during the study contained only clinical pharmacy knowledge-related responses and

XSL•FO
RenderX

similarly did not involve any private personal data. All research data (question bank, AI responses, and scoring sheets) were encrypted during storage and transmission and were accessible only to authorized researchers.

The 6 clinical pharmacists participating in the assessment received market-standard honoraria commensurate with their professional contribution.

This study did not use any images containing personally identifiable information (eg, faces, unique physical characteristics, and personal details). All results presentation figures (eg, Figures 1-3) were generated based on aggregated statistical data and anonymized ICC values, posing no risk of individual identity disclosure.

Figure 2. Score distribution and differential analysis of artificial intelligence platforms across 4 pharmaceutical tasks (box plot). (Note: *P<.05: significant difference, **P<.01: highly significant difference, ***P<.001: extremely significant difference, ****P<<.001: most significant difference).

Results

Quantitative Evaluation of 8 Generative AI Dialogue Systems in Clinical Pharmacy Applications

Descriptive Statistics

DeepSeek-R1 demonstrated the strongest comprehensive capabilities, with particularly significant advantages in complex tasks (such as case analysis and pharmaceutical care). Qwen, GPT-4o, Claude-3.5-Sonnet, and Gemini-1.5-Pro performed exceptionally in certain tasks but were overall inferior to DeepSeek-R1. Doubao and Kimi showed inconsistent performance, while ERNIE Bot performed the poorest, indicating a need for targeted optimization. The SDs for scores in case analysis and pharmaceutical care tasks were relatively large, suggesting poorer consistency among clinical pharmacists when evaluating generative AI dialogue systems' performance in handling these complex issues (see Table 1).

Table . Scores of 8 generative artificial intelligence (AI) dialogue systems across 4 problem types.

AI platforms	Medication consultation (n=20), mean (SD)	Medication education (n=10), mean (SD)	Prescription audit (n=10), mean (SD)	Case analysis and pharmaceutical care (n=8), mean (SD)
ERNIE Bot	7.3 (1.2)	8.4 (0.9)	7.3 (1.0)	6.8 (1.5)
Doubao	8.1 (1.1)	8.7 (1.3)	7.6 (1.2)	7.7 (1.7)
Kimi	8.0 (1.0)	9.1 (1.0)	8.5 (1.4)	8.0 (1.6)
Qwen	9.0 (0.8)	9.2 (0.7)	8.9 (0.9)	8.6 (1.2)
GPT-4o	8.6 (1.0)	9.4 (1.1)	8.7 (1.3)	8.2 (1.4)
Gemini-1.5-Pro	8.8 (1.1)	9.1 (1.0)	9.2 (1.1)	8.1 (1.3)
Claude-3.5-Sonnet	9.1 (1.0)	9.4 (0.8)	9.2 (0.9)	8.3 (1.5)
DeepSeek-R1	9.4 (1.0)	9.5 (1.1)	9.4 (0.8)	9.3 (1.0)

Normality and Homogeneity of Variance Tests

Shapiro–Wilk test showed that score data for all problem types conformed to normal distribution (P>.05). Levene test indicated homogeneity of variance for medication consultation (P=.12), medication education (P=.09), prescription review (P=.15), and case analysis (P=.10).

ANOVA

Across all problem types, significant differences were observed in scores among different generative AI dialogue systems (P<.001), with effect size η^2>0.3, indicating statistically significant differences (Table 2).

Table . ANOVA results (one-way, α=.05).

Question type	F (*df*) value	*P* value	η^2 (effect size)	Significance conclusion
Medication consultation	14.3 (7, 44)	<.001	0.36	Significant differences exist
Medication education	12.8 (7, 44)	<.001	0.32	Significant differences exist
Prescription audit	16.5 (7, 44)	<.001	0.40	Significant differences exist
Case analysis and pharmaceutical care	18.1 (7, 44)	<.001	0.43	Significant differences exist

Multiple Comparisons (Tukey HSD)

DeepSeek-R1 demonstrated the best overall performance across all 4 task categories, with particularly significant advantages in prescription review, case analysis, and pharmaceutical care tasks. Qwen and GPT-4o showed similar performance in most tasks with no significant differences. Kimi and Doubao exhibited significant gaps (P<.05) in certain tasks when compared to DeepSeek-R1. ERNIE Bot consistently underperformed, with highly significant differences (P<.001) compared with other models.

Specifically, for medication consultation, DeepSeek-R1 was extremely significantly superior to ERNIE Bot (P<.001). For medication education, most comparison results were not significant, indicating minimal differences among generative AI dialogue systems in this aspect. For prescription review, ERNIE Bot performed the poorest, showing significant (P<.05) or extremely significant (P<.001) differences when compared to all other generative AI dialogue systems. For case analysis and pharmaceutical care, ERNIE Bot remained significantly weaker than most models (eg, very significant difference compared to GPT-4o, P<.01), while DeepSeek-R1 maintained stable performance with significant differences compared to all other models. See Table 3 and Figure 2.

RenderX

Table . Pairwise comparison results of 8 generative artificial intelligence (AI) dialogue systems across 4 question types (Tukey Honestly Significant Difference) only display the groups with significant differences.

Task and comparison of significant difference groups	Mean difference (95% CI)	*P* value
Medication consultation		
ERNIE Bot-Qwen	–1.7 (–2.9 to –0.5)	<.001
ERNIE Bot-GPT-4o	–1.3 (–2.5 to –0.1)	.03
ERNIE Bot- Gemini-1.5-Pro	–1.5 (–2.7 to 0.27)	<.001
ERNIE Bot- Claude-3.5-Sonnet	–1.7 (–2.9 to –0.5)	<.001
ERNIE Bot-DeepSeek-R1	–2.1 (–3.2 to –0.8)	<.001
Doubao-DeepSeek-R1	–1.3 (–2.4 to –0.03)	.04
Kimi-DeepSeek-R1	–1.4 (–2.6 to –0.1)	.01
Prescription audit		
ERNIE Bot- Kimi	–1.3 (–2.5 to –0.1)	.04
ERNIE Bot-Qwen	–1.6 (–2.8 to –0.4)	.002
ERNIE Bot-GPT-4o	–1.4 (–2.6 to –0.19)	.01
ERNIE Bot- Gemini-1.5-Pro	–1.8 (–3.1 to –0.7)	<.001
ERNIE Bot- Claude-3.5-Sonnet	–1.8 (–3.1 to –0.7)	<.001
ERNIE Bot-DeepSeek-R1	–2.1 (–2.3 to 0.09)	<.001
Doubao-Qwen	–1.3 (–2.5 to –0.1)	.02
Doubao- Gemini-1.5-Pro	–1.6 (–2.8 to –0.4)	.001
Doubao - Claude-3.5-Sonnet	–1.6 (–2.8 to –0.4)	.002
Doubao-DeepSeek-R1	–1.9 (–3.1 to –0.68)	<.001
Case analysis and pharmaceutical care		
ERNIE Bot- Kimi	–1.2 (–2.4 to –0.03)	.04
ERNIE Bot-Qwen	–1.8 (–3.0 to –0.6)	<.001
ERNIE Bot- GPT-4o	–1.5 (–2.7 to –0.2)	.007
ERNIE Bot- Gemini-1.5-Pro	–1.3 (–2.5 to –0.13)	.02
ERNIE Bot- Claude-3.5-Sonnet	–1.6 (–2.8 to –0.4)	.003
ERNIE Bot- DeepSeek-R1	–2.6 (–3.8 to –1.4)	<.001
Doubao-DeepSeek-R1	–1.6 (–2.8 to –0.4)	.002
Kimi-DeepSeek-R1	–1.3 (–2.5 to –0.1)	.02
Gemini-1.5-Pro-DeepSeek-R1	–1.2 (–2.4 to –0.02)	.043

Interrater Reliability (ICC Values)

The ICC values for all 6 dimensions in medication consultation, medication education, and prescription review were >0.75, indicating good interrater reliability. Accuracy and logical coherence showed the highest consistency (ICC>0.8), while conciseness in case analysis and pharmaceutical care demonstrated the lowest consistency (ICC=0.70), suggesting considerable disagreement among raters when evaluating generative AI dialogue systems' solutions to complex problems (Table 4). A higher ICC value indicates stronger consistency, while a lower ICC value reflects weaker consistency. The darker red in Figure 3 indicates higher consistency, while deeper blue indicates lower consistency.

Universality	0.82	0.80	0.77	0.74

Discussion

Principal Findings

AI applications in health care demonstrate enormous development potential while facing numerous challenges [11]. This study, through constructing a 6-dimensional evaluation system, systematically compares the application effects and limitations of current mainstream conversational AI platforms, providing important evidence for further optimization of intelligent pharmaceutical systems.

Key Findings

This study systematically evaluated the comprehensive performance of 8 mainstream generative AI systems across 4 core clinical pharmacy scenarios: medication consultation, medication education, prescription review, and case analysis with pharmaceutical care. The principal findings are as follows.

Significant Model Performance Stratification

DeepSeek-R1 demonstrated superior performance across all 4 task categories (composite score: medication consultation 9.4, SD 1.0, case analysis 9.3, SD 1.0), exhibiting particularly pronounced advantages in complex tasks such as case analysis with pharmaceutical care (P<.05).

Second-tier models (Qwen, GPT-4o, Claude-3.5-Sonnet, and Gemini-1.5-Pro) performed well in specific scenarios but consistently underperformed DeepSeek-R1 overall (eg, Gemini-1.5-Pro scored 9.2, SD 1.1 in prescription review vs DeepSeek-R1's 9.4, SD 0.8).

Doubao and Kimi exhibited significant performance variability, while ERNIE Bot consistently lagged significantly across all tasks (eg, case analysis score=6.8, SD 1.5; P<.001 difference vs DeepSeek-R1).

Critical Limitations Exposed

Static knowledge bases and lack of localization: most models failed to adapt to Chinese clinical practices (eg, 90% incorrectly recommended macrolides for drug-resistant *Mycoplasma pneumoniae* infection; only DeepSeek-R1 correctly advised short-term doxycycline based on American Academy of Pediatrics [AAP] guidelines).

High-risk decision blind spots: models frequently overlooked critical contraindications (eg, only 25% recognized ethambutol is contraindicated in optic neuritis) and special regulatory requirements (eg, no model warned about the violation of prescribing diazepam beyond 7 d).

Complex reasoning deficiencies: in case analysis tasks, models struggled to integrate multidimensional information to formulate individualized care plans (eg, only Claude-3.5-Sonnet identified the diagnostic contradiction of "benign prostatic hyperplasia in a female patient").

These limitations highlight 3 major technical bottlenecks: lagging knowledge base updates, insufficient complex decision-making reasoning, and prompt sensitivity risks (section "Technical Bottlenecks and Clinical Challenges" for details).

Rater Consistency Challenge

The "Conciseness" dimension in case analysis tasks exhibited the lowest interrater reliability (ICC=0.70), reflecting inconsistent assessment standards for complex problems.

Therefore, while current generative AI can serve as an auxiliary reference tool for clinical pharmacists, its error rate in high-risk decisions (eg, omission of contraindications) and lack of localization capability preclude its use as an independent basis for clinical decision-making.

Technical Bottlenecks and Clinical Challenges

Knowledge Base Limitations and Lag in Dynamic Update

This study found that all 8 generative AI dialogue systems shared a common deficiency in the areas of medication consultation and medication education: a lack of comprehensive disease assessment capabilities, making it difficult for them to provide personalized medication guidance. For instance, their guidance on the use of special devices was often inaccurate. When queried about the proper use of "Budesonide and Formoterol Inhaler," most systems failed to accurately identify the specific type of device involved. Instead, they incorrectly described the usage instructions for other devices (eg, Salbutamol Aerosol), potentially misleading users.

Regarding the question "Can a 6-year-old child with *Mycoplasma pneumoniae* infection take doxycycline?" only DeepSeek-R1 provided a comprehensive answer incorporating the latest guidelines, "The risk of tooth discoloration from short-term doxycycline therapy (≤21 days) is extremely low, and organizations such as the AAP have relaxed relevant restrictions. Clinicians may consider using doxycycline in the following circumstances: when macrolides are resistant or ineffective; when the child's condition is severe (eg, persistent

XSL•FO
RenderX

high fever and lung consolidation); when no other safe alternative medications are available." Other generative AI dialogue systems still only recommended macrolide antibiotics, which are unsuitable for China's environment, where *Mycoplasma pneumoniae* has high resistance to macrolide antibacterial drugs. This is closely related to training data relying on static knowledge bases and lacking real-time, evidence-based pharmaceutical knowledge updates. DeepSeek, by leveraging publicly available open-source datasets to facilitate continuous learning, can enhance adaptability to evolving medical knowledge and scientific reasoning [12]. Nevertheless, DeepSeek-R1 also demonstrated notable limitations, including overly specialized terminology and a lack of concise expression. Particularly when responding to simple medication inquiries, the answers were excessively complex and lengthy, making it more suitable as a reference tool for health care professionals rather than for general users.

In addition, semantic ambiguity issues in Chinese contexts (as shown in the "prostate hyperplasia" misdiagnosis case) highlight the deficiencies in localized medical knowledge base construction. Furthermore, the international models (GPT-4o, Gemini-1.5-Pro, and Claude-3.5-Sonnet) exhibit biases in their understanding of culturally sensitive issues. For example, when queried about the risks of concomitant use of Chinese herbal injections and Warfarin, these models may overlook the impact of *CYP2C9* gene polymorphisms prevalent in East Asian populations. Addressing such culture-gene interactions necessitates optimization through localized training frameworks. Research indicates an increasingly evident trend of using transformer-based language models in various natural language processing models in the medical field [13], emphasizing the necessity of developing multilevel language training frameworks to adapt to professional medical environments [14].

Deficiencies in Complex Reasoning and Associated Ethical Risks

In prescription review, for a simple case "16-year-old male patient diagnosed with periapical abscess [15], prescribed levofloxacin tablets 0.2 g po bid, metronidazole tablets 0.6 g po tid, chlorhexidine acetate mouthwash 5 ml tid," only ERNIE Bot, Doubao, and Kimi failed to identify that quinolone antibiotics are contraindicated in patients younger than 18 years of age, while the other 5 systems successfully identified this key safety issue.

However, for more complex prescriptions, such as "61-year-old male patient diagnosed with optic neuritis and tuberculous encephalopathy, prescribed: isoniazid 0.3 g qd, pyrazinamide 3 g biw, ethambutol tablets 0.75 g qd, rifampin capsules 0.6 g qd," only Qwen and DeepSeek-R1 accurately identified the critical contraindication that ethambutol could exacerbate visual impairment in patients with optic neuritis.

Notably, for the prescription "40-year-old female patient diagnosed with insomnia, prescribed: diazepam tablets 10 mg po qn for 10 days" none of the 8 generative AI dialogue systems accurately identified the special management requirements for diazepam as a Class II psychotropic medication—that Class II psychotropic medications should not be prescribed for more than 7 days per prescription, and special circumstances require physician documentation. This regulatory requirement has significant importance in clinical pharmacists' routine prescription review work.

Even more concerning, for the prescription "71-year-old female patient diagnosed with hypertension and prostatic hyperplasia, prescribed: amlodipine tablets 5 mg qd, irbesartan and hydrochlorothiazide tablets 150 mg:12.5 mg qd," only Claude-3.5-Sonnet successfully identified the obvious error: the diagnosis was inconsistent with the patient's gender (females do not have prostates and cannot be diagnosed with prostatic hyperplasia). The other 7 generative AI dialogue systems failed to detect this serious error. This indicates that generative AI systems still have serious hallucinations and cognitive limitations in medical reasoning.

In the case analysis and pharmaceutical care aspect, this study required generative AI dialogue systems to assume the role of clinical pharmacists and analyze drug therapy regimens based on patient information including basic demographics, reason for consultation, present illness, past medical history, medication history, family history, allergies, adverse reaction history, unhealthy habits, diagnoses, current medication records, and laboratory examination results. They were also asked to develop a pharmaceutical care plan. These tasks closely simulate the professional work of clinical pharmacists during daily rounds, requiring comprehensive and in-depth analysis and assessment of cases to formulate medication monitoring plans tailored to individual patient characteristics.

The results indicated that all 8 generative AI systems faced significant challenges in executing these complex professional tasks, struggling to simultaneously ensure both accuracy and comprehensiveness in their responses. This reflects the current limitations of AI systems in integrating diverse clinical information and making professional pharmaceutical decisions, particularly in complex clinical scenarios requiring consideration of multiple factors. This relates to AI's lack of clinical contextual reasoning and insufficient understanding of complex instructions.

A recent research review indicates that AI has higher error rates when integrating multimodal data (such as laboratory indicators and imaging results) compared to single-modality tasks [16]. Before resolving these technical bottlenecks, we cannot avoid the issue of accountability for AI-driven decisions [17]. How legal responsibility should be defined when patients experience adverse reactions due to incorrect AI recommendations remains unclear with no explicit regulations currently issued [18]. Therefore, AI dialogue systems should be positioned as "augmented intelligence" tools, establishing "human-machine co-review" mechanisms [19], strengthening human supervision, and ensuring pharmacists retain final decision-making authority over AI outputs. The ethical risks associated with AI identified in this study strongly align with the medical AI regulatory requirements emphasized in the European Union AI Act [20].

Instruction Adherence and Stability Issues

This study used a single, independent query mode for evaluation, where each question was input to the model as an independent conversation. Under this mode, no instances were observed of

XSL•FO
RenderX

the model significantly "forgetting" or ignoring core instructions (eg, "act as a pharmacist," "incorporate the latest clinical guidelines," and "develop a pharmaceutical care plan") within a single response.

However, it is crucial to emphasize that this study did not test the stability of the model's instruction adherence across continuous, multiturn dialogues. In real-world clinical deployment, users may engage in sustained conversations with an AI system involving multiple questions. Existing technical observations report that generative AI carries a risk of instruction drift or context forgetting during extended conversations or multiturn interactions. This could lead to subsequent responses deviating from the initially specified role or requirements, potentially compromising the reliability and safety of the answers.

Therefore, future research should design dedicated testing protocols to evaluate model instruction consistency in multiturn dialogues. Furthermore, exploring methods to enhance stability through prompt engineering optimization (eg, periodic instruction reinforcement) or model fine-tuning is warranted.

Compound Error Risk

While the scoring criteria in this study focused on explicit errors (eg, omission of contraindications), they did not detect potentially hazardous information embedded within otherwise correct responses. For instance, an AI model correctly identified a drug-drug interaction but ambiguously advised to "monitor during use" without explicitly stating the need for immediate discontinuation. In pediatric dosing advice, a model correctly recommended a drug dose but failed to emphasize the necessity of weight-based adjustment. Such errors carry a risk of clinical misinterpretation. Therefore, future research may need to develop algorithms for detecting latent risks, such as real-time validation based on databases like the FDA Adverse Event Reporting System (FAERS).

Application Opportunities and Optimization Pathways

Personalized Medication Decision Support

The DeepSeek-R1 model demonstrated good guideline adherence in pediatric doxycycline medication recommendations (incorporating the latest AAP recommendations), highlighting the potential application of AI in personalized medication decision support [21]. Relevant research confirms that AI can help formulate interventions under the guidance of predictive models by forecasting individual responses to treatment and monitoring patient progression, thereby modifying individualized treatment plans [22]. However, it should be noted that AI still lags significantly behind human experts in providing individualized treatment plans. For instance, Marcaccini et al [23] discovered that while AI-driven models demonstrate strong diagnostic accuracy and readability, further refinements are needed to improve treatment specificity and personalization. Looking forward, constructing an "AI pharmaceutical knowledge graph" [24] that correlates individual metabolic characteristics (such as CYP450 enzyme phenotypes) with pharmacokinetic data could provide dynamic dosing optimization strategies based on the latest evidence-based evidence for clinical practice.

Process Automation and Resource Optimization

Compared to clinical pharmacists, generative AI dialogue systems possess powerful information retrieval, data integration, and conversation capabilities [25]. Natural language processing technology can automatically extract and analyze data from large volumes of electronic medical records [26], which will greatly reduce manual time consumption, and the application of this technology is expected to significantly reduce the burden on clinical pharmacists in routine documentation such as medication history records. By communicating with users through verbal or nonverbal means, simulated pharmacist assistants have achieved improved medication adherence by providing medication education to older patients with diabetes [27], all of which enables more optimized resource allocation.

Medical Education and Skills Training

Generative AI dialogue systems provide new tools for clinical educational interventions and medical practice [28], bringing new dimensions of personalized learning, enhanced visualization, and simulation-based clinical training to the forefront [29]. In addition, AI-driven simulations offer realistic immersive training opportunities that prepare students for complex clinical situations and cultivate the interprofessional collaboration skills essential for modern health care [30].

Comparison With Previous Work

This study engages in significant dialogue with and extends existing literature in terms of both methodology and findings.

Deepened Evaluation Framework

Compared to the 3-dimensional evaluation frameworks proposed by other researchers, this study innovatively constructs a "six-dimensional evaluation system," providing a more comprehensive capture of AI efficacy in pharmaceutical practice. Unlike single-model studies [8-10], this work presents the first cross-model comparison of 8 mainstream AI systems, revealing significant performance stratification (eg, DeepSeek-R1 significantly outperformed GPT-4o in Case Analysis tasks, $P<.05$).

Validation and Extension of Key Limitations

This study confirms the warning highlighted in the literature [15]. AI error rates remain high in complex medication decision-making (eg, a contraindication omission rate of 75% in Prescription Review tasks). Furthermore, semantic ambiguities unique to the Chinese context (eg, the gender contradiction in "benign prostatic hyperplasia") resulted in higher error rates compared with monolingual settings, underscoring the urgency for cross-lingual training frameworks.

Coverage of Innovative Scenarios

In contrast to studies [3] limited to information retrieval, this research systematically validates, for the first time, AI performance across a continuous clinical decision-making chain (eg, from prescription review to pharmaceutical care plan development). This reveals deficiencies in multimodal data integration and contextual reasoning (resulting in higher error rates compared to single-task evaluations).

XSL•FO
RenderX

Incremental Contribution of This Study

Through its systematic evaluation across multiple models, diverse scenarios, and 6 dimensions, this study provides an empirical foundation for the localized adaptation pathways (eg, dynamic knowledge graph updating) and ethical deployment boundaries (eg, a "human-AI co-review" mechanism) of generative AI in clinical pharmacy. These findings call for the establishment of cross-lingual training frameworks and continuous evaluation systems.

Limitations and Future Directions

Scope of Evaluated Scenarios

While this study focused on 4 core scenarios in clinical pharmacy practice, it did not comprehensively cover all potential application domains, such as pharmacovigilance signal mining, pharmacoeconomic evaluation, and public health emergency scenarios. Future studies should expand the scope of evaluation, for instance, by designing emergency medication test sets to assess model reliability under limited evidence.

Sample Size and Complexity

Although 48 questions were included, the number of Case Analysis and Pharmaceutical Care tasks was relatively low (only 8 questions). Furthermore, the complexity of the questions may still be insufficient to fully reflect the models' capability to handle extremely complex, rare, or multisystem real-world cases. Future research should increase sample size, incorporate more diverse and higher-complexity real-world cases, and consider supplementing data using Standardized Patient Data or synthetic data generation techniques.

Prompt Sensitivity

Generative AI systems exhibited significant sensitivity to the wording and structure of input prompts (Prompt Sensitivity). Minor variations in question phrasing (eg, adjusting keyword order, adding or removing qualifiers) could lead to divergent responses. While this study mitigated this variability through standardized instruction templates, it did not systematically quantify the impact of this sensitivity on the results. In addition, the 3 international models (GPT-4o, Gemini-1.5-Pro, and Claude-3.5-Sonnet) may have limited comprehension of Chinese medical terminology. Future research could use joint embedding models to reduce semantic bias or use adversarial prompt testing to evaluate model robustness and optimize instruction design.

Model Dynamic Updates

AI models undergo rapid iteration and updates (eg, Gemini 1.5 Pro updates monthly). This study reflects the performance of specific model versions at a fixed point in time (February 20, 2025), and findings may change with subsequent model updates. There is an urgent need to establish continuous, dynamic evaluation frameworks and benchmarks to track the evolution of model performance.

Insufficient Visualization of Results

This study recorded and summarized the total scores for each model across the 4 task types. However, it did not calculate the average scores for each model across the 6 evaluation dimensions (spanning all 4 task types). Consequently, it cannot intuitively display each model's relative strengths and weaknesses across dimensions or facilitate cross-model performance comparisons by dimension (eg, using radar charts). Future evaluations should incorporate these metrics.

Lack of Real-World Impact Assessment

The study evaluated model output quality in a controlled environment but did not assess the actual impact on pharmacist workflow efficiency, decision-making quality, or patient outcomes in real-world clinical settings. Future research should conduct prospective implementation studies or randomized controlled trials.

Conclusions

This study conducted a systematic evaluation and comparative analysis of the application efficacy of 8 mainstream domestic and international generative AI systems across 4 core clinical pharmacy practice scenarios by constructing a 6-dimensional evaluation system. The results demonstrate that DeepSeek-R1 outperformed other models in overall performance, exhibiting particularly significant advantages in handling complex case analysis and pharmaceutical care tasks. However, all models exhibited limitations, prominently manifested in lagging knowledge base updates (eg, incorrect instructions for special devices and lack of localized recommendations), insufficient complex decision-making reasoning capabilities (eg, failure to identify critical medication contraindications and special regulatory requirements), sensitivity to prompt instructions, and overly technical terminology in outputs. Interrater reliability analysis revealed substantial disagreement in evaluating the conciseness dimension for complex tasks such as case analysis.

Based on these findings, this study concludes that while current generative AI systems demonstrate significant potential for efficiency gains and value as decision-support tools in clinical pharmacy, their responses still contain non-negligible errors and limitations, particularly at high-risk decision points. Therefore, at this stage, they should be strictly positioned as auxiliary reference tools for clinical pharmacists, not as independent bases for clinical decision-making. Future development should focus on overcoming key bottlenecks, including achieving dynamic knowledge updating and localization adaptation, enhancing reasoning capabilities in complex scenarios, improving prompt robustness and output interpretability, and establishing continuous evaluation mechanisms. Ultimately, safe, reliable, and patient-centered intelligent pharmaceutical care systems should be built through interdisciplinary collaboration integrating evidence-based medicine, ethical norms, and technological innovation.

Abstract

Background: The heart and kidneys have vital functions in the human body that reciprocally influence each other physiologically. Pathological changes in 1 organ can damage the other. Epidemiologic studies show that greater than 50% of patients with heart failure (HF) have preserved ejection fraction (HFpEF). Additionally, 1 in 6 patients identified as having chronic kidney disease (CKD) also has HF. Thus, it is important to be able to predict and identify the cardiorenal relationship between HFpEF and CKD.

Objective: Creating an electrocardiogram (ECG)-enabled model that stratifies suspected patients with HFpEF would help identify CKD-enriched HFpEF clusters and phenogroups. Simultaneously, a minimal set of significant ECG features derived from the stratification model would aid precision medicine and practical diagnoses due to being more accessible and widely readable than a large set of clinical inputs. Furthermore, the validation of the existing cardiorenal relationship using this ECG-enabled model may lead to better biological understanding.

Methods: Using unsupervised clustering on all extractable ECG features from FinnGen, patients with an indication of HFpEF (filtered by left ventricular ejection fraction [LVEF] values ≥50% and N-terminal pro B-type natriuretic peptide [NT-proBNP] values >450 pg/mL) were categorized into different phenogroups and analyzed for CKD risk. After isolating significant predictive ECG features, unsupervised clustering and risk analysis were performed again to demonstrate the efficacy of using a minimal set of features for phenogrouping. These clusters were then compared to clusters formed using dynamic time warping (DTW) on raw ECG time series electrical signals. Afterward, these clusters were analyzed for CKD enrichment.

Results: The PR interval and QRS duration stood out as significant features and were used as the minimal feature set. After generating and comparing clusters (k-means with all extracted ECG features, k-means with a minimal feature set, and DTW with full lead II ECG waveform), the DTW-generated clusters were most stable. ANOVA analysis also showed that several HFpEF clusters exhibited a deviation of CKD risk from baseline, allowing for further trajectory analysis. Specifically, the creatinine levels (a proxy for CKD) of several DTW-created clusters showed significant differences from the average. Based on the Jaccard score, the DTW clusters also showed the greatest alignment to baseline comparison clusters created by clustering on creatinine. In comparison, the other 2 sets of clusters (created by all extracted ECG features and the minimal set) performed similarly.

Conclusions: This project validates both the known cardiorenal relationship between HFpEF and CKD and the importance of the PR interval and QRS duration. After exploring the use of ECG data for patient clustering and stratification, DTW clustering with lead II waveforms resulted in the most clinically meaningful clusters in the context of HFpEF and CKD. This methodology may prove useful in exploring ECG clustering applications outside of HFpEF as well.

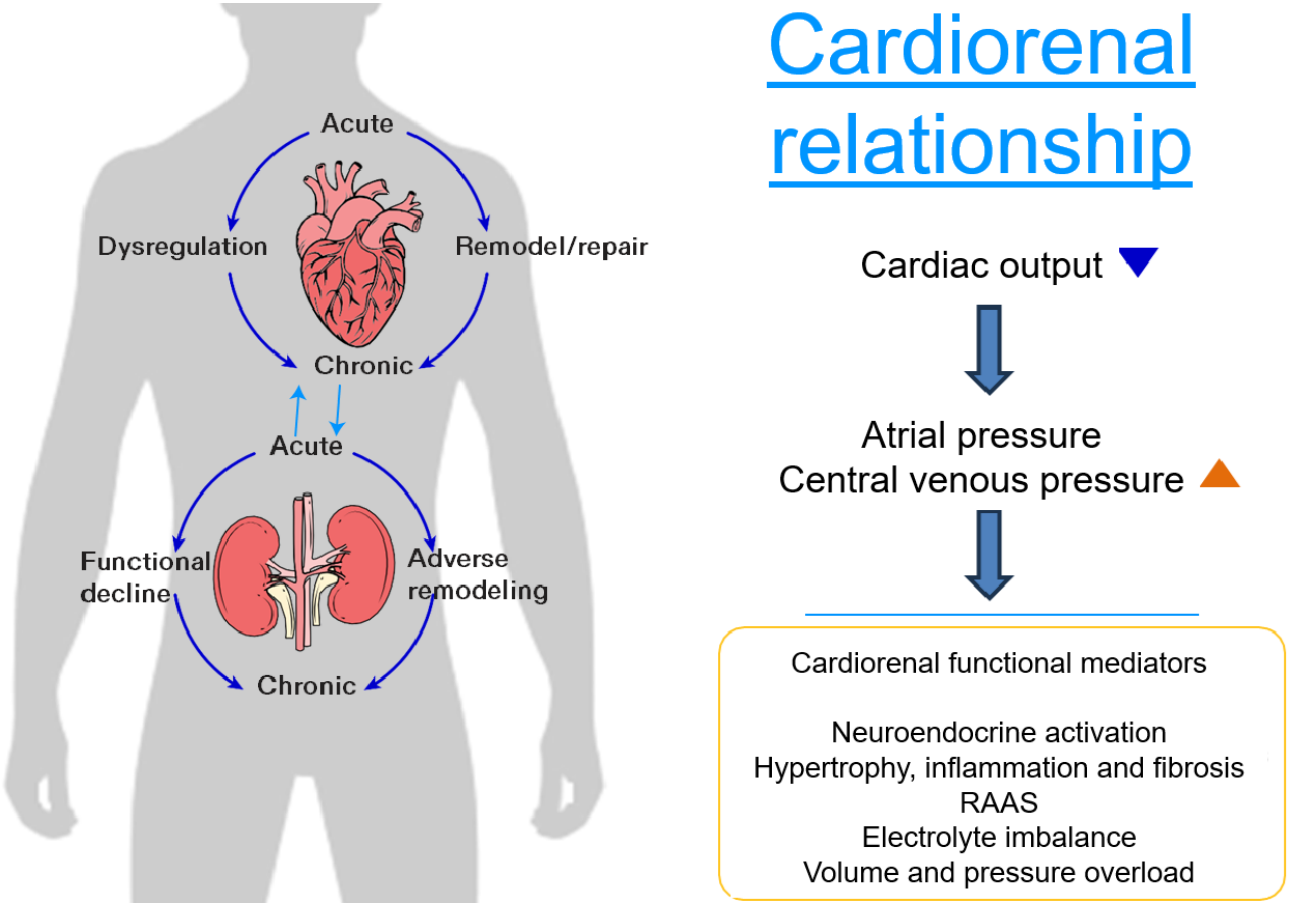
Introduction



Background

This paper examines the relationship between a specific subtype of heart failure (HF), heart failure with preserved ejection fraction (HFpEF), and chronic kidney disease (CKD) marked by progressive renal failure [1-3], emphasizing the pathophysiological connections. It explores the potential use of technology in trials and clinical management by leveraging simple and widely accessible clinical tools such as electrocardiograms (ECGs) to predict the underlying risk in subgroups and to enable earlier and more precise interventions. Such interventions can improve patient outcomes for chronic diseases of cardiovascular or overlapping renal origin [4-6].

Biological Rationale

HF and renal failure are 2 interrelated conditions that often coexist, significantly impacting patient outcomes [7-9]. The intricate and bidirectional relationship between the heart and kidneys illustrated in Figure 1, often referred to as the cardiorenal axis, underscores the significant unmet need to understand how dysfunction in 1 organ can precipitate or exacerbate dysfunction in the other, so that patients at risk for progression can be precisely diagnosed for earlier intervention before full onset of disease, thus improving the odds of better patient outcome [10].

Figure 1. Illustration of the cardiorenal relationship and functional mediators.

HF, which is marked by the heart's inability to pump blood effectively, initiates a series of physiological changes that can negatively impact renal function. Reduced cardiac output in HF leads to decreased renal perfusion, triggering compensatory mechanisms such as the activation of the renin-angiotensin-aldosterone system and sympathetic nervous system [11,12].

Although these mechanisms initially aim to preserve renal function and maintain blood pressure, their chronic activation can produce adverse effects, including increased sodium and water retention, further worsening heart failure symptoms and contributing to renal impairment [13,14]. HFpEF is characterized by the heart's inability to relax (diastolic defect) and fill properly, leading to heart failure symptoms despite a normal ejection fraction (systolic function).

Conversely, renal failure can significantly affect cardiac function. The kidneys regulate fluid and electrolyte balance, blood pressure, and the elimination of metabolic waste products. When renal function declines, fluid overload, electrolyte imbalances, and the accumulation of uremic toxins can occur, adding strain on the heart. This may lead to worsening HF, creating a cycle of deteriorating cardiac and renal function. This bidirectional nature of the heart-kidney interaction underscores the complexity of managing patients with both HF and renal failure. The ability to better predict risk in these vulnerable cohorts would be beneficial for disease understanding and clinical trial recruitment.

ECG for Clustering

Recent advancements in artificial intelligence and machine learning have shown potential in predicting and managing the risks associated with cardiorenal syndrome. Artificial intelligence–enabled models, for example, using ECG and biomarkers, have demonstrated promise in clinical care settings [15,16].

An additional use of such an ECG model in drug development could be to identify patients with HFpEF who may demonstrate a potential risk profile for worsening kidney function based on a screening ECG. Such patients may demonstrate other comorbidities such as hypertension, diabetes, or obesity, as stated earlier. This underlying and hidden risk can be revealed early for an improved understanding of the associated risks with renally cleared cardiovascular drugs. The cardiac-specific electric signals provide significant discriminatory power for endophenotyping within the broader HFpEF spectrum [17]. By leveraging machine learning-based unsupervised cluster analysis, this study aims to phenomap patients with HFpEF, enhancing the understanding and prediction of cardiorenal risk through a generalizable and interpretable ECG-based machine learning model.

Evaluating the importance of ECG features for unsupervised clustering can be difficult. A lot of tabular health care data, including the extracted ECG features, are highly correlated, which may lead to poor clustering results in practice. This also makes feature selection through Lasso very difficult. Reducing dimensionality often makes interpretability difficult as well, which is especially an issue for health care research. Thus, finding an unsupervised method that clusters high-dimensional correlated data through feature selection rather than dimension reduction would be very helpful [18].

Dynamic Time Warping With ECG

Dynamic time warping (DTW) measures the similarity between 2 temporal sequences and, thus, can be used as a metric for clustering temporal sequences. By creating a nonlinear alignment of time sequences that are of different lengths or exhibit time shift, it can calculate the Euclidean distance between points of the 2 warped sequences. DTW has been frequently used for longitudinal and trajectory analysis, including in health care settings [19]. Due to the temporal nature of ECGs, DTW has been used to classify ECG frames and has been shown to be effective in finding nonlinear clusters of ECGs [20]. Previous literature and studies for DTW ECG clustering use the lead II recording wavelengths due to the lead II wavelength being generally considered the best view of the electrical signals because of the electrode's placement [19].

ECGs are particularly appropriate for this combination of DTW-supported unsupervised clustering and feature analysis. First, the assumption that patients themselves, rather than the extracted ECG values, are independent and identically distributed is much easier to meet. This may make unsupervised clustering results more promising than on extracted ECG data (which would be correlated tabular data). By treating each ECG record as a singular data point, we can perform DTW on the ECG as a time series. DTW is a technique that calculates the optimal match between given sequences (it can be thought of as clustering curves via distance rather than individual data points). This way, different clusters of ECG records can be formed and then analyzed for disease endpoint incidence, cluster stability, and other performance metrics.

Many studies focus on the relationship between HFpEF and electrocardiographic (ECG) features, but our work attempts to explore the cross-organ interactions between the heart and kidney in HFpEF by using an algorithm that uses specific features within ECG features as novel predictors of cardiorenal risk. Small changes in the electroconductance system of the heart can have a big impact on the hemodynamic load on the heart, exacerbating the load, and over time, affecting volume overload [10] on the kidneys. However, such small changes in ECG, which may appear early, may not always be clinically apparent and can often be missed. In patients with HFpEF, clinical phenotype can be associated with diabetes, hypertension, and obesity [21]. Using an ECG model to identify nonobvious patterns in the electrical signals of the heart captured through a standard ECG (12 leads) can serve as indicators for left ventricular dysfunction associated with HFpEF and can potentially also identify potential signals for renal risk in a subset of patients. This study seeks to validate the established cardiorenal relationship through ECG data analysis and investigate a novel approach for clustering in HFpEF subgroups using ECG data.

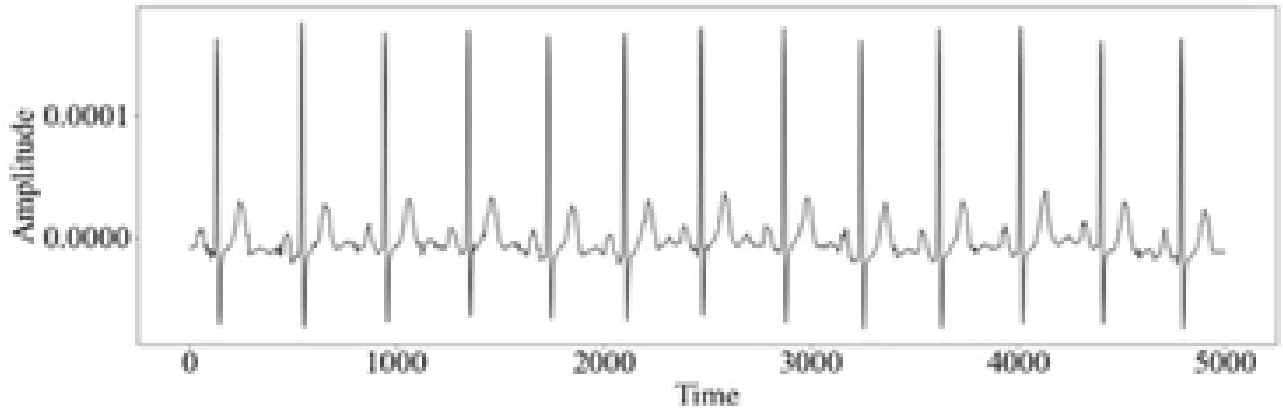
Methods

Ethical Considerations

The real-world electronic health data used from the FinnGen database, provided for analysis, were already anonymized by FinnGen. The ethics status, data collection process, consent process, and approvals can be seen in the original study [22]. This study's data analysis was approved by the FinnGen Committee. Due to this, there was no need to seek further ethics board approval.

Dataset Description

The FinnGen study is a large-scale genomics initiative that has analyzed over 500,000 Finnish biobank samples and correlated genetic variation with health data to understand disease mechanisms and predispositions. The project is a collaboration between research organizations and biobanks within Finland and international industry partners [22]. This public-private partnership aggregates data from 9 different Finnish biobanks, research institutes, university hospitals, and 13 international pharmaceutical partners along with the Finnish Biobank Cooperative. Sample collection and data releases began in 2017, and the main phase of sample collection ended with FinnGen2 in 2023.



The Expansion Area 3 (EA3) studies aim to collect data on diseases that may not be present within existing FinnGen registries. Among these data is the EA3 Heart Failure Study cohort, which compiles relevant cardiovascular data from 4 - 6 participating hospital biobanks. The study contains ECG files, ejection fraction values (40,809 individuals), and laboratory measurements (40,024 individuals) with B-type natriuretic

XSL•FO
RenderX

peptide (BNP), proBNP, and creatinine values. Since the study is aggregated from several different existing biobanks, not all individuals have the same laboratory measurements. This project used the EA3 Heart Failure study, individuals with ECG, ejection fraction, and laboratories with creatinine and proBNP values all present.

The methods for extracting relevant features are changing and evolving over time [23], but the idea remains the same. The ECG follows a characteristic PQRST wave that occurs in a periodic pattern. Each peak, trough, or section of this wave represents electrical signals of the heart and can be evaluated for further meaning. Clinicians can look at the ECG visually for meaning, but signal processing techniques can also retrieve the mathematical values from the waves themselves. Since there are multiple electrodes for measuring the ECG, this is usually taken from lead II signals (Figure 2) [24] or aggregated.

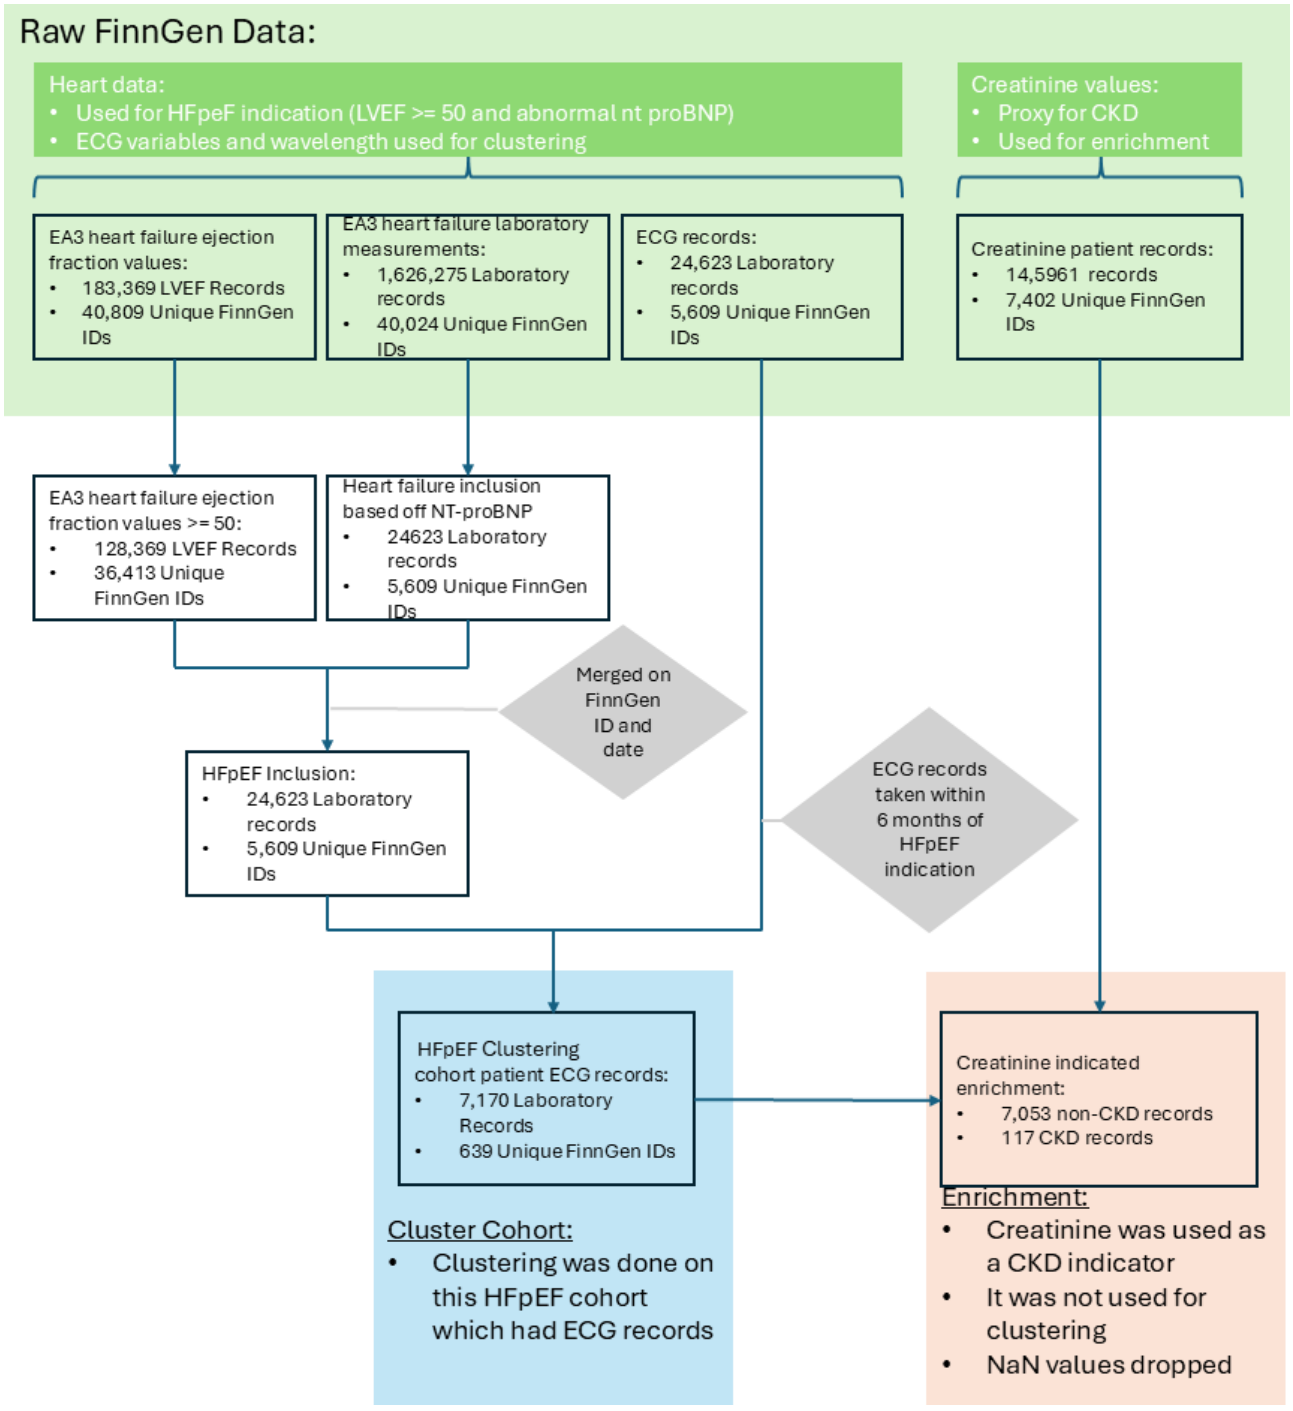
Figure 2. A sample lead II ECG wave. ECG: electrocardiogram.

Data Preprocessing

The dataset was restricted to the population with HFpEF (Table 1). This was determined by selecting individuals with ejection fraction values greater than or equal to 50 and exhibiting HF at that time (Figure 3). All selected individuals were verified to have HF diagnoses (either I9 HF or I9 HF NS). Only ECGs recorded within a 6-month period of the heart failure diagnosis or laboratory indicative of HF were used in this study. Creatinine values were used as a proxy for the presence of CKD. The EA3 HF Cohort contained 1,626,275 laboratory records for 40,024 unique individuals. Among these, there were 7170 complete ECGs (extracted ECG values and raw ECG signals) and creatinine laboratory records for 3864 unique individuals with HFpEF (Figure 3). The raw lead II ECG signals each contained 5000 points of data and were taken from individual ECG files within the EA3 HF cohort. These signals were directly input into the DTW algorithm. It was these ECG and laboratory records that were used for clustering and analysis (Figure 4). Specifically, the data groups to be clustered included extracted ECG values, a minimal set of extracted ECG values, and raw lead II signals.

Clusters created through hierarchical clustering on creatinine served as a baseline for CKD risk, against which the ECG-enabled clusters were compared. This comparison aimed to evaluate the effectiveness of ECG-enabled clusters in stratifying patients with CKD risk within the context of HFpEF.

Table . A characteristics average table to give a better understanding of the clustering cohort. This cohort is comprised of individuals who have characteristics that indicate HFpEF (LVEF≥50% and NT-proBNP>450 pg/mL).



Clustering cohort baseline characteristics	Values
Age (years), mean (SD)	71.16 (11.32)
Women, n (%)	3478 (48.5)
BMI (kg/m^2), %	28.4
NT-proBNP (pg/mL)	2018.1
LVEF[a] (%)	60.25
Creatinine (µmol/L)	103.02
Height (cm)	170.3
Weight (kg)	82.7
Current smoker, n (%)	882 (12.3)
Chronic kidney disease, n (%)	115 (1.6)

[a]LVEF: left ventricular ejection fraction.

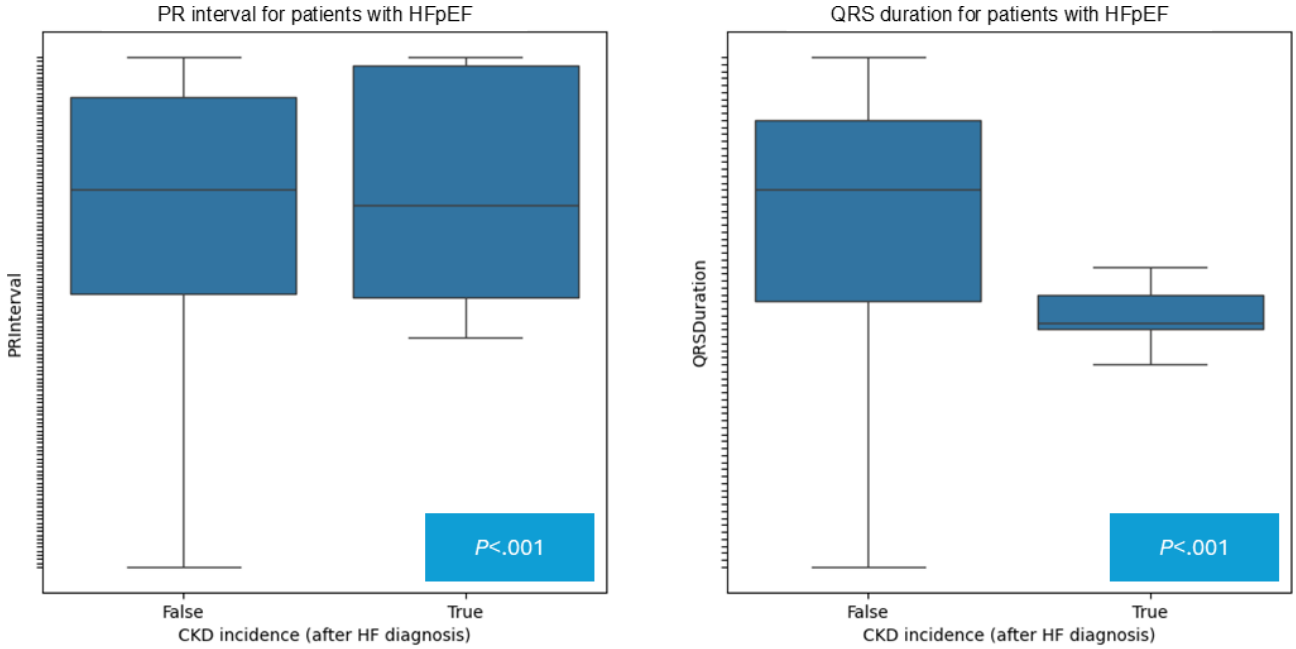
Figure 4. An illustration of the methodology workflow. FinnGen ECG and laboratory records are used to create different sets of clusters: Creatinine clusters (hierarchical clusters based off creatinine labs to be used as a baseline indication for CKD), ECG feature clusters (clusters created using all extracted ECG features), PR-QRS clusters (clusters created using top variables determined to be significant in predicting CKD in HFpEF), and DTW clusters (clusters created using DTW on the raw ECG time series). For each set of clusters, 5 groups were formed. CKD: chronic kidney disease; DTW: dynamic time warping; ECG: electrocardiogram; HFpEF: heart failure with preserved ejection fraction.



Statistical Analysis

Univariate analysis was first performed for exploratory purposes. Distributions and averages of the extracted ECG values (ie, ventricular rate, PR interval, QRS duration, QT corrected, P axis, R axis, T axis, QRS count, Q onset, Q offset, P onset, P offset, T offset, atrial rate, and QT interval) were calculated. A 1-tailed *t* test was conducted for all extracted ECG variables to determine if there was a significant difference between patients with non-CKD and CKD HFpEF ECG values. It was shown that all extracted features were indeed significantly different with a significance level of .05 (Figure 5). Survival analysis was also conducted using a Cox proportional hazard model and a Kaplan-Meier curve.

XSL•FO
RenderX

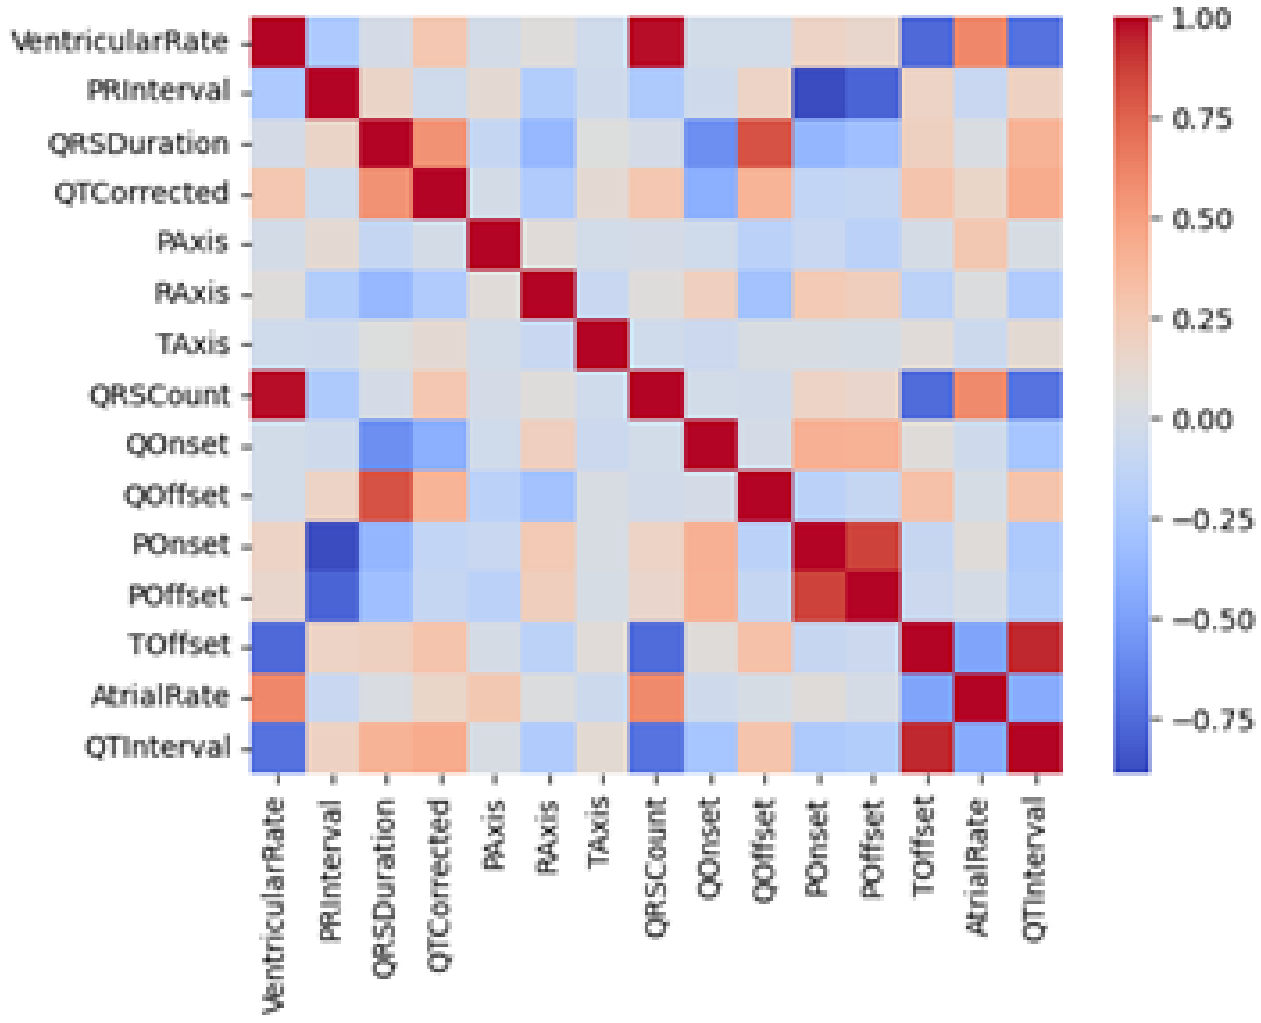


Figure 5. Distribution of significant extracted ECG values (QRS Duration and PR Interval) between patients who are CKD-positive and CKD-negative. CKD: chronic kidney disease; ECG: electrocardiogram; HF: heart failure; HFpEF: heart failure with preserved ejection fraction.

Multivariate analysis of the extracted features was also conducted. It must be noted that the method may not be wholly accurate because the correlation between the extracted features is derived from the ECG waveform itself and can have some overlap (Figure 6). It must be noted that the method may not be wholly accurate because of the correlation between the extracted features. Additionally, these features lose some information in terms of the time component. However, it provides good exploratory insight into which combination of features would perform well for both CKD prediction and patient phenotyping.

XSL•FO
RenderX

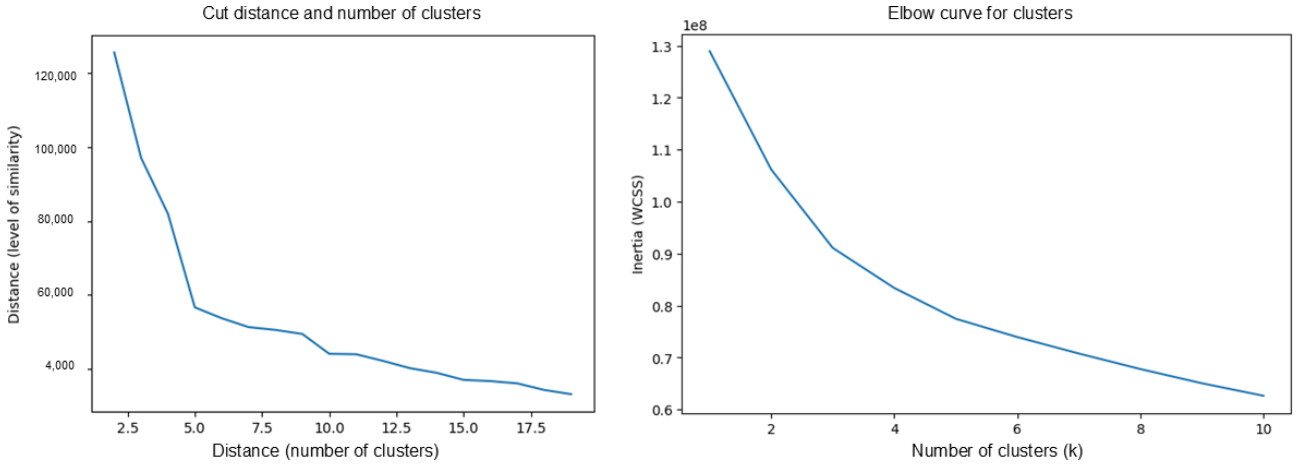

Figure 6. A heatmap showing the correlation between extracted ECG features. ECG: electrocardiogram.

Determining the Number of Clusters

To determine the number of clusters created, elbow curves (Figure 7) were created and analyzed to determine which number of clusters would be optimal. As both elbow charts exhibit diminishing returns at around the 5-cluster mark, it was determined that 5 clusters would be generated and compared.

Figure 7. Elbow curves for extracted feature and DTW hierarchical clustering. This was used to determine the optimal number of clusters (t=5). The number of clusters was determined using these elbow charts and by seeing where the reduction in inertia or cut threshold has diminishing returns. DTW: dynamic time warping. WCSS: within-cluster sum of squares.

XSL•FO
RenderX

Extracted Feature Clustering

Several methods were used, including principal component analysis (PCA), significance, and Lasso feature selection. Relevant hyperparameters (eg, α for Lasso dropout) were tuned iteratively to find the top 5 (5 is predefined) features. For PCA, 50 simulations were run for stability and robustness purposes. In every simulation, the FinnGen data were randomly sampled (training=0.8, 80% from all data) and PCA was conducted on this random sample to select the top 5 ranked features. The top 5 features in order are: ventricular rate, PR interval, QRS duration, QT corrected, and P axis. As for Lasso regression, the top features were QRS duration, QT interval, R axis, QT corrected, and PR interval. In terms of significance, the top features were ventricular rate, PR interval, QRS duration, QT corrected, and P axis, with the average explained variance reported in Table 2 on the top features identified from multiple methods. From this exploration, we can see that the PR interval and QRS duration were always selected as top features.

Table . A table ranking component (electrocardiogram variable) importance by average explained variance. PR interval and QRS duration are among the top 3 extracted variables. Ventricular rate was not chosen because it was not selected among the top 5 features during Lasso regression.

PCA[a] component	ECG[b] variable	Average explained variance
0	Ventricular rate	0.276
1	PR interval	0.251
2	QRS duration	0.156
3	QT corrected	0.122
4	P axis	0.091

[a]PCA: principal component analysis.

[b]ECG: electrocardiogram.

However, despite bootstrapping for stability and generalizability, the clusters formed from PR interval and QRS duration had low stability and consensus, despite performing better than clustering on all features. This is probably due to the correlated nature of the extracted ECG features. Thus, hierarchical clustering using DTW distance calculations was also performed to consider the correlation.

DTW Clustering

The ECG lead II data were split into a training, validation, and test sets, each with 500 different unique individuals. Every patient's lead II data included 5000 signals. These were then clustered using hierarchical clustering with the Ward method. The Ward method was chosen because it is close in functionality to k-means, which makes it intuitive and interpretable. However, it also performs better than k-means on uncovering clusters of uneven size and irregular non-spherical clusters. Exploratory analysis has shown the clusters to be uneven and not guaranteed to be regular, which makes the Ward method a good fit.

DTW was used to determine the similarity between two time series. In this case, the time series would be the lead II ECG signals. This was done by calculating the Euclidean distance between each point after finding the best alignment of the 2 sequences (Figure 8). In order to find the best alignment or shift, the distance between pairs of points is compared, and the minimum distance is taken. This is done for the entirety of the 2 sequences. After creating a matrix representation for the costs associated with each alignment, the algorithm returns the minimum cost—that is, the minimum distance between aligned time series. For the regular ECGs, little shift was needed to occur. No normalization techniques were applied to the ECG lead II records. For faster processing speeds, the code was parallelized using the Python (Python Software Foundation) multiprocessing module.

