Self-regulation within self-management theory is an iterative process in which individuals utilize a variety of skills and abilities to achieve healthy behavior change [29]. The BCW, a classic theoretical model for explaining behavior change—particularly in the contexts of health promotion and disease prevention [33]—provides an important reference for selecting self-regulation–related characteristic variables in this study. The BCW posits that healthy behavior change can be achieved only when individuals possess capability, motivation, and opportunity [34]. Capability refers to the knowledge and skills required to engage in a particular behavior [35]. In the context of using mHealth for health management, essential knowledge and skills are reflected in 2 aspects: health management and the use of digital technology. eHealth literacy is among the most commonly used indicators for assessing an individual's ability to acquire health management information and utilize electronic health information to address health issues [36,37]. Accordingly, this study selects eHealth literacy to characterize self-regulation skills and abilities. In addition, motivation in the BCW refers to the beliefs that trigger behavioral change, encompassing reflective motivation and intrinsic motivation [34]. Motivation for health management can be divided into proactive health management intention and passive health management intention triggered by perceived health status, corresponding to reflective motivation and intrinsic motivation, respectively. Therefore, this study selects health management intention [38] and perceived health status [39] to further characterize the motivational dimension of self-management behavior. In summary, this study selects a total of 8 variables to analyze self-management characteristics among mHealth users. The definitions of each variable are presented in Table 1.

Table 1. mHealth[a] user self-management characteristics: a framework of 8 variables for user categorization.

User self-management characteristics	Definition
Perceived susceptibility	Beliefs about the likelihood of getting a disease or condition [31].
Perceived severity	Feelings about the seriousness of contracting an illness or of leaving it untreated, including evaluations of both medical and clinical consequences and possible social consequences [31].
Perceived benefits	Beliefs that engaging in health behaviors can help decrease the risk of diseases and health problems [40].
Perceived barriers	An individual's assessment of the difficulties and cost of adopting behaviors [32].
Health self-efficacy	The confidence individuals have in their ability to use their skills to complete health management tasks [41].
eHealth literacy	The ability to seek, find, evaluate, and use electronic health information from electronic resources to address health issues [36].
Perceived health status	The perception of one's own health status [39].
Health management intention	The degree of intention to engage in health protection [38].

[a]mHealth: mobile health.

Identification of Study Targets

The main purpose of this study is to delineate individuals' health management characteristics and classify users based on their levels of health management characteristics, and to further analyze differences in satisfaction with various mHealth app functional designs across user categories. Therefore, it is necessary to clarify the main functional designs of mHealth apps. Previous studies have summarized common mHealth app functional designs through systematic reviews and content analyses [42-44], categorizing functions according to their primary implementation purposes, such as education, tracking, social interaction, gamification, and motivational features [42]. Building on prior research, this study reorganizes the functional characteristics reported in the literature to propose a classification of mHealth app functional designs for analysis (see Table 2).

XSL•FO
RenderX

Table 2. Five functional designs and features of the mHealth[a] apps analyzed in this study

Functional designs	Definition	Features
Health guidance	Providing advice based on health plans and applications may provide real-time feedback and advice based on health plans and status [45], or offer strategies for behavior change that can contribute to improving health conditions [46].	Intelligent virtual assistants and communication with health care personnel [43]; interaction with medical staff [45]; and development of health plans and goal setting [46].
Health education	Offering necessary knowledge to achieve health behavior change [47].	Personalized education and general knowledge education [42]; image-based education, video education, and audio education [47].
Health monitoring	Recording past and current health statuses [47].	Health records and health diaries [43]; trackers, data entry, and data export [42]; and self-tracking [46].
Social function	Providing a platform for user interaction, communication, and maintaining connections [47].	Community forums and social media [42]; and social sharing [47].
Gamification	Integrating gaming mechanisms or elements into mHealth apps and enhancing the user experience with gamelike features [48].	Personalized avatars, challenges, tasks, health, and rewards [43]; points, badges, and levels [42].

[a]mHealth: mobile health.

To achieve the aforementioned research objectives, this study selected appropriate objects of study for empirical analysis. First, the comparability of different mHealth app functional designs was considered. To minimize the influence of differences in core service content across app types on comparability, this study selected a homogeneous category of apps as the empirical focus, thereby reducing potential confounding effects. Second, the application domains of different mHealth app categories were considered. Exercise, fitness, and weight management align with substantial health needs. These domains represent important modalities for primary prevention, and exercise therapy also serves as a key approach for tertiary prevention (disease management) in various conditions, such as cardiac rehabilitation, pulmonary rehabilitation, tumor rehabilitation, and metabolic disease management [49]. Given that exercise, fitness, and weight management apps account for more than half of all mHealth apps [50], and that these functions represent 48.37% of users' motivations for using mHealth apps [51], we selected exercise, fitness, and weight management apps as the units of analysis to represent a broader and more heterogeneous user population.

This study did not restrict respondents to users of a specific app for the following reasons. First, as the aim of this study is to examine the satisfaction of different user types with various mHealth functional designs in real-world contexts and to provide generalizable recommendations, the focus is on mHealth functional modules rather than on specific app design implementations. Accordingly, the research sample was not limited to users of a single app. Moreover, this questionnaire-based data collection approach captures multiple implementations of the same functional module (eg, health education), thereby enhancing sample diversity and improving the generalizability of the findings [52,53]. Second, this study was conducted in real-world settings, which differ from laboratory-based studies that examine factors influencing mHealth satisfaction. In laboratory environments, variables must be tightly controlled to quantify the idealized effects of specific factors, often requiring the use of a single app as the research object. By contrast, this study emphasizes user satisfaction with mHealth in real-world contexts, where the use of multiple similar apps by the same user is common. Analyzing such data provides real-world evidence that can inform future research and practical mHealth design.

Measurement Instrument

Based on the constructed User Health Management Characteristics Framework, this study measures 8 independent variables and 5 dependent variables reflecting satisfaction with mHealth functionalities. To achieve the aforementioned research objectives, it was necessary to select appropriate and measurable items corresponding to the characteristics defined within the framework. To ensure the rational design of the measurement scale, this study undertook a careful process of adapting previously validated scales, making nuanced adjustments to align them with the specific research objectives.

Specifically, the User Health Management Characteristics Framework includes 4 variables derived from the HBM (perceived severity, perceived susceptibility, perceived barriers, and perceived benefits), with measurement items adapted from HBM-related studies by Ahadzadeh et al [54], Saghafi-Asl et al [32], and McArthur et al [55]. Two variables were derived from the BCW (eHealth literacy and perceived health status), with measurement items drawn from BCW-related studies [39,56,57] and the Brief Health Literacy Screen scale [58]. In addition, 2 variables integrating both models (health self-efficacy and health management intention) were included, with measurement items adapted from health management–related studies, such as Zhou et al [59] and Li et al [38]. For the measurement of satisfaction with the 5 mHealth functional designs, this study first provided definitions and specific design examples of each function in the questionnaire, followed by item-based measurement. The satisfaction items were adapted from relevant studies on mHealth satisfaction [8]. All measurement items used a 5-point Likert scale, ranging from 1 (strongly disagree) to 5 (strongly agree).

A multistage validation and refinement process was implemented to ensure the conceptual accuracy and cultural

XSL•FO
RenderX

appropriateness of the English-originated scales within the Chinese context. First, the preliminary translation and adaptation of the scale items were collaboratively conducted by research team members proficient in both Chinese and English and with expertise in health informatics. Through group discussions, each item was refined to preserve the core meaning of the original construct while aligning with Chinese linguistic norms and the research context. Second, before the formal survey, 24 participants with backgrounds in medical informatics were invited to complete a pretest of the questionnaire. Participants were asked not only to respond to the questionnaire but also to provide feedback on the clarity and contextual appropriateness of the items. Based on this feedback, the wording of the questionnaire was further refined to eliminate ambiguities and improve readability, resulting in the final version used in the formal survey. Finally, during the data analysis phase, reliability and validity tests were conducted on the measurement model, thereby verifying the effectiveness and reliability of the measurement instrument from a data-driven perspective (see Multimedia Appendix 1).

Data Collection

The survey targeted individuals who had used exercise, fitness, or weight loss apps within the preceding 3 months. According to the N:q hypothesis [60], the ratio of sample size to item parameters in a scale should range from 20:1 to 10:1. In this study, a total of 51 items were included for measurement; therefore, applying the more conservative ratio of 20:1, the required sample size was approximately 1020.

From June 28, 2022, to September 8, 2022, a snowball sampling survey was conducted via the WeChat platform (Tencent Holdings Limited). The questionnaire link, generated using Wenjuanxing, was distributed through Moments (Tencent Holdings Limited) and various group chats. In total, 2518 questionnaires were collected. Of these, 902 respondents reported that they had not used the target apps within the preceding 3 months. A quality control item was included in the questionnaire: “This question is an attention test to ensure careful completion of the questionnaire. For this question, please select ‘strongly disagree’.” The correct response to this item was “1. strongly disagree.” Responses that answered this item incorrectly were considered to have failed the quality control check. In addition, given the length of the questionnaire, responses completed in less than 3 minutes or with identical answers across all scale items were deemed insufficiently attentive and were also excluded. Through this screening process, 591 responses were removed. Consequently, 1025 valid questionnaires remained for subsequent analysis. Before completing the questionnaire, all participants were informed of the study’s overall purpose and detailed procedures.

In this study, item-level missing data were addressed using mode imputation based on each respondent’s answers to other items within the same variable. Specifically, there were 3 missing values in total: 1 in perceived susceptibility, 1 in eHealth literacy, and 1 in gamification. As the questionnaire employed Likert scales, which represent ordinal rather than strictly continuous data, each missing value was replaced with the mode of the remaining items within the same scale for that respondent. The imputed values were 3, 5, and 3, respectively. Given that the dataset comprised a total of 45,100 item responses, the proportion of missing values was 0.0067%, which is negligible and unlikely to affect the results.

Data Analysis

To address the question “What are the common combinations of health management characteristics in users during the process of using mHealth?” we employed cluster analysis. Cluster analysis is an unsupervised machine learning technique that divides a set of observations into multiple clusters composed of similar objects and can identify the structural composition of different clusters. In clustering, similarity between observations within the same cluster is high, whereas similarity between observations from different clusters is low. Among various clustering methods, the k-means algorithm produces results that are easy to interpret, are suitable for clustering high-dimensional data, and demonstrate good scalability and efficiency when dealing with large datasets [61]. The clustering in this study was based on 8 health management characteristics (Table 1), and the sample size was moderate; therefore, k-means was appropriate for this study. The k-means algorithm requires the number of clusters to be predetermined. We determined the optimal number of clusters by integrating the Elbow Method and the Silhouette Coefficient. The Elbow Method identifies the inflection point by analyzing the relationship between the within-cluster sum of squared errors (SSE) and the number of clusters, while the Silhouette Coefficient is used to mathematically assess the compactness and separation of the clustering structure. The results showed that when the number of clusters was 6, an inflection point appeared in the SSE curve, and the Silhouette Coefficient reached a locally optimal value of 0.1514 (see Multimedia Appendix 2), indicating that this clustering solution maintains good within-cluster compactness while achieving favorable between-cluster separation. Therefore, we ultimately set the number of clusters to 6. To further verify the stability of this 6-cluster solution, we performed 10 repeated experiments with random initializations. The results showed a relative fluctuation rate of only 0.002% in the SSE values, demonstrating that the 6-cluster solution exhibits high repeatability and stability. We conducted the cluster analysis to determine the grouping of mHealth app users using sklearn.cluster in Python 3.8 (Python Foundation; see Multimedia Appendix 3).

To answer the question “Is there a difference in satisfaction with the functional design of mHealth apps among different types of users?” we performed rank sum tests to examine satisfaction and preferences regarding functionalities across user groups using SPSS 26 (IBM Corp). To address the question “How do health management characteristics affect users’ satisfaction and preferences for the functional design of mHealth apps?” we conducted a partial least squares analysis using SmartPLS 4 (SmartPLS GmbH). The significance level was set at $P<.05$ for 2-tailed tests.

The data collected for this study were analyzed to assess potential nonresponse bias. To accomplish this and examine nonresponse bias [11], the Mann-Whitney *U* test was used to compare responses from the first 20% (205/1025) and the last

XSL•FO
RenderX

20% (205/1025) of the sample. The results showed no significant differences between the 2 groups for the health guidance (z=−0.728, P=.47), health education (z=−1.171, P=.24), health monitoring (z=−0.857, P=.39), social function (z=−1.794, P=.07), and gamification (z=−0.260, P=.80) constructs. Therefore, nonresponse bias was not a concern in this study. This study followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) reporting standard (see Multimedia Appendix 4).

Ethical Considerations

This study utilized an online questionnaire survey. On the first page of the questionnaire, the research purpose, content, potential risks, data usage, confidentiality terms, and researcher contact information were clearly explained to participants. By checking a box, participants confirmed that they had read and understood the above information and voluntarily agreed to participate in the study, thereby providing informed consent. Participants who did not agree with the above content were directed to exit the online questionnaire. The questionnaire materials for this study were destroyed after the completion of quality control and transcription, within 6 months after the survey concluded. Any associated information, such as source IP addresses, collection time stamps, and serial numbers, was also destroyed to ensure privacy protection. Following transcription, the data were renumbered sequentially, starting from 1. All images and data presented in the manuscript or multimedia appendices are fully anonymized and cannot be used to identify any individual participant or user. No financial compensation was provided to participants. Approval was obtained from the Biomedical Ethics Committee of the Second Affiliated Hospital, School of Medicine, Zhejiang University, China (approval number IRB-2021-841).

Results

Demographic Information

The demographic characteristics of the included sample are presented in Table 3. The sample exhibited a balanced gender distribution (female: 553/1025, 53.95%; male: 472/1025, 46.05%), with participants predominantly aged 19-30 years (500/1025, 48.78%). In terms of education, most respondents held college degrees (519/1025, 50.63%), followed by master's degrees (269/1025, 26.24%). Income distribution showed that nearly one-quarter of participants (244/1025, 23.80%) earned ≤2500 RMB (1 RMB=US $0.14) monthly, whereas a smaller proportion (49/1025, 4.78%) reported incomes of 50,001 or higher. Regarding usage patterns, the largest group reported using the service 2-3 times per week (370/1025, 36.10%), while a minority were frequent users (>7 times per week: 59/1025, 5.76%). In terms of occupation, students constituted the largest subgroup (283/1025, 27.61%), followed by public servants/clerks (208/1025, 20.29%) and professional technical personnel (196/1025, 19.12%). Overall, 664 of 1025 (64.78%) users reported using 1 app.

Data Characteristics

A descriptive analysis of the 8 self-management characteristics and satisfaction with the 5 functional designs was conducted. First, we calculated the average score of multiple items measuring each characteristic variable to represent the level of that variable. However, because the distributions of the average

XSL•FO
RenderX

values for each variable were not normally distributed, medians and IQRs were used for presentation, as shown in Table 4.

Table 4. Descriptive statistics (median and IQR) of the 8 health management characteristics and satisfaction with the 5 functional designs for the analyzed sample (n=1025).

Characteristics	Median	First quartile (Q1)	Third quartile (Q3)	IQR
Health-specific determinants				
Perceived severity	4.25	3.75	5.00	1.25
Perceived susceptibility	3.50	3.00	4.00	1.00
Perceived barrier	2.50	2.00	3.50	1.50
Perceived benefit	4.75	4.00	5.00	1.00
Health self-efficacy	4.00	3.33	4.33	1.00
Perceived health status	3.67	3.00	4.00	1.00
eHealth literacy	4.00	3.50	4.50	1.00
Health management intention	4.00	3.33	4.33	1.00
Satisfaction				
Satisfaction with health guidance	4.00	3.00	4.00	1.00
Satisfaction with health education	3.67	3.00	4.00	1.00
Satisfaction with health monitoring	4.00	3.33	4.33	1.00
Satisfaction with social function	3.33	3.00	4.00	1.00
Satisfaction with gamification	3.00	3.00	4.00	1.00

Cluster Analysis of User Self-Management Characteristics and Determination of User Types

The determination of the optimal number of clusters in this study, which was set at 6, was based on the relationship between the within-cluster SSE and the number of clusters. Subsequently, cluster analysis was performed on the sample using *z* score–standardized values of the 8 health management indicators. The distribution across the 6 clusters was relatively uniform (140, 135, 189, 218, 180, and 163). Figure 2 shows the distribution of each indicator across the 6 clusters obtained from the analysis. A *z* score close to 0 indicates that the corresponding indicator in a given cluster approximates the overall average level, whereas a positive *z* score indicates that the indicator is above the average level in that cluster.

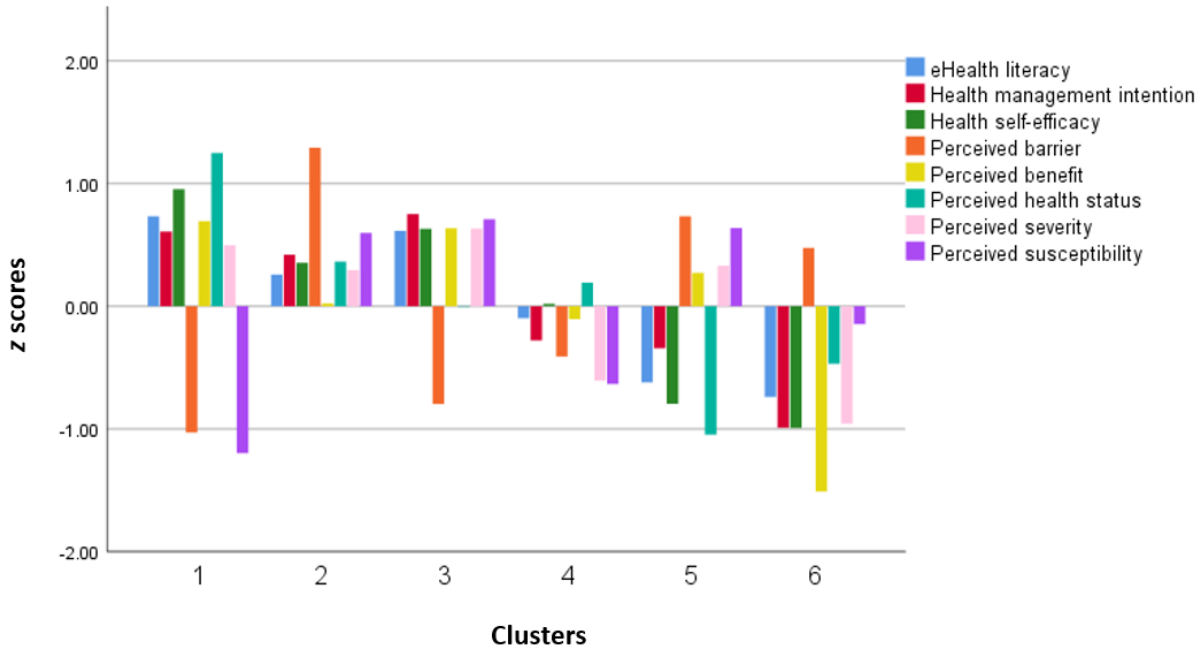
We further analyzed differences in each indicator across the 6 clusters using the Kruskal-Wallis test to assess the distinctiveness of each cluster. The results of the Kruskal-Wallis test demonstrated statistically significant differences in the *z* scores of all indicators across the 6 clusters (P<.001 for all). Specifically, significant differences were observed for the following: perceived severity, $H(5)=400.947$ (P<.001); perceived susceptibility, $H(5)=522.425$, (P<.001); perceived barrier, $H(5)=673.985$, (P<.001); perceived benefit, $H(5)=492.630$, (P<.001;) health self-efficacy, $H(5)=518.298$, (P<.001); perceived health status, $H(5)=490.411$, (P<.001); eHealth literacy, $H(5)=362.910$, (P<.001); and health management intention, $H(5)=390.573$, (P<.001). These findings indicate that the 6 clusters exhibit distinct patterns and magnitudes of health management characteristics, as reflected by the significant differences in the *z* scores of the respective indicators. The detailed *z* scores and pairwise comparison results for each indicator across the 6 clusters are presented in Table 5, allowing for a detailed examination of how each cluster differs from the others in terms of specific health management characteristics. Detailed test statistics are provided in Multimedia Appendix 5, which presents pairwise comparisons of health management characteristics among user groups.

The distribution of the 8 health management traits varied across individual users. To further understand user health management characteristics and provide references for personalized services in mHealth apps, this study categorized users based on combinations of their 8 current health management factors. Given the distinctiveness of each user group, the 6 types were named according to the indicator profiles within each cluster to reflect the main health management characteristics of users in each type. Cluster 1 was labeled “positively proactive energizers.” Users in this cluster exhibited higher perceived health status, health management self-efficacy, and health management intention than proactive intenders, along with substantially lower perceived barriers and perceived susceptibility.

Cluster 2 was labeled “proactive intenders,” characterized by users whose perceived health status, eHealth literacy, and health management intention are all above average, but who also report higher perceived barriers and perceived susceptibility. Proactive intenders (135/1025, 13.17%), the smallest group, represent users who demonstrate strong proactivity in health management, recognize their potential risk for health problems, and actively manage their health despite the presence of perceived barriers.

Cluster 3 was labeled “negatively proactive energizers.” Compared with positively proactive energizers, users in this cluster have slightly below-average perceived health status and

XSL•FO
RenderX



higher perceived susceptibility, yet they exhibit higher health management intention, health management self-efficacy, and eHealth literacy. Both positively proactive energizers (140/1025, 13.66%) and negatively proactive energizers (189/1025, 18.44%) represent groups with high levels of health management cognition, literacy, and capability, along with strong health management intention, making them the primary beneficiaries of current mHealth apps. The key difference between these 2 groups lies in perceived health status, which is higher among positively proactive energizers and below average among negatively proactive energizers. Cluster 4 was labeled "low health management demanders." Users in this cluster tend to have average perceived health status, with perceived susceptibility, perceived severity, and health management intention all below the average level. Low health management demanders constitute the largest proportion of users (218/1025, 21.27%) and represent a group with relatively good current health, limited emphasis on health management, insufficient awareness of health risks and potential harm, and consequently lower intention to engage in health management.

Cluster 5 was labeled "potential health management demanders." Users in this cluster have below-average perceived health status and, although their perceived benefits, perceived susceptibility, and perceived severity are above average, they exhibit lower health management intention and higher perceived barriers. Potential health management demanders (180/1025, 17.56%) represent individuals with poor current health status who are aware of the harms associated with health risks and recognize the benefits of health management for improving their condition, yet face substantial barriers to engaging in health management and therefore have a lower intention to do so. This group has both a clear recognition of the importance of health management and an objective need for it due to their poor health status.

Cluster 6 was labeled "passive attitude holders," comprising users whose perceived health status is below average and who report very low perceived benefits, health management self-efficacy, perceived severity, and health management intention. Passive attitude holders (163/1025, 15.90%) share similarities with low health management demanders, including low perceived benefits, health management self-efficacy, perceived severity, and intention for health management. However, they differ in that passive attitude holders perceive their health status as below average and face higher perceived barriers. This group perceives a decline in health status but lacks the willingness to improve it, placing them at high risk for illness.

From the perspective of age distribution, the 6 user categories exhibited distinct age-structure characteristics. Positively proactive energizers (n=140) comprised 48 (34.3%) aged 19-30 years, 48 (34.3%) aged 31-45 years, 42 (30.0%) aged 46-60 years, and 2 (1.4%) aged ≥61. Proactive intenders (n=135) consisted of 71 (52.6%) aged 19-30 years, 50 (37.0%) aged 31-45 years, 12 (8.9%) aged 46-60 years, and 2 (1.5%) aged ≥61. Negatively proactive energizers (n=189) included 2 (1.1%) aged ≤18, 65 (34.4%) aged 19-30 years, 79 (41.8%) aged 31-45 years, 41 (21.7%) aged 46-60 years, and 2 (1.1%) aged ≥61. Low health management demanders (n=218) comprised 1 (0.5%) aged ≤18, 103 (47.2%) aged 19-30 years, 69 (31.7%) aged 31-45 years, 44 (20.2%) aged 46-60 years, and 1 (0.5%) aged ≥61. Potential health management demanders (n=180) included 2 (1.1%) aged ≤18, 97 (53.9%) aged 19-30 years, 54 (30.0%) aged 31-45 years, 26 (14.4%) aged 46-60 years, and 1 (0.6%) aged ≥61. Passive attitude holders (n=163) were distributed as 1 (0.6%) aged ≤18, 116 (71.2%) aged 19-30 years, 37 (22.7%) aged 31-45 years, and 9 (5.5%) aged 46-60 years. Chi-square tests indicated that the associations between user clusters and both age (Cramer *V*=0.145) and education (Cramer *V*=0.116) groups were weak.

Figure 2. Cluster analysis–derived profiles of 6 user groups across 8 health management characteristics (*z* scores).

XSL•FO
RenderX

Table 5. Mean z scores and Kruskal-Wallis group comparisons of the 8 health management characteristics across the 6 user clusters.

Clustering variables	Cluster 1: positively proactive energizers (n=140)	Cluster 2: proactive intenders (n=135)	Cluster 3: negatively proactive energizers (n=189)	Cluster 4: low health management demanders (n=218)	Cluster 5: potential health management demanders (n=180)	Cluster 6: passive attitude holders (n=163)
Perceived severity	0.496[a,b,c]	0.294[b,e]	0.632[c]	–0.607[d]	0.331[a,e]	–0.956[f]
Perceived susceptibility	–1.197[a]	0.598[b,c,e]	0.709[c,e]	–0.634[d]	0.638[e]	–0.146[f]
Perceived barrier	–1.029[a,c]	1.292[b]	–0.796[c]	–0.410[d]	0.733[e,f]	0.476[f]
Perceived benefit	0.693[a,c]	0.022[b,d]	0.636[c]	–0.106[d]	0.273[e]	–1.510[f]
Health self-efficacy	0.955[a]	0.354[b,c]	0.630[c]	0.020[d]	–0.795[e,f]	–0.993[f]
Perceived health status	1.249[a]	0.363[b,d]	–0.004[c,d]	0.192[d]	–1.047[e]	–0.469[f]
eHealth literacy	0.733[a,c]	0.258[b]	0.615[c]	–0.097[d]	–0.621[e,f]	–0.740[f]
Health management intention	0.608[a,b,c]	0.419[b]	0.751[c]	–0.278[d,e]	–0.342[e]	–0.990[f]

[a-f]In the same row of data, if the same characteristic across the 6 clusters shares the same superscript (eg, "b"), it indicates that the difference between them is not statistically significant. Conversely, if the same characteristic across the 6 clusters does not share the same superscript, it suggests that the difference between them is statistically significant. For instance, cluster 1's perceived barrier is denoted as –1.029[a,c], and cluster 3's perceived barrier is denoted as –0.796[c]; the presence of the superscript "c" in both indicates that the Kruskal-Wallis test for the *z* scores of perceived barrier between cluster 1 and cluster 3 is not statistically significant. Conversely, cluster 2's perceived barrier is denoted as 1.292[b]. The absence of a common superscript implies that the Kruskal-Wallis test for the *z* scores of perceived barrier between cluster 1 and cluster 2 is statistically significant.

Differences in Satisfaction With mHealth App Functional Design Among Different Types of Health Users

First, the Kruskal-Wallis test was used to analyze differences in satisfaction with the 5 functional designs of the mHealth app among all users. The Kruskal-Wallis test indicated significant variations in user satisfaction with the 5 functional designs of mHealth apps—$H(4)=445.388$, $P<.001$. Specifically, the median satisfaction levels for the 5 functional dimensions among all users are presented in Table 6. Among these dimensions, health monitoring and health guidance exhibited the highest levels of satisfaction. Detailed satisfaction scores for the 5 functional designs, as well as pairwise comparisons of satisfaction among the 6 clusters, are also presented in Table 6. These results allow for a detailed examination of how each cluster differs from the others in terms of satisfaction with specific functional designs. Detailed test statistics are provided in Multimedia Appendix 6, which presents pairwise comparisons of satisfaction with the 5 functions across user groups.

Specifically, satisfaction with health guidance was higher in clusters 1, 2, 3, and 5 than in cluster 6. Pairwise comparisons revealed that clusters 1 ($z=6.246$, Bonferroni-adjusted $P<.001$), 2 ($z=8.404$, Bonferroni-adjusted $P<.001$), 3 ($z=6.887$, Bonferroni-adjusted $P<.001$), and 5 ($z=3.674$, Bonferroni-adjusted $P=.004$) differed significantly from cluster 6. Satisfaction with health education and health monitoring was significantly higher in clusters 1–3 than in clusters 4–6, with all 9 cross-group pairwise comparisons for each domain yielding statistically significant differences (health education: $z=2.77$-7.95, Bonferroni-adjusted $P<.001$ to .02 and health monitoring: $z=3.05$-7.88, Bonferroni-adjusted $P<.001$ to .03). With respect to social functions and gamification, users in cluster 2 reported higher satisfaction than those in the other 5 clusters. Pairwise comparisons revealed that cluster 2 differed significantly from cluster 1 ($z=–3.584$, Bonferroni-adjusted $P=.005$), cluster 3 ($z=4.599$, Bonferroni-adjusted $P<.001$), cluster 4 ($z=6.857$, Bonferroni-adjusted $P<.001$), cluster 5 ($z=7.392$, Bonferroni-adjusted $P<.001$), and cluster 6 ($z=5.992$, Bonferroni-adjusted $P<.001$) in social function; and from cluster 1 ($z=–3.999$, Bonferroni-adjusted $P=.001$), cluster 3 ($z=5.015$, Bonferroni-adjusted $P<.001$), cluster 4 ($z=5.880$, Bonferroni-adjusted $P<.001$), cluster 5 ($z=7.200$, Bonferroni-adjusted $P<.001$), and cluster 6 ($z=6.083$, Bonferroni-adjusted $P<.001$) in gamification.

Table 6. Median satisfaction and Kruskal-Wallis group comparisons regarding the 5 functional designs across the 6 user types.

Dependent variables	Median (IQR)						
	All users (n=1025)	Cluster 1: positively proactive energizers (n=140)	Cluster 2: proactive intenders (n=135)	Cluster 3: negatively proactive energizers (n=189)	Cluster 4: low health management demanders (n=218)	Cluster 5: potential health management demanders (n=180)	Cluster 6: passive attitude holders (n=163)
Satisfaction with health guidance	4.00 (1.00)	4.00[a,b,c,e] (1.67)	4.00[b,c] (1.00)	4.00[c] (1.00)	3.67[d,e,f] (1.00)	4.00[e] (1.00)	3.33[f] (1.00)
Satisfaction with health education	3.67 (1.00)	4.00[a,b,c] (1.67)	4.00[b,c] (1.33)	4.00[c] (1.33)	3.67[d,e] (1.00)	3.67[e,f] (1.00)	3.33[f] (1.00)
Satisfaction with health monitoring	4.00 (1.00)	4.00[a,b,c] (0.92)	4.00[b,c] (1.00)	4.00[c] (1.33)	3.67[d,e,f] (1.00)	4.00[e] (0.67)	3.67[f] (1.00)
Satisfaction with social function	3.33 (1.00)	3.33[a,f,c] (1.00)	4.00[b] (1.00)	3.33[c,d,f] (1.00)	3.00[d,e,f] (0.67)	3.00[e,f] (1.00)	3.33[f] (0.67)
Satisfaction with gamification	3.00 (1.00)	3.00[a,c,d,f] (1.00)	4.00[b] (1.33)	3.00[c,d,e,f] (1.33)	3.00[d,e,f] (0.67)	3.00[e,f] (1.33)	3.00[f] (0.33)

[a]In the same row of data, the group with a superscript "a" is statistically distinct from that with "b," "c," "d," and "e". However, the group with a superscript "b" is statistically not distinct from that with "b, c" because they share the superscript "b." Differing grouping labels indicate the heterogeneity across clusters.

Associations Between User Self-Management Characteristics and Satisfaction With mHealth App Functional Design

In this study, confirmatory factor analysis was used to test the reliability and validity of the questionnaire. The results, as shown in Multimedia Appendix 7, indicate that all constructs had Cronbach α and composite reliability values above 0.7; the average variance extracted for each construct was greater than 0.6; and the factor loadings for all items exceeded 0.7, demonstrating good reliability and convergent validity for all constructs. The heterotrait-monotrait ratio (HTMT) method was used to assess discriminant validity. The commonly accepted criterion for establishing discriminant validity is an HTMT value below 0.85. The results indicate that all construct pairs exhibited HTMT values below 0.85, supporting the discriminant validity of the measurement model. Using 8 health management characteristics as independent variables and satisfaction with 5 feature designs as dependent variables, partial least squares analysis was conducted to examine the impact of health management characteristics on satisfaction with the functional design of mHealth apps. The R^2 value represents the proportion of variance in the dependent variable explained by the independent variables and is used to interpret the goodness-of-fit of the regression equation, while β indicates the correlation between variables. Table 7 displays the β values and statistical significance of R^2 for the independent and dependent variables. Specifically, perceived barriers (β=.177, *z*=3.586, *P*<.001), perceived susceptibility (β=.076, *z*=2.056, *P*=.04), health self-efficacy (β=.140, *z*=3.307, *P*=.001), perceived health status (β=.111, *z*=2.967, *P*=.003), eHealth literacy (β=.153, *z*=3.947, *P*<.001), and health management intention (β=.148, *z*=3.966, *P*<.001) had a significant positive impact on satisfaction with health guidance; perceived barriers (β=0.143, *z*=3.130, *P*=.002), health self-efficacy (β=0.147, *z*=3.491, *P*<.001), perceived health status (β= 0.120, *z*=3.072, *P*=.002), eHealth literacy (β= 0.131, *z*=3.362, *P*=.001), and health management intention (β= 0.175, *z*=4.670, *P*<.001) had a significant positive impact on satisfaction with health education; perceived severity (β=.118, *z*=3.235, *P*=.001), perceived barriers (β=.107, *z*=2.194, *P*=.03), perceived benefits (β=.089, *z*=2.428, *P*=.02), perceived health status (β=.088, *z*=2.188, *P*=.03), eHealth literacy (β=.170, *z*=4.561, *P*<.001), and health management intention (β=.083, *z*=2.064, *P*=.04) had a significant positive impact on satisfaction with health monitoring; perceived susceptibility (β=.098, *z*=2.314, *P*=.02), perceived barriers (β=.150, *z*=3.032, *P*=.002), health self-efficacy (β=.195, *z*=4.598, *P*<.001), perceived health status (β=.135, *z*=3.391, *P*=.001), eHealth literacy (β=.118, *z*=2.805, *P*=.005), and health management intention (β=.139, *z*=3.396, *P*=.001) had a significant positive impact on satisfaction with social functions, whereas perceived benefits (β=–.210, *z*=5.906, *P*<.001) had a significant negative impact and perceived susceptibility (β=.099, *z*=2.200, *P*=.03), perceived barriers (β=.139, *z*=3.074, *P*=.002), health self-efficacy (β=.137, *z*=3.076, *P*=.002), perceived health status (β=.122, *z*=2.834, *P*=.005), eHealth literacy (β=.119, *z*=2.771, *P*=.006), and health management intention (β=.100, *z*=2.354, *P*=.02) had a significant positive impact on satisfaction with gamification, while perceived benefits (β=–.165, *z*=5.011, *P*<.001) had a significant negative impact. These results help explain why different types of users exhibit varying levels of satisfaction with different functional designs. The statistical analysis results for each path are presented in Multimedia Appendix 8.

Discussion

Principal Findings

Understanding the heterogeneity of mHealth users and analyzing distribution differences in satisfaction with mHealth function design among user groups with distinct characteristics have significant referential value for personalized mHealth design. Therefore, guided by self-management theory and driven by self-management characteristics, this study constructed mHealth user personas encompassing 6 categories, analyzed the main characteristics and attributes of these 6 types of mHealth users, and examined differences in satisfaction with various mHealth function designs across user types. The results show that levels of user self-management characteristics are unevenly distributed and that different combinations of self-management characteristics can explain user heterogeneity. Moreover, a clear correlation exists between user heterogeneity arising from self-management characteristics and satisfaction with specific function designs. The findings of this study mutually confirm and extend existing literature on differences in mHealth intervention effects, user participation motivation, and technology design principles.

User Profiles of Fitness and Weight Management Apps Based on Health Management Characteristics

This study categorizes mHealth users into 6 distinct groups based on their self-management characteristics, revealing a complex classification derived from self-management–related attributes such as knowledge, beliefs, self-regulation skills and abilities, and motivation. This classification system differs from traditional approaches that rely on broad demographic labels (such as age and education level), offering a more refined and interpretable psychographic user profile. Although the sample in this study is predominantly composed of young-to-middle-aged and highly educated users, comparison with the 50th Statistical Report on China's Internet Development (2022) [62] shows that while individuals aged 20-49 account for 56.6% of all Chinese internet users, only 28.5% have used online medical services. This indicates that even within the broadly age-eligible internet population, active adopters of digital health services constitute a specific subgroup. Accordingly, this study employed an online snowball sampling method to reach and recruit active users with genuine interest and engagement in mHealth management. The "young-to-middle-aged, well-educated" characteristics of the sample, to some extent, reflect the profile of individuals who pay close attention to such apps. However, chi-square test results show that the associations between user classification and age (Cramer V=0.145) and education level (Cramer V=0.116) are weak. Furthermore, analysis of the age composition of each user group revealed that every category spans multiple age layers, suggesting that single demographic labels are insufficient to capture the characteristics of the 6 user categories identified in this analysis. The uneven distribution of multiple features across different user categories indicates that there is no complete positive correlation between individuals' perceived health status and their health management abilities and motivations. The differentiation of users' characteristic attributes is consistent with relevant theories such as BCWs. Potential health management demanders and passive attitude holders both exhibit low health management intention, but their underlying mechanisms differ: the former perceive susceptibility and severity but face higher perceived barriers, whereas the latter generally lack recognition of the perceived benefits and health self-efficacy of health management. This is consistent with phenomena observed in studies of smoking cessation apps [63], namely that when users remain at the level of understanding health information but fail to convert it into personalized risk perception and action confidence, behavioral intentions are difficult to activate. Based on the results of this study, targeted interventions in mHealth management are needed according to individuals' motivation status and health perceptions, to facilitate the transformation of different perception characteristics into internal motivation and to address differences

XSL•FO
RenderX

in health management behaviors arising from varying motivation statuses [64]. In addition, although negatively proactive energizers perceive an average health status, they exhibit high health management intention and self-efficacy. This finding indicates that perceived health status alone is not the sole determinant of mHealth service use, which is also supported by existing studies [65], showing that patients' satisfaction with mHealth services may be influenced by individual differences in disease progression, perceived service attitudes, and understanding of diagnostic and treatment outcomes. Correspondingly, passive attitude holders exhibit low levels of perceived health status, perceived benefits, health self-efficacy, and health management intention, which aligns with a previous study [66] identifying lack of motivation and low perceived value as significant barriers to mHealth participation. In general, obtaining a positive mHealth service experience often depends on whether services can be personalized or adaptively adjusted to accommodate different user needs and motivations, and user heterogeneity is strongly correlated with self-management characteristics [67].