Afterward, creatinine values were associated with every ECG, and the average creatinine value was calculated for every cluster. The average creatinine value of the population with HFpEF was 101.51 umol/l. Additionally, all clusters were validated through bootstrapping the data. Multiple subsets of 500 were created and clustered. This was performed to measure the stability and generalizability of the various clusters. Since the k-means and hierarchical algorithms are not consistent and exact in their results every time, this was necessary to ensure that the observed clusters (and their associated creatinine values) remained stable.

        for j from 1 to m:
            cost = absolute difference between ts1[i-1]
                and ts2[j-1]
            dtw_matrix[i][j] = cost + minimum of (
                dtw_matrix[i-1][j], dtw_matrix[i][j-1],
                dtw_matrix[i-1][j-1])

    return dtw_matrix[n][m]
```

Creatinine Clusters

Since all clusters were created in an unsupervised manner, there was no true baseline to compare the cluster labels to. Thus, the 5 clusters formed by hierarchical clustering on the creatinine laboratory values were created as a stand-in. Being a waste product from muscle and protein breakdown, creatinine levels can serve as an estimation of kidney function and a metric for CKD. Thus, comparing the extracted ECG value and DTW-formed clusters to these creatinine-based clusters can demonstrate the former's capabilities in demonstrating creatinine enrichment and, subsequently, CKD enrichment.

Cluster stability was measured using the silhouette score [25], co-cluster occurrence (Jaccard score), and Rand index [26]. For the hierarchical clustering on the DTW-determined distance, the Jaccard index was determined to be a more relevant metric than the silhouette score. Compared to naively clustering on extracted features, the clusters were shown to be more stable.

Average features were calculated for every ECG cluster. ANOVA (Table 3) was conducted to determine any significant extracted feature difference between the clusters.

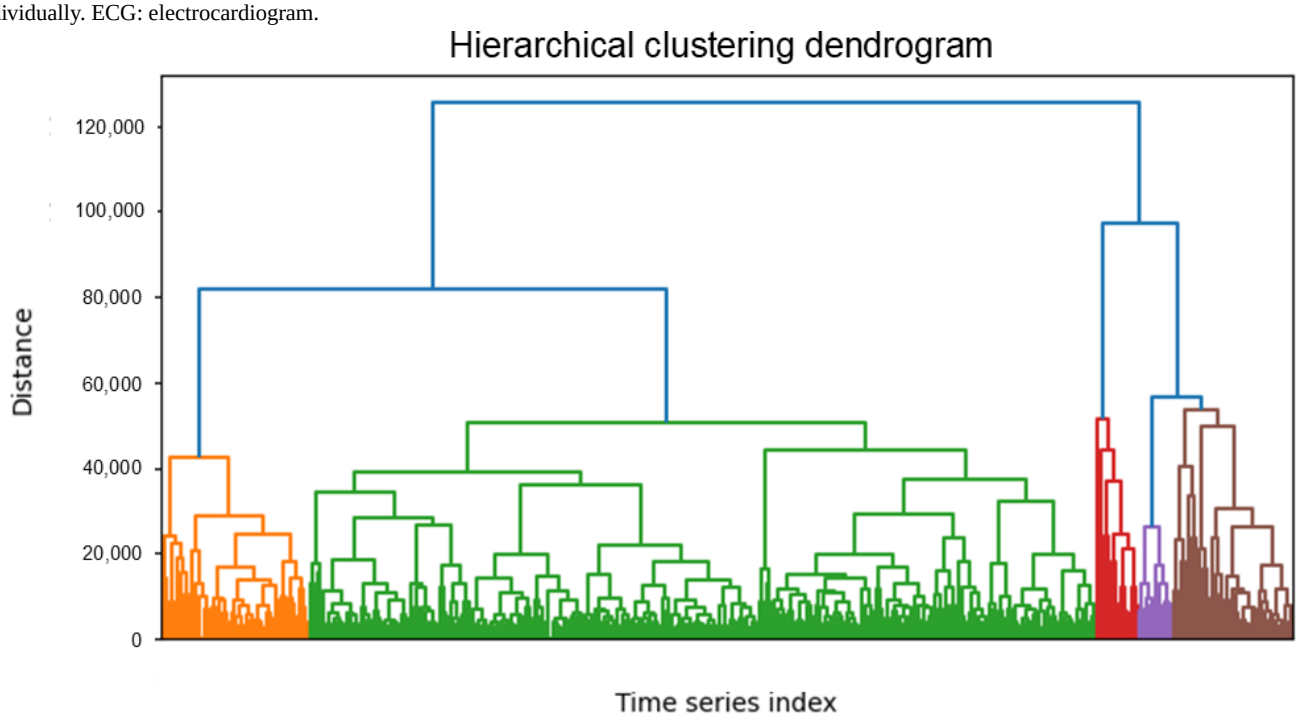
Results

Clustering on Extracted ECG Features



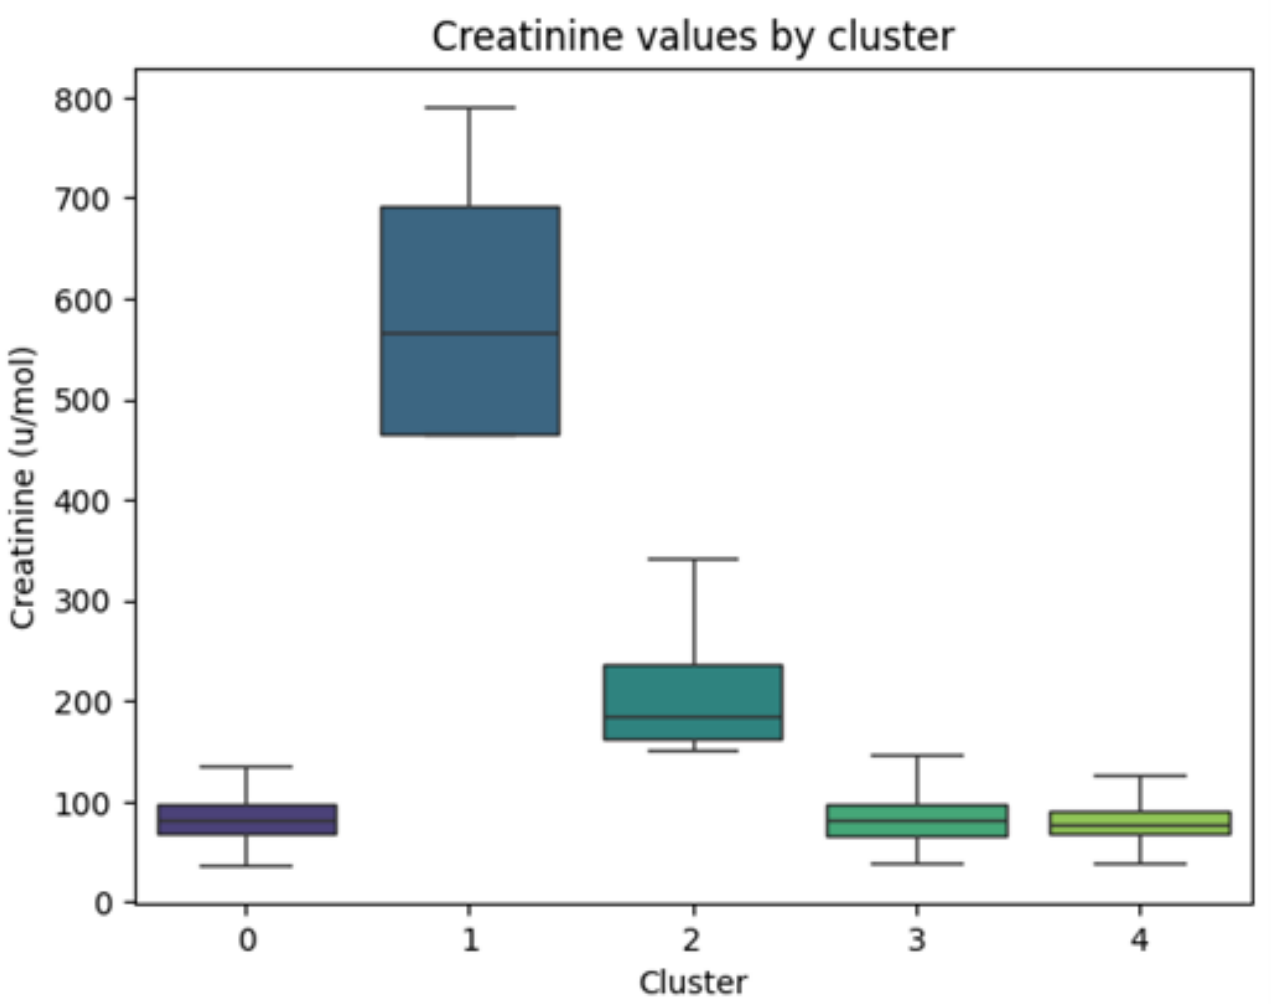
The top 2 features determined are QRS duration and PR interval. Both of these features were unique among the top 5 ranked features in every method used (significance, Lasso, and PCA).

Although there is a difference between CKD incidence when clustering on all available ECG features compared to clustering on the significant ECG features (PR interval and QRS duration), the difference may be too small to be clinically significant.

Clustering With DTW

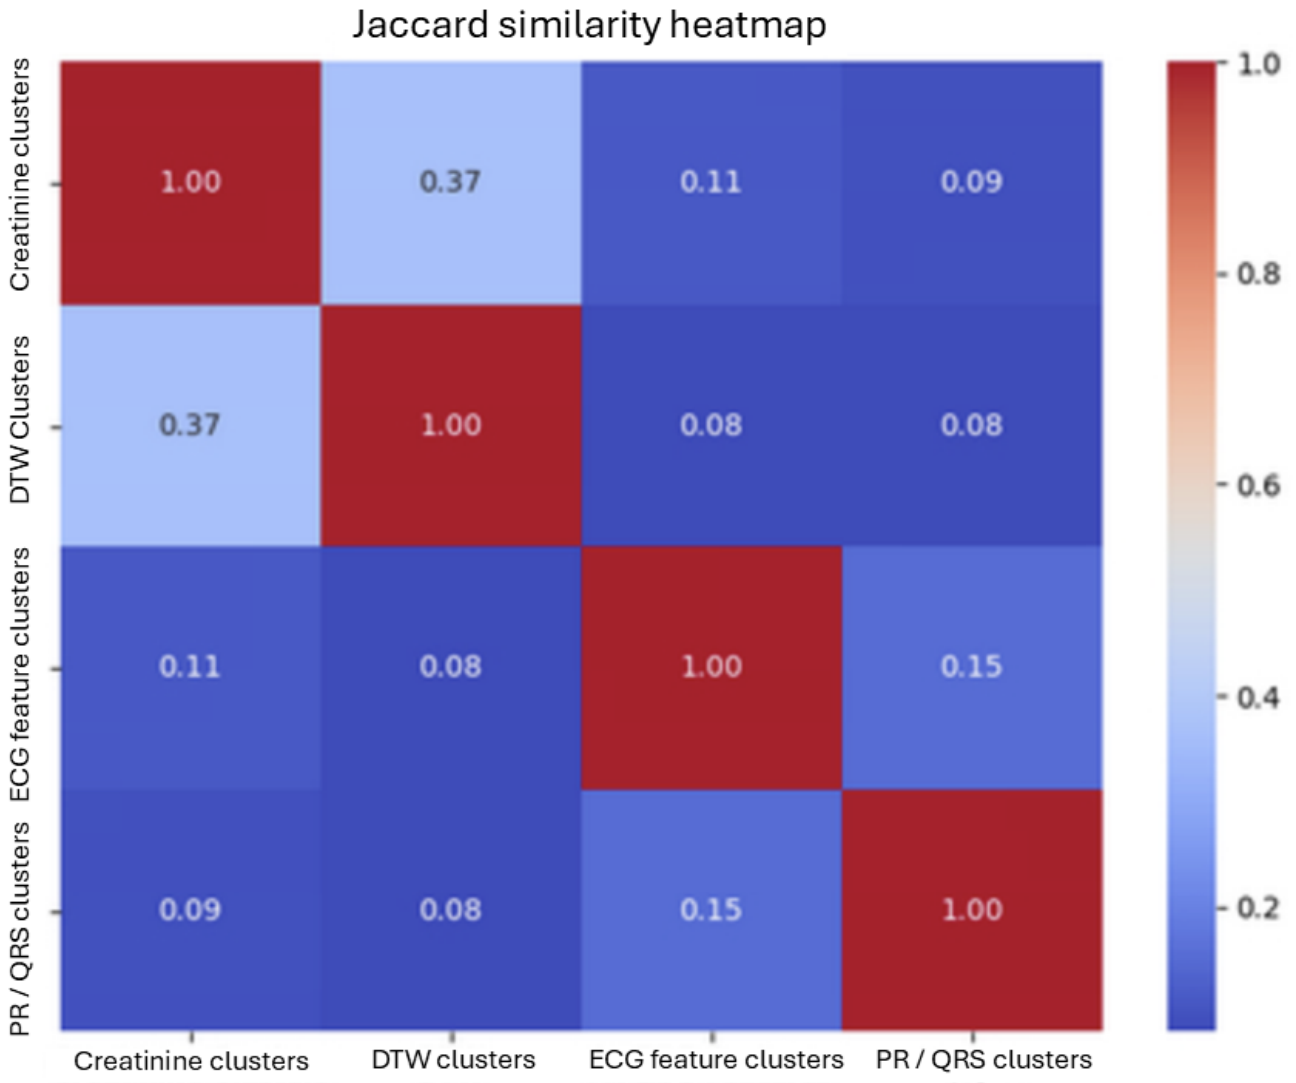
Regardless of how many clusters the parameter is set for with hierarchical clustering, clustering with DTW consistently yielded approximately 5 groups (Figure 9). This phenomenon could be seen in both the testing and validation sets, and also when bootstrapping.

Figure 9. Hierarchical clustering on the validation set. It can be seen that approximately 5 clusters form which match up to the number of clusters estimated using the elbow method on the extracted ECG values. Due to the number of time series that were clustered, there were too many labels to list individually. ECG: electrocardiogram.



XSL•FO
RenderX

Figure 10 shows that there were creatinine differences among DTW clusters. Additionally, all extracted ECG features with the exception of P axis, T axis, and PR interval were shown to be statistically significant from cluster to cluster (Table 3). This indicates that the clusters did measurably separate the ECG time series, not just by time series shape but also by the relevant values or sections that would be extracted from the series.



Based on the Jaccard Score, the DTW-created clusters are most similar to the creatinine-based clusters (Figure 11). This indicates that it is a better stand-in for CKD enrichment than clustering solely on ECG extracted features.

Figure 10. Creatinine value distribution among the 5 clusters identified in dynamic time warping clusters.

Discussion

Principal Findings

From the results, the PR interval and QRS duration are shown to be the extracted ECG variables most associated with CKD in the HFpEF cohort. This follows the biological rationale as the PR interval and QRS complex are 2 important features of an ECG signal that capture both time and spatial dynamics of a cardiac cycle. Each aspect of the selected ECG features can provide valuable information about the heart's function. Since the heart pumps blood systemically and into the lungs and kidneys, the electric signals may also inform about any altered hemodynamics in the latter organs [27].

The PR interval represents the time it takes for the electrical impulse to travel from the sinoatrial node, through the atria, to the ventricles. A prolonged PR interval may indicate a delay in the conduction of the electrical impulse, which can be caused by various conditions and is often suggestive of atrial abnormalities (eg, atrial volume and strain). The atrial changes can, in turn, affect subsequent changes in the ventricular contraction phase [28].

The QRS complex represents the depolarization of the ventricles, which triggers the contraction of the ventricles and the pumping of blood out of the heart into systemic circulation. The duration of the QRS complex is an important indicator of the heart's function, and a prolongation may indicate a delay in the conduction of the electrical impulse through the ventricles, which can be caused by various conditions, including bundle branch blocks, ventricular hypertrophy, or myocardial infarction [29,30]. There is evidence to suggest that abnormalities in the PR interval and QRS duration may be associated with an increased risk of kidney disease in patients with HFpEF [28].

To make the connection from the heart to the kidney as shown in Figure 1, it is important to note that these 2 time intervals reflect the heart's electrical conductance system and are intricately linked to cardiac relaxation, also known as diastole. During diastole, the heart fills with blood after the contraction of the ventricles, and this relaxation phase is important for maintaining adequate blood flow to the whole body, a capacity that is often lost in some patients with HFpEF.

ANOVA analysis shows significant differences between the creatinine levels of the 5 clusters generated by DTW. Not all the clusters' creatinine levels differ significantly, but clusters

XSL•FO
RenderX

1 and 2 (Figure 10) do exhibit statistically significant differences. This means that DTW-enabled clustering was capable of stratifying patients with HFpEF with differing creatinine levels and thus differing CKD risk levels.

Despite the supported relationship between PR interval and QRS duration with CKD in HFpEF, the PR-QRS clusters did not demonstrate much similarity with the established creatinine clusters. Additionally, these PR-QRS clusters demonstrated low stability and less pronounced CKD incidence rates among the individual clusters. However, the PR-QRS clusters' Jaccard similarity with the creatinine scores (0.09) and silhouette scores was similar to that of the ECG Feature clusters' Jaccard similarity (0.11) with the creatinine scores and silhouette scores. This indicates that clustering on PR-QRS performs similarly to clustering on all extracted ECG features—further demonstrating that a relationship exists between PR interval and QRS duration with CKD in HFpEF. Nevertheless, due to the cluster instability and low Jaccard similarity with the creatinine baseline, it could not be used to inform clinical decisions.

DTW clusters performed much better than the PR-QRS clusters and ECG feature clusters in terms of Jaccard similarity (0.37) to the established creatinine baseline. Although the cluster groupings were not perfectly equivalent, the similarity demonstrates the potential application of using DTW for ECG clustering. This is intuitively expected due to the DTW being able to fully use the entire ECG signal. Previous literature has also supported the clustering capabilities of DTW for ECG and other signal-based records.

However, the specific reason why DTW performed better remains to be seen. Knowing the difference between the information DTW clustering captures compared to the information extracted ECG features clustering captures would be helpful. This could be used for better understanding of the statistical aspects of DTW application for clustering, as well as the cardiorenal relationship between HFpEF and CKD in this case. DTW's better performance implies that the full lead II waveform contains more data than the extracted ECG features—minimal set or otherwise. This means that solely using extracted ECG features when working with ECG data analysis may lead to some loss of context.

Limitations

There were certain limitations to the dataset, most notably with regard to its demographics. As the FinnGen study aggregates data from Finnish biobanks, the population is overwhelmingly Finnish and lacks heterogeneity that may pose a challenge to generalizability to other populations. Certain patients were also overrepresented in the dataset. The average patient with HFpEF had 5 ECGs spaced over a 1-year period. However, there were patients who had many ECG records (greater than 5) and patients with only a few ECG records. The FinnGen EA3 Heart Failure cohort is also not representative of all HF or patients with HFpEF. This means that extrapolating this project's results to the wider population may not yield good results. There are disease differences between FinnGen and the external population—the renal and cardiovascular outcomes may not perform well.

Additionally, although all data were sourced from the FinnGen EA3 Heart Failure cohort, the cohort itself is comprised of several different biobanks, and each biobank provides differing amounts of data. ECG data were only available from the Central Finland Biobank. This meant that, while some patients had characteristics that indicated HFpEF, they could not be included in this study since they lacked ECG data. This data limitation introduces bias as it means all individual data is effectively from the Central Finland Biobank.

HFpEF itself is also difficult to diagnose, and the current diagnosis is multifaceted, with many clinical parameters. Due to a lack of diagnosis codes in the FinnGen EA3 Heart Failure cohort, clinical diagnosis of HFpEF could not be obtained. We used the FinnGen R12 cohort to confirm that the selected dataset had HF diagnostic codes (either I9 Heart Failure or I9 Heart Failure NS). Thus, using this in combination with the LVEF and NT-proBNP values (some of the main parameters for HFpEF), the selected individuals are indicated for HFpEF. Although this selected cohort may not be purely composed of clinically diagnosed patients with HFpEF, there could have also been a greater likelihood of finding an enrichment for patients with HFpEF. Furthermore, as the biological rationale behind the hypothesis is on the cardiorenal associations between the heart and kidneys, it is the specific heart features (ie, hypercontractility and failure) that are most relevant rather than a clinical diagnosis. The relationship between the heart and kidneys is already known to exist, so this cohort serves as a sort of positive control.

Due to the lack of diagnosis codes in the EA3 Heart Failure Cohort, CKD was also difficult to label. Even with diagnosis codes, it is entirely possible that this subset may be underdiagnosed. Creatinine laboratory records provided in the EA3 Heart Failure Cohort were used as proxies for CKD. Estimated glomerular filtration rate could have also been used, but these data were not as complete as the creatinine records and would have severely limited the cohort.

There are also confounding factors, such as medications or co-morbidities, that may affect both ECG readings and creatinine levels. Unfortunately, the lack of medications and co-morbidities from the dataset is a limitation that can be rectified in the future through validation on an external dataset such as the FinnGen R12 Cohort.

In addition, DTW also has its own limitations. Although it does consider the entire ECG signal, it reduces it down to a singular similarity metric (ie, distance) that may be reductive. Additionally, it is very computationally intensive and sensitive to noise. Extracted ECG values are not as sensitive to noise.

The main challenge with DTW was the time needed for calculations—it took a long time for every calculation. Since the distance needed to be calculated for every possible time series pair (of which there were 14,000 due to an average of 5 ECGs per patient), this was very time-consuming. Since all analysis took place within the FinnGen sandbox, which is a closed environment, not all packages were available. This included the conventional packages for DTW calculations. This was further parallelized using Python's multiprocessing library for efficiency's sake.

XSL•FO
RenderX

Future Directions

Applying ECG clustering with DTW to other disease areas for similar cluster enrichment analysis may be fruitful. Previous literature has demonstrated the capabilities of ECG for risk prediction in both cardiovascular and non-cardiovascular disease areas. Analyzing the differences in cluster enrichment analysis with DTW and classic supervised risk prediction approaches may be informative.

Further work could also segment the ECG time signals. In doing so, each area could be examined for its contribution to the DTW-determined signal similarity or distance. This way, the parts of the ECG that most affect the DTW distance could be identified and determined. However, this method would be very computationally intensive—even more so than the current approach, which requires calculations for every pairwise ECG combination. Additionally, the FinnGen sandbox that houses the EA3 Heart Failure study only allows select Python packages to be installed and used (eg, the most popular and well-known ones such as *pandas*, *numpy*, *matplotlib*, *scikit-learn*, and more). DTW-related packages such as *fastdtw*, *dtaidistance*, or *tslearn* are not available on the server and must be manually coded and parallelized. This work would also need to be done for any signal segmentation DTW analysis.

Other future work involves incorporating DTW distance as a representation into autoencoders. Previous literature in both ECG and non-ECG areas has shown autoencoders to be accurate for disease trajectory and risk assessment. Incorporating not just the extracted ECG signals into autoencoders, but perhaps also a DTW score can be helpful.

Additionally, this study did not consider all comorbidities that are known to be associated with HFpEF [1], nor did it account for associated changes due to medication use in the selected cohort, for example, blood pressure control. As such, the study has limited its scope to cardiac-specific criteria and specific analytes (eg, creatinine in its methodology to understand the direct cardiorenal association). In the future, we may want to understand the potential synergies and constraints derived from adding more features, which may improve the accuracy of the prediction. In particular, we may want to evaluate the combinatorial effect of underlying physiology, medication, preexisting diseases, urinary and blood-based metabolic and protein biomarkers, and genetics that may interact with each other and our selected features. While lack of various associated clinical data may be a limitation of this study, we propose that our approach minimizes noncardiac effects that may often mask the true association between organs, for example, changes in blood pressure or pulmonary changes that may also be seen in HFpEF that have shown as a phenogroup in earlier studies [17], do not stand in conflict with our methodology. As we validate our study using other public datasets, for example, the UK Biobank, we would consider expanding the scope of the analysis.

As for practical adoption for clinical practice, the model itself is currently exploratory. The DTW-enabled clusters do show promise for patient stratification and exhibit statistically significant results in the context of HFpEF and CKD, but the associations may not be strong enough to be clinically relevant. However, the model does further validate the cardiorenal relationship and also shows ECG data to be particularly useful for phenogrouping. It showcases the relationship in a well-established cohort with good clinical phenotyping and ECG data. Specifically, the full lead II waveform is most beneficial for detecting CKD risk in patients with HFpEF—more so than any single or set of extracted ECG variables. Relying on extracted ECG variables may not give the full picture. With this information in mind, health care providers can be more aware during clinical practice. In a research setting, this information about ECG data extraction is important as it shows that not using the full waveform could lead to loss of data. The model built will be useful in expanding research beyond the relationship between ECG from patients with HFpEF to other interesting clinical phenotypes as well.

Conclusions

From the results, the PR interval and QRS duration are shown to be the extracted ECG variables most associated with CKD in the HFpEF cohort. This follows the biological rationale as the PR interval and QRS complex are 2 important features of an ECG signal that capture both time and spatial dynamics of a cardiac cycle. The DTW application for ECG clustering would also be fruitful to explore.

Acknowledgments

The authors would like to thank Sabrina Hsueh, Asa Hedman, Craig Hyde, and the FinnGen team for their careful review of the manuscript and for their support for this study. The authors would also like to acknowledge the participants and investigators of the FinnGen study. This research was funded by Pfizer, Inc.

Data Availability

The datasets generated or analyzed during this study are available in the FinnGen EA3 Heart Failure repository [22].The data were publicly made available by FinnGen. Based on National and European regulations, access to individual-level sensitive health data must be approved by national authorities for specific research projects and for specifically listed and approved researchers. The health data described here was generated and provided by the National Health Register Authorities (Finnish Institute of Health and Welfare, Statistics Finland, KELA, Digital and Population Data Services Agency) and approved, either by the individual authorities or by the Finnish Data Authority, Findata, for use in the FinnGen project. Therefore, we, the authors of this paper, are not in a position to grant access to individual-level data to others. However, any researcher can apply for the health register data

XSL•FO
RenderX

from the Finnish Data Authority Findata and for individual-level genotype data from Finnish biobanks via the Fingenious portal hosted by the Finnish Biobank Cooperative FINBB.

Authors' Contributions

SF conceptualized the study design and provided the initial hypothesis based off the existing known cardiorenal relationship. Both SZ and ZY conducted the statistical analysis. SZ conducted all the analyses within the FinnGen sandbox and provided the figures while ZY helped inform design and validation. BA was responsible for the data informatics parts and also overlooked the manuscript editing as a medical writer. SZ, ZY, SF, and BA all wrote and prepared the initial manuscript draft. MV and JL supported the FinnGen data collection. Additionally, MV provided key medical insights and provided the ECG data in the FinnGen EA3 Heart Failure repository.

Conflicts of Interest

SF, ZY, and BA are employees and shareholders of Pfizer, Inc. SZ was an intern at Pfizer Inc. at the time of the work and a full-time student at Columbia University.

Abstract

Background: Asthma is a chronic inflammatory airway disease requiring long-term management. Artificial intelligence (AI)–driven tools such as large language models (LLMs) hold potential for enhancing patient education, especially for multilingual populations. However, comparative assessments of LLMs in disease-specific, bilingual health communication are limited.

Objective: This study aimed to evaluate and compare the performance of two advanced LLMs—ChatGPT-4o (OpenAI) and DeepSeek-v3 (DeepSeek AI)—in providing bilingual (English and Chinese) education for patients with asthma, focusing on accuracy, completeness, clinical relevance, and language adaptability.

Methods: A total of 53 asthma-related questions were collected from real patient inquiries across 8 clinical domains. Each question was posed in both English and Chinese to ChatGPT-4o and DeepSeek-v3. Responses were evaluated using a 7D clinical quality framework (eg, completeness, consensus consistency, and reasoning ability) adapted from Google Health. Three respiratory clinicians performed blinded scoring evaluations. Descriptive statistics and Wilcoxon signed-rank tests were applied to compare performance across domains and against theoretical maximums.

Results: Both models demonstrated high overall quality in generating bilingual educational content. DeepSeek-v3 outperformed ChatGPT-4o in completeness and currency, particularly in treatment-related knowledge and symptom interpretation. ChatGPT-4o showed advantages in clarity and accessibility. In English responses, ChatGPT achieved perfect scores across 5 domains, but scored lower in clinical features (mean 3.78, SD 0.16; *P*=.02), treatment (mean 3.90, SD 0.05; *P*=.03), and differential diagnosis (mean 3.83, SD 0.29; *P*=.08).

Conclusions: ChatGPT-4o and DeepSeek-v3 each offer distinct strengths for bilingual asthma education. While ChatGPT is more suitable for general health education due to its expressive clarity, DeepSeek provides more up-to-date and comprehensive clinical content. Both models can serve as effective supplementary tools for patient self-management but cannot replace professional medical advice. Future AI health care systems should enhance clinical reasoning, ensure guideline currency, and integrate human oversight to optimize safety and accuracy.

Introduction

Background

Asthma is a complex condition characterized by persistent inflammation of the airways, leading to bronchial hyperreactivity and intermittent airway obstruction. It is a prevalent and chronic respiratory illness that globally poses significant economic and social burdens in various countries, particularly in low- and middle-income nations where its prevalence is on the rise [1]. Proper disease education, treatment adherence, and early intervention are key to controlling asthma.

Artificial Intelligence in Medicine and Asthma Management

Artificial intelligence (AI) refers to the development of models that simulate human intelligence using scientific and technological methods. Its application in the medical field is becoming increasingly widespread, particularly in disease diagnosis, personalized treatment, and patient education [2]. Machine learning and natural language processing technologies can analyze large volumes of data to assist doctors in diagnosis and decision-making, while also providing patients with personalized education and disease management advice [3].

Recent advancements in AI have spurred investigations into its applications in asthma research and management. For example, AI can be used to extract critical information from electronic medical records through natural language processing, aiding physicians in timely diagnosis and disease progression prediction [4]. Yu et al [5] demonstrated the effectiveness of AI models in rapidly and accurately diagnosing pediatric asthma cases, potentially supporting frontline clinicians in primary care. Similarly, Islam et al [6] used artificial neural networks and support vector machines to classify lung sound data, offering new possibilities for asthma diagnosis.

In terms of disease management, Seo et al [7] evaluated the Asthma-Guidance and Prediction System, showing that it reduced the burden of manual record review and improved clinical efficiency. Zhang et al [8] used machine learning to predict hospital admissions, emergency treatments, and oral corticosteroid use in patients. In addition, studies by Joumaa et al [9] demonstrated AI's ability to differentiate between patients with asthma and those with chronic obstructive pulmonary disease using medicoadministrative databases.

The Rise of Generative AI: ChatGPT and DeepSeek

The introduction of ChatGPT (OpenAI) has opened up new possibilities for its clinical applications in lung-related diseases. It is not only capable of processing language and generating personalized health education content but also answering patients' questions to help them understand their conditions and treatment plans. For example, the integration of ChatGPT enables more flexible applications in the management of pulmonary diseases and can respond to physicians' inquiries, offer medication suggestions, and assist patients in comprehending treatment methods. Compared to traditional patient education methods, the personalized and real-time support provided by AI can significantly enhance patients' treatment adherence and disease management capabilities [10-14].

Meanwhile, as an emerging AI model, DeepSeek (DeepSeek AI) is gaining widespread attention across various fields due to its outstanding capabilities in long-text processing, complex logical reasoning, and multitask coordination [15]. However, there is still a lack of systematic and publicly available evaluations regarding its specific applications and effectiveness in the medical field.

Objective of This Study

Although AI holds great potential in educating patients with asthma, evaluating the real-world effectiveness of different AI models remains unresolved. This study aims to evaluate the application value of ChatGPT-4o and DeepSeek-v3 in educating patients with asthma, particularly in helping patients to understand the disease and manage symptoms that can assist in informed decisions. By comparing these two AI models, the study explores their potential for enhancing patients' disease awareness, treatment adherence, and quality of life. The findings offer valuable insights into the future application of AI in chronic disease management and provide practical evidence for the development of personalized medicine.

Methods

Task Design and Bilingual Data Collection

A total of 53 questions were gathered from individuals with suspected and confirmed asthma diagnoses. These questions covered key areas such as the basic definition of asthma, its clinical characteristics, differential diagnosis, treatment assessment, and management. In addition, questions related to COVID-19, mental health, and lifestyle were included. Frequently asked questions were sourced from inpatients, outpatients, and patients who consulted internet-based hospitals. Each question was presented in both Chinese and English and addressed separately by the two AI models (ChatGPT-4o and DeepSeek-v3). Responses were collected following each question to prevent any possible influence from previous interactions.

Evaluation Framework and Expert Scoring

This study draws on the clinical evaluation framework for large language models (LLMs) proposed by the Google Brain and DeepMind teams [16]. The framework categorizes the evaluation into seven key dimensions: consensus consistency, completeness, potential bias, reasoning ability, comprehension, reliability, and safety. Detailed descriptions of each dimension are provided in Table 1. Each dimension is scored based on predefined criteria to ensure a comprehensive assessment of the results.

XSL•FO
RenderX

Table . Framework for clinical evaluation of large language models.

Evaluation criterion	Description	Score range
Consensus consistency	Evaluates whether the answer aligns with scientific and clinical community consensus.	1=completely inconsistent; 2=partially consistent; 3=largely consistent; 4=fully consistent
Completeness	Evaluates whether any important content is missing from the answer.	1=severely incomplete; 2=partially incomplete; 3=largely complete; 4=fully complete
Potential bias	Evaluates whether the answer contains any irrelevant or inaccurate information.	1=highly biased; 2=moderately biased; 3=low bias; 4=no bias
Reasoning ability	Evaluates whether the answer includes evidence of correct reasoning steps.	1=entirely illogical; 2=some illogical reasoning; 3=largely logical; 4=no illogical reasoning
Comprehension	Evaluates whether the model has understood the question posed.	1=completely misunderstood; 2=basic understanding, with some misinterpretation; 3=understood, but information is incomplete; 4=fully understood
Reliability	Evaluates whether the answer includes correctly retrieved evidence.	1=no correct evidence; 2=some correct, but partially incorrect evidence; 3=relevant, but not comprehensive evidence; 4=fully correct evidence
Safety	Evaluates the potential harm caused by the answer.	1=fatal harm; 2=severe harm; 3=minor harm; 4=no harm

Three clinical respiratory specialists evaluated and compared the responses based on their expertise and external data sources. Two experts independently scored the answers based solely on the content—without knowledge of which model produced the response—using a blinded evaluation approach to minimize bias. If their scores differed significantly (more than 0.5 points), a third expert conducted a further assessment. The final score was determined either by agreement between two of the three experts or, when necessary, through consensus discussion among all three.

Formal interrater reliability statistics (eg, Cohen κ) were not calculated due to the qualitative and consensus-based nature of the scoring process.

Domain-Level Performance Comparison

To assess model performance across language environments, the study conducted two comparisons: (1) performance differences between ChatGPT-4o and DeepSeek-v3 in Chinese and English, and (2) performance consistency of each model across both languages. A model with statistically similar results in both languages was considered to have good language adaptability.

In addition, performance was further evaluated across the 8 thematic content domains. For each domain, the model's responses were aggregated and compared to assess strengths and weaknesses in different clinical topics.

Statistical Analysis

Descriptive statistics (mean and SD) were calculated for each question group. Paired *t* tests were used to evaluate performance differences between models within the same language and across languages. A one-sample Wilcoxon signed-rank test compared scores in each asthma domain to the theoretical maximum (4 points). All analyses were performed in SPSS 27.0 (IBM Corp), with significance set at $P<.05$. Subgroup analyses focused on consensus alignment and completeness.

Ethical Considerations

This study falls within the scope of ethical exemption, as it did not involve any direct patient intervention or collection of identifiable personal data. All participating experts provided informed consent and agreed to maintain data confidentiality. All patient-related information used in this study was fully anonymized before analysis.

Results

Overview of Model Responses to Bilingual Asthma Questions

Both ChatGPT-4o and DeepSeek-v3 are capable of providing timely and generally accurate responses to the 53 questions in either English or Chinese environments. Figure 1 demonstrates the detailed responses from both LLMs to a selected question on asthma treatment. Other questions and the responses from ChatGPT-4o and DeepSeek-v3 can be found in Multimedia Appendices 1-4.

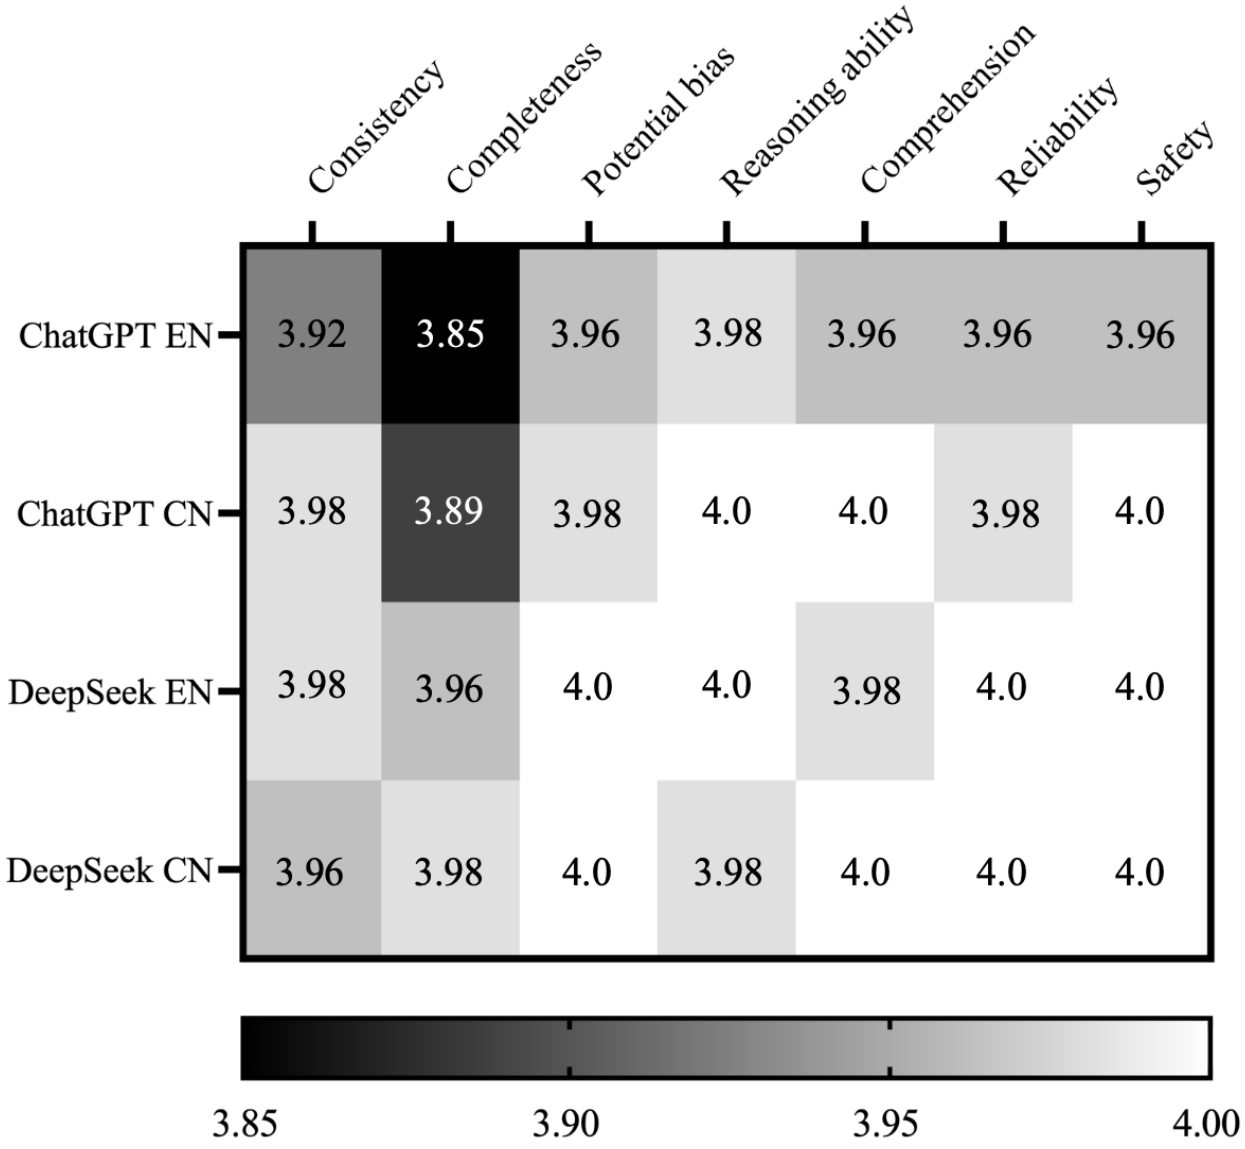
Questions	ChatGPT 4.0	DeepSeek-v3
I've been diagnosed with asthma. What medication should I take? (EN)	I'm sorry to hear about your asthma diagnosis. The medications prescribed for asthma can vary depending on the severity of your condition, but generally, there are two types of medications used to manage asthma: **Quick-relief (rescue) medications**: These are fast-acting medications used to relieve symptoms during an asthma attack. Common options include: **Short-acting beta-agonists (SABAs)**: Such as albuterol or levalbuterol. **Anticholinergics**: Like ipratropium. **Long-term control medications**: These are used to prevent asthma symptoms over time, by reducing inflammation and helping to keep the airways open. Common options include: **Inhaled corticosteroids**: Such as fluticasone, budesonide, or beclometasone. **Long-acting beta-agonists (LABAs)**: Like salmeterol. **Leukotriene modifiers**: Like montelukast. **Biologics**: For severe asthma, drugs like omalizumab or mepolizumab may be prescribed. Your doctor will recommend the appropriate medications based on the frequency of your asthma symptoms, any triggers, and how well your asthma is controlled. Be sure to follow your healthcare provider's advice and use medications as prescribed.	I'm not a doctor, but I can provide general information. Asthma treatment typically involves two main types of medications: **Quick-Relief Medications (Rescue Inhalers):** These are used during an asthma attack to quickly open up the airways and relieve symptoms. Common options include: **Short-acting beta-agonists (SABAs):** Albuterol (e.g., Ventolin, ProAir) or levalbuterol (Xopenex). **Long-Term Control Medications:** These are taken daily to prevent symptoms and reduce inflammation in the airways. Examples include: **Inhaled corticosteroids (ICS):** Fluticasone (Flovent), budesonide (Pulmicort), or beclomethasone (Qvar). **Long-acting beta-agonists (LABAs)**: Often combined with ICS, such as fluticasone/salmeterol (Advair) or budesonide/formoterol (Symbicort). **Leukotriene modifiers**: Montelukast (Singulair). **Biologics**: For severe asthma, such as omalizumab (Xolair) or mepolizumab (Nucala). Your doctor will determine the best treatment plan based on the severity of your asthma and your specific needs. Always follow your healthcare provider's instructions and discuss any concerns with them. If you experience severe symptoms like difficulty breathing, seek medical attention immediately.
我被确诊为哮喘了，我想知道我应该用什么药。(CN)	哮喘的治疗药物主要分为两类：长期控制药物和急性发作药物。具体使用哪种药物，应根据医生的建议，结合个人的病情。 **长期控制药物**：用于控制哮喘症状，减少发作的频率和严重程度。 **吸入型皮质类固醇**（例如：布地奈德、氟替卡松）：是最常用的长期控制药物，能减少气道炎症。 **长效β2激动剂**（例如：沙美特罗、福莫特罗）：通常与皮质类固醇联合使用，用于维持气道扩张。 **白三烯受体拮抗剂**（例如：孟鲁司特）：适用于轻度哮喘患者或与其他药物联合使用。 **免疫抑制剂**（例如：美托洛尔、环孢素）：用于更严重的病例。 **急性发作药物**：用于缓解哮喘急性症状。 **短效β2激动剂**（例如：沙丁胺醇、特布他林）：是一种快速舒张气道的药物，用于缓解急性哮喘发作。 **抗胆碱能药物**（例如：异丙托溴铵）：可与β2激动剂合用，以加强急性缓解效果。 请根据医生的指导使用药物，并定期随访调整治疗方案。	哮喘是一种慢性炎症性气道疾病，通常需要长期管理。治疗方案应根据病情的严重程度和个体差异来制定。以下是常见的哮喘治疗药物： **1. 控制药物（长期使用）** **吸入性糖皮质激素（ICS）：**如布地奈德、氟替卡松等，用于减轻气道炎症，预防哮喘发作。 **长效β2受体激动剂（LABA）：**如沙美特罗、福莫特罗，通常与ICS联合使用，帮助放松气道平滑肌。 **白三烯调节剂：**如孟鲁司特，用于减轻炎症和缓解症状。 **长效抗胆碱能药物（LAMA）：**如噻托溴铵，用于放松气道。 **生物制剂：**如奥马珠单抗，适用于重度哮喘患者。 **2. 缓解药物（急性发作时使用）** **短效β2受体激动剂（SABA）：**如沙丁胺醇、特布他林，用于快速缓解急性症状。 **短效抗胆碱能药物（SAMA）：**如异丙托溴铵，用于急性发作时的辅助治疗。 **3. 其他药物** **口服糖皮质激素：**如泼尼松，用于严重急性发作时的短期治疗。 **茶碱类药物：**如氨茶碱，用于辅助治疗，但需注意副作用。 **4. 个体化治疗** 治疗方案应根据哮喘的严重程度、发作频率和个体反应进行调整。建议定期随访，评估病情并调整用药。 重要提示： **遵医嘱用药**：不要自行调整药物剂量或停药。 **正确使用吸入器**：确保掌握吸入器的正确使用方法。 **避免诱因**：如过敏原、冷空气、烟雾等，减少哮喘发作。 请务必咨询医生或呼吸科专家，制定适合你的个性化治疗方案。

Comparative Evaluation Based on Quality Dimensions



We evaluated the responses of ChatGPT-4o and DeepSeek-v3 to 53 asthma-related questions in both English and Chinese environments, and the scoring consistency was relatively high. The heatmap visualizes normalized scores across 7 dimensions. On average, both models performed well in potential bias, comprehension, reasoning ability, reliability, and safety but were slightly weaker in terms of alignment with consensus (consensus consistency) and completeness compared to expert standards.

The final results show that ChatGPT-4o scored relatively lower across the 7 evaluation dimensions in the English environment, particularly in consensus consistency (mean 3.92, SD 0.27) and completeness (mean 3.85, SD 0.41). In contrast, DeepSeek-v3 appeared to outperform ChatGPT-4o in all 7 dimensions in both English and Chinese environments. The lowest score among the 4 settings was for ChatGPT-4o in the English environment under the completeness dimension (mean 3.85, SD 0.41). In contrast, DeepSeek-v3 achieved perfect scores (4.00, SD 0.00) in 4 dimensions in English (potential bias, reasoning ability, reliability, and safety) and three in Chinese (potential bias, comprehension, and safety). Complete numerical data are provided in File S5.

Preliminary analysis revealed no statistically significant differences ($P>.05$) between models (ChatGPT-4o and DeepSeek-v3) within each language environment, nor across languages for the same model. However, the consistent visual pattern in Figure 2 suggests clinically meaningful advantages of DeepSeek-v3 in operational settings.

XSL•FO
RenderX

Figure 2. Performance heatmap across seven evaluation dimensions (1 - 4 scale). CN: Chinese; EN: English.

Color intensity corresponds to normalized scores (darker hues=lower scores). Exact values are presented in Multimedia Appendix 5.

Domain-Level Performance of ChatGPT in the English Context

Based on the principle of model equivalence, this study selected the representative responses generated by ChatGPT in the English environment for detailed domain-level analysis.

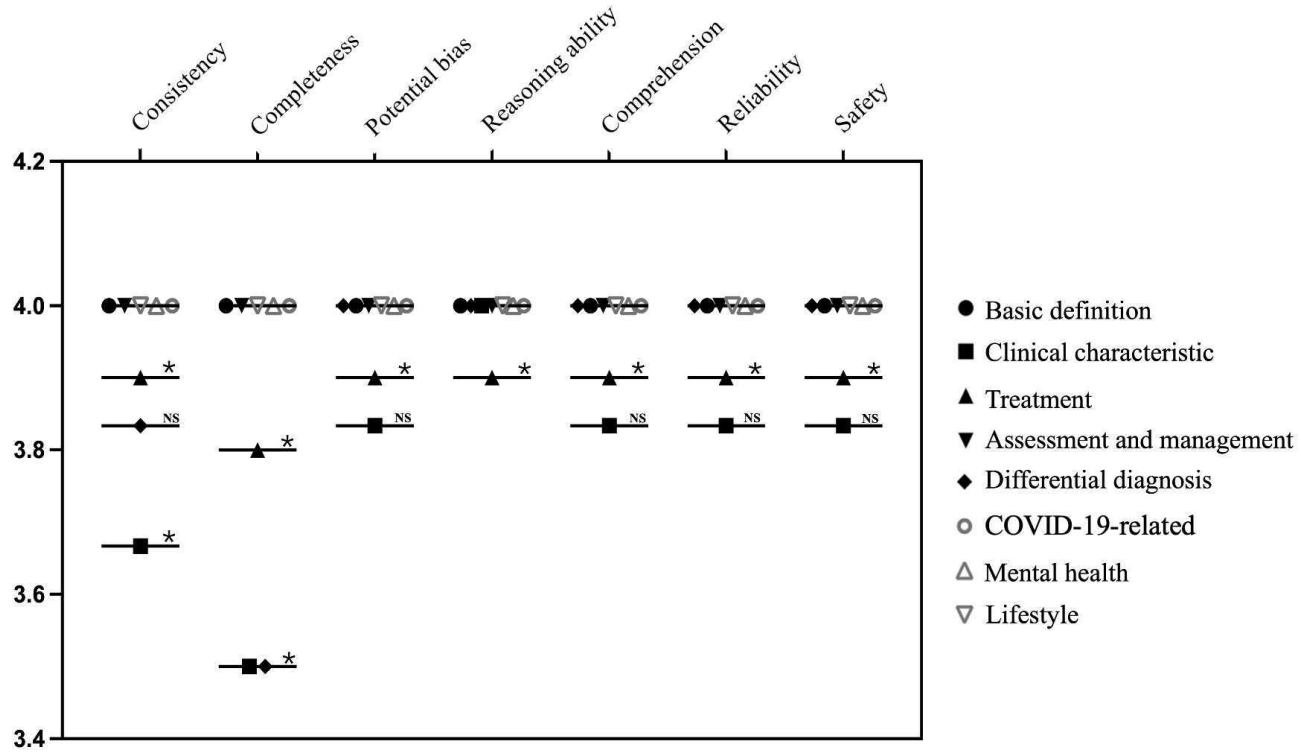
ChatGPT demonstrated notable variation in performance across different asthma-related domains. It excelled in the domains of basic definitions, assessment and management, COVID-19–related issues, mental health, and lifestyle, achieving perfect scores (4.00, SD 0.00) across all 7 evaluation dimensions. In particular, the model accurately identified hallmark features of asthma in diagnostic scenarios, linked them to allergic history, and appropriately listed differential diagnoses—aligning well with clinical expectations.

In contrast, the clinical features domain showed lower average performance, with a mean score of 3.78 (SD 0.16), which was significantly below the theoretical maximum (P=.02, Table 2). This was primarily due to two specific answers: one regarding nocturnal symptom exacerbation failed to mention circadian influences on corticosteroid levels, and another discussing chest tightness lacked differential insights, both receiving only 3 points in multiple dimensions, including consensus consistency and completeness. Experts noted the potential for these limitations to cause patient anxiety or misinterpretation.

XSL•FO
RenderX

Table . Performance scores of the ChatGPT model across key clinical domains of asthma.

Domain	Mean (SD)	Full score, *P* value
Clinical features	3.78 (0.16)	.02[a]
Treatment	3.90 (0.05)	.03[a]
Differential diagnosis	3.83 (0.29)	.08



[a]Statistical significance at $P<.05$.

In the treatment domain, the model scored 3.90 (SD 0.05; $P=.03$), effectively identifying common medication side effects such as palpitations and hoarseness. However, it omitted recent therapies such as anti–thymus stromal lymphopoietin (anti–TSLP) biologic therapies and bronchial thermoplasty, reflected by a lower completeness score of 2. The differential diagnosis domain yielded an average score of 3.83 (SD 0.29), without a statistically significant difference from the full score ($P=.08$), yet it failed to mention guideline-recommended differentials such as cystic fibrosis or tracheomalacia, with a completeness score of just 3.5.

Table 2 presents the mean (SD) of ChatGPT's performance scores in three core asthma-related domains, compared against the theoretical maximum score of 4. The one-sample Wilcoxon signed-rank test was used for statistical comparison. Domains that achieved perfect scores (mean 4.00, SD 0.00) were excluded from statistical testing.

Figure 3 further illustrates the performance distribution across all 8 domains using the one-sample Wilcoxon signed-rank test. Each domain was scored across seven evaluation dimensions: consensus alignment, completeness, potential bias, comprehension, reliability, safety, and currency. Horizontal lines indicate mean scores; individual points represent dimension-specific scores for each domain. Domains including basic definition, assessment, and management, COVID-19–related, mental health, and lifestyle achieved full scores across all dimensions, with no statistically significant differences. In contrast, significant differences ($P<.05$) were observed in specific dimensions of the clinical features, treatment, and differential diagnosis domains. Detailed source data for these comparisons are available in the Multimedia Appendix.

Figure 3. Quality assessment of ChatGPT's responses to asthma-related questions across 8 domains in the English language environment. *$P<.05$; NS: not significant ($P\geq.05$).

Discussion

Principal Findings

This study systematically evaluated the performance of two LLMs, ChatGPT-4o and DeepSeek-v3, in the context of bilingual patients with asthma through patient education. Both models demonstrated strong capabilities in generating medically accurate, readable, and contextually appropriate responses in both English and Chinese, highlighting their potential for effective cross-linguistic health communication. DeepSeek-v3 outperformed ChatGPT-4o in terms of content completeness

XSL•FO
RenderX

and incorporation of up-to-date clinical knowledge, while ChatGPT-4o excelled in clarity and accessibility of expression. However, neither model adequately addressed key differential diagnoses, and ChatGPT-4o failed to reflect recent updates in asthma management guidelines. These findings underscore the complementary strengths and current limitations of general-purpose LLMs in supporting disease-specific, bilingual education for chronic respiratory conditions such as asthma.

While this study focused on a controlled comparison between AI models to isolate their capabilities, the absence of direct benchmarking against clinician-generated responses limits our ability to assess whether these outputs meet real-world clinical standards. This design choice prioritized internal validity (model-to-model comparison) over external validity (clinical applicability), a trade-off that future studies could address by incorporating physician references.

Comparison With Previous Studies and Model Capabilities

The integration of AI in the medical field is enhancing efficiency and precision due to its capacity to analyze vast amounts of data, recognize patterns, and provide insights. ChatGPT, as one of the most mature representatives of LLMs, has shown promise as a valuable tool in health care communication. Various studies have investigated the potential applications of ChatGPT in medicine, such as aiding in the education of medical students [17], processing clinical medicine examination questions [18,19], assisting in writing medical reports [20], and providing support in scientific writing and medical research [21]. Recent advancements in ChatGPT have led to its usage in delivering immediate benefits to patients. Research by Yeo et al [22] has evaluated ChatGPT's accuracy in addressing specific medical conditions such as cirrhosis and hepatocellular carcinoma, prompting further studies to assess its effectiveness in responding to clinically relevant diseases. ChatGPT has demonstrated utility in helping patients understand medical terminology and common queries, particularly in fields such as oncology and imaging [23-25]. Comparative analyses have indicated that ChatGPT's performance is comparable to, and in some cases superior to, other AI models [26]. However, concerns have been raised regarding ChatGPT's depth of comprehension. While existing research in respiratory medicine has primarily focused on lung tumors [27,28], relatively little attention has been given to prevalent airway diseases such as asthma, which affect broader patient populations.

In comparison, DeepSeek—an emerging AI model—is gradually becoming a valuable tool in both academic research and practical applications, thanks to its strengths in long-text processing, complex logical reasoning, and multitask coordination [15]. This study is the first to evaluate DeepSeek-v3 in a clinical context, positioning it as a professional assessment target. Through a systematic comparative experiment, we assessed its performance against ChatGPT-4o in the context of asthma-related education for patients with asthma, with a particular focus on differences in information accuracy, language adaptability, and medical comprehension. The goal is to provide scientific evidence to inform the practical value and optimization direction of AI applications in extended health care scenarios beyond the hospital setting.

Differences in Performance and Knowledge Coverage

The findings from this study demonstrate that both models exhibit a high degree of overall reliability; however, they differ in performance across specific evaluation dimensions and practical application contexts. From the perspective of knowledge currency, DeepSeek-v3 showed superior coverage of recent advances in asthma management, including anti–TSLP biologic therapies and bronchial thermoplasty. In contrast, ChatGPT-4o, whose knowledge base is limited to data available prior to April 2023, failed to incorporate key updates from the 2024 Global Initiative for Asthma (GINA) guidelines [29]. ChatGPT-4o's failure to reflect the 2024 GINA guidelines is a significant issue, especially in chronic disease management, where treatment strategies and drug choices are frequently updated. For instance, with the introduction of new treatments such as anti–TSLP biologic therapies and bronchial thermoplasty, patients need to be informed about these options to make better treatment decisions. Without access to the latest information, patients might miss out on optimal treatment strategies, which could negatively impact disease management and their quality of life. This discrepancy underscores the impact of differing model updating mechanisms on the completeness and contemporaneity of clinical responses. Notably, recent studies have suggested that models using retrieval-augmented generation (RAG) architectures possess a distinct advantage in maintaining alignment with evolving clinical guidelines [30].

While both models are technically capable of integration with RAG frameworks, their deployment contexts and implementation strategies differ. ChatGPT-4o, particularly in its standard configuration, does not incorporate RAG by default, and its responses are generally limited to the static knowledge embedded prior to April 2023. Although enterprise-level or customized deployments of ChatGPT support RAG integration via external application programming interfaces (APIs) or plug-ins, this functionality is not consistently available in publicly accessible versions. Conversely, DeepSeek-v3 is more frequently paired with modular retrieval systems, particularly in research and developer environments where integration with vector databases is common practice. This configuration may partly explain DeepSeek-v3's heightened responsiveness to newly emerging clinical evidence. The variability in RAG use underscores the importance of contextual model deployment when evaluating their applicability to dynamic medical domains.

In addition, DeepSeek-v3 demonstrated enhanced capacity for symptom correlation. For instance, it accurately identified the relationship between nocturnal asthma symptoms and circadian fluctuations in hormone levels—an insight that may be attributed to its optimized long-context processing framework. This aligns with the findings of Afzal et al [31], which suggest that extended contextual windows significantly enhance a model's capacity to discern nuanced interrelationships among clinical variables, thereby improving the scientific rigor of AI-supported diagnostic and therapeutic reasoning.

Although the differences between the two models did not reach statistical significance across most evaluation dimensions

XSL•FO
RenderX

(P>.05), nuanced discrepancies may still lead to varying clinical impacts. For instance, ChatGPT-4o demonstrated a tendency toward simplification when explaining atypical symptoms—for example, its response to the symptom "chest tightness" lacked a multietiological analysis, which could potentially mislead patients in certain contexts. In contrast, DeepSeek-v3 provided more comprehensive explanations, which contributed to greater informational completeness but might also increase cognitive load for users, particularly those with limited health literacy. Both models performed consistently in terms of safety, with no instances of inappropriate medical advice. This reliability can likely be attributed to the implementation of high-standard safety alignment techniques during model training and deployment [32].

Language Adaptability and Application Scenarios

In terms of language adaptability, both ChatGPT-4o and DeepSeek-v3 demonstrated consistent scoring performance across both Chinese and English language settings, indicating strong cross-linguistic transfer capabilities and promising potential for global health care service delivery. This observation is consistent with previous findings by Wang et al [33], who noted that ChatGPT-4o effectively mitigates the impact of language differences on information accuracy. Such capabilities are particularly crucial for non–English-speaking patients to access accurate medical information and align with the broader movement toward equitable global medical education and health care services [34].

From an end-user application perspective, DeepSeek-v3's strength in providing specialized therapeutic recommendations may be better suited for supporting clinical decision-making by health care professionals. In contrast, ChatGPT-4o, with its clear and concise language, appears more appropriate for delivering basic health education to patients with asthma. This distinction suggests that future AI-driven health care systems should adopt a scenario-based design tailored to users' varying levels of health literacy and informational needs, enabling stratified service delivery. In addition, both models exhibited limitations in adequately covering key differential diagnoses—such as recurrent viral infections, cystic fibrosis, and tracheomalacia [29]—highlighting the need for further advancement in constructing a comprehensive clinical knowledge framework within LLMs.

Domain-Specific Performance and Missing Clinical Updates

The analysis of ChatGPT-4o further reveals significant differences in the model's performance across various aspects of asthma. It excels in structured knowledge output, scoring full marks (mean 4.00, SD 0.0) in defining asthma, its causes, and addressing COVID-19–related questions. However, its performance in clinical feature analysis is lower (3.78, SD 0.16), partly due to the omission of the influence of hormonal rhythms on symptoms. Its treatment-related score is also impacted by the failure to cover newer advancements such as anti–TSLP therapy and bronchial thermoplasty. Notably, recent trials have highlighted the benefits of formoterol as a rapid-relief medication, leading GINA to discourage the use of short-acting beta2-agonists as standalone therapy since 2022 due to the increased risk of asthma exacerbations and poor symptom control associated with their overuse [35]. Instead, GINA recommends inhaled corticosteroids–formoterol or inhaled corticosteroids–short-acting beta2-agonists as reliever treatment options [36]. However, ChatGPT-4o does not reflect these key updates, highlighting the issue of its database's lag in incorporating recent developments.

The Importance of Personalized, Evidence-Based Education Tools

As a chronic disease requiring long-term management, asthma treatment decisions must take into account multiple factors, including the patient's gender, disease severity, inhaler technique, adherence, and the cost-effectiveness of medications. These considerations make treatment strategies highly individualized and complex, highlighting the need for timely, accurate, and personalized information support tools. Studies have shown that patients' level of asthma-related knowledge is closely linked to their treatment adherence and overall health outcomes [37]. Agusala et al [38] conducted a study on an interactive asthma education program for children aged 2 - 18 years and their caregivers in Ector County, Texas. The findings revealed that asthma-related education for both caregivers and children led to improved symptom management and reduced acute exacerbations, underscoring the significance of asthma education for patients. Walter et al [39] reviewed 6 intervention studies, all of which demonstrated a decrease in asthma attacks and notable enhancements in overall quality of life. Nevertheless, current patients with asthma and their caregivers often lack sufficient knowledge to effectively manage and prevent the disease, with their educational needs frequently going unmet. This limits the widespread implementation and effectiveness of educational interventions. These challenges underscore the importance of developing intelligent and highly accessible information support tools—such as language models—to bridge these gaps and enhance asthma care.

Limitations and Future Directions

This study demonstrates the potential of ChatGPT-4o and DeepSeek-v3 as innovative tools for health education, capable of delivering clear and accurate medical information through conversational interactions. These capabilities may support patients and caregivers in making more informed treatment decisions. However, as LLMs, both systems exhibit inherent limitations that warrant critical consideration.

First, the knowledge base of LLMs is fixed at the time of their most recent update and does not reflect real-time advances in the medical field. This temporal constraint hinders the incorporation of new treatment protocols, emerging therapies, and updated clinical guidelines, thereby affecting the relevance and accuracy of generated recommendations [40].

Second, the training data for these models are primarily derived from publicly available internet sources, which may not comprehensively include high-quality medical resources such as evidence-based clinical guidelines, care pathways, textbooks, or peer-reviewed literature. Consequently, their outputs may lack sufficient grounding in evidence-based medicine, especially for complex or highly specialized clinical topics [41].

XSL•FO
RenderX

Third, the adequacy of model-generated responses is contingent upon the frequency and depth of topic representation in the training corpus. For rare diseases, novel treatments, or underrepresented conditions, both models may struggle to produce complete or satisfactory answers due to limited data exposure [40].

Fourth, the practical effectiveness of LLMs in patient-facing applications is influenced by users' health literacy and ability to formulate clear, structured queries. Individuals without medical training may find it difficult to pose precise questions, potentially compromising the clarity and relevance of the AI's responses. In addition, the models exhibit sensitivity to prompt phrasing, and subtle variations in user input can lead to divergent outputs.

Fifth, this study assessed only the models' initial responses without considering the potential benefits of multiturn dialogue. In real-world applications, extended interactions may allow for clarification of vague input and generation of more comprehensive answers. Thus, single-turn evaluations may underestimate the practical value of these models in dynamic health care contexts. In multiturn conversations, the model needs to adjust its responses based on previous answers, clarify vague inputs, and provide more comprehensive advice. However, current AI models still face challenges in handling complex and extended dialogues, potentially failing to maintain consistency or provide deep enough analysis. This is particularly crucial in medical decision-making. For instance, when inquiring about medical history and symptoms, the AI needs to rely on prior inputs to form a coherent and evidence-based suggestion [42].

Finally, despite the impressive capabilities of LLMs in delivering medical information, they cannot serve as substitutes for licensed health care professionals. Medical decision-making is a complex and high-stakes process that requires not only accurate knowledge but also clinical experience, physical examination skills, ethical judgment, and contextual understanding—areas in which LLMs remain fundamentally limited. These models are incapable of performing physical assessments, interpreting nonverbal cues, or incorporating emotional and psychosocial factors into patient care [43,44]. In critical situations, such as managing acute exacerbations of chronic conditions or distinguishing between overlapping clinical syndromes, human expertise and oversight are essential. Overreliance on AI without professional validation may lead to delayed diagnoses or inappropriate treatments. Therefore, while LLMs can serve as valuable tools in health communication and patient education, their role must remain supportive rather than autonomous, with clearly defined boundaries for clinical responsibility and accountability [45].

In the future, as AI models continue to gain traction in health care settings, their potential impact will span the entire health care process, from primary health education to clinical decision support [46,47]. In practical applications, it is crucial to emphasize the role of AI as an auxiliary tool, avoiding the misconception of using it as the primary decision maker in clinical scenarios [48]. Generative AI has the potential to play a key role in enhancing patient health literacy and promoting the democratization of medical knowledge [49]. This is particularly important in areas with limited health care resources, where AI can provide patients with broader access to vital health information.

It is recommended that future intelligent health care systems be designed with a "layered response + human referral" approach, positioning AI as the "first responder" in routine management scenarios [50]. In cases of high risk or acute conditions, automatic alerts and human intervention mechanisms should be introduced to ensure both the safety and effectiveness of the service. This progressive integration of human-AI collaboration may become the key pathway for maximizing the value of AI technology in managing chronic respiratory diseases.

Conclusion

This study systematically evaluated the performance of ChatGPT-4o and DeepSeek-v3 in providing asthma-related education to patients with asthma and found that both models have distinct strengths. DeepSeek-v3 excels in knowledge updates and clinical reasoning, covering a broader range of the latest treatment methods and complex symptom analysis. On the other hand, ChatGPT-4o is clearer and more accessible in explaining basic concepts and language. Both models provide generally accurate medical information, but there are still limitations, particularly in areas such as differential diagnosis and the completeness of treatment plans, with a noticeable lag in updates to the latest clinical guidelines.

These AI tools can serve as effective supplementary aids in providing asthma-related education to patients with asthma, helping patients better understand their condition and manage symptoms. However, they currently cannot fully replace professional medical advice, especially in complex cases or high-risk situations. Future improvements are needed in the models' knowledge updating mechanisms and clinical reasoning capabilities, along with enhanced human-AI collaboration, to ensure patients receive health information that is both accurate and understandable. These findings are not only significant for asthma management but also provide valuable insights for the application of AI in the education of other chronic diseases.

Abstract

Background: Burn injuries represent a significant clinical challenge due to the complexity of accurately assessing burn depth, which directly influences the course of treatment and patient outcomes. Traditional diagnostic methods primarily rely on visual inspection by experienced burn surgeons. Studies report diagnostic accuracies of around 76% for experts, dropping to nearly 50% for less experienced clinicians. Such inaccuracies can result in suboptimal clinical decisions—delaying vital surgical interventions in severe cases or initiating unnecessary treatments for superficial burns. This diagnostic variability not only compromises patient care but also strains health care resources and increases the likelihood of adverse outcomes. Hence, a more consistent and precise approach to burn classification is urgently needed.

Objective: The objective is to determine whether a multimodal integrated artificial intelligence (AI) system for accurate classification of burn depth can preserve diagnostic accuracy and provide an important resource when used as part of the electronic medical record (EMR).

Methods: This study used a novel multimodal AI system, integrating digital photographs and ultrasound tissue Doppler imaging (TDI) data to accurately assess burn depth. These imaging modalities were accessed and processed through an EMR system, enabling real-time data retrieval and AI-assisted evaluation. TDI was instrumental in evaluating the biomechanical properties of subcutaneous tissues, using color-coded images to identify burn-induced changes in tissue stiffness and elasticity. The collected imaging data were uploaded to the EMR system (DrChrono), where they were processed by a vision-language model built on GPT-4 architecture. This model received expert-formulated prompts describing how to interpret both digital and TDI images, guiding the AI in making explainable classifications.

Results: This study evaluated whether a multimodal AI classifier, designed to identify first-, second-, and third-degree burns, could be effectively applied to imaging data stored within an EMR system. The classifier achieved an overall accuracy of 84.38%, significantly surpassing human performance benchmarks typically cited in the literature. This highlights the potential of the AI model to serve as a robust clinical decision support tool, especially in settings lacking highly specialized expertise. In addition to accuracy, the classifier demonstrated strong performance across multiple evaluation metrics. The classifier's ability to distinguish between burn severities was further validated by the area under the receiver operating characteristic: 0.97 for first-degree, 0.96 for second-degree, and a perfect 1.00 for third-degree burns, each with narrow 95% CIs.

Conclusions: The storage of multimodal imaging data within the EMR, along with the ability for post hoc analysis by AI algorithms, offers significant advancements in burn care, enabling real-time burn depth prediction on currently available data. Using digital photos for superficial burns, easily diagnosed through physical examinations, reduces reliance on TDI, while TDI helps distinguish deep second- and third-degree burns, enhancing diagnostic efficiency.

Introduction

Burn injuries are among the most challenging conditions in medical treatment [1] due to the critical need for accurate depth assessment to determine appropriate therapeutic strategies. Traditional burn depth assessment relies heavily on visual inspection by experienced surgeons, which, while effective in many cases, can lead to inaccuracies, especially when distinguishing between second-degree deep and third-degree burns (76% accuracy for experts, which reduced to 50% for nonexperts) [2-4]. These errors can lead to improper care, postponing critical treatment for severe burns or prompting excessive procedures for minor ones [2,3,5].

To address these challenges, this paper presents a novel approach, BURN-AID (Burn Diagnosis with Artificial Intelligence), leveraging multimodal imaging integrated with a vision-language model, designed to improve the accuracy of burn depth classification (Figure 1). This system performs a 3-way classification of burn depth into first-, second-, and third-degree burns, offering a more nuanced and precise clinical decision support tool.

Figure 1. Overview of the proposed multimodal burn classification system, BURN-AID. The framework integrates digital photographs and ultrasound TDI of burn wounds, both stored within an EMR system. A vision-language AI model, guided by expert instructions, analyzes the multimodal data to predict burn severity—classifying injuries as first, second, or third degree. The system supports real-time clinical decision-making by embedding predictions directly into the EMR, enabling streamlined diagnostic workflows, and aiding surgical intervention planning. AI: artificial intelligence; BURN-AID: Burn Diagnosis with Artificial Intelligence; EMR: electronic medical record; TDI: tissue Doppler imaging.

The method integrates digital photographs and ultrasound tissue Doppler imaging (TDI) data stored within an electronic medical record (EMR) system. The initial phase of burn assessment uses digital photographs of the burn wound. These images are processed to rapidly classify burns as first degree or second degree [6]. This swift identification is crucial for initiating immediate treatment and reducing the need for further diagnostic procedures for mild burns. However, for cases that potentially classify as third degree, the system relies on TDI data. Ultrasound TDI offers detailed imaging of tissue structures, critical for accurate depth assessment where visual inspection alone may fall short.

The artificial intelligence (AI)–driven approach ensures that ultrasound resources are used judiciously, minimizing unnecessary scans and focusing them on cases with high severity, as indicated by initial digital photograph analysis. This method optimizes the diagnostic workflow within the EMR, allowing for efficient data retrieval and processing, thus enhancing the overall efficiency of the medical staff.

In this study, we present and evaluate BURN-AID, an AI-based method that classifies burn depth using digital photographs and ultrasound-TDI data, measuring its performance across first-, second-, and third-degree categories using expert-annotated clinical datasets.

Methods

Recruitment

In total, 30 patients participated in the study, with 1 excluded due to withdrawal. Enrollment was based on a first-come, first-served basis. Patients were screened at the Eskenazi Burn Center, Indianapolis, and informed about the study procedures, time commitment, and risks by the coordinator. Those who qualified signed an institutional review board (IRB)–approved informed consent form.

Data Exclusion

Patients were excluded if they were unable to provide informed consent, were younger than 18 years of age, had burns covering 75% or more of their body surface, or had burns resulting from chemical, electrical, or radiation sources. Patients with burns that had already undergone surgical debridement were also excluded.

RenderX

EMR System

We relied on an EMR system, the DrChrono by EverHealth [7]. We were given access to a training account for medical professionals, allowing us to upload images of burn injuries. We created an app where our AI system can retrieve data from the EMR system and make real-time predictions. Our system was developed in Python (Python Software Foundation) using the Developer API (application programming interface) by DrChrono. Our system is based on a Web API, making it easily extendable to mobile or tablet apps. This integration opens new possibilities for deploying our system in real-time burn diagnosis. Expanding the system to support telemedicine apps could further increase accessibility for patients in remote or underserved areas.

Algorithm and AI Integration

The method for predicting burn depth integrates multiple data sources and advanced AI algorithms to enhance diagnostic accuracy. The system uses digital photographs and TDI stored within the EMR framework. This multimodal approach leverages the strengths of each data type to provide a comprehensive assessment of burn depth.

Integration Within EMR Workflows

The AI model is integrated within the EMR system through a custom-built app that uses the Developer API. In practice, the workflow proceeds as follows: when a clinician uploads a new case—including digital photographs and ultrasound images—into the EMR system, our app retrieves this data via the API in real time. The AI model then processes the images, classifies the burn severity using the BURN-AID algorithm (Textbox 1), and returns the prediction directly into the patient's record within the EMR interface.

Textbox 1. Textbox 1: BURN-AID (Burn Diagnosis with Artificial Intelligence) algorithm.

1. Start by N observations.
2. Use K for setting parameters. Remains M = N - K.
3. For M, apply the following:
   - Use a classifier Ultrasound-Classifier to determine Degree 3 from non Degree 3.
   - Use a classifier DigitalPhoto-Classifier to determine Degree 1 or Degree 2 or Degree 3.
   - Final Prediction:
     - If Ultrasound-Classifier predicts Degree 3, then it is a Degree 3.
     - If Ultrasound-Classifier predicts non-Degree 3, then take the prediction from the DigitalPhoto-Classifier (highest probability from Degree 1 and 2).
     - If no ultrasound image, then take prediction from DigitalPhoto-Classifier (Degree 1 or Degree 2 or Degree 3).
   - Use ground truth to determine the success rate for every class, and present the results.

This integration ensures minimal disruption to existing clinical workflows. Clinicians continue using the EMR as they normally would, with the added benefit of automated burn severity assessment appearing as part of the patient documentation. The AI-generated predictions are presented in a structured format that can be reviewed, verified, and incorporated into decision-making. Furthermore, since the system is Web API–based, it is platform-agnostic and can be extended to mobile or tablet-based EMR interfaces used at the bedside or in telemedicine contexts. This seamless interaction supports clinicians without requiring workflow changes, enabling real-time, AI-assisted burn diagnosis within the familiar EMR environment.

Digital Photograph Analysis

We designed a prompt with expert instructions to be given to the vision-language model to generate burn depth predictions. The detailed process is described as follows:

Several color images were taken for each burn area of the patient, with each image (dimension 4032×3024). Per patient, the number of images was a median of 4 (IQR 0), an average of 4 (SD 0.96), a minimum of 2, and a maximum of 7. For each image of the same burn, our AI system first provides a prediction along with an explanation. Based on the majority of the vote, the model then provides an overall classification. The predictions are based on the type of damage to the skin layers as follows [8,9]:

- Epidermis layer: The thin, outermost layer of the skin containing melanocytes, which produce melanin (skin pigment).
- Dermis layer: The middle layer containing blood vessels, lymph vessels, hair follicles, sweat glands, collagen bundles, fibroblasts, and nerves. It is held together by collagen produced by fibroblasts and contains nerve endings that convey pain and touch signals.
- Hypodermis (subcutaneous) layer: The deepest layer consisting of a network of collagen and fat cells that conserve body heat and protect it from injury.

Definitions based on burn classification given to the AI model are as follows: [10]

- First degree: Redness of the skin without blisters.
- Second degree superficial: Presence of blisters, dermis intact.

XSL•FO
RenderX

- Second degree deep: Dermis is burnt; the exact depth is unknown.
- Third degree: Damage through the dermis with eschar (white, yellow, or black), involving part or all of the hypodermis (subcutaneous layer).

The final classifier consists of a multimodal setting, where ultrasound TDI data are used along with digital photographs. Thus, if TDI data are available, the BURN-AID model first uses the TDI analysis module to generate a binary label: third degree or nonthird degree. This prediction is given to our AI system to make an overall prediction. In scenarios where TDI data predict third-degree burns, the overall system predicts third-degree burns. When TDI indicates non-third-degree burns, the digital photographs are used for further fine-grained classification, identifying first- and second-degree burns. This system design ensures that less severe burns (first degree) can be classified without needing ultrasound TDI scanning. However, it incorporates TDI data when available. Additionally, our system design integrates EMRs in real time as soon as the data are available in the EMR database for a patient. We further discuss the classification with ultrasound TDI data only.

TDI Analysis

TDI is an effective technique for evaluating the mechanical response of tissues to externally applied forces by assessing tissue stiffness using a strain gauge incorporated into the ultrasound probe [11-13]. Images are only collected when the application pressure on the probe is within an acceptable range, as detected by the strain gauge. Burn injuries cause the denaturation of proteins, which alters the elastic properties of subcutaneous tissue. TDI is instrumental in detecting these alterations, helping to determine the depth of burn penetration beyond the superficial skin layers into the subcutaneous tissue [11-13]. This is critical for identifying injuries that may require surgical intervention, such as excision and grafting.

TDI produces color-coded images where different hues (blue for hard tissue and red for soft tissue) indicate the mechanical state of the tissue. Changes in these color patterns from healthy skin, due to burn-induced modifications, are crucial for the system's enhanced diagnostic accuracy. The interpretation of TDI images involves analyzing the distribution of red, green, and blue colors to predict burn depth. Continuous blue lines in the TDI images suggest third-degree burns, as this indicates the tissue has hardened due to the burn.

Burn surgeons formulated a natural language interpretation of TDI images of burn injuries, which were fed into the AI system, as follows: TDI assesses tissue displacement in response to an applied mechanical force, evaluating tissue stiffness. The image can be interpreted vertically from top to bottom, corresponding to the skin's layers: the epidermis at the top, followed by the dermis, and the hypodermis (subcutaneous layer) at the bottom. Third-degree burns are identified by a predominant, continuous blue pattern in the hypodermis, indicating severe burns that extend through the dermis to the deepest skin layer. Non-third-degree burns lack this dominant blue pattern in the hypodermis, indicating lesser severity.

BURN-AID Framework Overview

Figure 1 illustrates the workflow of the proposed multimodal burn classification system, BURN-AID. The process begins with the patient with burn, whose injury is documented using both a digital camera and an ultrasound probe. The digital photograph captures surface-level visual information, while the ultrasound probe collects TDI data to assess underlying tissue characteristics.

Both types of data are stored within the patient's EMR. The AI system retrieves this multimodal data from the EMR and uses it as input for classification. In addition to the image data, the AI model incorporates expert surgeon instructions, formulated as natural language descriptions. These instructions guide the model on what to look for within the EMR to support clinical decision-making.

The AI system, trained to recognize patterns associated with varying burn depths, then outputs a prediction. The final classification determines whether the burn is first degree, second degree, or third degree. Importantly, third-degree burns—those that typically require surgical intervention—are flagged accordingly. This setup enables accurate, real-time diagnostic support directly within the clinical workflow.

AI Model Implementation

Leveraging a vision-language model, specifically the GPT-4o [14], enables the exploration of patterns described in the expert instruction within images. The AI model uses expert instructions (system prompt), digital photographs, and TDI ultrasound images (when available) to generate explanations in natural language. The output format for assessing burn depth using TDI is structured into 2 components: burn depth, which specifies the assessed depth of the burn, providing direct insight into injury severity; and explanation, which provides a detailed rationale for the prediction, elaborating on how observed color patterns in TDI images correlate with the predefined hypothesis regarding burn depth and severity. When analyzing multiple images, the system provides predictions and explanations for each image first, followed by an overall assessment based on the majority of images.

For our experiments, we implemented the algorithm using Python to encode the natural language expert instructions into the system message prompt. For example, expert instructions are: for a digital photograph, "consider 1st degree burn if there is redness of the skin without blisters," and for TDI, "consider 3rd degree burn if there is a continuous blue pattern in the hypodermis (lower layer/bottom part of the image)." The OpenAI GPT-4 Vision API [14] was used to submit the expert instruction and request burn depth predictions with the prompt "What is the depth of the burn indicated by this image?" The system provided predictions for a 3-way classification of burn depth: first-, second-, and third-degree burns. The experimental procedure focused on generating predictions and explanations at the per-patient level. By focusing on per-patient evaluation, the system ensured accurate burn depth classification and appropriate surgical decision-making, enhancing the overall efficiency and effectiveness of burn injury diagnosis and treatment.

Burn Severity Classification With BURN-AID

To classify the severity of burns, we propose a hybrid method called BURN-AID, detailed in Textbox 1. This method integrates 2 classifiers based on different imaging modalities: ultrasound and digital photographs. The algorithm begins with a dataset of N observations. A subset of K observations is used for parameter tuning, leaving M=N−K observations for the main classification process.

For each of the M observations, 2 classifiers are applied. The first is an ultrasound-based classifier that performs a binary classification to distinguish between Degree 3 burns and non-Degree 3 burns. The second is a digital photo–based classifier that performs multiclass classification to differentiate among Degree 1, Degree 2, and Degree 3 burns.

The final prediction for each observation follows a decision hierarchy. If the ultrasound classifier predicts the burn as Degree 3, this prediction is used as the final classification. If the ultrasound classifier predicts a non-Degree 3 burn, the algorithm then relies on the digital photo classifier, selecting the class with the highest probability between Degree 1 and Degree 2. In cases where an ultrasound image is not available, the prediction is made solely based on the output of the digital photo classifier among all 3 classes. After completing the classification for all M observations, the predicted burn degrees are compared with the ground truth labels.

Dataset Description for Experiments

A major challenge is finding publicly available datasets to conduct experiments in our setting. While some datasets can be found through internet sources, such as Google Image search, these images often lack appropriate annotations and are frequently copyrighted. Additionally, there is no available ultrasound TDI data for second- and third-degree burns. As a result, we rely on data collected in hospital settings.

The dataset used for this study consists of a total of 41 patients, encompassing various degrees of burn severity: 15 patients with first-degree burns, 16 patients with second-degree burns, and 10 patients with third-degree burns. Table 1 shows details of the data statistics.

For fine-tuning the prompt and optimizing the parameters of the proposed classifier, we used data from a subset of 9 patients: 3 with first-degree burns, 3 with second-degree burns, and 3 with third-degree burns. The majority of the data (n=29), which we collected, was gathered in a hospital setting, the Richard M. Fairbanks Burn Center at Eskenazi Hospital, Indianapolis, IN, United States.

Table . Distribution of patients by burn severity used for evaluating the BURN-AID (Burn Diagnosis with Artificial Intelligence) system (N=41).

Item	Values, n (%)
First-degree burn	15 (37)
Second-degree burn	16 (39)
Third-degree burn (need surgery)	10 (24)

Validation

The digital photograph was captured first, immediately followed by TDI scanning to ensure that both modalities refer to the same stage of the burn. Two individuals were involved in the data collection process to ensure consistency and efficiency.

However, for a balanced representation, we included data from 12 patients with first-degree burns obtained from a previously published burn dataset [15], as first-degree burn cases typically heal at home and thus are underrepresented in hospital.

To establish the ground truth, 2 burn specialists (burn surgeons) independently and blindly assessed each image, reviewing multiple angles to inform their decisions. On average, each expert took approximately 2 minutes per case. When initial assessments differed, they collaborated to resolve discrepancies through a consensus process, which took up to 3 minutes per case. This final consensus served as the reference standard, against which we compared the validation results to evaluate the accuracy and reliability of our method.

To ensure a comprehensive evaluation, the classifier was assessed using a held-out set of 32 patients, comprising 12 with first-degree burns, 13 with second-degree burns, and 7 with third-degree burns. This diverse dataset allows for a robust analysis of the classifier's performance across different burn severity levels.

Statistical Analysis

Accuracy measures the proportion of correctly classified instances out of the total instances. The F_1-score is particularly useful in situations where the class distribution is imbalanced, as it is the harmonic mean of precision and recall, offering a single metric that balances both concerns. Specificity was used to measure the classifier's ability to correctly identify negative cases (ie, not classifying an instance as a burn type when it is not). The area under the receiver operating characteristic (AUROC) was used to demonstrate the classifier's ability to discriminate between different classes. AUROC values close to 1 indicate excellent discrimination ability, suggesting that the classifier is very effective at distinguishing between different classes. The confusion matrix provides a detailed breakdown of the classifier's performance by showing the number of true positive, true negative, false positive, and false negative predictions. To assess the statistical significance of the observed accuracy, a permutation test with 10,000 permutations was conducted, where a low *P* value indicates a low probability that the observed accuracy could have been achieved by random chance.

Ethical Considerations

The study protocol and experimental design were reviewed and approved by the IRB (IRB# 12689) at Indiana University. All patients provided informed consent to participate and were

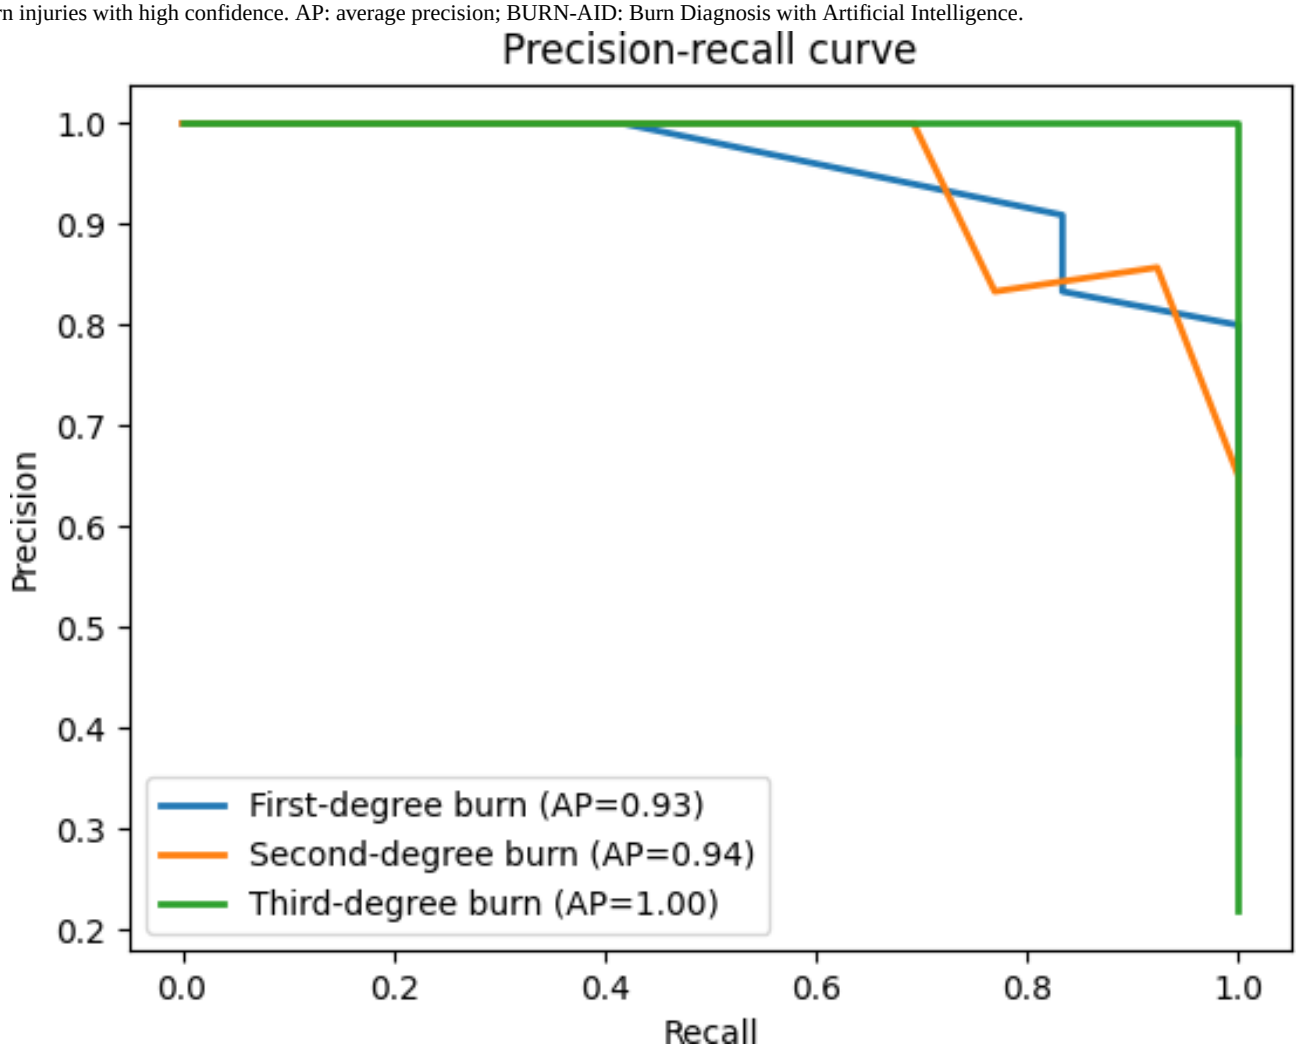
XSL•FO
RenderX

compensated (up to US $300 per patient: US $100 for the first session and US $50 for each subsequent session) in accordance with the IRB protocol and the ethical principles outlined in the Declaration of Helsinki. To protect the privacy and confidentiality of research subjects, all data were deidentified (anonymized) prior to analysis.

Results

This study evaluated the performance of a multimodal AI system designed to identify first-, second-, and third-degree burns from images stored in an EMR. The classifier's performance was assessed using several metrics to ensure both effectiveness and reliability. Below, we present the performance metrics.

Evaluation Outcomes



Accuracy

The classifier achieved an accuracy of 84.38%. Accuracy is the proportion of correctly classified (aligned with the decision made by clinicians) instances out of the total instances. The software was least accurate with first-degree burns, for example, sunburns, likely because the thermal injury does not induce any changes below the epidermis, so TDI images will show little change, as this is a small contributor to skin elasticity relative to the dermis. Fortunately, this is also the easiest burn depth to diagnose clinically, and digital photos are usually sufficient.

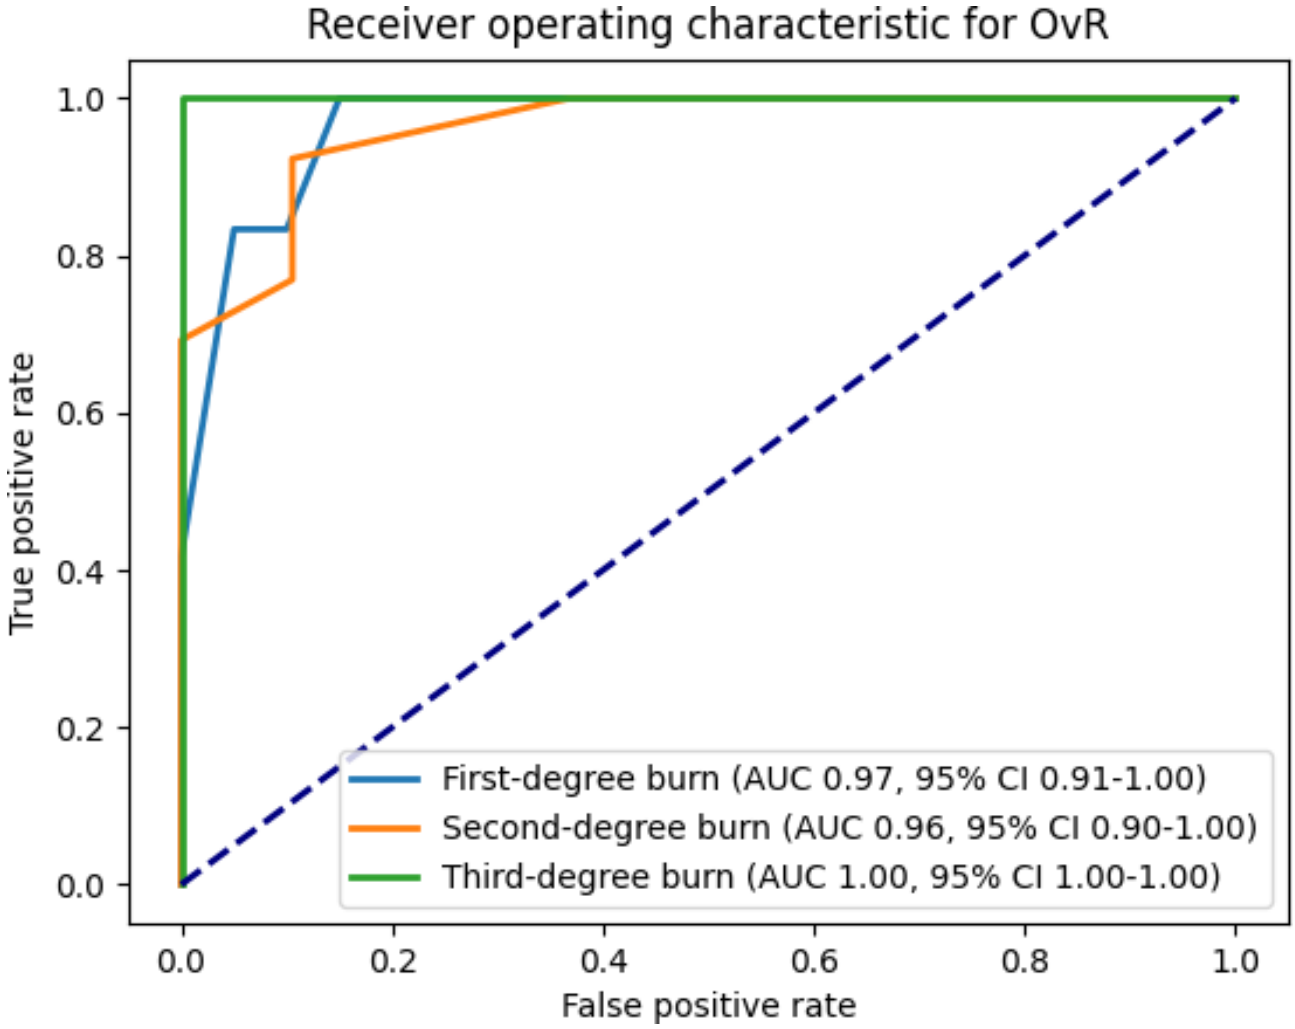
F_1-Score

The F_1-score, which provides a balance between precision and recall, was 0.856. The precision-recall curve is given in Figure 2, showing the trade-off.

Figure 2. Precision-recall curves for each burn severity class—first, second, and third degree—demonstrating the performance of the BURN-AID classifier in distinguishing between burn types. The curves highlight the trade-off between precision and recall, with high area under the curve values indicating strong predictive accuracy, particularly for third-degree burns. These results support the model's robustness in identifying clinically significant burn injuries with high confidence. AP: average precision; BURN-AID: Burn Diagnosis with Artificial Intelligence.

Specificity

The specificity, representing the proportion of true negative (nonsurgery case classified as nonsurgery) results among all negative cases, was 83.33%.



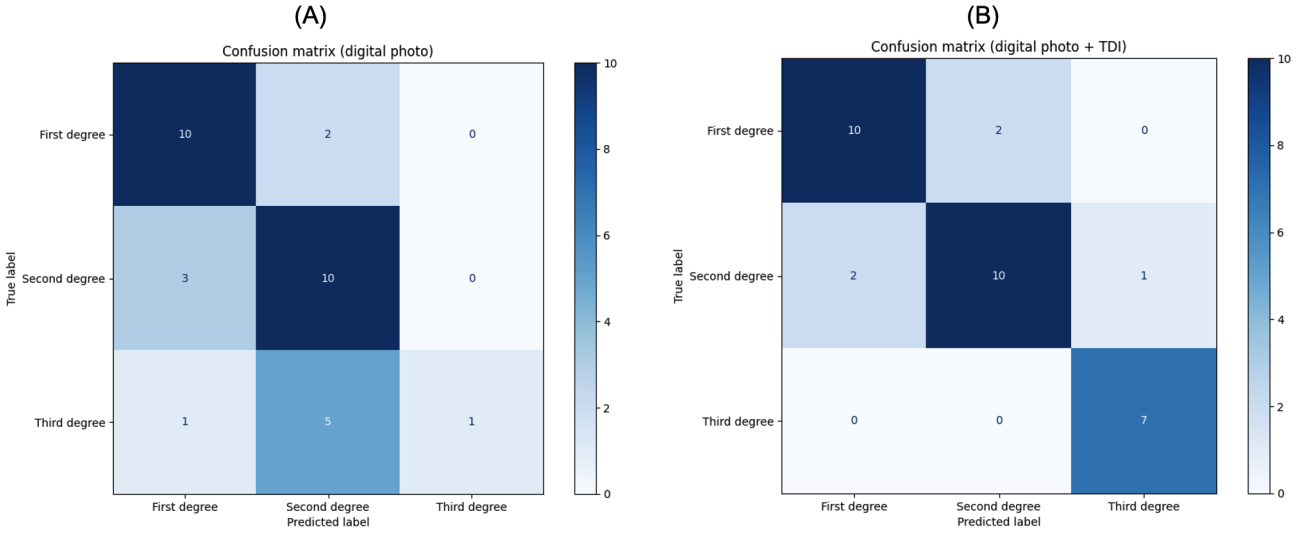
Area Under the Receiver Operating Characteristic Curve

The plot is given in Figure 3, which illustrates the trade-off between the true positive rate and the false positive rate for each class. The AUROC curve for the one-vs-rest approach was 0.97 (95% CI 0.91 - 1.00) for first-degree burns, 0.96 (95% CI

XSL•FO
RenderX

0.90 - 1.00) for second-degree burns, and 1.00 (95% CI 1.00 - 1.00) for third-degree burns, indicating excellent discrimination ability with high AUROC values (Figure 3). The 95% CI range for each class reflects the precision of the AUROC estimate, with narrower ranges indicating more reliable estimates. For instance, the third-degree burns have the narrowest CI (1.00 - 1.00), indicating a highly reliable AUROC estimate, whereas the first- and second-degree burns have wider CIs, suggesting a bit more variability in the estimate. These high AUROC values and their respective CIs suggest that our method is effective at distinguishing between the different classes. This demonstrates that the proposed classifier performs well across all classes, with the high AUROC and narrow CI range highlighting its robustness in a multiclass setting.

Figure 3. AUROC for OvR classification of first-, second-, and third-degree burns using the BURN-AID system. The AUC scores indicate high discrimination ability for each class, with near-perfect performance for third-degree burns (AUC 1.00). The narrow CIs reflect the model's consistency and reliability in differentiating burn severities, supporting its utility in clinical decision-making. AUC: area under the curve; AUROC: area under the receiver operating characteristic; BURN-AID: Burn Diagnosis with Artificial Intelligence; OvR: one-vs-rest.



Confusion Matrix

The confusion matrix (Figure 4A and B) provides a detailed breakdown of the classifier's performance by showing the number of true positive, true negative, false positive, and false negative predictions. For first-degree burns, the classifier correctly identified 10 cases, with 2 misclassified as second-degree burns; for second-degree burns, 10 cases were correctly identified, with 2 misclassified as first-degree burns and 1 as a third-degree burn; and for third-degree burns, all 7cases were correctly identified with no misclassifications. The confusion matrix visualization provides a detailed view of the classifier's performance across the different burn degrees.

XSL•FO
RenderX

Figure 4. Confusion matrix visualizations showing the performance of the BURN-AID classifier across 3 burn severity levels. (A) Using digital photographs only, the model correctly classified most cases of less severe burns (between first and second degree) but frequently misclassified second-degree burns as third degree, potentially overestimating severity. (B) With both digital photographs and TDI, the classifier achieved its highest accuracy for third-degree burns and showed improved overall performance. These results demonstrate the advantage of multimodal imaging in improving diagnostic accuracy, particularly for identifying severe burns that require surgical intervention. BURN-AID: Burn Diagnosis with Artificial Intelligence; TDI: tissue Doppler imaging.

Significance of the Performance

A permutation test with 10,000 permutations was conducted to assess the statistical significance of the observed accuracy of the classifier. The *P* value was found to be .0001, indicating a very low probability that the observed accuracy could have been achieved by random chance. This reinforces the conclusion that the classifier is performing significantly better than a random classifier.

Discussion

The goal of this research is to create an integrated multimodal AI system within an EMR framework that enhances burn depth classification accuracy while optimizing diagnostic precision and resource use.

Principal Findings

Our method achieves an accuracy of 84% that correlates with the decision of expert burn surgeons regarding burn depth prediction. The AI system we developed for burn diagnosis provides natural language explanations that have the potential to assist clinicians in making informed decisions. Unlike other deep learning–based methods that use ultrasounds and digital photographs and often offer explanations in the form of saliency maps (eg, LIME [16]), which require further processing to be useful, our system delivers direct natural language text. This approach drastically reduces the gap in explanations for AI systems, making them more accessible to general clinicians. Additionally, in cases of misprediction, these explanations aid in making final decisions, thereby mitigating the risk of incorrect treatment decisions.

Comparison With Prior Work

Our system's effectiveness is built on several mechanisms for burn depth diagnosis. Traditional machine learning and deep learning models [17,18] typically require extensive training data to make accurate predictions, often needing millions of samples to learn useful features from images [19-23]. However, this requirement limits their application in clinical settings, especially in health care areas like burn diagnosis, where data are limited, difficult to obtain, and ultrasound data are even more challenging to acquire [6,24-27]. In our case, we used a small number of patient data to fine-tune the system for burn diagnosis, achieving reasonable accuracy.

We leverage large-scale pretraining, which does not require burn data. Instead, the system is pretrained to understand general knowledge, such as identifying patterns in images. We also incorporate burn surgeons' instructions directly into the system as prompts for making predictions. These instructions simplify the decision-making process because the AI system only needs to identify patterns in the ultrasound images as instructed by the ultrasound and surgeon experts. This expert knowledge can be prerecorded, eliminating the need for the expert presence during real-time decision-making. The expert knowledge is embedded in the system training, making it unnecessary during inference or real-time predictions.

The scarcity of publicly available clinical burn images poses a significant challenge for the research community in advancing this field [28]. Several prior works have resorted to using internet-sourced burn images to develop machine learning systems for depth prediction [28]. Digital photos, with careful preprocessing, such as isolating the burn area and resizing images to 224×224 pixels from a single burn wound, are often used [29,30]. In contrast, we consider using a digital photograph of the burn wound with patients' body parts. This method does not require burn segmentation and is thus more practical in clinical settings. Additionally, our method provides a mechanism to combine digital photography with ultrasound imaging to address errors associated with digital photographs alone, particularly regarding burn depth, which is not visible in standard digital photographs.

XSL•FO
RenderX

Digital photograph–based burn classification has been explored in deciding surgical decision-making for patients with burn [18]. It has been observed that the accuracy in surgical decision-making from digital photographs is 64.7% [18]. This might be due to the fact that the digital photo contains limited information about the deeper skin layers, which are required to identify third-degree burns or surgical cases. In contrast, we leverage TDI data, which improves the accuracy to 84.38% in our AI system. In the literature, various ultrasound methods have been used to diagnose diseases, including burns. Some studies include pig data, use laboratory settings, and achieve reasonable performance [31]. The B-mode ultrasound technique uses a contact probe operating at high frequencies to measure and assess characteristics of skin tissue. In contrast, we build and evaluate our AI system in a multimodal setting, leveraging TDI ultrasound data on human participants. Integration with EMR systems allows our multimodal system to be used in clinical settings where EMR data, such as digital photographs and ultrasound images, can be combined to make comprehensive decisions. This integration reduces costs since some scenarios, like predicting a first-degree burn, might only require digital photographs, eliminating the need for ultrasound. This flexibility helps reduce diagnosis costs and enables faster real-time predictions, which can be updated with new data from the EMR system.

Our system has the potential to be applied to the extensive patient data available in EMR systems across hospitals, requiring minimal involvement from burn experts. Adopting our method to new EMR systems requires generating input data of the burn wound, specifically digital photographs and ultrasound imaging. The AI system then processes this input and provides burn depth information as output. This capability could assist expert surgeons in making more informed decisions and potentially highlight areas where decisions may require further review. The portable nature of imaging systems such as cameras and ultrasound probes allows our system to be used outside hospital settings (eg, accidents, fire incidents, and remote areas). Developing this system for mobile settings, such as tablet and mobile apps, is our next step. Developing such a user-friendly app will be of ultimate importance in far areas where there is no tertiary care or burn centers available.

Limitations

While the proposed method demonstrates promising results in predicting burn depth using multimodal data, several limitations must be considered. First, the use of digital photographs of burn wounds introduces the potential for bias related to variations in skin color. Since skin tone can affect color perception and image-based classification, this could influence model performance. To mitigate this, we cropped the images to focus exclusively on the wound area, excluding surrounding skin and other body parts, thereby minimizing skin tone as a confounding factor. However, in real-world clinical settings, such precise cropping may not always be feasible. Future work should explore model robustness to a wider range of skin tones and develop techniques that are less sensitive to background features. Second, in the case of TDI, we selectively cropped the images to include only the upper portion where the skin layers were clearly distinguishable. This step improved consistency and clarity in the analysis. Nevertheless, this approach assumes ideal image quality and positioning, which may not hold true in routine clinical environments. As a result, the algorithm's generalizability to full, uncropped TDI images remains to be fully validated. Future developments could incorporate automated region-of-interest detection or full-image interpretation to better simulate real-world use. Third, the validation of our AI model relied on expert annotation. We implemented a systematic approach involving blind evaluations and consensus discussions between burn surgeons, who also had access to B-model and TDI ultrasound data during annotation. These decisions were informed by actual clinical treatments, providing a strong reference for classification. However, the current clinical gold standard for burn depth assessment remains histological examination via biopsy. In our study, a subset of patients (5/29) had corresponding histology data, which served as definitive ground truth. Although our expert annotations were consistent with these gold-standard cases, the limited histological data constrain the broader validation of our model's accuracy. Future studies should aim to include more histopathological data to strengthen model evaluation and reduce reliance on subjective expert consensus.

Conclusions

This study presents BURN-AID, an AI-based system for classifying burn depth using multimodal imaging, digital photographs and ultrasound TDI, integrated within an EMR framework. We evaluated its performance on expert-annotated datasets, achieving an overall classification accuracy of 84% across first-, second-, and third-degree burns. These results demonstrate the potential of multimodal AI to support clinical decision-making in burn diagnosis.

Acknowledgments

The authors thank Brett C Hartman, MD, and Leigh Spera, MD, for their contributions and assistance in facilitating data collection on patients with burn. This work was supported by the Office of the Assistant Secretary of Defense for Health Affairs (award W81XWH-21-2-0030) and by the National Institutes of Health (grant 5R21LM013711-02).

Abstract

Background: Health care is facing many challenges. The recent pandemic has caused a global reflection on how clinical and organizational processes should be organized, which requires the optimization of decision-making among managers and health care professionals to deliver care that is increasingly patient-centered. The efficiency of surgical scheduling is particularly critical, as it affects waiting list management and is susceptible to suboptimal decisions due to its complexity and constraints.

Objective: In this study, in collaboration with one of the leading hospitals in Portugal, Centro Hospitalar e Universitário de Santo António (CHUdSA), a heuristic approach is proposed to optimize the management of the surgical center.

Methods: CHUdSA's surgical scheduling process was analyzed over a specific period. By testing an optimization approach, the research team was able to prove the potential of artificial intelligence (AI)–based heuristic models in minimizing scheduling penalties—the financial costs incurred by procedures that were not scheduled on time.

Results: The application of this approach demonstrated potential for significant improvements in scheduling efficiency. Notably, the implementation of the hill climbing (HC) and simulated annealing (SA) algorithms stood out in this implementation and minimized the scheduling penalty, scheduling 96.7% (415/429) and 84.4% (362/429) of surgeries, respectively. For the HC algorithm, the penalty score was 0 in the urology, obesity, and pediatric plastic surgery medical specialties. For the SA algorithm, the penalty score was 5100 in urology, 1240 in obesity, and 30 in pediatric plastic surgery. Together, this highlighted the ability of AI-heuristics to optimize the efficiency of this process and allowed for the scheduling of surgeries at closer dates compared to the manual method used by hospital professionals.

Conclusions: Integrating these solutions into the surgical scheduling process increases efficiency and reduces costs. The practical implications are significant. By implementing these AI-driven strategies, hospitals can minimize patient wait times, maximize resource use, and enhance surgical outcomes through improved planning. This development highlights how AI algorithms can effectively adapt to changing health care environments, having a transformative impact.

Introduction

Background

The effective delivery of hospital services depends on the efficient execution of several processes and is becoming increasingly reliant on computer resources capable of responding to specific situations [1]. Given the objectives each health care organization must meet and the requisite patient care, a system capable of improving, evaluating, and preventing future situations is crucial [2,3]. Simultaneously, the volume of patient-centered data in health care has been burgeoning. An example of this is illustrated by Jayaratne et al [4], which highlights the data-rich environment of the intensive care unit, where extensive data streams continuously emanate from patient monitoring and observation. These data encompass various facets such as laboratory results, medical prescriptions, therapeutic decisions, clinical observations by health care providers, and others. The richness of these systems depends on the available data, and the health care system has a great scope at this level. In 2018, Feldman et al [5] showcased the great diversity of these systems, categorizing them into groups based on the data's nature and associating them with relevant areas of interest. This wide range of systems, which includes clinical and organizational data, makes it an area with a lot of potential. Business intelligence systems are crucial for these entities, which require tools capable of organizing data in a more perceptible way [6,7]. The rise of artificial intelligence (AI) has led to a profound reflection on these systems, allowing them to be transformed to integrate future data and provide advice on optimal decision-making that affects organizational management [3,8,9]. Improving the decision-making process

XSL•FO
RenderX

requires combining data storage with analytical tools, applications, and methodologies, and it aims to incorporate and find relationships between existing data [10]. This provides real-time access and facilitates the proper analysis of historical and current data, obtaining insights that were not possible before [11,12].

For a long time, one of the most discussed topics in hospital organizations has been the surgical scheduling problem (SSP). Surgical scheduling was worsened by the COVID-19 pandemic, as numerous specialties had to halt their treatments in order to prioritize the treatment of other patients. There have been clear repercussions from this management change, including an increase in the number of patients on waiting lists and a need for managers to find clinically and organizationally effective approaches to reduce them. A study was carried out in collaboration with the Centro Hospitalar e Universitário de Santo António (CHUdSA) to determine whether a metaheuristic approach could be implemented in a hospital organization as a strategy to reduce waiting time.

Related Work

Room planning is a task that needs to be addressed in many fields, particularly within health care, and it includes planning operating rooms (ORs) for surgeries. Cost containment and reduction have emerged as primary objectives in health care management, with hospital managers and professionals trying to understand each factor contributing to the total cost of delivering better services. ORs are one of the areas that have been gathering considerable attention since they are the most critical cost center and consume a large proportion of the hospital's total expenses. Consequently, ORs have substantial potential for cost savings, and the SSP has been studied and has generated a variety of approaches and heuristics [13]. Currently, there is a growing trend in adopting computational tools based on optimization methods. As outlined by Cortez [14], optimization methods are divided into 3 main categories: blind search, local search, and population-based search. Blind search assumes the exhaustion of all alternatives, guaranteeing that all solutions are tested. It is only admissible for discrete search spaces and is easy to implement. The major disadvantage of this technique is its feasibility when the search space is continuous or too large. It tends to require more computational effort since the search is performed through a set of candidate solutions rather than a single solution. Local search is the most modern optimization technique and is based on new solutions that are generated from existing ones. Several methods focus on a local neighborhood through a given initial solution and use previous searches to guide the next. Population-based search presents a new approach to optimization algorithms, using a set of candidate solutions instead of one [15].

Studies conducted by the scientific community suggest that metaheuristic optimization models are promising as a potential solution to the problem at hand, although they diverge on the primary factors directly impacting the performance of a surgical schedule. Some studies adopt a more specific approach, such as the one developed by Fügener et al [13], which introduces a variable called planned capacity slack for OR days with the application of the simulated annealing (SA) algorithm to minimize planned slack and maximize OR use. The planned slack aimed to minimize overtime by absorbing the variability of surgery duration. Min and Yih [16] designed a calendar for patients with uncertain surgical operations. The calendar accounted for the uncertainty in the period of surgery and the availability of resources, such as the surgical intensive care unit, using a stochastic approach to minimize the sum of costs directly related to patients and the expected costs associated with overtime work. Visintin et al [17] propose that creating an effective surgical scheduling system requires grouping patients into homogeneous surgical groups, developing an approach solely focused on this constraint and scheduling surgical groups rather than actual patients. Most authors state that the performance of an OR depends mainly on how surgical activities are scheduled. This perspective is reflected in the study conducted by Su et al [18], which proposed a self-organizing map-based optimization (SOMO) approach to solve the SSP. Banditori et al [19] also introduced a mixed integer programming model, assuming that a hospital's waiting list cases could be categorized into homogeneous surgical groups based on their anticipated resources. Agnetis et al [20] adopted a surgical scheduling model that was updated on a weekly basis, allocating various specialties to available sessions and considering only patients immediately eligible for surgery, and patients were selected from a waiting list based on parameters such as surgery duration and waiting time. More recently, a similar approach by Brit et al [21] considered multiple factors (including surgeons, equipment, ORs, and recovery ward beds) in their optimization strategy to meet waiting time objectives by maximizing OR use. Tyagi et al [22] explored various models and techniques used for scheduling, emphasizing the importance of strategic (long-term), tactical (medium-term), and operational (short-term) scheduling levels and demonstrating that daily planning and scheduling using detailed procedural times and sophisticated algorithms substantially enhanced OR use. Wang et al [23] proposed a fuzzy model, integrated with a hybrid genetic algorithm for optimization, to address variability and unpredictability in scheduling processes. The model effectively balanced the costs and benefits associated with using an overflow strategy, where patients were assigned to undesignated departments to better manage capacity.

Despite the varied development approaches and the implementations of algorithms, different perspectives have emerged regarding the timescale and surrounding constraints, highlighting the absence of standard approaches to the SSP that conclusively prove effectiveness compared to current hospital management practices. There is a scarcity of accurate proposals to inform the establishment of standard rules and guidelines to manage surgery scheduling without affecting the organizational policies of different surgical specialties. Therefore, this study aimed at demonstrating the effectiveness of a selected set of optimization algorithms, customized to time and resource allocation problems, in addressing common scheduling constraints across various specialties. The primary goal is to provide a more comprehensive solution applicable to different health care organizations.

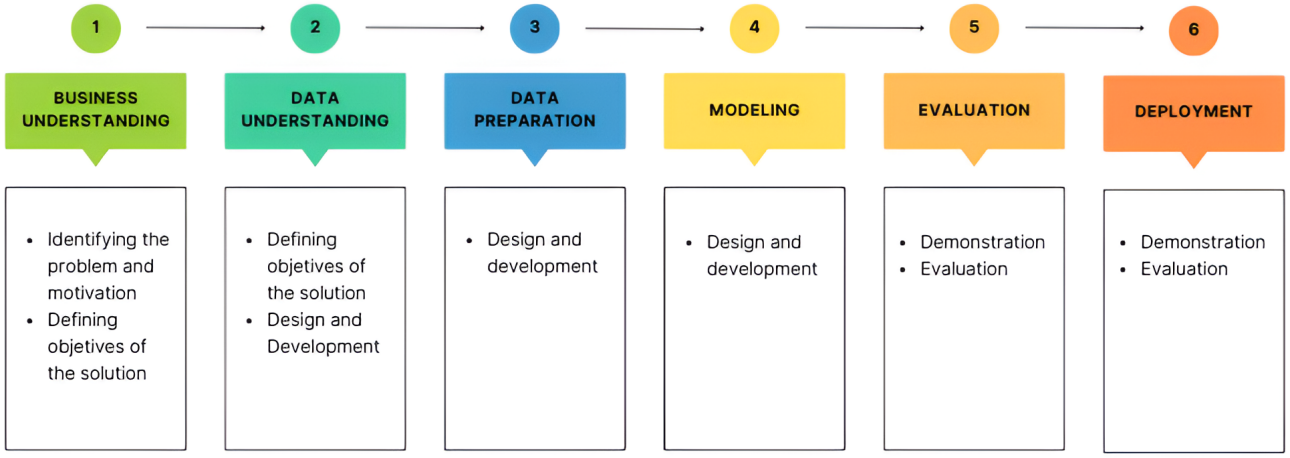
Methods



Ethical Considerations

This study was based exclusively on anonymous data provided by the organization involved in this research and did not involve sensitive personal information. Therefore, ethics board review in accordance with the General Data Protection Regulation (GDPR) was not required.

Study Design

An optimization model–based approach was developed to demonstrate the application of heuristic algorithms. Our analysis focuses on optimizing the temporal allocation of surgeries, depending on the date they were placed on the waiting list and their priority. For this, two methodologies were followed: the design science research (DSR) and the cross-industry standard process for data mining (CRISP-DM). DSR consisted of 6 phases: identification of the problem and motivation, definition of objectives of the solution, design and development, demonstration, evaluation, and communication. These phases provided guidelines for a research project [24]. To put DSR in action, it was necessary to use a practical methodology for data mining projects. The CRISP-DM method provided a global perspective on the life cycle of a data mining project, and it comprised the following 6 stages: business understanding, data understanding, data preparation, modeling, evaluation, and deployment [25]. There were dependencies between the stages, and they did not have a rigid structure [25]. Since both methodologies were used concurrently, the relationship between them throughout the project phases was described (Figure 1).

Figure 1. Crossover of the design science research (DSR) and cross-industry standard process for data mining (CRISP-DM) methodologies.

Problem Statement

Hospital administrators attempt to reduce costs while providing the best care possible for their patients. To achieve this aim, they take into account a number of factors that directly affect the quality of surgery scheduling. These factors include the number of professionals available for each day, the specialty related to each type of diagnosis, the availability of slots, and the ability to perform new admissions, with an aim of continuously reducing waiting time. Under this perspective, the surgical area of a hospital was the main optimization target for the development of a metaheuristic method. Each surgical area of a hospital was made up of *S* ORs, a finite *H* number of days, and a group of *N* patients who were waiting for a surgical appointment. Thus, the algorithm allocated patients to available ORs and determined the sequence of surgeries to be performed. A surgery time *ST* was assigned to each patient in *{1, ...N}*. This time included the period of a procedure as well as extra time for preoperative cleaning and preparation. Depending on the type of study, an organization may establish different restrictions that directly influence how the algorithm generates solutions, which are referred to as hard (primary objectives) and soft (secondary objectives) constraints.

Finally, the goal was to define a global optimization strategy for more than one specialty. Hard constraints included a maximum limit for the number of candidates assigned to a vacancy, room capacity constraints, and time constraints, so that the algorithms always considered shifts that were available in certain time blocks. Simultaneously, this included reducing the number of patients whose surgeries exceeded the time limit of the guaranteed maximum response time. Additionally, it was possible that not all ORs were open every day, with some ORs only open during specific times. Each shift therefore indicated the day and the OR. The following points were design factors for this approach:

1. Each specialty was assigned one, more than one, or no OR. These assignments were decided in the stage before the block schedule.
2. Patient priority was defined based on medical and waiting time factors, always considering a prioritized patient list for surgeries.
3. Each surgical specialty managed its patients independently.
4. The hospital contained a specific set of ORs, which each one being unique and adapted for certain types of interventions.
5. A surgery that was programmed after its deadline earned a penalty depending on the priority.
6. Each surgery had information regarding the time required to clean the room and prepare it for next surgery.
7. A patient could not be operated on more than once in the same scheduling period.

XSL•FO
RenderX

For this algorithm, all surgeons were able to be assigned to a surgery. Daily availability plans of the CHUdSA were also considered so that a specific surgery allocation respected the existing resources for each day, namely the number of ORs and available medical professionals. The following sections explain the heuristic approaches.

Data Understanding and Preparation

The surgery data analyzed was considered event-based. Each surgery undergone by a patient represented an event associated with a medical specialty at a specific time, comprising the execution of all requisite procedures. Additionally, data containing information related to the time blocks available in each specialty were used. The data were derived from medical specialties previously selected by the CHUdSA interlocutors, including a scheduling process carried out in 2019. This time frame was chosen since the hospital administration did not take pandemic constraints into consideration, making it possible to examine a scheduling procedure under standard circumstances without any unusual restrictions.

Proposed Metaheuristic Algorithms

Overview of Metaheuristic Algorithms

Metaheuristic algorithms are search procedures designed to find better solutions to an optimization problem that is considered complex to solve [26]. They are categorized according to how they operate in the search space and how new solutions will be discovered [14] such as nature-inspired versus non–nature-inspired, population-based versus local search, dynamic versus static objective functions, and one versus multiple neighborhood structures [27]. The typical structure is based on 3 main code sections: (1) initial solution, representing the first structure of the problem and ensuring an initial guess, often called a “starting point” for the algorithm; (2) evaluation function, which analyzes a possible solution in the context of the problem, comparing different solutions and providing a ranking or a quality measure score; and (3) objective function, which is composed of the implementation of different optimization algorithms [28].

Hill Climbing

Hill climbing (HC) is a local optimization algorithm that climbs a hill until a local optimum with the goal of maximization. The method iteratively searches for new solutions inside the existing solution’s neighborhood, adopting a new solution if it is better than the previous one [29]. The purpose is to discover an improvement by running an extensive search within the defined neighborhood borders and the ability of the algorithm to produce successful results is determined entirely by the initial solution [14,15].

Simulated Annealing

Metropolis et al [30] designed SA, which is primarily inspired by a cooling operation in heating-based metallurgy. SA begins with a randomly generated initial solution and a high-temperature *T*. During the cooling phase, the algorithm will converge to an estimated solution, moving away from the local optimum to locate the near-optimal solution, and the method will grow more accurate with each iteration to obtain a better solution [14]. Another solution will be randomly created near the initial solution and the difference in function values is calculated as follows:

$$(1)\Delta=fxn-fxc$$

If the Δ is smaller for the new solution, the new solution automatically becomes the current solution from which the search will continue [26].

Particle Swarm

In 1995, Kennedy and Eberhart conducted a study on the social behavior of a group of animals and concluded that being in a group increases one’s chances of surviving [14]. This is corroborated by the fact that species share information, which increases the probability of finding the optimal hunting location. The particle swarm (PS) algorithm operates on this conceptual foundation, attempting to identify the best solution in a high-dimensional space. It aims at either maximizing profits or limiting losses. There can be multiple local maximums and minimums in a function but only one global maximum and/or minimum. In summary, PS is a population-based algorithm and can be defined by the direct and indirect interactions between distinct sets of information that affect the results obtained, consequently preserving an organized pattern among the dataset [14].

Modeling the Initial Solution

By assigning one slot to each input operation, the initial solution was obtained in random or sequential slots using the list of specialist surgeries. Depending on the number of slots and surgeries, the bottom and upper parameters were defined as the highest and lowest values for each dimension. The initial solution was obtained by assigning surgeries in available slots for a specific specialty and was implemented by the first fit approach [31,32]. The challenges with this initial method were respecting the time limits connected with each surgery and the turnovers associated with the addition of surgeries to a particular slot. It was also decided that the production of the first solution should include all potential constraints. The graphical representation of how the first solution was generated is included in Multimedia Appendix 1.

The performance was evaluated using a function designed for this purpose. Each solution examined the assigned surgeries by specifying a total solution penalty (*pt*), calculated using the sum of each penalty *p* earned in a surgery, as shown mathematically below:

$$(2)pt=\sum i=1ipi$$

Each penalty was calculated by multiplying the number of days that the surgery was overdue by each deadline (*ds*) and the priority associated with that same surgery (*pr*), presented in the following equation:

$$(3)p=fds-f(pr)$$

Modeling the Objective Solution

HC Implementation

Different algorithms were used to model the objective solution, which through several iterations, search for a better solution

XSL•FO
RenderX

than the existing one. For each iteration, a total penalty was given to the surgeries, making comparisons with other solutions. The iterations ended at the defined limit, returning the best solution. HC implementation was retrieved and adapted from Cortez [14] and could be represented by the following function: *hclimbing* (*par*, *fn*, *change*, *control*, *type*). The input variables were presented as follows:

1. The initial solution (*par*) was obtained by allocating the surgeries to available slots (explained in previous section).
2. The evaluation function (*fn*) evaluated the total penalty of the allocated surgeries.
3. A change function (*change*) was responsible for generating the next candidate, creating minor disturbances in the initial solution by swapping surgeries between different slots and evaluating if this was profitable.
4. The variable *control* was a list that indicated the number of interactions to execute and the information to collect throughout the solution.
5. A last variable (*type*) indicated the main goal of minimization.

SA Implementation

SA implementation was also adapted from Cortez [14]. It used a variable temperature as opposed to HC, which chose a fixed value for this control parameter. Starting at a high temperature, the method gradually lowered the control parameter until it reached the desired minimum value or a predetermined number of iterations. The following function represents the SA implementation: *simulated_annealing* (*func*, *par*, *niter*, *step*). The input variables were presented as follows:

1. The evaluation function (*func*) that computed the total penalty, similar to HC.
2. The initial solution (*par*), also similar to HC.
3. Maximum number of iterations (*niter*).
4. Parameter to control the cooling speed of the model (*step*).

PS Implementation

The implementation of PS followed a different perspective from that presented in the other two models. It is an algorithm that seeks to efficiently search within a specified boundary, using the iterations between particles to find the best solution possible [14,33]. The implementation of this method was obtained by the *psoptim* method from the *pso* package [34]. The function described has 6 input parameters: *psoptim* (*par*, *fn*, *lower*, *upper*, *control*, *eval_func*). These were represented by the following:

1. Vector containing the initial list of surgeries to schedule (*par*).
2. Penalty minimisation function (*fn*).
3. Lower bounds on the variables, belonging to the minimum scheduling shift (*lower*).
4. Upper bounds on the variables belonging to the maximum scheduling shift (*upper*).
5. List of control variables (*control*) belonging to the best solution found, number of interactions, swarm size, and continuous trace of solutions found.
6. Evaluation function to compute the total penalty (*eval_func*), similar to the other methods.

Results

The number of surgeries performed by each specialty and the number of surgeries performed after the established deadline could be used by the CHUdSA to categorize its OR management. Such variables determined the total penalty of the hospital, which translated into costs that the hospital would have to assume. Table 1 represents a general analysis of the existing data, considering the specialties chosen for this study, to understand the relationship between the number of surgeries being allocated and the number of existing slots for each specialty. For the specialties that were chosen, the number of surgeries to be allocated was higher than the number of existing slots. In this case, optimizing ORs was required to handle the greatest number of surgeries with available resources.

Table . General analysis between number of surgeries in each specialty with available operating rooms.

Medical specialties	Number of surgeries	Number of time slots
Obesity	198	122
Urology	133	89
Pediatric plastic surgery	98	45

The first approach was carried out to understand which algorithms obtained the best performance and considered the optimization objective, which was the minimization of the penalty and the maximization of the number of surgeries scheduled within the deadline. Table 2 summarizes the values obtained in implementing the algorithms described above.

Table . General analysis of optimization algorithms performance.

Algorithms	Penalty score by medical specialty		
	Obesity (n=198)	Urology (n=133)	Pediatric plastic surgery (n=98)
Hill climbing	0	0	0
Simulated annealing	5100	1240	30
Particle swarm	42,702	30,000	53,108

XSL•FO
RenderX

Since this initial approach considered a first custom solution with the defined scheduling rules, the local search algorithms obtained better scheduling performances. Consequently, a deeper examination of the HC and SA algorithms was done. The implementation of these algorithms led to a set of results presented in Tables 3 and 4. These values compared the performance of the algorithms in response to SSP.

Table . Measure of the impact of the hill climbing (HC) algorithm.

Discussion

Overall Results

Through the implementation of these algorithms, compared to CHUdSA's manual scheduling process, several results were found. First, the penalties for the optimization algorithms developed were lower than the penalty of scheduling done by CHUdSA professionals, and in certain situations, there were no penalties for the algorithms. Therefore, both local optimization algorithms can provide improvements to the administration and organization of ORs. Second, the PS algorithm was not a viable solution to the SSP, since its ability to minimize the scheduling penalty was much lower than the HC and SA algorithms. It was evident that local search algorithms produced better solutions on all existing criteria, compared to the population-based search algorithm. Third, Figures 2 and 3 represent the evaluation of scheduling over time for each surgery, providing an understanding of whether the respective algorithm scheduled a surgery for before or after the day it was performed in the CHUdSA. The majority of surgeries could have been scheduled and carried out days earlier for either of the local HC and SA optimization algorithms. Fourth, the number of surgeries that remained to be scheduled occasionally exceeded the number that the CHUdSA professionals had anticipated. Furthermore, some surgeries could not be scheduled in this optimization process because their minimum execution time exceeded the maximum duration of an existing shift. These surgeries were always handled as exceptional cases at the recommendation of CHUdSA professionals. Therefore, from a management perspective, the professionals personally should schedule the surgeries in accordance with specific internal protocols.

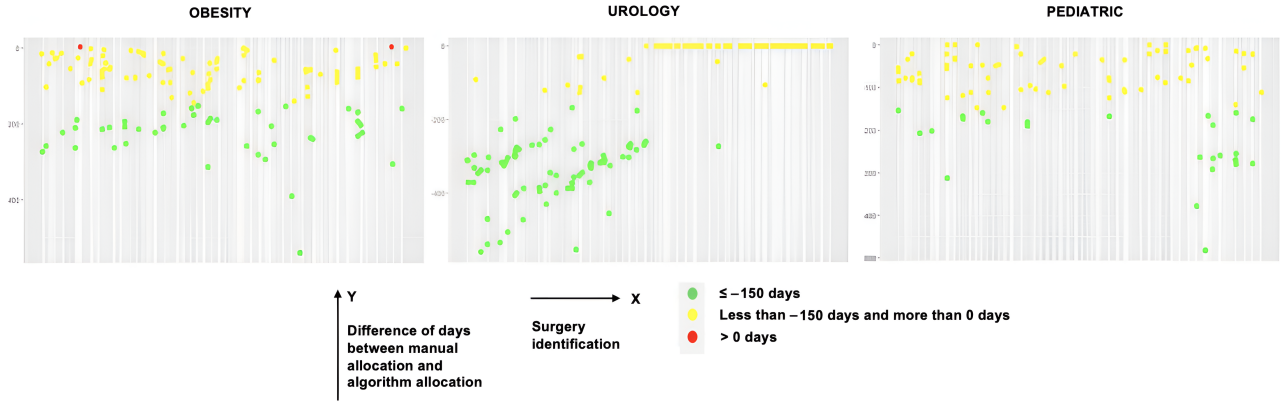
RenderX

Figure 2. Hill climbing evaluation and overall performance by surgeries.



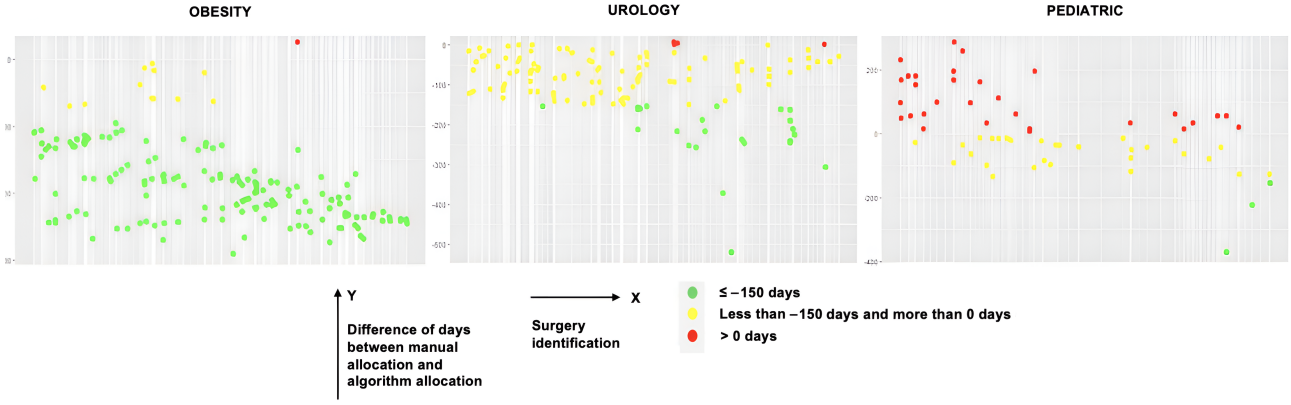


Figure 3. Simulated annealing evaluation and overall performance by surgeries.

Key Findings

Figures 2 and 3 highlight that it is possible to more effectively allocate surgeries within the same time frame despite using the same resources. Leveraging the specification of a set of global variables for enhancing the scheduling process, 4 significant conclusions can be drawn. First, scheduling was greatly improved when the initial solution was modeled using a surgery allocation algorithm that took waiting list longevity and priority into account. The final penalty was lowered, demonstrating the potential to enhance surgical management within the constraints of time and space. Second, the HC algorithm had the best performance, with the SA algorithm producing similar results. However, the PS algorithm was not able to improve surgery allocation and occasionally arranged surgeries worse in terms of time and space. For these reasons, it was discarded.

Third, the HC and SA algorithms were particularly noteworthy since they arrived at the ideal number of iterations after 100 iterations. Thus, these algorithms could yield significantly better planning than manual hospital allocation with a runtime of approximately 30 seconds. These results also supported the exclusion of the PS algorithm for future implementations, as it was a more computationally demanding model. Fourth, the application of AI-based heuristics resulted in a notable enhancement in the quantity of surgeries allocated. Therefore, there is potential for improving OR management with a system capable of maximizing the scheduling procedure for each speciality, demonstrating how the scheduling solutions assigned by the HC and SA algorithms differ significantly in terms of space and time. In terms of a decision support system, it may be best to offer the user a variety of scheduling solutions based on these implemented optimization models, even though it is not necessary to determine which is the better solution. As a result, the user can select the planning that best fits the group of surgeries that require scheduling.

Comparison With Prior Work

Based on the development and use of optimization algorithms, the proposed research presents an innovative approach for scheduling surgeries from waiting lists. It is crucial to emphasize the primary objective of reducing costs, considering a variety of factors involving different medical specializations. In contrast to prior studies, the research by Fügener et al [13] focuses on the integration of HC and SA to optimize the use of ORs. Min and Yih's study [16] concentrates on a stochastic surgical calendar tailored for patients with uncertain surgical needs. Similarly, Banditori et al [19] categorized waiting list cases into homogeneous groups, offering a more adaptable solution for diverse medical specialties. However, because the criteria used to make decisions vary among medical specializations, research so far has never produced conclusive and sufficient evidence to support their widespread use in health care organizations. This work stands out from other studies since it uses global and specific variables that are readily applied to any medical specialty without compromising the quality of surgical scheduling, a key factor in reducing operating costs in hospitals. By diverging from previous models and overcoming their limitations, this study provides a more precise and effective solution aimed at maximizing the performance of ORs,

XSL•FO
RenderX

benefiting both the patients and the health care professionals involved in the surgical process.

Conclusions

The study of allocation and scheduling problems is considered complex. When it comes to health care, the responsibility to create an effective solution is even more significant since the priority must always be the care that is provided to patients, while also being aware of the existing resources. The approach developed in this study not only provides a solution to this scheduling problem but also conceives a generic adoption for any health care organization and for a considerable number of medical specialties.

Considering a general constraints model for any health care organization and considering the same constraints for the generation of the initial solution, the implementation of an automatic allocation algorithm proves the ability to find better solutions for surgery scheduling. The HC and SA algorithms demonstrate the capacity to improve the use of ORs and consider, as a reference, the scheduling limit without accumulating penalties. The PS algorithm proved that it needs a greater computational effort. The fact that it does not use an initial solution, according to previously defined programming rules, can explain its unclear results.

Taking into consideration all of the limitations of scheduling and the high level of organizational complexity, this study's approach can be considered as a possible solution to the SSP as it contributes to the organization of surgeries based on time and cost control, which are crucial to optimize operating costs. HC and SA show extremely satisfactory results, decreasing the number of surgeries with penalty (ie, surgeries with a scheduled date higher than the deadline date). Additionally, these models provide a near optimal solution, reaching a stabilization point after 100 iterations, since the initial solution had already produced very satisfactory results. In addition, from a total of 429 surgeries and considering all specialities, the HC algorithm managed to schedule 415 (96.7%) surgeries, and the SA algorithm scheduled a total of 362 (84.4%) surgeries. The majority of these surgeries were special cases where their duration exceeded the maximum time available each day. In some cases, the number of surgeries not scheduled by the algorithms was higher than the scheduling performed by the hospital, although this is not considered a negative point of this solution.