Satisfaction of Various User Types With mHealth App Functionality Design

There are significant differences in satisfaction with mHealth function designs among different user types, providing counterevidence to the "one-size-fits-all" function design strategy and underscoring the necessity of personalized design. This study found that proactive intenders and positively proactive energizers, characterized by high self-efficacy and strong health management intention, reported higher satisfaction with goal-oriented and interactive functions such as health guidance, health education, and health monitoring. This finding is consistent with multiple studies [63,68,69], indicating that users who actively focus on their own well-being demonstrate higher levels of engagement with mHealth. Features such as progress tracking, personalized feedback, and access to educational content are often welcomed and perceived as useful by these users.

Low health management demanders and passive attitude holders report lower satisfaction with most mHealth functions. This finding is consistent with a previous study [70], which indicated that for users with low intrinsic motivation or insufficient perceived value, complex functions or interfaces may act as barriers to use; such users require designs that are concise, intuitive, provide immediate and intuitive feedback, and involve low operational barriers. Notably, prior research has demonstrated a positive correlation between eHealth literacy and mHealth usage [71]. However, our findings offer a contrasting perspective, showing that potential health management demanders, despite having lower-than-average eHealth literacy, report high satisfaction with health guidance and health monitoring functions. This may be because this group's higher perceived benefits and perceived susceptibility compensate for their lower capability, thereby increasing their interest in tools that enhance health benefits and reduce health risks. This phenomenon may also be partially explained by the Dunning-Kruger effect, whereby users lacking specialized knowledge may be less able to critically evaluate application limitations, leading to inflated satisfaction ratings for mHealth. Individuals with low health literacy have been shown to report levels of confidence about their knowledge comparable to, or even higher than, those with high literacy [72]. Conversely, users with stronger health knowledge reserves tend to use educational materials and support functions in mHealth apps more frequently, thereby enhancing recognition and evaluation of specific functions [73]. The user-centered design concept, combined with the user types constructed in this study, can therefore provide valuable reference for mHealth designs that address the diverse needs of different user groups.

Recommendations

The findings of this study provide clear implications for the personalized design and practical application of mHealth. mHealth developers should adopt a user-centered design approach and, based on the user types constructed in this study, tailor functional modules accordingly. For positively proactive energizers, further development of data tracking, personalized goal setting, and systematic educational content can be pursued, alongside the appropriate introduction of gamification elements to enhance users' sense of enjoyment [74]. For potential health management demanders, design efforts should focus on lowering usage barriers, providing clear and step-by-step health guidance and monitoring tools, and strengthening health-related beliefs. For passive attitude holders, the primary objective may be to establish initial engagement and trust through simple designs and light-touch interventions, while incorporating social features to help this group build social support [75], increase awareness of health risks, and enhance beliefs in health management. Furthermore, the study's results suggest that when evaluating the effectiveness of mHealth functions, user heterogeneity must be considered, as overall average satisfaction may obscure substantial differences among user subgroups.

Limitations and Future Research

Although this study was carefully designed in terms of methodology and empirical analysis, several limitations should be acknowledged. First, to avoid comparability issues arising from differences in functional design across mHealth apps with different core service content, and to recruit as diverse a user sample as possible, this study selected exercise, fitness, and weight management apps as the objects of study. However, these apps cannot fully represent all types of mHealth apps. Nevertheless, by conducting empirical research on one of the most widely used and numerous categories of mHealth apps, this study verifies that individuals' self-management characteristics have important referential value for mHealth user classification. The results demonstrate significant differences in satisfaction with various functional designs across user types, and that the effects of self-management characteristics on satisfaction differ across functional design dimensions. These results provide direct empirical reference for the personalized design of fitness and weight loss apps, and the research conclusions may also offer inspiration for user classification–related studies in other types of mHealth apps. Second, although questionnaires are an effective research method, they cannot fully represent all users. Access to feedback data from the entire mHealth user population would enable a more refined classification of user types. At present, limited

XSL•FO
RenderX

research on mHealth apps has focused on users' health cognition and self-management abilities, which constrains the analysis of comprehensive user characteristics from a big data perspective. To mitigate sampling bias, data were collected from 34 regions across China, and the sample size was substantially larger than that of comparable studies, supporting the representativeness of the findings. Third, although empirical results indicate that 8 self-management characteristics significantly influence user satisfaction, these characteristics explain only a limited proportion of the variance in satisfaction with mHealth (R^2=0.094-0.183). Although the identified pathways were statistically significant, a substantial proportion of the variance in satisfaction remains unexplained by these characteristics. Given that the primary aim of this study was to examine whether the effects of heterogeneous user types on satisfaction differ—that is, to construct user profiles based on self-management characteristics and analyze differences in satisfaction across user types—we did not conduct an in-depth examination of other potential determinants of satisfaction (eg, usage context, service quality, and user experience). Future research on factors influencing mHealth satisfaction could incorporate additional predictive variables to improve the explanatory power of the model.

Conclusions

This study identified 6 distinct mHealth user typologies (fitness and weight management apps) derived from a comprehensive set of self-management characteristics. The results reveal an uneven distribution of multidimensional characteristics across different user categories. This granular classification provides a deeper understanding of user heterogeneity than traditional demographic-based approaches. Overall, the primary contribution of this work is an empirically validated framework that offers a structured approach to understanding mHealth user diversity. The identified user typologies and their differential functional satisfaction profiles yield actionable insights for the personalized design of fitness and weight management apps. Specifically, for health guidance and education features, proactive intenders, positively proactive energizers, and negatively proactive energizers report higher satisfaction. For health monitoring functions, potential health management demanders, proactive intenders, positively proactive energizers, and negatively proactive energizers demonstrate higher satisfaction. For social features and gamification design, proactive intenders exhibit significantly higher satisfaction than the other 5 user types. From a practical perspective, these findings underscore the importance of adapting mHealth features to the distinct self-management needs and preferences of specific user groups. Such adaptation is essential for enhancing user satisfaction, fostering sustained engagement, and ultimately improving the perceived usefulness of digital health solutions.

Abstract

Background: Electronic health records are essential for advancing research aimed at improving clinical outcomes. However, stringent data protection and privacy concerns severely limit the accessibility and use of real clinical data, particularly within Child and Adolescent Mental Health Services (CAMHS) involving vulnerable young individuals. This challenge can be effectively addressed through synthetic data generation, which safeguards individual privacy while facilitating comprehensive analyses of clinical information.

Objective: This study aims to investigate whether hierarchical synthetic data generators (SDGs) can effectively replicate the statistical properties, preserve the utility, and maintain the privacy of real CAMHS clinical data, thereby enabling data sharing and broader access to research-ready datasets.

Methods: This retrospective cohort study used electronic medical record data from 6924 distinct patients from CAMHS in Stavanger, Norway, comprising 7730 referral periods and 58,524 episodes of care. An 80%-20% split was used for training and testing. A hierarchical synthetic data generation model was trained to generate synthetic referral periods and associated episodes of care. Data quality was evaluated using SDMetrics for distribution (Kolmogorov-Smirnov Complement [KSC]/Total Variation Complement [TVC]), correlation (CorrelationSimilarity [CS]), and cardinality (CardinalityShapeSimilarity [CSS]) similarity. Privacy was evaluated using the Anonymeter library to simulate singling out, linkability, and inference reidentification attacks. Utility was assessed using the train synthetic test real (TSTR) pattern, comparing the predictive performance using precision-recall area under the curve [PRAUC] of models trained on synthetic vs real data for classifying the intensity of care.

Results: The hierarchical SDG created highly reproducible synthetic CAMHS data. The average statistical similarity scores were high across all metrics: KSC/TVC at 0.92, CS at 0.77 (intertable CS at 0.75), and CSS at 0.92. The synthetic data also demonstrated a low risk under simulated privacy attacks on a control dataset (n=1546): the average success rate was 6/1546 (0.39%) for singling out and 77/1546 (5%) for multivariate attacks. The average linkability risk was 54/1546 (0.5%), and the highest inference risk for a sensitive variable was 2/1546 (0.12%). The classification model trained on synthetic data (TSTR) produced comparable predictive performance (PRAUC=0.40) to the model trained on real data (PRAUC=0.43) for classifying

XSL•FO
RenderX

the intensity of care (low vs medium or higher). Shapley additive explanations analysis confirmed that the synthetic model's explanations aligned with real-world insights, validating its ability to capture fundamental predictive patterns.

Conclusions: Synthetic data can be used to build trust and promote collaboration among CAMHS researchers by offering access to extensive, representative samples with a low risk of patient identification. This approach expands the breadth of research while safeguarding patient privacy. Effective implementation of synthetic data generation depends on the model's ability to accurately identify and replicate the complex, sequential patterns present in real data.

Introduction

The preservation of patient confidentiality is frequently identified as a significant barrier to conducting research with mental health care datasets [1]. Researchers appropriately face strict regulations and ethical considerations that limit access to real patient data. This is further complicated by selection bias [2], digital barriers [3], and high levels of sensitivity of mental health information, which, if disclosed, could lead to additional stigma, discrimination, and other negative consequences for individuals [4].

While these challenges are present across all mental health research, the use of large-scale data from patient records becomes significantly more complex with Child and Adolescent Mental Health Services (CAMHS) data. This is due to a set of problems associated with this vulnerable population. First, the variability in developmental stages among children and adolescents means that symptoms and diagnoses manifest differently across age groups (eg, anxiety in a 5-year-old compared to a 16-year-old), making data standardization and longitudinal analysis inherently difficult. Second, the necessity for age-appropriate interventions and evolving care pathways creates complex, nonlinear data structures that are challenging to model consistently [5]. Perhaps most critically, the ethical considerations surrounding privacy and consent for minors are far more stringent than for adult populations. Researchers must navigate nuanced consent processes involving both parents or guardians and the child's assent, often with varying legal requirements based on age and local jurisdiction [6,7]. This multilayered consent, coupled with heightened safeguarding responsibilities, severely restricts data sharing. Furthermore, due to their inherent nature, which includes stringent privacy regulations and the fragmented structure of care pathways, CAMHS datasets are typically smaller, exhibit greater structural fragmentation, and are consequently more challenging to access large-scale, generalizable research than adult health datasets.

These challenges can be effectively addressed by the generation of synthetic data. Synthetic data not only safeguard individual privacy but also permit comprehensive analyses of large-scale clinical data obtained directly from electronic medical records (EMRs) and other clinical data sources, even in sensitive areas such as CAMHS.

Previous studies have applied synthetic mental health data in data augmentation, privacy preservation, and fairness [8]. The SynthNotes framework, developed by Begoli et al [9], is notable for its ability to produce realistic and high-fidelity synthetic mental health documentation on a large scale. The framework facilitates benchmarking, optimization, and training for biomedical NLP, information extraction, and machine learning systems, all while ensuring strict privacy preservation. To ensure accurate and generalizable research results, synthetic data must accurately represent diverse minority subgroups. This is particularly important in addressing child and adolescent mental health inequities exacerbated by events like the COVID-19 pandemic [10]. Addressing these biases requires expertise in the underlying model and an understanding of fairness concepts like unawareness, demographic parity, and conditional fairness [8]. One approach involves directly de-biasing existing datasets to create "fair data," a process similar to synthetic data generation [11,12]. Alternatively, some researchers view data de-biasing as a "ground-up" generation problem, focusing on developing generative models that inherently incorporate fairness [13].

Predictive models trained on synthetic data for mental health have yielded encouraging findings in numerous studies, highlighting the critical importance of data quality, ethical considerations, and the necessity for ongoing research. A study by Rankin et al [14] used a deep learning approach to predict mental health quality using synthetic data derived from functional network connectivity data from resting-state functional magnetic resonance imaging, achieving high accuracy in classifying mental health quality. Using models trained on synthetic data, Ajith et al [15] combined data from multiple longitudinal mobile sensing studies to predict mental health symptoms, showing improved generalization across different datasets. While these models frequently failed to capture intricate patterns and subtleties, especially within diverse populations [16], their results highlight the potential of synthetic data to enhance predictive modeling in mental health, while addressing privacy and fairness concerns.

While prior synthetic health data studies focused on adult mental health, our research specifically examines how synthetic data generators (SDGs) effectively capture complex patterns and relationships in CAMHS data. We assess the essential trade-offs involving data quality, patient privacy, analytical utility, and optimal synthetic sample size to ensure generated data remains representative and valuable for research.

Methods

Data Source

This study was conducted using a retrospectively collected cohort from the Child and Adolescent Mental Health Department (CAMHD) at Stavanger University Hospital (SUS). The hospital functions as a referral center for about half a million inhabitants in the Rogaland metropolitan area and had an annual admission ranging from 17,000 to 19,000 during the study period. CAMHD at SUS provides assessment, diagnosis, and treatment for young people aged 18 years or younger, experiencing mental health issues such as depression, anxiety, trauma, developmental disorders like autism or attention-deficit/hyperactivity disorder (ADHD), and psychosis.

As detailed in Table 1, the dataset included 6924 distinct patients, 7730 referral periods, and a total of 58,524 episodes of care. Data extraction was performed using the electronic health record system (Distrubuert Informasjons og Pasientdatasystem i Sykehuset [DIPS]; Helse Vest IKT). The system provided access to administrative details like time of admission, department, and clinical personnel, as well as clinical information such as age, sex, and diagnosis for each episode of care.

Each episode is directly linked to a specific referral through a unique identifier. Allowing for comprehensive and continuous tracking of a patient's journey from their initial referral through all subsequent clinical interactions.

cond1axisVIGrp	Consultation/stay	*ICD-10* Axis VI, global functioning (CGAS[c])	• Unique values=7 • Most frequent=6999

[a]N/A: not applicable.

[b]ICD-10: International Statistical Classification of Diseases, Tenth Revision.

[c]CGAS: Children Global Assessment Score.

Missing Data

The dataset contains *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) diagnostic codes categorized across different axes or levels of detail. The *ICD-10* uses a multiaxial system for mental and behavioral disorders, including Axis I (clinical syndromes), Axis II (disabilities), and Axis III (environmental/lifestyle factors).

XSL•FO
RenderX

A key characteristic of the Axis columns is the high rate of missing data, which indicates "not applicable" rather than an error, as is common in clinical coding. For instance, the first condition in Axis I is nearly complete (0.7% missing), but subsequent codes within the same axis show drastically increased missingness (eg, 6th condition, 99.8% missing). This trend continues across other axes, like Axis II (eg, 3rd condition 99.6% missing). This consistent pattern of missing values signifies that a code was not relevant to a clinical episode, making data imputation inappropriate.

Ethical Considerations

The study is a quality assurance initiative directly building on the results of the "PILOT SYNDATA" project. The project was conducted as a collaboration between CAMHD SUS, the analytical department at SUS, and Helse Vest IKT (the regional IT service delivery company). The project's main purpose was to explore the safe use of synthetic data in mental health care.

The data for the "PILOT SYNDATA" project were collected from DIPS, and Helse Vest IKT performed the deidentification and aggregation procedures, with the resulting anonymized data then being used for synthetic data generation in the next phase. This entire process was conducted under a formal agreement that permits the secondary use of health data for research and quality assurance while ensuring patient privacy and confidentiality. Due to the complete deidentification and aggregation of the data, a waiver was not required to use the data in this study.

The study used a synthetic data generation process that creates entirely new, statistically representative data points. The process is fully compliant with HIPAA (Health Insurance Portability and Accountability Act) and GDPR (General Data Protection Regulation) regulations, significantly reducing the risk of an attacker reidentifying individuals or uncovering sensitive patient details from the original dataset.

As this was a retrospective analysis of existing data, no financial compensation was provided to participants. Additionally, it is not possible to identify any individual participants in the figures or supplementary materials. The images are illustrative and use a "real-like path" to represent an anonymized, generalized patient journey.

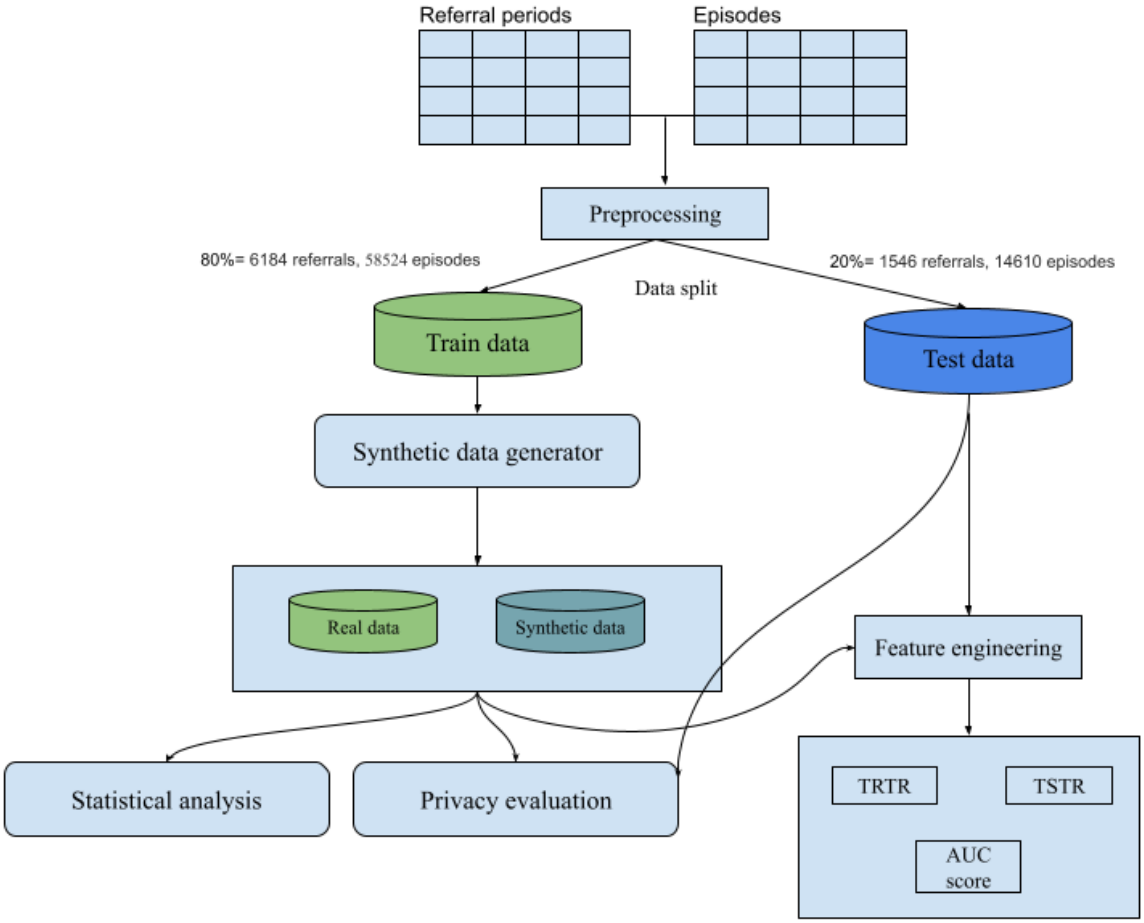
Synthetic Data Generation

We use HMASynthetiser, a multitable algorithm within the Synthetic Data Vault framework [17]. HMASynthetiser is a class model that implements a "hierarchical modeling algorithm" to analyze data structured in multiple levels, often called nested data. These models are particularly useful when dealing with complex datasets in which observations are grouped at different levels, such as referral periods and episodes of care (Multimedia Appendix 1).

The SDG systematically processes the real CAMHS dataset, examining how information is structured across the referrals and episodes of care tables. It uses a Gaussian copula to map the complex relationships between every data field. A Gaussian Copula [18] is a statistical model used to identify the dependency structure between the nested dataset (referrals/episodes). The approach ensures that the SDG process accurately mirrors the statistical patterns and distributions present in the original patient records, even for variables with nonstandard or highly dependent relationships. In addition, the parameters of the SDG are customized for each individual table in the hierarchy, allowing fine-tuning of the synthetic data generation process. Hierarchical modeling, combined with the statistical method, is essential for accurately capturing the complex dependency structures within CAMHS variables.

Data Modeling

To optimize data utility and patient privacy, the real CAMHS dataset underwent comprehensive preprocessing prior to synthetic data generation. This involved the systematic categorization of variables, such as age and admission type, into broader, analytically meaningful groupings. Specifically, age was discretized into decennial intervals, while variables, such as "performing personnel" and "admission type," were recorded by mapping their original granular values to more generalized, descriptive categories. Additionally, diagnostic Axes I-IV were grouped based on the *ICD-10* hierarchy, and Axis VI (Children's Global Assessment Score) underwent specific binning and categorization to abstract sensitive medical codes.



These comprehensive preprocessing steps ensured the data were optimally structured for generating high-fidelity synthetic data and accurately reflected real-world patterns while rigorously upholding patient data protection.

Experimental Setup

Figure 1 displays the experimental setup. The experiments performed in this study followed 3 structures: sample size, privacy risk assessment, and utility assessment.

XSL•FO
RenderX

Figure 1. General study design. AUC: area under the curve; TRTR: train real test real; TSTR: train synthetic test real.

Sample Size

To evaluate the impact of sample size on predictive model performance (Multimedia Appendix 2), 4 distinct training sets (619, 1546, 3092, and 6184 referrals) were created from the real-world CAMHS data. For each of these sizes, a corresponding synthetic dataset was generated to enable a comparison of predictive model performance using both real and synthetic data across various data availability scenarios.

Privacy Risk Assessment

To measure the privacy risk in the generated synthetic data, we used the experimental approach via the Python library Anonymeter [19] (Multimedia Appendix 3). Initially, the attack uses synthetic data to create a series of guesses. The model then evaluates these guesses by comparing them to the values present in the original dataset, thereby assessing the effectiveness of the attack. The privacy model requires the adversary to conduct the same attack on a control dataset (records that were not used in the SDG). By contrasting the success rates of the attack on both training records and control records, a sensitive and significant measure of risk is established. Three types of privacy risk attacks were simulated and analyzed to evaluate the potential for reidentification: singling out, linkability, and inference risks.

Utility Assessment

Prediction tasks represent a robust and frequently used methodology for evaluating synthetic data utility, offering distinct advantages beyond conventional statistical comparisons. The method directly confirms the data's real-world applicability by assessing its capacity to replicate complex, nonlinear relationships for applications such as individualized mental health care planning or treatment pathway optimization. Furthermore, the approach validates the functional equivalence of synthetic data and provides a user-centric, interpretable metric of its inherent value, thereby facilitating the detection of subtle discrepancies overlooked by simpler analytical techniques [20]. To assess synthetic data utility, we formulated a downstream prediction task (Multimedia Appendix 4): classifying patient referral periods by intensity of care. Following Beckers et al [21], "intensity of care" was initially defined as low (<15 sessions/year), medium (15-51 sessions/year), or high (≥52 sessions/year). We extracted primary diagnosis of the first episode, sex, age, and total past referrals as predictor variables. Due to significant skewness (386/7730 high, 2087/7730 medium, and 5874/7730 low), the "medium intensity" and "high intensity" categories were merged into a "medium- or higher-intensity care" group. The combined group was selected to create a sufficiently sized positive class for stable model training, given the constraints of the severely skewed original distribution.

XSL•FO
RenderX

The dataset was then stratified by intensity and split into an 80% training set (6184 referral periods and 58,527 episodes) and a 20% independent test set (1546 referral periods and 14,610 episodes; Multimedia Appendix 5). The stratification ensured balanced distribution and kept all related patient data within either the training or test set; the test set was used solely for evaluation. A random forest model [22] was then trained using synthetic data generated at various scale factors (1, 2, 5, 10). The trained models were evaluated using the Train Synthetic, Test Real evaluation method [23], which involves training a model on synthetic data and testing it on real data.

Model performances were measured using precision-recall area under the curve (PRAUC), a robust metric particularly suited for imbalanced datasets [24,25]. We specifically chose PRAUC over the traditional area under the receiver operating characteristic curve because PRAUC is less susceptible to inflation from the majority (low intensity) class, providing a more accurate and rigorous measure of performance on the positive (medium- or higher-intensity care) class [24]. Results are presented as the median of a stratified 4-fold cross-validation.

Finally, SHAP (Shapley additive explanations) values [26] were computed for both models to assess variable interactions.

Statistical Analysis

To quantify the similarity between real and synthetic data, we used 4 key metrics from the SDMetrics Python library [23]. For numerical column distributions, we used the Kolmogorov-Smirnov Complement (KSC), while the Total Variation Complement (TVC) measured discrete column distributions. The preservation of intercolumn correlation patterns was evaluated using CorrelationSimilarity (CS), and CardinalityShapeSimilarity (CSS) was applied to assess the similarity in cardinality distributions within multitable datasets.

For privacy risk evaluation, we conducted 3 attack-based assessments focused on factual anonymization indicators: singling out determined the potential for identifying individual records; linkability assessed the risk of linking synthetic data back to the real dataset; and an inference attack was used to attempt to deduce sensitive individual information from seemingly nonsensitive data. A low inference risk means it is highly unlikely that an attacker could uncover specific, private details about individual patients from the original dataset.

Qualitative Visualization of Care Pathways

For the qualitative assessment, the specific “real patient path” was selected randomly from the overall real dataset after the synthetic data generation process was completed to ensure the visualization was not conditioned on the selected patient’s attributes prior to generation. This patient, a 12-year-old male diagnosed with “behavioral and emotional disorders” (F90-F98), represents a highly frequent and common clinical profile in our cohort. The corresponding “synthetic path” was then extracted from the synthetic data by identifying a synthetic patient with identical starting attributes (age, sex, and primary diagnosis) to provide a valid, anonymized, and attribute-matched comparison for event sequencing and density.

Results

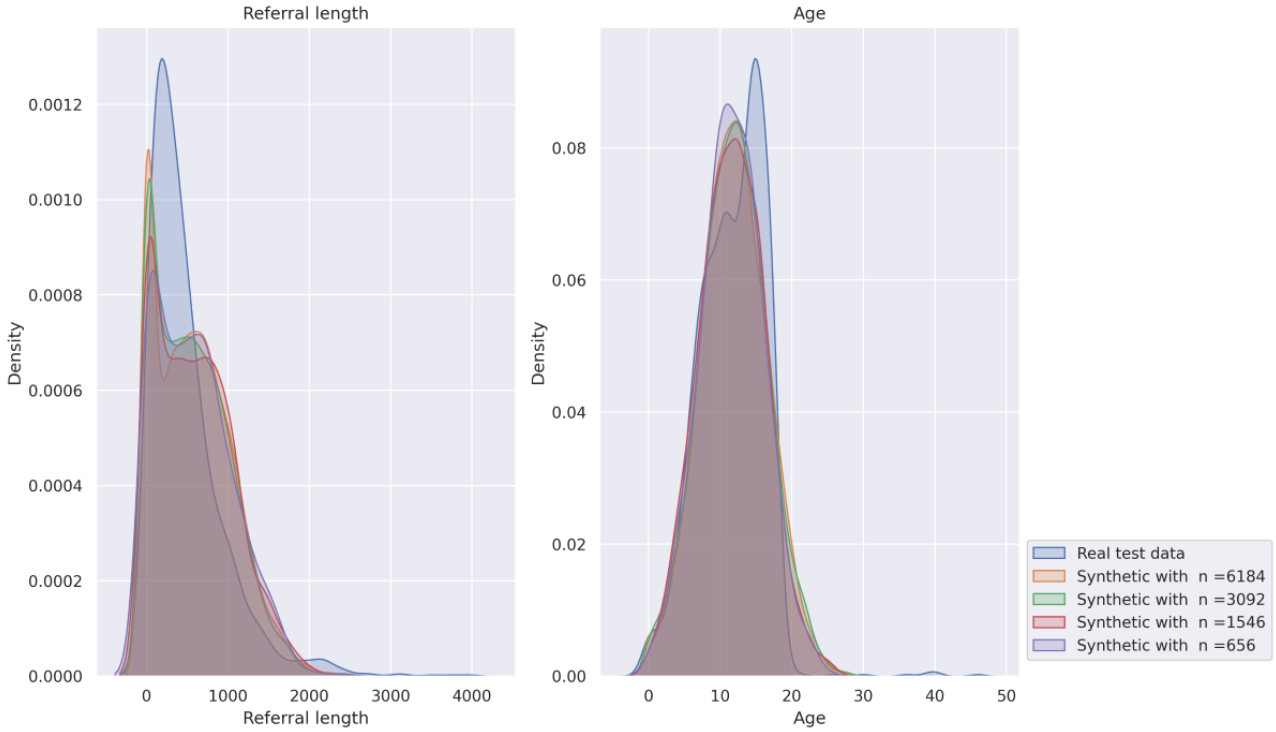
Similarity and Quality Assessment of Synthetic CAMHS Data

As detailed in Table 2, the SDG produced CAMHS data that demonstrated high statistical similarity to the “real-world” CAMHS dataset. The result was evident across all reported metrics (KSC/TVC score=0.92; CS=0.75; CS (intertable)=0.73; CSS=0.9), with good fidelity remaining consistent regardless of the amount of “real-world” training samples provided to the algorithm.

Figure 2 presents 2 kernel density estimate plots, offering a visual comparison of feature distributions between real-world CAMHS data and synthetic data generated at various sample sizes. The left plot, illustrating “referral length,” reveals that the synthetic data distributions, particularly those derived from larger sample sizes (n=6184 and n=3092), closely align with the real test data’s distribution in the high-density range. While the synthetic data effectively captures the predominant patterns of referral lengths, there are minor deviations observed in the extreme tails, suggesting a slight challenge in perfectly replicating infrequent, very long referrals.

Similarly, the right plot, depicting “age,” demonstrates exceptionally high fidelity. All synthetic age distributions, regardless of the sample size, exhibit remarkable overlap with the real test data’s distribution. The peaks and overall shapes are nearly identical, indicating that the synthetic data generation process is highly successful in preserving the univariate statistical characteristics of patient age.

The observed high scores across the various quality metrics and kernel density estimates provide robust evidence that the synthetic data accurately replicates the original patient information’s characteristics and inherent relationships. Specifically, the significant KSC/TVC scores confirm that individual statistical distributions of each variable within the synthetic dataset demonstrate strong consistency with those observed in the real data, which implies that features like patient age ranges or referral lengths exhibit statistical properties consistent with their real-world counterparts. Furthermore, the high CS scores, including both intratable and intertable relationships, confirm the accurate preservation of complex dependencies and interactions between distinct variables. For example, critical correlational structures, such as the frequent association of specific diagnoses with treatment pathways or demographic profiles in the real data, are accurately maintained within the synthetic dataset. Finally, the high CSS scores confirm that the structural properties of the data, including the diversity of unique values within categorical fields and the overall shape of numerical distributions, are accurately replicated.



The consistent high scores underscore that the synthetic data not only replicates individual variable characteristics but also captures the intervariable relationships and the overall statistical integrity of the original, sensitive CAMHS patient information. The observed fidelity is critical for establishing synthetic data’s suitability for subsequent analytical and research applications.

Synthetic Data Privacy Evaluation

To assess the potential for patient reidentification and information revelation, we performed 3 attack-based privacy evaluations: singling out, linkability, and attribute inference. Table 3 provides an overview of the success rate associated with the 3 simulated privacy attacks using synthetic data on a control real dataset (n=1546), highlighting the success rate achieved with various sample sizes. Specifically, the analysis reveals that both univariate and multivariate singling out attacks yield minimal average success rates, recorded at just 6/1546 (0.4%) and 77/1546 (5%), respectively. This indicates that the likelihood of successfully executing these types of attacks is low, regardless of the volume of data being analyzed. Furthermore, the table presents insights into the risk of linkability when using clinical and demographic variables as auxiliary data. The average risk of linkability is calculated to be 0.5% (8/1546), suggesting that while there is some potential for linking data to individuals, the overall risk remains quite low.

Similarly, inference risk of sensitive variables from patient age and sex was minimal for most attributes (Figure 3), with “admission week number” presenting the highest, yet still low, risk (2/1546, 0.12%).

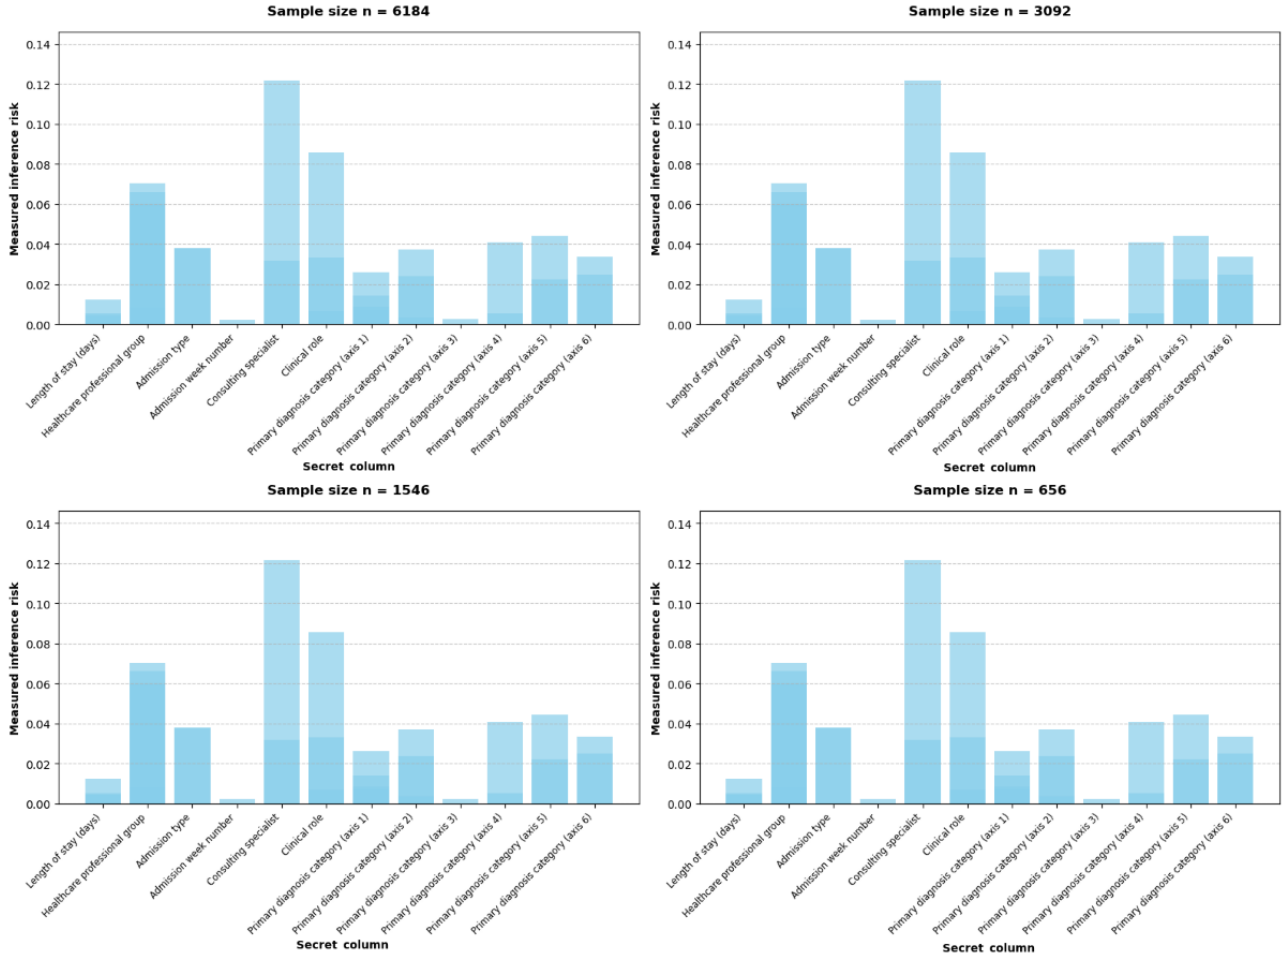
A low percentage, for instance, a range of 0%-5%, indicates that an attacker’s capacity to deduce private details from the synthetic data is only marginally superior to random chance. To contextualize this, if Figure 3 reveals an inference risk of, for example, 2%, it signifies that an attacker possessing auxiliary nonsensitive information (eg, a patient’s age and gender from an external source) would still have only a 2% likelihood of accurately determining a specific sensitive attribute, such as a rare mental health diagnosis, from the synthetic dataset. The low probability demonstrates the robust privacy preservation achieved, reinforcing the suitability of this approach for sensitive health care data.

The results clearly demonstrate the robust capability of the synthetic data to effectively protect individual privacy. The protection is provided by the synthetic data generation process, which creates entirely new, statistically representative data points rather than simply masking or perturbing original records, thereby breaking any direct link to individual patients. As a result, it becomes highly unlikely for an attacker to reidentify specific individuals or uncover private, sensitive details about

XSL•FO
RenderX

patients from the original dataset, even if they possess some auxiliary information. This significantly mitigates risks associated with reidentification or attribute inference attacks, enabling a secure environment for data sharing.

Table 3. Success rate of singling out, linkability, and inference attacks on control data using various synthetic Child and Adolescent Mental Health Services data samples.



Risk type	6184 referrals, n/N (%)	3092 referrals, n/N (%)	1546 referrals, n/N (%)	619 referrals, n/N (%)
Singling out (univariate)[a] success rate	6/1546 (0.38)	6/1546 (0.38)	6/1546 (0.38)	7/1546 (0.43)
Singling out (multivariate)[b] success rate	46/1546 (3)	93/1546 (6)	62/1546 (4)	108/1546 (7)
Linkability[c] success rate	2/1546 (0.13)	5/1546 (0.34)	11/1546 (0.69)	13/1546 (0.84)

[a]Singling out (univariate) represents the percentage of successful attempts to uniquely identify an individual in the synthetic dataset using a single characteristic (based on 500 attacks). Lower values indicate better privacy.

[b]Singling out (multivariate) represents the percentage of successful attempts to uniquely identify an individual in the synthetic dataset using multiple combined characteristics (based on 100 attacks). Lower values indicate better privacy.

[c]Linkability represents the percentage of successful attempts to link synthetic records back to their original real records (based on 2000 attacks and 10 neighbors). Lower values indicate better privacy.

Figure 3. Inference risk.

Synthetic Data Utility Evaluation

The target variable to be classified (intensity of care) in the utility evaluation was highly unbalanced in the real dataset, with 4111/6136 (67%) categorized as low intensity (<15 sessions annually), 2024/6136 (33%) as medium or higher intensity of care (>15 per year). We use the PRAUC metric to compare the predictive performance of machine learning models trained on real CAMHS data versus those trained on synthetic CAMHS data across different input sizes. Given the positive class prevalence of 33%, the random chance baseline (PRAUC baseline) is 0.33. As Table 4 illustrates, increasing sample size consistently improved predictive performance for both real and synthetic data models. In the most data-scarce setting (619 records), the random forest model's ability to classify medium-

XSL•FO
RenderX

or higher-intensity care patients was limited (real data: average PRAUC=0.39; synthetic data: PRAUC=0.32), However, when we increase the training set size to 6184 records, the model performance improved, with the average PRAUC for real data rising to 0.43 (a 30% increase over baseline) and for synthetic data to 0.40 (a 21% increase over baseline) demonstrating that the synthetic data preserves the analytical utility necessary to exceed the random threshold and capture real-world signals.

Our findings suggest that while privacy safeguards around children's data are paramount and often lead to smaller datasets, the value of more data in building accurate and robust predictive tools cannot be overstated. Simply put, the more comprehensive the data, the better equipped the models are to provide meaningful insights that can ultimately support patient care.

Table 4. Comparison of random forest–based prediction models trained on real, tested on real (TRTR) Child and Adolescent Mental Health Services (CAMHS) data alone versus those trained on synthetic, tested on real (TSTR) CAMHS data.

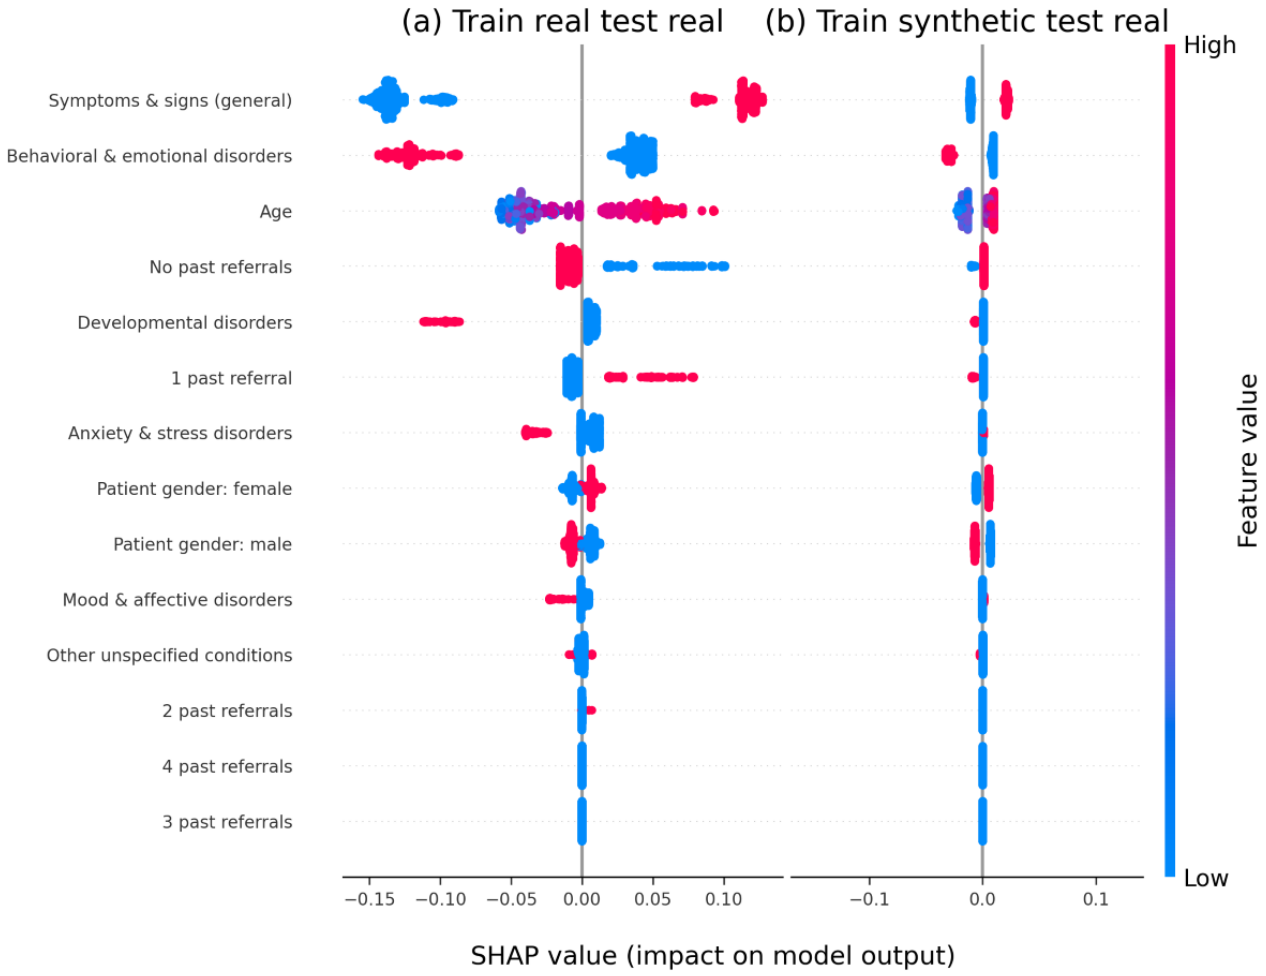
Sample size	TRTR, PRAUC[a] (range)	TSTR, PRAUC (range)
619 referrals	0.39 (0.34-0.44)	0.32 (0.28-0.38)
1546 referrals	0.40 (0.36-0.47)	0.33 (0.29-0.38)
3092 referrals	0.41 (0.37-0.47)	0.34 (0.30-0.39)
6184 referrals	0.43 (0.38-0.49)	0.40 (0.35-0.45)

[a]PRAUC: precision-recall area under the curve.

Reproducibility of Feature Interpretability (SHAP)

SHAP analysis, presented in Figure 4, provides an insight into how different patient characteristics impact the predicted intensity of care, both when the model is trained on real patient data and when it is trained on synthetic patient data.

The model consistently showed that a lower prevalence of "behavioral and emotional disorders" (F90-F98) led to a higher predicted intensity of care. This finding is a clinically meaningful observation rooted in the structure of CAMHS resource allocation; because F90-F98 diagnoses (eg, ADHD, externalizing difficulties) are highly prevalent and typically managed via lower-intensity, first-line support, their presence is not a strong predictor of high-intensity service use. Therefore, the absence of this common, low-intensity diagnosis in a patient referred for complex care suggests the presence of a less common, more severe, or highly comorbid condition that immediately necessitates the allocation of higher-intensity resources [27].



Conversely, a greater presence of "symptoms and signs (general)" (R40-R46) or "developmental disorders" (F80-F89) contributed to a lower predicted intensity of care. Patient age also presented a clear and consistent trend; younger patients were generally predicted to require higher intensity care, while older patients were associated with lower predicted intensity. On the plots, lower values for a feature are typically shown in gray, higher values in black; features increasing predicted intensity extend to the right, while those decreasing it extend to the left.

While the models showed consistent variable impact on the target prediction (intensity of care), we noted a significant difference in the strength of this impact between the synthetic and the real prediction models. The model trained on actual patient data showed a much wider range of impacts from individual features (SHAP values ranging from approximately –0.15 to 0.15), suggesting that real patient characteristics could lead to more pronounced shifts in the predicted intensity of care. In contrast, the model trained on synthetic data displayed a significantly narrower range of influence (approximately –0.03 to 0.03). The "flattening" of the variables' impact on the predicted intensity of care implies that while synthetic data helps the model learn the general direction of how patient characteristics relate to care intensity, it reduces the overall sensitivity of the model to the nuanced, individual variations found in real patient data. This effect, however, can be mitigated by using more advanced synthetic data generation techniques.

Despite the observed reduced variable impact in the synthetic model, the consistency in the direction of SHAP-based explanations remains clinically valuable. It effectively validates synthetic data's ability to capture fundamental predictive patterns in sensitive health care records, making synthetic datasets particularly useful for privacy-preserving exploratory research and facilitating hypothesis generation and validation. While acknowledging the continued need for further efforts to precisely replicate nuanced quantitative impacts for high-stakes clinical predictions, the qualitative fidelity of the result offers an effective tool for initial understanding and safe experimentation in CAMHS health research.

XSL•FO
RenderX

Figure 4. Shapley additive explanations (SHAP) values for intensity of care in (A) train real test real and (B) train synthetic test real models (n=6184).

Synthetic and Real Individual Care Paths

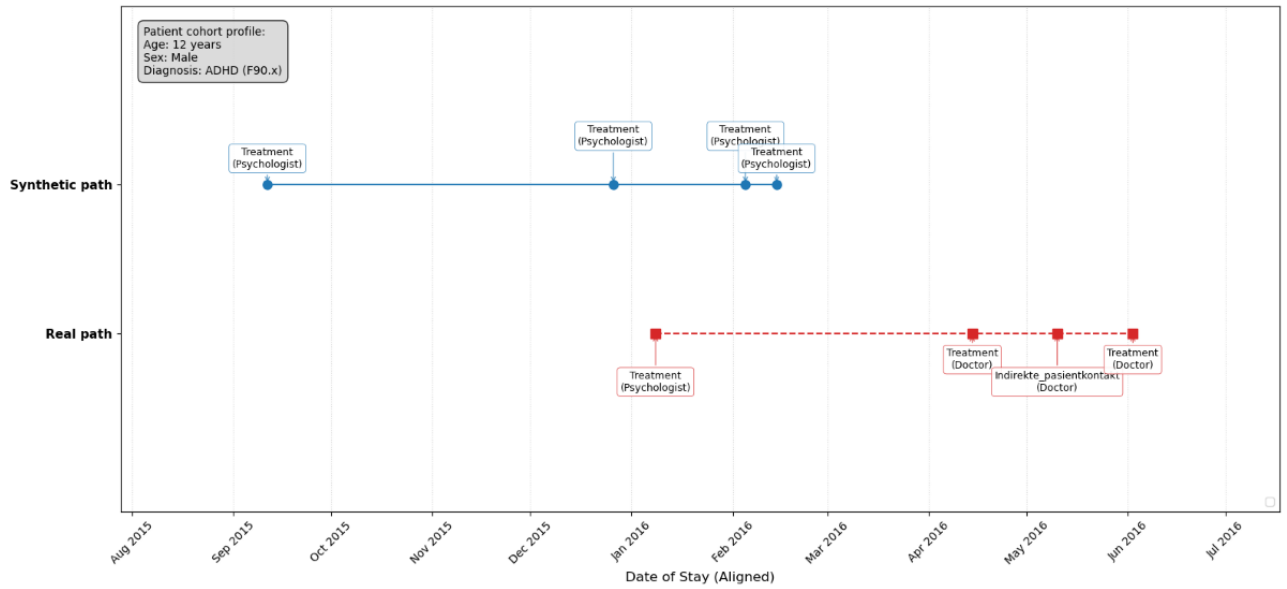


Figure 5 compares 2 distinct care pathways for a 12-year-old male patient diagnosed with "behavioral and emotional disorders" (F90-F98). Both paths are presented on a shared timeline (x-axis) that has been aligned to start at a common point, allowing for direct comparison of event sequencing and density.

The figure serves as a comparative visualization, highlighting potential differences in the flow, types of interventions, and personnel involvement between a synthetic and a more real care path.

While synthetic CAMHS data successfully captures the overarching statistical patterns of the real CAMHS dataset, divergences at the individual patient level offer valuable insights. The differences result from synthetic data representing the most common trajectories, an average derived from the entire dataset that naturally filters out the unique noise and unobserved idiosyncratic factors influencing real-world care. Real CAMHS care is inherently nonlinear and dynamic, shaped by patient responses, unforeseen crises, resource constraints, and patient/family agency. These complexities, including feedback loops and real-world bottlenecks such as waiting lists, are challenging for synthetic data to perfectly replicate at an individual level, leading to the observed divergence.

XSL•FO
RenderX

Figure 5. Comparison of real-like and synthetic care paths for an attention-deficit/hyperactivity disorder (ADHD) patient. The x-axis (Date of stay [Aligned]) shows the progression of time. The y-axis separates the "Synthetic path" (top, solid line) from the "Real path" (bottom, dashed line). Individual markers represent stay events, annotated with stay types and personnel categories. The grey box (top left) indicates shared patient demographics for both trajectories.

Discussion

Principal Findings

This study demonstrates the significant potential of synthetic data to enhance the utility of electronic health care records within CAMHS. Our methodology, using a hierarchical SDG, generated synthetic datasets that exhibited high statistical fidelity to real-world CAMHS data, as confirmed by various quality metrics (KSC/TVC, CS, CSS) and visual density comparisons. While minor quality variations were observed with decreasing sample sizes [28], the results confirm that our approach broadly preserves variable behaviors and dependencies between variables in the generated synthetic datasets [29]. However, identifying the precise minimum real data sample size for generating truly useful and high-fidelity synthetic CAMHS data is complex and highly dependent on the specific research scope and applications.

Models trained on synthetic data demonstrated predictive performance in classifying patient “intensity of care” (low vs medium or higher) that was comparable to models trained on real data. While the absolute predictive power of the model was modest (PRAUC=0.40-0.43 over a 0.33 random baseline), the key finding is the preservation of this utility in the synthetic data, as evidenced by the comparable scores**.**

The SHAP analysis confirmed that the synthetic model’s explainability aligned with real-world insights, underscoring the consistent importance of age and CAMHS diagnosis (eg, anxiety disorders, depression, ADHD, and autism spectrum disorder) in assessing care needs [30,31]. Furthermore, our findings provide strong evidence that synthetic data effectively protects individual privacy. The data generation process makes it highly unlikely for attackers to reidentify patients or uncover sensitive details from the original dataset, a critical requirement given the highly personal nature of CAMHS data.

The implications of high-fidelity, privacy-preserving synthetic CAMHS datasets are profound for children and adolescent mental health research and practice. Their availability removes critical barriers to data sharing and collaborative research, enabling more thorough investigations into mental health aspects across diverse populations [32], especially for vulnerable ones like those served by CAMHS. This capability facilitates a deeper understanding of mental disorder patterns and contributes to the development of more effective, personalized treatment methodologies [33]. Moreover, given that young adolescents often withhold important information from health care providers due to privacy concerns, which hinders effective diagnosis and treatment [34], synthetic data allows researchers to explore critical questions that would be impossible with real, incomplete data. These include understanding the impact of stigma on treatment adherence, evaluating novel personalized interventions, investigating the influence of “hidden” family dynamics, and simulating the effects of systemic barriers on access to care for vulnerable groups.

Furthermore, maintaining highly accurate long-term temporal and sequential relationships across numerous event types remains challenging in synthetic data generation. Most synthetic data quality metrics prioritize aggregate statistical properties over the exact fidelity of unique individual sequences. This means a synthetic dataset can be excellent at the population level but still show microlevel divergence in individual trajectories. Despite these differences, the divergence is valuable. It highlights that synthetic data, while not predicting exact individual pathways, excels at understanding general care models, developing system-level interventions via cohort simulations, and creating privacy-preserving case studies for training. It effectively complements the detailed study of highly personalized real-world clinical journeys.

Future Work

To improve upon the findings of this investigation, future research can focus on enhancing the synthetic data generation process. Conditional generative models, such as variational autoencoders [35] and generative adversarial networks [36], could be trained to produce synthetic data that reflects specific referral reasons or treatment modalities, conditioned on existing basic patient information. These advanced models are adept at learning complex data distributions, leading to higher-quality and more diverse synthetic outputs, which are crucial for capturing the varied presentations within CAMHS.

Beyond static data generation, further research can also explore integrating synthetic data with process mining techniques to enhance the modeling of complex care sequences. Specifically, synthetic process mining offers a powerful avenue for generating and analyzing event logs that mimic real patient journeys, but with full privacy control [37]. This would enable the creation of highly detailed, longitudinal synthetic care pathways, allowing researchers to simulate and analyze "what if" scenarios for process optimization without touching real patient data (eg, assessing the impact of adding a new therapy step or reducing wait times on patient flow). Furthermore, synthetic process mining could also generate diverse and comprehensive training data for predictive models focused on patient trajectories and outcomes, especially for rare events or complex multistage interventions where real CAMHS data are scarce or incomplete. This capability would significantly advance our understanding of care delivery dynamics and improve operational efficiency in CAMHS, ultimately benefiting young people awaiting and receiving support.

Limitations

It is important to recognize that our dataset had limitations in terms of clinical parameters. Our analysis revealed modest predictive power in the classification model (PRAUC approximately 0.43 on real data and 0.40 on synthetic data), necessitating caution in interpreting the absolute predictive accuracy. While the primary goal of this work was to establish the comparable utility between the synthetic and real datasets—which the similar PRAUC scores confirm—the absolute performance remains constrained. This constraint is likely attributable to 2 factors: severe class imbalance in the target variable (necessitating the aggregation of the rare high-intensity category into the 33% positive class) and the inherently limited, aggregated feature set available from administrative EMR. These limitations emphasize that the model should not be used in isolation for clinical prediction but rather that the synthetic data successfully preserves the utility inherent in the original feature space.

Furthermore, our dataset had limitations in terms of clinical parameters. Although we had access to basic data such as sex, age, and clinical primary diagnosis, our dataset lacked detailed information on the specific reason for the referral and the amount of additional care (eg, medication, group sessions, art therapy, physical therapy, and sheltered workshop). These clinical details are crucial for accurately assessing and classifying service intensity. The absence of these detailed clinical parameters may have impacted the accuracy of our analyses and the general applicability of our findings to a broader clinical context. Future research will benefit from a more comprehensive dataset that includes these key clinical parameters.

Regarding fairness evaluation, Norway's highly inclusive public health care system inherently minimizes selection bias. However, we acknowledge the potential for underrepresentation of underserved minorities and rare diagnoses. These issues can be effectively addressed by augmenting the data with synthetic samples of these specific groups and applying fairness measures tailored to the analytical goals of research aimed at serving these minority populations. While the methodology for creating synthetic CAMHS data is highly generalizable across different data environments and health care systems, it is crucial to recognize that the interpretation and applicability of findings derived from such synthetic data would always need to be contextualized within the specific health care system from which the original data was sourced. This underscores the need for localized validation and careful consideration of systemic differences when applying research findings across international borders.

Conclusions

This study provides evidence that synthetic data can be generated from CAMHS EMR that achieves a favorable balance between utility and privacy. The main findings confirm that the hierarchical synthetic data model produces datasets with high statistical fidelity and comparable predictive utility to real data, while simultaneously demonstrating a reduced risk of patient reidentification. This pilot study suggests that synthetic data, developed from standard EMR clinic records, offers a method compliant with HIPAA and GDPR regulations, facilitating clinical and administrative research that was previously unattainable. This advancement creates critical new opportunities for CAMHS research to progress despite confidentiality restrictions.

Acknowledgments

We gratefully acknowledge the invaluable help of the Individualized Digital Decision Assist System project, BUP Helse Stavanger, and Helse Vest IKT, Synnøve Olset, for bringing the collaborators together and providing valuable feedback in preparing this manuscript.

The authors confirm that generative artificial intelligence tools, specifically Gemini by Google, were used for three specific and limited purposes during the preparation of this manuscript and the revision process:

XSL•FO
RenderX

1. Language polishing: minor language refinement and grammatical correction throughout the manuscript text to improve readability and flow.

2. Structural drafting: generating the initial structural outline for the author's response emails to the academic editor during the peer-review process.

3. Content generation: generating the visual representation for Figure 5, based on the data and themes analyzed in this study. The authors take full responsibility for the content, integrity, and scientific accuracy of the research presented.

Data Availability

The underlying dataset can be shared upon reasonable request after signing a data transfer agreement with the receiving institution to ensure the protection of personal information. The code underlying these analyses is available from GitHub [38].

Multimedia Appendix 1
Entity-relationship diagram of the patient data schema. This diagram illustrates the relationship between the "referral" and "stay" entities, detailing the attributes and their data types (ID, datetime, numerical, categorical) for each, along with their respective primary and foreign keys.
[PNG File , 41 KB - medinform_v14i1e71819_app1.png]

Multimedia Appendix 2
Synthetic generation process. We used a constant input for the synthetic data generator HMSynthetiser (ie, a fixed subsample from the real dataset) to output 4 different synthetic CAMHS data. The similarity between each of the datasets was compared to the real training data by performing KSC/TVC, CS, and CSS metrics via the SDMetrics Python package.
[PNG File , 60 KB - medinform_v14i1e71819_app2.png]

Multimedia Appendix 3
Privacy evaluation. The Main attack (1) uses synthetic data to create a series of guesses. Anonymeter evaluates (2) these guesses by comparing them to the values present in the original dataset, to assess the effectiveness of the attack. Anonymeter requires the adversary to conduct the same attack on a control dataset (control attack), which consists of records that were not utilized in the generation of the synthetic data. Any insights the attacker gains regarding the control records from the synthetic dataset cannot be linked to privacy violations, as the design ensures that no information from the control dataset is incorporated into the synthetic dataset. By contrasting the success rates of the attack on both training records and control records, a sensitive measure of risk (3) is calculated.
[PNG File , 35 KB - medinform_v14i1e71819_app3.png]

Multimedia Appendix 4
Train synthetic test real. To evaluate model efficacy, the train synthetic test real (TSTR) approach was used. Two machine learning models were developed: one trained on real data and the other on synthetic data, both targeting patients with referral duration under 18 months to predict Child and Adolescent Mental Health Services (CAMHS) care intensity across three categories: fewer than 15 sessions, 15 or more sessions annually. The latter two categories were combined due to low occurrence of high intensity. Model performance was assessed using a 20% test subset from the real dataset, allowing comparison of synthetic and real data effectiveness. SHAP values were computed to analyze feature significance.

Abstract

Background: Many studies have evaluated the use of wearable monitoring systems to improve patient safety in hospital. Although some have demonstrated effects on intensive care admissions, there remains little evidence of impact on patient outcomes such as mortality, hospital length of stay, and time to antibiotic administration. Very few studies have focused on how wearable monitoring systems are used in clinical practice, including how the rate of manual vital sign measurements (MVSMs) is affected.

Objective: Our primary aim was to describe the physiological pattern of vital signs in hospitalized patients treated for COVID-19 outside of critical care. We also report an exploratory post hoc analysis of the impact of displaying wearable monitoring system data on the frequency of intermittent MVSMs.

Methods: We conducted a retrospective study during the COVID-19 pandemic following deployment of a wearable monitoring system that continuously displayed heart rate, respiratory rate, and oxygen saturation levels. We included patients treated for COVID-19 in 3 isolation wards in a large UK hospital. Wearable monitoring system data were displayed on a dashboard in the center of each ward. We analyzed the patterns of vital signs in patients monitored using the wearable monitoring system. We compared the time to next observation (led by nursing staff) for routinely collected MVSMs between periods when patients were continuously monitored and those when they were not. In exploratory post hoc analysis, we tested whether the difference varied between stable (early warning score [EWS] above the escalation threshold) and unstable patients.

Results: Patients (N=144) had continuous vital signs above the EWS threshold for escalation for 32.7% (2133/6528) of time monitored. The unadjusted median time between MVSMs for continuously monitored periods was 39 minutes (95% CI 29-49; $P<.001$) longer than for unmonitored periods. When adjusted for EWS category and participant-level clustering, the effect was attenuated but remained significant (14.6 minutes; $P<.001$). In exploratory post hoc analysis, we found that increases were larger during stable observation periods (51 minutes, 95% CI 39-62; $P<.001$) than during unstable periods (16 minutes, 95% CI 8-24; $P<.001$). However, adjusted analyses did not support a significant difference between stable and unstable periods.

XSL•FO
RenderX

Conclusions: Patients in this study were at elevated risk of deterioration, spending a third of monitored time at or above the escalation threshold. We found that, by offering additional vital sign data between manual measurements, the time between routine MVSMs increased, which may reflect changes in nursing task prioritization. Although patient safety outcomes were not directly measured, we found no indication that reducing observation frequency adversely affected patient safety.

Introduction

Background

Among patients in the United Kingdom hospitalized with COVID-19 during the pandemic, 42% required ventilatory support or high-dependency or critical care or died in hospital [1]. Therefore, patients diagnosed with COVID-19 managed in hospital wards required close monitoring of vital signs to ensure that deterioration was identified promptly and care was escalated appropriately. In usual care, patients at high risk of deterioration are placed in high-visibility areas of the ward so that nurses can observe them closely. However, due to the elevated risk of COVID-19 transmission both to other patients and staff, patients were often cared for in single isolation rooms or closed cohort bays [2]. Isolation, plus the time required by staff to don personal protective equipment (PPE), posed challenges to the close observation required to ensure the safety of these patients who are acutely ill.

Continuous monitoring of vital signs using wearable devices has long been recognized as having the potential to detect deterioration earlier than intermittent measurements [3-5]. Early in the pandemic, it was recognized that patients diagnosed with COVID-19 had elevated respiratory rates and rapidly worsening oxygen saturation levels that required high levels of supplemental oxygen [6]. As a result, the use of wearable vital sign monitoring escalated, with devices commonly used to allow low-risk patients to be managed at home [7].

At the start of the COVID-19 pandemic, we were close to completing development of a wearable system for the continuous monitoring of heart rate, respiratory rate, and oxygen saturation in hospital wards as part of a research project. Multiple phases of development had been completed that assessed the wearability, accuracy, and reliability of the wearable devices and system [8-10]. Given the concerns about maintaining patient and staff safety in wards with patients with COVID-19, it was clear that this system had the potential to support local clinical care in wards receiving patients with COVID-19. Implementation was therefore accelerated, and the system was deployed in a ward in late March 2020, the day on which the United Kingdom first entered lockdown, with the aim of supporting nurses in managing these high-risk patients.

Although wearable monitoring is increasingly being used in ward-based care internationally to support patient safety [3], little is known about the mechanism of impact [5]. Studies to date have focused on improving patient safety–related outcomes (such as in-hospital mortality and length of stay) [3], whereas studies of staff and patient views of wearable monitoring system (WMS) use have focused on safety and reassurance [11-13]. The presence of WMSs alone cannot improve patient outcomes, and the impact of WMSs on nurse behaviors related to vital sign monitoring is not well understood [5].

Aim

The primary aim of this retrospective data study was to describe the physiological pattern of vital signs over the course of SARS-CoV-2 infection for hospitalized patients outside of critical care. In this paper, we also report a post hoc analysis exploring the impact of displaying data from the WMS on the timing of nurses recording intermittent manual vital sign measurements (MVSMs).

Methods

The system was implemented into usual care as part of a local service evaluation (Datix: 5973). Following deployment of the system, we sought approval to conduct a retrospective data study linking continuous vital sign data from wearable monitoring with early warning score (EWS) values from the electronic patient record (EPR) and limited outcome data, which were then pseudonymized and extracted from the hospital's EPR (Cerner Millennium [14]).

Setting

The service evaluation was undertaken in an isolation ward with 19 side rooms and two 24-bed medical wards where patients with COVID-19 were cohorted in open bays within a large tertiary referral hospital in the United Kingdom.

Participants

We included all patients diagnosed with COVID-19 (confirmed via laboratory polymerase chain reaction test) and remotely monitored at any point during their stay in 1 of the 3 wards where we deployed the wearable system between March 23, 2020, and February 28, 2021.

Vital Signs Monitoring

Intermittent EWS Measurements

During the service evaluation period, a locally developed EWS was used [15,16]. According to local policy, based on national guidance at the time (prior to implementation of the National Early Warning Score 2), patients with an EWS of 0, 1, or 2 required observations every 4 hours. For a score of 3 or more, the frequency of observations was increased to hourly measurements. Vital sign measurements taken intermittently by nurses were obtained using their usual ward equipment and

XSL•FO
RenderX

recorded in an electronic device that transferred data to the EPR for each patient [17].

Wearable Monitoring System

We published the technological aspects of the system previously [18]. The WMS consists of a chest-worn patch monitoring heart rate and respiratory rate (VitalPatch; VitalConnect) and a wrist-worn pulse oximeter measuring pulse rate and peripheral oxygen saturation (SpO_2; Nonin WristOx2 3150). Both devices were connected via Bluetooth Low Energy to a bedside Android Samsung Galaxy Tab A (2016). Partial EWSs were calculated every 5 minutes for the continuous wearable data by adding the individual scores for heart rate, respiratory rate, and SpO_2 obtained by computing the 5-minute medians for each of these variables.

The WMS was developed as part of a research project following extensive wearability, functionality, and usability testing [3,9,18] leading to selection of the most reliable, wearable, and accurate devices. Selection of the pulse oximeter device was supported by reliability testing, including hypoxia testing, which identified extensive variability in accuracy between several devices. The device finally selected for the WMS was found to underestimate SpO_2 values by up to 2% [9]. However, it was assessed as the most reliable device as it under- rather than overestimated oxygen saturation (deemed to be safer in clinical practice) and was the most reliable in terms of connectivity and usability. This potential underestimation of oxygen saturation was conveyed to staff during training in the use of the system.

Table S1 in Multimedia Appendix 1 shows the sources of each vital sign recorded by the WMS and the intermittent nurse observations. The levels of agreement between these 2 sources of vital sign data, presented in Figures S1-S4 in Multimedia Appendix 1, reflect measurements obtained under routine ward conditions, including patient movement and intermittent removal or adjustment of oxygen interfaces at the time of nurse observation, rather than a controlled validation setting.

Staff Interface

Continuous vital sign data were transmitted in real time from the Android tablet to an in-hospital server installation via Wi-Fi. A user interface displayed real-time and time-stamped 5-minute median estimates of heart rate, respiratory rate, and SpO_2 (as well as the 1-lead electrocardiogram and photoplethysmogram waveforms) and corresponding partial EWSs alongside intermittent vital sign measurements recorded by the nursing staff and the corresponding overall EWS. The interface used a "traffic light" scheme in displaying these data, with individual cards highlighted in green (EWS of 0), amber (EWS of 1-2), and red (EWS of ≥3) according to the calculated partial EWS from wearable monitoring. This was displayed on dedicated desktop screens at the central nurses' station in each ward. No audible or visual alerts were implemented. The user interface was also viewable on other devices (using log-in credentials) by research and clinical staff. In total, 20 sets of wearable monitoring equipment were available to staff in the 3 wards, and monitoring use was based on the clinical judgment of the nursing staff.

Data Extraction and Management

Pseudonymized data were retrospectively extracted from the local National Health Service (NHS) hospital data warehouse by hospital employees and associated with the wearable data via a link table (mapping local record numbers to system identifiers) after applying the NHS digital data opt-out service. All data were stored on a secure hospital server for analysis and only accessible within the hospital network.

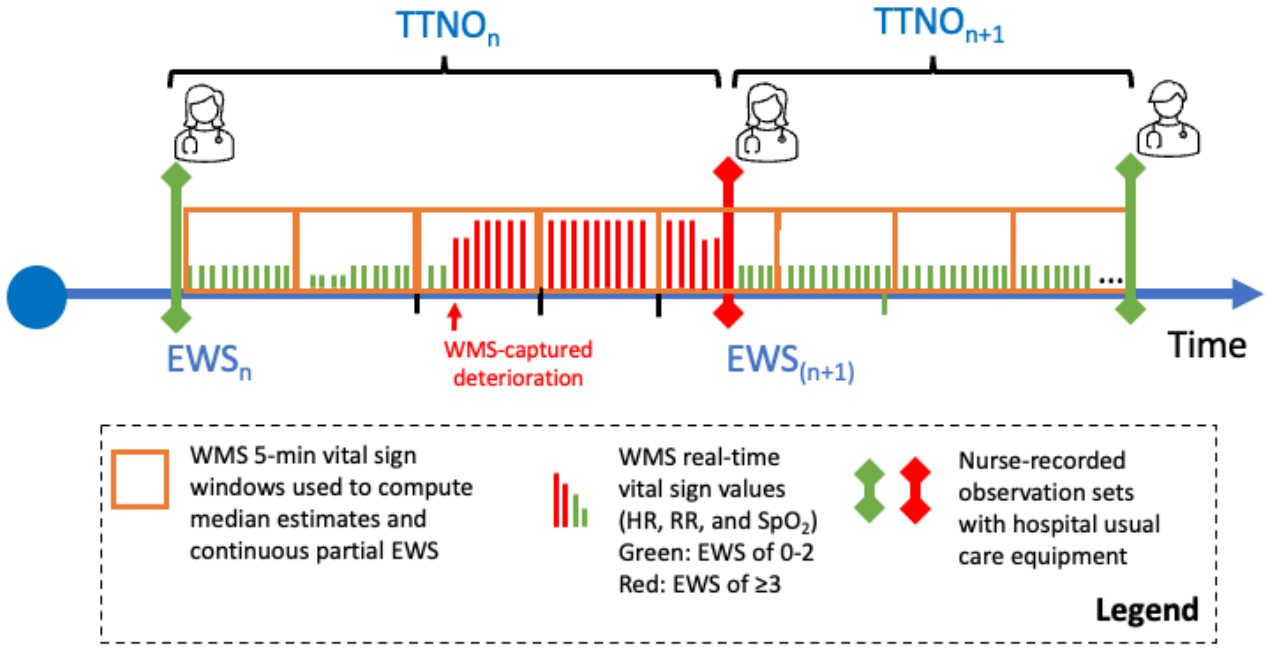
Data extraction was limited to the following variables:

- Patient demographics (age and sex)
- Ward admission and discharge time stamps
- Intermittently measured vital sign values, corresponding EWSs, and time stamps
- Outcome data, including in-hospital death, admission to the intensive care unit (ICU), and cardiac arrest call

Extracted data were limited to the duration of hospital admission. There was no follow-up, and study duration ended at death or hospital discharge.

All patients had periods without continuous monitoring data before and/or after being on the WMS. These data were split into 2 datasets: periods A (periods without wearable monitoring data—"unmonitored periods") and B (periods during which wearable monitoring data were recorded—"monitored periods"). Therefore, the 2 datasets were generated from the same cohort of patients. Given the retrospective design, it was not possible to access intermittent vital sign data from a nonmonitored cohort of patients.

Patients with no monitoring data were not included in the analysis. Once a patient was considered to have been monitored using wearable devices, data availability was calculated as the percentage of at least one vital sign value being received within a 5-minute interval between the first and last wearable data point received.



Analysis

Time to Next Observation

The time to next observation (TTNO) was defined as the time interval in minutes between 2 consecutive nurse-led recorded observation sets (EWS_n and EWS_{n+1}; Figure 1). We compared the TTNO between periods A (unmonitored periods) and B (monitored periods) and between subgroups of "stable" (EWS of 0-2) and "unstable" (EWS of ≥3) periods, reporting the median and 95% CIs.

XSL•FO
RenderX

Figure 1. Visualization of time to next observation (TTNO) and wearable data capture. EWS: early warning score; HR: heart rate; RR: respiratory rate; SpO2: peripheral oxygen saturation; WMS: wearable monitoring system.

Distribution of TTNO Values

Distribution of TTNO values was split into quartiles and compared between periods A (unmonitored periods) and B (monitored periods). To explore the potential safety impact of monitoring, we compared the change in EWS between consecutive nurse observations when nurse observation was much later than expected (within the highest quartile [fourth] of the TTNO distribution) for unmonitored periods vs monitored periods.

Only complete sets of intermittent vital sign measurements from nurse observations (heart rate, respiratory rate, SpO_2, blood pressure, and temperature) were included in the analysis. We excluded all EWS_{n+1} sets with a TTNO of less than 10 minutes as we assessed that the nurse was unlikely to have left the isolation room between 2 sets of measurements so close in time. We excluded EWS_{n+1} sets with a TTNO of 900 minutes or more as this indicated that the patient had left the ward for a prolonged period (ie, transferred from and subsequently readmitted to the ward).