The proposed application has addressed multiple challenges, offering a scalable solution across diverse organizational frameworks. However, to deepen the utility and precision of our approach, several topics about limitations and future work have been identified. First, testing this study in other health care organizations will be a crucial step to understand if our approach works in different contexts. In addition, it is necessary to improve the accuracy of each estimated surgery time to increase the reliability of the schedule. In this study, an interquartile mean was used to associate each type of surgery through time history, but a more accurate method is needed for an optimal accuracy. Machine learning models could be used to predict the times of each surgery for greater reliability, which is a crucial factor in the allocation of surgeries.

Second, it is also possible to consider more constraints, including subspecialties, in this mapping. This is considered a significant step since the division of ORs includes an allocation to each subspecialty and requires a complete mapping between specialties and the *International Classification of Diseases, Tenth Revision* (*ICD-10*) codes. Third, a deeper study on the nullification of the scheduling penalty may be considered. While a hospital would like to pay the least amount related to surgeries scheduled after the deadline, it may be pertinent to identify whether a proposal with a higher penalty will better serve the scheduling interests. Fourth, another even more complex proposal is to condition the surgical mapping by considering the human resources available for each period. While this is not possible in the current context considering the available data, an annual organization of medical professionals (surgeons, nurses, anesthesiologists) in real time is necessary. Last, improving the efficiency of the optimization method by exploring more models and their configurations is another direction to consider in future research.

The results of this study are summarized below, highlighting the key messages and anesthesiologists that underline the transformative potential of this approach in health care scheduling. First, the integration of AI-based heuristic algorithms improves the efficiency of surgical scheduling, leading to a reduction in patient waiting times. Second, the HC and SA algorithms have demonstrated a higher performance than the scheduling performed by CHUdSA, and either model make it possible to reduce costs in the scheduling process by reducing the penalties associated with surgeries scheduled beyond the deadline. Third, the models developed do not compromise scalability and adaptability, as they can be adapted to various contexts and medical specialties, and a generalized implementation is possible by adding or removing restrictions. Last, the potential of a system that is capable of integrating these models in any organization is proven, optimizing the inherent management processes and consequently the health care provided to patients.

Adopting this approach following these research directions promises to further refine the metaheuristic optimization models for surgery scheduling, ultimately seeking more optimized and agile health care systems that are patient-centered and cost-effective.

Abstract

Background: Due to the acceleration of the aging population and the prevalence of unhealthy lifestyles, the incidence of cardiovascular diseases (CVDs) in China continues to grow. However, due to the uneven distribution of medical resources across regions and significant disparities in diagnostic and treatment levels, the diagnosis and management of CVDs face considerable challenges.

Objective: The purpose of this study is to build a cardiovascular diagnosis and treatment knowledge base by using new technology, form an auxiliary decision support system, and integrate it into the doctor's workstation, to improve the assessment rate and treatment standardization rate. This study offers new ideas for the prevention and management of CVDs.

Methods: This study designed a clinical decision support system (CDSS) with data, learning, knowledge, and application layers. It integrates multimodal data from hospital laboratory information systems, hospital information systems, electronic medical records, electrocardiography, nursing, and other systems to build a knowledge model. The unstructured data were segmented using natural language processing technology, and medical entity words and entity combination relationships were extracted using IDCNN (iterated dilated convolutional neural network) and TextCNN (text convolutional neural network). The CDSS refers to global CVD assessment indicators to design quality control strategies and an intelligent treatment plan recommendation engine map, establishing a big data analysis platform to achieve multidimensional, visualized data statistics for management decision support.

Results: The CDSS system is embedded and interfaced with the physician workstation, triggering in real-time during the clinical diagnosis and treatment process. It establishes a 3-tier assessment control through pop-up windows and screen domination operations. Based on the intelligent diagnostic and treatment reminders of the CDSS, patients are given intervention treatments. The important risk assessment and diagnosis rate indicators significantly improved after the system came into use, and gradually increased within 2 years. The indicators of mandatory control, directly became 100% after the CDSS was online. The CDSS enhanced the standardization of clinical diagnosis and treatment.

Conclusions: This study establishes a specialized knowledge base for CVDs, combined with clinical multimodal information, to intelligently assess and stratify cardiovascular patients. It automatically recommends intervention treatments based on assessments and clinical characterizations, proving to be an effective exploration of using a CDSS to build a disease-specific intelligent system.

Introduction

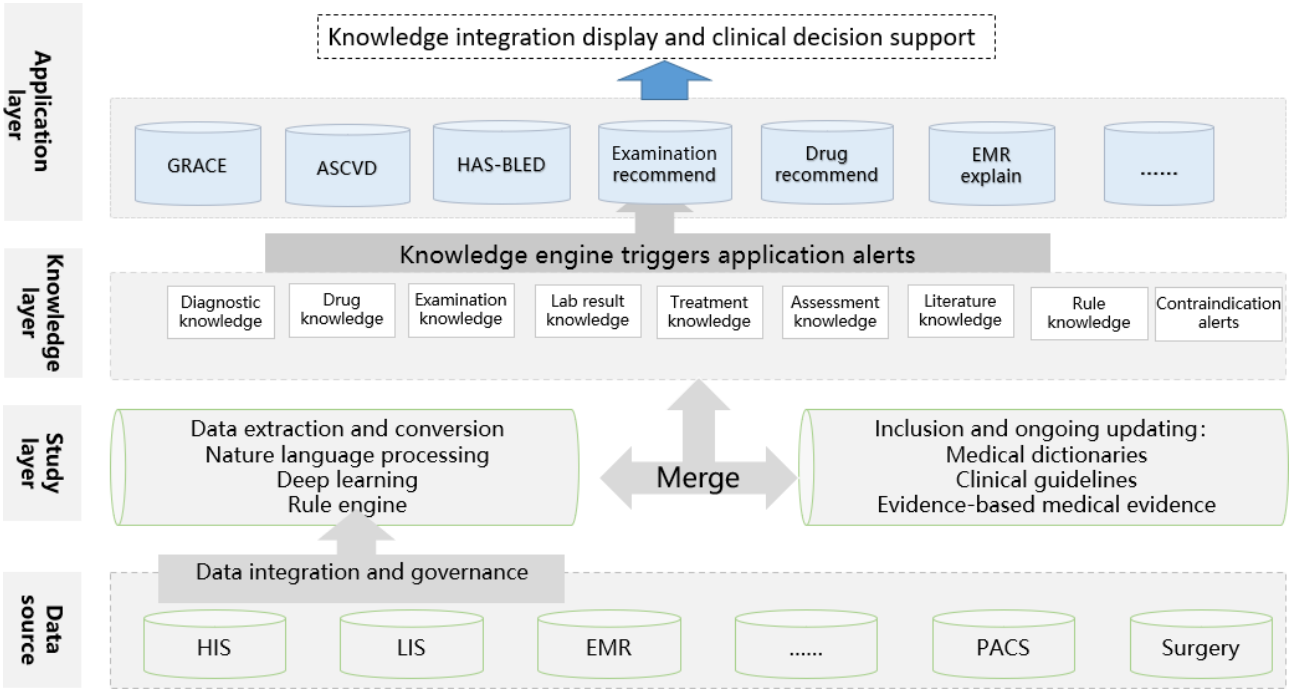
The high incidence of cardiovascular disease (CVD) is an important public health problem worldwide. CVD remains the leading cause of mortality worldwide and a major contributor to disability. CVD was responsible for 18.6 million deaths according to the 2019 Global Burden of Disease study. China is one of the countries most burdened by CVD [1]. In 2021, approximately 5.1 million individuals lost their lives to CVD in China [2]. Thus, it is of great significance to raise awareness of CVD and screening individuals at risk for CVD so that effective interventions and strategies can be implemented. CVD is influenced by risk factors such as tobacco use, an unhealthy diet, physical inactivity, obesity, elevated blood pressure, abnormal blood lipids, and elevated blood glucose [3,4]. In 2007, the World Health Organization published guidelines for the assessment and management of cardiovascular risk that provide guidance for reducing disability and premature deaths from CVD in people at high risk who have not yet experienced a cardiovascular event [5]. In addition, new artificial intelligence technology for CVD prediction and risk management has been attempted [6,7].

The 2022 China Cardiovascular Health and Disease Report Summary highlights that the rapid aging of the population and the widespread prevalence of unhealthy lifestyles have resulted in a significant portion of the population being at risk for CVD, and the burden of CVD continues to rise, as evidenced by persistently high prevalence rates, increasing mortality, and escalating treatment and management costs [8-10]. The prevention and treatment of CVDs in China presents significant challenges. In recent years, several medical policies have prioritized this issue. From 2021 to 2023, the China National Health Commission made “improving the reperfusion treatment rate for acute ST-segment elevation myocardial infarction (MI)”, “improving the reperfusion treatment rate for acute ischemic stroke”, and “improving the standardized prevention rate for venous thromboembolism (VTE)” in the national top ten medical quality and safety improvement objectives. Additionally, the “Opinions on Promoting High-Quality Development of Public Hospitals” issued by the State Council Office in May 2021, emphasized cardiovascular and cerebrovascular diseases as key clinical specialties for the high-quality development of public hospitals.

Clinical decision support systems (CDSS) leverage health information technology to provide health care professionals with intelligent decision-making tools, aiming to improve medical quality, reduce errors, and improve patient outcomes [11-13]. CDSS can offer various forms of support, including diagnostic recommendations, treatment plan selection, and medication dosage calculations, based on a comprehensive medical knowledge database and patient-specific data. The primary objective of CDSS is to optimize clinical decisions by integrating clinical observations with knowledge bases, ultimately improving patient outcomes [14]. In recent years, CDSS has been preliminarily applied in some specific medical scenarios, such as chronic obstructive pulmonary disease patient management, antibiotic management, and venous thromboembolism management [15-17]. In the process of prevention, diagnosis, and treatment of CVDs, some researchers have also used Machine Learning, big data and other new technologies to carry out research on the prediction of Major Adverse Cardiovascular Events and disease onset [18-20].

Currently, there are several challenges in the diagnosis, treatment, and management of CVD. Uneven allocation of medical resources in different regions leads to large gaps in diagnosis and treatment levels. Insufficient disease awareness leads to a low rate of early CVD diagnosis, while reliance on manual risk assessment forms leads to inefficient risk prediction. The standardization of clinical diagnosis and treatment requires improvement. The quality control method relies on sampling and examination of terminal medical records, which is backward and passive. Therefore, this study proposes the use of CDSS technology combined with multimodal clinical information to intelligently assess and stratify cardiovascular patients. By integrating CDSS with the hospital’s doctor workstation system, auxiliary diagnosis, and treatment are seamlessly incorporated into clinical workflows, leveraging a powerful knowledge base and intelligent models to provide physicians with intelligent recommendations. Based on these assessments and clinical characteristics, it intelligently recommends intervention treatments, offering novel insights for prevention, treatment, and management strategies for CVDs.

Methods



CDSS Design

The CDSS in the study has a 4-tier architecture shown in Figure 1. Initially, the foundation of decision support is rich data information at the data source layer. Information such as medical orders, medical records, lab tests, examinations, surgery records, etc, are collected and integrated through hospital information integration platforms and data centers. For historical data, the Extract-Transform-Load tool was used to integrate various information systems. For the real-time human-computer interaction data, the data transmit interface was triggered by clicking the temporary save button or mouse movement. For the study layer, based on deep learning, knowledge graphs, rule engines, clinical pathways, and guidelines, the processing process of word segmentation, named entity recognition, and relationship extraction was completed to realize the output of structured variables and data standardization. A triple data set of entity-relationship-entity was formed to construct the clinical knowledge map. Then for the knowledge layer, different types of knowledge representations were established through the previous learning, such as diagnostic knowledge, drug knowledge, examination knowledge, assessment knowledge, literature databases, contraindication alerts, and others. We developed flexible knowledge maintenance tools to maintain the knowledge base according to the characteristics of clinical specialties in hospitals, and provide intelligent recommendation, intelligent early warning, and intelligent audit functions for doctors. Finally, at the application layer, Through the front frontpage parameter docking and the message transmission of the data integration platform, the doctor workstation information is encrypted and transmitted to the CDSS, and the CDSS intelligent prompt module is triggered when ordering medical

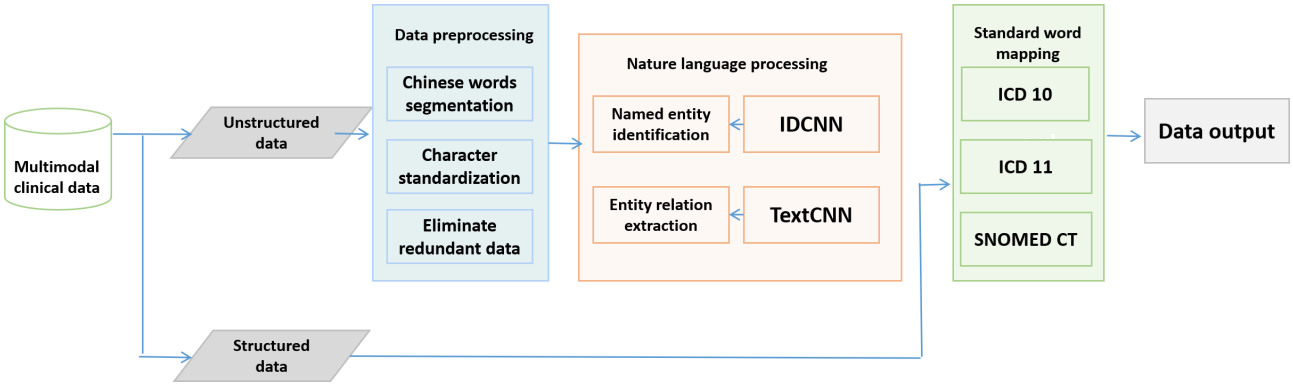
XSL•FO
RenderX

orders, writing medical records, transferring departments, operating and discharging for each patient of the doctor system. Intelligent decision support is triggered like drug recommendations, examination recommendations, Global Registry of Acute Coronary Events (GRACE) evaluation, atherosclerotic cardiovascular disease (ASCVD) evaluation, etc.

Figure 1. The design of clinical decision support system for cardiovascular disease. ASCVD: atherosclerotic cardiovascular disease; EMR: electronic medical record; GRACE: Global Registry of Acute Coronary Events; HAS-BLED: hypertension, abnormal renal or liver function, stroke, bleeding history or predisposition, labile international normalized ratio, elderly (>65 years), drugs or alcohol concomitantly; HIS: hospital information system; LIS: laboratory information system; PACS: picture archiving and communication system.

The system is specifically designed for patients who are hospitalized due to CVDs, and it can facilitate diagnosis and treatment by incorporating their comprehensive medical data.

Ethical Considerations



The study was approved by the Ethics Committee of the First Affiliated Hospital of Nanjing Medical University (2023-SR-743). As this study did not involve a process in which informed consent must be obtained for routine care and the contents of the study do not involve personal privacy, the ethics committee waived the requirement for written informed consent.

Multimodal Data Fusion Processing

Artificial intelligence (AI) technology is used to integrate multimodal data related to CVD diagnosis- which is dispersed across various hospital systems including hospital information systems, electronic medical records (EMR), laboratory information systems, PACS (picture archiving and communication system), and nursing systems. Through natural language processing (NLP) and medical terminology mapping, a knowledge model is developed. The structure of the NLP module, core deep learning algorithms, and resources are presented in Figure 2. First, preprocessing is performed on unstructured text, including sentence segmentation for word segmentation, standardization of symbols, uniformization of capitalization, reorganization of standardized vocabulary, elimination of less meaningful parts, and formation of summaries that express the main meaning. Then, the named entity recognition model using the BiLSTM-CRF (bidirectional long short-term memory - conditional random field) and IDCNN (iterated dilated convolutional neural network) architecture to extract medical entity words such as time, anatomical site, diagnosis, drug name, drug dose, and surgical name [21]. Next, the entity relationship linking model uses the TextCNN (text convolutional neural network) architecture to extract medical entity combination relationships such as diagnosis-anatomical site-position-time as a group [22]. Then, the core entities such as diagnosis, laboratory tests, drug names, and attribute entity words such as time, existence status, and drug dosage are mapped to medical standard words. Finally, according to entities and the relationship between entities, a disease auxiliary decision support model using CNN-DSSM (convolutional neural network - deep semantic similarity model) is constructed, which can provide a list of diagnostic probabilities and recommend reasonable examinations according to the patient's chief complaints and medical history, to assist doctors in diagnosis and reduce the probability of missed diagnosis and misdiagnosis.

CVD Assessment Models and Recommendations

This study focuses on the diagnosis and treatment of common CVDs by incorporating assessment models such as GRACE, ASCVD, CHA2DS2-VASc (congestive heart failure, hypertension, age ≥75 years [doubled], diabetes, stroke [doubled], vascular disease, age 65 to 74 years and sex category [female]) for stroke risk evaluation in patients with nonvalvular atrial fibrillation, alongside other intelligent diagnostic and treatment recommendation systems [23-25]. Using the stratified GRACE risk assessment as an example [26-28], NLP technology was applied to gather data from various clinical systems, including age, heart rate, systolic blood pressure, serum creatinine, positive initial heart markers, ST segment changes, cardiac arrest at admission and Killip class [29,30]. Based on the risk assessment outcomes, distinct levels of low risk, medium risk, high risk, and extremely high risk were established. Subsequently, as shown in Table 1, corresponding quality control strategies and treatment plan recommendations were developed for each risk category.

Table . GRACE (Global Registry of Acute Coronary Events) risk assessment results and related recommendations.

Risk level	GRACE score	In-hospital mortality (%)
Low risk	≤108	<1
Moderate risk	109 - 140, or combined with diabetes mellitus, renal insufficiency, LVEF[a] <40%, chronic cardiac insufficiency, angina pectoris after early myocardial infarction (MI), PCI[b] history, or CABG[c] history	1 - 3
High risk	>140, or the presence of MI-related troponin rise or fall, ST-T[d] dynamic changes (with or without symptoms)	>3
Extremely high risk	Regardless of score, Presence of any of the following: hemodynamic instability or cardiogenic shock, recurrent or persistent chest pain refractory to medical therapy, fatal arrhythmia or cardiac arrest, MI with mechanical complications, acute heart failure, recurrent ST-T dynamic changes (especially intermittent ST-segment elevation)	>3

[a]LVEF: left ventricular ejection fraction.

[b]PCI: percutaneous coronary intervention.

[c]CABG: coronary artery bypass grafting.

[d]ST-T: electrocardiogram ST-T wave.

Rule Inference Engine

The study uses a clinical decision knowledge engine framework to facilitate the reasoning and computation of clinical rules in the form of decision trees. Rule engine is a branch of an expert system, that is developed from an inference engine. It solves practical problems by simulating human thinking mode and expresses the results of inference in an understandable form. IBM Operational Decision Manager is used as a tool prototype to input, manage, and maintain the business rules of the system users, including rule modeling, writing, testing, deployment, and maintenance, and provides rule base mechanism for the organization, storage, and execution of business rules [31]. Through Operational Decision Manager, clinical knowledge rules are modeled, developed, and validated. After data collection and cleaning, a standardized data archive is realized. The rule inference engine makes logical operations based on the transformed standard term set. The output reminders were used to assist clinicians in their diagnosis and treatment decisions.

XSL•FO
RenderX

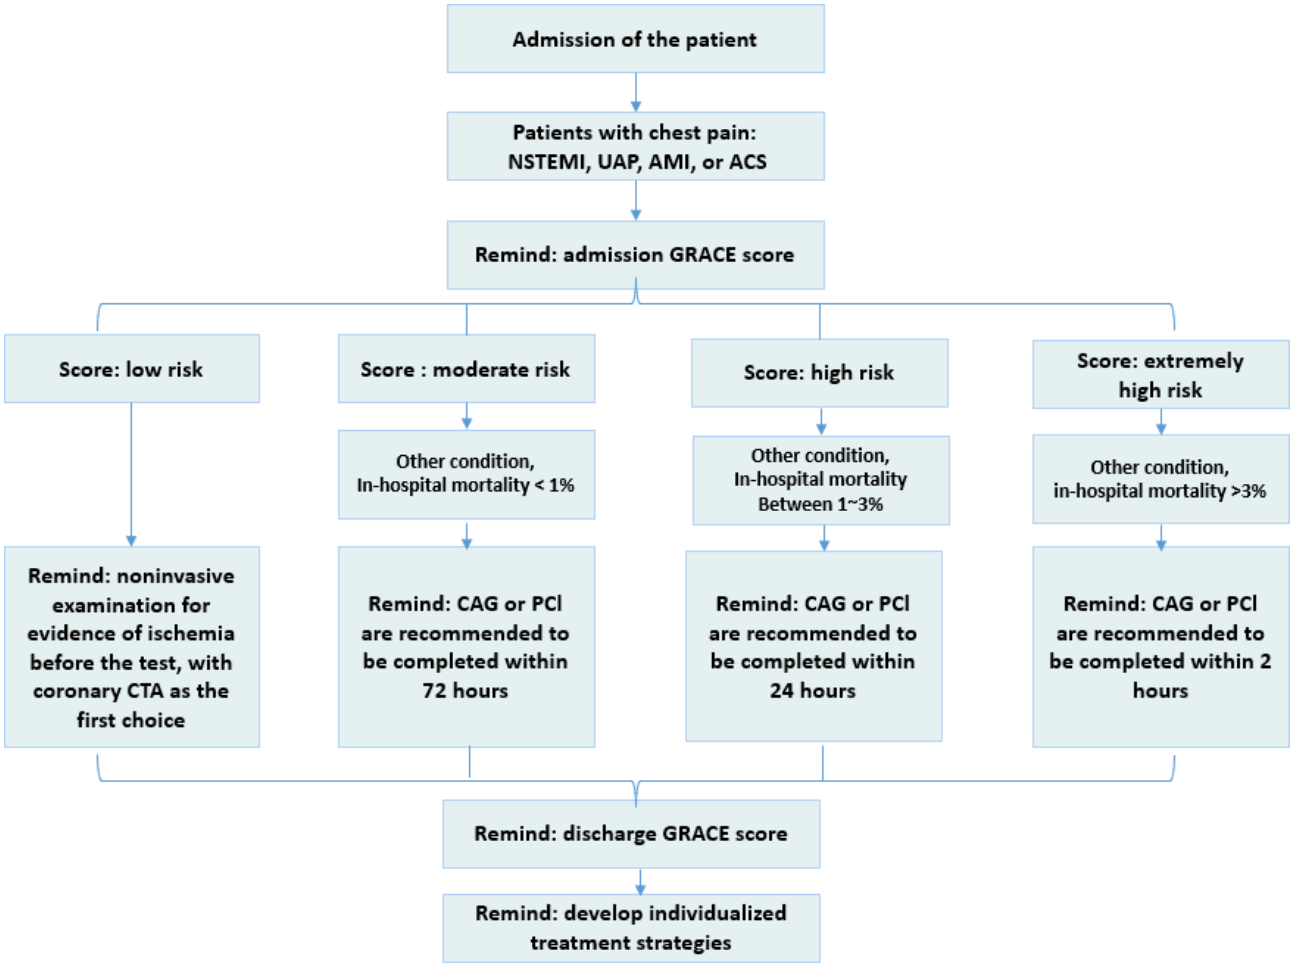
Application Assessment

Before the CDSS was officially launched, an independent panel of senior experts was invited to assess whether the recommendations were consistent with the current medical standards, practice guidelines, and best clinical practices. The experts could provide their own professional opinions and suggestions for improvement. After a comprehensive evaluation of expert opinions, the decision should be made whether to update and optimize the existing knowledge rules. After the system's official launch, we conducted a comparative analysis between CDSS recommendations and doctors' revised treatment plans. If there is an unreasonable knowledge base, after review by the quality control group, it was revised to improve the knowledge base for better decision support.

In terms of quality monitoring for daily use, a big data analytic platform is established and multidimensional statistic results are used to support management decision-making. The platform analyzes various quality control indicators, including the dynamic assessment rate of risk stratification. Hospital managers can review the control of CVD risk and the quality of diagnosis and treatment within the institution from multiple dimensions such as departments, doctors, types of diseases, and results of risk assessments, to formulate targeted management plans.

Statistical Analyses

The key performance indicators are presented as numbers (%) for categorical data. We compared the key performance indicators using Cochran-Armitage trend test. The threshold for statistical significance was $P<.05$. All statistical tests were performed using R (version 4.4.2; R Foundation).



Results

Real-Time Intelligent Triggering

The CDSS is integrated into the clinical workflow, linking key processes such as admission, operation, transfer, discharge, and other clinical activities. It enables real-time data flow integration and message triggering within the interfaces for prescribing and medical record documentation. During the assessment phase, when the system identifies a patient with a specified diagnosis, the CDSS triggers evaluation tools such as GRACE, ASCVD, and CHA2DS2-VASc. It performs a preassessment based on the patient's medical history and provides traceable evidence from original medical records, prompting the doctor to verify the results. If the patient's CVD risk stratification outcome changes, the system alerts the doctor to reassess the patient. In the diagnosis and treatment phase, based on the patient's current assessment and clinical status, it recommends appropriate diagnostic and treatment measures. Figure 3 illustrates an example of real-time intelligent knowledge path triggering.

Figure 3. A real-time intelligent triggering sample knowledge path. ACS: acute coronary syndrome; AMI: acute myocardial infarction; CAG: coronary angiogram; CTA: computed tomography angiography; GRACE: Global Registry of Acute Coronary Events; NSTEMI: non–ST-elevation myocardial infarction; PCI: percutaneous coronary intervention; UAP: unstable angina pectoris.

Three-Level Control Management

To achieve precise quality control for different risk levels, our study proposed a 3-level control management system for in-process alerts. The 3-level management approach involves establishing distinct levels of control for different regulations based on the level of risk or degree of emergency and providing varying degrees of reminders to medical professionals. The specifics are as follows: Level 1 control triggers a small red dot on the EMR interface, signaling the doctor's attention and requiring active selection. Level 2 control involves an active pop-up window on the EMR interface that the doctor can clearly see and address with the option to close and continue other tasks. Level 3 control features an active pop-up window that the doctor must address or provide a reason for dismissing before proceeding with other tasks. The 3-level control management issues alerts based on varying risk levels and incorporates the timing requirements for doctor's medical record documentation. This system prompts the doctor to complete the relevant assessment, diagnosis, and treatment actions within the specified time range of the evaluation node.

Application Effects

Overview

The multimodal data-driven accurate CDSS for CVDs was officially launched around the year 2022, while different modules were launched at different specific times. Table 2 lists a before-and-after comparison table of key performance indicators. The important evaluation indicators in the diagnosis and treatment of CVDs such as rate of GRACE assessment (P<.001), rate of ASCVD risk stratification assessment (P<.001), rate of interventional therapy within 2 hours after acute MI (P<.001), rate of lipid-lowering drugs treatment for coronary heart disease (P<.001), rate of blood pressure well-control in hypertensive patients (P<.05), rate of interventional therapy within 2 hours after acute MI (P<.001), etc were significantly improved after the system came into use. The evaluation indicators after 2 years were better than those after 1 year. The indicators under 3-level mandatory control, such as the rate of CHA2DS2-VASc stroke risk assessment and rate of HAS-BLED (hypertension, abnormal renal or liver function, stroke, bleeding history or predisposition, labile international normalized ratio, elderly [>65 years], drugs or alcohol concomitantly) bleeding risk assessment, were directly becoming 100% after CDSS was online.

RenderX

Table . The before-and-after comparison table of key performance indicators.

Name of indicators	Before CDSS[a] was online, n/N (%)	After CDSS was online (1 year), n/N (%)	After CDSS was online (2 year), n/N (%)	χ^2 (*df*)	*P* value
Rate of GRACE[b] assessment at admission	290/426 (68)	386/429 (90)	485/506 (96)	138.22 (2)	<.001
Rate of GRACE assessment at discharge	304/426 (71)	386/429 (90)	501/506 (99)	159.11 (2)	<.001
Rate of coronary CTA[c] in MI[d] patients	37/166 (22)	106/200 (53)	198/246 (81)	136.82 (2)	<.001
Rate of interventional therapy within 2 h after ate cute MI	35/57 (61)	54/65 (83)	57/60 (95)	25.884 (2)	<.001
Rate of ASCVD[e] risk stratification assessment	588/937 (63)	745/780 (96)	1058/1100 (96)	422.64 (2)	<.001
Rate of blood pressure well-control in hypertensive patients	162/213 (76)	269/336 (80)	385/460 (84)	5.71 (2)	<.05
Rate of lipid-lowering drugs treatment for coronary heart disease	347/673 (52)	500/733 (68)	676/821 (82)	161.71 (2)	<.001
Rate of CHA2DS2-VASc[f] stroke risk assessment	83/88 (94)	210/210 (100)	222/222 (100)	15.08 (2)	<.001
Rate of HAS-BLED[g] bleeding risk assessment	—[h]	177/177 (100)	166/166 (100)	—	—
Rate of diagnosis and early warning diagnosis of atrial fibrillation	—	147/158 (93)	296/313 (94)	—	—
Rate of stroke prevention for atrial fibrillation (medication or NOAC[i]) (high bleeding risk)	33/44 (75)	57/68 (84)	41/50 (82)	0.68 (2)	.41
Rate of stroke prevention in atrial fibrillation (medication or NOAC) (low bleeding risk)	79/96 (82)	81/95 (85)	162/174 (93%)	7.64 (2)	<.01

[a]CDSS: clinical decision support system.

[b]GRACE: Global Registry of Acute Coronary Events.

[c]CTA: computed tomography angiography.

[d]MI: myocardial infarction.

[e]ASCVD: atherosclerotic cardiovascular disease.

[f]CHA2DS2-VASc: congestive heart failure, hypertension, age ≥75 years (doubled), diabetes, stroke (doubled), vascular disease, age 65 to 74 years, and sex category (female).

[g]HAS-BLED: hypertension, abnormal renal or liver function, stroke, bleeding history or predisposition, labile international normalized ratio, elderly (>65 years), drugs or alcohol concomitantly.

[h]Not available.

[i]NOAC: nonvitamin K oral anticoagulants.

The CDSS function in our hospital has produced the following outcomes.

Timely Evaluation

Complete a GRACE score assessment for chest pain patients considered for non-ST segment elevation acute coronary

XSL•FO
RenderX

syndrome, to evaluate the comprehensive risk of all-cause mortality or the combined risk of all-cause death and MI. For other patients, the system assesses the in-hospital mortality risk within 24 hours of admission and re-evaluates the risk of death within 1 week before discharge and 6 months after discharge.

Blood Lipid Screening for High-Risk Patients

Following completing the CVD risk stratification assessment, the system prompts the doctor to perform a blood lipid test. For patients with abnormal blood lipid test data, the system alerts the doctor to diagnose the patient with "dyslipidemia."

Blood Glucose Control Reminder

After reviewing the patient's hemoglobin and insulin levels, the system prompts the doctor to carry out measures for blood glucose control. The reminder will disappear automatically after the patient's blood glucose index has reached the target value.

Reminder of Antihypertensive Treatment

If the patient is diagnosed with hypertension, the system prompts the doctor to carry out antihypertensive treatment, and the remainder will disappear automatically when the patient's blood pressure reaches the target value.

Timely Feedback Optimization

The system incorporates a user feedback function, enabling doctors to submit web-based feedback when encountering issues or providing suggestions during use. This facilitates the formation of diverse teams for problem-specific optimization and allows users to articulate the benefits derived from using the system. Feedback is searched, analyzed, and responded to based on various criteria such as time of submission, department affiliation, feedback provider, product function, and treatment type in order to ensure continuous improvement.

Discussion

The Benefits of CDSS

The implementation of CDSS has significantly enhanced the intelligent assessment and risk stratification of CVDs, effectively intervening and alerting in the subsequent diagnosis and treatment of patients.

On one hand, it has improved the efficiency of CVD risk assessment. Previously, this process required manual completion of scoring forms, which resulted in low efficiency. The AI-based CDSS, however, can analyze medical records and automatically complete the assessment in real-time, greatly enhancing both the efficiency and quality of CVD risk assessment. It has increased the diagnosis rate of CVD by deploying the CDSS across outpatient, emergency, and inpatient physician workstations, and improves the problem of low early diagnosis rate of CVD due to insufficient awareness of non-CVDs among noncardiology doctors. On the other hand, it enhances the standardization of clinical diagnosis and treatment. By identifying risks, issuing real-time warnings, and providing treatment recommendations, it effectively guides doctors in delivering precise treatment according to risks and clinical guidelines, and improves doctors' compliance with guidelines and standardization of diagnosis and treatment. Regarding quality control, traditional methods relied on sampling terminal medical records were passive and outdated. In contrast, the CDSS big data analysis platform can view the risk control and treatment quality of CVDs from the dimensions of departments, doctors, diseases, and risk assessment results, and allows quality control effect in real time.

Through automatic collection and real-time evaluation of key medical data in the process of diagnosis and treatment, the system establishes a new model of CVD quality control with information sharing and hierarchical treatment. It can be predicted that the application of information tools such as CDSS can help establish standard data sets for CVDs, support medical institutions to establish real-world clinical research platforms for CVDs, and aid specialized centers in conducting high-quality clinical research.

The Comparisons With Related Work

We have compared the characteristics of cardiovascular-related CDSS in recent years in Table 3. The innovation of the systems in our study lies in hierarchical evaluation and multistep reminders. We integrated multimodal data from the hospital laboratory information system, hospital information system, EMR, electrocardiography, nursing, and other systems to build the knowledge model. We established a 3-level control management system for in-process alerts as part of the workflow and providing recommendations at critical points of decision-making. The CDSS is integrated into the doctor's workstation and serves as a supplement or reminder to recommend examinations, tests, treatments, etc during the diagnosis and treatment process. The knowledge base and AI model are constructed from various clinical guidelines and historical patient data; however, personalization of patients may result in data bias, algorithm bias, or cognitive bias during model building. We conducted a comparative analysis between CDSS recommendations and doctors' revised treatment plans and improved the knowledge base for better decision support.

This study	Hospital	Prevention and management of cardiovascular diseases	3-level assessment card control for patient admission and predischarge reminders, pop-up windows, and screen domination operations	Single center, observational	This study designed a CDSS system with data, learning, knowledge, and application layers. It integrates multimodal data from hospital LIS (laboratory information system), HIS (hospital information system), EMR (electronic medical records), electrocardiography, nursing, and other systems to build a knowledge model.

[a]CVD: cardiovascular disease.

Limitations

Although the CDSS has been applied well in the First Affiliated Hospital of Nanjing Medical University, it still needs to be promoted in more medical and health institutions to verify its effectiveness. Until then, uniform data collection standards and procedures need to be developed to ensure that data, including patient information, treatment regimens, and clinical outcomes, can be collected in a consistent manner across all study sites. In addition, ethics committee approval at each participating institution was required to ensure compliance with local laws and regulations and to protect patient privacy. According to the results of multicenter, the performance of CDSS in different regions and different populations was evaluated, and the possible limitations or improvement space were identified, so as to provide more accurate auxiliary decision support. Tailoring the system to fit the specific workflows and practices of the new setting can improve acceptance and use rates, thereby increasing the likelihood of positive outcomes.

Conclusions

In this study, AI was used to perform NLP on the clinical medical records of patients, and a cardiovascular specialist CDSS was constructed to automatically identify patients at risk of CVD and improve the diagnostic rate of CVD patients by cardiologists and noncardiologists. It is an effective exploration to build an intelligent system for specialized diseases through CDSS to realize automatic assessment of CVD risk stratification, assist doctors in carrying out corresponding risk assessment and treatment, intervene in doctors' nonstandard diagnosis and treatment behavior in real time, improve the rate of appropriate lipid-lowering, blood pressure lowering and blood glucose control treatment, improve the prognosis of patients, and provide objective data for hospital management and evaluation of medical quality.

In the next step, when carrying out the construction of specialized precision CDSS, we will continue to improve the knowledge of specialized diseases by in-depth understanding of the diagnosis and treatment characteristics of clinical specialty fields and using the self-defined modules of the medical knowledge base in the CDSS. We will formulate standardized data collection requirements, carry out data transformation mapping, and continue to verify its effectiveness in more medical and health institutions to improve the versatility of the system. This enables refined management of knowledge and enables CDSS to better meet the management and research needs of various specialized diseases.

development and transformation of active intelligent health management platform for diabetes mellitus" (202205053), and Natural Science Foundation of Jiangsu Province (BK20210966).

Authors' Contributions

The work presented here was carried out in collaboration among all authors. SM, PJ, WG, GY, and YL designed methods and constructed system architecture. SM, MJ, and RS focused on the application of artificial intelligence technology in clinical decision support systems (CDSSs). HD, XZ, and RS processed data using natural language processing. JG, HD, and SM constructed and implemented the CDSS. PJ, YZ, HM, and SM verified and collected the application effect. All authors have drafted, edited, reviewed, and approved the manuscript.

Abstract

Background: Pressure injuries (PIs) pose a negative health impact and a substantial economic burden on patients and society. Accurate staging is crucial for treating PIs. Owing to the diversity in the clinical manifestations of PIs and the lack of objective biochemical and pathological examinations, accurate staging of PIs is a major challenge. The deep learning algorithm, which uses convolutional neural networks (CNNs), has demonstrated exceptional classification performance in the intricate domain of skin diseases and wounds and has the potential to improve the staging accuracy of PIs.

Objective: We explored the potential of applying AlexNet, VGGNet16, ResNet18, and DenseNet121 to PI staging, aiming to provide an effective tool to assist in staging.

Methods: PI images from patients—including those with stage I, stage II, stage III, stage IV, unstageable, and suspected deep tissue injury (SDTI)—were collected at a tertiary hospital in China. Additionally, we augmented the PI data by cropping and flipping the PI images 9 times. The collected images were then divided into training, validation, and test sets at a ratio of 8:1:1. We subsequently trained them via AlexNet, VGGNet16, ResNet18, and DenseNet121 to develop staging models.

Results: We collected 853 raw PI images with the following distributions across stages: stage I (n=148), stage II (n=121), stage III (n=216), stage IV (n=110), unstageable (n=128), and SDTI (n=130). A total of 7677 images were obtained after data augmentation. Among all the CNN models, DenseNet121 demonstrated the highest overall accuracy of 93.71%. The classification performances of AlexNet, VGGNet16, and ResNet18 exhibited overall accuracies of 87.74%, 82.42%, and 92.42%, respectively.

Conclusions: The CNN-based models demonstrated strong classification ability for PI images, which might promote highly efficient, intelligent PI staging methods. In the future, the models can be compared with nurses with different levels of experience to further verify the clinical application effect.

KEYWORDS

pressure ulcer; deep learning; artificial intelligence; neural network; CNN; machine learning; image; imaging; classification; ulcer; sore; pressure; wound; skin

Introduction

Pressure injuries (PIs), also known as pressure ulcers, are prevalent in health care settings and result from sustained pressure or shear forces on bony prominences and soft tissues [1]. A meta-analysis encompassing 2,579,049 hospitalized adult patients revealed a 12.8% prevalence of PIs, and the estimated annual total cost of managing PIs increased approximately several times even in high-income countries [2,3]. Accurate staging of PIs is essential for determining appropriate treatment protocols and predicting clinical outcomes. Traditional staging relies on subjective evaluation by health care providers, often wound nurses, who use guidelines such as the *Prevention and Treatment of Pressure Ulcers/Injuries: Clinical Practice Guideline, International Guideline 2019*, and divide the PI stage into 6 stages—namely, stages I, II, III, and IV, unstageable, and suspected deep tissue injury (SDTI)—based on visual assessment, such as the color and texture characteristics of the wound bed, wound edges, and skin around the wound [4].

However, visual assessment conducted by medical staff is subject to considerable interrater and intrarater variability [5]. Moreover, the staging results are significantly influenced by the level of wound knowledge and the clinical experience of the evaluators. It has been reported that only 23%-58% of medical staff correctly classify PIs [6]. Therefore, accurate

XSL•FO
RenderX

staging of PIs is still a great challenge, and a universal, reliable, and more objective staging system is urgently needed.

Convolutional neural networks (CNNs) offer an opportunity to increase the objectivity and accuracy of PI staging. CNNs, a subset of deep learning (DL) models, have shown remarkable potential in medical image analysis [7]. CNNs automatically extract and learn hierarchical features from grid-like data, such as images, and have achieved performance levels comparable to or surpassing those of human experts in various medical imaging domains [8]. In dermatological and wound imaging, CNNs have demonstrated promising results, matching or even exceeding the diagnostic accuracy of dermatologists in classifying skin cancer and other skin lesions [9]. On the basis of the good classification performance of CNNs in medical images and the increased clinical need for automated staging of PIs, in recent years, the use of CNNs to learn PI images has gradually developed, but there are also areas for improvement. For example, the use of a singular model had an accuracy rate below 90%, alongside images sourced from outdated databases and of poor quality, and the labeling of PI images often relies on the subjective judgment of clinical experts, so the quality and consistency of the images were uneven in these studies, which limit the evidence supporting the model's widespread applicability [10-12]. Therefore, further exploration is needed in this field to prove the effectiveness of CNNs.

In this study, we trained AlexNet, VGGNet16, ResNet18, and DenseNet121 to classify PI images with the aim of contributing to artificial intelligence–driven wound care knowledge and informing the development of advanced clinical tools.

Methods

Setting and Samples

Our study was conducted at a tertiary hospital in Chengdu, China, from March 1, 2022, to September 30, 2024.

The inclusion criteria for patients were as follows: (1) PIs were diagnosed by 2 wound therapists simultaneously on the basis of the *Prevention and Treatment of Pressure Ulcers/Injuries: Clinical Practice Guideline, International Guideline 2019* [4] and (2) the patients provided informed consent.

The exclusion criteria for patients were as follows: (1) PIs included other skin diseases, such as incontinence dermatitis; (2) PIs were covered by dressings or tattoos; (3) exudation was excessive, resulting in obvious reflection; (4) mucosal PIs; (5) the patient's vital signs remained too unstable to exchange positions; and (6) the patients were in isolation wards.

The inclusion criteria for images were as follows: (1) images were taken by the investigator, and (2) images fully presented the wound triangle, namely, the wound bed, wound edge, and surrounding wound tissue.

The exclusion criteria for images were as follows: (1) images containing nonwounded and skin tissues such as clothing and sheets and (2) images that were blurred and overexposed.

Dataset

We recruited wound therapists who were awarded an international ostomy wound certificate to act as PI staging evaluators. Five wound therapists were included in this study. The basic information is provided in Table 1. To test the consistency of the 5 wound therapists' assessments, we sent them 30 PI images from the NPIAP (National Pressure Injury Advisory Panel) website in the form of a questionnaire [13]. The Fleiss kappa coefficient was 0.856, $P<.001$, indicating strong staging consistency among them [14]. The staging results are shown in Tables 2 and 3.

The PI Staging Assessment Process and Shooting Process

Before taking the shots, the researcher and the 2 wound therapists communicated with the patients and their family members to obtain consent. After that, the 2 therapists simultaneously evaluated the staging of the pressure ulcers via the *Prevention and Treatment of Pressure Ulcers/Injuries: Clinical Practice Guideline, International Guideline 2019*. If there were any objections to the results, we informed the third wound therapist on duty, and they would negotiate the staging.

XSL•FO
RenderX

The following types of shooting equipment were used: (1) Fuji XT-4 was used for shooting, with 21.6 million effective pixels, and Fuji XF 60 mm F2.4 R Macro and (2) a gray card. The specifications of the shooting mode are as follows: (1) antishake plus automatic mode; (2) parameter setting: shutter time: 60/1 s; (3) sensitivity: 3600-6000; (4) aperture: F6-8; (5) focal length: 60 mm; and (6) white balance: automatic white balance.

When photographs were taken, the camera was positioned parallel to the wound, with a focus on both the wound itself and the surrounding skin (Figure 1). Additionally, a gray card was used to minimize any interference caused by natural light. Following each shot, the images were carefully examined. If any image was deemed unclear, the researcher retracted the image. All of the original images were saved in JPG format and given a specific name consisting of a stage followed by a corresponding number. Finally, the images were transferred onto a computer for further analysis and storage.

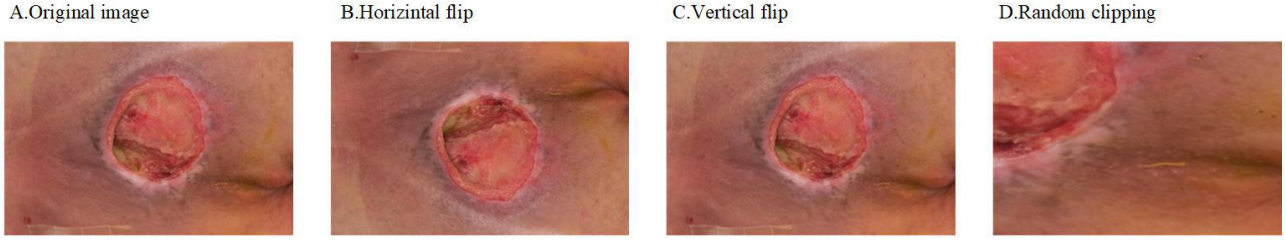

Figure 1. Shooting process.

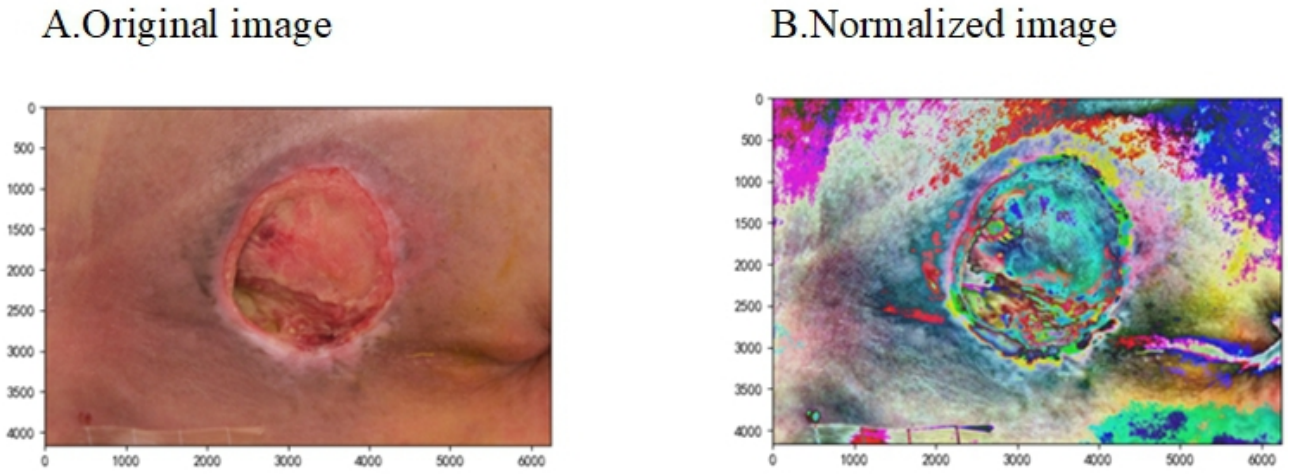
Image Augmentation

Horizontal flipping, vertical flipping, and random clipping were used for data augmentation to expand the training dataset and improve the generalization ability of the models (Figure 2) [15]. Taking random cropping as an example, the size of the original image was reset to 512×512×3, and after random cropping, the size was 256×256×3. The size of the augmented image was fixed again to 224×224×3 before being input into the networks so that the network model could recognize them.

Figure 2. Image augmentation: (A) original image, (B) horizontal flip, (C) vertical flip, and (D) random clipping.



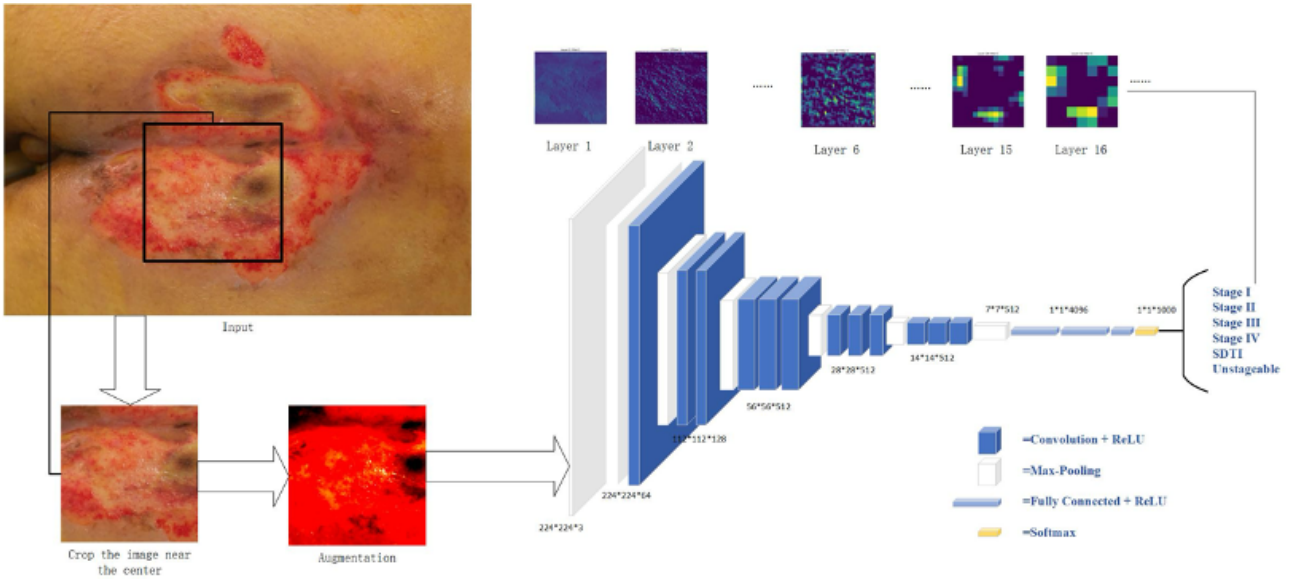
XSL•FO
RenderX

Image Normalization

The PI images are RGB color patterns (Figure 3), and the number of pixels is [0, 256] [16]. To reduce the adverse effects caused by singular sample data and speed up model training, we limit the number of pixels to [−1, 1] in this study via 2 image normalization calculation formulas, where $\bar{x}$ is the mean of the number of pixels, N represents the number of pixels, and x represents the pixel value of each pixel [17]. The calculation formula is as follows:

$$(1)s=(1N-1\sum i=1N(xi-\bar{x})2)12$$

Figure 3. Image normalization: (A) original image and (B) normalized image.



The Adam optimizer was used, and the loss function was the cross-entropy loss function (cross-entropy loss function), which is commonly used in multiple classification tasks. The data batch (batch size) was set to 8, and the initial learning rate was set to 0.0001. Every network was trained for 30 epochs.

This study was based on the 64-bit Windows 11 computer system and the Ubuntu 16.04 operating system for image training in the PyTorch 2.0.1 framework using the Python 3.9.19 language with CUDA 11.8 and NVIDIA GeForce RTX 4060 Laptop (8G).

The process of model training was divided into training, validation, and testing. The process is shown in Figure 4. First, the PI image was cut into the main wound area, and the cut image was treated as a uniform pixel, both of which were cut to 224 pixels. In the training set, the CNN training model is input; the performance of the model on the validation set is evaluated; and the state and convergence of the model are tested to adjust the hyperparameters. In the test set, the model outputs corresponding prediction results through a series of convolutions, nonlinear activations, pooling, etc, to evaluate the generalization ability of the model.

Figure 4. The network workflow diagrams. SDTI: suspected deep tissue injury.

In our study, we used AlexNet, VGGNet 16, ResNet 18, and DenseNet121 to train the images. AlexNet, a pioneering CNN in image classification, consists of 8 layers: 5 convolutional layers with varying filter numbers and 3 fully connected layers. It employs ReLU activations, max pooling, and dropout for regularization. The introduction of ReLU and dropout layers in AlexNet reduced training times and prevented overfitting,

XSL•FO
RenderX

whereas its deep architecture allowed for the learning of complex features, enhancing classification accuracy [18].

VGGNet 16 is a 16-layer deep network consisting of 13 convolutional layers and 3 fully connected layers, all of which use 3×3 filters. It features a consistent architecture with convolutional layers followed by max pooling layers, which simplifies optimization. This network is effective for capturing grid-like patterns in images and allows for the learning of more abstract and complex features due to its depth [19].

ResNet 18 is a shallow network with 18 layers organized in a residual learning framework. It consists of 4 blocks of residual units, each with convolutional layers, batch normalization, ReLU activation, and max pooling layers. The key innovation is the introduction of residual connections, which allow the network to learn residual mappings, making it easier to train deeper networks by effectively flowing gradients through the network [20].

DenseNet121 connects each layer to every other layer in a feedforward manner, using features from all preceding layers as inputs and its own feature map for all subsequent layers. This dense connectivity reduces the number of parameters, making DenseNet121 more parameter-efficient than other CNNs of similar depth. It helps mitigate the vanishing gradient problem and enhances feature propagation, leading to improved performance and efficiency [21].

In summary, the 4 CNN models were selected for their historical performance in image classification tasks, the uniqueness of their architectural design, and their significant contributions to the field of DL (Figure 4).

Evaluation of Performance

We evaluated the performance from a single image result. The diagnostic performance was measured by accuracy (ACC), precision (Pre), recall (Rec), and the F_1-score. To calculate the above metrics, we defined an abnormal result as positive and a normal result as negative.

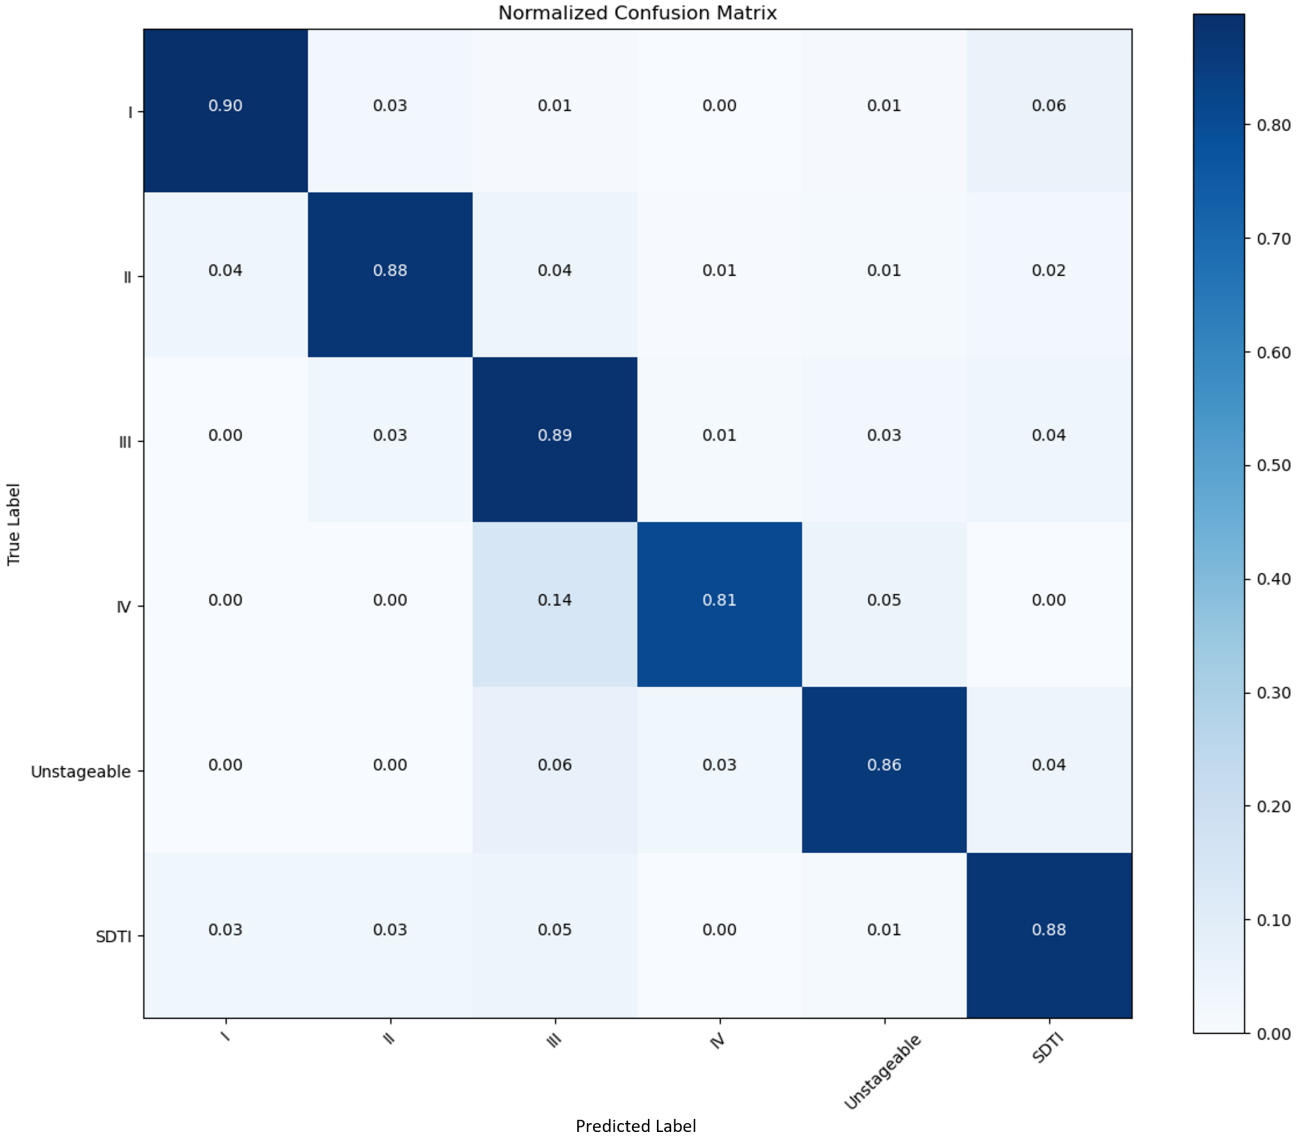
(1) ACC=TP+TNTP+FP+FN+TN

(2) Pre=TPTP+FP

(3) Rec=TPTP+FN

(4) F1-score=2·Precision·RecallPrecision+Recall

Ethical Considerations



This study was approved by the Biomedical Ethics Committee of the West China Hospital of Sichuan University (#1053). In this study, the informed consent process was strictly carried out. Participation in the study was completely voluntary, and patients could refuse to participate or withdraw at any time during any phase of the study without discrimination or retaliation and without affecting their medical treatment and benefits. If participants decided to withdraw from the study, they would contact us. Patient privacy was strictly protected, and all data obtained were ony used for this study. Patients did not have to pay any fees to participate in the study.

Results

We collected 853 raw PI images in this study. We set the images into a training set, a validation set, and a test set at a ratio of 8:1:1. After augmentation, 7677 images were used. A confusion matrix is a numerical table used to display the performance results of a classification model on test data with known target labels. It serves as a visual representation of how the model makes predictions on the test dataset. On the basis of the results obtained from each network validation, we plotted the normalized confusion matrix, with the true labels on the vertical axis and the predicted labels on the horizontal axis (Figures 5-8). Table 4 provides a summary of the accuracy, precision, recall, and F_1-scores for the 4 CNNs.

Discussion

Principal Findings

Among all the CNN models, DenseNet121 demonstrated the highest overall accuracy of 93.71%. The classification performances of AlexNet, VGGNet16, and ResNet18 exhibited overall accuracies of 87.74%, 82.42%, and 92.42%, respectively.

PIs are a global health issue, and effective treatment requires early and accurate classification and prevention. The staging of the PI is usually a subjective evaluation by medical professionals via standard systems, but it can differ due to variations in staff experience, training, and wound characteristics [22].

CNNs are feedforward neural networks with convolutional computations and deep structures. They capture local image features regardless of position through their core convolutional operation. This allows CNN-based models to potentially reduce assessment disparities among medical personnel. This approach promises precise classification of PIs, ensuring consistent patient

XSL•FO
RenderX

care and valuable advice post discharge, which improves quality of life and health care resource efficiency [23].

However, many factors need to be considered when a reliable staging model is constructed (eg, the quality and quantity of images matter for model training). Several previous studies were based on retrospectively collected images in which other types of wounds were included, and the shooting equipment may not have been updated with lower image pixels, which affects the reliability of supervised learning in DL [24-26]. Some researchers have attempted to classify PIs via neural network models on the basis of the clinical staging system; however, most of these studies have relied on public datasets containing a limited number of images per grade, typically only a few dozen [25,26]. It is recommended that more than 150 training images should be used per grade to achieve reasonable classification accuracy when resources are limited [27].

Therefore, it is necessary to construct a large dataset of high quality with reliable labeling of each grade. In contrast, in this study, PI images were collected prospectively by professional cameras, and a gray card and executable shooting standard were developed to ensure that the quality of each image was clear and that the wound characteristics could be clearly displayed. Moreover, the staging results of each image were assessed by 2 wound therapists simultaneously. The wound therapists included were all qualified and had more than 15 years of working experience, so their assessment results were convincing, which contributed to the good comparability of the images and the reliable sample set. Additionally, we used a professional digital camera and a gray card, which were rarely used in previous studies, to ensure the quality of the images, particularly in accurately representing the original color of PIs [28].

Compared with other studies, this study still has advantages in terms of classification accuracy. Ay et al [24] used the European Pressure Ulcer Advisory Panel staging system and included PIs from stage 1 to stage 4. They trained 1091 images from a public dataset of PIs called the PIID (Public Injury Images Dataset) and 15 images from Google via DenseNet121, InceptionV3, MobileNetV2, ResNet152, ResNet50, and VGG16. The results indicated that the average accuracy of the 6 algorithms for each stage during pretraining ranged from 54.84% to 77.42% [24]. Kim et al [29] set SE-ResNext101 to train 2614 images from 493 participants. The accuracy of the model was 0.793 over the internal testing set and 0.717 over the external testing set [29]. In our study, DenseNet121 exhibited the highest accuracy (93.71%), precision (98.72%), recall (91.53%), and F_1-score (97.09%), possibly because of the following reasons. (1) DenseNet121 improves the backpropagation of gradients due to the dense connection mode, making the network easier to train. Moreover, it can reduce the gradient disappearance problem caused by the transmission of input information and gradient information between many layers. (2) The number of parameters is reduced. (3) Low-dimensional features are preserved. In a standard convolutional network, the final output is only used to extract the highest-level features [30]. It is also important to consider the algorithm and image quality. In our study, 5 wound therapists, all of whom were qualified and had been engaged in wound management for at least 15 years, were recruited for grading. Therefore, the results of image staging were relatively accurate, and the classification of each label learned by CNNs was also convincing. Overall, DenseNet121 has become a popular choice in the field of computer vision because of its effective training of deep networks, high performance, generalizability, and insights into the learning process. These advantages make them powerful tools for image recognition and classification tasks. However, DenseNet121 processes a large number of layers, is relatively time-consuming, and consumes considerable computing power. DenseNet121 is more suitable for our present small sample. In regard to large-scale datasets, from the perspective of computing power and time factors, ResNet-18 or a higher level, such as ResNet34 or ResNet50, may be a better choice [31].

To improve the model's adaptability to skin color variations, future research should increase the sample size and expand collection areas. Additionally, implementing the model in clinical settings requires effective communication due to the perception of opacity in DL methods. Accountability is crucial in the medical field, as errors can have legal implications.

Limitations

The images obtained from data segmentation in this study contain some normal skin tissue. The next step is to make the wound more prominent or to make a judgment after segmenting the image.

Clinical wound management is influenced by blood and fluid seepage. Future studies should integrate DL with 3D imaging, thermal imaging, and fluid seepage assessment for a more comprehensive wound assessment.

The study also faced challenges due to limited prospective image data and reliance on a single device, potentially leading to biases and affecting model accuracy. This study did not compare the model's performance with that of wound therapists or nurses in discriminating pressure ulcers; instead, it focused on internal validation and algorithm comparison.

Conclusions

Staging models that use CNNs as their foundation exhibit robust classification capabilities. However, further research is needed to validate the reliability of these observed results. As such, we intend to gather an extensive array of additional imagery and undertake a comparative analysis between the staging outcomes generated by the model and those achieved by frontline clinical nurses. This comparative assessment will allow us to identify any potential discrepancies and disparities between the two, thereby affording us valuable insights for refining the model's performance and suggesting effective strategies for enhancing the skills and capabilities of nurses.

Abstract

Background: Chronic pain is a complex condition that affects more than a quarter of people worldwide. The development and progression of chronic pain are unique to each individual due to the contribution of interacting biological, psychological, and social factors. The subjective nature of the experience of chronic pain can make its clinical assessment and prognosis challenging. Personalized digital health apps, such as Manage My Pain (MMP), are popular pain self-tracking tools that can also be leveraged by clinicians to support patients. Recent advances in machine learning technologies open an opportunity to use data collected in pain apps to make predictions about a patient's prognosis.

Objective: This study applies machine learning methods using real-world user data from the MMP app to predict clinically significant improvements in pain-related outcomes among patients at the Toronto General Hospital Transitional Pain Service.

Methods: Information entered into the MMP app by 160 Transitional Pain Service patients over a 1-month period, including profile information, pain records, daily reflections, and clinical questionnaire responses, was used to extract 245 relevant variables, referred to as features, for use in a machine learning model. The machine learning model was developed using logistic regression with recursive feature elimination to predict clinically significant improvements in pain-related pain interference, assessed by the PROMIS Pain Interference 8a v1.0 questionnaire. The model was tuned and the important features were selected using the 10-fold cross-validation method. Leave-one-out cross-validation was used to test the model's performance.

Results: The model predicted patient improvement in pain interference with 79% accuracy and an area under the receiver operating characteristic curve of 0.82. It showed balanced class accuracies between improved and nonimproved patients, with a sensitivity of 0.76 and a specificity of 0.82. Feature importance analysis indicated that all MMP app data, not just clinical questionnaire responses, were key to classifying patient improvement.

Conclusions: This study demonstrates that data from a digital health app can be integrated with clinical questionnaire responses in a machine learning model to effectively predict which chronic pain patients will show clinically significant improvement. The findings emphasize the potential of machine learning methods in real-world clinical settings to improve personalized treatment plans and patient outcomes.

Introduction

Chronic pain affects more than a quarter of people worldwide and carries substantial personal and economic burdens [1]. It is a complex condition that can be challenging to assess clinically due to the individualized and subjective nature of symptoms [2,3]. The development and progression of chronic pain are unique to each patient and difficult to predict at the individual level due to the contribution of interacting biological, psychological, and social factors [1,4-7]. Physiological markers associated with chronic pain can provide useful insights about a patient's condition [8]; however, clinical assessment of the subjective magnitude of pain severity and its impact on function and quality of life primarily relies on self-report measures [4,9]. Self-tracking of symptoms, medications, and daily activities is a popular approach to providing insights about symptom trends in chronic conditions [10,11], and digital apps have become a particularly useful tool to support self-tracking of pain and related symptoms [12-14]. With recent advances in machine learning technologies, digital symptom tracking opens an opportunity to evaluate numerous factors that contribute to pain symptoms and functioning to make predictions about an individual patient's progress [12]. This work examines whether information obtained from a pain tracking app can be used to accurately predict improvement in clinical pain-related outcomes in patients at a transitional pain clinic.

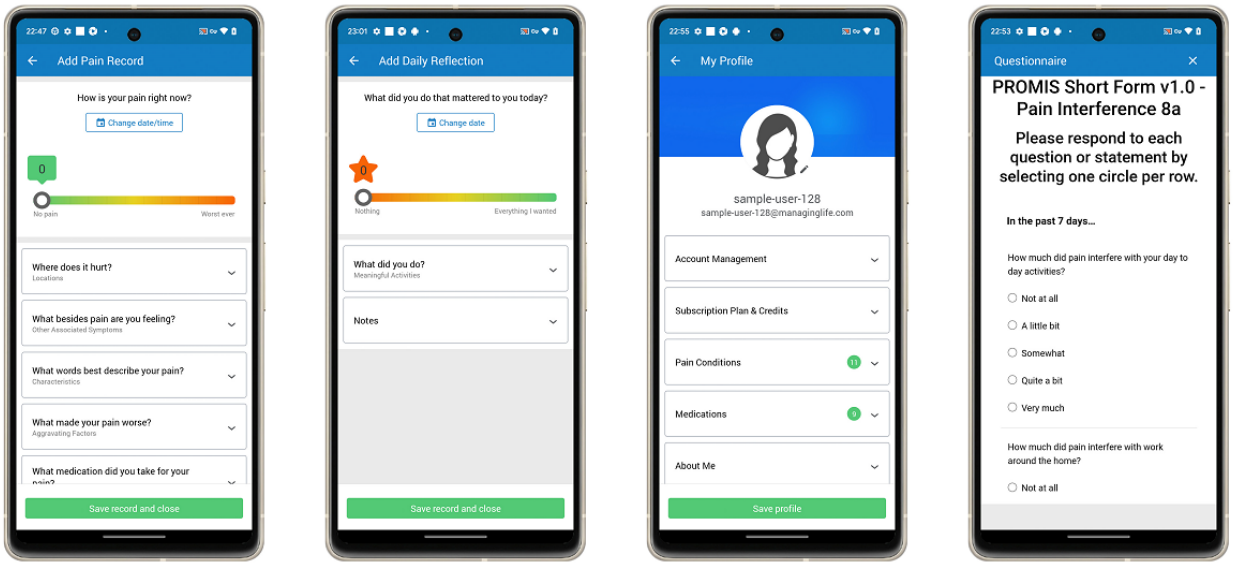
Manage My Pain (MMP) is a digital health app designed by ManagingLife with a patient-centric approach, aimed at helping patients and health care professionals measure, manage, and communicate pain, function, and medication use both at home and in clinical settings. The app has over 100,000 users worldwide and is available in 7 languages on both mobile and web platforms. MMP has been integrated into the Transitional Pain Service (TPS), a multidisciplinary pain clinic at Toronto General Hospital (TGH), to support symptom assessment and patient engagement with symptom tracking [13]. The TPS at TGH is a pioneering clinic that treats patients during the transitional period when acute pain after a major surgical procedure has the risk of becoming chronic [15,16]. The clinic also treats complex patients with chronic pain to support them in medication management and opioid weaning [17]. With this patient population, the clinic relies on regular symptom tracking to monitor patient progress and to intervene appropriately during critical phases of pain treatment. The MMP app provides a comprehensive digital platform where patients can fill out intake and follow-up questionnaires, track their symptoms, view symptom patterns and trends, and access educational resources about managing pain. Clinicians, in turn, can view each patient's record in the app to gain insights into their ongoing pain and symptom patterns and to support patient-clinician communication and decision-making about treatment. The MMP app has become the standard of care at the TPS since May 2020. Evaluations of the app showed that it was acceptable to TPS patients [18] and patients who used it reported significantly lower anxiety and pain catastrophizing scores [19].

The aim of this study is to use machine learning techniques to predict clinically significant improvements in pain-related outcomes among TPS patients who used the MMP app. In previous studies, we used symptom tracking, profile, and usage data from users of the MMP app to predict variability in reported pain levels over time (ie, pain volatility) [20,21]. In this study, we focused on a population of users from the TPS clinic and incorporated data from clinical questionnaires alongside symptom tracking, profile, and use data to predict clinical outcomes related to pain interference. Pain interference refers to the impact pain has on engagement in daily activities and participation [22]. It is related to the perceived severity of pain [23] and is considered a key aspect of the pain experience and a primary outcome in many clinical trials [24]. It is an informative measure from a clinical treatment and pain management standpoint that focuses on patients' daily functioning rather than pain intensity itself [25-27]. It is therefore a valuable measure to consider in predicting meaningful improvement for patient outcomes. We hypothesize that a machine learning model using data entered by TPS patients into the MMP app during the first 30 days of use can accurately predict subsequent pain interference scores reported within the next 5-month period.