Statistical Analysis

Statistical analysis was conducted using Python (Python Software Foundation) and R software (R Foundation for Statistical Computing). Medians, IQRs, and normalized histograms (Seaborn version 12.1 [19]) were used to compare the TTNOs between the unmonitored and monitored periods. Bootstrap with replacement (n=5000) was used to compute 95% CIs. The Mann-Whitney *U* test was used to determine significance ($P<.05$) between skewed distributions. The *z* test was used to determine significance ($P<.05$) between normal distributions (confirmed using the Shapiro test).

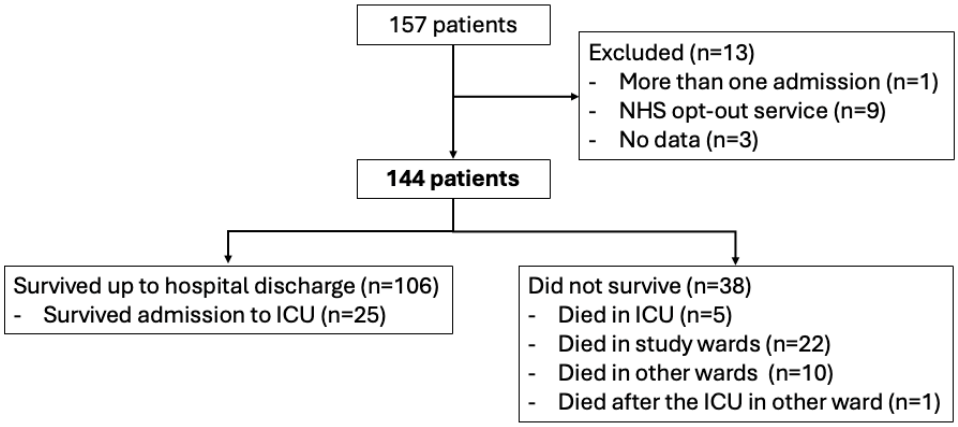
Using the GAMLSS library (version 5.4.3) [20], the following mixed effects model was applied to test for the effect of the monitoring period on the TTNO (in Wilkinson notation): $TTNO_n \sim EWS_unstable_n + monitoring_period_n + (1|participant)$, where $TTNO_n$ is the TTNO from the current observation set *n*, $EWS_unstable_n$ is a binary variable with a value of 1 if the EWS for the current set of observations *n* (which drives the TTNO) was equal to or above 3 and 0 otherwise, and $monitoring_period_n$ is a binary variable with a value of 1 if the patients were monitored using the wearables at the time of the set of observations *n* (both variables modeled as fixed effects). Random effects were considered for each participant (1|participant), indicating that the model includes a random intercept for each participant. We assumed a normal distribution for the random effects and error term. Sensitivity analyses using gamma and log-normal mixed models were performed to assess the impact of skewness. An α value of .05 was used to assess the significance of the effect of wearable monitoring ($monitoring_period_n$). As a robustness check, the model was also re-estimated treating EWS as a continuous variable rather than a binary variable. An interaction between clinical stability and monitoring period was also explored as an additional analysis.

WMS-recorded EWS trajectories were summarized relative to normalized hospital length of stay (0%-100%) to mitigate confounding introduced by variable lengths of stay and to align patients by comparable phases of hospitalization or relative to normalized wearable monitoring time to align trajectories by comparable phases of monitoring regardless of monitoring duration. Trajectories indexed to relative monitoring time should be interpreted with caution as varying monitoring durations may introduce survivorship and compositional biases at later time points, where fewer patients contribute to the estimates. At each relative percentage point, the mean of the maximum EWS values from all contributing patients was calculated to generate group-level trajectories. The 95% CIs were estimated

XSL•FO
RenderX

using nonparametric bootstrap resampling. WMS-recorded EWS trajectories were also compared between patient subgroups defined as wave 1 (patients monitored between March 2020 and August 2020) and wave 2 (patients monitored between September 2020 and February 2021) [21]. Analyses were descriptive and intended to characterize patterns of EWS trajectories across patient groups.

Ethical Considerations



As this was a retrospective data study that did not use any identifiable data, Health Research Authority approval was sought and granted (12/HRA/1234), and the study was registered (ISRCTN 85624923).

Results

Overview

A total of 157 unique patients were monitored using the WMS between March 23, 2020, and February 28, 2021, with data on 144 (91.7%) patients available after exclusions were applied (Figure 2). There were no missing outcome data from included patients. The median age was 62.5 (IQR 47-77) years, and 29.9% (43/144) of the patients were female. The age distributions of patients admitted during waves 1 and 2 are shown in Figure S5 in Multimedia Appendix 1. Of the 144 patients included in the analysis, 97 (67.4%) were admitted to side rooms in an isolation ward, and 47 (32.6%) were admitted to cohorted bays in 2 medical wards.

Figure 2. Patient cohort flow diagram. ICU: intensive care unit; NHS: National Health Service.

Trajectory of Illness and Pattern of Vital Signs During SARS-CoV-2 Infection

Of the 144 patients available for analysis, 38 (26.4%) died during their hospital admission, 31 (21.5%) were admitted to ICU, and none had a cardiac arrest call. The duration of hospital stay ranged from 0.7 to 141.9 (median 8.9, IQR 5.6-19.8) days. The wearable monitoring period ranged from 0.15 to 440.2 (median 35.5, IQR 9.23-97.02) hours. Once a patient was placed on wearable monitoring, the median data availability was 88.5% (IQR 71.95%-98%). A total of 11,634 intermittent EWSs were recorded. During wearable monitoring, patients had continuous vital sign values that exceeded the EWS escalation threshold for 32.7% (2133/6528) of the total hours. The maximum intermittent EWS recorded was 17. The maximum continuous/partial EWS recorded was 9. The median maximum continuous/partial EWS for the duration of waves 1 and 2 was 3 (IQR 2-4) and 2 (IQR 1-4), respectively. Additional graphs showing the patterns of vital signs based on patient outcome and pandemic wave can be found in Multimedia Appendix 2.

TTNO Results

For all data, the median increase in TTNO for monitored periods was 39 minutes (95% CI 29-49; *P*<.001; Table 1) longer than unmonitored periods. Figure 3 compares the distribution of TTNO values for these 2 periods, with the median values reported in Table 1 for the EWSs of all patients. Figure 3 shows that the 120-minute peak in TTNO for unmonitored periods was not present in monitored periods.

For stable periods (EWS of 0-2), the increase in median TTNO during monitored periods was 51 minutes (95% CI 39-62; *P*<.001) compared with unmonitored periods (Table 2). For unstable periods (EWS of ≥3), the increase in median TTNO during monitored periods was 16 minutes (95% CI 8-24; *P*<.001; Table 2).

Table 1. Comparison of median times to next observation (TTNOs) with and without wearable monitoring for all the early warning scores (0-17) of all patients.

	TTNO[a] (min), median (IQR; 95% CI)	Difference (monitored – unmonitored; min; 95% CI)	*P* value
EWS of 0-17		+39 (29-49)	<.001
Without wearables (n=8866 TTNOs)	159 (101-275; 155-163)		
With wearables (n=1963 TTNOs)	198 (109-326. 190-208)		

[a]Reported sample sizes exclude TTNO values of less than 10 minutes or of 900 minutes or more, as described in the Methods section.

Figure 3. Normalized histogram of time to next observation (TTNO) values for all patients with and without wearable monitoring.

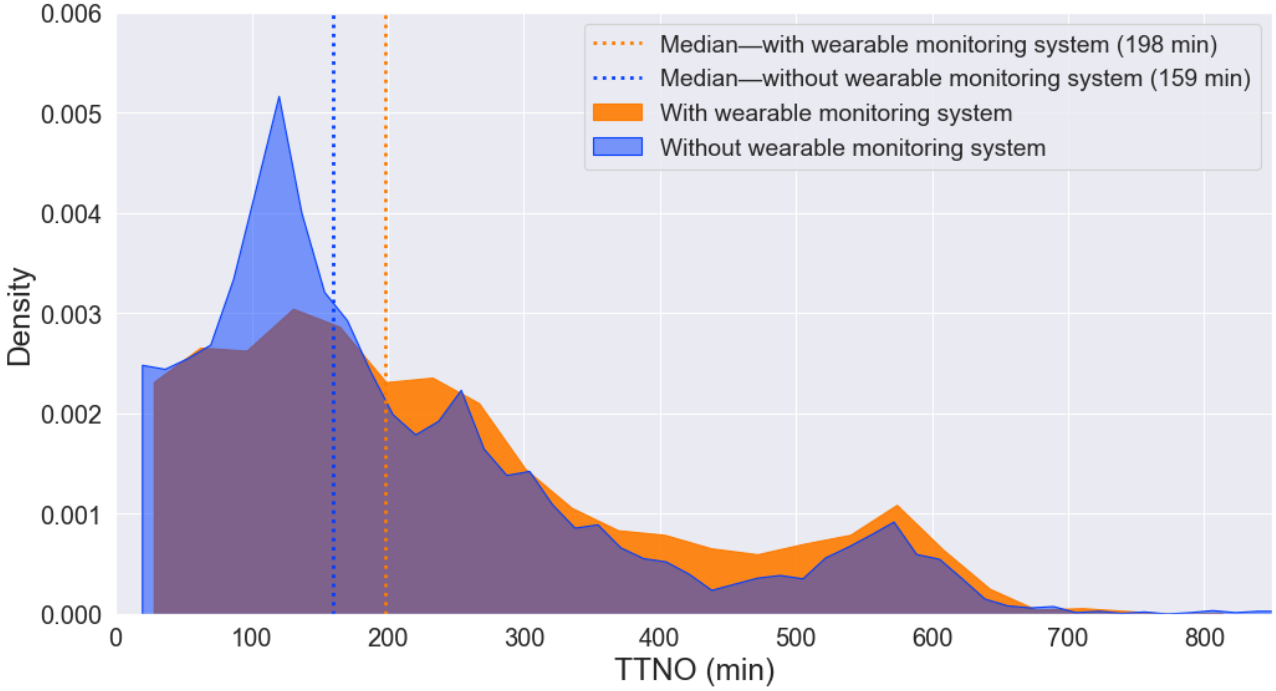

Table 2. Comparison of median time to next observation (TTNO) with and without wearable monitoring for stable periods (early warning score [EWS] of 0-2) and unstable periods (EWS of ≥3).

	TTNO[a] (min), median (IQR; 95% CI)	Difference (monitored – unmonitored; min; 95% CI)	*P* value
EWS of 0-2		+51 (39-62)	<.001
Without wearables (n=6043 TTNOs)	187 (116-310; 182-192)		
With wearables (n=1240 TTNOs)	238 (146-386; 228-248)		
EWS of ≥3		+16 (8-24)	<.001
Without wearables (n=2823)	123 (74-193; 120-126)		
With wearables (n=723)	139 (76-239; 131-146)		

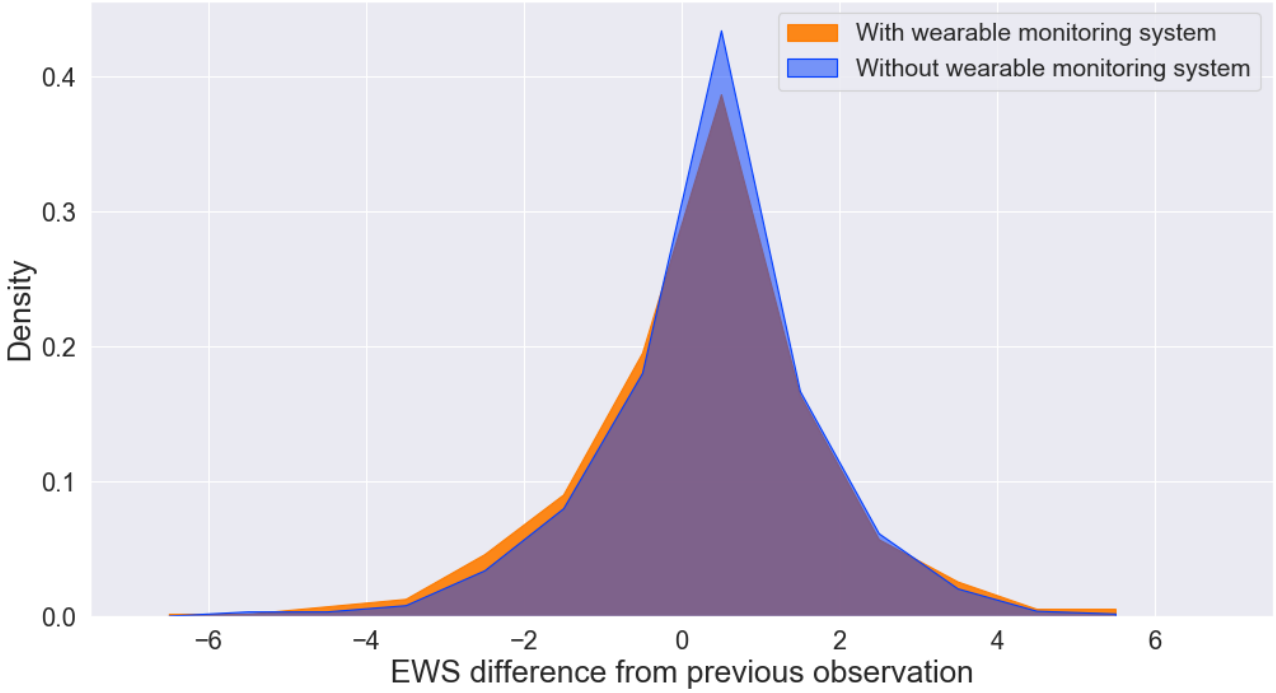
[a]Reported sample sizes exclude TTNO values of less than 10 minutes or of 900 minutes or more, as described in the Methods section.

Mixed Effects Model

The mixed effects model results for all patients (Table 3) show that both the use of wearable monitoring and unstable EWS periods were statistically significant (*P*<.001 for both terms) in association with TTNO. When adjusting for EWS category and participant-level clustering, the effect was attenuated but remained significant (14.6 minutes; *P*<.001). Re-estimating the model with EWS treated as a continuous variable showed similar results (*P*<.001 for both terms). Sensitivity analyses using gamma and log-normal mixed models showed consistent results in terms of direction and statistical significance. There was no evidence of interaction between clinical stability and monitoring period (*P*=.35), indicating that the effect of wearable monitoring on TTNO did not differ significantly between stable and unstable observations.

Table 3. Impact of early warning score (EWS) and monitoring period on the time to next observation for all EWSs (current observations)a.

	Fixed-effect coefficient (SE)	*t* test	*P* value
Intercept	239.043 (1.822)	131.234	<.001
Unstable EWS (≥3)	−83.129 (2.995)	−27.757	<.001
Wearable monitoring period	14.634 (3.648)	4.011	<.001



[a]Coefficients represent fixed effects from the GAMLSS model. *t* values are calculated as the ratio of the coefficient to its SE, and *P* values are based on asymptotic inference. Residual for the fitted model were 10707.9.

Impact of Delayed Vital Signs Measurements

Figure 4 compares normalized score differences in EWS in the fourth quartile of TTNO for periods A (unmonitored periods: 275-898 minutes) and B (monitored periods: 326-830 minutes), demonstrating little difference between them (P=.92).

Figure 4. Normalized histogram of early warning score (EWS) differences between the current and previous set of observations for times to next observation within the fourth quartile.

Discussion

Principal Findings

Overview

In this retrospective data analysis study of a large dataset of 11,634 vital signs measurements, we mapped the trajectory of vital signs during SARS-CoV-2 infection. We found that this cohort was acutely unwell, with almost a third of the continuous monitoring duration at or above the threshold for escalation and a very high peak of nurse-recorded EWSs at 17. This is reflected in the outcomes for this patient group, with 26.4% (38/144) of patients dying in hospital and 21.5% (31/144) admitted to intensive care.

TTNO Measurement

Our post hoc analysis suggests that the availability of continuous patient monitoring data using clinical-grade wearables enabled a change in nurse behavior. Nursing staff increased the time they took before they returned to a patient to make the next set of observations by 39 minutes (P<.001) in unadjusted analysis. The effect was attenuated but remained significant (14.6 minutes; P<.001) when adjusted for EWS category and participant-level clustering. This would indicate that the nurses trusted the vital sign data acquired by the wearable system, which enabled them to monitor patients remotely using the live data and 5-minute median summaries of heart rate, respiratory rate, and SpO_2 shown on the desktop screen at the central nurses' station. Figure 3 suggests that nurses returned to observe patients for whom they had a concern within 120 minutes during unmonitored periods but did not do so during monitored periods, suggesting that wearable monitoring may have provided reassurance that the patients' condition was unchanged. This reduced entries to the isolation rooms, minimizing risks of exposure to the virus and saving nurse time in donning and doffing PPE.

Impact on Patient Safety

Although our data show that the TTNO after an EWS of 3 or more was mostly longer than the protocolized 60 minutes (median of 123 and 139 minutes without and with wearables, respectively), this delay in hourly observation measurements is recognized as a common feature in both pandemic and nonpandemic conditions [22,23], with compliance as low as 30% [24]. Multiple barriers have been identified that contribute to these delays, which are likely to have been worsened in the context of the pandemic [25].

There was no difference in the EWS distributions (P=.92; Figure 4) for the times with wearable monitoring and those without it evaluated on the fourth quartile of TTNO distribution as this represents the longest intervals between consecutive observations. Figure 3 shows that, proportionally, there were many more instances of increased TTNOs during the monitored periods (WMS in use) with respect to the unmonitored periods (no WMS). Figure 4 provides some reassurance that this difference was not associated with increased physiological instability (increase in EWS with respect to the previous observation). However, this finding should be considered in the context of our exploratory observational study design. This was also identified in our parallel qualitative study of staff use of the system [26]. Interviews with multi-professional staff demonstrated that the WMS afforded reassurance that the patient

XSL•FO
RenderX

was stable between vital sign observations, allowing nurses to manage their workload as they felt appropriate. Although this perceived prioritization was reflected in the exploratory TTNO analyses, with larger TTNOs during stable periods than during unstable periods (+51 vs +16 minutes; *P*<.001 for both; Table 2), adjusted analyses did not demonstrate a significant difference between stable and unstable periods.

Similar to other work [27], we have shown that episodes of moderate and severe vital sign deviations in hospitalized patients with COVID-19 are common. Without continuous monitoring, detection of deterioration may be delayed until the next set of nurse observations as no additional vital sign data are available. Continuous SpO_2 monitoring can be considered an easily applicable tool for the early recognition of patients with the potential for acute respiratory deterioration. The wearable data values and associated EWSs were updated every 2 seconds on the desktop screen (for multiple patients in parallel in the real-time dashboard view), and their trends, updated every 5 minutes using the vital sign medians, were stored and could be reviewed at any time (patient chart view). The lack of visual and audible alerts, apart from the EWS traffic light color scheme for its display on the desktop screens, did not allow us to know whether the nurses were observing the screen when deterioration set in.

Our finding that, during monitored periods, TTNO could be extended suggests that wearables may help nurses with clinical time management. Any changes resulting from the implementation of a WMS would also need to be reflected in the approach to vital signs measurements in standard care, for example, in the frequency of observations for stable patients.

Several barriers to the successful in-hospital deployment of clinical-grade wearable technologies on a larger scale are still to be overcome, including cost, reliability, efficiency, and the use of data processing systems [3,5,28]. In future work, the use of the National Early Warning Score 2 scoring system, adopted nationwide in the United Kingdom from April 2021, after the data reported in this paper were acquired, would provide more generalizable results, with a broader understanding and easier applicability.

Strengths and Limitations

The prospective registration and the use of a rigorously developed unique WMS are strengths of this study. However, there are limitations that should be considered. Although we report a novel analysis that has the potential to advance our understanding of the impact of WMSs on nurse behavior, this analysis was post hoc and not included in our study registration.

The WMS was deployed under considerable pressure in the context of the COVID-19 pandemic and into a dynamic clinical setting including 3 different wards, which incurred several limitations. First, nurse behaviors during this time may have varied depending on the ward setting or evolved during the course of the pandemic and may not be comparable to conditions since the pandemic given the very high workload and stress at that time. Second, due to limited availability of equipment, nursing staff chose which patients to monitor using the system, which may have introduced selection bias as they were more likely to monitor those assessed at highest risk of deterioration. In addition, nurses may have taken fewer intermittent vital sign observations as patients recovered and neared discharge. However, discharge from hospital was accelerated during the pandemic due to resource pressures, which may have offered some mitigation against this potential confounder of the TTNO analyses. Third, the comparison between different time windows for the same patients could have been influenced by clinical staff who knew the patients by the time they were on the WMS. Thus, the observed pattern of monitoring might be more (or less) spaced given this potential bias and reflect the impact of competing clinical priorities. Fourth, the criteria for hospital admission and discharge evolved across the 2 pandemic waves, resulting in variability between patient clinical acuity at hospital admission and discharge, potentially confounding the TTNO analyses. Given the nature of this study, it was not possible to compare a completely nonmonitored cohort, which would have mitigated these first 4 limitations. Future research under nonpandemic conditions should consider using a separate unmonitored control group and setting specific eligibility criteria for commencing and ceasing monitoring to facilitate consistency of use. Fifth, although vital sign values from nurse-measured and wearable sources were compared, these 2 methods of measurement do incur differences, such as accuracy of devices and mode of measurement, which should be considered in the context of this analysis. In particular, nurse-measured respiratory rates may differ significantly from those measured using the WMS due to monitoring behaviors such as “digit preference” (where respiratory rate distribution shows peaks at 20 and 24 breaths per second). This suggests either estimation of respiratory rate based on observation or measuring over a shorter period of 15 seconds and multiplying by 4 [29,30]. Future research should consider protocolizing nurse-measured vital signs to ensure accuracy and avoid these behaviors.

We identified one limitation related to the WMS, which included a pulse oximeter device known to consistently underestimate oxygen saturation by up to 2%. However, the device was selected as the most reliable and accurate of those tested for the system [9], and notification of this underestimation was included in staff training and deemed by the nurses to be manageable and preferable to overestimation [26]. This may have resulted in nurses unnecessarily returning to patients to check their vital signs but did not provide false reassurance or risk masking hypoxia. Future studies should consider the impact of the comparative accuracy of devices on nurse monitoring behaviors.

There are some limitations to the data available. First, we planned to include additional adverse outcomes, including escalation to high-frequency nasal oxygen and noninvasive ventilation, in our analysis. However, these data were not available in the extracted dataset as patients undergoing these interventions were moved to a separate high-dependency ward. Future studies should ensure that data on these additional outcomes are available. Second, 5.7% (9/157) of the initial patients were not included in the analysis as they had registered for the NHS digital data opt-out service. Although this omission may pose a risk of selection bias, given the small number, this is unlikely to have impacted the results. Future research using electronic patient data will need to consider how missing data

XSL•FO
RenderX

due to the opt-out service are handled if the proportion of patients choosing to opt out increases over time.

From a modeling perspective, TTNO was right skewed. Although we used a linear mixed effects model to preserve the interpretability of effect estimates as absolute differences in minutes, sensitivity analyses using alternative distributional assumptions (gamma and log-normal models) provided consistent results. However, departures from normality may have affected estimate precision.

Finally, our data were from a single hospital with a high percentage of ICU admissions (31/144, 21.5%). We acknowledge that these factors limit the generalizability of our findings. Future research should focus on exploring the impact of WMSs on nurse behaviors in nonpandemic conditions and comparing robust and distinct patient groups. Future consideration should also be given to the cost-benefit of the system given the impact on nurse behaviors and patient safety.

Conclusions

In this retrospective data study, patients were at high risk of deterioration, spending a third of the monitored time at or above the escalation threshold. Our post hoc analysis showed that, by offering additional vital sign data between intermittent EWS measurements, the WMS may have improved task prioritization by allowing the nursing staff to extend the time between routine MVSMs. We found no indication in our analysis that this increase in time between vital signs measurements adversely affected patient safety. The increase in time between observations was not associated with a difference in EWS distributions, providing some reassurance that this difference was not associated with increased physiological instability.

Acknowledgments

The authors would like to acknowledge the research team who supported this study, including Carlos Areia, Chris Biggs, Holly Edmundson, and Annika Jarman. They also gratefully acknowledge the patients who participated in this study and the clinical staff who willingly and rapidly adopted the system into their practice under extremely difficult circumstances.

Abstract

Background: Clinical retrieval-augmented generation depends on embedding models. A companion study found that non–retrieval-trained encoders underperformed retrieval-trained general-purpose embeddings and produced near-degenerate embedding geometry, but did not localize the architectural origin, separate training-domain from training-objective effects, or test whether the degradation can be corrected without retraining.

Objective: This study aimed to (1) characterize layer-wise retrieval and geometric trajectories across 13 transformer configurations on clinical documents, (2) separate training-objective from training-domain effects through matched architectural comparisons, (3) reanalyze the panel under a per-query layer-wise linear mixed-effects (LME) framework, and (4) evaluate deployment-relevant post hoc geometric correction.

Methods: Layer-wise embeddings were extracted from 13 transformer configurations on 3 clinical corpora (n=100 documents each: MTSamples, PMC-Patients, and Mistral-7B-Instruct–generated synthetic notes) under 2 query formats (keyword and natural-language via GPT-4o). Retrieval performance (mean reciprocal rank at cutoff 10 [MRR@10] and recall at cutoff 10 [recall@10]) and geometric properties (participation ratio, average pairwise cosine, and anisotropy) were measured at every layer. A per-query layer-wise LME model was fit independently per configuration. Corpus-only zero-phase component analysis (ZCA) whitening was evaluated as the primary deployment-relevant intervention, with 5-fold cross-validation, an epsilon sweep, a lexical-overlap audit, and a chunking sensitivity analysis.

Results: Document embeddings clustered into 3 anisotropy tiers: extreme (average pairwise cosine >0.92) for non–retrieval-trained encoders and large language models (LLMs), moderate (0.65-0.92) for general retrievers and most LLMs, and reduced (<0.65) for BioLORD-2023, instruction-tuned E5-Mistral-7B, and Nomic-embed-text-nopfx. The per-query random-slope LME identified 2 layer-depth patterns: classical degradation with depth in 3 non–retrieval-trained encoders (all P<.001), vs net improvement with depth in the remaining 10 models (all P<.001), with the strongest negative coefficients in decoder LLMs. Matched-contrast tests confirmed significant training-objective × layer-depth interactions in all 3 matched pairs (all P<.001). Corpus-only ZCA whitening produced a 2-tier pattern under 5-fold cross-validation: tier 2 non–retrieval-trained models showed positive ΔMRR@10 (+0.066 to +0.304), while tier 1 retrieval-trained models showed negative ΔMRR@10 (–0.021 to –0.051). Best Match 25-vs-embedding Spearman rank correlations spanned –0.02 to 0.37, indicating substantial nonlexical contribution to retrieval. Same-source ranking stability replicated at 4-5× corpus scale (ρ=0.952 for PMC-500, ρ=0.929 for MTSamples-400) for the BERT-scale subset.

Conclusions: Anisotropy in transformer embeddings is widespread across architectural classes and is lower in configurations with retrieval-specific training. Corpus-only ZCA whitening is a deployment-compatible, retraining-free post hoc correction candidate that improved retrieval for non–retrieval-trained models on this controlled benchmark but requires target-corpus validation before clinical deployment. The matched-comparison evidence supports training objective rather than training domain

XSL•FO

as the stronger explanatory axis, though residual confounding is not eliminated. The principal contribution is mechanistic: layer-level localization of embedding degradation and the geometric basis for the 2-tier intervention response.

Introduction

Overview

Retrieval-augmented generation (RAG) is the dominant approach for grounding large language model (LLM) outputs in verifiable evidence sources [1,2]. In a clinical RAG pipeline, the embedding model transforms queries and documents into vector representations, and retrieval quality depends on the geometry of the resulting embedding space. When embeddings cluster in a narrow region of the vector space, a phenomenon known as anisotropy, cosine similarity becomes less discriminative, and retrieval may fail regardless of downstream generation quality.

Retrieval failure in clinical RAG settings may affect downstream outputs consumed by practitioners or clinical decision support systems. This study does not evaluate clinical task performance, patient outcomes, or production electronic health record (EHR) deployment; it addresses the upstream question of where in the model architecture retrieval performance is determined and whether geometric properties can be corrected without retraining.

Companion Study and Motivating Context

A recently accepted companion benchmark study [3] evaluated 10 embedding models across 3 clinical corpora and 294 experimental conditions. Two findings motivated the present analysis. First, model choice and clinical-context variables (corpus type and query format) contributed comparably to variance in mean reciprocal rank at cutoff 10 (MRR@10). Second, domain-specific models, BioBERT [4] and ClinicalBERT [5], produced near-degenerate embedding geometry, with pairwise cosine similarities exceeding 0.90, whereas general-purpose models (Beijing Academy of Artificial Intelligence General Embedding [BGE]-base [6], General Text Embeddings [GTE]-base [7], Nomic-embed-text [8]) achieved higher MRR@10 and more dispersed geometry. The companion study established that domain-pretrained encoders underperform but did not localize *where* in the network the gap appears, *what* causes it, or *whether* it can be corrected.

Comparing BERT-architecture domain encoders with retrieval-trained text-embedding models can conflate training domain (biomedical vs general) with training objective (retrieval-trained vs not). The present analysis therefore adds matched architectural controls to separate these dimensions as much as possible within the public model space.

Scope and Demarcation

Retrieval failures in production systems arise from multiple sources beyond embedding model behavior: corpus heterogeneity, query formulation, chunking strategy, indexing choices, and vocabulary mismatch between queries and documents. This study isolates the embedding model's contribution by holding corpus, query generation, and indexing constant across conditions, while the factorial design models residual corpus and query-format effects directly. Chunking effects were negligible in the companion study (η^2=0.002) [3] but are reassessed here on a representative subset of 4 models to ensure robustness. The interventions evaluated here target embedding geometry; they do not address retrieval failures driven by vocabulary mismatch or chunking strategy at scale.

Research Questions

The four research questions addressed are:

- RQ1: How does retrieval performance vary with transformer layer depth across the 13 model configurations, and what layer-wise patterns are consistent across architectural classes?
- RQ2: How much variation in retrieval performance is associated with model configuration vs clinical-context factors (corpus, query format), and does this attribution change with layer depth?
- RQ3: In matched architectural comparisons that hold the training objective constant or the training domain constant, which axis, the training objective or the training domain, drives the performance gap between models?
- RQ4: Can deployment-relevant post hoc geometric correction (corpus-only zero-phase component analysis [ZCA] whitening, fit on document embeddings alone) recover retrieval performance to a substantively meaningful extent in this controlled benchmark, and does this correction generalize across documents not used to fit the transform?

RQ2 is phrased in terms of association rather than causation because the study cannot fully isolate training objective from architecture, pooling, model size, tokenizer, and training data; it therefore quantifies variation associated with model configuration as a whole. RQ3 addresses the training-objective vs training-domain contrast using matched architectural comparisons.

The intended contribution is mechanistic and methodological. This study does not propose a deployment standard; practical implications are presented as discussion-level diagnostic considerations that require prospective validation on target institutional corpora before use in clinical retrieval systems.

Relationship to Companion Study

This manuscript is a mechanistic companion to the accepted benchmark study [3]. It reuses the same clinical retrieval setting, corpora, and metadata-derived query design, but adds layer-wise

XSL•FO
RenderX

extraction, geometric trajectory analysis, matched controls, ZCA evaluation, and per-query, layer-wise modeling. The 2 manuscripts are therefore complementary rather than duplicative.

Related Work

Anisotropy and Embedding Geometry in Transformer Representations

The anisotropy of contextual word representations was characterized by Ethayarajh [9], who showed that contextual embeddings from BERT, GPT-2, and ELMo occupy a narrow cone in representation space across all noninput layers. Razzhigaev et al [10] demonstrated distinct anisotropy profiles for encoder vs decoder models. Mechanistic accounts diverge: Machina and Mercer [11] attribute anisotropy to tied input/output embedding matrices, whereas Godey et al [12] link it to sharp attention patterns. Subsequent work has explored isotropy-promoting training objectives (BioLORD-2023 [13] adopts an explicit isotropy term in its contrastive loss) and post hoc whitening transforms [14-16] that compress eigenspectra. These studies focus on general-domain text; to the author's knowledge, no prior work has conducted layer-level geometric and retrieval analyses of clinical or biomedical text across the architectural classes evaluated here.

Clinical Embedding Benchmarks

In the clinical embedding benchmarking literature, Myers et al [17] evaluated 7 embedding models with different pooling strategies for EHR retrieval and reported that BGE-base outperformed domain-specific models, consistent with the companion study's findings. Soffer et al [18] evaluated 39 embedding models across 7 medical semantic similarity tasks. Hosseini et al [19] showed that combining intermediate BERT layers improved semantic textual similarity by up to 16% in Spearman correlation, though this was evaluated on general-domain similarity tasks rather than clinical retrieval. None of these studies conducted layer-level analysis on clinical retrieval data.

Retrieval Evaluation Methodology

The information retrieval evaluation literature provides the methodological foundation for the metrics used here. The Massive Text Embedding Benchmark [20] established standardized retrieval evaluation across diverse domains, and the Benchmarking Information Retrieval (BEIR) suit [21] provided heterogeneous-domain retrieval benchmarks emphasizing zero-shot generalization. Both highlight that ranking metrics computed on small candidate sets can overestimate performance relative to production-scale retrieval, a consideration that motivated the validation experiments at 4-5× scale in this study.

Dense retrieval architectures pioneered by Karpukhin et al [22] have been widely adopted for clinical and biomedical retrieval, with their failure modes subsequently characterized in BEIR-style evaluations [23]. Reranking pipelines such as ColBERT [24] and BERT-based rerankers [25] partially mitigate the limitations of single-stage dense retrieval. Calibration of embedding similarity scores [26] is an active area; the present ZCA correction is a form of post hoc calibration applied at the embedding-vector level rather than at the score level. Clinical information retrieval evaluation has emphasized known-item retrieval [27] and the impact of query-document lexical overlap on apparent performance [23]; both inform the lexical-overlap audit reported below.

Gap Addressed by This Study

To the author's knowledge, no prior study has conducted (1) layer-level geometric and retrieval analyses of clinical documents across 13 transformer configurations, including matched architectural controls that separate training-objective from training-domain effects; (2) layer-wise per-query linear mixed-effects (LME) analysis of retrieval performance; or (3) cross-validated evaluation of corpus-only ZCA whitening as a deployment-relevant geometric correction. This study addresses each of these gaps directly.

Methods

Models

Overview

A total of 11 transformer models across 13 configurations were evaluated (Table 1). The panel aligns with the companion study [3] by excluding the OpenAI application programming interface model (no hidden-state access) and Best Match 25 (BM25; nonneural), and by adding 2 new configurations to enable matched comparisons across training objective and training domain dimensions. The models span 6 categories: domain encoders (BioBERT [4], ClinicalBERT [5]), general encoders (BERT-base-uncased [28]), biomedical retrievers (BioLORD-2023 [13], MedCPT [29]), general-purpose retrievers (BGE-base [6], GTE-base [7], Nomic-embed-text [8]), general LLMs (E5-Mistral-7B [30], Phi-3-mini [31]), and biomedical LLMs (BioMistral-7B [32]). Two ablation variants are retained from the companion design: E5-Mistral-7B with mean pooling and no instruction prefix and Nomic-embed-text without search_query/search_document prefixes.

ClinicalBERT uses a DistilBERT architecture (6 transformer layers) rather than BERT-base (12 layers); this architectural difference is noted where relevant. BERT-base-scale models have 13 extraction points (input embeddings plus 12 transformer layers). LLM-scale models (E5-Mistral-7B, Phi-3-mini, BioMistral-7B, and the E5-Mistral-7B-ablation variant) have 33 extraction points (including the input and 32 layers). MedCPT, a dual-encoder model, was evaluated by extracting layers from the query and article encoders separately.

[m]DL: domain large language model.

Matched-Comparison Rationale

Two configurations were added beyond the companion panel to help separate the training objective from the training domain. BERT-base-uncased serves as a non–retrieval-trained BERT-base control for BioBERT and the BERT-family retrievers. BioMistral-7B serves as a biomedical Mistral-7B control for E5-Mistral-7B. These comparisons are architecture-matched or partially matched, but residual confounding from the tokenizer, instruction data, pooling, and model scale remains.

Corpora and Queries

Overview

Three clinical corpora were reused from the companion study [3] at a 100-document working scale per corpus to enable mechanistic layer-by-layer analysis: MTSamples (n=100), PMC-Patients case reports from PubMed Central (n=100) [20], and synthetic clinical notes generated by Mistral-7B-Instruct-v0.2 (n=100). For each corpus, 100 keywords and 100 natural-language queries were generated from document metadata using GPT-4o, following the reduced-lexical-dependence design used in the companion study's validation experiment [3]. Each query corresponds to a single known-relevant document (known-item retrieval design). The complete GPT-4o prompt is provided in Multimedia Appendix 1.

The known-item retrieval design with 100 documents per corpus provides a controlled environment for mechanistic, layer-by-layer analysis but is substantially smaller than production indices; absolute results should not be extrapolated directly to production-scale retrieval. Validation at 4-5× scale (500 PMC-Patients and 400 MTSamples) is reported in the "Validation on Independent Corpora" subsection of the Results section.

XSL•FO
RenderX

Alignment Audit for the Synthetic Corpus

The layer-extraction pipeline preserved the document order used to generate the metadata queries. A locally cached synthetic CSV used to reload the corpus for a sensitivity analysis had been resorted by synth_id, breaking the index alignment; query-document pairing for that sensitivity analysis was therefore recovered via BM25 top-1 matching with greedy one-to-one deduplication, replicating the alignment-recovery procedure documented in the companion study [3]. The full audit table is reproduced in Multimedia Appendix 2. The primary per-query layer-wise LME uses ranks derived from the original-pipeline alignment, not the recovered alignment.

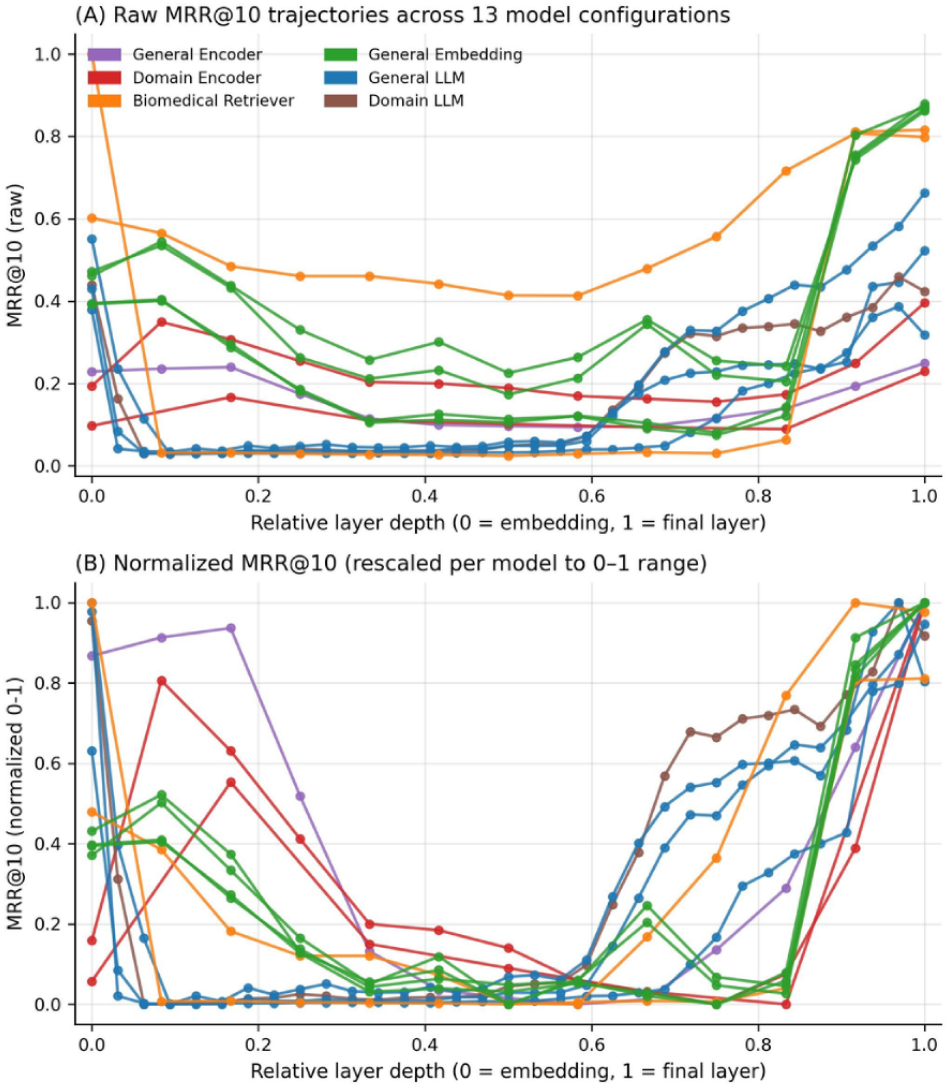
BM25 Alignment-Check Baselines

Alignment between queries and documents was verified using BM25 on the 100-document subset before evaluating each embedding model, yielding MRR@10 of 0.87 (MTSamples), 0.92 (PMC-Patients), and 0.96 (synthetic). These baselines confirm that the queries are appropriately aligned with their target documents at the lexical level and serve as a sanity check on the experimental design. They are not evidence that retrieval can be reduced to lexical matching: the lexical-overlap audit measures the BM25-vs-embedding rank correlation directly across the 13 models and confirms a substantial nonlexical contribution to embedding-based retrieval (Spearman ρ range –0.02 to 0.37). This finding directly addresses the apparent contradiction between high BM25 baselines and the manuscript's claim of reduced lexical dependence.

Layer-Level Measurements

Overview

For each model and layer, embeddings were extracted across the 6 corpus × query format conditions using output_hidden_states=True (or equivalent forward hooks for architectures that do not support this parameter). Pooling matched vendor specifications: mean pooling for most models, classification token pooling for MedCPT, and last-token (end-of-sequence [EOS]) pooling for E5-Mistral-7B. All embeddings were L2-normalized.



Geometric Measures (Computed on Document Embeddings)

The following geometric measures were used:

- Participation ratio (PR): PR = (sum_i sigma_i^2)^2/sum_i sigma_i^4, where sigma_i are the singular values of the centered embedding matrix. PR reflects the effective number of dimensions used by the embedding distribution; lower values indicate more collapsed representations.
- Average pairwise cosine similarity (average pairwise cosine): the mean cosine similarity across 10,000 randomly sampled embedding pairs. Higher values indicate a narrower embedding cone (more anisotropic).
- Anisotropy singular value decomposition–based: the top squared singular value as a fraction of the sum of all squared singular values, indicating concentration of variance along a single direction.
- Retrieval measures: MRR@10 was the primary retrieval metric. Recall at cutoff 10 (Recall@10; the proportion of queries for which the relevant document appeared in the top 10 results) was reported as a secondary metric. Both were computed by ranking documents using cosine similarity with a one-to-one query-document mapping.
- Normalized mean reciprocal rank (MRR): computed for cross-model trajectory visualization by rescaling each model's layer-wise MRR@10 values to the 0-1 range. Raw MRR@10 values are reported alongside the normalized values in Figure 1.

XSL•FO
RenderX

Figure 1. Layer-wise mean reciprocal rank at cutoff 10 (MRR@10) trajectories across all 13 model configurations. (A) Raw MRR@10 by relative layer depth (0=input embedding layer, 1=final layer); each line is one model configuration averaged across the 6 corpus × query-format conditions, color-coded by category. (B) The same data, minimum-maximum normalized per model to a 0-1 range to aid cross-model trajectory comparison (absolute performance differences are suppressed by the normalization). Most configurations show U-shaped or monotonically improving curves. In the per-query mixed-effects model, 3 non–retrieval-trained encoders worsen with depth (BERT-base-uncased, BioBERT, ClinicalBERT; positive rel_layer coefficients), whereas the remaining 10 configurations improve with depth, with the greatest improvement in the decoder large language models.

Summary Trajectory Metrics

For the descriptive characterization of layer-wise trajectories, the following derived metrics are defined in the Methods section:

- Recovery ratio: (MRR_final – MRR_trough)/(MRR_peak – MRR_trough), where MRR_peak is the highest MRR@10 among layers 0%-25% of network depth, MRR_trough is the lowest MRR@10 among layers 35%-55% of network depth, and MRR_final is the final-layer MRR@10. Values above 1.0 indicate that the final layer exceeds the early-layer peak; values below 1.0 indicate incomplete recovery. The recovery ratio is a study-defined descriptive index, not a standard metric. Per-model values are descriptive observations rather than formal statistical tests. The 1.85 threshold used for a "strong recovery" classification is data-derived and reported as a hypothesis-generating screening signal only, not a deployment criterion.
- PR expansion: PR_final/PR_trough, where the trough is the layer with the lowest within-model PR. Values above 1.0 indicate dimensionality expansion at the final layer.

Document Length Analysis (Exploratory)

As an exploratory analysis, documents within each corpus were partitioned into terciles based on approximate token count (whitespace-tokenized). The following token boundaries were used (33.3rd and 66.7th word-count percentiles of each corpus's 100-document working set): MTSamples (short ≤286 words, medium 287-453, long >453), PMC-Patients (short ≤331, medium 332-518, long >518), and synthetic (short ≤290, medium 291-308, long >308). The compressed synthetic range reflects that corpus's structural uniformity. Per-tercile sample sizes are approximately 33 documents, and analyses at this sample size are statistically underpowered. Per-tercile retrieval metrics are reported in Multimedia Appendix 3; the main text reports only directional summaries.

RenderX

Statistical Analysis

The primary inferential analysis used a per-query, layer-wise LME model, fit separately for each of the 13 configurations. The outcome was log(rank+1), where rank is the position of the known relevant document among 100 candidates based on cosine similarity. The core model was log(rank+1) ~ C(intervention) + C(corpus) + C(query_format) + rel_layer, with a random intercept and random slope on rel_layer by corpus_query_idx (100 queries × 3 corpora = 300 groups per model). rel_layer was normalized to the range 0 to 1. Detailed coefficients, SEs, and convergence diagnostics are reported in Multimedia Appendix 4.

The primary specification was a random-slope model with a random intercept and a random slope for rel_layer by query identity. Each query was treated as a distinct group within its source corpus (300 query groups per model: 100 queries × 3 corpora). All 13 configurations converged. The estimated intraclass correlation coefficient ranged from 0.06 to 0.55 (median 0.41) across models, indicating substantial between-query variance in retrieval difficulty and supporting the per-query random-effects specification. Bootstrap CIs from 3 representative models aligned with Wald intervals in direction and approximate width. Fixed-effect *P* values are reported descriptively without multiple-comparison correction.

No formal multiple-comparison correction was applied across layers. Layer-level *P* values from the per-query LMEs are interpreted descriptively within the LME inferential framework rather than as confirmatory hypothesis tests. The principal inferences in this manuscript rest on the random-slope fixed-effect coefficients and the matched-comparison contrasts, not on layer-by-layer significance counts.

Cluster-bootstrap 95% CIs for the rel_layer fixed-effect coefficient were computed for 3 representative configurations spanning the model panel—BERT-base-uncased (β=+0.624, Wald 95% CI +0.537 to +0.712, bootstrap 95% CI +0.553 to +0.694), BGE-base (β=–0.165, Wald 95% CI –0.245 to –0.086, bootstrap 95% CI –0.229 to –0.104), and E5-Mistral-7B-ablation (β=–1.317, Wald 95% CI –1.392 to –1.243, bootstrap 95% CI –1.391 to –1.276)—using 50 cluster-bootstrap iterations clustered on corpus_query_idx. Bootstrap and Wald intervals agreed in sign, coefficient ordering, and approximate width across all 3 configurations; parametric SEs therefore provide a reasonable representation of uncertainty in the primary rel_layer coefficient.

For the matched architectural comparisons reported in the Results section (BERT-base architecture: BGE-base vs BERT-base-uncased; Mistral-7B architecture: E5-Mistral-7B-ablation vs BioMistral-7B; biomedical encoders: BioLORD-2023 vs BioBERT), 3 pairwise pooled LME models were fit with the specification log(rank + 1) ~ rel_layer × C(model) + C(corpus) + C(query_format), with a random intercept and random slope on rel_layer by corpus_query_idx. The rel_layer × C(model) interaction term tested whether the 2 paired configurations differed in layer-depth trajectory; the reported *P* values are from Wald tests on the interaction coefficient. The additive per-configuration models described above and the pairwise pooled interaction models here address different inferential questions: the per-configuration slopes describe each model's own layer-depth pattern, whereas the pooled interaction tests whether paired configurations differ in that pattern within a shared architecture.

The cross-validation design used to evaluate the corpus-only ZCA intervention (post hoc interventions, below) fits the ZCA covariance from 80 training-fold documents per fold in a hidden-state space of 768-4096 dimensions, depending on the model. The resulting sample covariance is rank-deficient by 689-4017 dimensions; the whitening transform relies on the ε ridge regularizer to be well-defined outside the empirical ~80-dimensional subspace captured by the nonzero eigenvalues, where it reduces to ε-scaled near-identity behavior. The ZCA intervention in this cross-validation setup therefore operates as a hybrid of data-driven whitening within the empirical 80-dimensional subspace and ε-regularized near-identity transformation in the residual subspace. Empirically, the ε sensitivity sweep reported in Multimedia Appendix 5 confirms that the intervention's effect on retrieval depends materially on ε within the explored range (10^{-7} to 10^{-2}): per-model ΔMRR@10 ranges of up to 0.75 in absolute magnitude were observed, with the sign of ΔMRR@10 changing across the sweep for several models. This is consistent with the hybrid behavior described above, where ε determines the whitening transform's behavior in the unspanned subspace. This is a mathematical property of small-sample covariance estimation in high-dimensional spaces, not specific to the present implementation; its consequences for the interpretation of the cross-validated intervention results are discussed in the Limitations section.

Post Hoc Interventions

A total of 5 no-retraining interventions were evaluated across all 13 configurations: corpus-only ZCA whitening (the primary deployment-relevant analysis), transductive ZCA whitening (a query-contaminated upper-bound reference), mean centering, post hoc layer selection, and post hoc layer combination. Layer selection and layer combination are reported only as descriptive ceilings because they select layers based on test-set performance.

For corpus-only ZCA, W = U(Λ + εI)^(–1/2) U^T and x' = W(x – μ_D)/||W(x – μ_D)||, where UΛU^T is the eigendecomposition of the centered document covariance, μ_D is the document mean, and ε is a ridge regularizer. W and μ_D are fit on document embeddings only; queries are transformed afterward using the same W. The default ε was 10^{-5}, with a sensitivity sweep over 10^{-7} to 10^{-2} (Multimedia Appendix 5). The sweep showed that $\varepsilon=10^{-5}$ is not panel-wide optimal: tier 2 models reached their largest gains at ε in the 10^{-5} to 10^{-3} range (most at 10^{-4}), whereas tier 1 models were degraded by corpus-only ZCA at every ε tested. The headline 2-tier pattern is preserved across the sweep; $\varepsilon=10^{-5}$ was retained as a single conservative default rather than a per-model tuned optimum.

Five-fold cross-validation was performed for corpus-only ZCA by fitting W and μ_D on 80 documents and evaluating on 20 held-out documents within each corpus and query-format

XSL•FO
RenderX

condition. This tests whether the transform generalizes beyond the documents used to fit it.

Lexical-Overlap Audit

To quantify the contribution of lexical matching to embedding-based retrieval across the 13 models, Spearman rank correlations between BM25 and embedding ranks were computed for each (model, corpus, and query format) condition. For each query, the BM25 rank assigns a position based on lexical overlap between the tokenized query and document; the embedding rank assigns a position based on cosine similarity between query and document embeddings. The Spearman correlation between these two ranks measures how well embedding-based retrieval recapitulates lexical matching: a correlation of 1.0 implies the embedding model is effectively BM25 with extra steps, while a correlation near 0 implies the embedding model uses purely nonlexical signal. Results are reported in the "Lexical Overlap Between BM25 and Embedding-Based Retrieval" subsection of the Results section and address the apparent contradiction between high BM25 baselines and the reduced-lexical-dependence claim.

Chunking Sensitivity

To assess sensitivity to document chunking, a sensitivity analysis was conducted on 4 representative models (BERT-base-uncased, BGE-base, MedCPT, and BioMistral-7B), each evaluated under 3 token-level truncation strategies. Documents were tokenized with the model-specific tokenizer; for the first strategy, the first N input tokens were retained, for the last strategy, the last N tokens were retained, and for the full strategy, the entire document was passed to the model with the tokenizer's native truncation at max_length. N was set to the model's max_length: 512 for BERT-base-uncased, BGE-base, and MedCPT; 2048 for BioMistral-7B. Because tokenizer-native truncation retained the leading max_length tokens, the full strategy produced the same leading-token input as the explicit first strategy. The last strategy therefore tested sensitivity to using document-tail rather than document-head content. Query texts remained unchanged across strategies. For each strategy, document embeddings were re-extracted, and retrieval performance was recomputed. The 4-model subset was chosen to span architecture classes: general encoder, general retriever, biomedical retriever, and biomedical LLM. Results are reported in the "Chunking Sensitivity" subsection of the Results section.

Validation Corpora

To evaluate generalization, the layer-level analysis was repeated on 2 independent validation corpora representing different clinical document types: 500 PMC-Patients case reports (random seed 123, no overlap with the primary 100-document sample) and 400 MTSamples medical transcriptions (the remaining documents after excluding the primary 100, drawn from the same locally cached CSV used in the companion study). Queries were generated using the same metadata-based GPT-4o approach as in the primary experiment. Validation was conducted in 2 stages. First, the 8 BERT-scale configurations from the original panel were evaluated on PMC-500 and MTSamples-400; results are reported in the "Validation on Independent Corpora" subsection of the Results section. Second, the 5 configurations not included in the first stage, BERT-base-uncased, BioMistral-7B, Phi-3-mini, E5-Mistral-7B, and E5-Mistral-7B-ablation, were evaluated on the same expanded natural-text corpora; results are reported in the "Independent Validation of the Remaining Configurations" subsection. Together, the 2 stages provide independent-corpus validation for all 13 panel configurations.

Ethical Considerations

This study used only publicly available, deidentified datasets and synthetic clinical notes generated by a language model. MTSamples comprises publicly posted, deidentified medical transcriptions accessed at MTSamples [33] in accordance with the site's terms of service. PMC-Patients comprises published case reports from PubMed Central [34]. Synthetic clinical notes were generated by Mistral-7B-Instruct-v0.2 and contain no real patient data.

No human subjects were involved in this study, and no institutional review board approval was required. No identifiable individual patient information appears in any of the corpora, the manuscript, or its supplementary materials. No compensation was provided because no participants were enrolled. As a secondary analysis of deidentified public datasets (MTSamples or PMC-Patients) and entirely model-generated synthetic notes, the study qualifies for ethics review exemption under common research ethics frameworks for non–human subject research. The original informed consent and license terms governing the source datasets cover secondary research use; no additional participant consent was applicable.

Compute Environment

The layer-extraction pipeline was run on Google Colab Pro+ with an NVIDIA H100 80GB GPU. Additional analyses, including matched comparisons, corpus-only ZCA cross-validation, per-query LME, lexical overlap, chunking sensitivity, and intervention sweeps, were run on Google Colab Pro+ with an NVIDIA RTX PRO 6000 Blackwell 96GB GPU. Pooling and precision choices align with the companion study configuration to ensure cross-paper reproducibility. Code is available as described in the Data Availability section.

Results

Layer-Wise Retrieval Trajectories Across 13 Configurations

All 13 model configurations exhibited identifiable layer-wise structure, but the dominant pattern across the panel is more heterogeneous than that of a single U-shaped collapse model. Figure 1 shows raw MRR@10 trajectories (panel A) and per-model minimum-maximum normalized trajectories (panel B) as a function of relative layer depth (0=embedding layer, 1=final layer), averaged across the 6 corpus × query-format conditions.

Two principal trajectory patterns emerge:

1. Classical midlayer collapse with final-layer recovery. Observed in retrieval-trained encoder models (BGE-base, GTE-base, BioLORD-2023, MedCPT, Nomic-embed-text, and Nomic-nopfx). These models drop from early-layer

XSL•FO
RenderX

MRR@10 of 0.40-0.60 to a midlayer trough of 0.04-0.25 (35%-55% relative depth), then recover sharply in the final 1-2 layers to MRR@10 of 0.80-0.88. The recovery is driven by a sharp geometric restructuring, as documented in the "Final-Layer Geometric Restructuring Is Associated With Retrieval Recovery" section.

2. Monotonic improvement with layer depth is observed in most decoder-LLM configurations (E5-Mistral-7B, Phi-3-mini, BioMistral-7B, and E5-Mistral-7B-ablation). These models show retrieval performance that increases with depth, without a deep midlayer trough; final-layer values are the highest within their trajectory.

A third, less common pattern, partial recovery with high final-layer anisotropy, appears in BioBERT, ClinicalBERT, and BERT-base-uncased. These 3 non–retrieval-trained encoder models show a midlayer dip but recover only modestly at the final layer (BioBERT 0.40, ClinicalBERT 0.23, and BERT-base-uncased 0.25), well below the retrieval-trained encoder family.

The per-model raw and normalized values are documented in Multimedia Appendix 6. The U-shaped trajectory is concentrated among retrieval-trained encoder models and partially evident in non–retrieval-trained encoders, but it is not characteristic of decoder LLMs. Raw MRR values and CIs are reported alongside the normalized values in Multimedia Appendix 6.

Final-Layer Trajectory Metrics

Table 2 summarizes per-model peak, trough, and final-layer MRR@10 values, along with the recovery ratio and PR expansion factors. Complete model-level baseline and intervention results are provided in Multimedia Appendix 7. MedCPT's layer-0 anomaly (MRR@10=1.000, an artifact of dual-encoder shared vocabulary embeddings) is excluded from the early-peak window. The recovery ratio is structurally degenerate for MedCPT because the early-layer MRR (L1-L6 ≈ 0.025-0.033) is essentially identical to the midlayer trough, producing a near-zero denominator. We report the value with this caveat and note that MedCPT's trajectory does not follow the U-shape geometry the metric was designed to summarize.

A descriptive threshold combining recovery ratio >1.85 and PR expansion >1.9× is associated with final-layer MRR@10 >0.80 in the retrieval-trained encoder subset (BGE-base, GTE-base, BioLORD-2023, Nomic family; all final MRR >0.80, all PR expansion ≥1.90×). The matched controls and LLM-scale models confirm that this threshold is data-derived and exploratory rather than a deployment criterion.

Cosine drop is negative for BioBERT (–0.030) and Phi-3-mini (–0.236), indicating that the final layer is more anisotropic than the early peak. Both fall into the extreme-anisotropy tier. The "geometric restructuring at the final layer" pattern observed in retrieval-trained encoders (positive cosine drop combined with substantial PR expansion) is therefore not a property of all transformer architectures but is specific to retrieval-objective-trained encoders.

Table 2. Layer-level trajectory characteristics per model.[a]

Model	Peak[b] (layer, MRR[c])	Trough[d] (layer, MRR)	Final MRR	Recovery	PR expansion[e]	Cosine drop[f]
BGE[g]-base	L1, 0.400	L4, 0.106	0.872	2.60	2.57×	+0.236
GTE[h]-base	L1, 0.408	L4, 0.110	0.881	2.59	2.63×	+0.172
BioLORD	L0, 0.602	L7, 0.414	0.798	2.04	1.90×	+0.439
Nomic	L1, 0.545	L6, 0.225	0.863	2.00	2.66×	+0.313
Nomic-nopfx	L1, 0.535	L6, 0.174	0.863	1.91	2.28×	+0.357
MedCPT[i]	L2, 0.033	L6, 0.025	0.816	Degenerate[i]	4.01×	+0.242
BERT-base	L2, 0.240	L7, 0.094	0.250	1.07	1.15×	+0.009
BioBERT	L1, 0.350	L7, 0.170	0.398	1.27	1.35×	–0.030
ClinicalBERT	L1, 0.167	L3, 0.102	0.230	1.97	1.38×	+0.025
BioMistral	L0, 0.440	L11, 0.035	0.424	0.96	1.45×	+0.144
Phi-3-mini	L0, 0.551	L12, 0.031	0.522	0.94	2.68×	–0.236
E5-Mistral	L0, 0.379	L11, 0.044	0.318	0.82	0.97×	+0.036
E5-Mistral-ablation	L0, 0.430	L11, 0.036	0.663	1.59	2.24×	+0.149

[a]All values are averaged across 6 corpus × query-format conditions. Final MRR values match the intervention-pipeline final-layer baseline; layer-wise trajectory extraction (streams A and G) produces final-layer MRR values differing by <1% from the intervention-pipeline baseline. Peak, Trough, PR expansion, and Cosine drop are computed from the layer-wise trajectory extraction. Values for new matched controls (BERT-base-uncased, BioMistral-7B) are highlighted.

[b]Early peak=highest MRR@10 in the first quarter of layers (excluding layer 0 for MedCPT).

[c]MRR: mean reciprocal rank.

[d]Trough=lowest MRR@10 in the middle layers (35%-55% relative depth).

[e]PR expansion=participation ratio at the final layer divided by participation ratio at the trough.

[f]Cosine drop=average cosine at the peak layer minus average cosine at the final layer (negative values indicate increased anisotropy from peak to final).

[g]BGE: Beijing Academy of Artificial Intelligence General Embedding.

[h]GTE: General Text Embeddings.

[i]MedCPT: layer-0 MRR@10=1.000 (excluded; reflects shared vocabulary embeddings in the dual-encoder architecture). Layers 1-6 produce near-zero MRR (range: 0.025-0.033) before a sharp recovery in the later layers; the recovery ratio, as defined in Methods, has a near-zero denominator (peak – trough ≈ 0.008) and is not meaningfully computable for this model. The PR expansion factor (4.01×) remains interpretable and is the largest in the panel.

Matched Architectural Comparisons Support the Training-Objective Interpretation Over Training Domain

The matched comparisons supported the training objective over the training domain as the stronger explanatory axis. BERT-base-uncased and BGE-base share the BERT-base architecture but differ in retrieval fine-tuning; final-layer MRR@10 was 0.250 vs 0.872. BioMistral-7B and E5-Mistral-7B share the Mistral-7B base; the E5-Mistral ablation with mean pooling reached 0.663 vs 0.424 for BioMistral-7B. BioBERT vs BioLORD-2023 was directionally consistent (0.398 vs 0.798) but confounded by the BERT vs MPNet architecture.

Formal pooled LMEs confirmed significant rel_layer × model interactions across all 3 reported contrasts (all $P<.001$). These findings are consistent with a role for retrieval-objective training but do not establish causality because tokenizer, pretraining corpus, instruction data, pooling, and scale remain potential confounders.

Final-Layer Geometric Restructuring Is Associated With Retrieval Recovery

Recovery from midlayer collapse in the retrieval-trained encoder family is driven by sharp geometric restructuring in the final 1-2 layers. For BGE-base, the PR expanded substantially across the final layers (eg, from layer 10 to layer 12), while average cosine similarity declined and MRR@10 increased sharply. GTE-base, MedCPT, and Nomic-embed-text exhibited similar transition patterns. Layer-to-layer PR, cosine, and MRR values per model are reported in Multimedia Appendix 6.

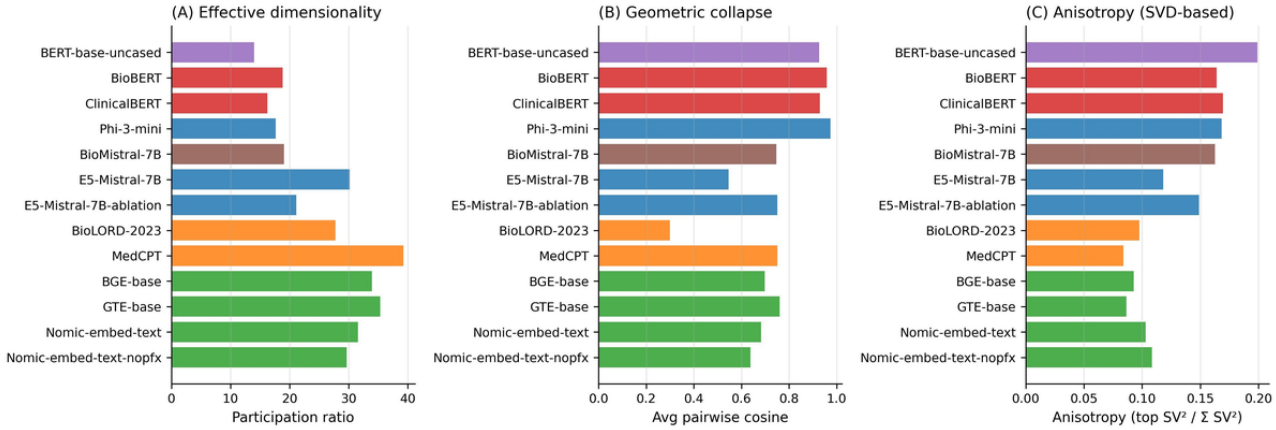
In contrast, BioBERT's PR increased modestly across layers, and its average cosine remained above 0.95 throughout. Its final-layer MRR@10 matched the value reported in Table 2. BERT-base-uncased, the matched control, exhibited similar limitations, with modest PR expansion. ClinicalBERT, with 6 transformer layers (DistilBERT architecture), lacked the depth required for a comparable recovery phase.

Across the full 13-model panel, the final-layer geometric properties are summarized by category in Figure 2, and the average document-embedding cosine is shown in the 3-tier visualization in Figure 3. The matched-control evidence and

XSL•FO
RenderX

geometric data converge: the retrieval-training mechanism that produces the final-layer dimensionality expansion is not produced by domain-specific pretraining alone.

Figure 2. Final-layer geometric diagnostics across all 13 model configurations. (A) Participation ratio (effective embedding dimensionality), (B) average pairwise cosine similarity (a measure of representational anisotropy), and (C) anisotropy index (largest squared singular value divided by the sum of squared singular values). All quantities are computed on document embeddings and averaged across the 6 corpus × query-format conditions; points are color-coded by model category. Extreme anisotropy (average cosine >0.92) appears in the non–retrieval-trained encoders and the decoder large language model Phi 3-mini (BERT-base-uncased, BioBERT, ClinicalBERT, and Phi-3-mini), whereas BioLORD-2023—whose contrastive training objective explicitly promotes isotropy—reaches the lowest average cosine in the panel (0.30).



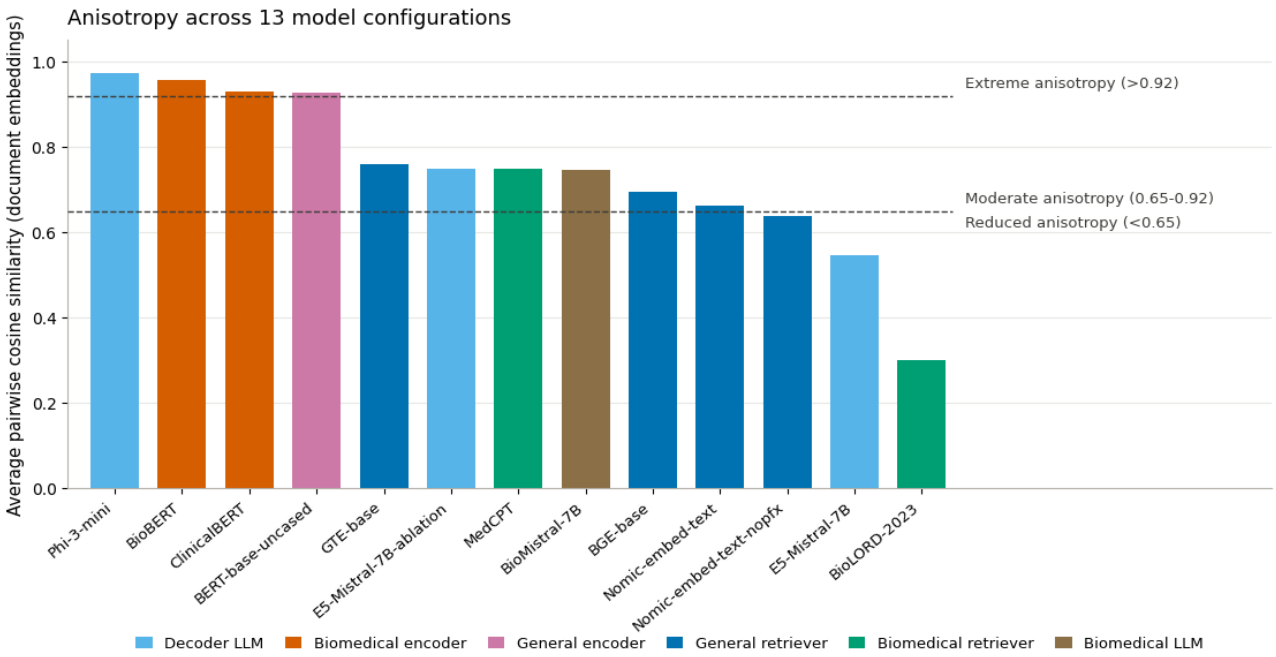


Figure 3. Anisotropy tiers in final-layer document embeddings across all 13 model configurations. Final-layer document-embedding average pairwise cosine similarity, sorted in descending order, revealing 3 empirical tiers. Extreme anisotropy (>0.92): Phi-3-mini (0.974), BioBERT (0.958), ClinicalBERT (0.930), and BERT-base-uncased (0.926). Moderate anisotropy (0.65-0.92): most general retrievers and the remaining large language models (LLMs). Reduced anisotropy (<0.65): Nomic-embed-text-nopfx (0.638), instruction-tuned E5 Mistral-7B (0.546), and BioLORD-2023 (0.300). BioLORD-2023's isotropy-promoting contrastive objective yields the lowest average cosine in the panel.

Per-Query Layer-Wise LME Analysis

The per-query random-slope LME converged for all 13 configurations, each of which was fit with 300 query groups (100 queries × 3 corpora). The intraclass correlation coefficient ranged from 0.06 to 0.55 (median 0.41), indicating that between-query difficulty accounted for a substantial share of variance and supporting the use of the per-query random-effects model. Two layer-depth patterns emerged. Three non–retrieval-trained encoders worsened with depth (positive rel_layer coefficients: BERT-base-uncased +0.62, BioBERT +0.22, ClinicalBERT +0.20; all P<.001), whereas the remaining 10 configurations improved with depth (negative rel_layer coefficients, all P<.001), with the strongest improvement in the decoder LLMs (E5-Mistral-7B=–1.77; E5-Mistral-7B-ablation=–1.32).

Additive LME coefficients for corpus-only ZCA—a layer-averaged summary—are heterogeneous across tier 1 models (negative for BGE-base, GTE-base, and Nomic-embed-text; positive for BioLORD-2023 and MedCPT)

XSL•FO
RenderX

and cannot be interpreted as evidence for a uniform final-layer effect. The primary evidence for the 2-tier ZCA response is the cross-validated corpus-only ZCA analysis in Table 3, where all 6 tier 1 configurations show final-layer ΔMRR@10 losses (0.021 to 0.051) and all 7 tier 2 configurations show gains (0.066-0.304). Layer-dependent intervention effects were not interpreted from the additive LME specification. A quadratic rel_layer sensitivity check was statistically preferred across all 11 cleanly fit models, confirming that many trajectories are nonmonotonic; the linear rel_layer term is therefore interpreted as a net-direction summary. Full coefficients and diagnostics are in Multimedia Appendix 4.

Table 3. Five-fold cross-validation (CV): corpus-only zero-phase component analysis mean reciprocal rank (MRR) at cutoff 10 vs baseline, per model, with SE across 30 observations per model (5 folds × 6 corpus × query-format conditions). Sorted by tier and Δ.

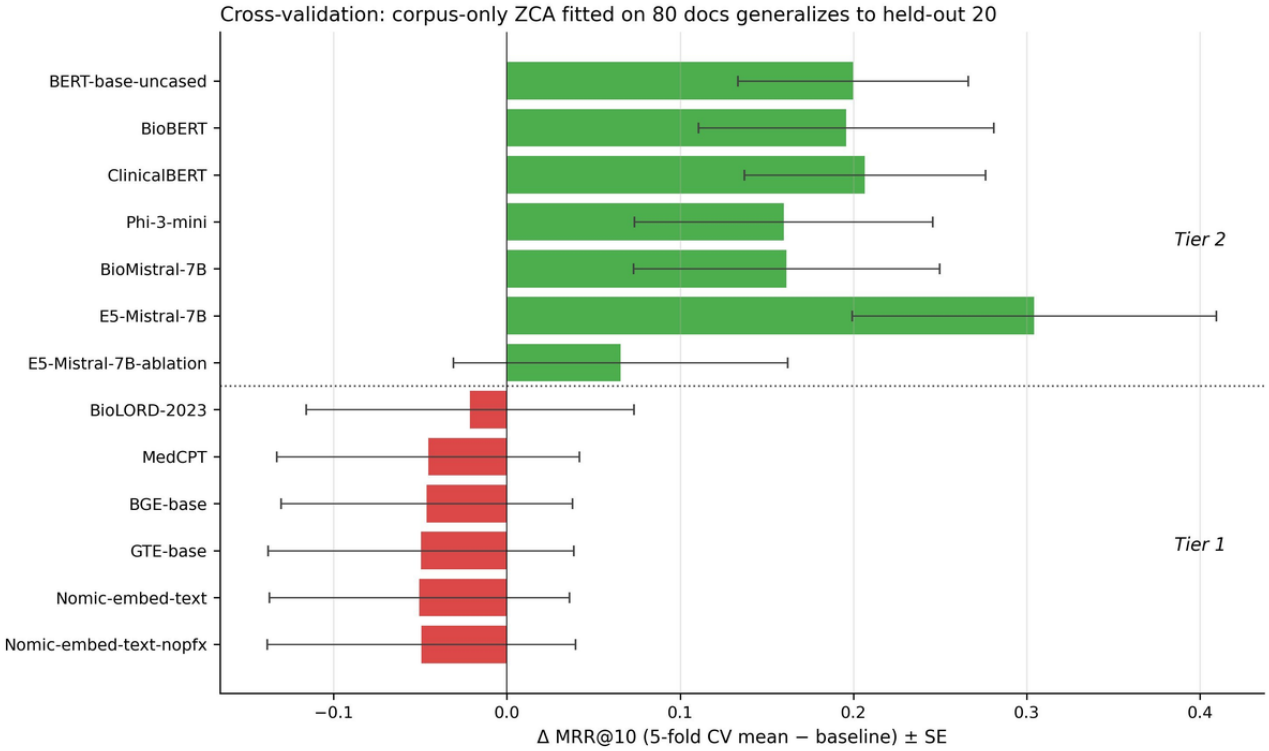
Model	Baseline MRR	ΔMRR@10, CV fold mean	ΔMRR	SE	n	Tier
BioLORD	0.798	0.777	–0.021	0.017	30	1
MedCPT	0.816	0.770	–0.045	0.022	30	1
BGE[a]-base	0.872	0.826	–0.046	0.017	30	1
Nomic-nopfx	0.867	0.818	–0.049	0.017	30	1
GTE[b]-base	0.879	0.830	–0.050	0.017	30	1
Nomic	0.862	0.811	–0.051	0.015	30	1
E5-Mistral	0.318	0.622	+0.304	0.023	30	2
ClinicalBERT	0.229	0.436	+0.207	0.029	30	2
BERT-base	0.250	0.449	+0.200	0.029	30	2
BioBERT	0.396	0.592	+0.196	0.033	30	2
BioMistral	0.424	0.585	+0.161	0.030	30	2
Phi-3-mini	0.523	0.683	+0.160	0.022	30	2
E5-Mistral-ablation	0.663	0.729	+0.066	0.032	30	2

[a]BGE: Beijing Academy of Artificial Intelligence General Embedding.