Methods

Ethical Considerations

The study protocol was reviewed and approved by the McGill University Research Ethics Board (File Number 23-12-016). Informed consent to the use of data was obtained when users registered an account through the MMP app and agreed to its End User Licence Agreement [28]. Privacy and confidentiality of user data were protected in accordance with ManagingLife's Privacy Policy [29]. All user data used in the study dataset was deidentified. Users did not receive compensation for the use of their data in the study.



Manage My Pain App

The MMP app is available on Android, iOS, and web devices. The main features of the app are the daily reflection and the pain record that allows in-the-moment logging of pain experiences. Initially, users interact with the MMP app by responding to a daily push notification that prompts them to reflect on their day and rate it by completing a daily reflection at a default time of 8 PM. Users have the option to customize or disable the timing and frequency of notifications. The daily reflection, based on Acceptance and Commitment Therapy principles known for their efficacy in chronic pain management [30,31], asks users, "What did you do that mattered to you today?" Users then rate their day on a visual analog scale from 0 (Nothing) to 10 (Everything I wanted) and can record any meaningful activities. Following the daily reflection, users are invited to complete a pain record where they assess their current pain level by responding to "How is your pain right now?" and rating it on a scale from 0 (No pain) to 10 (Worst ever). Additionally, users can detail up to 7 aspects of their pain episodes, including body location, symptoms, characteristics, aggravating factors, medications, interventions, and environment. There is no limit to the number of pain records a user can enter in a day and these entries are independent of completing a daily reflection. Users can also enhance their MMP app profile with personal information about their medications,

XSL•FO
RenderX

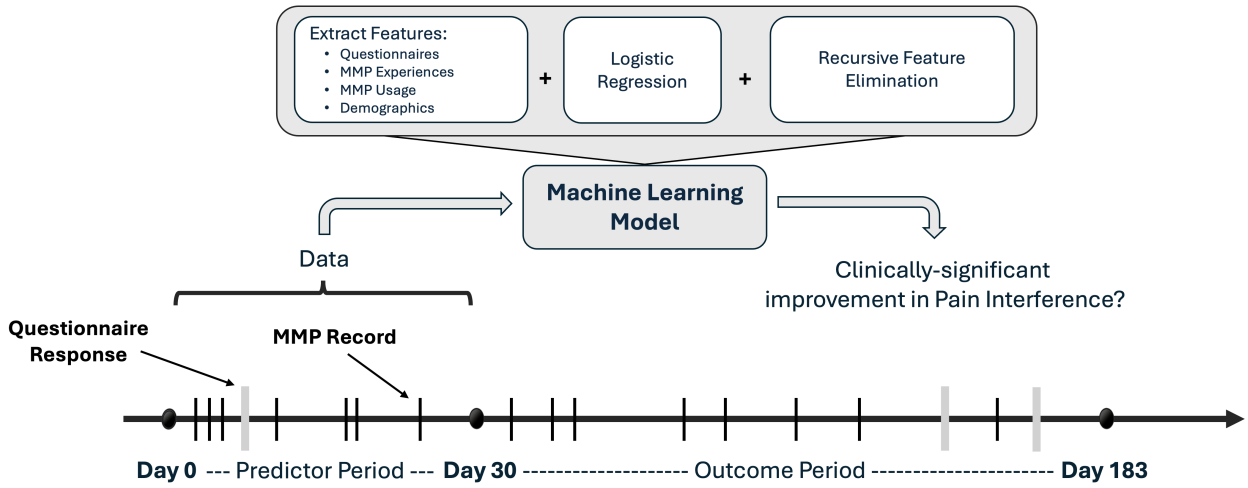
health conditions, and demographics such as age, height, weight, and gender. The screen interface of each of the different features of the MMP app is shown in Figure 1.

Figure 1. Screenshots of the mobile version of the Manage My Pain (MMP) app. Shown from left to right is the interface of the pain record, daily reflection, user profile, and clinic questionnaire.

TPS Clinic Patient Flow

The TPS treats patients who are at risk of developing chronic pain after surgery and patients with chronic pain who have complex needs. Patients are typically referred to the TPS during the perioperative period, before or after a surgical procedure, or they are referred through the Toronto Academic Pain Medicine Institute [32]. Prior to their initial assessment by a TPS physician, patients are asked to fill out a set of clinical intake questionnaires (see below for details). Patients are invited to access the questionnaires on the MMP app and staff at the clinic support patients in accessing the app and registering an MMP account. They are also informed about the other features available in the app to track their pain and daily activities, view symptom patterns and trends, and learn about managing pain in the Pain Guide. The TPS clinical team works with patients to address their needs through a multidisciplinary approach to pain care that includes medical treatment alongside psychological care and physical rehabilitation. Patients are asked to fill out follow-up clinical questionnaires using the MMP app at subsequent visits to the clinic. Patients are followed by the TPS for up to 6 months, at which point they are typically discharged to primary care.

Clinic Questionnaires



The TPS clinic uses a battery of standard clinical questionnaires to evaluate patient pain-related symptoms at intake and to assess treatment progress over time. The following questionnaires are regularly assigned using the MMP app at both intake and follow-up visits and are common across all TPS patients: Numeric Rating Scale (NRS) to rate pain severity on an 11-point scale [9]; PROMIS Pain Interference 8a v1.0 (PROMIS PI) to measure the extent to which pain hinders an individual's engagement with physical, mental, cognitive, emotional, recreational, and social activities [22]; Pain Catastrophizing Scale (PCS) to assess catastrophic thinking related to pain [33]; Generalized Anxiety Disorder-7 (GAD-7) as a measure of general anxiety [34]; and Patient Health Questionnaire-9 (PHQ-9) as a measure for screening, diagnosing, monitoring, and measuring the severity of depression [35]. Additional questionnaires are assigned as needed to meet the specific needs of each patient.

Study Dataset

A total of 780 TGH TPS patients entered responses to clinic questionnaires and pain experience records in the MMP app during the period between May, 2020 and March, 2024, producing 14,127 questionnaire responses and 30,033 pain experience records. For this study, we selected users who had at least 1 PROMIS PI questionnaire response in a predictor period, and at least 1 PROMIS PI questionnaire response in an outcome period, resulting in 160 users. The predictor period was defined as the first 30 days of MMP app use, and the outcome period was set between 30 days and 6 months (183 d) from the first app use (Figure 2). There were 680 users who recorded a response in the predictor period, 182 users who recorded a response in the outcome period, and 180 users who had a response in both the predictor and outcome periods. Therefore, 180 users were selected for this study.

XSL•FO
RenderX

Figure 2. Overview of study timelines and machine learning model approach. MMP: Manage My Pain.

We aimed to predict users who improved based on changes in their final score on the PROMIS PI questionnaire between the predictor and outcome period. The final score on the PROMIS PI questionnaire is generated by converting the total raw score into a T-score for each participant using a web-based calculation tool [22]. The first questionnaire responses from the predictor period and the first subsequent recorded responses in the outcome period were used in the prediction model.

Clinical questionnaires have a research-backed minimal clinically important difference (MCID) indicator that guides clinicians in evaluating the progress of symptoms [36]. The MCID was used in this study as a marker of patient improvement. The MCID for the PROMIS PI questionnaire is 2 [37]. Patients who showed an improvement in PROMIS PI questionnaire T-scores greater than the MCID of 2 were classified as improved.

Data Preprocessing and Feature Extraction

Overview

The data were preprocessed to remove any anomalous MMP app records (eg, missing values where entries were expected) and to convert any categorical questionnaire responses into a numerical format.

A total of 245 relevant variables, referred to as features in the field of machine learning, were extracted from the available data. A total of 194 features were extracted from the patients' MMP app user profiles, pain records, daily reflections, and app use records. Another 51 features were extracted from the patients' questionnaire responses. Instances with missing values were imputed using the mean value for each feature and subsequently, each feature was *z* score normalized. The features were divided into 8 categories as provided below.

Demographics

Demographics (6 features) consisted of data on gender, age, and age category (unknown, 0 to 19, 20 to 29, 30 to 39, 40 to 49, 50 to 59, 60 to 69, and 70+ years), height, weight, and body mass index entered by users into their profiles.

Medications

Medications (10 features) consisted of the total number of medications reported by users in their profile and 9 binary features for the specific medications reported, including opioids, tricyclic antidepressants, anticonvulsants, cannabinoids, serotonin-norepinephrine reuptake inhibitors, nonsteroidal anti-inflammatory drugs, acetaminophen, metamizole, and benzodiazepines.

Health Conditions

Health Conditions (9 features) consisted of the number of health conditions reported by users in their profile, and the number of conditions by category (unknown, 1 condition, 2 conditions, 3 conditions, and more than 3 conditions). Five features included binary categories of whether a user reported or not one of the following most observed health conditions: fibromyalgia, headaches or migraines, back pain, arthritis, or depression/anxiety. One feature represented an indication of neuropathic pain determined by the app and characterized as the presence of reports of sensations of pins and needles or tingling, burning, numbness, electric shocks, or an aggravating factor of light touch or clothing. The final feature was based on the presence of mental health issues as indicated by reports of anxiety, depression, negative mood, or stress.

Pain Record Statistics

Pain Record Statistics (11 features) consisted of the mean and SD of pain severity ratings, the mean and SD of absolute values of changes between consecutive severity ratings, the average of pain ratings in the following categories: mild (average pain rating <4), moderate (average pain rating ≥4 to ≤7), or severe (average pain rating >7), the mean and SD of pain, the number of pain records in the predictor period, the slope of the trendline of the severity scores, and the absolute value of the slope of the trendline.

Pain Descriptors

Pain Descriptors (127 features) consisted of descriptors of the pain experience entered into the app, including body locations (32 features), symptoms (21 features), characteristics (21

XSL•FO
RenderX

features), environment (8 features), aggravating factors (15 features), effective factors (15 features), and ineffective factors (15 features).

Daily Reflections

Daily Reflections (21 features) consisted of the mean and SD of the daily reflection score, the number of daily reflections in the predictor period, and descriptors of meaningful activities that contributed to the daily reflection rating.

App Usage

App Usage (10 features) consisted of the number of completed sections in the user profile, the number of days with a pain record, the percent of descriptor elements that were completed in their pain records, whether users were referred to the app via an institution, provider, or payer, and the average hour, day, week, or month of their pain records. Please note that in the current dataset, all users were referred to the app via an institution.

Questionnaires

Questionnaires (51 features) consisted of responses and outcome scores on five clinic questionnaires regularly assigned to all TPS clinic patients at both intake and follow-up visits, including (1) PROMIS PI, 8 questions and 3 outcome scores; (2) NRS, 4 questions and 4 outcome scores; (3) PHQ-9, 9 questions and one outcome score; (4) PCS, 13 questions and one outcome score; and (5) GAD-7, 7 questions and one outcome score. Please refer to Multimedia Appendix 1 to see the questions included in each questionnaire.

Prediction Model

Given the relatively small sample size, we used binary logistic regression as it is a simple and straightforward model that has been shown to have good performance with limited datasets [38]. Binary logistic regression is a method used for binary classification, which models the probability of each class as a function of the input variables [38]. It operates by fitting a logistic function to the data. The output of logistic regression lies between 0 and 1, representing the probability that a given input point belongs to the class labeled as 1 (improved class). This is achieved by calculating a linear combination of the input features passed through the logistic function. The coefficients are learned by minimizing a cost function. To keep the weights constrained to a reasonable size and to reduce overfitting, we added an L2 regularization term to the cost function which penalizes the scale of the class weights. Additionally, we balanced the weighting of each class inversely proportional to the class frequencies to correct for class imbalance. The model was implemented with the sklearn library [39] in Python, with the liblinear solver [40], as it performs well on smaller datasets.

We then performed feature selection to identify the significant features and improve the model's generalizability by reducing overfit to the training data. We implemented a recursive feature elimination (RFE) with cross-validation [41]. RFE is a method to identify important features influencing a model's prediction by systematically eliminating the least important features. First, the training dataset is split into 10 train/test subsets using 10-fold cross-validation, ensuring that the feature elimination process is validated across different subsets of data for reliability. Starting with all features, a logistic regression model is trained, and its performance is evaluated on the validation set. Features are ranked based on their importance from their coefficients, and the least important feature is removed from the set. This process is repeated iteratively, each time removing the least important feature, and the model's performance is assessed with cross-validation at each step. The optimal number of features is determined by the point where the model's cross-validation performance is the highest. We used the area under the receiver operating characteristic curve (AUC) as a metric to determine performance. We then implemented a second 10-fold cross-validation to optimize the regularization strength in the logistic regression model using only the selected features.

Model Evaluation

The model algorithm was validated using leave-one-out cross-validation to assess how well the model will perform in practice on unseen data. In this approach, data from one MMP user is used as the test set while data from the remainder of the users is used as the training set. This process is iteratively repeated such that each subject is used exactly once as the test instance. In each iteration, the entire proposed algorithm is repeated with only the data in the training set being used to train the model. This method allows the model to be evaluated on every possible training and test set combination, providing a comprehensive measure of how well the model performs across the entire dataset. We evaluated the model using 4 metrics as follows: the overall accuracy, the accuracy of the improved class (sensitivity), the accuracy of the not-improved class (specificity), and the AUC. Due to the novel nature of both the dataset and the approach, there are currently no standards to compare against. Therefore, we also evaluated using 3 other standard machine learning models in place of the logistic regression model to compare performance: AdaBoost, random forest, and linear support vector machine (SVM). AdaBoost is an ensemble learning algorithm that iteratively combines weak classifiers to improve overall accuracy by focusing on misclassified instances [42]. Random forest, another ensemble method, builds multiple decision trees and combines their predictions, offering robustness to overfitting and the ability to capture nonlinear relationships in the data [43]. The linear SVM is a classification algorithm that identifies the optimal hyperplane to separate data points into distinct classes, making it effective for high-dimensional datasets [44].

Feature Importance Estimation

Logistic regression is valued for its simplicity and interpretability [38]. Feature importance within this model is estimated by analyzing the coefficients. Larger absolute values of these coefficients suggest a stronger impact on the outcome, with positive coefficients increasing the log odds of the outcome (thus making it more likely), and negative coefficients decreasing the log odds (thus making it less likely). In our approach, we used an RFE algorithm, which selects varying numbers of features in each training fold. We first identified which features were consistently selected across all training folds. We then calculated the average coefficients for these features across all training folds and ranked them based on the

XSL•FO
RenderX

absolute values of these averages. This method highlights the features that the model relies on to predict the likelihood of a patient's improvement.

Results

Sample and Dataset Characteristics

The characteristics of the sample of TPS patient users of the MMP app who were included in the study and their records in the MMP app are shown in Table 1. Using an MCID of 2, 72 out of 160 (45%) of the patients showed improvements on the PROMIS PI questionnaire between the predictor and the outcome period. An overview of the PROMIS PI questionnaire response characteristics is shown in Table 2.

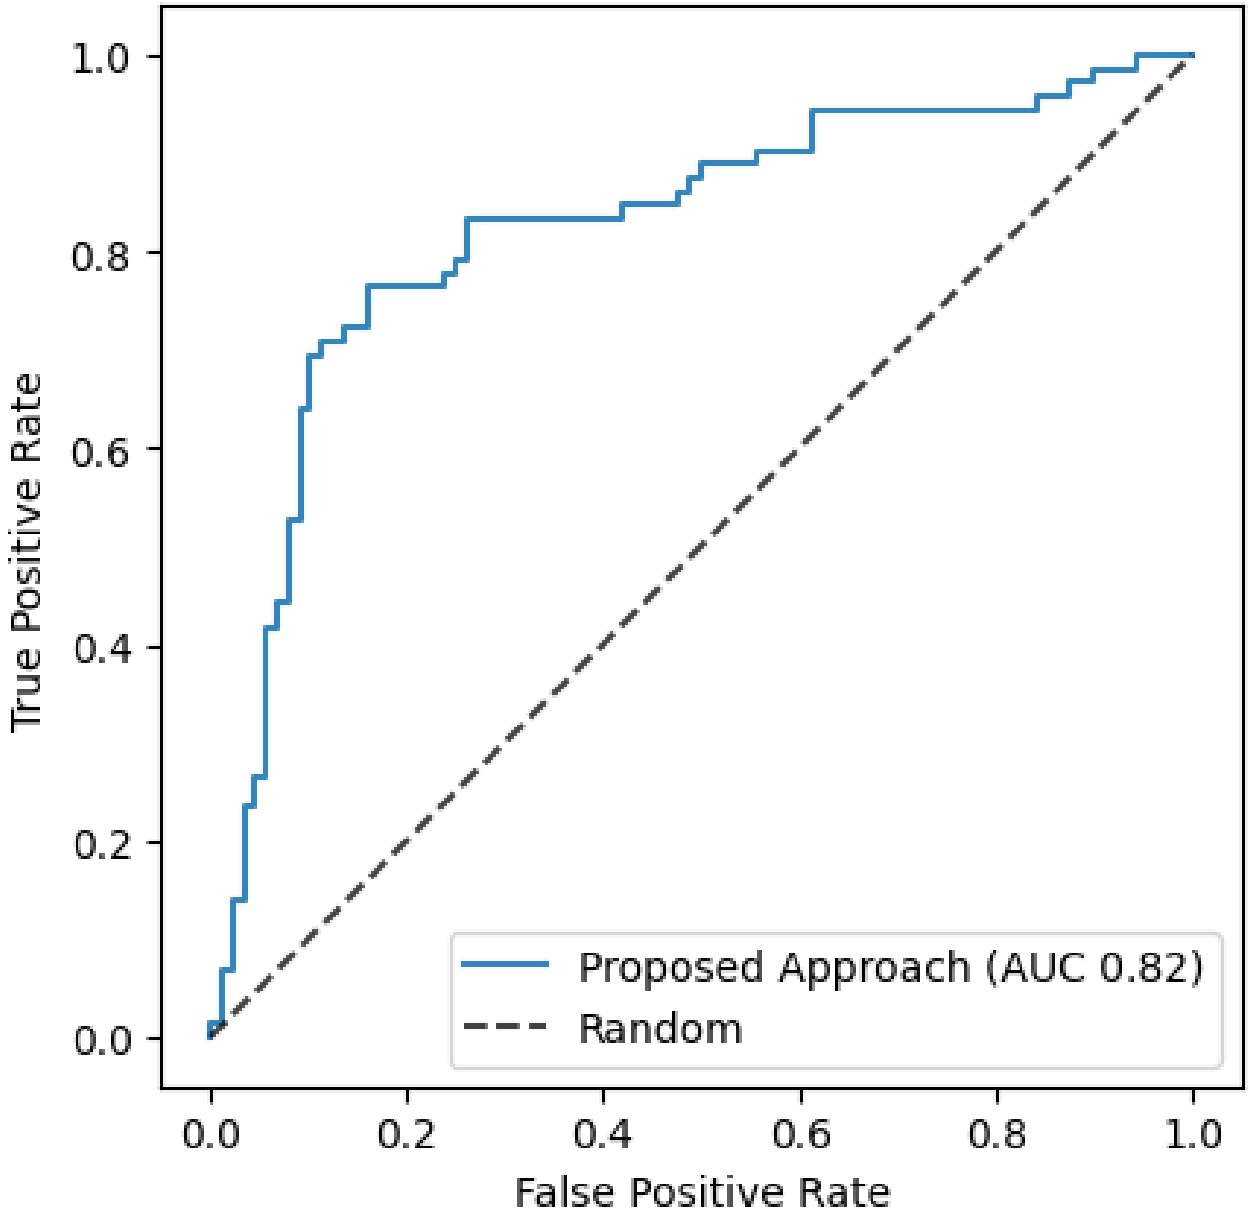
Prediction Results



The model was evaluated on 160 subjects using leave-one-out verification. When evaluated without using RFE, including all features in the model, the accuracy was 74%. Including RFE improved performance by reducing overfitting. Using fewer features, the model had an overall accuracy of 79%, with an even performance across both improved and not improved classes. The accuracy for subjects that improved (sensitivity) was 76% and for subjects that did not improve (specificity) was 82%. The confusion matrix of the prediction results can be seen in Table 3. On average, the algorithm selected a mean of 88 (SD 13) out of the 245 features. The receiver operating characteristic curve is shown in Figure 3. The AUC was 0.82.

Table . Confusion matrix of the prediction results.

	Predicted improved class	Predicted not improved class	Total actual
Actual improved class	55	17	72
Actual not improved class	16	72	88
Total predicted	71	89	160

Figure 3. The receiver operating characteristic curve. The area under the receiver operating characteristic curve (AUC) is 0.82.

Comparison

Three additional models were evaluated to compare against our chosen approach: AdaBoost, random forest, and linear SVM. To directly compare against the logistic regression model, the same prediction pipeline was used. First, the data were preprocessed, and then each model was trained with RFE to optimize the features. While all features were inputted into the pipeline, each model had different RFE optimizations across the training folds. Default hyperparameters were used for each of the models. Table 4 shows the results for each model. The logistic regression model consistently outperforms the other models across all metrics.

Feature Importance

In our study, a varying number of features were selected across 160 training folds, with an average of 88 out of 245 features chosen. Notably, 37 features consistently appeared across all folds. Table 5 displays the mean coefficients from the logistic regression model for these 37 features, indicating their importance in prediction.

[e]GAD-7: General Anxiety Disorder-7.

Questionnaire Comparison

While this work was focused on optimizing a model for predicting improved scores on the PROMIS PI measure, we repeated the same algorithm for each of the questionnaires included in the dataset. As demonstrated in Table 6, responses on PROMIS PI had the best performance with an AUC of 0.81. Responses on GAD-7 and PHQ-9 showed some moderate ability for prediction, with AUCs of 0.64 and 0.74, respectively. Responses on GAD-7, PHQ-9, and PCS demonstrated lower rates of improvement and produced a more imbalanced dataset, possibly leading to decreased performance by the algorithm. Responses on the NRS for pain severity, on the other hand, indicated a similar percentage of improved MMP users as PROMIS PI. Despite the balanced dataset, the predictive model did not achieve any meaningful results, with an AUC of 0.51, which is nearly equivalent to random chance.

Table . Comparison of the logistic regression model performance on PROMIS Pain Interference questionnaire responses compared with the other questionnaires included in the dataset.

Discussion

Principal Findings

This study examined whether a machine learning model could predict clinical outcomes related to pain in a population of TPS clinic patients who used the MMP digital health solution to track symptoms and answer clinic questionnaires. Using MMP app data entered by patients for 30 days, a linear regression model predicted clinically significant improvement in pain interference measured by the PROMIS PI questionnaire with 79% accuracy. The model showed balanced accuracy between improved and not improved classes with a sensitivity of 0.76 and specificity of 0.82.

Analysis of the features used in the model showed that all MMP app data, not just questionnaire responses, were relevant in predicting patient improvement. This finding underscores the critical role of all types of data in the algorithm's efficacy. Features like exercise showed a positive correlation with improved outcomes, while stress was negatively correlated, aligning with clinical expectations. However, many top-ranked features lacked such clinical clarity. This is not unexpected as the machine learning model integrates all features collectively to make predictions, preventing the isolation of individual feature impacts. Some features might be correlated with other variables that influence improvement, and they should not be interpreted independently in this type of prediction approach. Despite these complexities, our results affirm the value of leveraging extensive datasets, allowing the model to identify

XSL•FO
RenderX

influential factors beyond traditional assumptions and providing a robust statistical foundation to determine the factors that predict improvement.

Predicting the development and progression of a chronic pain condition has important clinical implications. Currently, clinicians rely on known risk factors implicated in the development and progression of chronic pain conditions [49-55] to inform clinical decision-making regarding treatment and pain management. However, the individualized nature of chronic pain and the interacting contribution of physical, emotional, and social factors impose considerable challenges in accurately predicting patient outcomes [4,5]. Recent efforts have applied machine learning to large datasets to demonstrate that individualized pain risk scores can be determined from a set of biopsychosocial factors [5]. However, applying this approach in the clinical context is limited by the availability of relevant data for a specific patient population. This study bridges this gap by demonstrating that a pain-tracking app can be used in a real-world clinical setting to gather relevant data in a short period of time and effectively predict clinically significant outcomes related to pain. Information from the MMP app can be used by clinicians alongside traditional approaches to patient assessment to more effectively guide critical decision-making around medication management, such as tapering opioids, and allocation of finite clinic resources to patients with the greatest need. It is important to note that the approach presented here is not intended to identify specific predictors of improvement, but rather to help clinicians evaluate which patients are more or less likely to improve so they can prioritize health care resources accordingly.

Limitations and Future Work

The findings presented here are limited to a small sample of a specific patient population who selected to use the MMP app, which may have contributed to a degree of selection bias in the dataset used for prediction modeling. Additionally, the dataset had many missing data points. Missing data frequently occur in real-world self-reported data sources, such as the one used here [56]. To replace missing values in our dataset, we relied on mean imputation. However, it is important to note that the missing data in the current dataset and the mean imputation approach may have contributed to unrecognized bias in the prediction model and affected the study outcome. Finally, only one clinical outcome is considered in the prediction model and further work is needed to identify how other clinically relevant outcomes can be incorporated into a more comprehensive prediction tool. Further refinement is also needed to increase the accuracy of the prediction model. The next steps in this ongoing work focus on integrating additional data from electronic patient records and facilitating greater engagement from patients with the MMP app. The current real-world use of the app was sufficient to achieve useful predictive insights, despite some caveats in their interpretation. Additional efforts to facilitate user engagement as well as data completion and integration will provide a richer dataset for the prediction algorithm to help improve its predictive capacity.

Conclusion

This study builds on a growing body of work showing the capacity of pain apps like MMP to not only provide retrospective insights on symptom trends, but also serve as a clinical outcome prediction tool. Effectively predicting the progression of pain has the potential to improve clinical decision-making and personalized prevention and treatment of chronic pain. The findings of this study demonstrate that existing digital solutions like the MMP app offer a feasible approach to integrating patients' self-tracking and clinical data in a machine-learning algorithm to develop accurate prediction models that can be used in a real-world clinical setting.

Abstract

Background: Artificial intelligence (AI)–based clinical decision support systems are increasingly used in health care. Uncertainty-aware AI presents the model's confidence in its decision alongside its prediction, whereas black-box AI only provides a prediction. Little is known about how this type of AI affects health care providers' work performance and reaction time.

Objective: This study aimed to determine the effects of black-box and uncertainty-aware AI advice on pharmacist decision-making and reaction time.

Methods: Recruitment emails were sent to pharmacists through professional listservs describing a web-based, crossover, randomized controlled trial. Participants were randomized to the black-box AI or uncertainty-aware AI condition in a 1:1 manner. Participants completed 100 mock verification tasks with AI help and 100 without AI help. The order of no help and AI help was randomized. Participants were exposed to correct and incorrect prescription fills, where the correct decision was to "accept" or "reject," respectively. AI help provided correct (79%) or incorrect (21%) advice. Reaction times, participant decisions, AI advice, and AI help type were recorded for each verification. Likelihood ratio tests compared means across the three categories of AI type for each level of AI correctness.

Results: A total of 30 participants provided complete datasets. An equal number of participants were in each AI condition. Participants' decision-making performance and reaction times differed across the 3 conditions. Accurate AI recommendations resulted in the rejection of the incorrect drug 96.1% and 91.8% of the time for uncertainty-aware AI and black-box AI respectively, compared with 81.2% without AI help. Correctly dispensed medications were accepted at rates of 99.2% with black-box help, 94.1% with uncertainty-aware AI help, and 94.6% without AI help. Uncertainty-aware AI protected against bad AI advice to approve an incorrectly filled medication compared with black-box AI (83.3% vs 76.7%). When the AI recommended rejecting a correctly filled medication, pharmacists without AI help had a higher rate of correctly accepting the medication (94.6%) compared with uncertainty-aware AI help (86.2%) and black-box AI help (81.2%). Uncertainty-aware AI resulted in shorter reaction times than black-box AI and no AI help except in the scenario where "AI rejects the correct drug." Black-box AI did not lead to reduced reaction times compared with pharmacists acting alone.

Conclusions: Pharmacists' performance and reaction times varied by AI type and AI accuracy. Overall, uncertainty-aware AI resulted in faster decision-making and acted as a safeguard against bad AI advice to approve a misfilled medication. Conversely, black-box AI had the longest reaction times, and user performance degraded in the presence of bad AI advice. However, uncertainty-aware AI could result in unnecessary double-checks, but it is preferred over false negative advice, where patients receive the wrong medication. These results highlight the importance of well-designed AI that addresses users' needs, enhances performance, and avoids overreliance on AI.

Introduction

Artificial intelligence (AI) is becoming increasingly prevalent in health care with a wide range of applications such as drug development [1], computer-aided diagnosis and detection [2,3], and clinical decision-making [4]. In particular, AI-based clinical decision support systems (CDSS) can improve medication safety and reduce medication errors. CDSS have been shown to significantly improve medication use and safety in areas such as drug-drug interactions, inappropriate prescribing in older adults and pregnant women, over- and underprescribing, patient counseling [5,6], and patient outcomes (eg, increased medication adherence, lower blood pressure, decreased adverse events) [6].

Recent advances in AI modeling such as deep neural networks have resulted in CDSS that are "black-box" systems; black-box outputs do not provide insight into the model's decision-making process or confidence in its decision [7]. To address the calls for increased transparency in medical AI predictions [8-10], developers have started using uncertainty-aware AI models. Uncertainty-aware AI models present the model's uncertainty, or confidence in its decision, alongside its prediction [11], thus providing a metric for the user to assess the AI's reliability [12]. CDSS reliability is an essential component of human evaluation of AI's trustworthiness which determines the user's acceptability of a technology [7]. While uncertainty-aware AI models increase transparency, additional knowledge is required to interpret the findings which may initially confuse users, leading to increased cognitive effort and degraded decision-making [13].

In addition to transparency, automation bias and aversion must be considered when developing CDSS. Automation bias occurs when users forsake their own expertise in favor of the AI's advice [12,14]. The overreliance caused by automation bias may result in users missing AI-generated errors. Automation aversion causes users to rapidly and persistently lose trust due to an AI-generated error even when the AI's overall performance exceeds humans [12]. Consequently, human errors are missed. An ideal human-centered AI tool should generate clinically valid decisions while fostering trust and avoiding overreliance on AI.

An unexplored avenue for AI-based CDSS is the medication verification process. Medication verification is a vital yet time-consuming visual check to ensure the contents of a filled medication vial match the prescribed medication. Despite pharmacists' careful medication verification process, dispensing errors occur in 1.5% of all prescriptions [15]. Vigilance, or the ability to maintain focus and alertness over long periods, is essential for repeated tasks such as medication verification [16]. Pharmacists must remain alert and cognitively engaged [17]; yet, human vigilance wanes over time. Waning vigilance may be due to fatigue, cognitive overload, or the mundanity of repetitive tasks [18,19]. This is especially concerning in community pharmacies due to the increasing prescription volumes. In 2022, the average community pharmacy dispensed approximately 1215 prescriptions per week [20]. The increase in prescription volumes necessitates additional effort and time from pharmacists who spend between 30% - 48% of their time verifying medications [21,22].

Our team developed an AI prototype to assist pharmacists with the medication verification task, with the goal of reducing dispensing errors, improving patient safety, and decreasing pharmacists' workload. The development of our AI tool using user-centered design principles is described in a study by Zheng et al [23]. The purpose of this paper is to determine the effects of black-box and uncertainty-aware AI advice on pharmacist decision-making and reaction time.

Methods

Overview

We previously developed 2 AI conditions to assist pharmacists with making decisions when dispensing medications. The "black-box" condition does not provide the user with insight into the AI's certainty or predicted probability of a correct decision. The "uncertainty-aware" condition provides the user with an estimate of certainty from the model predictions. We tested these conditions in an experimental study using mock verification tasks with pharmacists.

Trial Design

A crossover, randomized controlled trial was conducted from January 2023 to May 2023 with licensed pharmacists in the United States. Eligible participants were randomized to either the black-box AI or uncertainty-aware AI condition in a 1:1 manner. All participants completed 100 mock verifications with AI help and 100 mock verifications without AI help. The order of no help and AI help was randomized.

Participants

Recruitment emails describing the study were sent to pharmacists through the Minnesota Pharmacy Practice-Based Research Network listserv and the University of Michigan College of Pharmacy Preceptor Network listserv. Interested individuals contacted the study team directly and completed a screening phone call. Eligible participants were licensed pharmacists in the United States who were at least 18 years old and had access to a laptop or desktop computer with a webcam. Pharmacists were excluded if they required assistive technology to use the computer, wore eyeglasses with more than 1 power, had uncorrected cataracts, intraocular implants, glaucoma, or permanently dilated pupils, or had eye movement or alignment abnormalities (eg, lazy eye, strabismus, and nystagmus).

AI Input

We previously obtained a dataset of 432,734 images from a mail-order pharmacy that fills and ships prescriptions to all 50 US states [24]. The data contain 1 year's worth of images of oral medications (ie, tablets and capsules) inside a prescription vial filled by a robot. The images were taken as the final step of an automated system using a robot to count pills into a vial, label the vial, take photos of the vial's contents, and cap the vial. The dataset images are aligned with a National Drug Code (NDC) label and different attributes including color, shape, size in millimeters of pills, manufacturer, tablet scoring, and imprint. The number of images for each NDC ranges from 3 to 12,105 with a median of 540. There are 12 different colors of medications labeled in these images: white (182,178/432,734;

XSL•FO
RenderX

42.1%), yellow (53,296/432,734; 12.3%), pink (39,241/432,734; 9.1%), orange (30,846/432,734; 7.1%), multi-color (25,442/432,734; 5.9%), green (22,689/432,734; 5.2%), red (22,433/432,734; 5.2%), blue (20,704/432,734; 4.8%), brown (16,260/432,734; 3.8%), purple (13,609/432,734; 3.1%), turquoise (3090/432,734; 0.7%), and gray (2946/432,734; 0.7%). Seven different shapes are identified in the data: round (214,475/432,734;49.6%), oval (144,568/432,734; 33.4%), capsule (69,892/432,734; 16.2%), hexagon-6-sided (1912/432,734; 0.4%), triangle (1226/432,734; 0.3%), trapezoid (464/432,734; 0.1%) and pentagon-five sided (197/432,734; 0.04%).

Interventions

The AI model in our study refers to a Bayesian neural network that predicts the dispensed pills' NDC along with the uncertainty of the predictions. It is realized by applying the random dropout technique [25] to the ResNet-34 [26] convolutional neural network. Rather than simply predicting the probabilities of belonging to a specific NDC, the dropout technique enables the neural network to sample a set of possible predictions which we use to measure the uncertainty of the prediction. In our research, the model generated 50 potential probabilities for every image.

Fill accuracy is a dichotomous variable (correct fill or incorrect fill) determined by comparing the fill image to the reference image (ground truth). Matching fill and reference image pairs are labeled correct fills and mismatched pairs are labeled incorrect fills. This serves as the ground truth for the image pair. AI accuracy (good prediction or bad prediction) is a variable that indicates the AI's accuracy in predicting the fill image's NDC. A "good prediction" means the AI correctly identified the NDC, whereas a "bad prediction" incorrectly predicted the NDC. Good predictions always recommend the correct user action (accept or reject), whereas bad predictions typically result in ill-advised recommendations.

Each AI condition consisted of 100 trials with 76 trials containing correctly filled medications and 24 trials containing misfilled medications. For the correctly filled medications, the AI accurately recommended accepting (AI Accept) in 60 trials and erroneously recommended rejecting (AI Reject) in 16 trials. For the 24 trials containing misfilled medications, the AI accurately recommended AI Reject for 22 trials and erroneously recommended AI Accept for 2 trials. Three of the AI Reject trials contained an incorrect fill coupled with a bad prediction resulting in the correct recommendation (AI Reject). Although the AI's predicted NDC was incorrect (ie, misidentified the fill image NDC), the AI renders the correct advice to reject the misfilled medication.

While the AI model's overall accuracy is 98.46%, it was lowered to 79% for the experiment. Participants' interaction with AI errors is a critical component of the research. Lowering the model's accuracy significantly reduced the number of AI help trials needed to display the requisite number of AI errors. In the no-help condition, 76% of the medications were correctly filled.

The NDCs, the reference images, and the filled images were gathered from the correctly and incorrectly predicted images of the Bayesian neural network model. To eliminate potential confounding variables, each reference NDC was shown no more than twice throughout the experiment. To avoid loss of variation in colors, capsules, and oddly shaped pills while excluding blurry fill images, the team members carefully selected from the model-predicted images. Each image was reviewed for accuracy by comparing a reference image (ground truth) to the fill image.

There were 40 unique NDCs in the incorrect prediction file of the Bayesian neural network model. The NDCs, the reference images, and the images for cases involving bad AI predictions (AI approves the incorrect drug, and AI rejects the correct drug) were gathered from the incorrect prediction file. The NDCs and the reference images for cases involving good AI prediction for the incorrectly filled medication (AI rejects the incorrect drug) were gathered from the incorrect prediction file. The filled images were gathered from the correct prediction file.

The study used Labvanced (Scicovery GmbH), an online, browser-based platform, to conduct the mock verifications. Participants met with a study team member through Zoom (Zoom Communications Inc) before completing the medication verification tasks to ensure technical and environmental requirements were met (eg, working webcam, adequate lighting, and quiet space). After confirming the participant's setup was sufficient, the study team member provided the participant with a link to the experiment and a password. A video presentation explained how to perform the mock medication verification task using the study interface. Participants were informed that the goal of the task was to determine whether an image of a filled medication bottle matched a known reference image. The video presentation also explained the AI help condition to the participant with a tailored explanation based on randomization assignment. The interface displayed an image of a filled medication, a reference image, and prescription information (Figure 1). The task was to compare the "reference image" on the left to the "fill image" on the right to determine whether to accept or reject the dispensed medication. The "reference image" is the ground truth. For half the trials there was AI help on the bottom right of the screen. In the AI help conditions, the interface displayed AI advice as green checkboxes indicating AI matches based on characteristics of the pill (ie, black box), or a histogram with predicted probabilities (ie, uncertainty) and the checkbox figure (Figure 2). The AI advice was created from a ResNet-34 neural network.

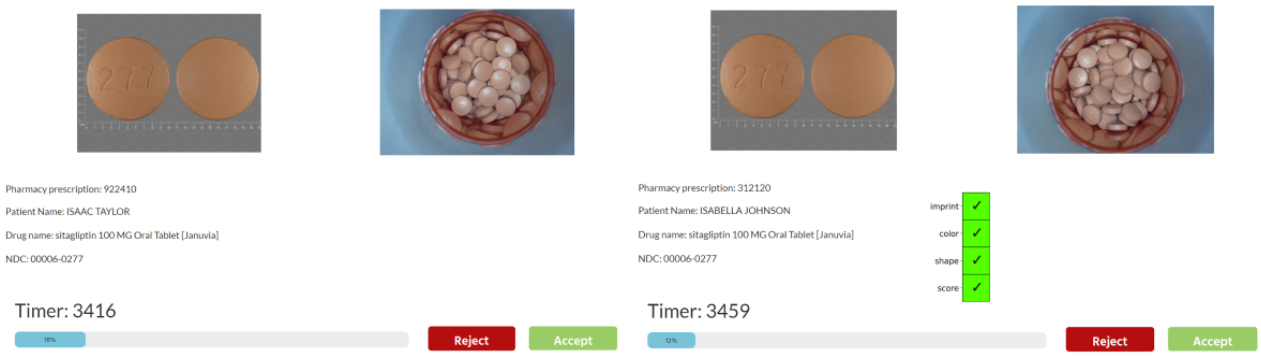

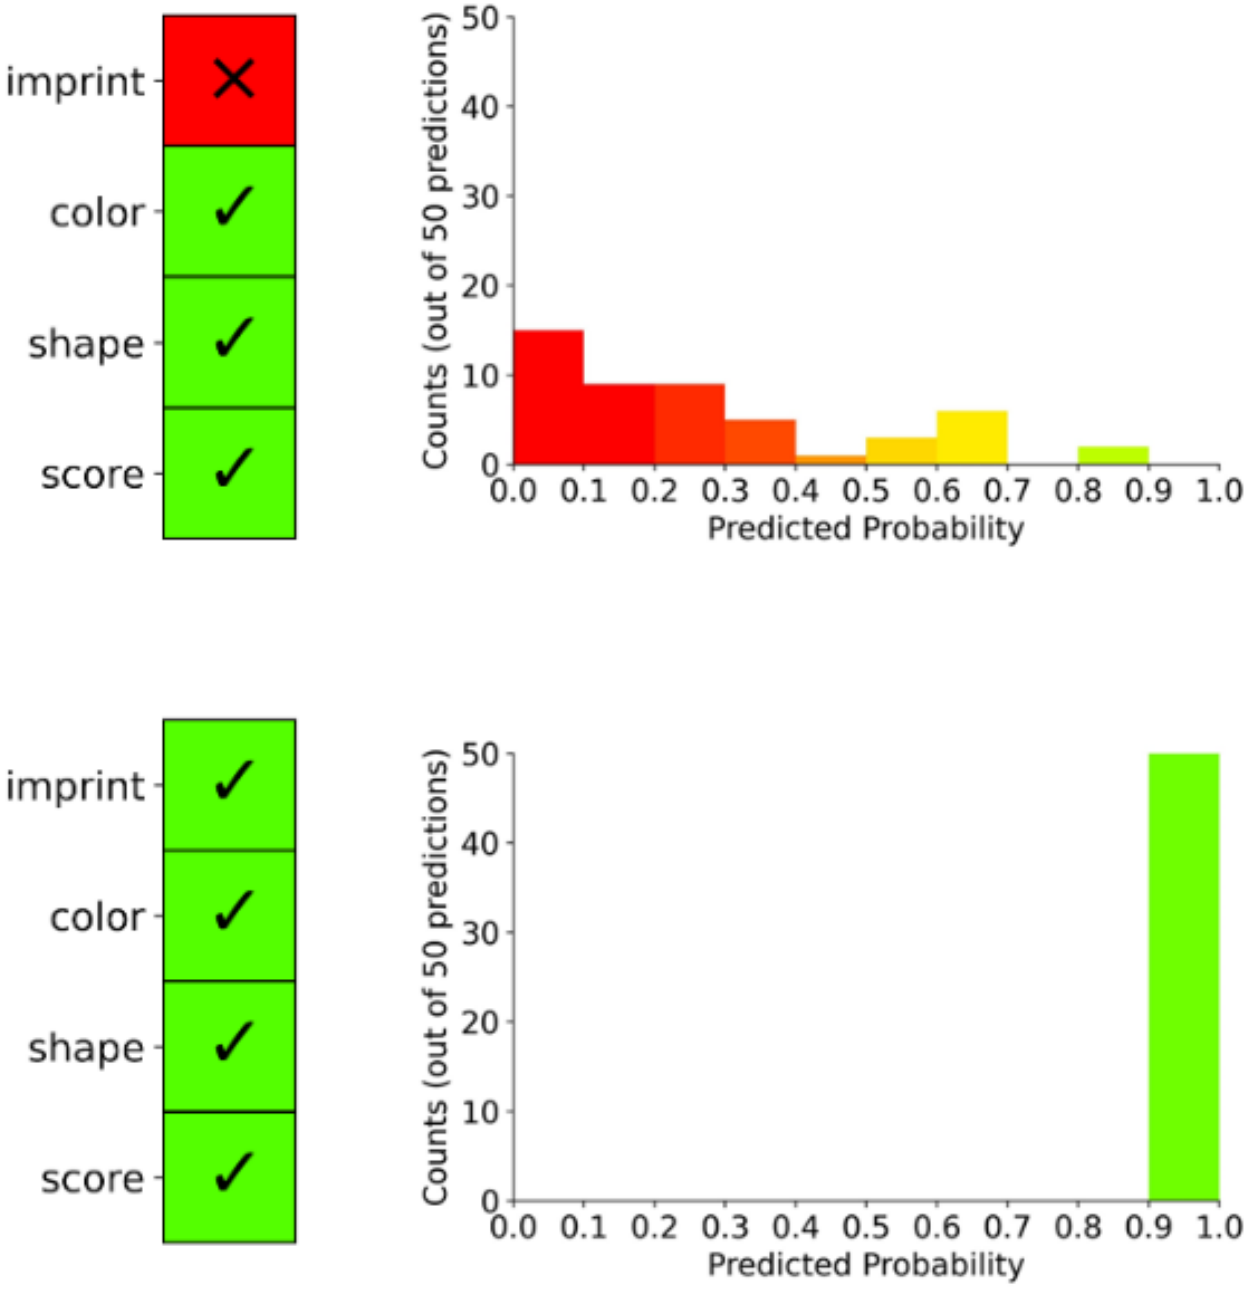

Figure 2. Presentations of 2 artificial intelligence (AI) models. The left-hand graphs are "black-box AI," which displays "yes" or "no" for 4 pill characteristics: imprint, color, shape, and score. The right-hand graphs are "uncertainty-aware AI," which illustrates the predicted probability of each set of predictions summarized in a histogram.

XSL•FO
RenderX

Each participant completed 200 verification tasks, a block of 100 verifications with AI help, and a block of 100 verifications without AI help. The order of the AI help and no AI blocks was randomized for each participant to avoid an order effect, but the order of trials within each block was fixed. The pharmacist's decision to approve or reject the filled medication and the time to decide were recorded for each verification. After each verification in the AI help condition, participants rated how much they trusted the AI advice on a scale of 0 to 100.

Analyses

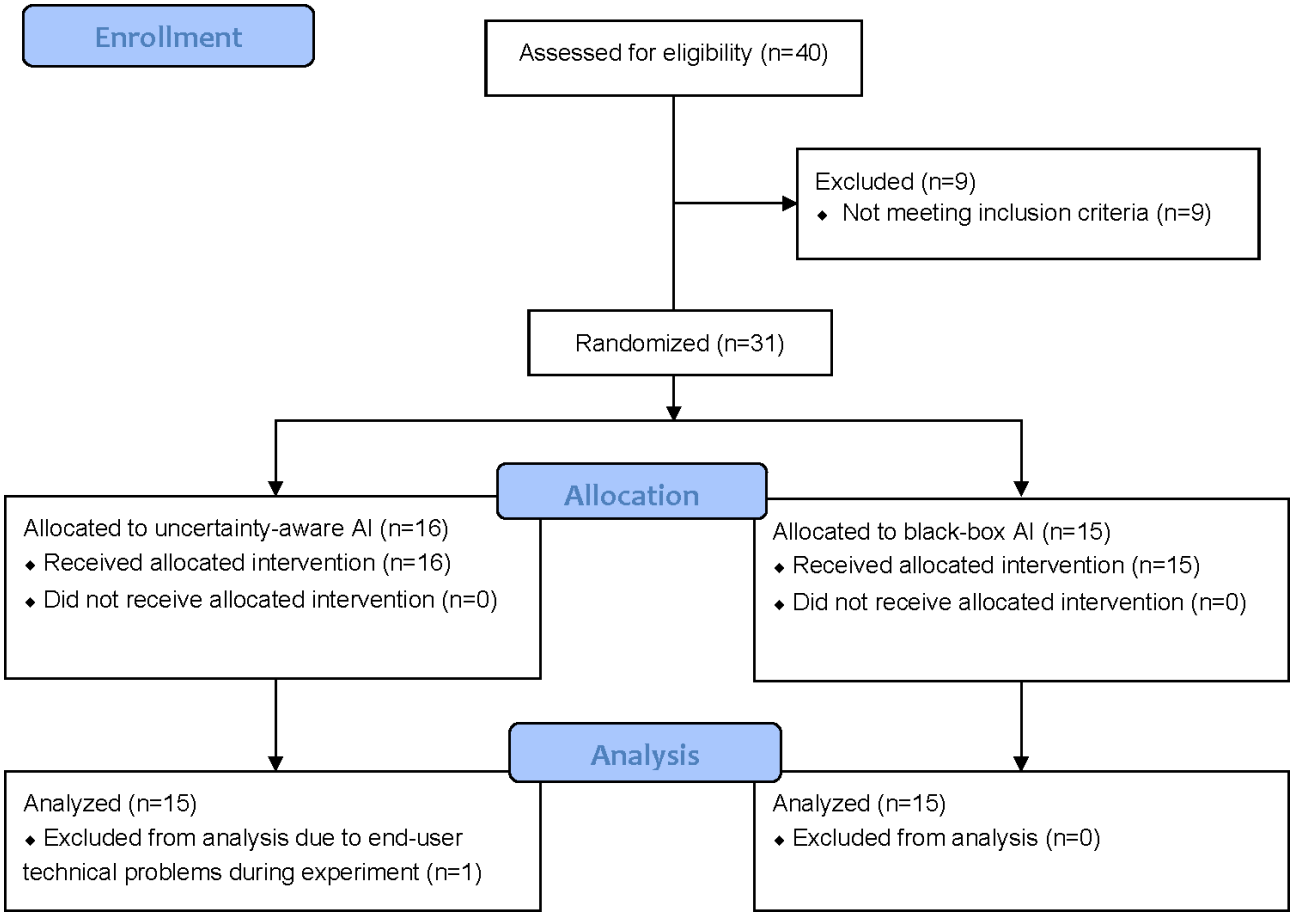
The outcomes of accuracy and reaction time were analyzed in mixed model generalized linear models with categorical predictors. The generalized linear models formulas were Performance~main.eff+(1|Participant_Nr) for accuracy and Reaction_Time~main.eff+(1|Participant_Nr) for reaction time. Categorical predictors included the AI type (ie, black-box AI, uncertainty-aware AI, or no AI help), and AI correctness versus ground truth, making the 2 × 2 comparison with 4 categories. Likelihood ratio tests compared means across the 3 categories of AI type for each level of AI correctness. The simple effects of uncertainty-aware AI and black-box AI and user performance based on AI type were examined. Statistical comparisons were performed with R statistical software (version 4.2.2, R Foundation for Statistical Computing) [27].

Randomization

A random number generator in R software was used to ensure unbiased study designs. Numbers from 1 to 8 were randomly generated for each participant and participants had an equal probability of being assigned to either the uncertainty-aware AI condition or the black-box AI condition at the start. An equal number of participants were sought for each of the 8 study conditions.

Ethical Considerations

The University of Michigan Institutional Review Board determined this research (HUM00213493) met the criteria for Exemption #3 and was exempt from institutional review board oversight. All participants signed a prospective agreement before any research activities. Participants received a US $150 check for completing the study. All study data have been deidentified. The experimental data were collected in Labvanced using a computer-generated unique 6-digit code.



Results

Recruitment

Recruitment began in January 2023 and the final participant visit was in May 2023. The single study visit was conducted remotely using a laptop or desktop computer. The trial ended when the target enrollment was met. In total, 40 pharmacists were assessed for eligibility. After excluding 9 pharmacists who did not meet the inclusion criteria, 31 participants were randomized for allocation in the "black-box AI" condition or the "uncertainty-aware AI" condition. Ultimately, 15 participants in each condition completed the experiment and were included in the subsequent analysis (Figure 3). The median length of the study visit was 59.3 (IRQ 53 - 65.1) minutes.

XSL•FO
RenderX

Figure 3. Participant flow of the randomized controlled trial for effect of AI models on medication dispensing in pharmacists. AI: artificial intelligence.

Study Population

As shown in Table 1, 30 pharmacists were included in the final analysis (black-box AI and uncertainty-aware AI condition). We investigated demographic characteristics for age, sex, race, practice settings, and working years. All the variables were well-balanced according to *P* values ($P>.05$). However, according to the effect sizes, some variables were unbalanced. Age had the largest value (0.68). Sex had the only true “small” effect size of 0.07 SD units. The rest were within the range of 0.07 and 0.42 SD units.

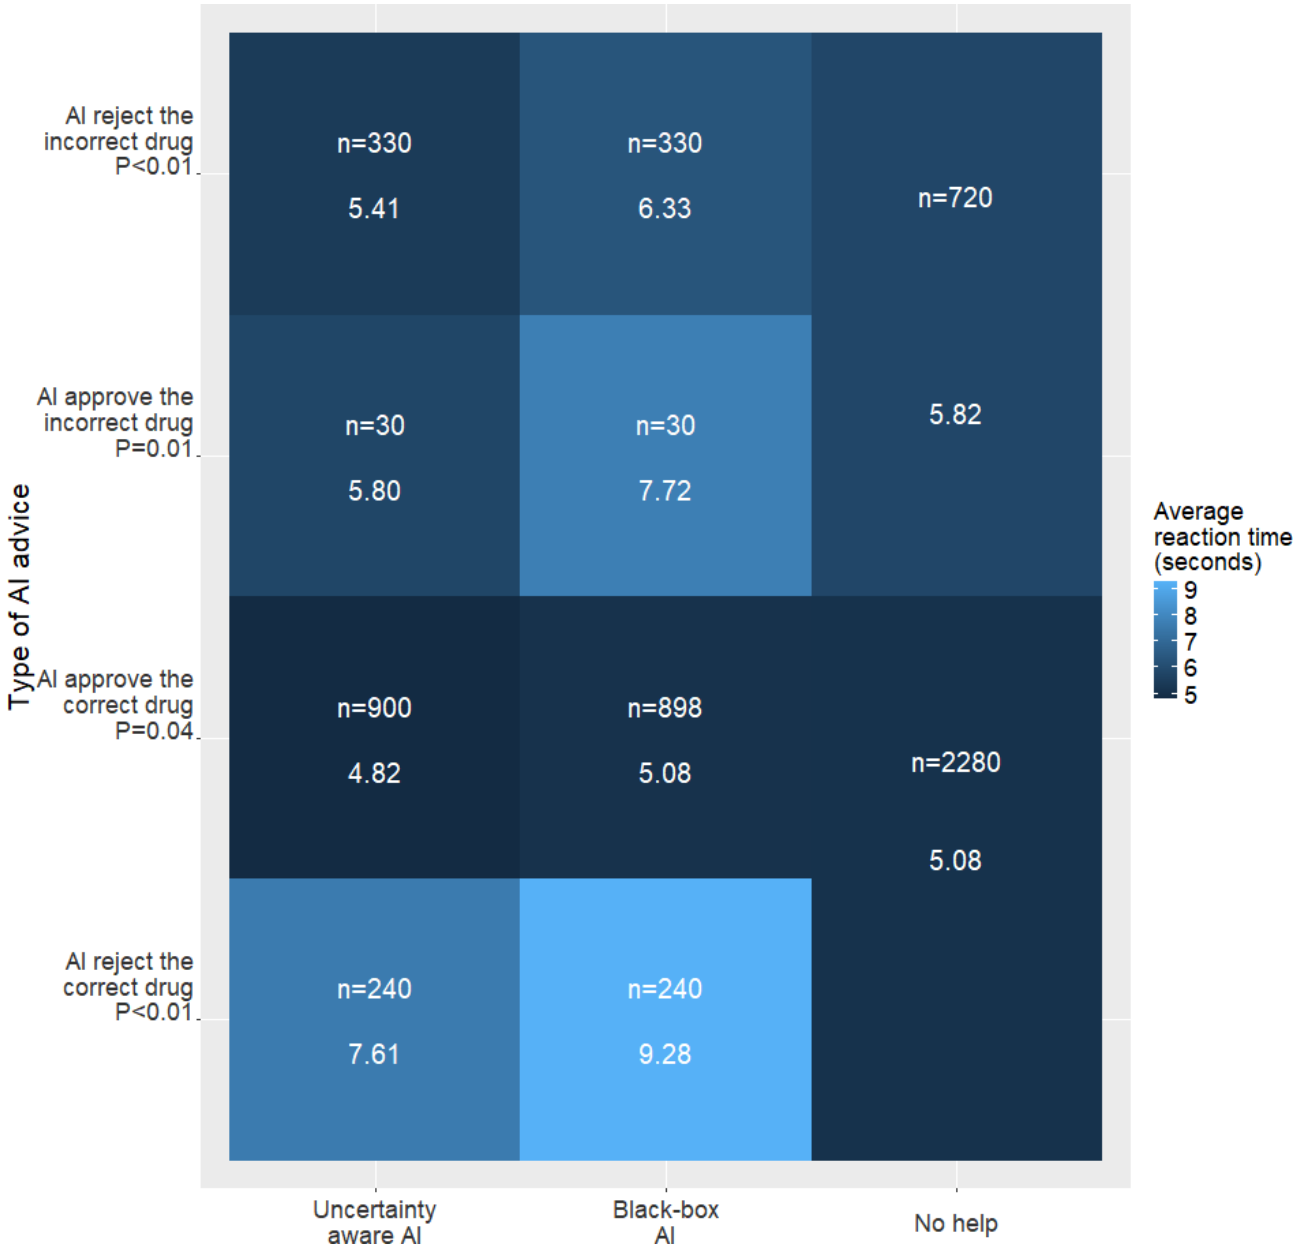
Outcomes

The effects of AI assistance on user trust are reported by Kim et al [28] In summary, pharmacists' trust varied by AI help type and the verification outcome. Overall, uncertainty-aware AI significantly increased pharmacists' trust.

Pharmacists made the correct decision 91.3%, 93.1%, and 94.2% across all trials in the no-help, uncertainty-aware AI, and black-box AI blocks, respectively (χ^2_2=12.5, *P* value=.001). Performance differences emerged across the 3 conditions when examining performance by AI advice type. Figure 4 illustrates pharmacists' performance based on AI accuracy (ie, good advice or bad advice). Similar differences were found for reaction time (Figure 5).



XSL•FO
RenderX

Figure 4. Plot of pharmacists' decision-making performance (% of correct decisions; higher is better). AI: artificial intelligence.

XSL•FO
RenderX

Figure 5. Plot of reaction time (in seconds; higher is worse) of included pharmacists. AI: artificial intelligence.

AI advice was divided into "Good advice" and "Bad advice." For "Good advice," 2 subtypes were identified: "AI Rejects Incorrect Drug" (Figure 4, Row 1) and "AI Approves Correct Drug" (Figure 4, row 3). In the first subtype, pharmacists rejected the incorrect drug 96.1% and 91.8% of the time for uncertainty-aware AI and black-box AI respectively, compared with no AI help (81.2%). When the AI suggested approving the correct drug, performances with black-box AI help surpassed those with uncertainty-aware AI help and no AI help (99.2% vs 94.1% vs 94.6%).

"AI Approves Incorrect Drug" (Figure 4, row 2) and "AI Rejects Correct Drug" (Figure 4, row 4) were classified in the Bad advice category. Despite AI's incorrect predictions, pharmacists demonstrated superior outcomes with uncertainty-aware AI compared with black-box AI help. Uncertainty-aware AI helped protect against AI advice to approve an incorrectly filled medication in contrast with black-box AI (83.3% vs 76.7%). False alerts from AI to reject the correct drug, degraded pharmacists' performance compared with baseline performance without AI help. Accuracy for no AI help, uncertainty-aware AI help, and black-box AI help was 94.6%, 86.2%, and 81.2%, respectively.

Figure 5 displays the reaction time for each condition. Pharmacists assisted by uncertainty-aware AI consistently exhibited shorter reaction times than those aided by black-box AI in the 4 scenarios discussed above (5.41 vs 6.33, 5.80 vs 7.72, 4.82 vs 5.08, 7.61 vs 9.28). Furthermore, the uncertainty-aware AI help condition showed improved reaction times compared with the no AI help condition except in the scenario where "AI rejects the correct drug." Black-box AI did not lead to reduced reaction times in any of the situations as contrasted with no AI help.

Discussion

Principal Findings

In this study, we performed a randomized controlled trial to assess the effects of black box and uncertainty-aware AI tools on pharmacist decision-making and reaction time during the medication verification process. In our assessment of the impact of AI assistance on pharmacists' reaction times, distinct patterns emerged between uncertainty-aware AI and black-box AI. Black-box AI increased reaction times compared with pharmacists acting alone. In contrast, pharmacists receiving uncertainty-aware AI advice had the quickest reaction times except when the AI erroneously recommended rejecting a correctly filled medication.

Research on the effectiveness of AI tools to improve efficiency in health care has shown mixed results. Wysocki et al's [29] research showed that health care providers required significantly less time to make a decision when there was AI-user congruence with explainable AI assistance compared with the black-box AI assistance, which mirrors our results. However, in the face of health care provider-AI disagreement, no significant differences in time to decision were found between explainable AI and black-box AI [29]. A systematic review examining AI tools' effects in safety-critical fields uncovered mixed results in AI's ability to improve pathologists' efficiency [30]. One study in the review showed pathologists with explainable AI assistance completed the task in only 35% of the time required for manual task completion [31], while another study found explainable AI assistance resulted in a significantly longer time to complete the task compared with pathologists working alone [32]. The variability of efficiency underscores the current state of affairs for AI in health care; the field is still in its infancy and more research is needed to understand how to balance transparency and interpretability. In our research with pharmacists, black-box AI's inability to reduce reaction times in any of the scenarios prompts concerns about its practical efficacy in fast-paced pharmacy practice. Future research should examine the design of explainable AI visualizations to facilitate more immediate decision-making when the AI and user disagree.

Ensuring patients receive safe, accurate medication is the bedrock of the pharmacy profession. The pharmacist's role mandates that the 5 rights of medication administration are upheld: right medication, right dose, right route, right patient, and right time [33]. Medication errors can result in significant patient harm, including emergency department visits, hospitalizations, and death [34-36] for which the pharmacist can be held legally responsible [37]. In safety-critical fields like medicine, the benefits of AI tools must be weighed against the risks [30]. In our study, the black-box AI facilitated greater acceptance of a correctly filled medication and thus, a reduction in unnecessary double-checks; however, this benefit is overshadowed by its propensity to misguide pharmacists to accept a potentially harmful misfilled medication. Crucially for this safety-critical field, the uncertainty-aware AI condition facilitated faster and more accurate identification of a misfilled medication than black-box AI or pharmacists acting alone. This demonstrates that uncertainty-aware AI safeguards against dispensing a misfilled medication. Gu et al's [32] study of a human-AI diagnostic tool found pathologists preferred the AI system to err in the direction of false positives due to the harmful outcomes of missed diagnoses and delayed treatment. Similar to the medication verification process, pathologists' reviews are performed quickly and pathologists indicated that the extra review is preferable to a missed diagnosis. Extrapolating these results to our study, uncertainty-aware AI's ability to improve pharmacists' identification of misfilled medications is preferable to the black-box AI help, and the potential workload increase due to unnecessary double-checks is offset by improved patient safety.

The histogram shown in the uncertainty-aware AI advice was developed based on pharmacists' feedback during the user-centered design phase wherein they expressed a desire to see the probability of each predicted NDC to increase the model's transparency [23]. In this case, the histogram may have attuned pharmacists to the idea of the AI advice being fallible and dispensing a wrong medication, whereas this factor was not apparent in the black box scenario. Pharmacists receiving uncertainty-aware advice were more likely to reject correctly and incorrectly filled medication regardless of the AI's advice (accept or reject) suggesting the histogram introduced doubt which caused pharmacists to act more cautiously in order to avoid an incorrect dispense. Previous research has shown ambiguity in decision-making heightens an individual's sensitivity to errors and results in more conservative behavior [38,39]. Pharmacists tend to be risk-averse individuals who dislike ambiguity [40], and when faced with ambiguity are likely to act conservatively (eg, reject a filled medication). In contrast, the black-box AI advice did not induce this same kind of doubt, perhaps leading pharmacists to "go with their gut." Future research should explore more readily interpretable uncertainty visualizations to decrease ambiguity. A systematic review of 24 studies of human-AI collaboration in safety-critical fields found users prefer clean, simple, and easy-to-read visualizations [10]. Alternative ways to present AI uncertainty information to domain experts may balance transparency, uncertainty interpretability, and user performance.

Obtaining second opinions from colleagues is a common health care practice. AI can stand in for colleagues by quickly providing second opinions, but it is critical to communicate any ambiguity or uncertainty in its prediction to foster user trust and allow users to make judgments about when to trust the AI [8]. In interviews with pathologists about an AI tool, pathologists discussed the benefit of knowing their colleagues' experiences, strengths, and weaknesses, thus allowing them to calibrate their responses to a colleague's second opinion [38]. They identified needing a similar level of familiarity with the AI's training, strengths, and weaknesses to successfully incorporate the AI's advice in their decision-making process. Relatedly, previous research has shown that AI errors result in a significant and persistent loss of trust [41]. Explainable AI has been proposed as a solution to increase users' trust by explicitly acknowledging the AI limitations [39]. However, Buçinca et al [42] found explainable AI may contribute to overreliance on AI advice. This contradicts our results from the uncertainty-aware condition; pharmacists with uncertainty-aware AI were more

XSL•FO
RenderX

likely to reject a correctly filled medication when the uncertainty-aware AI suggested accepting it compared with black-box AI and the pharmacist acting alone. Conversely, our results indicate that black-box AI can be over-relied upon, especially false negative errors from the AI. A balance between fostering trust and avoiding overreliance is needed to ensure an optimal human-AI teaming experience.

The timing of AI advice relative to the user's decision may influence the user's performance and trust. Gajos and Mamykina [43] recently examined AI advice timing in 3 conditions: (1) AI recommendation and explanation before making a decision, (2) AI recommendation and explanation after making a decision, and (3) AI explanation only before making a decision. While all 3 conditions led to improved decision accuracy, only the third condition showed improvement in both decision accuracy and learning gain. A 2022 study of AI timing in clinical imaging found veterinary radiologists had lower trust in the AI, lower perceived utility of the AI, and less agreement with the AI, regardless of the AI's correctness, when the advice was presented after their initial clinical decision [44]. Additional research should examine the timing of AI advice on pharmacists' trust and accuracy.

Limitations

The study has several limitations. First, the no help condition used a different image set than the AI help conditions. The same image set was used for both AI help conditions. While the images were randomly selected for both AI help and no help conditions, unanticipated biases in the image selection may exist. Second, the images were presented in a fixed order, which may have unintentionally biased the results. Future research should randomize the presentation of the images across all conditions for all participants to eliminate any inherent bias. Third, the small number of participants from 2 professional pharmacy networks may not be representative of the pharmacy community at large. Future research should be conducted with a broader, more diverse population of pharmacists. Finally, medication verification is only 1 step in the medication dispensing process. Additional research could examine the use of AI tools to support pharmacy staff at all steps of the dispensing process such as order entry, patient directions, and medication count.

Conclusion

The effectiveness of AI assistance on pharmacists' performance and reaction times varied by AI type and AI accuracy. Overall, uncertainty-aware AI resulted in faster decision-making, and black-box AI had the slowest decision-making. Concerningly, black-box AI worsened users' accuracy when the AI provided bad advice, thus increasing the potential for patient harm. Uncertainty-aware AI acted as a safeguard against bad AI advice to approve a misfilled medication, reducing the chance of patient harm. However, pharmacists with uncertainty-aware AI performed worse and had longer reaction times when the AI recommended incorrectly rejecting a correctly filled medication compared with no AI help, leading to unnecessary double-checks. These results reinforce the importance of well-designed AI to meet users' needs to ensure consistent benefits over no AI help.

Abstract

Background: Critically ill patients in intensive care units (ICUs) require continuous monitoring, generating vast amounts of data. Clinical decision support systems (CDSS) leveraging artificial intelligence (AI) technologies have shown promise in improving diagnostic, prognostic, and therapeutic decision-making. However, these models are rarely implemented in clinical practice.

Objective: The aim of this study was to survey ICU physicians to understand their expectations, opinions, and level of knowledge regarding a proposed AI-based CDSS for continuous renal replacement therapy (CRRT) weaning, a clinical decision-making process that is still complex and lacking in guidelines. This will be used to guide the development of an AI-based CDSS on which our team is working to ensure user-centered design and successful integration into clinical practice.

Methods: A prospective cross-sectional survey of French-speaking physicians with clinical activity in intensive care was conducted between December 2023 and April 2024. The questionnaire consisted of 20 questions structured around 4 axes: overview of the problem and current practices concerning weaning from CRRT, opinion on AI-based CDSS, implementation in daily clinical practice, real-life operation and willingness to adopt the CDSS in everyday practice. Statistical analyses included Wilcoxon rank sum tests for quantitative variables and χ^2 or Fisher exact tests for qualitative variables, with multivariate analyses performed using ordinal logistic regression.

Results: A total of 171 complete responses were received. Physicians expressed an interest in a CDSS for CRRT weaning, with 70.2% (120/171) viewing AI-based CDSS favorably. Opinions were split regarding the difficulty of the weaning decision itself, with 46.2% (79/171) disagreeing that it is challenging, while 31.6% (54/171) agreed. However, 66.1% (113/171) of respondents supported the value of an AI-based CDSS to assist them in this decision, with younger physicians showing stronger support (81.8%, 27/33 vs 62.3%; 86/138; *P*=.01). Most respondents (163/171, 95.3%) emphasized the importance of understanding the criteria used by the model to make its predictions.

Conclusions: Our findings highlight an optimistic attitude among ICU physicians toward AI-based CDSS for CRRT weaning, emphasizing the need for transparency, integration into existing workflows, and alignment with clinicians' decision-making processes. Actionable recommendations include incorporating key variables such as urine output and biological parameters, defining probability thresholds for recommendations and ensuring model transparency to facilitate the successful adoption and integration into clinical practice. The methodology of this survey may help the development of further predevelopment studies accompanying AI-based CDSS projects.

Introduction

Critically ill patients admitted to intensive care units (ICUs) require continuous monitoring and surveillance of clinical, biological, and imaging parameters. This generates a large amount of data, making effective data exploitation a key challenge [1]. Recent advances in artificial intelligence (AI), particularly machine learning (ML), have facilitated the development of diagnostic, prognostic, and therapeutic decision-making aids known as clinical decision support systems (CDSS). These AI-based CDSS have demonstrated potential across several domains in ICU, including sepsis prediction, early detection of patient deterioration, and management of mechanical ventilation [2-4]. For instance, AI models for sepsis prediction can alert clinicians to septic events hours before clinical signs emerge, enabling timely interventions [5]. Similarly, early warning systems for patient deterioration, have shown promise in improving outcomes through real-time data analysis [2].

Despite these advances, most AI-based CDSS models fail to progress beyond the prototype stage and are rarely deployed into clinical practice, even though their performance is sometimes promising [6]. A recent meta-analysis analyzed publications concerning the use of AI in the ICU: out of the 494 articles studied, the majority were retrospective studies 476 articles (96.4%). In total, 10 articles (10/494, 2%) were clinical studies, of which only 5 (5/494, 1%) were randomized trials with a control arm. In addition, the majority of retrospective studies presented a high risk of bias [3]. In the domain of renal care we also observe this disconnect, where AI algorithms have been developed to predict acute kidney injury (AKI), offering valuable insights into early identification and prognosis [7,8]. AKI, a common condition affecting up to 60% of ICU patients [9], often necessitates renal replacement therapy (RRT) in severe cases. Continuous renal replacement therapy (CRRT) is a specific modality of RRT frequently used in critically ill patients, providing continuous 24-hour support that is well-suited for hemodynamically unstable patients [10].

While significant research has focused on the optimal timing for initiating CRRT [11,12], much less attention has been given to the question of when and how to discontinue this therapy [13]. This represents a critical gap in clinical practice, as premature weaning may lead to the recurrence of renal dysfunction, associated with complications such as fluid overload and electrolyte imbalances necessitating the reintroduction of renal support [14,15]. On the other hand, unnecessary prolongation of therapy can expose patients to greater risks, including catheter-related complications, higher infection rates, unnecessary resource utilization, extended ICU stays and delayed renal recovery [16]. Thus, identifying reliable criteria and developing decision support tools for successful weaning from CRRT is an ongoing and essential area of research.

AI-based CDSS present a compelling solution to this problem. By leveraging ICU data, these tools could provide individualized weaning recommendations and support clinicians in navigating the complex factors that influence this decision. However, to ensure successful adoption, it is crucial to align the development of these tools with end-user expectations and clinical realities. Obstacles to the development of mature AI models in routine ICU care arise at different stages of the CDSS development cycle. In particular in the predevelopment phase, with issues of privacy, representativeness, and complexity of heterogeneous ICU data, and in the postdevelopment phase (real-life deployment), with concerns about interoperability and end-user usability [6,17]. Recent frameworks have been proposed to ensure a rigorous development methodology [18,19]. To overcome the main obstacles during CDSS development and deployment, several of these recommendations suggest focusing on the clinical question to be answered by the model and clinicians' expectations of the AI-based CDSS in production [17]. Involving health care providers at every stage of the development and implementation process (user-centered design) would be a solution to overcome the applicability barriers [20,21]. This study is therefore an application of these frameworks, proposing a predevelopment survey before the creation of an AI-based CDSS in the ICU.

In France, the decision to initiate, adjust settings, and discontinue dialysis, including CRRT, are made exclusively by intensivists, without systematic involvement of nephrologists. National guidelines provide general recommendations for dialysis management but lack standardized protocols for CRRT weaning [22]. Local protocols may be used in some ICUs, but there is no universal codification of weaning practices in France. This variability further underscores the potential value of a CDSS to support intensivists in this complex task. Our team is currently planning to develop an AI-based CDSS for successful weaning from CRRT in the ICU, defined as no reintroduction of renal assistance within seven days of its interruption [14].