[b]GTE: General Text Embeddings.

Pooling and Instruction Effects in LLM-Scale Models

The E5-Mistral-7B ablation provides complementary evidence on the pooling strategy. Mean pooling without an instruction prefix achieved a final-layer MRR@10 of 0.663, compared with 0.318 for vendor-specified EOS pooling with an instruction prefix; the +0.345 net improvement is consistent with the combined effects of mean pooling and removal of the instruction prefix and cannot be decomposed into pooling-only and instruction-only contributions from the available data, since both factors are confounded in the ablation. This finding motivates a deeper intervention sweep on E5-Mistral-7B-ablation.



Cross-Validation of Corpus-Only ZCA Generalizes to Held-Out Documents

Five-fold cross-validation was performed across all 13 models to assess the risk of test-set contamination. The ZCA transform was fit on 80 documents per fold and evaluated on the held-out 20 documents, with results ranked against the full 100-document candidate set. The mean ΔMRR@10 across folds, relative to the no-intervention baseline, is summarized in Figure 4 and Table 3.

The 2-tier pattern is clear under cross-validated evaluation. Tier 2 non–retrieval-trained models show positive ΔMRR@10 of +0.066 to +0.304 (mean +0.185 across the 7 tier 2 models). Tier 1 retrieval-trained models show negative ΔMRR@10 of –0.021 to –0.051 (mean –0.044 across the 6 tier 1 models). The cross-validation confirms that the ZCA transform fitted on 80 documents (1) generalizes to held-out documents within the same corpus, and (2) produces the expected bimodal effect: it helps the uncalibrated, modestly hurts the already-calibrated. The smallest tier 2 gain (E5-Mistral-7B-ablation=+0.066) cannot be cleanly attributed to model scale. The ablation removes the instruction prefix and switches from EOS to mean pooling simultaneously, so neither factor's effect can be measured in isolation. Mean pooling is mathematically expected to reduce anisotropy compared with EOS pooling and may contribute to the small gain; however, the empirical anisotropy values for the 2 configurations (mean-pooled ablation 0.751; EOS-pooled instruction-tuned 0.546) represent the net difference associated with both changes simultaneously and cannot be decomposed without matched contrasts that separately vary pooling strategy and instruction formatting on the same underlying checkpoint.

XSL•FO
RenderX

Figure 4. Cross-validated corpus-only zero-phase component analysis (ZCA) whitening across all 13 model configurations. Mean change in mean reciprocal rank at cutoff 10 (ΔMRR@10; corpus-only ZCA minus no-intervention baseline) per model under 5-fold cross-validation (CV). Within each fold, the ZCA transform was fit on 80 documents and evaluated on the held-out 20 documents, ranked against the full 100-document candidate set; bars show the mean across the 30 observations per model (5 folds × 6 corpus × query-format conditions), with error bars giving the standard error of that mean. The 2-tier pattern is preserved under cross-validation: tier 2 (non–retrieval-trained) models show positive deltas (+0.066 to +0.304), while tier 1 (retrieval-trained) models show small negative deltas (–0.021 to –0.051). Exact per-model values are reported in Table 3. The result confirms that the whitening transform generalizes from the fitting documents to held-out documents, helping uncalibrated encoders while modestly degrading already-calibrated retrieval models.

Anisotropy Across 13 Models

Document-embedding geometry divided the panel into 3 tiers based on average cosine. Extreme anisotropy (>0.92) was observed in Phi-3-mini (0.974), BioBERT (0.958), ClinicalBERT (0.930), and BERT-base-uncased (0.926). Moderate anisotropy (0.65-0.92) encompassed most general retrievers and LLMs. Reduced anisotropy (<0.65) was observed in Nomic-embed-text-nopfx (0.638), E5-Mistral-7B with instruction (0.546), and BioLORD-2023 (0.300). Across all 13 models, the final-layer PR showed a descriptive correlation with final-layer MRR@10 (Spearman ρ=0.74; n=13). Per-condition geometry is reported in Multimedia Appendix 6.

Per-model, layer-wise Spearman correlations between PR and MRR@10, and between average pairwise cosine and MRR@10, were computed across layers for the 11 configurations included in the full per-layer geometric correlation table in Multimedia Appendix 8. BERT-base-uncased and BioMistral-7B were extracted layer-wise for the trajectory metrics reported in Table 2 and for the rel_layer LME analysis, but were not included in the Multimedia Appendix 8 correlation table. Layer-wise PR-vs-MRR Spearman ρ ranged from +0.017 (MedCPT) to +0.989 (GTE-base), with a median of +0.939; the absolute value of the corresponding cosine-vs-MRR ρ was smaller than that of PR-vs-MRR for 9 of the 11 configurations. The 2 exceptions are MedCPT, where neither correlation reaches significance because of the layer-0 dual-encoder artifact discussed earlier, and instruction-tuned E5-Mistral-7B, whose layer-wise cosine-vs-MRR ρ is positive (+0.488; *P*=.004), opposite in sign to the other 10 configurations and consistent with this model's anomalous instruction-conditioned trajectory. Across the 11 configurations, the PR is the more reliable layer-wise diagnostic. The full per-model correlation table is reported in Multimedia Appendix 8.

Lexical Overlap Between BM25 and Embedding-Based Retrieval

BM25-vs-embedding Spearman rank correlations were low to moderate across the panel, ranging from near zero for E5-Mistral-7B (median ρ=–0.017) to 0.366 for GTE-base. No model exceeded ρ=0.37. The high BM25 alignment baselines therefore indicate that the generated queries are aligned with their targets, while the low-to-moderate BM25-embedding correlations show that embedding retrieval is not simply lexical matching.

Chunking Sensitivity

For 4 representative models, BERT-base-uncased (general encoder), BGE-base (general retriever), MedCPT (biomedical retriever, dual-encoder), and BioMistral-7B (biomedical LLM), document embeddings were re-extracted using 3 chunking strategies (first-N tokens, last-N tokens, and full document, where N is each model's maximum sequence length), and retrieval was re-evaluated. Mean MRR@10 across 6 corpus × query-format conditions are reported in Table 4.

XSL•FO
RenderX

First-N and Full produce identical inputs for the three 512-ceiling models (BERT-base-uncased, BGE-base, and MedCPT) because the Full strategy relies on the tokenizer's default front-truncation at max_length, yielding the same leading N tokens as the explicit First-N slice regardless of document length. That some documents do exceed N tokens is separately established by the Last-N vs First-N gap for these 3 models (BERT-base 0.219 vs 0.250; BGE-base 0.790 vs 0.872; MedCPT 0.782 vs 0.816); if no document exceeded 512 tokens, First-N and Last-N would return identical text for these models. For BioMistral-7B (max_length=2048), Last-N essentially matches First/Full (0.423 vs 0.424), consistent with no document exceeding 2048 tokens in the present evaluation corpora. Last-N underperforms First/Full for the three 512-ceiling encoder/retriever models by 3-8 percentage points (BERT-base 0.219 vs 0.250=–0.031; BGE-base 0.790 vs 0.872=–0.082; MedCPT 0.782 vs 0.816=–0.034) and is essentially neutral for BioMistral-7B (0.423 vs 0.424=–0.001). The pattern is consistent with clinical notes structurally front-loading key diagnostic and presenting-complaint information; encoders without retrieval-specific positional weighting perform worse when the late portion is the only input. For BioMistral-7B, the 3 strategies coincide in the present evaluation because no document required truncation within the 2048-token context window.

The chunking sensitivity analysis assesses whether the principal findings are robust to alternative chunking choices. Results across the 4 representative models indicate that First-N chunking is equivalent to Full-document encoding under tokenizer-native leading truncation, and that retrieval performance is materially affected by the choice between document-head and document-tail truncation in the 512-ceiling encoder/retriever models. The principal findings are therefore not driven by the chunking choice.

Table 4. Chunking sensitivity for 4 representative models under token-level truncation.[a]

Model	First-N[b]	Full[c]	Last-N[d]
BERT-base	0.250	0.250	0.219
BGE-base	0.872	0.872	0.790
MedCPT	0.816	0.816	0.782
BioMistral	0.424	0.424	0.423

[a]N=2048 for BioMistral-7B. Full uses tokenizer-native leading truncation at max_length; therefore, for tokenizer-default front truncation, Full and First-N produce the same leading-token input. Values are the MRR@10 across the 6 corpus × query-format conditions.

[b]First-N=first N input tokens.

[c]Full=full document with tokenizer-level truncation at max_length.

[d]Last-N=last N input tokens. N is each model's max_length: N=512 for BERT-base, BGE-base, and MedCPT.

Synthetic Corpus Distributional Audit

To characterize differences between the synthetic and natural-text corpora, descriptive statistics were calculated; per-corpus document-length, vocabulary size, and type-token ratio statistics are reported in Multimedia Appendix 9.

The synthetic corpus has a mean document length that is approximately 30% shorter, a vocabulary that is 58% smaller, and a type-token ratio that is 40% lower than those of the natural-text corpora. These distributional differences explain why MedCPT and other retrieval models trained on real biomedical text underperform on synthetic data, and why corpus-only ZCA whitening is less effective on the synthetic corpus; the low-rank covariance structure of the more uniform synthetic corpus amplifies noise during whitening. This finding informs the discussion of the limitations and appropriateness of synthetic data.

Post Hoc Interventions: Corpus-Only ZCA as Primary Methodology

Corpus-only ZCA was the primary post hoc intervention because it applies the transform only to document embeddings. Transductive ZCA was retained as a query-contaminated reference. Table 3 (cross-validated) shows the 2-tier pattern, and Multimedia Appendix 7 reports the aggregate intervention results averaged across the 6 corpus × query-format conditions: non–retrieval-trained tier 2 models generally improved under corpus-only ZCA, whereas retrieval-trained tier 1 models were degraded by additional whitening.

Corpus-Dependent Collapse Patterns

Midlayer collapse varied across corpora: for BioBERT, MTSamples showed a substantial decline, whereas the synthetic corpus showed minimal collapse. Natural-language queries produced deeper troughs than keyword queries but recovered to match keyword performance at the final layer. At intermediate layers, model rankings inverted relative to the final layer (Kendall τ=–0.524 between layer-9 and layer-12 rankings of the 8 BERT-scale configurations); intermediate-layer representation quality does not predict final-layer retrieval performance. Per-corpus values are reported in Multimedia Appendix 6.

Validation on Independent Corpora

The first-stage validation evaluated 8 BERT-scale configurations on 500 PMC-Patients case reports and 400 MTSamples medical transcriptions. Rankings were consistent with the primary experiment (PMC-500 ρ=0.952; P<.001; MTSamples-400 ρ=0.929; P=.001). Cross-source ranking between PMC case reports and medical transcriptions was high (ρ=0.976; P<.001), but this primarily reflects categorical stability, as the subset separates strongly into retrieval-trained and non–retrieval-trained groups.

XSL•FO
RenderX

Independent Validation of the Remaining Configurations

The second-stage validation evaluated the 5 configurations not covered by the first-stage BERT-scale subset (BERT-base-uncased, BioMistral-7B, Phi-3-mini, E5-Mistral-7B, and E5-Mistral-7B-ablation)—4 LLM-scale configurations plus the BERT-base-uncased matched-comparison addition, which was not part of the original 8 BERT-scale configurations covered in the first stage—on the same expanded PMC-Patients (500) and MTSamples (400) corpora. Across the 20 evaluation conditions (5 models × 2 corpora × 2 query formats), Spearman rank correlation between primary-experiment final-layer MRR@10 and validation-corpus final-layer MRR@10 was ρ=0.839 (Kendall τ=0.632; P<.001; n=20). All 20 conditions showed lower MRR@10 on the validation scale than on the primary 100-document scale, consistent with the expected effect of larger candidate pools on retrieval difficulty. Per-model mean ΔMRR@10 (averaged across the 4 corpus-by-query-format conditions per model) ranged from –0.097 for E5-Mistral-7B (smallest mean drop) to –0.247 for E5-Mistral-7B-ablation (largest), with intermediate values for BERT-base-uncased (–0.109), BioMistral-7B (–0.218), and Phi-3-mini (–0.241). The rank ordering of the 5 configurations was preserved at validation scale: E5-Mistral-7B-ablation produced the highest validation MRR@10 in all 4 corpus-by-query-format cells (matching its ordering in the primary experiment), BERT-base-uncased the lowest in all 4, and the previously reported anomaly that E5-Mistral-7B-ablation outperforms its instruction-tuned counterpart in known-item retrieval was preserved across all 4 paired validation cells. Combined with the BERT-scale validation reported above, the 2 stages together provide independent-corpus rank-stability evidence for all 13 panel configurations. Per-condition raw MRR@10 values are reported in Multimedia Appendix 6.

Discussion

Principal Results

Overview

The results support 4 principal conclusions. First, anisotropy is widespread across model classes, and retrieval-objective training is associated with reduced anisotropy. Second, corpus-only ZCA explicitly reduces anisotropy and shows a 2-tier effect: it improves non–retrieval-trained models and degrades already calibrated retrieval-trained models. Third, layer-wise dynamics are heterogeneous rather than uniformly U-shaped: retrieval-trained encoders show midlayer collapse with strong final-layer recovery, non–retrieval-trained encoders recover incompletely, and decoder LLMs generally improve with depth. Fourth, BM25-overlap audits indicate that the findings are not merely lexical artifacts.

The central mechanistic finding is that high final-layer retrieval performance depends on final-layer geometric restructuring rather than on the absence of midlayer collapse. In retrieval-trained encoders, midlayer troughs are followed by participation-ratio expansion and reduced cosine collapse; in non–retrieval-trained encoders, the final layer remains anisotropic, and retrieval performance remains lower. This pattern aligns with the architecture of contrastive and instruction-tuning training objectives, which compute discrimination losses at the final-layer output, making the final layer the natural locus of representation specialization. In this reading, midlayer collapse in retrieval-trained encoders is a design property of the training objective rather than a failure mode; the failure mode is the absence of subsequent final-layer geometric restructuring, which distinguishes non–retrieval-trained encoders. This framing also explains why corpus-only ZCA can approximate the geometric pattern associated with retrieval-objective training: both are associated with reshaped final-layer geometry, one through training and the other through post hoc covariance correction.

Generalization to Larger and Noisier Corpora

The primary 100-document known-item design is smaller and simpler than production clinical retrieval. Validation at 4-5× scale partially addresses this, but production corpora contain near-duplicates, copy-forwarded text, abbreviations, templated sections, deidentification artifacts, and institution-specific terminology. ZCA effectiveness depends on the covariance structure, so direct testing on production-scale institutional corpora remains necessary.

Comparison With Prior Work

The present analysis builds on and refines 3 threads of prior literature. First, Ethayarajh's [9] characterization of anisotropy across BERT, GPT-2, and ELMo embeddings is corroborated in the clinical retrieval setting, with 2 additions: the 13-model layer-level analysis localizes anisotropy to specific model classes (extreme in non–retrieval-trained encoders and Phi-3-mini; moderate in retrieval-trained encoders and most LLMs; reduced in BioLORD-2023 and instruction-tuned E5-Mistral-7B), and the matched-comparison evidence supports training-objective choice rather than training-domain choice as the stronger explanatory axis for the observed anisotropy differences. Second, the geometric-correction literature is extended by Su et al's [16] BERT-whitening, a transductive ZCA variant, to a deployment-relevant, corpus-only ZCA variant fitted to document embeddings without test-query information. The 2-tier pattern observed here (tier 2 models gain, tier 1 models degrade) refines the conventional framing of ZCA as a uniform improvement: the correction approximately reproduces the geometric pattern associated with retrieval-objective training. Tier membership is defined empirically by the response to whitening and, therefore, by the embedding geometry, rather than by the nominal training label. E5-Mistral-7B is the instructive exception: although it is retrieval-instruction-tuned, its decoder embeddings remain geometrically uncalibrated (final-layer average cosine 0.55, baseline MRR@10 0.32), and it shows the largest cross-validated gain in the panel (+0.304), placing it with the tier 2 models. This dissociation between the training label and geometric calibration reinforces the central claim that it is the geometry of the final-layer representation, not the training objective per se, that determines whether post hoc whitening helps. A directly parallel pattern has recently been reported in the code-search domain by Diera et al [15],

XSL•FO
RenderX

who applied Soft-ZCA whitening to 3 code language models (CodeBERT, CodeT5+, and Code Llama) and observed the same 2-tier effect: standard ZCA improved pretrained models substantially but degraded contrastively fine-tuned variants, with the latter requiring much smaller eigenvalue regularizers for benefit. Where retrieval-calibrated geometry is absent, ZCA tends to help; where such geometry is already present, additional whitening tends to disrupt. Third, the clinical embedding benchmarking literature, including Myers et al [17] on clinical-trial retrieval, Soffer et al [18] on 39 embedding models across 7 medical semantic similarity tasks reframed as retrieval problems, Khodadad et al [35] on a 51-task medical embedding benchmark spanning classification, clustering, and retrieval, and the companion benchmark study [3] across 3 clinical corpora and 294 conditions, is extended along 2 dimensions: layer-level analysis replaces final-layer-only evaluation, and matched-architectural controls begin to separate training-objective from training-domain contributions to performance gaps. The present manuscript is positioned as a mechanistic companion to [3]: the empirical performance claim is replicated and localized rather than displaced.

Limitations

The study has several limitations. The primary corpora contain only 100 documents each and include a single known-relevant document per query, whereas production retrieval involves larger indices and multiple relevant documents. Queries were generated from metadata rather than written by clinicians, so they may be more label-like and less noisy than real clinical queries. The synthetic corpus differs from natural text in length, vocabulary size, and type-token ratio, limiting the generalizability of results from synthetic-only experiments.

The LME uses a random-slope specification, fit separately for each of the 13 configurations, with each query treated as a distinct group within its source corpus. All models converged, showing substantial between-query variance (median intraclass correlation coefficient 0.41), computed as the variance attributable to the query random intercept divided by the total variance, per Nakagawa and Schielzeth [36]. Quadratic sensitivity analyses support the substantive conclusions. Recovery ratio and PR-expansion thresholds are data-derived and should not be treated as deployment criteria. Geometry-retrieval correlations are descriptive and computed across nonindependent observations. Finally, this is a single-author study.

Two further limitations and one observation merit explicit treatment. First, the known-item retrieval design assigns one relevant document per query, whereas many production clinical RAG settings involve multiple relevant documents per query, near-duplicates, and copy-forwarded notes. Multirelevant-document scoring (graded relevance, normalized discounted cumulative gain, or set-based recall) may yield different model orderings than the binary MRR@10/recall@10 used here, particularly for retrieval-trained models whose contrastive objective is optimized for single-document discrimination. Second, exploratory query-level inspection of failure cases (queries where final-layer MRR@10 was below 0.10 in the primary experiment) did not reveal a systematic pattern associated with query length, clinical specialty, or BM25-vs-embedding rank divergence; this is consistent with the BM25-vs-embedding Spearman rank correlations of –0.02 to 0.37 reported above, which indicate that embedding retrieval relies on substantial nonlexical signal that the present analysis does not further decompose. Third, the cross-source ranking stability (ρ=0.976 between PMC case reports and MTSamples medical transcriptions) primarily reflects the bimodal separation of the 8 BERT-scale subset into retrieval-trained and non–retrieval-trained groups, rather than fine-grained within-group rank stability.

The corpus-only ZCA cross-validation fits the whitening transform from 80 training-fold documents per fold in a 768- to 4096-dimensional hidden-state space; the resulting sample covariance is rank-deficient by 689-4017 dimensions, and the whitening transform relies heavily on the ε ridge regularizer to be well-defined outside the empirical ~80-dimensional subspace. For the corpus covariance to be approximately full-rank (eigenvalue magnitudes dominating ε across all relevant dimensions), the number of training-fold documents must approach or exceed the hidden-state dimensionality, at least ~768 documents for BERT-scale models and ~4096 for LLM-scale. Institutional EHR corpora at the scale of 10^4-10^6 documents are therefore expected to produce well-conditioned covariance estimates across all model classes evaluated here. The 80-document fold rank-deficiency is best understood as a methodological constraint of the diagnostic cross-validation design rather than a property of the intervention itself: at deployment scale, the covariance estimate is expected to be well-conditioned, the ε regularizer to be immaterial relative to the data-driven eigenstructure, and the ZCA intervention's behavior to be governed by corpus geometry rather than small-sample subspace structure. Prospective evaluation at institutional scale is therefore required before any operational claim about ZCA-based correction at scale can be supported.

Future Work

Production-scale validation on institutional EHR corpora is the most important next step. Such validation should include (1) multirelevant-document labeling with graded relevance scoring rather than known-item retrieval; (2) clinician-authored queries reflecting real information needs rather than metadata-derived queries; (3) larger candidate indices in the 10^4-10^6 document range; (4) near-duplicate notes, copy-forwarded text, abbreviations, templated sections, and deidentification artifacts characteristic of production EHRs; (5) temporal-drift testing across calendar periods to detect concept-drift effects on embedding geometry; (6) integration with reranking and approximate-nearest-neighbor indexing layers downstream of embedding retrieval; and (7) prospective failure analysis of retrieval misses against clinician-judged relevance. The corpus-only ZCA whitening intervention should be re-evaluated under each of these conditions before being considered for clinical deployment; the synthetic-corpus failure observed here suggests that ZCA effectiveness depends materially on the covariance structure of the deployment corpus. The matched-comparison framework introduced here should be extended to include additional clean architectural pairs as new

XSL•FO
RenderX

domain-trained and retrieval-trained models become available, particularly matched LLM-scale pairs that differ only in training objective. None of the screening thresholds reported in this manuscript should be treated as deployment criteria without independent prospective validation.

Matched contrasts on a single underlying model are also required to separate the pooling-attributable from the instruction-formatting-attributable components of the E5-Mistral-7B-ablation's small post-ZCA gain. Specifically, mean-pooled and EOS-pooled representations should be compared under the same instruction-formatting protocol, and instruction-prefixed vs no-prefix representations should be compared under the same pooling strategy. These contrasts were not performed in this study and are identified as specific follow-up investigations.

Conclusions

Across 13 transformer configurations, retrieval performance was strongly associated with embedding geometry. Retrieval-specific training was associated with lower anisotropy, whereas corpus-only ZCA reduced anisotropy explicitly as a post hoc correction. The resulting 2-tier pattern is the central finding: non–retrieval-trained models generally improved under ZCA, whereas retrieval-trained models were degraded by additional whitening. Matched architectural contrasts support the training objective rather than the biomedical training domain as the stronger explanatory axis, although residual confounding remains.

These findings provide a mechanistic basis for layer-level diagnostics and post hoc geometric correction in clinical retrieval benchmarks. They do not constitute deployment guidance. Institutional EHR validation using real queries, larger indices, multirelevant-document labels, and downstream RAG evaluation is required before clinical deployment.

Acknowledgments

The author thanks the JMIR Medical Informatics editorial team and the peer reviewers for constructive comments that improved the manuscript.

Mistral-7B-Instruct-v0.2 (mistralai, accessed via Hugging Face) was used in the companion study [3] to generate the synthetic clinical notes reused here. GPT-4o (gpt-4o-2024-05-13, OpenAI) was used to generate metadata-derived queries (temperature 0.3) following the procedure described in the companion study; the full prompt is provided in Multimedia Appendix 1. Claude (Anthropic) served as a coding assistant for compute scripts and statistical analyses and as a writing assistant for initial drafting and revision of the manuscript text. Grammarly was used for spelling and grammar. All code was reviewed, validated, and executed by the author. The manuscript was critically reviewed, revised, and finalized by the author, who takes full responsibility for the scientific content, interpretation, and conclusions.

Funding

This research received no specific grant from any funding agency in the public, commercial, or nonprofit sectors. Computational resources were provided via Google Colab Pro+.

Data Availability

Code, layer-level results, intervention data, validation results, analysis scripts, and figure-generation code are available in the GitHub repository for this study, with archived snapshots at Zenodo [37] under a CC BY 4.0 license. The compute scripts and outputs are included in the same repository. Query sets, synthetic clinical notes, and the MTSamples cache used here are available in the companion study repository [38]. The ZCA whitening implementation evaluated here is available as the clinical-embedding-fix software library, deposited on Zenodo [39]. PMC-Patients data can be reproduced from the zhengyun21/PMC-Patients dataset using the seeds specified in the analysis scripts.

Authors' Contributions

YM contributed to conceptualization, methodology, software, validation, formal analysis, investigation, data curation, writing—original draft, writing—review and editing, and visualization. The author read and approved the final manuscript.

Conflicts of Interest

The author serves as the Chief Medical Officer of AlgiPharma AS. AlgiPharma has no products or commercial interests related to embedding models, retrieval-augmented generation, or clinical informatics systems. No other competing interests are disclosed.

Abstract

Background: The Charlson Comorbidity Index (CCI) is widely used to quantify comorbidity burden in observational research. Applying it to real-world data requires accurate *International Classification of Diseases*–based mappings. The commonly used mapping does not reflect current German coding standards.

Objective: This study aimed to develop year-specific mappings (2004 to 2026) based on the German modification of the *International Classification of Diseases, 10th Revision* (*ICD-10-GM*), for the CCI with an open-source implementation and compare them with the commonly used mapping.

Methods: For each year, mappings were curated via independent dual review with consensus. In 515,827 inpatient cases from a German tertiary center (2010-2024), year-appropriate mappings and the commonly used mapping were applied, and the results were pooled into 2 corresponding datasets that were subsequently compared. Agreement was assessed using the intraclass correlation coefficient (2-way mixed-effects model for absolute agreement based on single measurement), and the significance of the discordances was measured using the McNemar test.

Results: Agreement was very high; 3.1% (16,136/515,827) of cases differed. A single code was present in 48.9% (7896/16,136) of the discordant cases and was intentionally excluded in the new mappings as it was not diagnostic for the category it was assigned to. Discordant results were found in 58.8% (10/17) of the categories ("peripheral vascular disease," "mild liver disease," and "severe liver disease") being present in, respectively, 51.7% (8339/16,136), 17.4% (2813/16,136), and 16.4% (2657/16,136) of the discordant cases. After filtering the dataset to only include observations with any diagnosis of a malignant disease, 6.9% (9377/136,607) of cases differed, and 79.3% (7434/9377) of those differences were caused by the "peripheral vascular disease" category, suggesting significant discrepancies for specific research questions.

Conclusions: We provide transparent, year-specific *ICD-10-GM* (2004-2026) mappings and an open-source tool for CCI calculation. The mappings align with current German coding practice and enable reproducible, year-appropriate comorbidity adjustment using administrative data.

Introduction

Background

In recent years, the increasing availability of real-world data from electronic health records, insurance claims, and clinical registries has opened new avenues for large-scale observational research [1]. These data sources often comprise hundreds of thousands of patient records and present opportunities to explore treatment effectiveness, patient outcomes, and health care use beyond the constraints of randomized controlled trials [2]. However, the heterogeneity and complexity of such datasets also necessitate robust methods for patient characterization, automated grouping, and risk stratification.

The Charlson Comorbidity Index (CCI) is one of the most widely used tools for quantifying a patient's burden of comorbid diseases. Initially developed to predict 1-year mortality based on the presence of specific comorbid conditions [3], the CCI has since become a widely used metric in retrospective cohort studies, serving as a predictor of morbidity, mortality, and health care outcomes across a broad range of clinical domains [4]. In the clinical setting, its use is suggested in several clinical guidelines, for example, the 2025 European Association of Urology guideline [5]; the German S3 guidelines on prostate cancer [6], multiple myeloma [7], and diverticulitis [8]; and the National Comprehensive Cancer Network's comprehensive geriatric assessment [9].

Over the years, many different adaptations of the original CCI have been created by adding or removing categories or changing their weights. These versions have been validated in different ways; however, they have rarely outperformed the original [4].

In 1992, Deyo et al [10] adapted the CCI for use with *International Classification of Diseases* (*ICD*), *Ninth Revision, Clinical Modification* (*ICD-9-CM*), administrative databases and modified it slightly, merging malignancy categories (solid tumors, lymphoma, and leukemia) into one, resulting in 17 instead of 19 different categories.

From that point on, a blueprint existed for using extracted administrative data to calculate a comorbidity index. Later, Sundararajan et al [11] translated the *ICD-9-CM* codes into the *ICD, 10th Revision* (*ICD-10*), *Australian Modification*. A year later, Quan et al [12] revised the codes again, creating a new *ICD-10* code list for every comorbidity.

Quan et al [12] intended to keep their mapping country independent by restricting the *ICD* codes to 4 characters (ie, the first letter and 3 digits) [12]. However, the list of *ICD* codes has since undergone substantial revisions, introducing new subcodes and modifying disease definitions, with many countries developing their own versions or modifications, such as the *ICD-10, German Modification* (*ICD-10-GM*). These refinements have been made predominantly at the most granular level (the fourth digit or the fifth character of a code), making country-specific mappings necessary—at least theoretically.

Despite these changes, the mapping published by Quan et al [12] in 2005 remains one of the most popular approaches and continues to be frequently cited in today's research (approximately 10,000 citations on Web of Science as of January 29, 2026) while also acting as the basis of automated CCI calculations in popular Python or R packages [13,14]. To our knowledge, there is currently no openly available mapping that has been developed specifically for German administrative data. Therefore, the aim of our study was to develop an open-source tool enabling reproducible comorbidity adjustment for German real-world data. We benchmarked our approach against the mappings by Quan et al [12] in a large cohort of 515,827 inpatient cases from a German tertiary care center (2010-2024) using year-specific mappings for each case and demonstrated that our mappings are better aligned with current German coding practice.

Objectives

To address this potential gap between the current German coding practices and the available mapping, we developed new mappings for calculating the CCI using the *ICD-10-GM* for the years 2004 to 2026. The goal of this study was to (1) create updated, country-specific, year-specific CCI mappings ensuring compatibility with current German coding standards; (2) compare the newly developed mappings with the widely available mapping by Quan et al [12] from 2005 evaluating agreement and category-level differences, thus investigating whether the new mapping is the optimal way to achieve the above-mentioned compatibility; and (3) provide an easy-to-use, transparent, open-source tool using the mapping, thus facilitating the optimal comorbidity classification for German patient data and future adaptations.

We aimed to improve the compliance of the automated comorbidity classification and scoring with actual clinical practice in German hospitals. This will enable more adequate stratification of the patients in retrospective clinical research.

As the goal of this project was not the revalidation of clinimetric properties of the CCI but, rather, updating the currently used mapping and keeping it compatible with other country-specific CCI adaptations, the very same categories and weights were used as in the version by Quan et al [12].

Methods

Mappings

As a reference, we used the *ICD-10* mapping as published by Quan et al [12] in 2005. We then constructed a single new mapping tailored to the 2024 *ICD-10-GM* using a prespecified, multistep process as follows.

XSL•FO
RenderX

First, we adopted the adaptation by Deyo et al [10] of the CCI (17 categories instead of 19), effectively setting the same framework for our mapping as Quan et al [12] did in 2005.

Second, 2 clinicians (FS and PPS; FS also being a coding expert with a decade of experience) independently screened the 2024 *ICD-10-GM* list as provided online by the German Federal Institute for Drugs and Medical Devices (Bundesinstitut für Arzneimittel und Medizinprodukte; BfArM) to identify candidate codes for every category. The selection process was based first on the clinical term defining the category and on the descriptions of the comorbid categories from the 1987 paper by Charlson et al [3].

Third, the independently created code sets were compared. Discrepancies were enumerated and resolved in a consensus meeting. For each discrepant code, discussion was held until a consensus was achieved. In cases in which no consensus was achieved, a disease-specific coding expert was consulted.

The 2024 iteration was developed first because it corresponded to the most recent year available in our patient data.

After establishing the 2024 mapping, we audited each *ICD-10-GM* annual release (2004-2026) and compiled a year-specific list of added, removed, split, merged, or redefined codes for each year. These changes were then independently revised by the same 2 clinicians, and the proposed changes in the mappings for each year underwent the same multistep process explained above. The resulting mappings were intended to be applied according to each case's discharge year.

A new feature as compared to the mapping by Quan et al [12] was the introduction of Boolean rules in some of the categories, which enabled more specific scoring (eg, code A and code B score points when they are both present but not separately).

To summarize, the new mappings included new sets of *ICD* codes chosen according to the above-mentioned algorithm. For each year, a new mapping was created, which enabled coding up to the most granular level, unlike the mapping by Quan et al [12], where the limitation of 4 characters per code was introduced with the intention of the single mapping being transferable to subsequent years and other countries' coding practices. The next level of granularity was achieved by the introduction of Boolean rules so that some codes could only score points in specific combinations according to German coding guidelines.

Algorithm Design

To practically use the mapping and calculate the CCI, we created a Python library with one core function requiring one or more *ICD* codes and a mapping definition as input and returning the score (number of points) and the scored categories.

The mapping definition was intentionally separated from the CCI scoring logic to enable easy modifications without having to change the central component of the algorithm.

The library consists of 24 separate mappings: a mapping described and validated beforehand by Quan et al [12] in an unchanged form and the 23 mappings built by authors FS and PPS based on the *ICD-10-GM* for years 2004 to 2026.

The algorithm was then applied to a large dataset of German patients' administrative data.

The results obtained by applying our year-specific mappings—for each case, the mapping for the corresponding year was applied—were pooled and compared with the results obtained using the mapping by Quan et al [12], which stayed the same throughout all years.

The mappings were developed—as mentioned above—for years 2004 to 2026. However, as our study population included records from the years 2010 to 2024 (see the Study Population and Data Source section), only the mappings for those years were deployed.

Statistical Analyses

The statistical analyses were conducted in Python (version 3.12.3; Python Software Foundation) [15] and R (version 4.4.2; R Foundation for Statistical Computing) [16]. For each case, we computed 2 total CCI scores: one using the year-specific *ICD-10-GM* mapping (selected by discharge year) and one using the mapping by Quan et al [12].

We first calculated the proportion of cases with different total CCI scores between the 2 approaches. To quantify the agreement, the intraclass correlation coefficient (ICC) was calculated. We used a 2-way mixed-effects model for absolute agreement based on single measurement because we wanted to assess only the absolute agreement of the scores (and not their consistency) between the 2 (fixed) alternative mappings [17]. The dependent variables in this analysis were the CCI scores per case. The analysis was conducted using the *irr* package [18] in R. We reported the resulting ICC and *P* value.

For each of the 17 categories, we applied the McNemar test to the discordant pairs. When the number of discordant pairs was less than 25, we used the exact binomial test; otherwise, continuity-corrected chi-square approximation was used. Tests were 2 sided, with an α of .05. Given the explorative nature of the analysis, no adjustment for multiplicity was applied. The calculation of the McNemar test was performed using the *statsmodels* library (version 0.15.0) [19] in Python.

Category-level concordance was displayed as a diverging bar chart ordered by total discordant count. Figures were produced using the *matplotlib* package (version 3.5.3) [20] in Python. Further investigation was undertaken when a significant difference was exhibited to determine whether the difference was the result of erroneous or better representation of *ICD* codes by one of the approaches. For the category with most total discrepancies, an additional bar chart was created to show its proportion in different diverging scores.

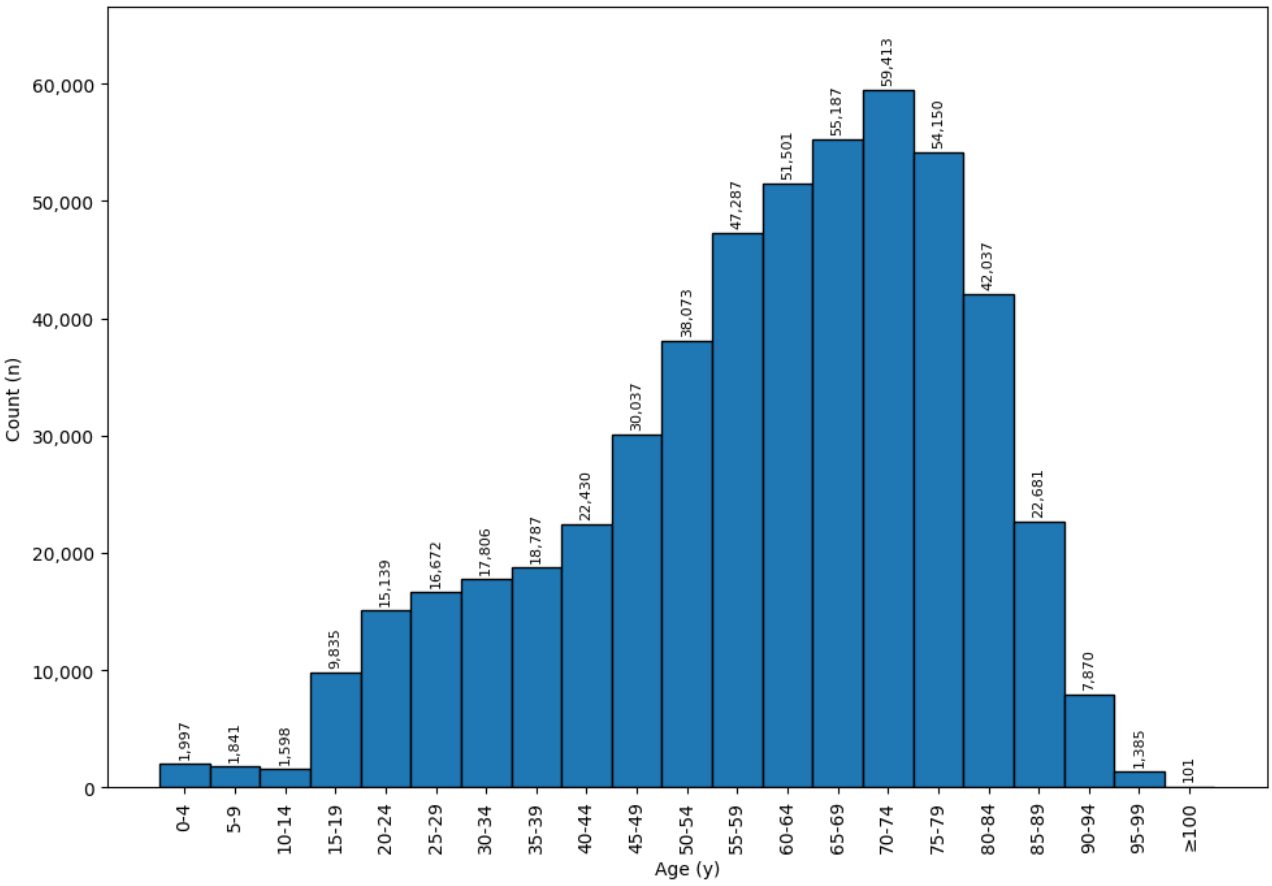
To assess the score-level impact of mapping discordance, we calculated ΔCCI for each case as the difference between the CCI obtained by our mapping and by the mapping by Quan et al [12]. We plotted the distribution of nonzero ΔCCI values.

Study Population and Data Source

Overview

Our dataset comprised all inpatient cases treated at the University Medical Center Mannheim in the years 2010 to 2024.

XSL•FO
RenderX



The data were pseudonymized before the analysis and included key administrative and clinical variables: a unique patient identifier, a case ID, the hospital admission time stamp, age, and a list of *ICD*-coded diagnoses per case. These data formed the basis for validating and testing the comorbidity scoring logic under real-world conditions.

The University Medical Center Mannheim is a tertiary care hospital and academic teaching hospital affiliated with Heidelberg University. As a maximum care provider, it covers nearly all medical specialties and treats a broad and diverse patient population, including highly complex and multimorbid cases. Its data structure and long-term digital archiving make it an ideal real-world reference for developing tools aimed at retrospective secondary use of routine clinical data.

Study Population Characteristics

A total of 515,827 cases were processed. As the data were pseudonymized for privacy protection reasons, age in the form of an integer was the only demographic information available. The age distribution of the study cohort is shown in Figure 1. Patient age ranged from 0 to 124 years, with a mean age of 59.31 (SD 18.71) years.

Figure 1. Age distribution in the study cohort.

ICD Coding System

The code list with descriptions (*ICD-10-GM* 2004-2026) was obtained from the official website of the BfArM [21].

Ethical Considerations

The study was approved by the Ethics Committee II, Medical Faculty Mannheim, Heidelberg University (approval ID 2024-885). The requirement for informed consent was waived due to the retrospective analysis of pseudonymized data.

Results

Mappings

Table 1 shows a comparison of the mapping by Quan et al [12] from 2005 and our mapping based on the *ICD-10-GM* from 2024 (developed using the process detailed in the Methods section). For clarity purposes, the other year-specific mappings are not presented in this table but are openly available online (see the Data Availability section).

[a]Shown are the newly developed ICD-10, German Modification, 2024 mapping and the original ICD-10 mapping by Quan et al [12]. The table lists ICD codes and logical conditions for each of the 17 CCI categories.

[b]ICD-10-GM: International Classification of Diseases, 10th Revision, German Modification (2024 edition).

[c]".x" denotes the inclusion of all subcodes.

Algorithm

Overview

The source code of the project is publicly available under the MIT License (see the Data Availability section). It is openly maintained and versioned to support transparency, reproducibility, and community collaboration.

The core programmatic interface of the library is the function "calculate_score(icd_codes, mapping, exact_codes)":

- "icd_codes"—a single *ICD-10* code or a list of codes
- "mapping"—selected mapping variant
- "exact_codes"—if "True," requires exact code matching in order to score points in a given category; "False" (default) applies prefix-based matching so all matching subcodes score points

The function returns a tuple (score and categories), where "score" is an integer from 0 to 29 and "categories" constitutes a list of strings representing the comorbidity groups that obtained positive scores. Mappings with weights and logical operators are stored in a structured JSON file (Textbox 1).

Textbox 1. Example function call.

Input

calculate_score(icd_codes=['E10.0', 'K71.1'], mapping = 'icd10gm_2024', exact_codes = False)

Output

(3, ['dm_simple', 'liver_severe'])

Exploration of Mapping Concordance

The first step of data exploration was the direct comparison of the discordant cases in terms of conflicting CCI scores. The "exact_codes" parameter of the algorithm was set to "False."

The proportion of records that produced different results when comparing the 2 mappings was 3.1% (16,136/515,827). After filtering the cohort to only contain cases with any malignancy diagnosis (to investigate the effects in a specialized cohort), this proportion increased to 6.9% (9377/136,607).

Agreement Between Mappings and Category-Level Discordance

To quantify overall agreement between the updated mapping and the original mapping by Quan et al [12], we calculated the ICC for the resulting scores. The ICC was 0.992 (P<.001), indicating excellent agreement between the comorbidity scores produced by the 2 mappings.

Despite this high overall concordance, category-level discordances were observed. Table 2 shows the number of cases that were scored in each comorbidity category using our mapping, the number of discordant cases, and their percentage.

Table 2. Category-level discordances. Categories are sorted by number of discordant cases (first column) in descending order.

	Discordant, n[a]	Discordant—only positive under Quan et al [12] mapping, n[b]	Discordant—only positive under our mapping, n[c]	Positive under both mappings, n	Disagreement, (%[d])
Peripheral vascular disease	8339	8339	0	20,837	28.58
Liver disease, mild	2813	1092	1721	11,352	19.86
Liver disease, severe	2657	849	1808	3876	40.67
Hemiplegia or paraplegia	1719	1636	83	16,284	9.55
Chronic pulmonary disease	1160	0	1160	28,707	3.88
Heart failure	1034	0	1034	41,040	2.46
Dementia	171	0	171	12,134	1.39
Malignancy (nonmetastatic)	99	0	99	98,465	0.10
Renal disease	32	13	19	32,709	0.10
AIDS	20	0	20	778	2.51
Metastatic malignancy	0	0	0	38,043	0
Myocardial infarction	0	0	0	22,252	0
Cerebrovascular disease	0	0	0	29,956	0
Diabetes, with complications	0	0	0	14,897	0
Peptic ulcer	0	0	0	4188	0
Diabetes, uncomplicated	0	0	0	54,128	0
Rheumatologic disease	0	0	0	3731	0

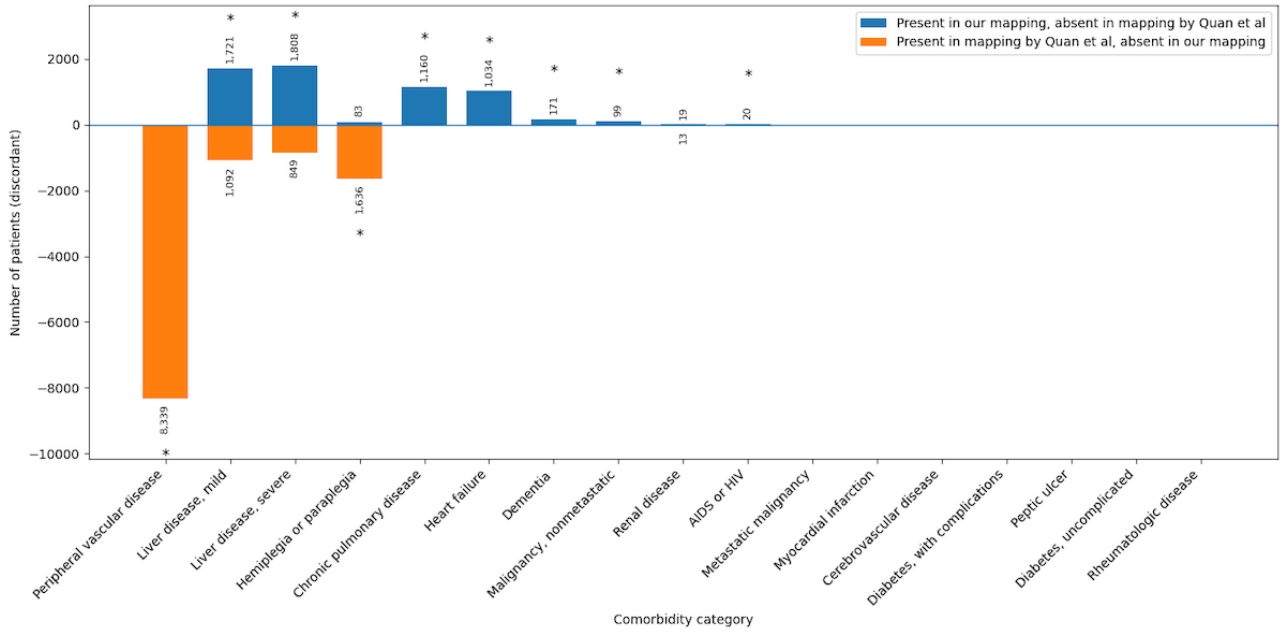
[a]The number of cases positive in only 1 of the 2 mappings.

[b]The number of cases positive for the category under the mapping by Quan et al [12] but negative under ours.

[c]The number of cases positive for the category under our mapping but negative under the mapping by Quan et al [12].

[d]Disagreement among cases positive under either mapping, calculated using the following formula: (discordant—only positive under Quan et al [12] mapping + discordant—only positive under our mapping)/(discordant—only positive under Quan et al [12] mapping + discordant—only positive under our mapping + positive under both mappings) × 100%.

Figure 2 shows the discordant case counts per comorbidity category, and Figure 3 shows the disagreement among cases who were positive for either mapping for each comorbidity category in percentages according to the following formula: (discordant—only positive under the Quan et al [12] mapping + discordant—only positive under our mapping)/(discordant—only positive under the Quan et al [12] mapping + discordant—only positive under our mapping + positive under both mappings) × 100%. Categories are ordered



XSL•FO
RenderX

in descending order, so those on the left drive the most differences.

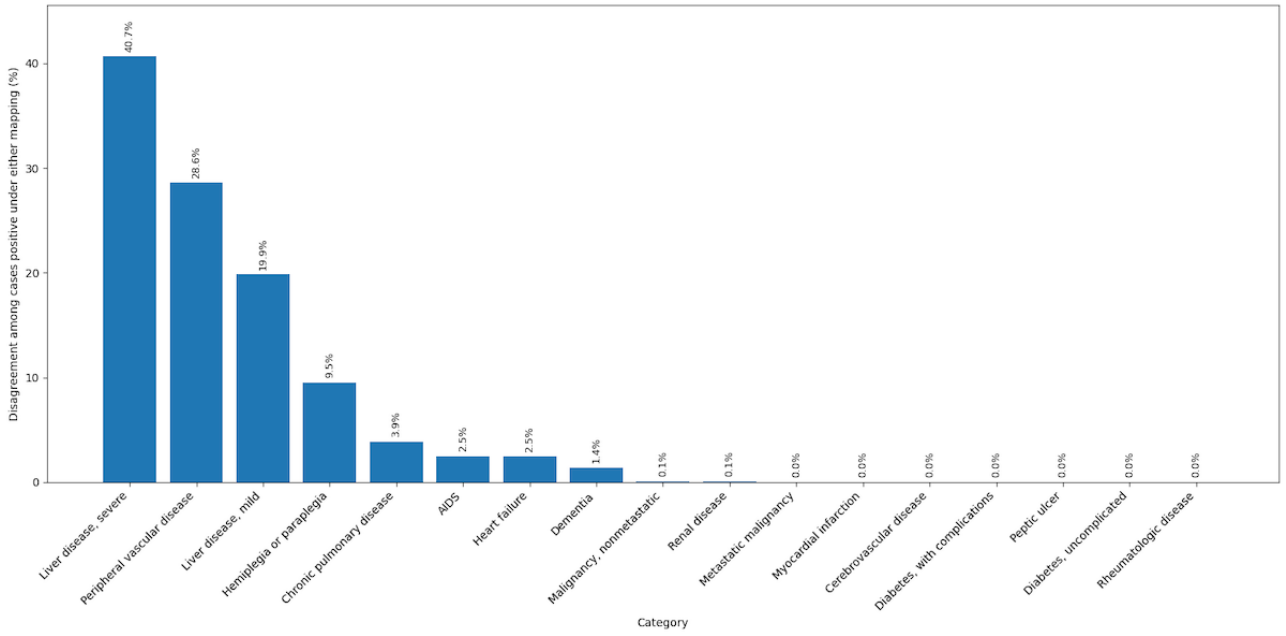
The largest discrepancy between the mapping by Quan et al [12] and ours was observed for "peripheral vascular disease." This category was scored positively using the mapping by Quan et al [12] and negatively using our mapping for 51.7% (8339/16,136) of all discordant results. It was followed by the categories "mild liver disease," and "severe liver disease" in, respectively, 17.4% (2813/16,136), and 16.4% (2657/16,136) of all discordant results. After filtering the data to only include the observations with a malignant disease diagnosis, this discordance in the category "peripheral vascular disease" affected 79.3% (7434/9377) of all the discordant cases.

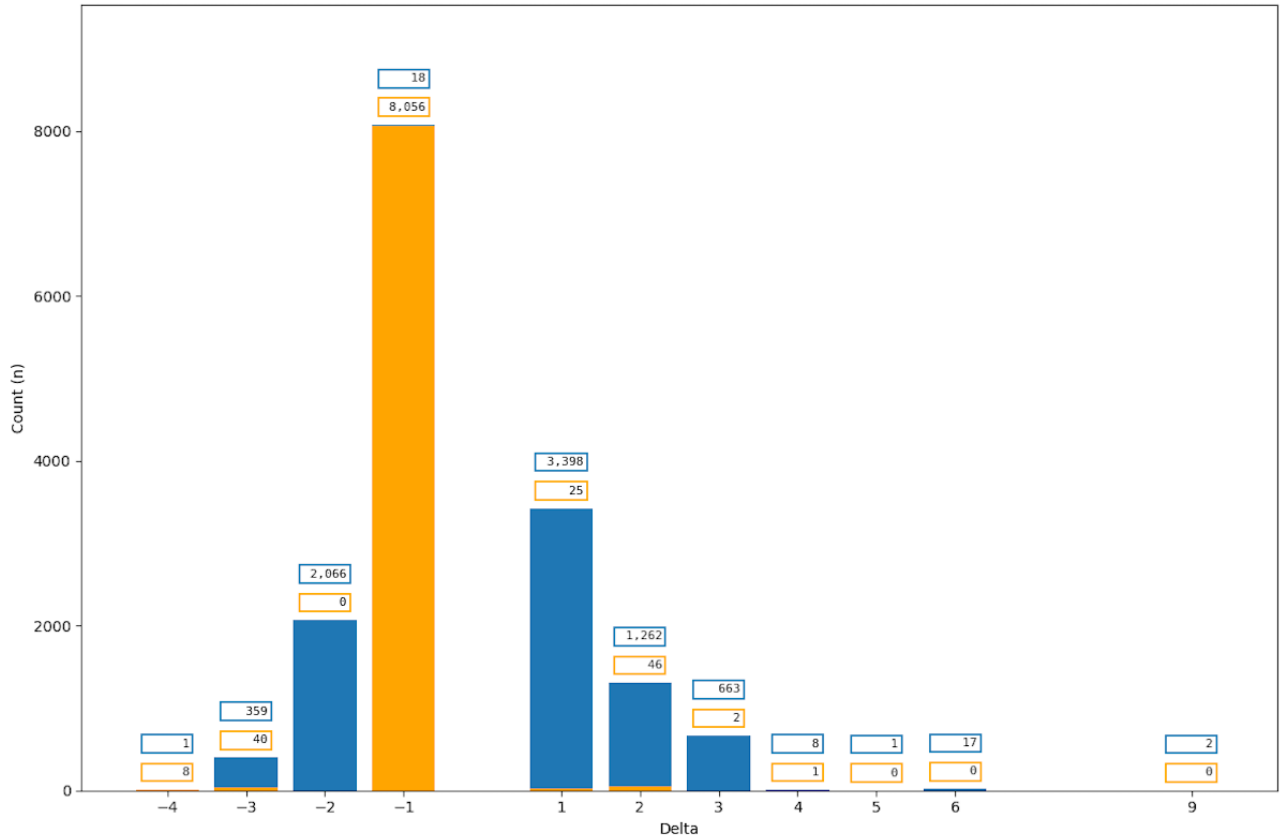
Figure 4 shows the distribution of score differences. The cases with identical scores (0 on the x-axis) were excluded for clarity. The orange segments of the bar chart show the cases with discordance in the "peripheral vascular disease" category. Because this category contributes 1 point to the CCI, it was most prominent among cases with this score differences and accounted for the overwhelming majority of these cases. Figure 5 shows the distribution after filtering the data to only include the observations with a malignant disease, showing how prominent a single category discordance can be in specific patient cohorts.

Figure 2. Discordant cases by comorbidity category. Categories are ordered left to right by total discordant count. Upward bars indicate cases identified by our mapping only; downward bars indicate cases identified by the mapping by Quan et al [12] only. *P<.05 (2-sided McNemar test; category-level 2-sided, unadjusted P<.001 for peripheral vascular disease; chronic pulmonary disease; heart failure; hemiplegia or paraplegia; liver disease, severe; dementia; liver disease, mild; malignancy [nonmetastatic]; and AIDS or HIV). P=.38 for renal disease (not significant). In the rest of the categories, there were no discordances.

XSL•FO
RenderX

Figure 3. Percentage disagreement among cases positive for either mapping by comorbidity category. The bar plot shows the proportion of cases in which only 1 of the 2 mappings identified a given comorbidity among all cases identified as positive by at least one mapping.





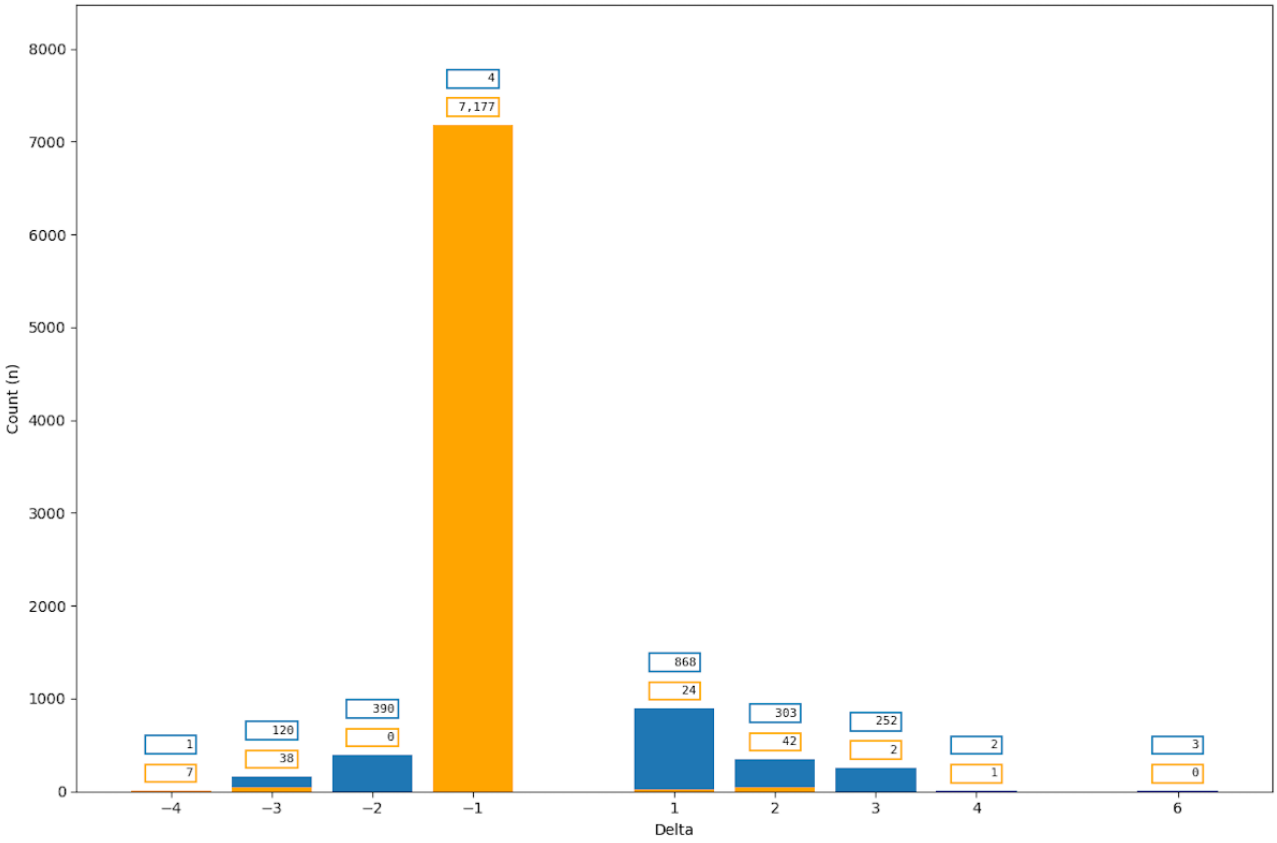


Figure 4. Distribution of score differences between the 2 mappings. Delta represents the score difference between our mapping and the mapping by Quan et al [12], calculated as score assigned by our mappings minus the score assigned by the mapping by Quan et al [12]. Bars show the number of cases for each delta value. Cases with identical scores were excluded. Orange segments indicate cases with discordance in the “peripheral vascular disease” category.

XSL•FO
RenderX

Figure 5. Distribution of score differences between the 2 mappings after filtering the data to only include the cases with a malignant disease diagnosis. Delta represents the score difference between our mapping and the mapping by Quan et al [12], calculated as score assigned by our mappings minus the score assigned by the mapping by Quan et al [12]. Bars show the number of cases for each delta value. Cases with identical scores were excluded. Orange segments indicate cases with discordance in the "peripheral vascular disease" category.

All cases in which the mapping by Quan et al [12] yielded a positive category score and ours did not can be explained by *ICD* codes that were intentionally excluded for inappropriateness. A detailed account of these codes is provided in Table 3. The most frequently observed code was Z95.81, accounting for 48.9% (7896/16,136) of all observed discordances. In the 2024 *ICD-10-GM*, Z95.81 denotes the presence of a surgically implanted vascular catheter system (eg, Broviac catheter or port system). Consequently, this code accounted for most discordances in the peripheral vascular disease category. Further examples—and very evident ones—would be the codes I85.0, I85.9, and I86.4 as the definition by the BfArM [21] states that these codes are to be used when the underlying condition is other than a liver disease.

Category and *ICD-10*[b] code	Mapping under which it was scored	Frequency, n	Description
Paraplegia and hemiplegia			
G83.2	Quan et al [12]	997	Monoparesis and monoplegia of an upper extremity
G83.1	Quan et al [12]	734	Monoparesis and monoplegia of a lower extremity
G83.41	Quan et al [12]	63	Incomplete cauda equina syndrome
G83.49	Quan et al [12]	47	Cauda equina syndrome, unspecified
G83.3	Quan et al [12]	28	Monoparesis and monoplegia, unspecified
G83.40	Quan et al [12]	16	Complete cauda equina syndrome
G80.0	Our mapping	78	Spastic quadriplegic cerebral palsy
G83.5	Our mapping	4	Locked-in syndrome
G83.80	Our mapping	1	Other specific paralytic syndromes

[a]Presented are all the discordant International Classification of Diseases (ICD) codes from the first 4 categories (as shown in Table 2 and Figure 2). The rest were not presented here for clarity of the material. The complete version of the table can be found in Multimedia Appendix 1. Code descriptions are based on the original Federal Institute for Drugs and Medical Devices ICD, 10th Revision, German Modification, definitions (translated from German by the authors).

[b]*ICD-10: International Classification of Diseases, 10th Revision*.

Discussion

Principal Results

We created year-specific *ICD-10-GM* mappings (2004-2026) via dual independent review with consensus and implemented them in an open-source Python library. The new mappings not only included corrected alignment of codes to the comorbidity categories but also introduced Boolean rules that allowed for an even more precise algorithm.

Applied to 515,827 inpatient cases from the years 2010 to 2024, the new mappings showed excellent agreement with the mapping by Quan et al [12] (ICC=0.992; $P<.001$), whereas 3.1% (16,136/515,827) of cases received different total CCI scores.

Discordance was highly concentrated in a single administrative code—Z95.81 (presence of an implanted port system)—which was present in almost half (7896/16,136, 48.9%) of all discordant cases; because this code is nondiagnostic for peripheral vascular disease, it was excluded in our mappings.

Other codes were excluded because their BfArM [21] definitions clearly indicated that they were not diagnostic of the respective comorbidity category.

By applying those changes, and after inspecting individual discordant codes, we conclude that our new, year-specific mappings more precisely reflect the coding reality in the German health care system.

Discordant Codes

We find it important to discuss some of the contents of Table 3 and the exclusion of selected codes that, in our opinion, are not diagnostic for the categories.

The most abundant discordant code, Z95.81, stands for the presence of a surgically implanted vascular catheter system (eg, Broviac catheter or port system). As the presence of a vascular access device does not, by itself, indicate peripheral vascular disease, this finding underscores the necessity of adapting automated comorbidity scoring tools to reflect contemporary coding definitions.

Codes starting with I85 denote esophageal varices. For codes I85.0, I85.9, and I86.4, the code definitions by BfArM [22] state clearly that they are not to be used if the underlying condition is liver disease. The coding guidelines designate combination codes I98.2 and I98.3 for these conditions, which were included in our definition via Boolean operators. In contrast, the *ICD-10, Clinical Modification* (*ICD-10-CM*), introduced codes for secondary esophageal varices as I85.10 and I85.11 in 2007 [23]. The definition by Quan et al [12] would include primary esophageal varices that are not due to underlying liver diseases both in current German and US coding standards.

Code I73.9 is described as “peripheral vascular disease” and was not scored as such in our mapping. This is because the code does not include claudication as a consequence of occlusion disease but, rather, describes functional causes such as arterial spasm [24].

Codes K74.71 and K74.72 were not scored in the category “mild liver disease” using our mapping but in “severe liver disease” as they describe advanced stages of liver cirrhosis [25].

K55.8 and its subcodes were excluded because, according to the *ICD-10-GM* classification, ischemic intestinal vascular diseases are specifically represented by K55.0 (“acute vascular disorders of intestine”) and K55.1 (“chronic vascular disorders of intestine”) [26]. K55.8 is reserved for other specified vascular diseases of the intestine not captured by these ischemic categories and was not considered equivalent to intestinal ischemia for the purpose of this mapping.

Z95.80, the presence of a cardiac assist system, does not unambiguously imply the condition of the peripheral vessels, which is why this code was excluded from the “peripheral vascular disease” category. Similarly, the current version of the *ICD-10-CM* includes code Z95.810, which signifies the

XSL•FO
RenderX

"presence of automatic (implantable) cardiac defibrillator" [27], which would also not be diagnostic for the comorbidity.

Cauda equina syndrome—codes G83.40, G83.41, and G83.49—does not inherently imply paraplegia or hemiplegia, which is why we removed it.

Limitations

The version of the CCI that we chose was the modification by Deyo et al [10], not the original one presented by Charlson et al [3] in 1987. We decided to use this modification because of the already available *ICD-10* mappings and their modifications, such as the one by Quan et al [12]. However, the original index with 2 additional comorbidity categories could deliver better, more precise results. This would require further investigation. Our transparent tooling could readily accommodate this in future analyses.

It is important to note that even a near-perfect algorithm and mappings are still dependent on the quality of clinical documentation and *ICD* coding practices. A Canadian 20-year validation of *ICD-10* administrative data using the CCI found that several comorbidities were increasingly undercoded over time [28]. Mapping accuracy cannot offset systematic undercoding, but errors compound. Each stage—documentation, coding, and mapping—matters for the validity and quality of retrospective observational research.

Even though modern statistical methods, often supported by—but not limited to—machine learning algorithms, can yield very cohort-specific comorbidity indexes with excellent local calibration, this methodology sacrifices comparability across studies and settings. General indexes such as the CCI enable risk adjustment and cross-study synthesis in national systems outside Europe, as shown in the Korean claim-based validation and scoping review by Shin and Han [29]. We therefore view tailored models as complementary to, not replacements for, standardized indexes such as the CCI.

Conclusions

We provide year-specific, versioned mappings that enable programmatic calculation of the CCI using German administrative database codes (*ICD-10-GM*). In a direct comparison with the widely used mapping by Quan et al [12], agreement was very high.

Inspection of the discordant codes suggests that the discrepancies reflect clinically implausible inclusions in the older mapping when applied to current *ICD-10-GM* definitions.

The obtained results demonstrate that country- and year-specific mappings are necessary to avoid misclassification when legacy mappings are applied to contemporary German coding practice and that a small set of high-frequency administrative codes can substantially bias automated scoring at scale. The released, versioned mappings and lightweight Python implementation enable reproducible, year-appropriate CCI scoring. Our work provides valuable practical tools for CCI scoring when using German administrative data.

The calculation of comorbidity indexes from *ICD* codes is not novel per se, with the first publications dating back to 1992 [10]. The novelty of our work lies in updating the mapping to reflect the country- and year-specific *ICD-10* codes used in the German health system and making it easily accessible, interoperable, reusable, and adaptable for future modifications.

This study quantifies, to our knowledge for the first time, the magnitude and origin of mapping-related misclassification risk when outdated mappings are applied to current coding practices—demonstrating that maintaining country- and year-specific mappings is critical for valid risk adjustment.

The mappings are designed to be regularly updated just as the *ICD-10* iterations are released every year. The implemented architecture, which stores the code lists in separate, open-format files, intentionally supports these updates. It also allows for the addition of new comorbidity scores (eg, that by Elixhauser or the original CCI).

Performance is bounded by and dependent on the coding quality of the processed data. The present work targeted the *ICD-10-GM* for the years 2004 to 2026, the implication being that it requires yearly maintenance and alignment to match the changes in coding practices as the German *ICD-10* list is updated every year.

For CCI scoring in German datasets, locale- and version-specific mappings should be preferred over international lists. The case of a single code being present in almost 50% of discordances (Z95.81) demonstrated that a single change may have significant implications for overall scoring when processing data programmatically. This impact might even be increased in specialized patient subcohorts.

When reporting comorbidity adjustment, the CCI variant and the applied mapping should be stated. In studies using *ICD*-coded data, implementations often follow the mapping by Deyo et al [10] via the *ICD* mapping by Quan et al [12], yet this is frequently left implicit and only becomes clear through the cited works. We therefore recommend clearly documenting (1) the CCI specification used (original 19-category CCI vs 17-category modification by Deyo et al [10]) and (2) the mapping source and its version to ensure reproducibility and comparability across studies, for example, "Comorbidities were assessed using the original 19-item Charlson Comorbidity Index; scoring was performed by manual chart review" or "Comorbidities were assessed using the 17-item Deyo modification of the Charlson Comorbidity Index; scoring was performed automatically from ICD-10-CM codes using Quan et al's mapping from 2005."

Acknowledgments

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the Generative AI Delegation Taxonomy (2025) [30], the following tasks were delegated to GenAI tools under full human supervision: proofreading

Abstract

Background: Controlled substances require strict life cycle management, but manual workflows can lead to documentation errors, traceability gaps, and delays in empty-ampoule recovery.

Objective: This study aimed to construct a quantifiable 3D closed-loop framework integrating technology, process redesign, and organizational accountability and to examine whether implementation was temporally associated with changes in controlled substance process indicators.

Methods: A single-center pre-post quality improvement study was conducted in a Healthcare Information and Management Systems Society (HIMSS) Electronic Medical Record Adoption Model (EMRAM) stage 7 hospital. The preintervention period was September 2024 to November 2024, and the postintervention period was December 2024 to February 2025. The intervention combined unique drug identifiers, personal digital assistant (PDA)–based bedside verification, smart medication cabinets, predispensing prescription review rules, batch-number traceability, daily reconciliation, tiered alerts, staff training, and anomaly-handling standard operating procedures (SOPs). Outcomes were prescription dispensing record compliance, batch-number management noncompliance, failure to complete empty-ampoule recovery and electronic documentation within 24 hours, and implementation fidelity. Proportions were reported with Wilson 95% CIs. Between-period absolute differences and 95% CIs were calculated using the Wald normal approximation for independent proportions. Comparisons used the chi-square test or Fisher exact test, as appropriate.

Results: The analysis included 3264 prescription dispensing records before implementation and 3311 prescription dispensing records after implementation. Prescription dispensing record compliance increased from 94.82% (3095/3264) to 98.7% (3268/3311). Batch-number management noncompliance decreased from 2.4% (24/1000) to 0.6% (6/1000). The rate of failure to complete empty-ampoule recovery and electronic documentation within 24 hours decreased from 5.61% (68/1213) to 0.78% (10/1274). Implementation fidelity indicators generated from operational logs were high across system stability, scanning execution, and anomaly closure.

Conclusions: Implementation of the 3D closed-loop framework was temporally associated with improvements in controlled substance process indicators in a digitally mature hospital. The implementation parameters may serve as a reference for local feasibility testing in other wards or institutions, but transferability remains to be evaluated. Multicenter studies are still needed to confirm sustainability and transferability.

KEYWORDS

controlled substances; medication safety; closed-loop management; digital health implementation; barcode administration; batch traceability; hospital information systems

Introduction

Background

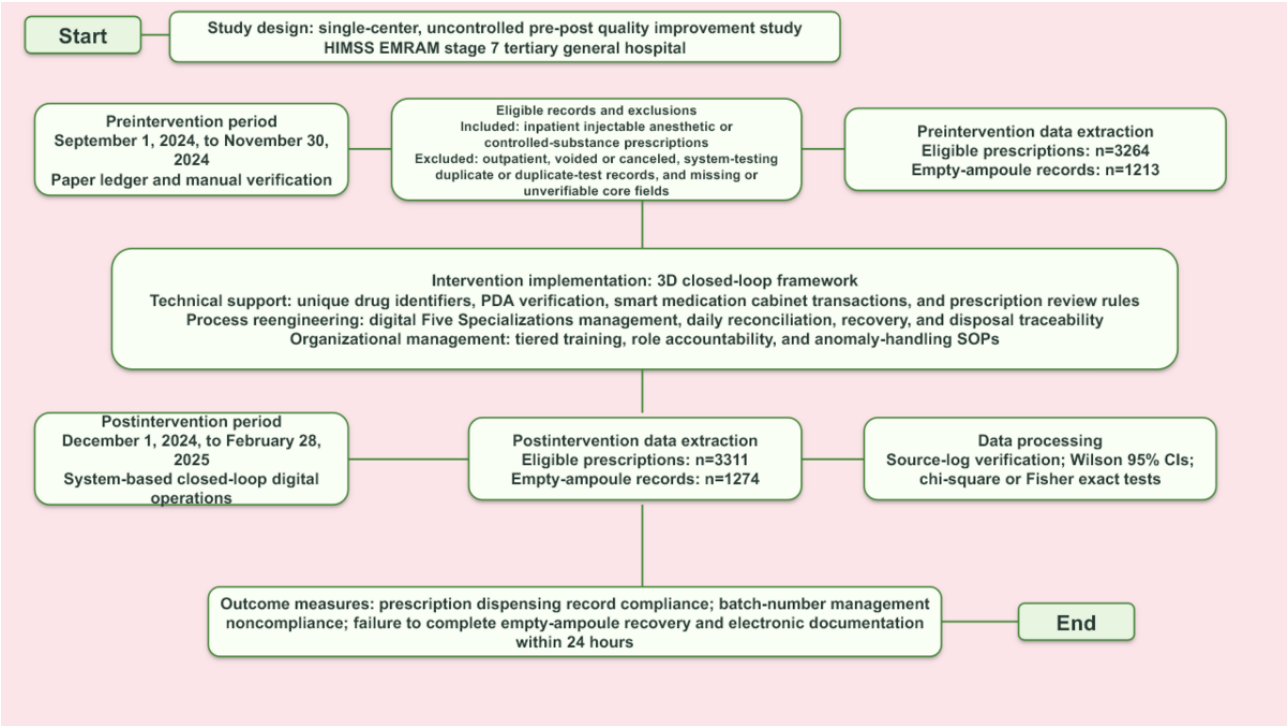
Before digitization, controlled substance management relied on paper logs, manual handoffs, and disconnected checks across the prescribing, dispensing, administration, and recovery stages. Global efforts to reduce medication-related harm have emphasized system-level redesign, and prior work has also documented persistent risks of controlled drug diversion and the need for broader patient safety safeguards [1-3]. These workflows are vulnerable to recording errors, weak end-to-end traceability, fragmented coordination, and delayed empty-ampoule recovery, highlighting the need for a fully digital closed-loop workflow [4].

Prior Work

Although barcode technology has been applied to pharmaceutical management [5], existing research still has 3 important gaps. First, many implementations have focused on a single node, meaning 1 isolated point in the medication-use workflow, such as prescribing, dispensing, administration, or return, rather than the entire life cycle. Second, few studies have reported reproducible implementation parameters, which limits replication by other institutions. Third, empirical evidence remains limited regarding which components within a bundled closed-loop framework may plausibly contribute to observed improvements in controlled substance process indicators.

Study Objective

The management of anesthetic drugs in health care institutions can be viewed as a sociotechnical system [6]. In a hospital that had achieved Healthcare Information and Management Systems Society (HIMSS) Electronic Medical Record Adoption Model (EMRAM) stage 7, we combined sociotechnical systems theory, the Systems Engineering Initiative for Patient Safety model, and closed-loop management theory [7-11] to build a quantifiable 3D framework spanning technology, process, and organization. We aimed to examine whether implementation of this bundled framework was temporally associated with changes in prescription dispensing record compliance, batch-number management, and failure of 24-hour empty-ampoule recovery and electronic documentation.