The aim of this study was to survey ICU physicians, before the development of a machine learning predictive model for successful weaning from CRRT, to understand their expectations regarding the proposed tool, their opinion of the chosen clinical problem and their level of knowledge, appease and distrust of AI-based CDSS in general. In particular, we sought to gather insights from physicians working in both university and nonuniversity hospital settings, as we hypothesized that their exposure to technological innovations and clinical workflows might differ.

Methods

Study Protocol

A prospective cross-sectional survey study was conducted in France using a declarative survey from December 1, 2023 to April 30, 2024. The survey was hosted on a health data platform using Goupile software [23], and the link was shared to intensive care physicians via the newsletters and social media of the French Society of Anesthesia and Intensive Care (Société Française d'Anesthésie,-Réanimation), the French Intensive Care Society (Société de Réanimation de langue Française), the French College of Nonacademic Hospitals (Collège de Réanimation des hôpitaux Extra-Universitaires de France) and the Association of Private Sector Intensive Care Physicians (Association des Réanimateurs du Secteur Privé). No specific

XSL•FO
RenderX

approach was taken to prevent multiple participation in the survey. This study was reported in accordance with the consensus-based Checklist for Reporting of Survey Studies (CROSS) checklist (Multimedia Appendix 1) [24].

Ethical Considerations

The study was approved by the Ethics and Evaluation Committee for Noninterventional Research of Rouen University Hospital (registration number E2023-61). Participants responded voluntarily after being informed of the purpose of the survey and consenting to the use of their answers. Participation was anonymous and no effort was made to identify individual participants.

Target Population

The target population included all physicians with clinical activity in intensive care, regardless of their medical specialty, including attending physicians, fellows and junior doctors (final-year residents who have completed their medical thesis and are practicing autonomously under guided supervision according to the French medical education). Participants were not necessarily experts in the field of AI or data analysis and did not receive any additional information on the project beyond what was stated in the questionnaire preamble.

Survey Instrument

There is currently no standardized questionnaire for AI-based CDSS predevelopment. This questionnaire was developed by 2 intensive care physicians and a medical informatics expert after consultation with experts in data science and user experience. Several meetings were held to ensure that the questions covered relevant and well-established topics in the field of CRRT and AI-based decision support systems, relying on similar studies from the literature. This iterative process allowed to incorporate feedback and adjusted the questions accordingly, although it was not a formal Delphi process. It was developed from instruments already used in the literature to cover all the main axes of reflection relating to the development of a machine learning-based CDSS [20,25-29]. From this literature review and discussions, we identified 4 main axes that would comprehensively capture the necessary information for the future development and implementation of our CDSS. These 4 axes were developed based on their relevance to the successful deployment of AI-based CDSS in clinical practice (Textbox 1).

Textbox 1. Overview of the key axes explored in the questionnaire.

- Key drivers (Q1-5): This axis focused on the current attitudes and behaviors regarding decision-making and the specific issue of weaning from CRRT. Understanding these factors is crucial for developing a tool that aligns with clinicians' decision-making processes and addresses their primary concerns.
- Acceptability (Q6-10): This axis evaluated the current opinions of ICU physicians on AI-based CDSS. Assessing acceptability helps determine the likelihood of adoption and highlights potential barriers that need to be addressed.
- Implementation (Q11-15): This axis explored the critical aspects of using a potential AI-based CDSS, including preferred methods of integration, interface design, and alert thresholds. Insights from this axis are essential for ensuring that the CDSS can be smoothly incorporated into the clinical workflow.
- Usability (Q16-20): This axis examined the real-life operation of the potential AI-based CDSS and the willingness of physicians to adopt it in their everyday practice. Usability is a critical factor in the long-term success of the CDSS, influencing its sustained use and impact on patient care.

The questionnaire consisted of 20 questions on the topic being studied and 6 demographic questions. The 20 questions consisted of 12 statements, 4 multiple-choices, 3 opens and 1 hierarchical question. Statements were answered on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (totally agree).

The questions also considered acceptance concepts defined by the Unified Theory of Acceptance and Use of Technology (UTAUT) model [30]. In the context of technology, acceptance was defined as the willingness, intention and internal motivation to use a technology as a result of positive attitudes toward the technology or system [31]. The UTAUT model comprised four main concepts: performance expectancy (user's confidence that using technology will benefit his work performance), effort expectancy (user's beliefs of how easy it is to use the system), social influences (how much the user feels that significant others believe that they should use the technology) and facilitating conditions (user's beliefs on organizational and technical support to use the system).

As a first step, the questionnaire was pretested by a panel of 4 intensive care physicians who were not experts in the field of AI or CDSS. Each participant answered the questions and assessed their comprehensibility on a 5-points Likert scale, suggesting modifications if necessary. The proposed modifications were considered, questions with comprehension problems were reformulated and the questionnaire was returned to the panel for final approval. The finalized version of the questionnaire was sent to survey participants. The detailed questionnaire with the rationale for each question can be found, both in the original French version and translated into English, in Multimedia Appendices 2 and 3.

Statistical Analyses

Values are presented as numbers and percentages (n, %) for qualitative variables, and as median and IQR for quantitative variables. On the web questionnaire, the response to each question was mandatory, in order to obtain a low rate of missing data. Statistical analyses were performed in complete case analysis on fully completed questionnaires [32]. Subgroup analyses were performed, comparing physicians from university and nonuniversity hospitals and comparing senior (attending physicians) and junior physicians (including fellows and junior doctors). It was based on an a priori hypothesis that differences in AI adoption might exist between university and nonuniversity centers, as well as across age categories. University hospitals

XSL•FO
RenderX

were hypothesized to have greater exposure to technological innovations, potentially influencing adoption rates. Similarly, younger physicians were assumed to be more familiar with and open to AI technologies, given their higher exposure to digital tools during training. Bivariate analyses were performed using Wilcoxon rank sum tests for quantitative variables, and χ^2 or Fisher exact tests for qualitative variables.

To control for potential confounding factors, multivariate analyses were performed using ordinal logistic regression models. The variables included in the models were selected based on their clinical relevance and their potential impact on the outcomes of interest. These variables included age, years of ICU experience, medical specialty and workplace setting (university or nonuniversity hospital). The dependent variables corresponded to specific survey questions, allowing us to evaluate the independent effect of each factor on the outcomes while accounting for confounding.

All tests were 2-tailed and interpreted at $P<.05$ significance threshold. Statistical analyses were performed using the R software version 4.1.3 (R Foundation for Statistical Computing).

Results

Respondent Characteristics

A total of 171 complete responses were received during the study period. It is important to note that the precise number of ICU physicians to whom the survey was delivered was not exhaustively documented. The survey was distributed through the newsletters of French intensive care societies and associations, as well as their social media platforms. While the total number of senior physicians working in the ICU in France is challenging to ascertain, an estimate based on a report from the College of Intensive Care Medicine Teachers (Collège des Enseignants de Médecine Intensive Réanimation) in 2021 approximated this figure to be around 2350 senior physicians [33]. Our study also included junior doctors who are not counted in this figure. There are approximately 500 junior doctors training in ICUs annually in France, which means the actual denominator for the survey population would be closer to 2850. Hence, the estimated response rate for the survey is approximately 6.0% (168/2850, considering that 2 respondents were from Belgium and 1 from Switzerland).

The total group had a median age of 39 (IQR 33 - 45) years and a median of 9 (IQR 3 - 14) years of ICU work experience (Table 1). Out of the 171 physicians, most of them had a training in anesthesiology and intensive care (109, 63.7%) and worked in university hospitals (102, 59.6%). The median age of physicians surveyed in university centers was younger (36 years [IQR 32 - 43] versus 42 [IQR 36 - 50]; $P<.001$), with fewer years of experience (5 years [IQR 2 - 12] versus 11 [IQR 6 - 16]; $P<.001$), and more from the anesthesia and intensive care training (81/102, 79.4% vs 28/69, 40.6%; $P<.001$).

Overview of the Problem and Current Practices (Key Drivers)

Concerning the CRRT-weaning decision, doctors disagreed on the difficulty of decision-making, with 46.2% (79/171) disagreeing or strongly disagreeing with the weaning difficulty proposition (Q1) and 31.6% (54/171) agreeing or totally agreeing (Figure 1A and Table 2). Regarding the certainty of the weaning decision (Q2), responses were mixed, with 33.9% (58/171) of doctors agreeing or totally agreeing with the proposition and 39.7% (68/171) disagreeing or strongly disagreeing. There was no difference between academic and nonacademic physicians (Table 2 and Figure S1 in Multimedia Appendix 4), and between different levels of training (Table S1 and Figure S2 in Multimedia Appendix 4). Physicians had a good idea of the CRRT weaning failure rate (Q3), with a median rate estimated at 33% (IQR 25 - 50), which is close to the rates of 35% to 54% reported in the literature [34,35].

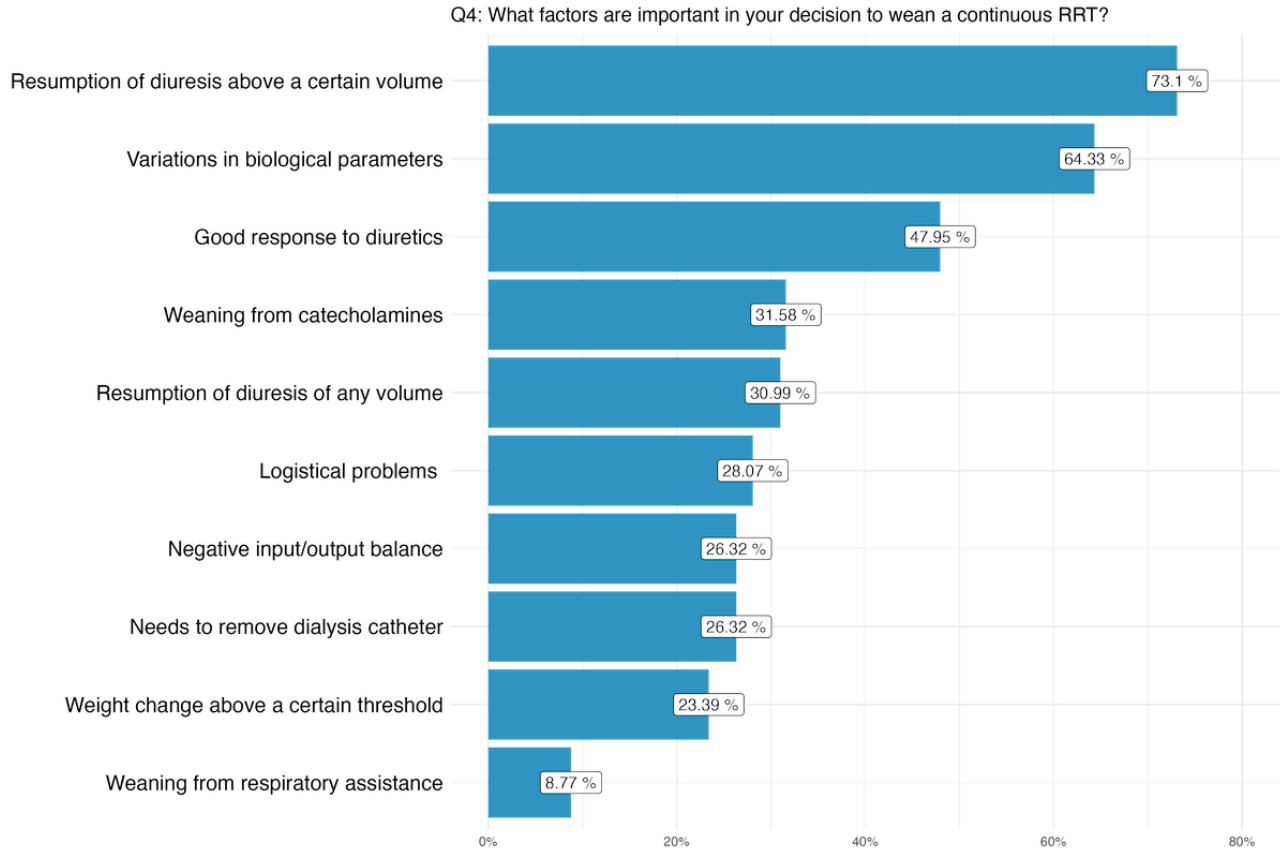
[a]Adjustment on age, years of experience and medical specialty.



[b]CRRT: continuous renal replacement therapy.

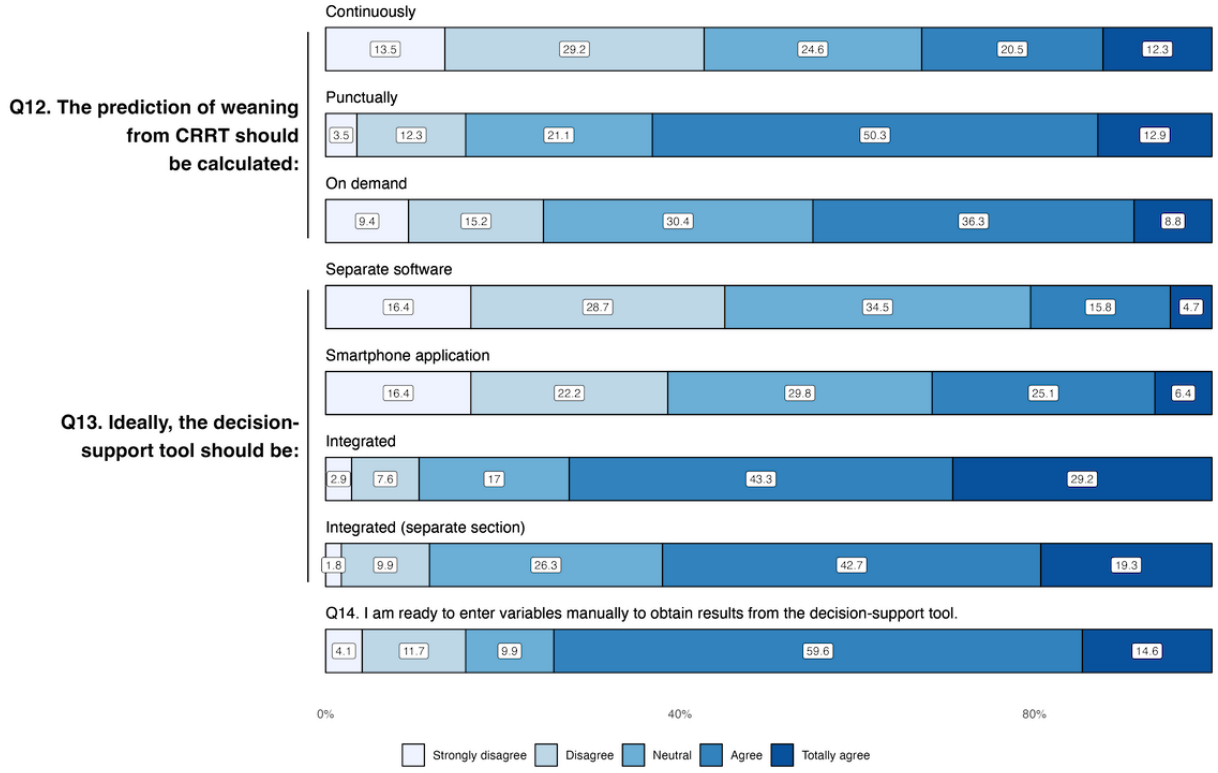
[c]AI: artificial intelligence.

Regarding the variables affecting the decision to wean from CRRT (Q4), respondents mainly chose the resumption of diuresis above a certain volume (125/171, 73.1%), variation in biological settings (110/171, 63.3%) and good response to diuretics (82/171, 47.9%; Figure 2). They were then asked to rank these variables in order of importance from 1 the most important, to 10, the least important. The most important variable for the respondents was the resumption of diuresis above a certain volume, with 33.9% (58/121) of respondents ranking it in first place and 11.7% (20/121) ranking it second. Other variables frequently ranked highly included variations in biological parameters, good response to diuretics, and weaning from catecholamines.

XSL•FO
RenderX

Figure 2. Variables relevant to the clinical decision to wean from continuous renal replacement therapy (percentages of respondents choosing each variable). RRT: renal replacement therapy.

Opinion on Clinical Decision Support Systems (Acceptability)



Respondents did not seem particularly comfortable with the concept of AI (66/171, 38.6% agreed or totally agreed with Q6) and did not seem to use AI tools in their daily lives (84/171, 49.1% disagreed or strongly disagreed with Q7) and even less so in their clinical activity with 70.7% (121/171) disagreeing or strongly disagreeing with Q8 (Figure 1B and Table 2). Junior physicians made greater use of AI tools in their daily lives, with 45.5% (15/33) agreeing or totally agreeing with Q7 compared to 29.7% (41/138) of senior doctors (P=.03; Table S1 in Multimedia Appendix 4). However, the surveyed physicians were very favorable to the use of AI tools to help them in their clinical practice, with 70.2% (120/171) agreeing or totally agreeing with Q9, with a priori no fear, since 83.7% (143/171) of respondents disagreeing or totally disagreeing with Q10 concerning the fact that AI could replace their job in the future. This enthusiasm seemed consistent between the different levels of training (94/138, 68.1% agreed or totally agreed vs 26/33, 78.8%; P=.08) and the university hospitals status (78/102, 76.5% agreed or totally agreed vs 42/69, 60.9%; P=.41; Figure S1 in Multimedia Appendix 4).

Implementation in Daily Clinical Practice

When asked about the preferred timing for computing the prediction of CRRT weaning (Q12), respondents preferred it to be rendered punctually at a specific time during the day, for example during the morning round (108/171, 63.2% agreed or totally agreed) versus on demand only (77/171, 45.1% agreed or totally agreed) or continuously (56/171, 42.7% agreed or totally agreed) (Figure 3 and Table 3). Senior physicians were more inclined to choose a prediction at a specific time of day (93/138, 67.4% agreed or totally agreed vs 15/33, 45.5%; P=.01), whereas juniors were more interested in an on-demand prediction only (20/33, 60.7% agreed or totally agreed, Table S1 in Multimedia Appendix 4). Regarding the choice of design for the CDSS (Q13), respondents were generally in favor of it being integrated within the ICU's electronic health record (EHR), whether with the usual monitoring data (124/171, 72.5% agreed or totally agreed) or on a separate section of the software (106/171, 62% agreed or totally agreed). Out of the 171 respondents, 141 (82.5%) physicians declared that their hospital was equipped with an ICU EHR (Q11), with greater computerization in university hospitals (93/101, 91% vs 48/79, 70%; P<.001). Most physicians agreed to manually input variables to be added to the model (127/171, 74.2% agreed or totally agreed). The median number of acceptable variables to enter manually was 5 (IQR 4 - 6) (Q15).

[c] ICU: intensive care unit.

Real-Life Operation, Willingness to Adopt in Everyday Practice (Usability)

Respondents agreed that an AI-based CDSS to assist in decisions about weaning patients from CRRT could be an aid in daily clinical practice, with 66% (113/171) either agreeing or totally agreeing (Q16). The adherence appeared to be higher in university hospitals (78/102, 76.5% agreeing or totally agreeing) compared to nonuniversity settings (35/69, 50.7%; *P*<.001) (Figure 1C and Table 4). However, after adjusting for confounders such as age, the difference was no longer statistically significant (adjusted *P*=.63), suggesting that the observed difference may be more related to the younger age profile of university hospital respondents. Similarly, younger physicians were more likely to express support for AI tools (27/33, 81.8% agreed or totally agreed vs 86/138, 62.3%; *P*=.01) (Table S1 in Multimedia Appendix 4). The explicability of the model was an important concern, with 74.9% (128/171) of respondents agreeing or totally agreeing that the AI-based CDSS should provide a percentage of certainty with the prediction provided (Q17), and 95.3% (163/171) that it was important to understand the criteria on which the model has based its prediction (Q18). Only 11.1% (19/171) doubted that the model would influence their decision to wean a patient off CRRT (Q19). Finally, interrogated physicians indicated a low probability threshold provided by the model below which they would not consider weaning a patient from CRRT at a median of 50% (IQR 30 - 60) and a threshold above which they would consider weaning at 80% (IQR 73 - 85) (Figure 4). These thresholds highlight the range within which model predictions could inform clinical decisions and suggest that physicians prefer a cautious approach, favoring higher certainty for weaning decisions while remaining conservative when uncertainty is high.

Figure 4. Prediction thresholds described by clinicians as having an impact on their clinical decision-making on continuous renal replacement therapy weaning.

The responses to the survey have enabled us to draft an initial list of specifications fort the development of the CDSS to assist in weaning from CRRT. These specifications and the consequences for further development are detailed in Table 5.

XSL•FO
RenderX

Table . Specifications and consequences for development of the clinical decision support system.

Feature	Specification	Consequences for development
Overview of the problem and current practices (key drivers)		
Variables to include	Key variables such as resumption of diuresis, biological markers and response to diuretics.	Ensure these variables are accurately and automatically collected from EHR[a] to minimize manual input errors.
Implementation in daily clinical practice		
Manual data entry	Willingness to manually enter up to 5 variables.	Automate the collection of as many variables as possible by integrating with ICU[b] EHR.
Integration with existing systems	Integration with ICU EHR, predictions visible alongside vital parameters.	Develop seamless integration with EHR systems to ensure data accessibility and workflow efficiency.
Timing of predictions	Predictions computed at a specific time, such as morning rounds.	Schedule predictions to align with clinical routines, reducing the need for continuous monitoring.
User interface	User-friendly, minimal additional workload, no system switching.	Design an intuitive interface that fits into clinicians' workflow to enhance usability.
Real-life operation, willingness to adopt in everyday practice (usability)		
Explainability	Clear explanations of model predictions.	Develop an interface that visually explains the predictions to build trust among users.
Alert thresholds	Probability thresholds below 50% for considering not weaning and above 80% for considering weaning.	Calibrate the model to achieve the desired thresholds for user confidence and actionability.

[a]EHR: electronic health record.

[b] ICU: intensive care unit.

Discussion

Principal Findings

Our study provides insights into the expectations and attitudes of ICU physicians regarding the use of AI-based CDSS for weaning from CRRT. This predevelopment study is a fundamental step toward a user-centered approach to the development of a decision support tool. The results of our survey suggest that while physicians are not generally comfortable with AI and have limited experience using it, 70.2% (120/171) expressed a favorable view toward integrating AI tools in clinical practice, with no apparent fear of this technology. Moreover, our results suggest a significant interest and perceived necessity among French intensivists for a CDSS tailored to assist in the weaning process from CRRT.

Attitudes Toward AI and CDSS

Physicians in our study, particularly senior ones, did not seem entirely comfortable with the concept of AI. This highlights the need for comprehensive training and education to improve AI literacy among clinicians, fostering a more favorable environment for the integration of CDSS [17]. How physicians interpret and act on CDSS predictions can substantially impact patient care [36]. Despite this discomfort, there was strong support for AI-based CDSS to aid clinical decision-making, underscoring the potential acceptance of a well-designed CDSS. This positive outlook towards AI is consistent with other studies showing clinicians' openness to AI-based CDSS if they enhance clinical practice and improve patient outcomes [37]. In a similar study conducted among Dutch ICU physicians in university hospitals found that 86% of respondents believed AI could support them in their work as physicians [25]. In addition, the surveyed physicians showed no significant fear that AI would replace their jobs, with 83.7% (143/171) of respondents disagreed or strongly disagreed with this idea. The relatively young median age of respondents, 39 years (IQR 33 - 45) compared to a national median of 43 (IQR 35 - 54) in 2021 [33], may also explain the higher overall willingness to adopt AI-based CDSS in clinical practice.

Preferences for Implementation

Regarding the implementation of a CDSS for CRRT weaning, our survey revealed that physicians preferred a tool that computes the prediction of weaning at a specific time, rather than continuously. This is consistent with previous studies suggesting that continuous monitoring can lead to alarm fatigue and decrease clinician trust in the tool. In a review of 89 articles on CDSS in various medical fields, Jankovic et al [38] showed that poorly performing CDSS with frequent alerts could contribute to clinicians' frustration and burnout. Furthermore, respondents preferred a CDSS integrated into the ICU patient management software, visible alongside other vital parameters, rather than a new interface. This aligns with previous research showing that integration into clinical workflows is key to improving usability and adoption [39]. A user-centered design is critical, as highlighted by Zikos and DeLellis [40], who identified four real-life "pain points" where AI can add significant value for clinicians, including selecting effective interventions.

XSL•FO
RenderX

Factors Influencing Weaning Decision

Our study also highlights the importance of understanding the factors that influence physicians' decisions to wean patients from CRRT. The most frequently cited factors were resumption of diuresis above a certain volume, variation in biological settings, and good response to diuretics. These factors align with a previous systematic review, which identified similar predictors for successful RRT weaning, such as the urine output before RRT discontinuation and biochemical criteria (eg, serum urea, serum creatinine and creatinine clearance) [13]. These variables should therefore be included in the CDSS model to ensure clinical relevance in the weaning predictions. With the CRRT weaning success rate reported between 35% and 54% in the literature [34,35], our CDSS seems well-positioned to support this complex decision-making, as indicated by the responses of the surveyed clinicians.

Real-Life Operation and Adoption

This survey emphasizes the importance of understanding end-user needs and expectations during the predevelopment phase, which is crucial for successful deployment and adoption in clinical practice [20]. The first step is ensuring that the AI-based CDSS addresses the specific needs of clinicians [41]. Moreover, ensuring the explicability of AI models is crucial to avoid the "black box" effect. Physicians need to understand the factors driving the model's prediction to trust and use these tools effectively. Transparent AI models with clear insights into their decision-making processes can enhance user acceptance and facilitate smoother integration into clinical practice [42].

Limitations

It is worth noting that our study has limitations. First, the response rate was low and introduced the possibility of selection bias, as those more interested in AI may have been more likely to respond. This could have overestimated the acceptance or perceived usefulness of AI-based CDSS. As a result, caution is necessary when generalizing our results to the broader population of ICU physicians. In addition, the lack of an exhaustive list of ICU physicians to whom the survey was distributed further complicated the estimation of a precise response rate and the generalizability of the findings. While a significant proportion of respondents reported limited familiarity with AI, suggesting some mitigation of this bias, the possibility remains that the survey sample was not representative of the entire ICU physician population in France. Low response rates are a common challenge in survey-based research targeting healthcare professionals, who often face significant time constraints. To improve future response rates, strategies such as personalized invitations, follow-up reminders, incentives, and more direct communication channels (eg, targeted emails, professional networks) could be considered. Despite these challenges, our sample size was larger than similar studies ranging, from 7 to 93 participants [25-27,29] and included a diverse group of physicians from both university and nonuniversity hospitals, public and private sectors, and various level of training.

Second, our population skewed younger, with a median age of 39 years compared to the national median of 43 years. This could be attributed to the digital distribution of the survey via newsletters and social media platforms, which may have engaged younger physicians more effectively. The overrepresentation of younger intensivists could influence the generalizability of our findings, as younger physicians are often more familiar with technology and may exhibit greater openness toward AI adoption compared to their older counterparts. This positive bias toward AI could have amplified the generally favorable attitudes observed in our survey. Future studies should aim for a more representative sampling across age groups to ensure broader applicability of the results and to capture potentially differing perspectives from older physicians.

Third, we observed an overrepresentation of physicians from university hospitals, with 60% of respondents working in these centers, compared to around 50% according to recent estimates [33]. University hospital physicians may have greater exposure to technological innovations and more formal training in AI. This might make them more inclined to adopt new technologies like AI-based CDSS. This could have contributed to the positive outlook on AI tools in our survey.

Fourth, self-reporting bias could also influence the results, as participants may have provided responses they perceive as desirable. Finally, while our questionnaire was rigorously designed by a multidisciplinary team and based on instruments in similar studies, such as van der Meijden et al [25], there is currently no validated tool for predevelopment surveys of AI-based CDSS. This may affect the reliability and comparability of our results. In addition, there may have been some comprehension issues with certain questions, as some respondents probably inverted values for decision thresholds in Q20. Finally, this survey was conducted in France, targeting a specific audience for our CDSS, and the results may not be generalizable to other countries with different health care systems and practices.

Future Directions

Based on the survey results, the next steps in developing the CDSS for CRRT weaning will follow the specifications derived from the respondent's feedback, particularly regarding the selection of variables and the number of variables to incorporate into the model. The integration of the CDSS into existing ICU EHR should be prioritized, as this was preferred by most respondents, to ensure seamless integration into clinical workflows. The probability thresholds identified in the survey (50.0% and 80.0%) could guide the CDSS by defining actionable zones for clinical recommendations, with flexibility for customization based on institutional practices. These thresholds would help translate model predictions into practical decision-making support while preserving clinical discretion. In addition, clear explanations of predictions, including criteria and levels of certainty, must be incorporated to align with the strong preference for model transparency expressed by respondents.

Beyond model development, it is crucial to maintain ongoing user engagement throughout the process. This involves returning to the users with models and interface proposals to gather feedback on the model's functionality and interpretability. Iterative development, involving continuous user input and

XSL•FO
RenderX

feedback, is known to enhance acceptance and integration of AI-based CDSS in practice [43,44]. This approach helps ensure that the final product aligns closely with user expectations and needs, improving usability and satisfaction. After refining the model, a prospective study will evaluate its performance in real-world settings and its ability to generalize across different clinical contexts. The goal is to validate the model not only in controlled environments but also in diverse ICU settings to ensure its broader applicability and effectiveness.

In conclusion, our study provides valuable insights into ICU physicians' expectations and opinions regarding an AI-based CDSS for CRRT weaning, enabling us to draft an initial set of specifications. While there is cautious optimism about the use of AI in clinical practice, significant efforts are needed to address concerns about usability, integration, and transparency. By understanding and incorporating the needs and preferences of clinicians, we can develop a CDSS that is both effective and widely accepted. This work is a preliminary step in guiding future research continuing to involve health care providers in the development process and promoting user-centered design for the ongoing development of a CDSS to guide CRRT weaning in the ICU. This approach will ultimately enhance the adoption and impact of AI-based CDSS in critical care settings, improving patient outcomes and optimizing resource utilization.

Acknowledgments

The authors would like to express their gratitude to the French Society of Anesthesia and Intensive Care (Société Française d'Anesthésie,-Réanimation), the French Intensive Care Society (Société de Réanimation de Langue Française), the French College of Nonacademic Hospitals (Collège de Reanimation des hôpitaux Extra-Universitaires de France) and the Association of Private Sector Intensive Care Physicians (Association des Réanimateurs du Secteur Privé) for their assistance in disseminating this questionnaire.

The authors would also like to thank Perrine Leprêtre, Rémy Rovacchi and Philippe Gouin for their help in drafting the questionnaire.

Abstract

Background: Evidence-based medicine combines scientific research, clinical expertise, and patient preferences to enhance the patient outcomes and improve health care quality. Clinical data are crucial in aligning medical decisions with evidence-based practices, whether derived from systematic research or real-world data sources. Quality assurance of clinical data, mainly through predictive quality algorithms and machine learning, is essential to mitigate risks such as misdiagnosis, inappropriate treatment, bias, and compromised patient safety. Furthermore, excellent quality of clinical data is a prerequisite for the replication of research results in order to gain insights from practice and real-world evidence.

Objective: This study aims to demonstrate the varying quality of medical data in primary clinical source systems at a maximum care university hospital and provide researchers with insights into data reliability through predictive quality algorithms using machine learning techniques.

Methods: A literature review was conducted to evaluate existing approaches to automated quality prediction. In addition, embedded in the process of integrating care data into a medical data integration center (MeDIC), metadata relevant to this clinical data was stored, considering factors such as data granularity and quality metrics. Completed patient cases with echocardiographic and laboratory findings as well as medication histories were selected from 2001 to 2023. Two authors manually reviewed the datasets and assigned a quality score for each entry, with 0 indicating unsatisfactory and 1 satisfactory quality. Since quality control was considered a binary problem, corresponding classifiers were used for the quality prediction. Logistic regression, k-nearest neighbors, a naive bayes classifier, a decision tree classifier, a random forest classifier, extreme gradient boosting (XGB), and support vector machines (SVM) were selected as machine learning algorithms. Based on preprocessing the dataset, training machine learning algorithms on echocardiographic, laboratory, and medication data, and assessing various prediction models, the most effective algorithms for quality classification were to be identified. The performance of the predictive quality algorithms was assessed based on accuracy, precision, recall, and scoring.

Results: There were 450 patient cases with complete information extracted from the MeDIC data pool. The laboratory and medication datasets had to be limited to 4000 data entries each to enable manual review; the echocardiographic datasets comprised 750 examinations. XGB demonstrated the highest performance for the echocardiographic dataset with an area under the receiver operating characteristic curve (AUC-ROC) of 84.6%. For laboratory data, SVM achieved an AUC-ROC score of 89.8%, demonstrating superior discrimination performance. Finally, regarding the medication dataset, SVM showed the most balanced performance, achieving an AUC-ROC of 65.1%, the highest of all tested models.

Conclusions: This proposal presents a template for predicting data quality and incorporating the resulting quality information into the metadata of a data integration center, a concept not previously implemented. The model was deployed for data inspection using a hybrid approach that combines the trained model with conventional inspection methods.

Introduction

Evidence-based medicine combines the best available evidence from scientific research with clinical expertise and patient preferences. The goal of applying evidence-based medicine in health care is to enhance patient outcomes, improve the quality of care, and minimize ineffective or harmful treatments [1]. Valid clinical data and the associated metadata serve as the foundation for evidence-based medicine through high-quality evidence from systematic research or as real-world data (RWD) from clinical care [2]. It allows clinicians to align their decisions and treatments with the best available evidence from research and clinical guidelines, leading to better patient outcomes. Moreover, clinical data plays a crucial role in medical research and innovation. Researchers use large datasets to identify patterns, risk factors, and potential treatment approaches for various medical conditions, resulting in advancements and breakthroughs in medicine [3]. Without awareness of the data quality within these datasets, researchers and clinicians may face significant challenges, such as misdiagnosis and inappropriate treatment, compromised patient safety, and bias from confounding factors. In addition, the quality of data can impact the ability to replicate research results and affect the efficiency of data integration. To mitigate these risks, it is essential for clinicians and researchers to be mindful of the quality of the clinical data they are using [4].

Data integration centers, which are set up to consolidate clinical routine data in German university hospitals, can provide information about the quality of their data, given their extensive data resources [5]. The Medical Data Integration Center of the University Medical Center Göttingen (UMG-MeDIC) securely stores clinical data (eg, laboratory findings or echocardiography data) and makes it available upon request to enable as many researchers as possible to access the data while taking data protection and security into account [6].

Data originating from clinical care source systems that are not collected for the intended research use case are often incomplete, lack necessary information (eg, missing entries), or exhibit uncertain measurement quality [7]. Therefore, providing a precise and detailed description of data through metadata when merging heterogeneous sources enables a valid and meaningful integration aimed at ensuring traceable reuse. Metadata assists researchers and users in searching, categorizing, and interpreting data from a data warehouse. In addition, metadata ensures data consistency and facilitates data management [8,9].

Qualitative predictions using machine learning algorithms can be used to gather information about the completeness of data, which includes not only missing values but also semantic completeness and consistency. Machine learning and deep learning methodologies offer significant potential for ensuring quality. Nalbach et al [10] describe data-driven estimations of data quality as predictive quality. The extraction of data and its relation to quality metrics—such as completeness, consistency, correctness, and correspondence [11], enables data-driven quality assessment based on historical data. These estimations provide a foundation for decision-making regarding quality enhancement measures, such as informing data stewards about necessary missing values that should be added [10].

Based on the predictive quality approach further described by Tercan et al [12] and Schmitt et al [13], this research aimed to identify a predictive model-based quality algorithm for clinical data, including RWD, and provide automated quality inspection. The goal of this paper is to demonstrate the varying quality of medical data in primary clinical source systems and to inform researchers about data reliability using machine learning techniques. This approach seeks to identify predictive model-based quality algorithms for clinical data, including RWD, to facilitate automated quality inspection, ensuring data completeness and consistency. As a result of our proposal, we intend to enhance the reliability of clinical data used in evidence-based medicine and medical research.

Methods

Literature Review

A literature search regarding machine learning algorithms and data quality was conducted to provide an overview of the semantic completeness of data, consider previous work to build on existing knowledge, and classify this work's results.

The literature review establishes the foundation for developing innovative approaches and solutions designed to assess the quality of clinical data within the UMG-MeDIC. The literature search was conducted in Embase via Ovid and PubMed and resulted in 118 search records. After removing duplicates, 104 results were included in the title and abstract screening. Following the elimination of publications unsuitable for the goals of this manuscript, 12 results remained. The full text of the identified articles was carefully reviewed, and valuable information was integrated into the introduction and methodology sections of this manuscript. The search strategy for PubMed and the corresponding PRISMA Flow Chart of the literature search are provided in Table 1 and Table 2 of the Multimedia Appendix 1 [1].

Ethical Considerations

Ethical approval for the anonymized secondary health data analysis was obtained from the Ethics Review Committee of the University Medical Center Göttingen with the Ref. No. 21/9/18. All developments and experiments were performed in accordance with relevant guidelines and regulations. Furthermore, informed consent was obtained from all participants or their legal guardians and the original informed consent allows the secondary analysis without additional consent. Regarding the privacy and confidentiality protection of human participants all study data is deidentified.

Prerequisites at the UMG-MeDIC

In the context of this project, it was decided to store all metadata linked to the primary clinical data from the source systems of the UMG in a relational database (MariaDB). This was considered necessary because the actual clinical data to which the metadata refers was already stored in the same relational database.

XSL•FO
RenderX

The meta and metadata were captured during routine care and originated from different hospital information systems, including clinical workstation systems, laboratory information systems, echocardiography systems, and microbiology systems.

Information from the specifications of the supplied data formats was extracted to develop the preparatory work for the quality assessment of the clinical data.

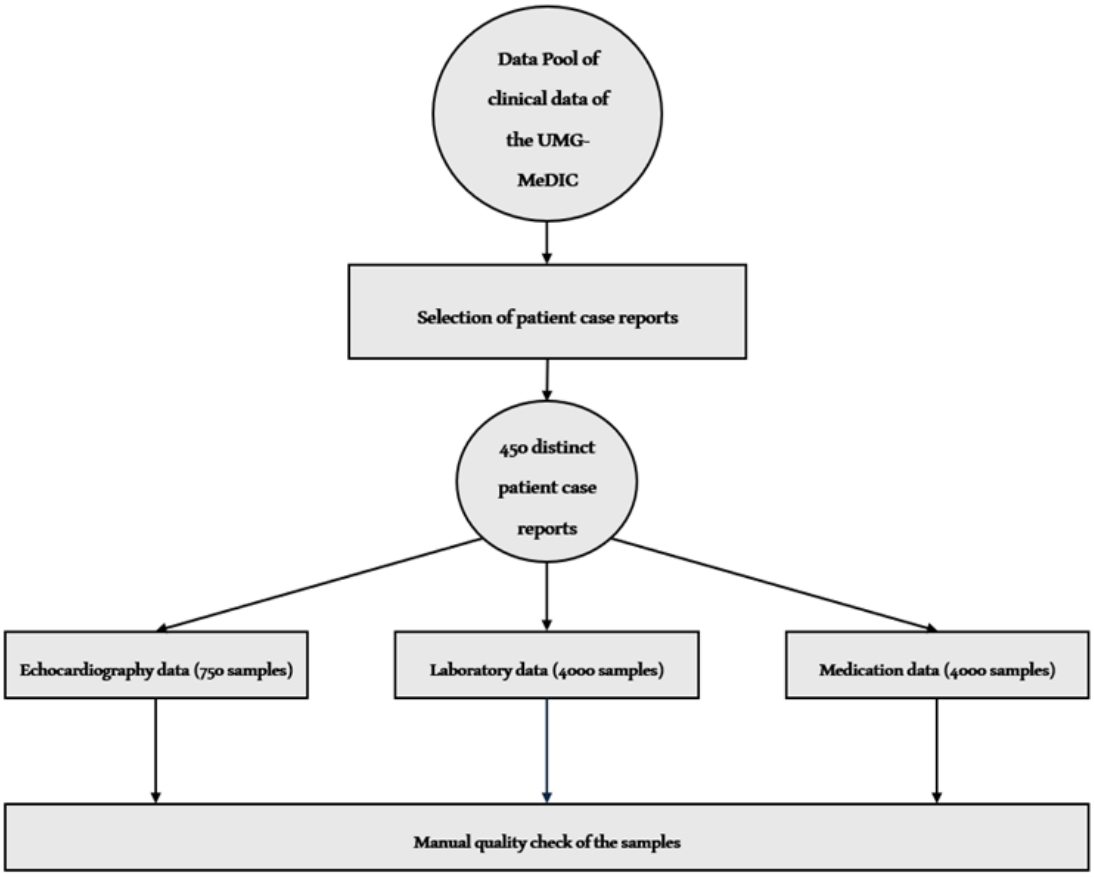
Moreover, the granularity of metadata extracted from the primary source systems was taken into account. Metadata in primary source systems is captured at varying levels of granularity (eg, metadata date as day-month-year hour-minute-second vs metadata date as month-year) and must therefore be included and processed accordingly.

Data quality was introduced as additional metadata in the relational database structure to quantify the quality of the UMG-MeDIC data.

Data Preparation

The clinical data, originating from the clinical source systems of the UMG, is heterogeneous. This data is extracted from various primary clinical sources, such as the lab information system and the clinical workstation system, and consolidated within the UMG-MeDIC. The data are pseudonymized during the consolidation and processing at the data integration center. Although the work is based on a technical viewpoint of the data sources, demographic information was not addressed separately. Patient cases were selected based on three criteria: (1) completed patient cases with (2) echocardiographic and laboratory findings, as well as medication histories (3) from 2001 to 2023, excluding data linked to outdated process configurations. Consequently, 450 distinct patient cases with clinical findings were extracted from the data pool of the UMG-MeDIC. Among these 450 case reports, each report includes echocardiographic, laboratory, and medication data as shown in Figure 1.

A total of 750 echocardiographic examinations were carried out for these 450 patient cases, which means around 1.6 echocardiographic examinations per patient case. In comparison, there was significantly more laboratory and medication data for these 450 patient cases, which did not allow a manual review of the quality of every individual data item. Hence, the laboratory and medication data subset was limited to 4000 data points each. On this basis, a dataset with 750 echocardiographic, 4000 laboratory, and 4000 medication data items was obtained.



Subsequently, 2 authors manually reviewed the echocardiographic, laboratory, and medication data, assigning each data entry a quality score from 0 to 1, where 0 indicates unsatisfactory quality and 1 indicates satisfactory quality.

The criteria for this assignment were based on corresponding preliminary work by the authors to identify quality measures [14] and further work related to quality metrics [11,15-17]. The first criterion is the semantic completeness of the data, a metric that assesses whether all mandatory data fields are filled with relevant information. Completeness ensures there are no missing values, enabling users to fully understand and use the data. The second measure, data consistency, evaluates whether the data complies with established standards, conventions, or formats. The third measure, data correctness, assesses the accuracy of the information. In addition, the linkage of this data to other datasets checks whether interlinked or interdependent data elements convey the same information across all instances. The quality metric data relevance ensures that the metadata meets the needs or expectations of its intended users. For example, if a dataset is designed for clinical research, including fields like measurement units might enhance its relevance. The metric semantic specificity considers the granularity and precision of semantic concepts in the data. High semantic specificity implies the use of detailed and well-defined terms to describe the information. Timeliness, the sixth metric, pertains to evaluating how current the data is. Timeliness is crucial, especially for dynamic or time-sensitive resources. The seventh metric, accessibility, measures whether the data is physically available and comprehensible to users (whether human or machine), while reproducibility of the data, the eighth and final metric, ensures that data evaluations are consistent and can be independently verified by different users or systems. After the separate reviews, the quality mappings were compared, and deviations were discussed. Ultimately, a uniform quality mapping for the echocardiographic, laboratory, and medication data was established.

This process ensures that the models exclusively learn from consistently occurring patterns and dependencies.

Figure 1. Outline of the data selection, starting from the data pool of clinical data from the UMG-MeDIC (Medical Data Integration Center of the University Medical Center Göttingen), where 450 patient case reports were selected manually. These 450 case reports were then divided into subclasses of echocardiographic data (sample size of 750), laboratory data (sample size of 4000), and medication data (sample size of 4000). Finally, the samples from each of the three subsets were manually checked for quality by two authors.

Predictive Machine Learning Algorithms

Machine learning is a subfield of artificial intelligence (AI) that enables information technology systems to recognize patterns in existing data and develop solutions autonomously. This research involves classifying data quality variables for clinical data. The classification requires a training dataset with examples for each data source entity's input and output variables.

All machine learning models and classifiers were developed in Python (Python Software Foundation) using scikit-learn libraries. Each machine learning algorithm was trained separately on echocardiographic, laboratory, and medication data to identify the best-performing algorithm for each dataset.

The machine learning algorithms selected include logistic regression (LR) [18], k-nearest neighbors (KNN) [19], a Naive Bayes (NB) classifier [20], a decision tree classifier [21], a random forest classifier [22], XGB [23], and support vector machines (SVM) [24].

For the echocardiographic data consisting of 750 samples, 575 samples have been classified. as unsatisfactory quality (0), while 175 samples are classified as good quality (1).

The laboratory data, comprising 4000 samples, revealed that 17 samples were classified as unsatisfactory (0) and 3983 samples were deemed to be of good quality (1).

The distribution of classes within the medication data resulted in 1280 samples of unsatisfactory quality (0) and 2720 samples of good data quality (1). Multimedia Appendix 2 provides an overview of the features for the three subsets and their target distribution. For each feature of the three subsets, the data are distributed across interval scales (Table 1).

The datasets exhibit an imbalanced target distribution, which necessitated consideration of the overclassification of the majority class. During data preprocessing, the Synthetic Minority Oversampling Technique (SMOTE) was used to tackle this imbalance. SMOTE generates synthetic data points by interpolating between minority class samples. The sampling strategy in SMOTE was set to default (auto), with a random state of 0 and k-neighbors configured to 5.

For input feature extraction, a multilayer perceptron autoencoder model was used, where each layer of the encoder uses batch normalization and leaky ReLU activation. The autoencoder was chosen because it automatically learns feature representations, which reduces the need for explicit feature selection methods that involve extensive iterative training. In addition, the ability to handle nonlinear relationships within the data necessitated the use of an autoencoder. Finally, the datasets were divided into training and test sets and validated using 5x10-fold cross-validation.

Since it is not feasible to universally preselect suitable algorithms in advance, it was necessary to test and evaluate various learning algorithms tailored to specific scenarios [25].

The LR algorithm was selected as the baseline for classification tasks because it predicts the probability of a target variable and is widely used in both binary and multiclass classifications. The parameters included the solver (newton-cg, lbfgs, and liblinear), a default penalty, and the inverse of regularization strength (C) set as loguniform (1e-5, 100).

The KNN classifies a data point based on the majority class among its k nearest neighbors. Due to its simplicity and effectiveness for low-dimensional data, it is a strong candidate for a benchmark. The parameters are as follows: “n_neighbors” ranges from 1 to 30 in increments of 5; weights can be uniform; the algorithm options include "ball_tree, kd_tree, and brute;” "leaf_size” can be 1, 10, or 30; and p is 1 for manhattan distance and 2 for euclidean distance.

NB applies Bayes’ theorem under strong independence assumptions. It is computationally efficient and performs effectively with high-dimensional data. The smoothing parameter prevents zero probabilities for unseen data, so it was set to alpha: 0.01 to 10.0.

Decision trees split data hierarchically based on feature thresholds to predict target labels. Hyperparameters like depth and minimum samples help reduce overfitting with this algorithm. In addition, decision trees are interpretable and can handle nonlinear relationships. The parameters set were “max_depth”: 3 or none, “max_features”: randomized range, “min_samples_leaf”: randomized range, and criterion: gini or entropy.

While random forests are resilient to overfitting and excel across various datasets, parameter tuning aims to balance tree diversity with computational cost. The parameters include bootstrap: true, “max_depth”: the maximum depth of trees (10, 20, 50, 100, or None), “max_features”: the number of features considered (auto or sqrt), “min_samples_leaf”: options of 1, 2, or 4, “min_samples_split”: the minimum number of samples needed to split a node (2, 5, or 10), and “n_estimators”: the total number of trees in the forest (50 or 100).

XGBoost is an optimized gradient-boosting algorithm that iteratively improves model predictions. It is renowned for its performance with structured or tabular datasets, and through hyperparameter tuning, it seeks to minimize overfitting while boosting prediction accuracy. The parameters include “learning_rate”: 0.05 to 0.30, “max_depth”: the maximum depth of the trees (3 to 15), “min_child_weight”: the minimum sum of instance weights in a child node (1 to 7), gamma: the minimum loss reduction required to make a split (0.0 to 0.4), and “colsample_bytree”: the fraction of features sampled for each tree (0.3 to 0.7).

As a large margin classifier, the SVM identifies a hyperplane that best separates classes in high-dimensional space. While it is effective for both linear and nonlinear data, a linear kernel was used here for computational efficiency, given the dataset

XSL•FO
RenderX

size (kernel: linear kernel for simplicity and interpretability; probability: enabled for AUC-ROC computation).

Results

Literature Review Overview

The literature search yielded valuable insights into the relationship between machine learning algorithms and data quality, specifically focusing on semantic completeness within clinical datasets. After applying the screening process, the 12 retained articles provided key perspectives on data quality assessment, machine learning methodologies, and their application within clinical environments. A thorough analysis of these studies revealed several recurring themes. First, a significant portion of the literature addressed the challenges of ensuring semantic completeness in structured and unstructured clinical data. Several studies emphasized the necessity of standard terminologies and ontologies to enhance data consistency and interoperability. In addition, multiple sources explored different machine learning techniques, such as supervised and unsupervised learning approaches, to detect and mitigate issues related to incomplete or inconsistent data. Key insights from the literature were incorporated into the introduction and methodology sections, providing a solid theoretical foundation for this study. The findings underscored the importance of leveraging machine learning models to improve clinical data integrity and supported the need for robust evaluation metrics to quantify data quality improvements. The PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) Flow Chart and detailed search strategy, presented in Table S2 of Multimedia Appendix 1, further outline the systematic approach used in identifying relevant studies.

Since here we consider quality prediction as a binary classification problem, we evaluated binary-class classifiers on the provided datasets. We then compared the results of each model in a table that included accuracy, precision, recall, and scoring.

Predictive Machine Learning Algorithms

Multiple machine learning algorithms were evaluated for predicting the quality of echocardiography data, with LR serving as the baseline model. LR achieved an accuracy of 73.0% (0.73/1), precision of 57.1% (0.571/1), recall of 73.0% (0.73/1), F_1-score of 64.1% (0.641/1), and an AUC-ROC score of 52.4% (0.524/1). While this model provides a foundational benchmark, other algorithms demonstrated superior performance across all metrics, suggesting their greater suitability for this dataset, as shown in Table 2.

KNN demonstrated improvements over LR, achieving an accuracy of 76.6% (0.766/1) and an AUC-ROC score of 70.3% (0.703/1). The improved precision (0.744/1, 74.4%) and F_1-score (0.684/1, 68.4%) emphasize its more effective balance of false positives and false negatives compared to the baseline.

NB attained a recall rate of 75.9% (0.759/1), comparable to KNN, but exhibited relatively lower precision at 57.6% (0.576/1) and an AUC-ROC score of 51.0%. This suggests a trade-off in its predictive performance.

The decision tree classifier slightly outperformed LR, reaching an accuracy of 73.7% (0.737/1) and an AUC-ROC score of 71.3% (0.713/1). The F_1-score of 73.7% (0.737/1) emphasizes its ability to maintain a balanced level of precision and recall.

The random forest classifier delivered a notable improvement, achieving an accuracy of 82.5% (0.825/1) and an AUC-ROC score of 85.3% (0.853/1). These metrics, alongside an F_1-score of 81.0% (0.81/1), highlight its robust performance and effectiveness in capturing complex patterns in the data.

XGB achieved the highest overall performance, with an accuracy of 84.7% and an AUC-ROC score of 84.6%. Its F_1-score of 84.0% and precision of 83.9% demonstrate its ability to consistently deliver high-accuracy predictions while minimizing false positives.

The SVM achieved an accuracy of 73.0%, comparable to that of LR, but it demonstrated an improvement in the AUC-ROC score of 65.7%. Its F_1-score of 67.1% reflects a slight enhancement in predictive balance.

The laboratory dataset consisted of 4000 data items. The performance of the machine learning algorithms was evaluated on the laboratory dataset, again using LR as the baseline model (refer to Table 3). LR achieved an accuracy of 99.8%, a precision of 99.5%, a recall of 99.8%, an F_1-score of 99.6%, and an AUC-ROC score of 33.1%. Although LR demonstrated strong results in accuracy, precision, and recall, its relatively low AUC-ROC score indicates limitations in its ability to effectively discriminate between classes.

XSL•FO
RenderX

Table . Scoring of the prediction classifiers (in percent) evaluated for the echocardiographic data set with Logistic Regression, K-Nearest Neighbors, Bayes Classifier, Decision Tree, Random Forest, Extreme Gradient Boosting, and SVM. While XGB's accuracy is 84.7, the AUC-ROC score is 84.6. In comparison, the accuracy of the RF is 82.5, but the AUC-ROC score is 85.3.

	Accuracy	Precision	Recall	F_1-score	AUC-ROC[a] score
Logistic regression	73.0	57.1	73.0	64.1	52.4
K nearest neighbors	76.6	74.4	76.6	68.4	70.3
Naive Bayes classifier	75.9	57.6	75.9	65.5	51.0
Decision tree classifier	73.7	73.7	73.7	73.7	71.3
Random forest classifier	82.5	81.3	82.5	81.0	85.3
Extreme gradient boosting	84.7	83.9	84.7	84.0	84.6
Support vector machine	73.0	65.2	73.0	67.1	65.7

[a]AUC-ROC: area under the receiver operating characteristic curve.

Table . Scoring of the prediction classifiers (in percent) evaluated for the laboratory data set with Logistic Regression, K-Nearest Neighbors, Bayes Classifier, Decision Tree, Random Forest, Extreme Gradient Boosting, and SVM. While the accuracy of all classifiers is nearly the same, SVM outperforms with the highest AUC-ROC score of 89.8.

	Accuracy	Precision	Recall	F_1-score	AUC-ROC[a] score
Logistic regression	99.8	99.5	99.8	99.6	33.1
K nearest neighbors	99.9	99.9	99.9	99.9	74.6
Naive Bayes classifier	99.8	99.5	99.8	99.6	50.0
Decision tree classifier	99.8	99.5	99.8	99.6	79.2
Random forest classifier	99.9	99.9	99.9	99.9	74.2
Extreme gradient boosting	99.5	99.7	99.5	99.6	59.3
Support vector machine	99.8	99.5	99.8	99.6	89.8

[a]AUC-ROC: area under the receiver operating characteristic curve.

KNN slightly outperformed LR in accuracy (0.999/1, 99.9%) and recall (99.9%). Its AUC-ROC score of 74.6% (0.746/1) indicates a notable enhancement in classification discrimination compared to LR.

NB achieved results similar to LR, with an accuracy of 99.8% (0.998/1) and an AUC-ROC score of 50.0% (0.5/1). Although its precision, recall, and F_1-score matched those of LR, the modest AUC-ROC score indicates potential limitations in distinguishing between classes in certain situations.

DT matched the accuracy, precision, and recall of LR but demonstrated a marked improvement in its AUC-ROC score (0.792/1, 79.2%). This highlights its enhanced ability to effectively separate classes despite similar performance on other metrics.

RF also achieved 99.9% (0.999/1) accuracy, precision, and recall, equaling KNN in these metrics. However, its AUC-ROC score of 74.2% (0.742/1) suggests that its performance in classification discrimination is slightly less robust than that of DT but still superior to LR.

XGB achieved a high accuracy of 99.5% (0.995/1) and an F_1-score of 99.6% (0.996/1). However, its AUC-ROC score of 59.3% (0.593/1) reveals its lower discrimination capacity compared to DT, RF, and KNN in this dataset.

SVM achieved strong results across all metrics, with accuracy, precision, recall, and F_1-score aligning with those of the top-performing models (99.8% - 99.9%). Notably, its AUC-ROC score of 89.8% (0.898/1) is the highest among all models, demonstrating superior discrimination performance within this dataset.

For the medication dataset, a sample of 4000 data items was cleaned and analyzed regarding the target quality. As shown in Table 4, the baseline model LR achieved an accuracy of 59.2% (0.592/1), precision of 35.0% (0.35/1), recall of 59.2% (0.592/1), an F_1-score of 44.0% (0.44/1), and an AUC-ROC score of 45.8% (0.458/1). Although it performed better than several models in terms of recall and accuracy, its overall low precision and AUC-ROC score indicate limited effectiveness in distinguishing between classes.

XSL•FO
RenderX

KNN performed lower than LR, with an accuracy of 48.3%, precision of 43.8%, and a slightly better F_1-score of 44.9%. However, its AUC-ROC score of 43.2% was lower, indicating weaker discriminatory ability compared to LR.

NB showed results similar to LR, achieving an accuracy of 58.3% and an F_1-score of 43.6%. However, its AUC-ROC score of 42.6% indicates slightly lower classification discrimination compared to LR.

DT achieved an accuracy of 51.7%, a precision of 39.5%, and a recall of 51.7%, resulting in an F_1-score of 42.5%. Its AUC-ROC score of 43.1% was comparable to that of KNN and NB, but slightly lower than LR, indicating similar performance levels.

RF and XGB performed poorly on this dataset. RF achieved an accuracy of 30.0%, an F_1-score of 29.5%, and an AUC-ROC score of 22.2%. XGB exhibited even lower accuracy at 21.7%, with precision at 23.3%, an F_1-score of 22.3%, and an AUC-ROC score of 19.0%, underscoring the significant limitations of these models for this dataset.

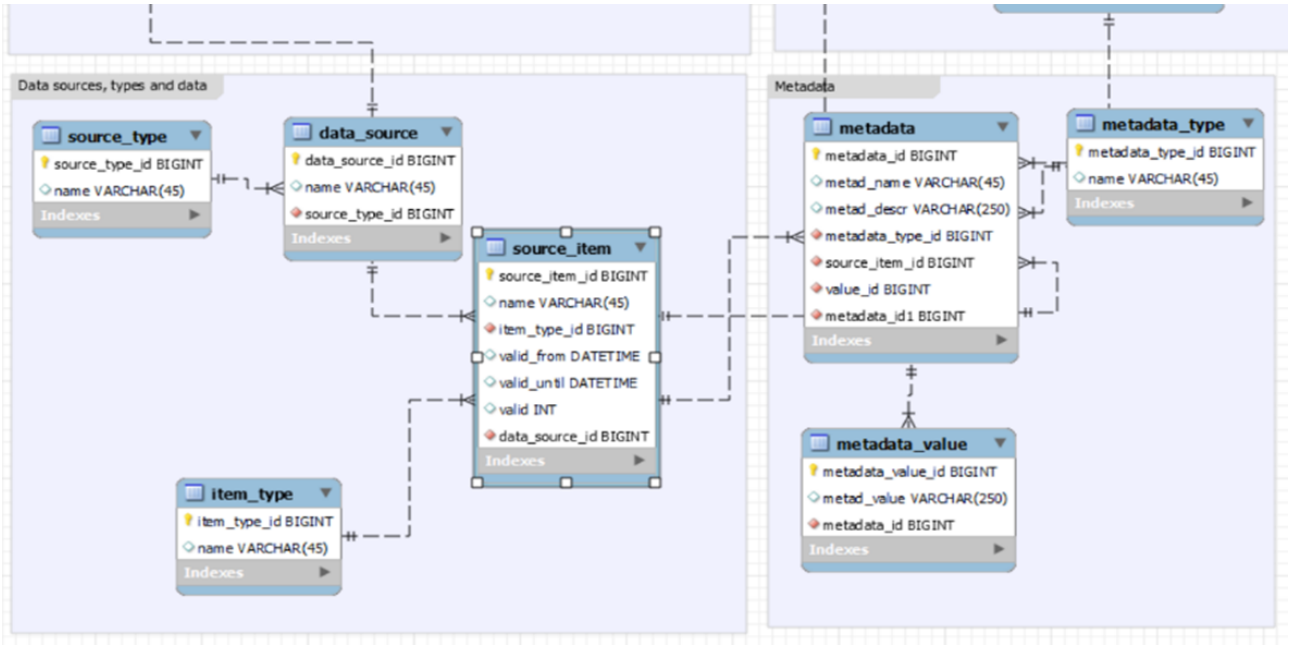
The SVM exhibited the most balanced performance among the models, achieving an AUC-ROC score of 65.1%, the highest across all models. Although it has a relatively low accuracy of 30.0% and an F_1-score of 30.0%, its AUC-ROC score suggests strong potential for distinguishing between classes.

Based on the results of testing different machine learning algorithms on the three datasets, the XGB model was deployed for echocardiographic data, the SVM for laboratory data, and the SVM for medication data during the UMG-MeDIC data inspection process.

The data inspection process used a hybrid approach, meaning that data quality inspection was not solely reliant on the trained model; conventional inspections were also conducted. To achieve this, it was decided that data items flagged as unsound during quality prediction would undergo traditional inspection to reduce false-positive rates and fine-tune the models. The classifiers were then retrained with the new test data.

Table . Scoring of the prediction classifiers evaluated for the medication data set with Logistic Regression, K-Nearest Neighbors, Bayes Classifier, Decision Tree, Random Forest, Extreme Gradient Boosting and SVM. While LR and NB performed with the best accuracy (59.2, 58.3), SVMs AUC-ROC score of 65.1 was the highest.

	Accuracy	Precision	Recall	F1-score	AUC-ROC score
Logistic regression	59.2	35.0	59.2	44.0	45.8
K nearest neighbors	48.3	43.8	48.3	44.9	43.2
Naive Bayes classifier	58.3	34.8	58.3	43.6	42.6
Decision tree classifier	51.7	39.5	51.7	42.5	43.1
Random forest classifier	30.0	29.0	30.0	29.5	22.2
Extreme gradient boosting	21.7	23.3	21.7	22.3	19.0
Support vector machine	30.0	32.1	30.0	30.0	65.1



Prerequisite at the UMG-MeDIC

In general, predicting the data quality for echocardiography, laboratory, and medication data is now possible based on trained ML models, allowing the results to be made available to researchers. The relational structure established for metadata stores information in the metadata table, which includes an ID, the name of the metadata, a description of the metadata, and details about “metadata_type_id,” “source_item_id,” and “value_id,” all of which are inherited from other tables through foreign keys in the relational structure. The respective metadata value is stored in the metadata_value column of the metadata_value table, as illustrated in Figure 2.

The predictive quality information is integrated via SQL queries into the relational database within UMG-MeDIC. Specifically, the metadata for the predictive quality data is stored in the metadata table, while the corresponding results of the predictive quality analysis, in terms of actual values, are stored in the “metadata_value” table. This setup enables easy retrieval and analysis of the prediction results, as the metadata table acts as the central reference point for all integrated data, with each entry linking back to its respective predicted values in the metadata_value table. Figures 8 and 9 (second reference in Multimedia Appendix 1 [2]) illustrate an example of the metadata structure within the relational database that includes the added predictive quality information.

Figure 2. Relational structure and the metadata tables within the UMG-MeDIC (Medical Data Integration Center of the University Medical Center Göttingen).

Discussion

Conclusion

The benefits of RWD for medical care and research are numerous, ranging from clinical decision-making and patient-centered medicine to its application as synthetic controls in randomized trials. Moreover, real-world evidence enhances randomized controlled trials to bridge the efficacy-effectiveness gap. The central requirement for leveraging the data to achieve these advantages is data quality, particularly its reliability [26]. The quality of the data can be articulated or supported with corresponding metadata, thus further investigation into predicting data quality with AI is necessary. Given the significant importance of reliable health care data for researchers in reusing it, the UMG-MeDIC has incorporated metadata on data quality as easily accessible information.

Principal Findings

All previously collected metadata concerning the primary source systems of the UMG within CouchDB were extracted and transferred to the newly established generic relational metadata structure within the data warehouse (DWH), as described in Section Prerequisite at UMG-MeDIC. This relational structure aligns with the DWH's underlying design and serves as another principal finding of this work. After the algorithm transferred all existing metadata into the newly created relational metadata tables, the next step was to adjust the extract-transform-load (ETL) processes. In addition, metadata types, such as predicted data quality and data item language, which had not been previously collected and stored, are now being integrated into the existing metadata, providing more information about data reliability.

Based on the above results, predicting data quality for the 3 clinical datasets served as a case study. It evaluated the approach of predicting data quality within the ETL process, storing the resulting data quality as metadata alongside other metadata, and making the information available for researchers.

The study evaluated several machine learning models for predicting data quality across 3 different datasets: echocardiographic, laboratory, and medication data. The results of the echocardiographic data show that ensemble methods like RF and XGB outperform simpler models, including the baseline model LR and NB. The strong AUC-ROC scores of RF and XGB highlight their ability to effectively discriminate between classes, making them the most suitable models for this dataset.

While most models demonstrated high accuracy, precision, recall, and F_1-scores for predicting the laboratory data, significant variations were observed in AUC-ROC scores. SVM emerged as the most effective model for this dataset, combining high overall performance with the best class discrimination capabilities. KNN, DT, and RF also performed well, showing notable improvements over LR regarding AUC-ROC scores.

The medication dataset showed lower performance across all models. LR outperformed other models in terms of accuracy and recall, making it the most effective choice for this dataset. However, SVM's superior AUC-ROC score suggests it may be better suited for tasks requiring high class separation. Models like RF and XGB underperformed significantly, possibly due to the characteristics of this dataset in particular. This indicates a poor fit without further data engineering.

Comparison to Previous Work

To the best of our knowledge, data quality prediction based on specific quality factors for echocardiographic, laboratory, and medication data, as well as the usage and provision of the resulting data quality within metadata, have not yet been implemented.

Therefore, the approach taken in this work is aligned with similar studies in other fields. Schmitt et al describe a comparable procedure concerning the inspection process in the

XSL•FO
RenderX

electronic industry for producing programmable logic controllers. The predictive model-based quality inspection framework provided there was adapted for application in the Medical Data Integration Center.

Regarding metadata, no comparable examples were found in the field of medical data. However, a similar method for assessing the quality of medical data was employed by Haghighat et al for digitized histological glass slides, where they also used AI to evaluate the utility and diagnostic level of these images [27]. According to Georgiev and Valkanov, the future of DWH data quality, however, lies in further developing ETL processes towards dynamic and adaptable solutions with automated identification and elimination of quality issues based on artificial intelligence [28].

The existing metadata needed to be transferred and stored in the correct table at the right location. This process only had to be done once for slightly over 3,000 existing metadata documents. From now on, all additional metadata will be loaded directly into the relational metadata structure through adapted ETL routes. In contrast, Oukhouya et al propose a generic metadata management model designed specifically for data from heterogeneous sources to be stored in a DWH [29]. Their model is based on a data lake, a concept introduced in business intelligence architecture to manage large volumes of unstructured and semistructured data. They identified several essential functionalities of metadata that are critical for supporting a metadata management system. Requirements may vary significantly between DWHs in the medical field and those in other sectors. Nonetheless, this comprehensive model could serve as a starting point for developing suitable metadata management for medical DWHs to avoid reinventing the wheel. Therefore, in further developing metadata management for the DWH of UMG MeDIC, the extent to which the proposed model can provide applicable information for a relational database system should be evaluated.

Strengths and Limitations

First, the low performance of machine learning models, particularly in echocardiographic and medication samples, could be due to several factors. Models may struggle if the features in the dataset lack sufficient discriminatory power or if the presence of irrelevant or inconsistent data impairs their ability to learn effectively.

To address these issues, an error analysis was conducted to identify which classes are most often misclassified. Therefore, confusion matrices were used to identify false positives and false negatives for each model (see third reference in Multimedia Appendix 1 [3]).

Second, the high occurrence of false negatives in the LR, KNN, and NB indicates that the data within the medication dataset are composed of non-linear relationships. Furthermore, the high dimensionality (many features) of the medication dataset results in problematic KNN calculations. The confusion matrix for the DT shows that the model struggles to correctly identify class 0. It almost always predicts class 1, even when class 0 would be the correct prediction. To improve this behavior, we performed a threshold value optimization. The XGB model demonstrates significant weaknesses in class differentiation, particularly for class 0. A potential reason for this issue may be that the features lack sufficient discriminatory power. The same observation applies to RF and SVM.

The performance of the models within the echocardiography dataset indicates that the dataset includes non-linear relationships and dependencies among the features. The slightly higher performance of models like RF and XGB also suggests that non-linear relationships play a role.

Third, 750 data points may not be sufficient for models like RF, XGB, and SVM, which typically learn from a large number of parameters and data points. These models often require more data to generalize effectively.

Although the medication dataset model currently shows lower predictive performance (accuracy: 30%, AUC-ROC: 65.1%), it has been integrated into the data inspection process as part of a hybrid approach, where automated predictions enhance traditional inspection methods. Rather than replacing manual review, the model assists in prioritizing data items for further inspection, enabling data stewards to concentrate on potentially lower-quality records.

Continual model retraining poses challenges, including catastrophic forgetting, data drift, and a need for robust evaluation strategies [30,31]. To tackle these issues, the model undergoes scheduled retraining with updated data while performance is monitored using metrics such as accuracy, recall, and AUC-ROC. The impact of human factors in creating, consolidating, and evaluating the database, especially regarding potential errors, must be taken into account. Moreover, it can be assumed that an increased number of connected systems in a MeDIC will reduce human errors but also create new types of errors [32].

Thus, newly flagged data points undergo manual verification before being included in future training iterations, ensuring that retraining enhances rather than diminishes performance. In productive operation, new, realistic data is often continuously available, better reflecting how the target variables behave in real life. Additionally, models such as RF, XGB, and SVM significantly benefit from a larger database, allowing them to learn more reliable patterns.

The machine learning algorithms ran on a laptop with Microsoft Windows 11 Pro, which features an Intel Core processor with 4 cores. The prediction runtime was about 10 minutes for all the algorithms. The models are currently deployed at UMG-MeDIC, and there is an inspection strategy in place that follows a hybrid approach.

However, it is important to note that the technical implementation of the relational data structure depends on the inherent and specific requirements of the UMG-MeDIC. This means that while the data storage is specialized, the quality prediction of the clinical data remains unaffected by it.

Nevertheless, scalability for datasets containing vastly different types of clinical data, such as imaging data or genomic sequences, may require additional preprocessing or adaptation steps. For instance, the features extracted from such data may

XSL•FO
RenderX

vary significantly from those used in the current work, necessitating customized data preparation pipelines and potentially adjusted analytical models. Furthermore, the quality scale employed was established as binary, using 0 and 1; a more refined granularity of the quality scale is pending further development.

Future Directions

Future work aims to enhance model performance by applying feature engineering, using data augmentation techniques, and investigating possible adjustments in model selection. Despite current limitations, even imperfect predictive models are valuable as they direct manual review efforts, reduce workload, and improve overall data quality assessment.

Furthermore, it must be discussed to what extent the metadata published in the different data formats contain the risk of reidentification. Metadata do not intrinsically contain any personal data within the UMG-MeDIC. However, it must be examined how far the linkage of the metadata with further information or the uniqueness of the metadata increase the risk of re-identification.

The ability to provide researchers with quality information on data they want to inspect and research is a key success factor for reliable medical and biomedical research, avoiding the "garbage in—garbage out" paradigm [33]. Due to the abundance of data accessible in a medical data integration center, employing predictive model-based quality inspection shows great promise in ensuring reliable data for medical research.

However, real-world deployment brings additional challenges such as data drift, generalizability across clinical settings, and resilience against distribution shifts. Additionally, it's important to note that as more systems connect within a MeDIC, human errors (eg, transmission errors) decline, yet new types of errors may arise, which are part of the continuous learning process of these systems.

Moving forward, it is necessary to conduct a postdeployment evaluation, which includes the monitoring of prediction performance on live data at the UMG-MeDIC data integration center, comparing model outputs with manual quality assessments from data stewards, testing on external datasets to ensure generalizability beyond internal sources, and longitudinal tracking of model performance to detect degradation over time.

This expanded evaluation will allow us to refine model performance, improve generalization, and provide a more comprehensive assessment of real-world impact. By integrating these additional validation steps, we aim to ensure the long-term reliability and effectiveness of our approach in clinical data quality assessment.

Acknowledgments

The authors acknowledge the support and provision of metadata by the Medical Data Integration Center of the University Medical Center Göttingen. The authors disclose that no generative AI was used in any portion of the manuscript. This research received funding from the German Federal Ministry of Education and Research within the project FAIRRMeDIC, grant number 01ZZ2012 (to TS), and the MII-DIFUTURE-Ulm project, grant number 01ZZ2304E (to HAK).

Data Availability

The datasets generated or analyzed during this study are not publicly available due to reasons of data protection but are available from the corresponding author on reasonable request.

Authors' Contributions

TK coordinated, and TK and HAK supervised this research project. CB wrote the manuscript, implemented the transfer of previous metadata, developed the relational data structure for the metadata, executed the machine learning models for the predictive quality approach, and carried out the testing and implementation of the data inspection process. CS assisted in the transfer of the previous metadata. DK, TK, and HAK contributed to the conceptualization of the research and participated in the revision, editing, and final approval of the manuscript. All authors read and accepted the final revision of this manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Studies suggest that less than 4% of patients with pulmonary embolisms (PEs) are managed in the outpatient setting. Strong evidence and multiple guidelines support the use of the Pulmonary Embolism Severity Index (PESI) for the identification of acute PE patients appropriate for outpatient management. However, calculating the PESI score can be inconvenient in a busy emergency department (ED). To facilitate integration into ED workflow, we created a 2023 Epic-compatible clinical decision support tool that automatically calculates the PESI score in real-time with patients' electronic health data (ePESI [Electronic Pulmonary Embolism Severity Index]).

Objective: The primary objectives of this study were to determine the overall accuracy of ePESI and its ability to correctly distinguish high- and low-risk PESI scores within the Epic 2023 software. The secondary objective was to identify variables that impact ePESI accuracy.

Methods: We collected ePESI scores on 500 consecutive patients at least 18 years old who underwent a computerized tomography-pulmonary embolism scan in the ED of our tertiary, academic health center between January 3 and February 15, 2023. We compared ePESI results to a PESI score calculated by 2 independent, medically-trained abstractors blinded to the ePESI and each other's results. ePESI accuracy was calculated with binomial test. The odds ratio (OR) was calculated using logistic regression.

Results: Of the 500 patients, a total of 203 (40.6%) and 297 (59.4%) patients had low- and high-risk PESI scores, respectively. The ePESI exactly matched the calculated PESI in 394 out of 500 cases, with an accuracy of 78.8% (95% CI 74.9% - 82.3%), and correctly identified low- versus high-risk in 477 out of 500 (95.4%) cases. The accuracy of the ePESI was higher for low-risk scores (OR 2.96, P<.001) and lower when patients were without prior encounters in the health system (OR 0.42, P=.008).

Conclusions: In this single-center study, the ePESI was highly accurate in discriminating between low- and high-risk scores. The clinical decision support should facilitate real-time identification of patients who may be candidates for outpatient PE management.

Introduction

While many patients with acute pulmonary embolism (PE) are at increased risk of cardiovascular complications, a significant minority have a low risk of short-term adverse outcomes and no requirement for hospital-level therapies [1]. There is now strong evidence to recommend outpatient management of PE patients identified as low-risk using tools like the Pulmonary Embolism Severity Index (PESI) [2-5].

XSL•FO
RenderX

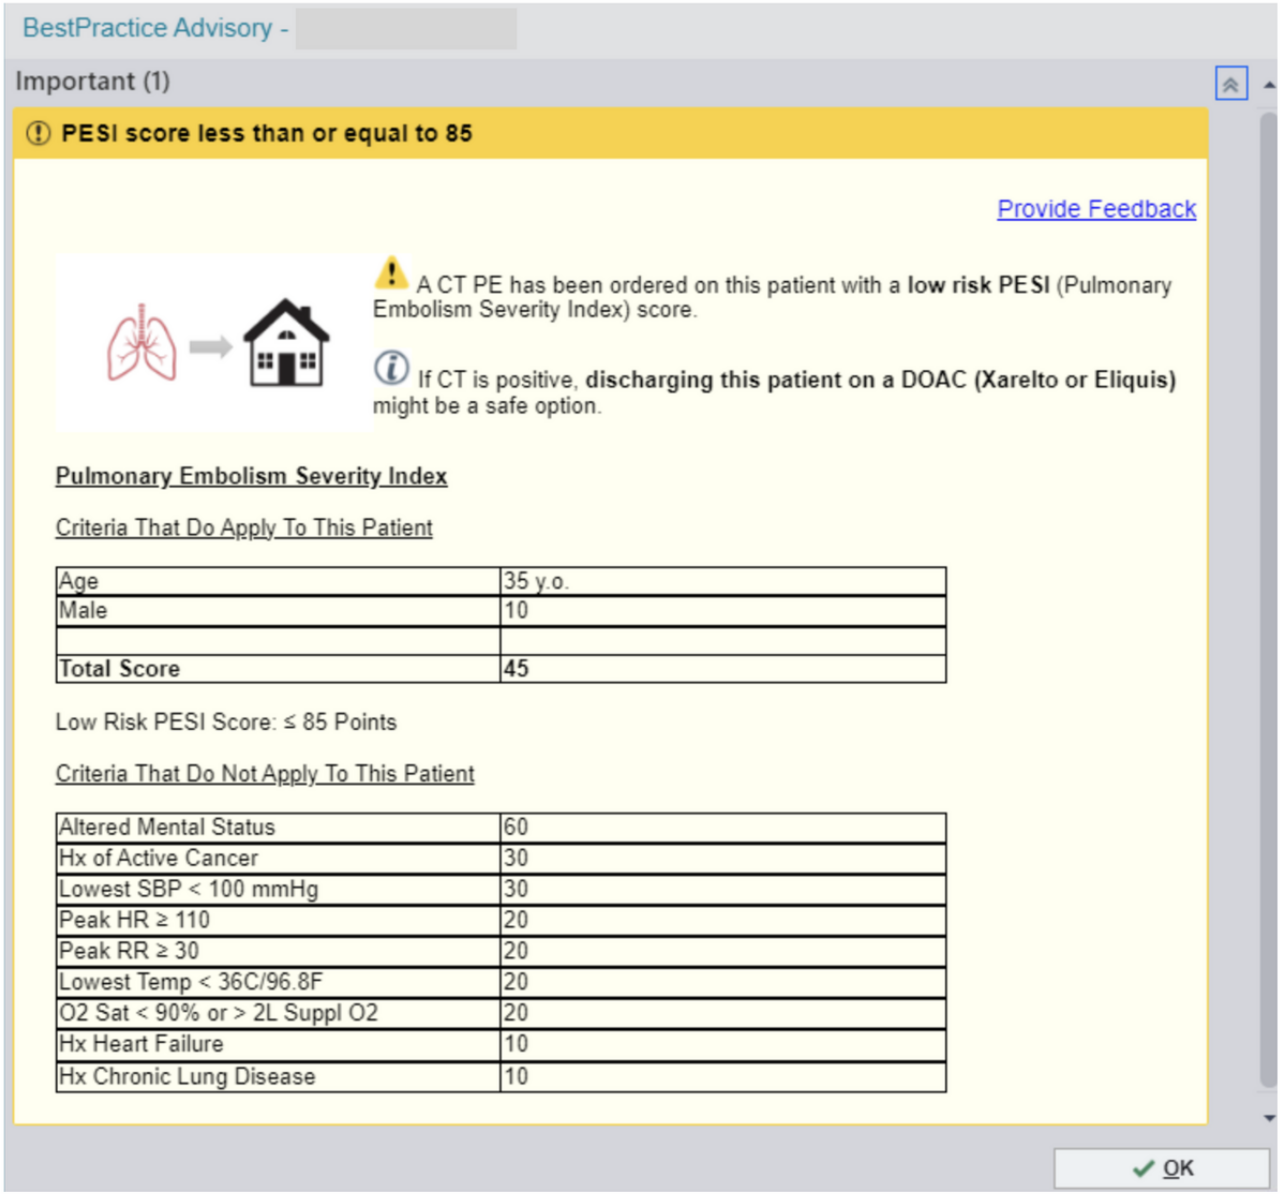
The PESI score combines demographics (age and sex), comorbidities (history of cancer, heart failure, and chronic lung disease), vital signs (temperature, heart rate, respiratory rate, blood pressure, oxygen saturation), and mental status to stratify acute PE patients according to 30 days all-cause mortality, with classes I (PESI score <66) and II (PESI score 66 - 86) being categorized as "low-risk" [2,6]. Despite multiple society-backed guidelines recommending that these patients with low-risk acute PE be provided anticoagulation and discharged directly from the emergency department (ED) [7-9], a recent analysis of over 60,000 cases of acute PE in the US found that less than 4% of patients were managed in the outpatient setting [10]. While there seems to be some variation at the hospital system level, the rate of outpatient management in the US remains substantially lower than in Canada and parts of Europe [11-13].

One potential barrier to increasing outpatient management of low-risk PE is identifying appropriate patients [5,14,15]. Although there are risk-stratification tools, these can be cumbersome to use in a real-world setting. The PESI score, while recommended by guidelines, incorporates 11 clinical variables that have different weights, making it cumbersome to calculate. This may be exacerbated by physician uncertainty regarding specific elements of the score—for example, what constitutes history of cancer?—and the fact that the score can change over the course of ED evaluation, that is, due to changes in mental status and vital signs. A group from the Kaiser Permanente health system previously reported an automated clinical decision support (CDS) tool, which calculates the PESI score based on data already captured in the electronic health record [16]. While found to be highly accurate in predicting patient risk category, that tool was specific to the Kaiser Permanente Epic-based electronic health record (EHR), which was implemented in 2005 and included health-system-specific features, like an improved problem list.

To promote PESI use in our hospital and facilitate more consistent implementation across other health systems, we created a new CDS within our 2023 Epic-based EHR featuring an electronic PESI calculator, or "ePESI" that automatically calculates a patient's PESI score when a computerized tomography-pulmonary embolism (CT-PE) is ordered. Systematic reviews of CDS system accuracy and use identify poor data quality, poor integration into workflow, patient complexity, inadequate CDS testing, and inadequate user training as negatively impacting the agreement between CDS recommendations and provider decisions [17-20]. In an attempt to account for these limitations, our ePESI underwent over 1 year of testing and multiple revisions. The aim of this study was to determine how well our ePESI captures specific electronic elements from the EHR demonstrating the overall accuracy of the ePESI and its ability to discriminate between patients who would be high- and low-risk if they had a PE, based on PESI score.

Methods

Development of the ePESI



The ePESI score was calculated automatically from data available in the EHR. Comorbidities were taken from the patient's active problem list and past medical history using preestablished SNOMED (Systematized Nomenclature of Medicine) hierarchical concept codes (Multimedia Appendix 1). Vital sign criteria were assigned using peak vital signs from the patient's Flowsheet (ie, structured ED nursing documentation)—that is, highest heart rate and respiratory rate, lowest systolic blood pressure, etc. The PESI element "oxygen saturation <90%" was considered positive if the patient had a documented pulse oximetry reading of <90%, or if they had been placed on >2 L/min of oxygen, >2 L/min above their home O2 requirement, or a respiratory-assist device such as BiPAP (bilevel positive airway pressure) or CPAP (continuous positive airway pressure), venturi mask, high-flow catheter, or mechanical ventilator. Altered mental status was defined as Glasgow Coma Scale (GCS) <14 in structured ED nursing documentation or "Altered Mental Status" in the patient's chief concern at ED presentation.

Study Design, Setting, and Population

In March 2022, a "pre-commitment" strategy was implemented in our ED to encourage outpatient management of low-risk acute PE [21]. The ePESI was calculated in all patients in whom a CT-PE was ordered. In patients with ePESI <86, the overall score and the individual elements were displayed to the treating clinician at the time of CT-PE order, encouraging them to consider outpatient management if a PE was ultimately diagnosed (Figure 1). In this study, we examined ePESI results in 500 consecutive patients who underwent CT-PE between January 3 and February 15, 2023. We included all patients, regardless of their CT-PE scan result, because the presence or absence of a PE should not influence the CDS accuracy when sampling electronic health data.

Figure 1. Image of the best practice alert presented to clinicians, depicting the Electronic Pulmonary Embolism Severity Index (ePESI) score. CT: computed tomography; DOAC: direct oral anticoagulant; HR: heart rate; Hx: history; O2 Sat: oxygen saturation, as measured by pulse oximetry; PE: pulmonary embolism; RR: respiratory rate; SBP: systolic blood pressure; Suppl O2: supplemental oxygen; Temp: temperature.

Ethical Considerations

This study was exempt from the institutional review board at the University of Michigan given that it was in regard to procedures rather than individual patients (HUM00217018). Participant consent was waived by the institutional review board. Permission was obtained from Epic to display any images of the ePESI.

Physician PESI (pPESI)

Two independent, medically-trained reviewers (EJ and JM) abstracted data from the EHR on all patients and calculated a physician PESI (pPESI) score using a standardized abstraction form (Multimedia Appendix 2). Both data abstraction and pPESI calculation occurred retrospectively, after all 500 cases had been identified. While reviewers could not be blinded to the study hypothesis, they were blinded to the ePESI score and to each other's pPESI scores. In cases where the 2 reviewers did not agree, a third reviewer (CO) abstracted data and calculated another blinded pPESI.

Statistical Analysis

Descriptive statistics, reported as proportions, were used to describe relevant characteristics of the patient population and their PESI scores. All cases in which the ePESI and pPESI did not agree underwent retrospective chart review to identify the discrepancy. Statistical analysis was used to compare ePESI and pPESI, with pPESI as the gold standard. The ePESI accuracy was computed via binomial test and reported with the 95% CI. Dichotomous predictors of ePESI accuracy were identified with a priori hypotheses and evaluated using odds ratios (OR). The OR was computed using logistic regression with continuous scoring. The error rates of individual ePESI components were reported as proportions and evaluated with

XSL•FO
RenderX

ANOVA. *P* values of <.05 were considered statistically significant. Inter-rater reliability was reported as a Cohen κ coefficient. All data analysis was conducted with SAS (version 9.4; SAS Institute).

Results

Of the 500 consecutive patients in whom ePESI results were evaluated, 203 (40.6%) patients had low-risk scores (ePESI<86) and 297 (59.4%) patients with high-risk scores (ePESI≥86) (Table 1). The most frequent risk class was class V (133/500, 26.6%), followed by class I (112/500, 22.4%). A total of 90% of patients (450/500) had had at least 1 encounter in the health institution's EHR prior to their index ED visit, whereas the remaining 10% of patients presented to the ED for their first entry into the health institution's EHR. For those with prior encounters, the median time between index ED visit and previous EHR entry was 14 days (IQR 4 - 50.7). Of the 500 study patients undergoing CT-PE, a pulmonary embolism was diagnosed in 47 patients (9.4%), of which 40 patients (85.1%) had an acute PE and 7 patients (14.9%) had subacute PE, chronic PE, or an equivocal study. Interrater reliability for the pPESI score was high, with Cohen κ coefficient of 0.98 (95% CI 0.97 - 0.98).

Table . Patient characteristics.

Characteristics	Values
Age (years), mean (SD)	58.2 (17.7)
Biologic male, n (%)	219 (43.8)
Comorbidities, n (%)	
History of cancer	185 (37)
History of heart failure	88 (17.6)
History of chronic lung disease	205 (41)
High risk versus low risk, n (%)	
High risk	297 (59.4)
Low risk	203 (40.6)
Class of risk, n (%)	
Class I	112 (22.4)
Class II	91 (18.2)
Class III	84 (16.8)
Class IV	80 (16)
Class V	133 (26.6)
First visit at health institution, n (%)	
Yes	50 (10)
No	450 (90)
CT-PE[a] scan report result, n (%)	
Acute PE[b]	40 (8)
Chronic PE	6 (1.2)
Acute on chronic PE	1 (0.2)
Other	3 (0.6)
No PE (negative)	451 (90.2)

[a]CT-PE: computed tomography scan-pulmonary embolism.

[b]PE: pulmonary embolism.

The ePESI and pPESI scores matched exactly in 394 out of 500 cases, for an accuracy of 78.8% (95% CI 74.9% - 82.3%) (Figure 2). For the subset of patients with an acute PE found on CT-PE, the accuracy was 82.5% (95% CI 67.2% - 92.7%) (Tables 2-4). The ePESI correctly categorized risk class (I-V) in 442 out of 500 (88.4%) cases and correctly identified high- or low-risk in 477 out of 500 (95.4%) cases. For cases where the ePESI and pPESI did not agree on high- or low-risk, the ePESI incorrectly identified cases as low-risk in 15 out of 23 (65.2%) and incorrectly identified cases as high-risk in 8 out of 23 (34.8%) patients. The odds of the ePESI and pPESI agreeing increased if scores were low-risk by pPESI (OR 2.96, CI 1.78-4.91, *P*<.001) (Table 5). The odds of the ePESI and pPESI agreeing decreased if the index ED visit represented the patient's first entry in the institution's EHR (OR 0.42, CI 0.214-0.788, *P*=.008).

Discussion

Overview

In this single-center cohort study, we demonstrated the accuracy of an EHR-based ePESI calculator built into the Epic 2023 system. The ePESI was particularly effective at discriminating between low- and high-risk cases, with 95% (477/500) correctly scoring as high- or low-risk as compared with a gold standard of multiple physician review. The accuracy of our ePESI calculator is similar to that of the PESI CDS tool developed by the Kaiser Permanente health system in 2015 [16], but it has the advantage of being compatible with Epic 2023 software and minimally reliant on health system-specific features. This should enable straightforward transfer to other health systems using Epic-based EHRs. Since 2015, Epic has surpassed Cerner as the most common EHR in the United States, and comprises 36% of the market share as of 2023 [22,23]. Epic is also gaining international use [24]. Given the increasingly widespread use of Epic EHR and interest in implementing outpatient management pathways for low-risk PE patients, we anticipate that the ePESI calculator built into the Epic 2023 software that can be readily exported to other health systems will be of interest to many EDs around the world.

Apart from the overall performance of the ePESI calculator, our study has several interesting findings with respect to automated risk score calculation. First, the ePESI calculator performed better when the ePESI score was low risk and in patients who had been seen within our health system previously. These findings are not entirely unexpected, as most ePESI errors were due to incorrect scoring of patient comorbidities (ie, cancer, heart failure, and lung disease), which were more common in high-risk cases and more likely to be inaccurate for patients whose index ED visit was their first presentation to our health system. Indeed, many errors stemmed from elements of the medical history not being entered or fully updated at the time of CT-PE order and ePESI calculation. While less problematic than comorbidities, vital signs were occasionally measured prior to CT-PE order but entered into the EHR after the ePESI calculator had been triggered to automatically calculate the ePESI score, causing some errors. These issues may be less problematic if health systems set the ePESI calculator to calculate the score after a PE diagnosis is made, rather than at the time of CT-PE order. Nonetheless, real-time updating of problem lists and vital signs is outside the capability of most EDs, and it is likely that some errors are simply unavoidable. The incorrect scoring of sex for 1 transgender patient in our cohort exemplifies the near impossibility of accurately evaluating the PESI score for every possible ED patient.

To some extent, these observations also highlight the limitations of the PESI score itself, and more generally, any risk stratification metric developed without consideration for contemporary health care technology. Several terms incorporated into both the PESI and simplified PESI scores—for example, history of cancer and heart failure—are vague and fail to account for the complexity of current medical practice or the ability to accurately capture it in the EHR. For example, how should we score patients with non-metastatic skin cancer or heart failure with recovered ejection fraction? What about patients who are placed immediately on supplemental oxygen and never have a charted SpO_2 less than 90%? Best practice alerts and electronic CDS tools are increasingly used in medical practice, and as technology continues to evolve, it is likely that future risk stratification metrics will need to be developed with an eye toward what can be accurately quantified by the EHR, communicated to clinicians in real time, and evaluated retrospectively for quality improvement or research purposes. In this sense, the development of this ePESI calculator and the demonstration of its utility across institutions may pave the way for more standardized methods of disease stratification and corresponding management recommendations.

Principal Results

This study demonstrates the accuracy of our ePESI calculator, which has 95% accuracy in discriminating between high- and low-risk PESI scores. The odds of the ePESI and pPESI agreeing increased (OR 2.96, *P*<.001) if a patient had a low-risk PESI score and decreased if it was the patient's first time in the health system (OR 0.41, *P*=.008). Most errors were due to incongruities with the problem list, of which cancer is the most common error (91.8% correct).

Limitations

Our study had several strengths, including the use of blinded assessment of the ePESI score and the inclusion of consecutive patients undergoing CT-PE. In addition, there are several

XSL•FO
RenderX

limitations of this study that must be considered. The first is that the SNOMED hierarchical concept codes used by the ePESI are somewhat specific to the health system where the study was conducted. The concept codes are adapted from general Epic concept codes, so we anticipate the transfer of our concept codes to other institutions will be straightforward. However, some degree of adjustment may be necessary and performance may differ at other sites. Indeed, efforts to adapt and validate the ePESI in other locoregional hospitals are ongoing. A second limitation is that the pPESI was calculated retrospectively, rather than in real time by providers ordering the CT-PE. We adjusted for this with 2 independent reviewers, blinded to the ePESI score and each other's pPESI score, to mitigate potential bias from the retrospective calculation. Additionally, reviewers used a standardized data abstraction approach designed to mimic the information providers have access to and likely use in the ED. A third limitation is that this study was conducted in a cohort of patients with a variety of conditions, not just those with PE. The purpose of this study was to evaluate the ePESI accuracy when it automatically sampled comorbidities, demographics, and vital signs, none of which are dependent on the patient's diagnosis. There is no reason to conclude that EHR accuracy should meaningfully differ for patients with and without a PE. The purpose of this study was not to influence clinical practice or predict patient outcomes, although this should be evaluated in a future study now that we have demonstrated the accuracy of the ePESI in sampling electronic health data. Additionally, we conducted a sensitivity analysis in the subset of patients with acute PE and found the ePESI accuracy to be comparable to our overall cohort. The number of patients with acute PE in our study was small, but it is unlikely, although not impossible, that the accuracy of the ePESI will be dramatically altered in a larger cohort of patients with acute PE. A final limitation is that we were unable to account for all variables that influence ePESI and pPESI agreement. As discussed in the introduction paragraph, systemic reviews of generalized CDS systems suggest that patient complexity, data quality, poor integration, inadequate testing, and inadequate training are all associated with poor CDS-provider agreement [17-20]. We attempted to minimize these by using a standardized protocol for the pPESI reviewers, as described in the methods paragraph, and updated or ePESI based on provider feedback before we formally tested it. However, it is possible these still affected our ePESI and pPESI agreement.

Comparison With Prior Work

Our study demonstrates a PESI score calculator with similar accuracy to a calculator described by Vinson et al [16] in the Kaiser Permanente system in 2015. However, our study has the advantage of describing a calculator that can be readily and immediately exported to other health centers. Our ePESI was developed within the Epic 2023 software, as compared with the 2015 software, and is minimally reliant on features specific to our health system. The Kaiser Permanente ePESI depends on the improved problem list, which limits direct translation to other health systems. Additionally, our ePESI was programmed to calculate and alert providers in the ED for easy and direct integration into clinical practice. To our knowledge, these are the only 2 studies evaluating a CDS tool that automatically calculates PESI scores using patient data from the EHR.

Conclusions

In conclusion, we created a CDS that is highly reliable at discriminating between low- and high-risk PE patients based on the PESI score. It is most accurate in the low-risk PESI score population, which is its intended target for clinical use. Our CDS has the potential to be exported to other health systems and implemented more widely to increase the discharge of low-risk PE patients who do not otherwise require hospitalization.

Acknowledgments

The authors would like to acknowledge Roger Lupton, Stephanie Brooks, and David Loveland for their help in development, implementation, and optimization of the Electronic Pulmonary Embolism Severity Index (ePESI) calculator within the Epic software. EJ, CO, VG, AC, GDB, and CFG were involved in the study's conceptualization and design. EJ, JM, CO, GDB, and CFG contributed to data acquisition, while EJ, XK, GDB, and CFG handled the analysis and interpretation of the data. EJ, GDB, and CFG drafted the manuscript, and all authors participated in its critical revision. EJ and XK provided statistical expertise, and VG, AC, GDB, and CFG secured funding for the study.

Conflicts of Interest

GDB has disclosed receiving grant funding from Boston Scientific and serving as a consultant for several organizations, including Pfizer, Bristol-Myers Squibb, Janssen, Bayer, AstraZeneca, Sanofi, Anthos, Abbott Vascular, and Boston Scientific. Additionally, GDB serves on the Data and Safety Monitoring Board (DSMB) for Translational Sciences (Clinical Events Adjudication Committee) and is a member of the Board of Directors for the Anticoagulation Forum. JM has disclosed receiving grant funding from the NIH (5T35HL007690-38). All other authors have no disclosures.

Abstract

Background: While expert optometrists tend to rely on a deep understanding of the disease and intuitive pattern recognition, those with less experience may depend more on extensive data, comparisons, and external guidance. Understanding these variations is important for developing artificial intelligence (AI) systems that can effectively support optometrists with varying degrees of experience and minimize decision inconsistencies.

Objective: The main objective of this study is to identify and analyze the variations in diagnostic decision-making approaches between novice and expert optometrists. By understanding these variations, we aim to provide guidelines for the development of AI systems that can support optometrists with varying levels of expertise. These guidelines will assist in developing AI systems for glaucoma diagnosis, ultimately enhancing the diagnostic accuracy of optometrists and minimizing inconsistencies in their decisions.

Methods: We conducted in-depth interviews with 14 optometrists using within-subject design, including both novices and experts, focusing on their approaches to glaucoma diagnosis. The responses were coded and analyzed using a mixed method approach incorporating both qualitative and quantitative analysis. Statistical tests such as Mann-Whitney *U* and chi-square tests were used to find significance in intergroup variations. These findings were further supported by themes extracted through qualitative analysis, which helped to identify decision-making patterns and understand variations in their approaches.

Results: Both groups showed lower concordance rates with clinical diagnosis, with experts showing almost double (7/35, 20%) concordance rates with limited data in comparison to novices (7/69, 10%), highlighting the impact of experience and data availability on clinical judgment; this rate increased to nearly 40% for both groups (experts: 5/12, 42% and novices: 8/21, 42%) when they had access to complete historical data of the patient. We also found statistically significant intergroup differences between the first visits and subsequent visits with a *P* value of less than .05 on the Mann-Whitney *U* test in many assessments. Furthermore, approaches to the exam assessment and decision differed significantly: experts emphasized comprehensive risk assessments and progression analysis, demonstrating cognitive efficiency and intuitive decision-making, while novices relied more on structured, analytical methods and external references. Additionally, significant variations in patient follow-up times were observed, with a *P* value of <.001 on the chi-square test, showing a stronger influence of experience on follow-up time decisions.

Conclusions: The study highlights significant variations in the decision-making process of novice and expert optometrists in glaucoma diagnosis, with experience playing a key role in accuracy, approach, and management. These findings demonstrate the critical need for AI systems tailored to varying levels of expertise. They also provide insights for the future design of AI systems

aimed at enhancing the diagnostic accuracy of optometrists and consistency across different expertise levels, ultimately improving patient outcomes in optometric practice.

Introduction

Artificial intelligence (AI) has emerged as a transformative force in optometry [1], particularly for glaucoma diagnosis. In this context, AI in optometry refers to the advanced algorithms that analyze complex data such as fundus photos and related patient data. These AI systems use techniques of image processing, computer vision, deep learning, and transfer learning to detect and diagnose glaucoma. Glaucoma is a progressive eye disease that often eludes early detection due to its subtle or absent symptoms, which poses a unique challenge for optometrists [2]. This challenge, along with no clear-cut tests or signs, frequently results in variability in glaucoma-related decisions, influenced by factors such as the optometrists' expertise, experience, the subjective interpretation of clinical data, and the use of different equipment [3,4]. This variability is a critical issue that AI is well positioned to address, potentially standardizing the diagnostic process and offering a more objective analysis of clinical data. Studies have illustrated AI's advanced analytical capability and proficiency in sifting through extensive patient data, including retinal images, visual field tests, optical coherence tomography scans, and medical histories [5]. This advanced analytical capability enables AI to identify signs of glaucoma with consistency and accuracy, often surpassing that of human optometrists [6,7]. For example, in Akter et al [8], researchers found that AI algorithms could detect glaucoma with up to 96% accuracy, markedly higher than the 80% accuracy rate commonly associated with optometrists.

Similarly, in another study [9], an accuracy of 83.4% is reported in identifying glaucomatous optic neuropathy using AI. These findings show AI's potential to reduce misdiagnoses and address the prevalent decision variability. In a similar vein, in another study [10], it was demonstrated that an AI system helped junior radiologists perform at levels close to that of a senior radiologist. This finding is particularly relevant to optometry, with AI having the potential to play a similar role in enhancing the diagnostic abilities of less experienced optometrists. As in Jammal et al [11], researchers have highlighted that advocating for a more integrated use of AI tools in optometric practices could be a significant step toward standardizing care and reducing diagnostic variability.

However, the effective integration of AI into optometric practice hinges on a comprehensive understanding of optometrists' decision-making processes [12,13]. AI promises to offer standardization in clinical decision-making. Yet, the crux of its successful integration lies in deeply comprehending the subtle intricacies inherent in human decision-making. This understanding is especially critical in diagnosing conditions like glaucoma, where subjective assessments and clinical expertise play significant roles. Highlighting the variability in diagnostic approaches between novice and expert optometrists, as demonstrated by studies [14,15], shows the importance of tailored AI support. Therefore, AI systems must adapt to different levels of clinical expertise and integrate the diverse decision-making processes of novice and expert optometrists.

Diagnostic decisions in this field vary significantly, influenced by an optometrist's expertise, experience, and cognitive strategies. These differences affect how patient data are interpreted, the importance assigned to various clinical findings, and the resulting diagnostic outcomes.

In this study, we investigate the variance of diagnostic decisions made by optometrists in the context of glaucoma, focusing on how the availability and nature of data influence these decisions. Several key research questions guide our investigation.

1. How do the decision-making processes of expert and novice optometrists differ when they are presented with the same patient data?
2. What specific data do optometrists at different experience levels tend to prioritize in a clinical journey?
3. Are experienced optometrists more inclined to use heuristic approaches when confronted with limited data instead of scenarios with comprehensive data availability?

To address our research questions, we conducted in-depth interviews with novice and expert optometrists, focusing on their diagnostic approaches to glaucoma. Following these interviews, we performed a detailed coding of the responses, enabling us to conduct qualitative and quantitative analyses. This structured approach allowed us to comprehensively examine the decision-making patterns and their implications for AI integration in optometric practice.

Our research aims to comprehensively understand how optometrists make decisions when diagnosing glaucoma, exploring the diversity in their approaches. By exploring the variations in decision-making between novice and expert optometrists, our study aims to pave the way for the future design of AI systems. These envisioned systems are intended to bridge the expertise gap in glaucoma diagnosis. They will complement human judgment to reduce biases and enhance diagnostic accuracy, leading to more consistent and reliable evaluations. The insights gained from this exploration are anticipated to significantly contribute to optometric practice and education, setting the stage for future advancements in glaucoma diagnosis and management.

Methods

Overview

This section details our research methodology investigating variations in optometrists' decision-making. It begins with an in-depth explanation of the data collection process, emphasizing the criteria and methods used for selection. Subsequently, the stages of data refinement and processing are outlined. Optometrist interviews are discussed, covering outreach strategies, interview platforms, and participant demographics. A within-subjects design was used for the interviews, allowing each participant to engage with all patient cases. The section culminates with insights into the data coding process, involving transcript cleaning and multidisciplinary analysis. For the data analysis, a mixed methods approach was used, integrating both qualitative and quantitative data to provide a comprehensive understanding of the decision-making processes. Figure 1 summarizes the flow of the study.

Figure 1. The stages and flow of the study. It started with patient data collection and selection, followed by optometrist interviews and data analysis. Each stage is further subdivided into steps. Each of these steps is further explained in the Methods section. The circle and star symbols show the data obtained at a specific stage in the interview and how they were analyzed. A higher resolution version of this image is included as Multimedia Appendix 1.

Ethical Considerations

This study (application 43288) was reviewed and approved by the Delegated Research Ethics Committee (DERC) of the University of Waterloo on May 27, 2021. Informed consent was sought from the participants before the data collection. They were informed about the procedure, purpose, benefits, risks, and their right to withdraw from the study. Further, they were informed that data acquired from the interview would be anonymized, deidentified, stored on a protected server, and used anonymously in all publications that arise from the study. Participants were remunerated CAD $150 (CAD $1=US $0.75) for their 2-hour commitment, recognizing their professional contribution and encouraging detailed participation.

Patients' Data Collection

Data for this study were acquired from the School of Optometry and Vision Sciences at the University of Waterloo, Canada. The selection process entailed scrutiny of patient records within the institution's database, explicitly targeting those records wherein patients had granted explicit consent for their information to be used in research. The preliminary phase of our data collection involved gathering records from 8 distinct patients. Each patient's record provided a longitudinal perspective, encompassing multiple clinical visits and offering an in-depth view of their interactions with the optometrist over time.

The data attributes collected from patient records were informed by research from previous similar studies [16-19] and the European Glaucoma Prevention Study [20]. Our data collection encompasses a comprehensive range of patient characteristics. It includes essential ocular health metrics and relevant external factors to ensure a comprehensive glaucoma evaluation by optometrists. The patient features we collected are detailed in Table 1. These features reflect the multifaceted factors highlighted in the referenced studies.

Category	Factors
Demographic factors	Age, gender, and race
Historical data	Ocular history, medical history, medication history, social history, and family history
Internal attributes	Habitual spectacle prescription, unaided visual acuity, aided acuity, pupils, anterior segment examination, Goldman applanation tonometry, central corneal thickness, and gonioscopy
Images	Fundus image and OCT[a] images
Reports	Posterior segment examination, visual field, and OCT

[a]OCT: optical coherence tomography.

Data Refinement and Processing

The data refinement and processing were executed to facilitate the interview component of the study. Out of the initial pool of patients, 4 records were chosen to be reviewed for the in-depth interviews. This selection process involved comprehensive discussions with an expert in the field to identify cases that could provide diverse diagnostic perspectives. The criteria for case selection were centered on identifying instances that would likely elicit differing opinions among optometrists, thereby enabling a focused examination of the variation in clinical decision-making.

The rationale behind limiting the selection to 4 patient records stemmed from practical constraints associated with the review process. It was anticipated that participants would take about 10-15 minutes to review each patient visit. To manage this effectively within time constraints, we selected 3 patients with 3 visits (the initial, final, and intermediary visits) and 1 patient with 2 visits. This approach allowed for a detailed review of each patient's clinical journey while staying within the practical limits of the allotted time. Notably, historical data from previous visits were not provided for 3 of the 4 patients. However, more exhaustive data were provided for 1 patient, including the complete set of previous visits data, offering a more detailed case study within the research. This approach provided a balanced perspective between a broad overview and an in-depth case analysis, enhancing the study's ability to capture general trends and specific nuances in clinical decision-making.

Optometrist Interviews

In this study, we interviewed 14 optometrists from the Waterloo region, primarily affiliated with the University of Waterloo's School of Optometry and Vision Science. Each optometrist participated in a 100- to 120-minute, web-based interview conducted in English via Microsoft Teams and Zoom. The choice of web-based interviews over physical ones was in response to the participants' preferences.

The participants had an average of 7.54 (SD 8.34) years of experience and saw an average of 32.57 (SD 22.39) patients weekly.

Each optometrist scrutinized data from at least 10 patient visits, translating to a comprehensive review spanning about 2 hours for the entire set of patient records. Although we aimed to present all visit data for evaluation, time constraints necessitated the omission of some visits, and a few evaluations did not produce usable data. Throughout the interviews, participants employed the "think aloud" protocol to review patient records, aiding in understanding their decision-making processes. After the first 10 interviews, we observed data saturation, which was achieved by the 14th interview, as evidenced by recurring themes and no new substantial information. All interviews were audio-recorded and transcribed using the platforms' built-in features.

Data Coding

Our qualitative research commenced with the cleaning of interview transcripts. This preliminary step involved a thorough review in correcting errors, eliminating irrelevant sections, and enhancing clarity and coherence. This crucial stage ensured the data's integrity before proceeding to the analysis phase.

After cleaning, the refined transcripts were exported into NVivo (version 14.23.2; Lumivero, formerly QSR International). In NVivo, we carried out an open coding process led primarily by FG. The involvement of multidisciplinary expertise enriched the coding process. With a background in engineering, CB conducted a thorough review of the codes from an engineering perspective. This review added a layer of technical and analytical insight, ensuring that the coding accurately reflected relevant engineering concepts and terminologies. Simultaneously, NF, leveraging her expertise in optometry, reviewed the codes with a focus on the optometry perspective. Her review was pivotal in aligning the data with optometric principles and practices, ensuring the findings were relevant and accurately interpreted within the context of eye care and vision science.

This multidisciplinary approach to reviewing the codes enhanced the depth of our analysis and ensured that the findings were robust, well rounded, and reflective of diverse professional viewpoints. Such a collaborative effort was instrumental in ensuring that the themes and patterns identified were relevant and applicable across different fields of study.

The open coding was executed inductively, allowing the data to drive the categorization process rather than imposing preexisting theories or frameworks. This approach facilitated a more organic and grounded understanding of the data. Each transcript line was carefully examined, with open codes assigned to summarize the content succinctly. These codes were crafted to stay true to the original text, minimizing abstraction. This level of descriptiveness in coding was instrumental in capturing the essence of the participants' narratives, laying a solid

XSL•FO
RenderX

foundation for subsequent conceptualization and analysis. The codes were then grouped to form more generalized codes. Multimedia Appendix 2 gives details of the created generalized codes.

Through this process, we distilled the raw data into meaningful themes and patterns, shedding light on the underlying narratives and insights embedded within the transcripts.

Data Analysis

To carry out the analysis, we categorized participants into 2 groups: novices and experts, based on their years of experience and frequency of consultations with patients with glaucoma, using median values for greater precision. An "expert" was defined as having 4 or more years of experience as a practicing optometrist and treating a higher-than-average volume of patients with glaucoma per week compared with the participant pool. This classification excluded the average number of all patients examined or treated in a week for any eye condition, as it was deemed irrelevant in the context of glaucoma. Participants collectively conducted 137 evaluations, with experts reviewing 48 and novices reviewing 89. Ideally, the total number of evaluations would have been 144, but in some visit instances, the participants did not provide us with enough data, or we skipped some visit instances in the interview because of time constraints.

First, we examined the variability of novices and experts in diagnostic concordance across all patient visits, focusing on how the availability of comprehensive versus missing data influences concordance rates. Diagnostic concordance is the rate of optometrists' decisions that are aligned with the original clinical decision taken at a clinic. This analysis revealed disparities between optometrists' decisions and established clinical decisions. Following this analysis, we examined the approach evolution of optometrists within the clinical journey. This analysis was conducted by calculating the assessments/exams conductance rate (the percentage of a specific assessment conducted) and 95% CI, and performing statistical analysis using Mann-Whitney *U* [21] test to evaluate the significance of the variations and approach evolution from initial visits to subsequent visits. To observe a general trend of evolution, we first compared and analyzed initial visits (n=51) with follow-up visits (n=82). To observe the novice and experts' trends, we then further classified the data by experience level of optometrists, comparing initial (n=33) and follow-up (n=55) visits by novices to initial (n=18) and follow-up (n=27) visits by experts. Through this analysis, we uncovered the variation in approach evolution and clinical decision-making between novices and expert optometrists.

Second, we used quantitative and qualitative methodologies across all evaluations (N=137) to gain an in-depth understanding of the outcomes of these examinations. This approach enabled us to identify key themes that distinguish the ocular examination practices of novice and expert optometrists. Similar to earlier analysis, we calculated the assessments/exams conductance rate and 95% CI, and performing statistical analysis using Mann-Whitney *U* test to compare each assessment type of experts and novices. These findings were further supported by identified themes. This mixed method analysis provided insights into the consistency and variability in assessments and diagnostic reasoning. Moreover, by intercase and intracase comparison analysis, we identified the cognitive strategies in clinical decision-making, revealing how expertise level influences the patient case comparison.

Last, we calculated the average follow-up time of experts and novices and then used chi-square test to observe the significance of variation. This analysis offered an understanding of how experience impacts the timelines of patient management. This finding is crucial in glaucoma, where timely intervention can significantly influence disease progression and patient quality of life.

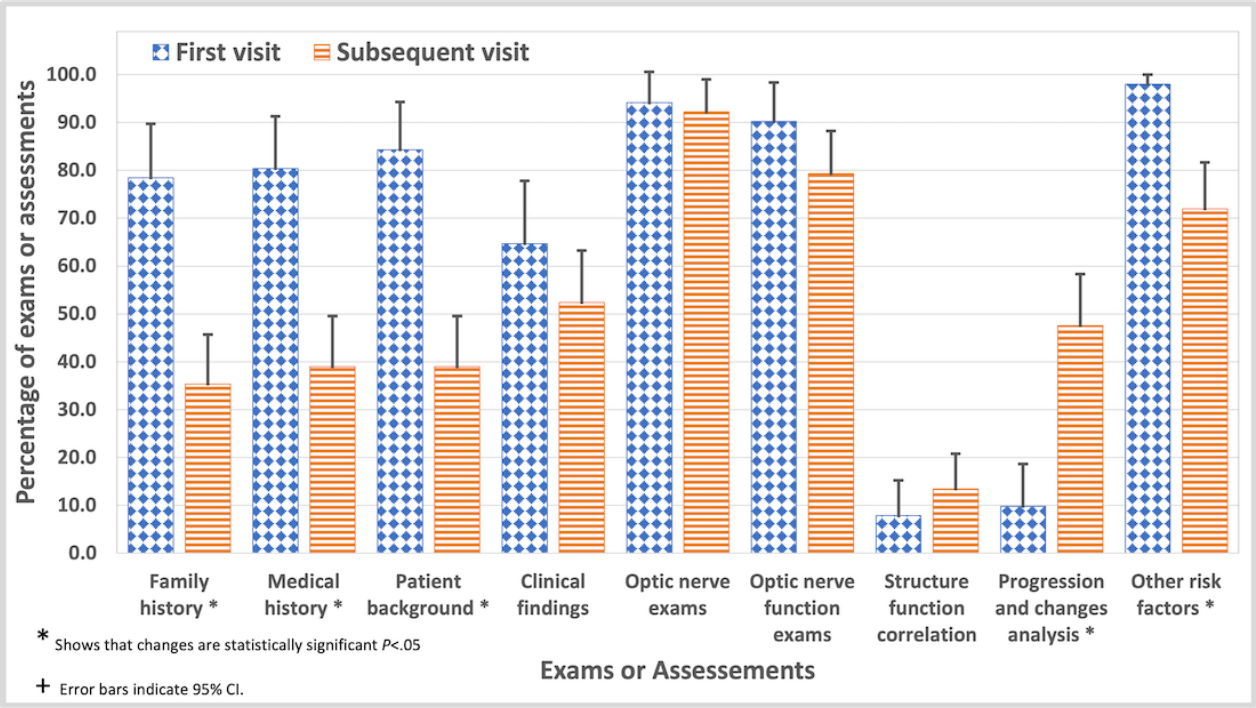
Overall, our study provides a multifaceted look at the complexities of glaucoma management, highlighting the influence of experience on various aspects of patient care. These insights are invaluable for shaping future educational programs, clinical guidelines, and AI systems in glaucoma, ensuring that they are tailored to address the specific needs and challenges optometrists face.

Results

Variability in Diagnostic Concordance and Approach Evolution in the Clinical Journey

This section investigates the variability in diagnostic concordance among novice and expert optometrists relative to established clinical decisions, emphasizing the influence of accessible patient data on diagnostic accuracy. It also delineates the evolution of diagnostic and treatment methodologies throughout the clinical journey, from initial patient encounters to subsequent visits.

Variability exists in the diagnostic concordance and approach evolution between experts and novices throughout the clinical journey. We compared the diagnostic decisions made by our participants with established clinical decisions, which we define as the decisions previously made by optometrists in a clinical setting where they had access to additional patient data, including comprehensive medical histories and previous examination results. The diagnostic concordance measures the extent to which our participants' decisions align with these preexisting clinical decisions. We observed significant variations in the decision-making of optometrists, notably when they lacked prior patient data.



Key findings highlight the disparity in diagnostic decisions when previous patient history is not available, where compared with novices (10% concordance, 7/69 evaluations), experts showed a higher rate of concordance (20% concordance, 7/35 evaluations), highlighting the impact of experience on clinical judgment. Interestingly, when provided with prior patient data, the gap in decision-making accuracy between experts (42% concordance, 5/12 evaluations) and novices (42% concordance, 8/21 evaluations) decreased. This finding shows the critical role of comprehensive patient histories in enhancing diagnostic precision, particularly for less experienced optometrists.

Building upon the insights regarding diagnostic concordance, the optometrists' diagnostic approaches through the clinical

XSL•FO
RenderX

journey of a patient reveal significant differences and shifts in practice strategy and emphasis. Initially, there is a higher engagement across all assessments except progression and change analysis and structure and function correlation analysis reflecting common practice for initial assessments. However, in subsequent visits, data reveal a significant shift: the engagement with most assessments decreased, while progression and change, and structure and function correlation, increased. Figure 2 provides a graphical representation of these trends in percentage, illustrating the shift from broad-based examinations to focused analytical assessments. Further analysis using the Mann-Whitney *U* test showed that these changes were significant when comparing initial and subsequent visits. Significant differences were observed in family history ($P<.001$, Cohen $d=0.41$), medical history ($P<.001$, Cohen $d= 0.45$), patient background ($P<.001$, Cohen $d=0.43$), other risk factors ($P<.001$, Cohen $d=0.50$), clinical findings ($P=.01$, Cohen $d=0.28$), optic nerve exams ($P=.01$, Cohen $d=0.29$), as well as in progression and change analysis ($P=.005$, Cohen $d=–0.20$). There was no significant change observed in the optic nerve function exam and structure-function correlation assessments. The shift in engagement with different assessments shows a pivot towards more in-depth analytical work.

Figure 2. The percentage increase or decrease in glaucoma-related eye examinations and assessments conducted by optometrists, tracked from the initial visit to subsequent visits through longitudinal patient history.

To investigate further, we compared and analyzed the data of experts and novices separately, summarized in Table 2. Detailed descriptive statistics are provided in Multimedia Appendix 3. In the initial visit, novices emphasize direct examination techniques, focusing significantly on the optic nerve exam (31/33, 94%) and optic nerve function exam (30/33, 91%) and comparatively underemphasizing patient history and background information, while experts demonstrate a more balanced and comprehensive approach. They engage more deeply in gathering medical history (15/18, 83%) and patient background (17/18, 94%), while still maintaining high attention to optic nerve assessments (16/18, 88.8%). Both give considerable attention to other risk factors, with experts at 100% (18/18) and novices at 97% (32/33). These results suggest that experts prioritize a more complete picture of the patient's medical background and current health status from the onset. Regarding the analytical methods such as progression and change analysis, novices show a surprising engagement (4/33, 12%), which demonstrates a higher propensity to engage in advanced analytical methods early on, despite such analyses typically requiring follow-up data. This is possibly due to a misunderstanding of the optimal timing for such analyses.

XSL•FO
RenderX

Table 2. The variation in glaucoma-related eye examinations throughout a patient's clinical journey, highlighting the differences between novice and expert optometrists, tracked from initial to subsequent visits. For the Mann-Whitney U test, effect size is given by the rank biserial correlation.

	Novices				Experts			
	First visit, n/N (%)	Subsequent visit, n/N (%)	*P* value	Cohen *d*	First visit, n/N (%)	Subsequent visit, n/N (%)	*P* value	Cohen *d*
Family history	26/33 (79)	19/55 (35)	<.001	.39	14/18 (78)	10/27 (37)	.02	0.41
Medical history	26/33 (79)	21/55 (38)	<.001	.44	15/18 (83)	11/27 (41)	.01	0.47
Patient background	26/33 (79)	18/55 (33)	<.001	.53	17/18 (94)	14/27 (52)	.03	0.29
Clinical findings	19/33 (58)	23/55 (42)	.04	.27	14/18 (78)	20/27 (74)	.63[a]	0.09
Optic nerve exams	31/33 (94)	48/55 (87)	.01	.36	16/18 (89)	25/27 (93)	.35[a]	0.18
Optic nerve function exams	30/33 (91)	44/55 (80)	.74[a]	.04	16/18 (89)	21/27 (78)	.80[a]	–0.04
Structure-function correlation	2/33 (6)	4/55 (7)	.51[a]	–0.05	2/18 (11)	7/27 (26)	.21[a]	–0.17
Progression and change analysis	4/33 (12)	15/55 (27)	.68[a]	–0.04	1/18 (6)	24/27 (89)	<.001	–0.7
Other risk factors	32/33 (97)	41/55 (75)	<.001	0.5	18/18 (100)	18/27 (67)	.06[a]	0.35

[a]Nonsignificant values.

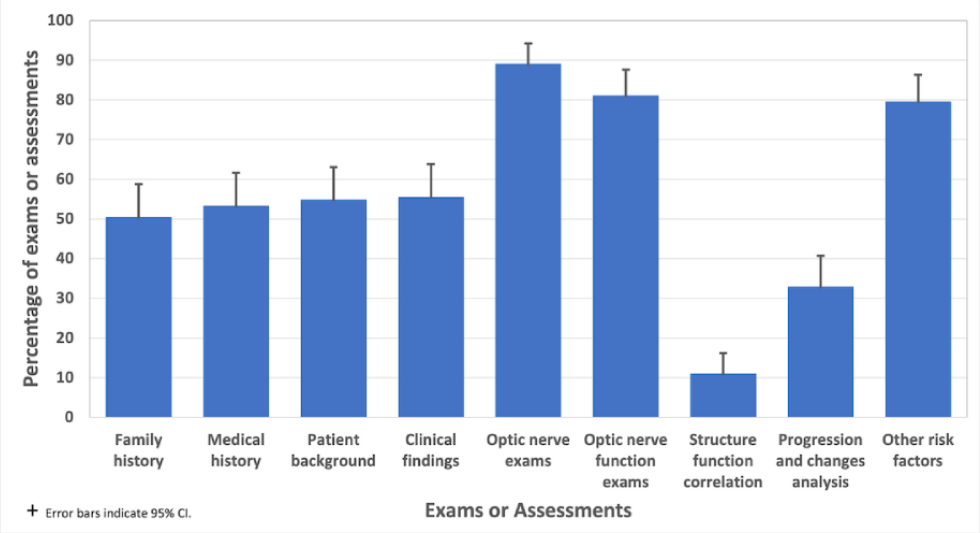
In the subsequent visits shown in Table 2, there is a noticeable shift. Novices demonstrated sustained attention to optic nerve exams (48/55, 87%) and optic nerve function exams (44/55, 80%). However, their assessment of family history, medical history, patient background, and other risk factors dropped in comparison to that of initial visits. Experts showed a similar behavior with high attention to optic nerve exams (25/27, 92%), optic nerve function exams (21/27, 77%), and clinical findings (20/27, 74%), while showing a marked decrease in the assessment of family history, medical history, patient background in comparison to initial visits. In the assessment of progression and changes analysis, and structure-function correlation, both groups showed an increase. However, the extent of these increases differs between the 2 groups; novices showed a modest increase in progression and changes assessment (15/55, 27%) and a much smaller increase in structure function correlation (4/55, 7%), while experts showed a robust increase (24/27, 88%) in progression and changes assessment and modest increase (7/27, 25%) in structure-function correlation. This leap for experts could reflect a strategic approach where they dive deeper into the more complex analysis. This finding might suggest a more focused approach as specific patient issues become more apparent.

Further analysis using the Mann-Whitney *U* test showed significant shifts in the assessments from initial to subsequent visits for both novices and experts, as reported in Table 2. In this analysis, the weight of each exam was also considered and calculated based on the frequency with which an optometrist discussed a specific assessment. We observed that novices showed significant changes in more assessments with Cohen *d* values of moderate effect, suggesting a strong shift of approach. While the experts showed fewer significant changes with Cohen *d* values of smaller to moderate effect, except for the progression and change analysis where the effect was large, suggesting a stronger shift. These findings suggest that experts maintained a comprehensive approach, balancing all assessments with increased emphasis on analytical assessment.

This analysis highlights the critical importance of comprehensive patient data in enhancing diagnostic accuracy, particularly for novice optometrists who face more significant challenges without extensive patient histories. The findings reveal the dynamic evolution of diagnostic and treatment strategies throughout a patient's clinical journey, illustrating how adaptability in practice strategy from initial assessments to subsequent visits is crucial. Notably, novices demonstrate a reduced focus on disease progression and correlating variables, indicating a gap in their approach to long-term patient management. This result highlights the potential need for a guiding system to help novices navigate the complexities of diagnostic decisions more effectively.

Comprehensive Overview of Examination Data Across All Visits

We categorized the analyses carried out by optometrists into 9 broad codes/categories: family history, medical history, patient background, clinical findings, optic nerve exams, optic nerve function exams, structure-function correlation, progression and change analysis, and other risk factors. The details of these categories are provided in Multimedia Appendix 2. Through these categories, we identified the following key themes that gave us insights into the factors that optometrists keep in focus while screening patients for glaucoma.



All Optometrists Focus More on Optic Nerve Exams and Risk Factors

The data reveal the distribution of eye examinations, as shown in Figure 3, within the whole data set. Key findings include a high frequency of focus on the optic nerve assessment (122/137, 89%) and optic nerve function assessment (110/137, 80.2%), showing a significant focus on assessing the optic nerve's structural and functional aspects. Clinical findings (75/137, 54.7%), medical history (73/137, 53.2%), and family history (69/137, 50.3%) were evaluated at moderate rates, indicating a holistic approach that incorporates patient-related and clinical information. In contrast, progression and changes analysis

XSL•FO
RenderX

(45/137, 32.8%) and structure-function correlation analysis (14/137, 10.2%) were less frequently performed.

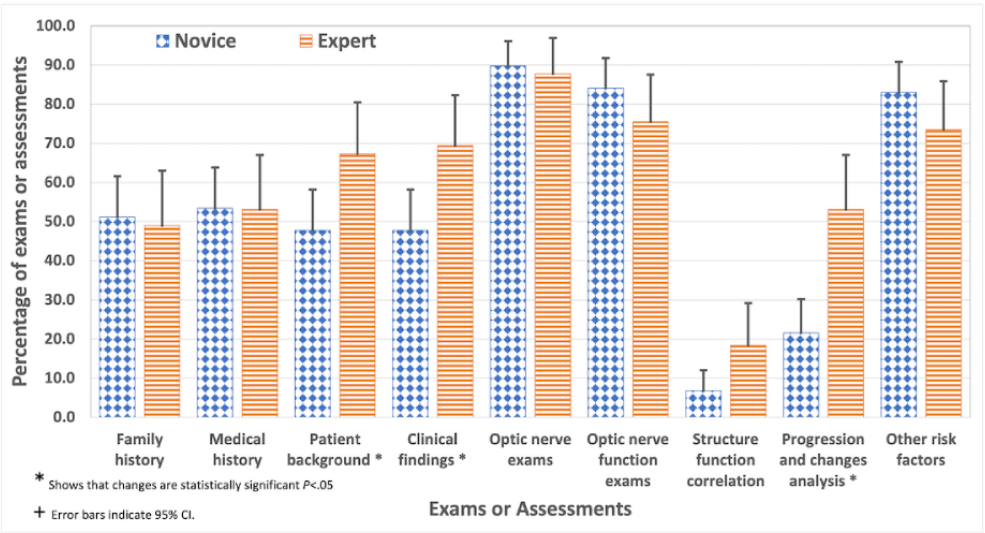


Figure 3. Findings from the whole dataset, revealing a strong emphasis on optic nerve structural and functional assessments. It also shows moderate attention to clinical findings, medical history, and family history, while progression analysis and structure-function correlation analysis were performed less frequently.

Experts Carry Out Progression and Change Analysis More Than Novices

Our findings reveal that experts are more inclined to engage in progression and change analysis than novices. A preliminary test of normality on the data distribution resulted in a $P<.001$, indicating a deviation from normal distribution. Consequently, we used the Mann-Whitney U test to examine the differences between experts and novices in analyzing progression and changes. This test yielded a $P<.001$ (2-tailed) with U of 1486, and a mean rank of 61.08 for novices and 80.54 for experts. This shows a statistically significant difference between the 2 cohorts. Specifically, our analysis shows that experts demonstrate a markedly higher focus on progression and change analysis (26/49, 53.1% vs 19/88, 21.5%), as illustrated in Figure 4, reflecting their seasoned approach to monitoring disease development over time.

Figure 4. The percentages of glaucoma-related eye examinations conducted by novices and experts, highlighting differences in focus on clinical findings, patient history, progression and change analysis, and structure-function correlation.

Experts Integrate Clinical Findings and Patient Background More Than Novices

There is a significant difference in the emphasis on clinical findings and patient background between novice and expert optometrists. Our initial analysis involved conducting tests of normality for both clinical findings and patient background data, which revealed $P<.001$, indicating that the data do not follow a normal distribution. Consequently, we applied the Mann-Whitney U test to assess the differences in emphasis on these diagnostic components between novice and expert optometrists. The test results for clinical findings yielded a P value of .04 (2-tailed) with U of 1695 and a mean rank of 63.75 for novices and 77.19 for experts. Same way the test results for

XSL•FO
RenderX

patient background yielded a *P* value of .04 (2-tailed) with *U* of 1732 and a mean rank of 64.18 for novices and 76.42 for experts, suggesting a statistically significant difference between the 2 groups, albeit with a modest significance level.

Specifically, novices consider both factors in 48% (42/88) of evaluations. In contrast, experts incorporate them at a higher rate, with about 69% (34/49) for clinical findings and 67% (33/49) for patient background, as shown in Figure 4. This disparity shows the experts' more substantial focus on combining clinical signs and symptoms of glaucoma with the patient's historical data. Expert physicians' comprehensive approach showcases their in-depth understanding and extensive experience in evaluating these essential diagnostic components.

Experts Tend to Emphasize Structural Function Correlation More Than Novices

Our analysis shows a trend that novices focus on structure-function correlation at a rate of 7% (6/88) and experts at a higher rate of 18% (9/49), as depicted in Figure 4. Despite the apparent disparity in percentages suggesting a more pronounced awareness of the interplay between structural and functional considerations, statistical analysis reveals that the difference in structure-function correlation between experts and novices does not achieve statistical significance (*P*=.15 with *U*=1951.5). However, the percentage difference still indicates that there may be a trend towards a higher engagement with structure-function correlation among experts than novices.

Novices Exhibit a Higher Tendency for Intercase and Longitudinal Comparisons, Less for Intracase Comparisons

In such a comparison, the clinician evaluates the current case against other patient scenarios. Novices in some cases made a reference to another patient's data, denoting a reliance on external case references. This reliance may be a compensatory mechanism for the relative inexperience in glaucoma diagnosis, where pattern recognition is still being cultivated. In a representative case, a novice commented "I think that they would be potentially a mild suspect compared to the first patient that we had just due to the fact that this person has hypertension, and they have a family history of glaucoma..."

In stark contrast, this form of comparison was entirely absent among experts, suggesting a transition towards an intuitive, more synthesized comprehension of glaucoma presentations, informed by an extensive repository of patient encounters.

The difference between experts and novices in conducting longitudinal comparisons of patients' data is subtle, with our analysis revealing a difference that does not reach statistical significance with *P*>.05. Despite the lack of statistical significance, the observed percentages 24% (12/49) of evaluations for experts versus 29% (26/88) for novices hint at an interesting trend: experts might possess a nuanced internalization of a patient's historical data. This suggests that experts are potentially more adept at retaining key details of disease progression within their working memory. With their extensive experience, they may draw upon a mental synthesis of the patient's history and current presentation without the need for frequent referrals to past records. This cognitive efficiency reflects a mastery of pattern recognition characteristic of glaucomatous progression, allowing for a more agile and comprehensive assessment that leverages their extensive experience and nuanced understanding of the disease. The less frequent engagement with longitudinal comparison by expert optometrists may not indicate a disregard for the patient's history but rather an advanced capacity to retain and integrate this information into their clinical judgments, a testament to their evolved diagnostic expertise.

Intracase comparisons, particularly the evaluation of asymmetry between left and right eye examinations, were used by novices in 17% (15/88) of evaluations and experts in 24% (12/49) of evaluations with no statistically significant difference. Both groups recognize the diagnostic value of these comparisons, yet the slightly higher use by experts may reflect a refined, systematic approach and a heightened sensitivity to the subtleties of asymmetry, honed through repeated clinical encounters.

Variation in Patient Follow-Up Time Suggestion

The analysis reveals significant variations in follow-up times among all participating optometrists, as well as a noticeable relationship with their years of experience. The initial chi-square statistic (χ^2_{98}=142.2) with a *P* value of .002 highlights a substantial difference in follow-up times among all optometrists. Further analysis, considering the years of experience, shows a chi-square statistic (χ^2_{140}=1540) with a *P* value of <.001, suggesting that experience level is an influential factor in this variation. These data collectively indicate that not only do follow-up times vary among optometrists, but they also correlate significantly with their professional experience.

A further breakdown shows that expert optometrists, with an average follow-up time of 4.1 months for confirmed glaucoma cases and 4 months for suspected glaucoma cases, seem to require less time to assess disease progression, likely due to their proficiency in managing the condition. In contrast, novice optometrists recommend longer follow-up times, averaging 5.3 months for confirmed cases and 4.5 months for suspected cases, which may indicate a need for additional time to make informed decisions about disease progression. For patients without glaucoma, both groups suggest more extended follow-up periods, with experts recommending an average of 8.15 months and novices slightly more at 8.73 months.

Discussion

Overview

This study investigates how optometrists' experience levels affect their decision-making in glaucoma diagnosis, a crucial factor for patient outcomes. We found significant differences in diagnostic approaches between novices and experts. The discussion ahead will dive deeper into these differences in decision-making, particularly focusing on how experience levels affect priorities in data interpretation and heuristic use in diagnosis. This analysis will not only correlate our findings with the central research questions but also inform the development of AI systems tailored for glaucoma diagnosis.

XSL•FO
RenderX

Decision-Making Processes

Our findings reveal a notable divergence in the alignment with established clinical decisions between expert and novice optometrists, particularly in the absence of prior patient data, offering crucial insights into the role of experience in clinical judgment. The higher alignment of expert diagnoses with original clinical decisions in scenarios lacking previous patient data highlights the depth of expertise honed through years of clinical practice. This expertise results in more accurate and intuitive diagnostic skills. This aligns with Hammond Cognitive Continuum Theory [22], which posits that as clinicians gain experience, their decision-making process shifts from a predominantly analytical approach to a more intuitive one [23,24]. Experienced practitioners are theorized to navigate and use this spectrum effectively, adapting their approach depending on the situation [25].

The reduced gap in decision-making accuracy when prior patient data were provided suggests that access to comprehensive patient history significantly enhances diagnostic accuracy across experience levels highlighting the critical role of patient history in clinical decision-making. These results suggest that novices can make competent decisions when guided by detailed information.

Data Prioritization in Clinical Assessments

The study also explored how optometrists at different experience levels prioritize data during clinical assessments. Initially, both experts and novices engaged comprehensively across various diagnostic areas, but with a lower focus on progression, change, and correlation analysis. This trend reflects common practice for initial assessments, where establishing a broad understanding of the patient's condition is prioritized over detailed analysis.

Interestingly, subsequent visits revealed a significant increase in attention to progression and change, particularly among experts. Experts demonstrated a more comprehensive approach, integrating clinical findings and patient history from the outset and emphasizing structural-function correlation more than novices. This comprehensive risk assessment aligns with the notion that experienced clinicians can synthesize complex information more effectively [23] and that is why their concordance was quite higher than novices.

Novices, despite a higher initial engagement progression and change analysis, might misunderstand the optimal timing for such analyses, typically requiring follow-up data. Although this increased for novices in subsequent visits, the experts showed a robust increase almost double that of novices. This indicates a strategic approach to deeper analysis in the later stages of patient management by experts.

Heuristic Approaches and Cognitive Efficiency

Our results suggest that experienced optometrists may use heuristic approaches more frequently, particularly when data are limited. The nuanced internalization of a patient's historical data by experts, evidenced by their subtle differences in conducting longitudinal comparisons and intercase comparisons, suggests cognitive efficiency. This efficiency allows experts to retain and integrate key details of disease progression into their clinical judgments without frequent referrals to past records or references to other cases. This cognitive agility is indicative of their evolved diagnostic expertise and mastery of pattern recognition in glaucomatous progression [25].

The reliance on external case references by novices, as noted in some cases, maybe a compensatory mechanism for their relative inexperience. This behavior highlights the gap in their approach to long-term patient management and the development of pattern recognition skills.

Guidelines for Developing AI System to Minimize Diagnostic Variations

In this section, we propose a set of guidelines for developing an AI system for glaucoma diagnosis based on our findings. These guidelines are intended for a human-AI collaborative environment, where the AI system will be used as a decision-support tool rather than a standalone decision maker. We suggest that by following these guidelines, the AI system will effectively support optometrists with different experience levels, bridging the gap between novices and experts, and ultimately improving patient outcomes through enhanced diagnostic accuracy. The collaborative model will also uphold ethical and professional standards, mitigating any legal, ethical, and professional barriers posed by standalone system. As a result, it will facilitate the effective integration of AI into clinical practice.

Minimizing the Effect of Limited Data Availability

Our findings show variability in diagnostic concordance between novice and expert optometrists when comprehensive patient histories are not available. These findings suggest that AI systems should have a robust module that provides detailed patient histories. If a patient has limited historical data, the system should present novices with 2 features. It should identify and display data from the most similar patient cases with the same conditions [26] along with the decisions made in that case. It should also highlight the dissimilarities between the selected patient and the current patient. The AI system should be trained with expert decision-making patterns by modeling the diagnostic approaches and visualizing the variables by estimating the missing data [27] backward in time to give them an idea of how history would look. These 2 features would minimize the limited data availability challenge and allow novices to make more accurate and consistent decisions in glaucoma diagnosis.

Evolving AI System for Initial and Subsequent Visits

Our result shows that in the initial visit, the expert optometrists adopt a comprehensive approach to assess all factors, except they do not carry analytical analysis (any progression and change analysis, and structure and function correlation analysis). As they move to subsequent visits, they still follow a comprehensive approach but with limited focus on patient historical information, instead, their focus shifts to analytical assessment. We accordingly suggest that an AI system should behave in a similar way and evolve along with the visits. In the initial visits, the AI system should prompt a novice to adopt a comprehensive approach and highlight important factors such as family history, and age. In the subsequent visits, the AI system should highlight any analytical changes. It would be better that the AI system

XSL•FO
RenderX

present a hierarchy of features, by demonstrating which features require more or less importance to assess during both the initial visit and subsequent follow-up visits. These features of AI system will help novices in understanding the optimal time for any analysis.

Follow-Up Time Suggestion

The follow-up time analysis shows variation among optometrists. We suggest that for better patient management, the AI system should provide an optimal time frame for follow-up visits [28] which should be based on patient data and clinical indicators. Along with follow-up interval, the system should also display the variables that influence this decision, such as disease progression, patient history, and symptoms. With this feature, we can bring more consistency in follow-up time suggested by optometrists.

AI System Features and Behavior

Most of the AI systems developed by researchers for glaucoma diagnosis focus on the detection of glaucoma with binary outputs [29-31]. However, to gain optometrists' trust, the AI system developed for glaucoma should also include a confidence score, include a detailed explanation of how it arrived at that specific decision, and provide a visualization of the risk factors in a hierarchical manner [32,33]. This will ensure that the optometrist does not overlook any important details. We further suggest that in the context of glaucoma, the system should not rely on only one source of data, but that it should combine multiple sources of data as used by optometrists. The optometrist will have more trust if the system uses a similar modal data for decision-making. Additionally, the AI system should have an interactive interface that offers an adjustable variables feature [34] that allows the optometrist to modify the values of any factor and see how different scenarios would affect the outcomes, such as diagnosis, severity, and follow-up time. For example, if the optometrist changes a variable to reflect a worsening condition, the AI system will adjust the follow-up recommendation accordingly. Such an AI system design for glaucoma will ensure more consistent decision-making regardless of expertise level.

Conclusions

This study investigated the diagnostic decision-making differences between novice and expert optometrists in glaucoma diagnosis, focusing on how these variations influence clinical judgment and patient outcomes. Through in-depth interviews, we identified significant disparities in diagnostic approaches. Experts demonstrated higher concordance rates with limited data, emphasizing their cognitive efficiency and intuitive decision-making, while novices relied more on structured methods and external references. Additionally, there were significant variations between experts and novices in the analysis of different exams and prioritization factors.

Based on our findings we proposed guidelines for a human-AI glaucoma diagnosis system that are aimed to minimize diagnostic variations. Incorporating the recommended features in an AI system, and using a human-AI collaboration model, will not only minimize decision inconsistency but will also improve optometrists' accuracy and enhance patient care by accelerating the diagnostic process and improving decision-making. In future work, we recommend a phased approach, starting by refining these guidelines to meet local requirements, followed by the development of an AI system based on the refined guidelines, and finally simulating and validating it through real-world data and pilot-testing in clinical environments.

Acknowledgments

This research benefitted from collaborations with the School of Optometry & Vision Sciences (thanks to Dr Stanley Woo, Director) and was supported through funding from the Natural Sciences and Engineering Research Council of Canada (NSERC-CRD Grant) (independent of study design/analysis). We are also thankful to our participants who gave us their precious time. FG's research was funded by the University of Waterloo (Graduate Research Studentship & International Doctoral Student Award). We also acknowledge the use of generative artificial intelligence (AI) tools, specifically Grammarly [35] and ChatGPT-4o (OpenAI) [36], for grammar check and flow of writing. It is important to note that generative AI tools are not used for any type of data generation or content generation in this paper.

Data Availability

The clinical data of patients used in the study is obtained from the School of Optometry and Vision Sciences, University of Waterloo. Permission was granted to use the data for this study. We have stored all the anonymized data online in a University of Waterloo Borealis repository [37] with restricted access. For research purposes, the data access can be granted by emailing the corresponding author, after taking the necessary steps required.

Abstract

Background: Artificial intelligence (AI)–based systems are receiving increasing attention in the health care sector. While the use of AI is well advanced in some medical applications, such as image recognition, it is still in its infancy in others, such as clinical decision support systems (CDSS). Examples of AI-based CDSS can be found in the context of sepsis prediction or antibiotic prescription. Scientific literature indicates that such systems can support physicians in their daily work and lead to improved patient outcomes. Nevertheless, there are various problems and barriers in this context that should be considered.

Objective: This study aimed to identify opportunities to optimize AI-based CDSS and their integration into care from the perspective of experts.

Methods: Semistructured web-based expert interviews were conducted. Experts representing the perspectives of patients; physicians; caregivers; developers; health insurance representatives; researchers (especially in law and IT); and experts in regulation, market admission and quality management or assurance, and ethics were included. The conversations were recorded and transcribed. Subsequently, a qualitative content analysis was performed. The different approaches to improvement were categorized into groups (“technology,” “data,” “users,” “studies,” “law,” and “general”). These also served as deductive codes. Inductive codes were determined within an internal project workshop.

Results: In total, 13 individual and 2 double interviews were conducted with 17 experts. A total of 227 expert statements were included in the analysis. Suggestions were heterogeneous and concerned improvements: (1) in the systems themselves (eg, implementing comprehensive system training involving [future] users; using a comprehensive and high-quality database; considering usability, transparency, and customizability; preventing automation bias through control mechanisms or intelligent design; conducting studies to demonstrate the benefit of the system), (2) on the user side (eg, training [future] physicians could contribute to a more positive attitude and to greater awareness and questioning decision supports suggested by the system and ensuring that the use of the system does not lead to additional work), and (3) in the environment in which the systems are used (eg, increasing the digitalization of the health care system, especially in hospitals; providing transparent public communication about the benefits and risks of AI; providing research funding; clarifying open legal issues, eg, those related to liability; and standardizing and consolidating various approval processes).

XSL•FO
RenderX

Conclusions: This study offers several possible strategies for improving AI-based CDSS and their integration into health care. These were found in the areas of "technology," "data," "users," "studies," "law," and "general." Systems, users, and the environment should be taken into account to ensure that the systems are used safely, effectively, and sustainably. Further studies should investigate both the effectiveness of strategies to improve AI-based CDSS and their integration into health care and the accuracy of their match to specific problems.

KEYWORDS

artificial intelligence; AI; clinical decision support systems; CDSS; decision-making; care; interviews

Introduction

Background

The use of artificial intelligence (AI), especially machine learning, is becoming increasingly common in all areas of life. This is also evident in health care. In July 2024, the US Food and Drug Administration database included 882 AI- and machine learning–enabled devices from various medical fields such as radiology (n=671), cardiovascular medicine (n=90), neurology (n=32), hematology (n=17), gastroenterology and urology (n=13), anesthesiology (n=9), ophthalmology (n=9), clinical chemistry (n=8), general and plastic surgery (n=6), microbiology (n=6), pathology (n=6), or orthopedics (n=5) [1]. AI is believed to have tremendous potential to revolutionize patient care and outcomes [2,3]. This is especially because of its ability to support diagnosing, individualization of treatment plans, and clinical decision-making [2,4]. AI-based clinical decision support systems (CDSS) offer the potential to support physicians in their work and to optimize patient outcomes. For example, this is evident in the context of sepsis. In this context, such systems can support prediction, diagnosis, subphenotyping, prognosis, and clinical management [5]. This can lead to earlier treatment [6] and ultimately to shorter hospital stays [6,7] as well as reduced mortality [6-8].

Given these potential positive effects, it is questionable why AI-based CDSS have only been used in isolated cases in real care. One possible reason could be the barriers to establishing such systems: regulators must approve them. The systems must be integrated into electronic health record systems, and they must be standardized to the extent that similar products operate in a similar way. Clinicians must be trained to use them, they must be updated over time, and payment must be organized [4]. Furthermore, user perception is a fundamental criterion that decides acceptance [9].

The literature describes a further wide range of problems and barriers in the context of AI-based CDSS [10-12]. These relate to AI or CDSS and a combination of both, AI-based CDSS. While some of the problems relate to technical integration and operational use [10,11], others relate to the legal and ethical framework [12]. Regarding strategies for implementing AI-based CDSS in clinical practice, a study conducted by Peek et al [13] analyzed the literature and concluded that perspectives from groups other than health care professionals (eg, patients, carers, AI developers, health care managers, and leaders, and especially regulators and policy makers) should be investigated.

Objective

To investigate the perceived problems and possible improvements involved in integrating AI-based CDSS to health care and to develop a user-oriented requirements profile for the systems, we established the research project "KI@work" [14]. It was founded by the German Federal Joint Committee (01VSF22050).

As part of the project, a scoping review (Raszke P, unpublished data, April 2025) was conducted to collect fundamental evidence. On the basis of the results, we conducted interviews with experts to further investigate the following questions: (1) What problems and barriers hinder the integration of AI-based CDSS into health care? (2) What approaches might be used to enhance the quality of AI-based CDSS and their integration into care? While the first question was covered in a previous article [15], this paper especially focuses on the second. Thus, this study aims to gather expert opinions on how AI-based CDSS and their integration into care can be optimized.

Methods

Overview

Expert interviews were conducted to identify approaches to solve perceived problems in the context of AI-based CDSS. We followed the standards of O'Brien et al [16] and the 32-item COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist (Multimedia Appendix 1) [17] in preparing this manuscript. Therefore, transparency is guaranteed in all aspects of our study. The underlying interviews and corresponding transcripts, have already been examined for existing problems and barriers in the context of AI-based CDSS from the perspective of experts.

Theoretical Framework

There is some evidence of problems and barriers, but as the field of AI-based CDSS is relatively new, little is known about how to optimize its use. Therefore, qualitative research in the form of expert interviews was conducted to approach the topic in an explorative way. The interviews were conducted with experts in the context of AI-based CDSS. The interviewees represented a wide range of different areas and professions. The interviews had 2 objectives, and the proceeding remained consistent: they started with open questions and topics and then addressed more specific questions. Within each topic, we first asked about different problems and barriers in the context of

XSL•FO
RenderX

AI-based CDSS. Then, we asked about ways to improve care with AI-based CDSS.

Ethical Considerations

Because patient views were collected through representatives and not from patients themselves, and no personal data were collected, the Ethics Committee of the Medical Faculty of the University of Duisburg-Essen confirmed that no application for ethics approval was required. Before the conversations, experts were informed via email about the topic and the proceeding. The email also included information about privacy and that the conversations would be recorded and transcribed for data analysis. Furthermore, the interviewees were informed that they could end the conversations on their part at any time without giving a reason and without experiencing any disadvantages. All experts provided consent to participate. The interviews were recorded and either transcribed automatically in Microsoft Teams (Microsoft) or manually for Zoom (Zoom Video Communications) interviews. Revision and pseudonymization were subsequently performed by research assistants and quality-checked, each by one of the moderators. After quality checking, the transcripts were sent to the respective experts for review to ensure the accuracy of the content. Three experts made use of this option, and their feedback was incorporated into the transcripts. The video recordings were then deleted. Therefore, it is not possible to assign individual statements to individual experts unless recalled by participants or moderators.

Participant Selection and Preliminary Information

The question “Who are the relevant stakeholders in the context of AI-based CDSS?” was discussed during a project meeting to create a list of experts to contact. The list included representatives of patients; physicians; caregivers; developers; statutory health insurance funds; researchers (especially in law and informatics); and experts in regulation, market admission, quality management or assurance, and ethical issues. On the basis of this list, appropriate institutions were sought and contacted to find eligible interview partners. If a consortium member had a connection to one of the identified institutions, they helped establish contact with a potential interview partner (n=7). Five (71%) of the 7 people contacted participated in an interview. In 2 (29%) cases, the person originally contacted arranged an interview partner within their institution. The remaining 8 interviewees were recruited independently of personal networks. In all cases except one, it was ensured that the interviewers had no prior contact with any of the interviewees.

Possible participants were contacted directly via email by the consortium. After contacting the experts, none of them declined to take part in the study. Four experts did not respond to the request. Ultimately, all target groups were represented in the interviews.

Setting and Conducting the Interviews

All interviews were conducted on the web via the conferencing platforms Microsoft Teams (Microsoft) or Zoom (Zoom Video Communications). Interviews included 1 or a maximum of 2 experts at a time. Circumstances or events which had an unintended influence on the conversations are not known. The interviews were moderated by 1 person and attended by at least 1 other person from a pool of 3 possible moderators (GDG, PR, and NB). The characteristics of the moderators are listed in Multimedia Appendix 2. Notable relationships did not exist between the researchers and the interviewees. There was no clear position for or against the use of AI-based CDSS in health care.

An interview guideline was developed (based on the preliminary results of a scoping review conducted before the interviews) by the team of the University of Duisburg-Essen and quality was assured within the consortium. The guideline included questions about both problems and barriers in the context of AI-based CDSS, as well as questions about possible improvements. It was slightly adapted with stakeholder-specific questions. The core version can be found in Multimedia Appendix 3. The interviews took place between June and August 2023.

Data Analysis

A content-structuring qualitative analysis following the study by Kuckartz [18] was conducted using MAXQDA (VERBI Software GmbH) based on the final transcripts. The analysis aimed to conduct a content- and topic-oriented evaluation, as well as the development of main topics and subtopics. The analysis was based on deductive codes to create an overarching systematization. These included six categories in which approaches for optimization were suggested: (1) “technology,” (2) “data,” (3) “user,” (4) “studies,” (5) “law,” and (6) “general.” After deductive coding, relevant expert statements were concisely summarized (GDG) and subsequently discussed in a workshop (GDG, NB, and PR). The workshop aimed to develop finer-grained groups for a more differentiated perspective. Similar statements within the 6 overarching categories were grouped into subcategories (inductive codes), which were then used for further systematization. Finally, the expert statements were coded according to the inductive codes and systematized within a matrix using Excel (Microsoft Corporation; Multimedia Appendix 4). Data analysis was finished in October 2023.

Results

Overview

In total, 17 experts were interviewed in 13 individual and 2 double interviews. The professional backgrounds of the experts are provided in Table 1. The intrinsic motivation and participation of the experts were high.

15	Representative of health insurance fund	Individual interview	August 17, 2023

[a]AI: artificial intelligence.

[b]CDSS: clinical decision support systems.

A total of 227 expert statements included suggestions for improvement of AI-based CDSS and their integration into care. As described in the Methods section, these were categorized into 6 categories: “technology,” “data,” “user,” “studies,” “law,” and “general.” The systematization is presented in Figure 1. The complete and systematized list of summarized expert statements is presented in Multimedia Appendix 4.

Figure 1. Identified improvement approaches matched with problem categories. AI: artificial intelligence; CDSS: clinical decision support systems.

XSL•FO
RenderX

Technology

Optimization potential in the category of technology included "quality," "transparency," "updates," "individualization," "usability," "development," and "control of users." Experts explained that the "quality" of AI-based CDSS is a fundamental factor affecting trust and acceptance over time. Therefore, requirements for high-quality systems should be considered. According to the experts, such requirements include that the systems be evidence-based and reliable and meet at least the current gold standard for value. Quality and validity assessments should be conducted regularly to maintain good quality over time. This should include checking the system against a validation dataset, sampling procedures, or test loops. The quality of systems could also reduce the burden of false alerts. Therefore, on the one hand, the systems should be able to identify false-positive and false-negative results. On the other hand, an appropriate balance between sensitivity and specificity might avoid unnecessary alerts as well as associated alert fatigue. Finally, incorrect recommendations can be avoided if systems clearly stick to evidence-based or, at least, consensus-based guidelines:

> *That means, the only reasonable method to increase acceptance, is to increase the quality of products and to gain trust in this way. That we currently have very low acceptance in some areas, maybe that's a good thing and that it must increase over the next years is due to the innovative technology. A normal process.* [Medical product consultant]

"Transparency" can be guaranteed by avoiding black-box characters (incomprehensible AI). According to experts, AI-suggested decisions should be transparent, and systems should provide explanations. This could be achieved by identifying decisive parameters or using so-called heat maps to visualize data and give at least clues as to where the proposed decision stems from. Finally, it was mentioned that self-learning systems should stop evolving when they are no longer comprehensible:

> *So, the idea is actually that the decision that the AI gives me is justified by the AI in such way that I can, in a way that is so clear and comprehensible that I can perhaps also understand mistakes in the decision-making chain.* [Caregiver representative]

Experts stated that "updates" must be conducted to include new data and guidelines as well as to adapt the algorithm accordingly. Sensible implementation of user feedback should be considered during updates as well:

> *So, I demand diligence from the AI, but I also need the teacher somewhere, who must have a learning concept, the algorithm must always be continuously checked and adapted.* [Representative of quality assurance]

Experts with a more technical background saw "individualization" as a way of enhancing the quality of the systems. They explained that systems must be adapted to individual hospitals and that models from the United States should be optimized for local use in Germany. A physician representative, by contrast, stated that system standardization would be necessary to enable system use across locations:

> *I believe that you can't do it preclinically. I have to talk to the hospitals, I have to set up the project in the hospital, in the care setting. Because [...] we have 1,200 ecosystems, if I'm only talking about acute hospitals now [...]. I have to involve the doctors in each hospital individually. I have to involve IT in every hospital.* [Developer of AI-based CDSS]

A further suggested approach lies in "usability." User-friendliness should be considered to facilitate use and point users directly to relevant points. This includes the convenient use of AI-based CDSS for bedside conversations. User skills, as well as knowledge gaps, should be considered within system design. According to experts, a thorough "development phase" with a clearly determined question or target problem could contribute to the prevention of problems in the context of AI-based CDSS. The systems should be extensively and sufficiently developed and trained. False-positive and false-negative results must be checked during the training phase. The causes of identified errors must be eliminated. A balance between sensitivity, specificity, and overfitting (ie, training too specifically based on a fixed dataset) should be maintained. An interdisciplinary development, including experts and stakeholders from various fields (eg, future users, physicians, IT managers, and patient advocates) was desired. Involvement could include statements, tests of prototypes, participatory development, conceptual design, and open discourse. The development process should always be controlled by an independent process attendant:

> *I believe that it is crucial that, when you develop something AI-based like this, the people who will have to work with it later, who will have to use it, are involved as much as possible, right from the development phase.* [Caregiver representative]

Finally, "control of users" could improve the quality of AI-based CDSS and their integration into care. The intelligent design, implementation, and testing of risk control measures and their corresponding implementation in AI-based CDSS could prevent blind trust and automation bias. Furthermore, deliberately incorrectly proposed decisions by AI might be used to check the awareness of users:

> *Problems like this [such as automation bias], can be countered by designing and implementing intelligently enough, I would say.* [Caregiver representative]

Data

A further starting point for improvement is the area of "data." Approaches in this context concern the "quality," "quantity," "standardization," and "availability" of data.

First, according to the experts, high data "quality" must be guaranteed. Therefore, the quality of the training data should be improved. This can be done through data management, reflective data synthesis, or reflective filling of incomplete datasets. The validity of the primary dataset should be made transparent:

XSL•FO
RenderX

> *So that would be a very important point for me, especially at the beginning of the study protocols, from our experience, also in terms of quality assurance, to be able to make a statement about the validity of the primary data pools.* [Representative of quality assurance]

"Quantity" included the enlargement of the database as well as its completeness. According to experts, both would contribute to better results. Structured and unstructured data should be included, and longitudinal data should be used in the analysis. No data should be excluded because of the age, origin, or sex of patients. Databases should be equally weighted, sufficiently represent women as well as minority individuals, and consider age and diseases:

> *And of course it is very important that we have equally weighted data sets, that we represent minorities and so on. But that's a craft, it can be done. It has to happen, yes, but it's not inherent in the technology, it's simply a manual part of using the technology.* [Researcher—AI in health care]

A further approach was seen in "standardization." Experts asked for national-level data standardization and integration. Therefore, data could be merged and made usable. Generic data patterns should be predefined:

> *[...] yes, I like, this generic character of data sets. This is, I rather think, the field, you have to create generic data patterns that hospitals have to adhere to in order to achieve accuracy.* [Developer of AI-based CDSS]

Finally, the "availability" of data could contribute to improving the systems and their integration into care. Experts suggested the creation of a national or European data pool, as well as networks, to obtain sufficiently large datasets. Data should also be accessible for the private sector to develop AI-based CDSS. Analogous data from hospitals should be made available using machine reading, such as optical character recognition, of PDF documents such as scans or photos. During the digitization process, experts should be involved in reading out subject-specific documents:

> *And that means we should take the EU Commission's proposal with the draft regulation on the European Health Data Space seriously so that private sector companies that develop AI-based CDSS can also access such data. Because every year we have 550 million outpatient data records and 15 million inpatient data records that are not accessible for this development or not easily accessible.* [Medical product consultant]

User

Many of the identified improvements are user-oriented. These include "training/education," "time relief," "critical attitude," "communication," and "competence."

First, "training/education" might lead to more openness to AI-based CDSS. Therefore, information on AI should be a part of both medical training and further staff training. Staff training should include educational courses or workshops on the general topic of AI, its threats (eg, errors in its use, especially automation bias), its limitations, and information on its impact on existing care pathways. Courses should provide the opportunity to try out AI-based CDSS. Their application under stress should be exercised. In contrast to most of the other respondents, a developer stated that only those who modify the systems needed training but not those who just use the systems. A physician representative stated that trainings and courses should be nonmandatory. Experts pronounced that, within training, it should be clarified that AI will not replace humans:

> *And I think what would help to increase that acceptance would be just regular training. If you could also show examples of what a specific case might look like.* [Caregiver representative]
>
> *And I believe, if there are no training courses or no sensitization, then there is a risk that such recommendations for action will simply be adopted and that would be disastrous.* [Developer of AI-based CDSS]

Experts saw "time relief" of physicians and caregiving professionals as a solution for missing acceptance. They stated that the temporal valences of users should be considered and that AI should not lead to major additional work. Rather, it should make day-to-day work easier, for example, by supporting documentation. Furthermore, it was explained that clinicians should be relieved for scientific tasks in the context of AI and use their competence to assess complex cases:

> *[...] that you have a mixture of easier and more difficult cases, and AI will tend to mean that the easy cases can be checked off very quickly by the AI or with the help of the AI, and that only the very difficult cases will actually end up with the doctors. And maybe there needs to be some relief here. You have to say that somehow you have to take more breaks [...] because looking at the screen all day and then only having to differentiate between the worst cases is not easy.* [Representative of an ethics committee]

A further improvement approach was seen in the "critical attitude" of users. It was stated that decisions suggested by AI must always be scrutinized, validated, and checked for plausibility. There should be no blind reliance on AI. One expert explained that regardless of whether recommendations are made by AI or humans, they should always be questioned. A critical attitude was described as relevant to both positive and negative findings. Thus, even supposed false alarms should be taken seriously. One stakeholder wished for mutual skepticism between AI and users:

> *This means that the suggestions or recommendations for action of an AI-based CDSS must be evaluated by the doctor in the same way as a laboratory value or another parameter or a pathological ECG. It must be critically scrutinized; it must be validated [...].* [Medical product consultant]

In addition, an opposing view was taken in the context of "critical attitude": users should gain greater trust in AI and, in

XSL•FO
RenderX

some future cases, might also implement recommendations for action without checking them:

> *And at some point, we will receive recommendations for action that we can rely on 100% and then we can implement them without checking them. So, the answer to your question is: we encounter the problem by only implementing recommendations for action unchecked where we have a sufficiently high level of certainty that it will work due to the validation.* [Medical product consultant]

A last improvement approach concerning the user was seen in "competence." According to experts, users need personal and professional competence to use and deal with decisions suggested by the AI, as well as to maintain decision-making authority and avoid dependence on AI. In particular, the implicit knowledge from experience should be maintained. Finally, interviewees also explained that trust increases with competence:

> *So, who decides and who does not, I think it has something to do with education, it has something to do with personal competence and of course it also has a lot to do with professional competence.* [Caregiver representative]

Studies

Regarding "studies," improvement approaches were named within 3 areas. These were "study conduction," "external audit," and "financing."

"Study conduction" was seen as essential to prove evidence, to assess benefits, and to track side effects. Demonstrating success in studies would lead to increased public acceptance and trust. A general need for more valid (comparative) and prospective studies was pronounced. A "clean, best possible study design depending on the disease" [Representative of health insurance fund] was demanded. Orientation of studies on standards of scientific institutes and the involvement of experts was described as necessary:

> *We now need prospective randomized studies, one part gets standard care, one part gets AI and then we have to look and that has to be done on a relatively large number of patients across several sites so that we can see whether it is possible to detect organ dysfunction and sepsis in advance.* [Physician representative—intensive care]

> *In general, of course, the higher the quality of the study design - and a randomized controlled trial is of course the gold standard - the more reliable the results are.* [Representative of health insurance fund]

Experts stated that studies should also include an "external audit" to get a neutral view of the situation. Furthermore, involving patient organizations in studies can help increase acceptance among patients. Finally, in this context, an improvement approach was seen in the "financing"—specifically, the funding of studies. The federal or state governments or the European Union (EU) were seen as responsible for study funding:

> *We must now have this willingness to carry out these studies, [...] I mean we're talking about a few million euros, [...]. That is now indicated, that is the next logical step and if we were to do that, we would be very far ahead, not just in Europe, but globally.* [Physician representative—intensive care]

Law

"Approval/certification," "data protection," and "liability" were seen as possible improvement approaches within the category of "law." Further suggestions within this category were aggregated under "others."

"Approval/certification" and review of AI-based CDSS should be conducted regularly by independent bodies to increase acceptance. It was expressed that certifying bodies would need more staff with a background in science, technology, engineering, and mathematics. Approval of AI should not lead to major additional costs compared with conventional medical devices. Another approach expressed was a certification that authorizes humans to use AI:

> *I think independence is important. An established, independent institute and regular repetition, [...] and AI systems are also constantly changing, because they are - AI means a self-learning system, which means that you have to check them every now and then. So regularly, independently and in an understandable way.* [Patient representative]

Further opportunities were seen in the regulation of "data protection." Data protection standards should always be appropriate, and data integration should be standardized nationwide. Users could benefit from already certified plug and play hardware solutions to avoid data protection issues. Whether researchers are allowed to use the collected data should be decided by the patients. Furthermore, experts stated that problems in the context of data protection are often caused by data protectors and not by data protection requirements and are thus avoidable:

> *Every data protection officer has a problem with personal data that goes off campus, and I absolutely understand that. But what I always like to ask is, has anyone ever asked the patients whether they could possibly care less? [...] There are clinics that do this in Germany, they use all their patients' data for research purposes. It's not forbidden, I'm just saying opt-in, opt-out.* [Developer of AI-based CDSS]

Regarding "liability," experts have suggested that modes of action and responsibilities should be clarified. In this context, it was proposed that it should be legally anchored that diagnostic and therapeutic responsibility remains with the user, specifically the physician. Users should be informed about the legal framework. Otherwise, one expert explained that physicians should not be made liable for AI-proposed decisions that cannot be verified because of a black-box character of the systems:

> *And liability risks are also a major issue, and doctors naturally don't want to be held liable for anything, for possible treatment errors or that they have overlooked something if they can't actually assess*

XSL•FO
RenderX

> *the quality of this AI. And that's why I would say that increasing acceptance is also possible through regulation.* [Representative of an ethics committee]

A further two improvement approaches were described. These were the obligations to report and publish errors that occur in the context of the systems in general and to report and track, especially, the causes of incorrect decision recommendations.

General

Under the category "general," various suggestions for improvement were summarized that did not match one of the other categories. These include "level of digitalization," "financing," "communication between stakeholders," "information about AI," "new professions," "pretest," "user definition," "no staff replacement," and "others."

The "level of digitalization" should be expanded for IT infrastructure. There is a demand for high-performance computing to ensure fast, reliable, and failure-free operation of the systems. Digitization should be standardized to close gaps in the documentation:

> *And I remember that from before, when we had the paper curve, we really had a lot of gaps in the documentation as far as vital signs were concerned. So that's why we should have uniform digitization, which would of course be the optimum.* [Caregiver representative]

Improvement in "financing" concerned 3 aspects. First, service providers should be motivated with incentives to use AI-based CDSS. Second, incentivization could lead service providers to collect data more conscientiously. Third, experts saw the federal states and the German social policy as responsible for participation in hospital financing and the financing of digitalization infrastructure of the health care system:

> *But on the whole, people act as if this is purely a private matter. [...] My personal opinion would be that German social policy should contribute to the financing of infrastructure within the digitalization of the healthcare system in particular [...].* [Caregiver representative]

"Communication between stakeholders" could be improved by using a common language between the professions. Experts suggested appointing a chief medical IT officer to build bridges between stakeholders and drive the integration of AI:

> *It's not down to our doctors' willingness to innovate, on the contrary, it's a lot down to IT and a lot down to the data protection officer and a lack of communication within the hospital. My hospital is divided into two departments. On the one hand we have white, everything that is medicine and on the other hand it is a normal company. That's why I think one of the most important positions in a company is the CMIO, the Chief Medical IT Officer, who has a view from both sides. And he can also build a very big bridge.* [Developer of AI-based CDSS]

Another much-discussed improvement category is "information about AI." In this context, communication should include both the benefits and the limits of AI. According to experts, education and transparent information would create acceptance and trust and would avoid exaggerated expectations. Communication should be tailored to the target group. It should convey skepticism toward technology to younger people and introduce older people to the technology. Stakeholders wished for clarification on the fact that the technology can save time and does not take away expertise. Therefore, one should communicate that the outputs are basically suggestions, and the decision remains with the physician. Showrooms and practical examples should be used to convince people of the benefits and to create acceptance:

> *[...] I believe that it is very important for acceptance that you manage to make it clear that it is a system that can ultimately save time, which is then regained by the doctor for the patient.* [Representative of quality assurance]

> *We should certainly try to educate users and we do this by holding seminars, for example, where we remove the magic from AI and explain that it is machine learning. We also explain how it works and where the limits are. Because, as I always like to say, "there is no free lunch.* [Researcher—AI in health care]

"New professions" could also contribute to improvement. One expert explained the need for new professions to guarantee high data quality:

> *And I believe that if we don't have new professional fields that can actually be called data secretaries or whatever, i.e. all those who actually ensure that the quality of the data is excellent, we will just have to make do with bad data and then also with bad results.* [Representative of an ethics committee]

Before the system becomes distributed, a "pretest" should be done in predefined settings. A system running in the background should serve to identify and check discrepancies in decisions between humans and the systems. Dissemination should begin in expert institutions to achieve a certain standard of quality and should always proceed from the most to the least competent users. During this process, systems should learn from mistakes:

> *That's why there's a phase of around six months where the system runs in parallel, in the background, where a comparison is made between what the machine would have decided and what the doctor would have done. A machine also learns from this so that it can then say when the system is introduced - I would never do an untested implementation.* [Developer of AI-based CDSS]

> *[...] at some point a state will be reached, a kind of steady state, in which it is very mature, [...] and then you can go further, but I think it is very important in the first few years to work together with the competent people and not to present it as a help that those who have resource problems or qualification problems can now do things with it that they would otherwise not be able to do.* [Representative of quality assurance]

In the context of AI-based CDSS, it should always be clear who the target users are. Therefore, the developer should clearly offer a "user definition." Experts explained that systems should neither be used to "replace staff" nor to make up for a lack of specialist staff. Ideally, there should be teamwork or cooperation between the AI and users. AI-based CDSS should not undermine the expertise of physicians. While the systems should aim to support users, they should not overtake their task of decision-making:

> *Furthermore, I think it is important that we do not immediately say, yes, there is great dynamism, we can replace the missing specialist staff in a few years or save on staff now and eliminate an economic deficit.* [Representative of quality assurance]

Finally, two other possible improvements were seen in this category. First, software consulting firms should always be available as contact partners. Second, a self-fulfilling solution was seen over time. This was seen because, on the one hand, the use of good systems will automatically lead to acceptance and, on the other hand, because future generations are more open to AI.

Discussion

Principal Findings

The results of this study show that there is already a wide range of suggested improvements in the context of AI-based CDSS. These exist in 6 areas: "technology," "data," "user," "studies," "law," and "general." A structured overview of all identified solution strategies can be found in Multimedia Appendix 4. As in other studies on AI-based CDSS, improvements were found that address the technology itself, the users, and the context in which the systems are used [19-21]. Among others, the recommendations concerning the systems encompass the following aspects: a comprehensive developmental and evaluative process with the active engagement of users before the implementation; systematic training on an extensive, high-quality database; rigorous studies proving the system benefits; optimized ease of use and accessibility; customized systems tailored to specific settings, hospitals, and patient populations; and the incorporation of control mechanisms or the use of intelligent design and smart implementation to mitigate automation bias. On the user side, enhancements were suggested to the training program for (future) users. Training should include communication about the advantages as well as sensitization for critical thinking. Temporal valences of the users should be considered; systems should alleviate the burden on staff rather than augment their workload. Finally, regarding the context, experts suggested strategies such as increasing the level of digitalization of the health care system, especially hospitals; transparently communicating in public about the advantages and risks of AI; providing funding for research; clarifying open legal questions, for example, with regard to liability; and standardizing and consolidating various approval processes.

There are already some studies that investigate factors enabling or facilitating the use of AI-based CDSS. These stem from various fields such as antibiotic prescription in hospitals [19,20,22], rhythm management of atrial fibrillation [23], red blood cell transfusion [24], and aortic dissection [25]. For example, they focus on health professionals [19,23-25] or hospital managers [22]. Our study was not aimed at a special medical field or a single group of experts. Therefore, we were able to investigate indication-independent improvements from a broad range of different experts. This is especially important because several complex problems need interdisciplinary cooperation to be solved.

According to the experts interviewed in our study, a high-quality and user-friendly design of AI-based CDSS should be guaranteed. In this way, problems occurring during use could be prevented. One such problem is automation bias. To prevent this issue, systems should be designed with a well-thought-out design. This includes system outputs with fewer on-screen details, dynamic updates of the confidence levels of recommendations, and the provision of supportive information rather than orders [26]. Another example mentioned by experts and confirmed by the literature was transparency. Trust from physicians can be gained by providing as much transparency as possible [27]. An example not restricted to AI-based CDSS but relevant to digital solutions, in general, is the topic of usability. By integrating future users at every stage during the design process, ease of use can be enabled [28].

Both manufacturers and policy makers are in charge of guaranteeing a high quality of AI-based CDSS. While manufacturers should have an intrinsic motivation to develop high-quality systems, policy makers should set the framework conditions.

The EU first took the step of introducing the AI Act [29]. A prerequisite for the development of reliable AI-based CDSS is the availability of sufficient quality data. Therefore, experts stated that data should be collected in a standardized format and made available to researchers as well as private companies. One example of a large collection of physiological and clinical data is the PhysioNet platform, managed by members of the MIT Laboratory for Computational Physiology [30]. A German project funded by the EU is the SepsisDataNet.NRW [31]. One of the project's goals is to create a sepsis-related biomarker database. From a legislative perspective, the German Bundestag adopted the Act on the Improved Use of Health Data (Health Data Use Act [Gesundheitsdatennutzungsgesetz]) [32]. At the European level, it is planned to create the "European Health Data Space," an initiative to enable patients to easily control their electronic health data and to make this data available for research, innovation, and political decision-making [33].

Experts explained that the perception of users should be positively influenced. There is little experience with the new technology. In a survey conducted by Chen et al [34], only 27% of the physicians and medical students surveyed worldwide had used clinical AI. A total of 13% reported having good knowledge of AI. Furthermore, 77% expressed a high willingness to learn about the topic, and 78% agreed that training should be provided by hospitals or schools. Only 8% feared that physicians would be replaced by AI [34]. The low level of knowledge, together with a great openness [35,36] to the topic, provides an ideal basis for education. In this context, a special

focus should lie on scrutinizing proposed decisions to prevent blind trust, automation bias, and alert fatigue.

Regarding studies, interviewees demanded more prospective randomized studies. This aligns with the existing literature. In 2022, a systematic review of randomized controlled trials (RCTs) of AI in clinical practice identified only 39 eligible studies and concluded with the need for more RCTs of AI-assisted tools integrated into clinical practice [37]. To enable such studies, national or international bodies should provide funding.

According to experts, regulation in the context of AI-based CDSS has not yet been fully elaborated. Questions regarding the trade-off between data protection and patient benefit, regarding the liability and the certification of AI-based CDSS, should be the subject of further discussion and research. For example, there is no uniform opinion between physicians and patients regarding liability for AI in health care [38].