Methods

Study Design

This was a single-center, uncontrolled pre-post quality improvement study. The preintervention period was September 1, 2024, to November 30, 2024, during which anesthetic drugs were managed through the traditional manual workflow. The postintervention period was December 1, 2024, to February 28, 2025, after implementation of the barcode-enabled closed-loop management framework. The same institution, medication-use process, and target records were evaluated before and after implementation; therefore, the design describes temporal associations but cannot establish causality, as shown in Figure 1. Reporting was guided by SQUIRE 2.0 (Standards for Quality Improvement Reporting Excellence) for quality improvement studies and iCHECK-DH (Guidelines and Checklist for the Reporting on Digital Health Implementations) for digital health implementations [12,13].

Ethical Considerations

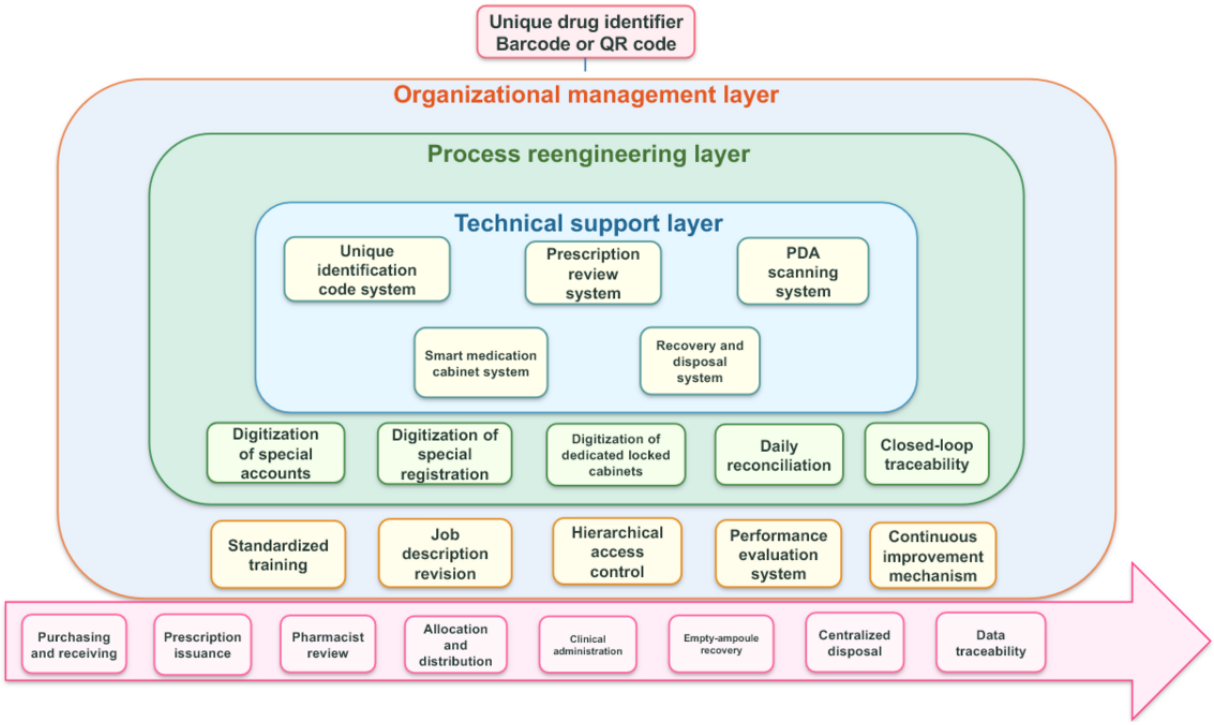
This retrospective quality improvement study was approved by the ethics committee of Ningbo Hospital of Integrated Traditional Chinese and Western Medicine (Yinzhou District Second Hospital; institutional ethics review, 2026; research approval 076) on August 25, 2026. The study involved a retrospective analysis of deidentified routine operational records generated during routine clinical care before ethics review. No additional patient contact, study-specific intervention, or prospective data collection was undertaken. Individual informed consent was not obtained because only deidentified operational records were analyzed.

Setting

The study was conducted at a tertiary general hospital that had achieved HIMSS EMRAM stage 7 certification [14]. HIMSS EMRAM stage 7 is the highest maturity stage in this model and indicates that an institution has implemented an advanced digital medical record environment, closed-loop medication-related workflows, and systematic use of electronic data and analytics to support clinical quality improvement [14]. In this context, a tertiary general hospital refers to a high-level referral hospital providing inpatient, surgical, emergency, intensive care, and specialty medical services. During the study period, the hospital had 1150 open beds according to hospital administrative reports, and the analytic dataset included controlled substance prescriptions from 34 active prescribing departments recorded in the prescription review system. The hospital used an integrated hospital information system, anesthesia information system, pharmacy management system, and nursing execution system. The nursing execution system refers to the nurse-facing electronic workflow module used for medication administration documentation and bedside verification. The integrated hospital information system, anesthesia information system, pharmacy management system, and nursing execution system were supplied by Neusoft Corporation. The prescription-review system was an integrated deployment combining Neusoft Corporation with the locally used YiYao prescription-review system. The bedside personal digital assistant (PDA) was a Neusoft Mobile Medical Care PDA manufactured by Neusoft Corporation; no separate numeric model identifier is legible on the available device label. The smart medication cabinets were NuboMed M2300 units manufactured by Shenzhen NuboMed Technology Co, Ltd.

Participants and Records

The primary analytic unit was the individual prescription dispensing record (line item). Each line item represented 1 ordered medication line and its ordered quantity. For injectable controlled substances, related verification, administration, recovery, and disposal records were linked through the relevant system identifiers when available. The empty-ampoule outcome was analyzed separately at the used-ampoule record level and was not inferred from the ordered quantity of a prescription dispensing record. Multiple line items could belong to the same prescription because of split dosing. Each record was assigned a unique analytic row identifier (row_id) in the cleaned dataset. The prescription identifier (rx_id) linked multiple line items belonging to the same prescription when split dosing generated >1 record.



The empty-ampoule outcome analysis was restricted to eligible used-ampoule records for injectable controlled substances and measured whether recovery and electronic documentation were completed within 24 hours. Because a single injectable prescription could generate >1 used ampoule, this outcome was counted at the ampoule record level rather than the prescription level.

XSL•FO
RenderX

Intervention

The intervention was a 3D closed-loop framework for controlled substance safety that integrated technical support, process reengineering, and organizational management (Figure 2). The framework used unique drug identification codes (Figure S1 in Multimedia Appendix 1) as the core traceability element and embedded prescription review together with 4 batch-verification checkpoints: dispensing, administration, empty-ampoule return, and daily reconciliation. Final disposal status was documented and reconciled at the fourth checkpoint rather than treated as a separate fifth verification node. The coding rules and 4-node batch-verification logic are provided in Section S1 in Multimedia Appendix 1; the 6 prescription review rule categories in Section S2 in Multimedia Appendix 1; interface fields and offline synchronization logic in Section S3 (Figures S2 and S3) in Multimedia Appendix 1; tiered alerts in Section S4 in Multimedia Appendix 1; and daily reconciliation and anomaly-handling standard operating procedures (SOPs) in Section S5 in Multimedia Appendix 1.

Figure 2. Architecture of the 3D closed-loop framework for controlled substance safety. The framework used the unique drug identification code (Figure S1 in Multimedia Appendix 1) as the core traceability element. The technical, process, and organizational layers jointly supported closed-loop management from inventory receipt to dispensing, administration, empty-ampoule recovery, daily reconciliation, and final disposal documentation. PDA: personal digital assistant.

The intervention evolved in 4 phases. Phase 1, in August 2024, focused on system configuration, drug coding, and hardware installation. Phase 2, during September 2024 and October 2024, used pilot testing in 2 surgical wards and 1 nonsurgical ward to refine the scanning workflow and exception-handling procedures based on frontline feedback. Phase 3, in November 2024, consisted of hospital-wide staff training, including classroom sessions and bedside drills, with role-specific certification for nurses and pharmacists. Phase 4 began on December 1, 2024, when the framework was implemented across all 34 prescribing departments. During medication administration, nurses used PDAs to scan the patient wristband, the active medical order, and the medication identifier before giving the medication; the system then performed triple verification of patient identity, order concordance, and medication identity. During empty-ampoule recovery, pharmacists or nurses used the PDA to scan eligible returned empty ampoules. During the first 2 weeks of full implementation, frontline staff required additional bedside support for scanning and exception handling; this adaptation was addressed through just-in-time pharmacy coaching and the placement of a quick-reference guide at each medication station.

In the prescription review system, indication matching used the primary diagnosis only; high-severity indication mismatches triggered an automatic block, whereas lower-severity mismatches triggered pharmacist review. This indication-mismatch severity ranking was separate from the level 1 to level 3 alert scale used in Section S4 in Multimedia Appendix 1. The pain-assessment rules in Section S2 in Multimedia Appendix 1 applied only to analgesic prescriptions when pain scoring was clinically applicable and were not mandatory criteria for intraoperative anesthetic administration or protocol-driven anesthesia induction or maintenance. The controlled substance rule library and study scope were limited to narcotic drugs and class 1 psychotropic drugs; class 2 psychotropic drugs were outside the analytic scope.

In the process reengineering layer, the “five dedicated” management principles for controlled substances [15], namely dedicated personnel, dedicated lockable cabinets, dedicated ledgers, dedicated prescriptions, and dedicated registration, were digitized into a traceable workflow covering dispensing, administration, empty-ampoule return, daily reconciliation, and final disposal documentation. The final disposal status was

XSL•FO
RenderX

captured during daily reconciliation and anomaly closure. Coding rules, 4-node batch verification, interface logic, daily reconciliation, and anomaly-handling SOPs are provided in Sections S1, S3, and S5 in Multimedia Appendix 1.

In the organizational management layer, pharmacists supervised batch-number traceability, audited process compliance, and instructed staff in system operation. Nurses performed the final bedside verification and were responsible for empty-ampoule recovery. Physicians remained responsible for rational prescribing and collaborated with pharmacy and nursing staff when exceptions occurred. Administrators monitored system performance, reviewed process metrics, coordinated optimization, and served as the regulatory liaison. These responsibilities were summarized in Table 1.

Table 1. Core responsibilities of staff under the closed-loop controlled substance workflow.

Positions	Traditional roles	Core responsibilities under the new process
Pharmacist	Medication dispenser	Batch-number tracing supervisor, process compliance auditor, and system operation instructor
Nurse	Order executor	Bedside final verifier and responsible for empty-ampoule recovery
Physician	Prescriber	Person responsible for rational drug use and collaborator in process compliance
Administrator	Daily supervisor	System backend monitor, metrics analyst, process optimization champion, and regulatory liaison

Outcomes

Batch-number management was evaluated separately using a simple random sample of 1000 unique eligible prescriptions from each period after duplicate and eligibility checks. This audit had a prescription-level denominator and was distinct from the prescription dispensing record denominator used for the primary compliance outcome. For medication lines with ordered quantities greater than 1, the same record could represent multiple tablets, patches, or injection units, and the linked batch-number and recovery or disposal logs therefore reflected the ordered quantity rather than a single physical unit. The operational definitions and calculation methods for each indicator are presented in Table 2.

Table 2. Operational definitions and calculation methods for each indicator.

Indicators	Calculation method	Judgment criteria (with authoritative basis)
Prescription dispensing record compliance rate	(Number of compliant prescription dispensing records/total number of included prescription dispensing records)×100% (95% CI)	• Appropriate indications: consistent with the hospital prescription review rule library and International Classification of Diseases, 10th Revision eligibility rules used during the study period (Section S2 in Multimedia Appendix 1) • Correct dosage: not exceeding the maximum dosage specified in the product insert or the institution-specific decision-support threshold • No drug-drug interactions: in accordance with the hospital prescription review and interaction-alert rules • Qualified prescribing authority: physicians with hospital-approved authorization to prescribe narcotic and class 1 psychotropic drugs [15]
Batch-number management noncompliance rate in the prescription audit sample	(Number of noncompliant prescriptions in the 1000-prescription audit sample/1000 audited prescriptions)×100% (95% CI)	• Mismatched batch numbers between the prescription and dispensed drugs • Incomplete batch-number records in electronic ledgers • Untraceable batch numbers during empty-ampoule recovery
Rate of failure to complete empty-ampoule recovery and electronic documentation within 24 hours	(Number of used ampoules without completed recovery and electronic documentation within 24 hours/total number of used anesthetic drug ampoules)×100% (95% CI)	• Failure to complete empty-ampoule recovery and electronic registration within 24 hours after drug use. Final disposal was performed once daily with 2-person verification and separate electronic closure in the same system.

Statistical Analysis

Two data extractors independently extracted the operational records and cross-checked them against the source documents. No record in the final source-verified dataset was altered; flagged records were either retained after source confirmation or excluded before outcome computation.

Interrater reliability was assessed using a prespecified stratified random sample of 500 records per outcome domain from the source-verified analytic dataset (n=250 preintervention and n=250 postintervention records per domain). Two reviewers independently classified each sampled record without access to each other's ratings. Cohen κ was calculated before adjudication from the 2 independent rating columns using the standard 2-by-2 agreement-table formula. The κ coefficients indicated high agreement: prescription dispensing record compliance, 0.898; batch-number management, 0.956; and empty-ampoule recovery, 0.964. Discrepant reviewer ratings were retained in the κ calculation and marked for adjudication in the audit dataset; the final adjudication or status column was not used to compute κ. The κ summary is provided in Table S4 in the Multimedia Appendix 1. The primary outcome analysis used the final source-verified analytic dataset. Detailed data-quality

XSL•FO
RenderX

verification and sensitivity analysis results are provided in Table S2 in the Multimedia Appendix 1. As a leave-2-records-out sensitivity analysis, the prescription dispensing record–compliance outcome was recalculated after excluding the 2 source-confirmed preintervention period flagged records, reducing the preintervention period denominator from 3264 to 3262.

Contextual and Confounding Factors

To contextualize the observation windows, we summarized surgical workload descriptively using surgical patient counts based on unique admission numbers. The preintervention and postintervention periods included 4837 and 4191 unique surgical admissions, respectively. Table S1 in Multimedia Appendix 1 also reports bed occupancy, open beds, staffing levels, prescribing-department counts, controlled substance prescription volume, and the prescription share of the 5 highest-volume departments. These indicators were used as descriptive context only and do not establish equivalence between periods or eliminate residual temporal confounding.

The same hospital information system, anesthesia information system, pharmacy management system, and nursing execution system were used during both periods, and no major platform upgrade was performed during the observation windows. Training and operational drills were completed before implementation; however, residual temporal confounding from holiday periods, staffing patterns, workload variation, and unmeasured case-mix differences could not be fully eliminated. Exploratory subgroup analyses were conducted by drug type when reliable denominators were available. Department-type subgroup estimates were not retained because a matched deidentified denominator was not available. No formal interaction test was performed, and subgroup results were interpreted descriptively.

Results

Study Sample and Context

The barcode-enabled closed-loop framework was implemented across the controlled substance medication-use workflow and generated stable operational logs during the postintervention period. The analysis included 3264 prescription dispensing records before implementation and 3311 prescription dispensing records after implementation.

The 2 observation windows included 4837 and 4191 unique surgical admissions, respectively. Table S1 in Multimedia Appendix 1 summarizes bed occupancy rates, open beds, prescribing departments, staffing, controlled substance prescription volume, and the prescription share of the 5 highest-volume departments. These data provide descriptive context only and do not establish equivalence between the periods. Residual confounding from the New Year and Spring Festival holiday periods cannot be fully excluded.

Prescription Dispensing Record Compliance

The total number of prescription dispensing records was 3264 before the intervention and 3311 after the intervention. Prescription dispensing record compliance increased from 94.82% (3095/3264) to 98.7% (3268/3311), while noncompliance decreased from 5.18% (169/3264) to 1.3% (43/3311). The difference was statistically significant (χ^2_1=79.26; *P*<.001), as shown in Table 3.

Table 3. Comparison of prescription dispensing record compliance rates.

Indicators	Preintervention period (n=3264), n (%; 95% CI)	Postintervention period (n=3311), n (%; 95% CI)	χ^2 test (*df*)	*P* value
Compliance	3095 (94.82; 94.01-95.53)	3268 (98.7; 98.26-99.03)	79.26 (1)	<.001
Noncompliance	169 (5.18; 4.47-5.99)	43 (1.3; 0.97-1.74)	79.26 (1)	<.001

Batch-Number Management

Using the same prescription-level audit frame of 1000 unique eligible prescriptions per period, the overall batch-number management noncompliance rate decreased from 2.4% (24/1000) to 0.6% (6/1000; χ^2_1=10.96; *P*=.001). Among the 3 nonmutually exclusive subcategories, prescription batch-number mismatch and incomplete electronic ledger records decreased significantly in Fisher exact tests, whereas batch-number mismatch during empty-ampoule recovery decreased in the same direction but did not reach statistical significance (*P*=.18; Table 4).

Table 4. Comparison of batch-number management noncompliance.

Indicators[a]	Preintervention period (n=1000)	Postintervention period (n=1000)	*P* value[b]
Prescription batch-number mismatch, n (%)	12 (1.2)	3 (0.3)	.03
Incomplete electronic ledger records, n (%)	12 (1.2)	3 (0.3)	.03
Batch-number mismatch in empty-ampoule recovery, n (%)	7 (0.7)	2 (0.2)	.18
Overall noncompliance rate, n (%; 95% CI)	24 (2.4; 1.62-3.55)	6 (0.6; 0.28-1.3)	.001

[a]The 3 subcategories were not mutually exclusive; a prescription could be counted in >1 category.

[b]The *P* values for the 3 individual noncompliance indicators were calculated using the Fisher exact test. The *P* value for the overall noncompliance rate was calculated using the chi-square test (χ^2_1=10.96).

Empty-Ampoule Recovery and Electronic Documentation Within 24 Hours

A total of 1213 used ampoules at baseline and 1274 postintervention used ampoules were analyzed. The rate of failure to complete empty-ampoule recovery and electronic documentation within 24 hours decreased from 5.61% (68/1213) to 0.78% (10/1274), a statistically significant difference (χ^2_1=47.54; *P*<.001; Table 5). Final disposal was performed once daily with 2-person verification and electronic closure in the same system, but disposal completion was not part of the 24-hour outcome denominator.

Table 5. Comparison of empty-ampoule recovery and electronic documentation within 24 hours before and after implementation.

Indicators	Preintervention period (n=1213), n (%; 95% CI)	Postintervention period (n=1274), n (%; 95% CI)	χ^2 test (*df*)	*P* value
Rate of failure to complete recovery and electronic documentation within 24 hours	68 (5.61, 4.45-7.05)	10 (0.78; 0.43-1.44)	47.54 (1)	<.001
Completed recovery and electronic documentation within 24 hours rate	1145 (94.39, 92.95-95.55)	1264 (99.22; 98.56-99.57)	47.54 (1)	<.001

Implementation Fidelity

Postintervention implementation fidelity was high according to operational system logs (Table 6). System stability was high: system uptime was 99.92% (30,216/30,240) monitored node-hours, calculated as 14 monitored nodes×90 days×24 hours and covering the full 90-day postintervention period, and smart medication cabinet network uptime was 99.88% (25,889/25,920) monitored cabinet-hours, calculated as 12 monitored cabinets×90 days×24 hours and covering the full 90-day postintervention period. Operational compliance was also high: PDA verification execution rate was 99.76% (3303/3311) of eligible medication administration verification events, with each event comprising wristband, order, and medication-ID verification. Medical order scan execution was 99.64% (3299/3311), wristband scan verification was 99.82% (3305/3311), drug identifier code scanning was 99.79% (3304/3311), empty-ampoule scanning within 24 hours was 99.22% (1264/1274), and abnormal-incident closure was 100% (52/52). Network downtime was counted as an uptime failure even when the local cache remained available, because the cabinet was not fully connected to the live system. These high rates reflect the system-enforced workflow design: required scans were embedded as mandatory steps before medication administration, dispensing, empty-ampoule recovery, or incident closure could be completed, and scan failures generated hard stops or exception logs rather than relying only on voluntary manual compliance. These indicators were organized to reflect multiple dimensions of implementation fidelity, including system stability, operational adherence to required workflow steps, data synchronization completeness, and anomaly-process closure [16].

Table 6. Core metrics for framework implementation fidelity.

Indicators	Result, n/N (%)	Data source
System stability		
System uptime (monitored node-hours)	30,216/30,240 (99.92)	System operation log
Smart medication cabinet network uptime (monitored cabinet-hours)	25,889/25,920 (99.88)	Cabinet network log
Data synchronization integrity rate during network outages	320/320 (100)	Offline synchronization log
Operational compliance[a]		
PDA[b] verification execution rate	3303/3311 (99.76)	PDA scan log
Medical order scan execution rate	3299/3311 (99.64)	Medical order scan execution log
Wristband scan verification rate	3305/3311 (99.82)	Wristband scan log
Scanning rate of drug identification codes	3304/3311 (99.79)	Drug identifier scan log
Empty-ampoule scanning rate within 24 hours	1264/1274 (99.22)	Empty-ampoule recovery scan log
Anomaly process: closure rate for abnormal incidents	52/52 (100)	Incident closure log

[a]For the operational-compliance indicators, the denominator was the number of eligible postintervention medication administration verification events (N=3311), unless otherwise specified. Each verification event required the wristband, medical order, and medication identifier scans. The empty-ampoule indicator used a separate denominator based on eligible used-ampoule records (N=1274).

[b]PDA: personal digital assistant.

Sensitivity and Subgroup Analyses

Four source-verified prescription dispensing records were flagged during source verification. Two preintervention period records were source-confirmed and retained in the primary analysis; 1 postintervention period duplicate record was excluded to avoid double counting, and 1 postintervention period

XSL•FO
RenderX

incomplete record was excluded because required fields were missing. In the leave-2-records-out sensitivity analysis, prescription dispensing record compliance was 94.82% (3093/3262) before implementation and 98.7% (3268/3311) after implementation, with the between-period comparison remaining statistically significant (P<.001). The batch-number and 24-hour empty-ampoule outcomes were unchanged after source verification. Exploratory prescription dispensing record–level descriptive subgroup results are shown in Table S3 in Multimedia Appendix 1; no formal interaction test was performed.

Discussion

Principal Findings

This single-center pre-post quality improvement study implemented a 3D closed-loop framework for controlled substance safety in a HIMSS EMRAM stage 7 hospital [10,16-18]. After implementation, 3 operational process indicators changed in a favorable direction: prescription dispensing record compliance, batch-number management, and 24-hour empty-ampoule recovery and electronic documentation. These findings suggest that routinely generated system logs and medication management records can be used to quantify the implementation of a closed-loop controlled substance workflow in a digitally mature hospital [10,16-18].

Comparison With Prior Work

Prior work on medication safety has often evaluated individual components, such as barcode medication administration, smart medication cabinets, electronic prescribing checks, or access-control rules [17,19-21]. These approaches are important but usually focus on a single stage of the medication-use process. The present framework differs by connecting several existing regulatory and best-practice requirements into an interlocked operational workflow. Rather than treating prescription review, batch-number documentation, cabinet access, bedside verification, empty-ampoule recovery, and anomaly handling as separate tasks, the framework links these tasks through shared identifiers, system-enforced checkpoints, and accountable roles.

The contribution of this study is therefore not that batch-number documentation, empty-ampoule recovery, prescription authority, or controlled substance accounting are new requirements. These are already expected in regulated medication management practice and are consistent with professional guidance on preventing controlled substance diversion [22]. The added value is the systematization of these requirements into a traceable and measurable digital process [8-10,16-18]. The framework makes the relationship between the physical medication, the electronic order, the batch number, the user action, and the final recovery or disposal record more explicit than in a paper ledger or a single-node electronic module [8-10,17,18]. National or institutional narcotics-management information systems have also shown the value of structured life cycle monitoring for medical narcotics [18]. In contrast to single-module optimization, the framework provides an integrated technology-process-organization model and discloses implementation parameters for coding, prescription rule interception, interface synchronization, tiered accountability, and anomaly SOPs [8-10,16-18].

Interpretation and Implications

End-to-end batch-number traceability may be an important component of the observed improvement in 24-hour empty-ampoule recovery and electronic documentation because it links the dispensing record, administration verification, returned ampoule, 24-hour recovery and documentation record, daily reconciliation record, and final disposal status. However, this component was implemented as part of a bundled intervention that also included prescription review rules, smart medication cabinets, PDA-based verification, staff training, role redefinition, daily reconciliation, and anomaly-handling SOPs. The study design cannot isolate the independent contribution of any single component. The most cautious interpretation is that batch-number traceability was a plausible contributing component within a broader sociotechnical intervention. The apparent effect of hard blocking may also reflect a short adaptation period in which frontline nurses and pharmacists adjusted to more explicit scanning and exception-handling routines. For hospitals with advanced digital maturity, the framework may offer a practical implementation reference; for hospitals with less integrated information systems, phased adaptation and local feasibility testing would be necessary [8-11,16-20].

Limitations

The principal limitation is that this was a single-hospital pre-post study without randomization or a concurrent control group, so the findings support temporal association rather than causal inference.

Several factors limit the generalizability of our findings. First, the study was conducted in a HIMSS EMRAM stage 7 hospital with integrated hospital information systems, PDA workflows, and smart medication cabinet support, so transferability to hospitals with lower digital maturity may be limited [4,5,10,16-18,20]. However, not all components of the framework require mature information systems: the organizational management layer, including role redefinition, daily reconciliation, and anomaly-handling SOPs, can be implemented in hospitals with basic IT infrastructure and then expanded stepwise as technical capacity improves [8-11,16-18]. Second, the study focused on process indicators rather than patient-level clinical outcomes, so whether the observed improvements translate into fewer diversion events, fewer adverse drug events, or better patient outcomes remains to be established. Potential unintended consequences, including additional scanning time, workflow burden, alert fatigue, and attempts to bypass system controls, were not systematically measured. Therefore, the absence of reported major unintended consequences should not be interpreted as evidence that such effects did not occur. Implementation costs, staff time, maintenance requirements, and opportunity costs were not prospectively itemized, so no formal cost or cost-effectiveness analysis was performed. Third, the single-center uncontrolled pre-post design limits external validity and precludes causal inference. Finally, the observation window included the New Year and Spring Festival holidays, which may have affected

XSL•FO
RenderX

staffing patterns and workload in ways that this workload indicator alone cannot fully capture. Sustainability was not formally evaluated, and continued rule maintenance, periodic refresher training, and local governance will be needed to preserve performance as workflows evolve.

Conclusions

This single-center pre-post study showed that a 3D closed-loop framework integrating technical traceability, process redesign, and organizational accountability was temporally associated with improved controlled substance process indicators in a HIMSS EMRAM stage 7 hospital.

Although the full framework assumes mature digital infrastructure, its components can be introduced incrementally. Hospitals with less integrated information systems may first strengthen the organizational management layer, including role redefinition, daily reconciliation, and anomaly-handling SOPs, and then progressively add technical supports such as PDA-based verification and smart medication cabinets. Because the framework relies on routinely generated operational logs, it may offer a practical quality improvement path even where digital maturity is limited.

Future multicenter studies with stronger designs and longer follow-up are needed to test sustainability, transferability, and effects on patient-level outcomes and controlled substance diversion events.

Acknowledgments

During manuscript revision in August and September 2026, the authors used ChatGPT (GPT-5; OpenAI) and Codex (GPT-5; OpenAI) for English-language editing, manuscript restructuring, consistency checks, preparation of reviewer-response materials, and independent verification of previously calculated aggregate statistics. The authors also used OpenAI's image-generation tool through Codex to create the proposed table-of-contents image; the generation method and prompt are disclosed in the image metadata. These tools were not used to generate or alter source data, determine record eligibility, conduct the primary statistical analyses, or independently make final scientific interpretations. All AI-assisted outputs were reviewed by the authors, who take responsibility for the final manuscript.

Abstract

Background: Purpose-built AI well-being tools—designed with clinical safeguards for everyday emotional difficulties such as stress, grief, and relationship conflict—represent a growing category of digital mental health support. When such tools are removed from the market, users must navigate alternatives on their own; however, no empirical data exist on where they actually turn.

Objective: We aimed to characterize real-world support-seeking after the withdrawal of a purpose-built AI well-being mobile app (Ash), specifically to (1) document where former users turned for emotional and mental health support, (2) characterize how general-purpose AI tools were used for mental health, (3) assess perceived changes in service access and subjective well-being, and (4) capture qualitative experiences of the transition.

Methods: We conducted a cross-sectional survey of 393 UK-based adults who had used Ash within 90 days before its withdrawal from the UK market in January 2026. Of 7415 randomly sampled eligible users invited by email, 393 (response rate 5.3%) responded and 364 (92.6%) completed all items. The survey assessed self-reported sources of emotional and mental health support following withdrawal, use of general-purpose AI tools, perceived changes in access to support, and subjective well-being. Free-text responses (n=272) were analyzed using codebook-based qualitative content analysis, with the codebook developed through a hybrid inductive-deductive process. Reporting follows the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) guidelines.

Results: The most common primary sources of mental health support since losing access to a purpose-built AI well-being application were general-purpose AI tools (27.1%, 104/384; 95% CI 22.9-31.7) and no support at all (26%, 100/384; 95% CI 21.9-30.7). Relatively fewer respondents reported turning to National Health Service services (19/384, 4.9%; 95% CI 3.2-7.6) or a private therapist (8.1%, 31/384; 95% CI 5.7-11.2) as their primary resource. Among the 157 respondents reporting use of general-purpose AI for mental health support, the dominant motivations were instant access (78.3%, 123/157) and cost (73.9%, 116/157) rather than perceived helpfulness (18.5%, 29/157). Overall, 60.2% (219/364; 95% CI 55.1-65.1) reported worse access to support, rising to 80.7% (71/88; 95% CI 71.2-87.6) among those who had not sought support since. Qualitative themes converged on these patterns: 33.8% (92/272) reported finding no suitable alternative, 22.8% (62/272) judged general-purpose AI inferior, and 15.8% (43/272) expressed emotional distress at the loss.

Conclusions: In this exploratory, retrospective survey, removing a purpose-built AI well-being tool was not associated with a redirection to human-led mental health services; most respondents turned to general-purpose AI or stopped seeking support entirely, and those who disengaged reported the poorest well-being. Regulatory frameworks should account for real-world care-seeking behavior when evaluating the risks and benefits of purpose-built AI tools for general wellness.

Introduction

As demand for mental health support far exceeds available supply [1], a growing number of people are turning to generative AI for emotional support [2,3]. A recent national survey found that 13% of US adolescents and young adults have used generative AI for mental health advice, with rates exceeding 22% among those aged 18 to 21 years [2]. A systematic review of 79 studies documented the rapid expansion of generative AI applications across mental health diagnosis, therapy, and clinician support [3]. The safety profile of many AI tools, however, remains concerning: studies have found that general-purpose AI chatbots frequently fail to recognize or appropriately respond to mental health crises [4], and even in nonacute settings, emerging evidence links their use to emotional dependency and reinforcement of harmful beliefs [4-7]. This creates a tension at the heart of digital mental health policy: millions of people are already using general-purpose AI tools for emotional support, while purpose-built AI tools designed for safe, effective psychological support face the highest regulatory barriers. What remains poorly understood is what happens when users who have access to a purpose-built AI well-being tool, designed with clinical safeguards and psychological expertise, lose access to that tool and are left to navigate the broader mental health support landscape on their own.

The gap between demand for mental health support and available supply is a global challenge, and one that has underscored a need to consider different support channels for the wide range of presentations that may drive help-seeking behavior. Even in high-income countries with well-resourced health systems, up to two-thirds of patients with depression receive no treatment [8] and wait times for psychological services routinely stretch to months or years. In the United Kingdom (the setting for the present study), an estimated 1.8 million people are currently on National Health Service (NHS) waiting lists for mental health services [9]. Mental health costs the UK economy an estimated £118 billion per year [10]. These figures span a broad spectrum from clinical disorders requiring specialist intervention to the everyday stress, relational difficulties, and life transitions that characterize most help-seeking. The UK Government has explicitly recognized this distinction: the Department of Health and Social Care's 2022 Mental Health and Wellbeing Plan states that "poor wellbeing is distinct from mental illness, and we do not want to 'medicalise' the normal worries and stresses of life" [11]. Social prescribing, the practice of referring patients to nonclinical community services, now embedded in primary care across the United Kingdom, reflects the same principle: not all support for emotional well-being requires clinical intervention [12].

Against this backdrop, a new category of digital tool has emerged: AI well-being applications designed specifically for the everyday emotional difficulties (eg, stress, grief, relational conflict, or life transitions) that constitute much of the unmet demand described in the preceding paragraph. These users may occupy what has been termed the "missing middle" of mental health care: people whose needs exceed self-help but who do not meet thresholds for specialist services [13]. Critically, the sustainability of such tools is not guaranteed, particularly in light of evolving regulatory policy. The NASSS framework (Non-adoption, Abandonment, Scale-up, Spread, and Sustainability) highlights how regulatory, organizational, and individual-level complexity can interact to disrupt access to health technologies, particularly when disruption originates outside the user-technology relationship [14]. What happens to users caught in such a disruption, however, has not been studied.

Purpose-built AI well-being tools extend the principle that not all emotional support requires clinical intervention into the digital realm, offering accessible, individualized support for stress management, resilience-building, and relational difficulties without requiring clinical resources or diagnostic labeling [15]. However, global regulatory frameworks governing such tools have not kept pace with either the technology or the demand. In the United States, the Food and Drug Administration's General Wellness Policy provides a structured pathway for low-risk wellness products that do not make diagnostic or treatment claims [16], and the Food and Drug Administration has adopted a policy of enforcement discretion for certain lower-risk digital health software functions [17]. The European Union's Medical Device Regulation explicitly states that "software intended for life-style and well-being purposes is not a medical device" [18]. In the United Kingdom, the Medicines and Healthcare Products Regulatory Agency has developed regulatory guidance for Digital Mental Health Devices, but the distinction between medical devices and well-being products is challenging to navigate; while, as of July 2026, the Medicines and Healthcare Products Regulatory Agency has created a regulatory sandbox that remains in testing [19], there is not yet a dedicated regulatory pathway for AI well-being products that clearly distinguishes them from medical devices. In practice, this means that purpose-built well-being tools may face medical device classification while general-purpose AI platforms, which are used at far greater scale for the same purposes and without equivalent safeguards, remain unregulated for mental health purposes in the United Kingdom. We use the term "unregulated" throughout the paper to mean "not regulated as a medical device for mental health purposes."

This regulatory asymmetry has real-world consequences. Ash, a consumer well-being mobile app developed by Slingshot AI for adults managing everyday emotional difficulties, was voluntarily withdrawn from the UK market in January 2026 following regulatory uncertainty about a general wellness pathway in the United Kingdom. The app was built alongside clinical psychologists with clinically informed safeguards and had a growing evidence base, including multiple single-arm trials showing improvements in loneliness, perceived social support, and social engagement [20,21], and an analysis of over 20,000 real-world conversations demonstrating that purpose-built suicide risk safeguards operated as designed [22]. The United Kingdom withdrawal thus defined a population of active users and temporal context for this post-withdrawal descriptive survey study.

The present study leverages this voluntary market withdrawal to address a question with implications beyond any single product or regulatory decision: when users of a purpose-built AI well-being tool lose access, where do they actually go?

XSL•FO
RenderX

Specifically, we aimed to (1) document where former users turned for emotional and mental health support, (2) characterize how general-purpose AI tools are being used for mental health in this population, (3) assess perceived changes in access to support and subjective well-being, and (4) capture qualitative experiences of the transition through open-ended responses. These aims correspond to four research questions (RQs): (RQ1) Where do former users turn for mental health support after losing access to a purpose-built AI well-being tool? (RQ2) How are general-purpose AI tools used for mental health support in this population? (RQ3) How do perceived access to support and subjective well-being change following service disruption? (RQ4) How do former users describe their experience of the transition?

Methods

Study Design and Context

This cross-sectional survey study examined where users of a purpose-built AI well-being mobile app turned for mental health support following an involuntary service disruption. The voluntary withdrawal of Ash from the UK market in January 2026, described above, created a defined study population and clear temporal boundary for the disruption. This study is described in accordance with the CHERRIES (Checklist for Reporting Results of Internet E-Surveys; Multimedia Appendix 1) [23].

Product Context

Ash is an AI specifically designed to support mental health. Purpose-built generative AI tools for mental health are distinct from general-purpose AI in that, at a minimum: (1) the base model distribution is modified through pretraining and fine-tuning to address mental health concerns, (2) the system architecture is further aligned through mental health-specific guardrails and targeted predeployment ("offline") evaluation procedures, and (3) reinforcement learning is driven by reward signals focused on health outcomes and clinical appropriateness in addition to or instead of pure engagement or user satisfaction signals [20,22,24]. For additional detail on the Ash model and product development, see [20,21].

Participants and Recruitment

Eligible participants were UK-based adults (aged 18+ years) who had used Ash (which was available for free at the time) within the 90 days before its withdrawal; no further inclusion or exclusion criteria were applied. Invitations were sent by the Slingshot AI team to the email address registered to each user's Ash account, with 7415 invitees drawn at random from all eligible users in the database. The survey was distributed through Tally [25] between February and March 2026. Of the 7415 invited, 618 (8.3%) opened the survey, of whom 393 (63.6%) responded, yielding an overall response rate of 5.3% (393/7415). Two follow-up reminders were sent by email to those who did not respond. A total of 364 (92.6%) completed all items; the remaining 29 respondents responded to the first half of the survey (support sources, AI use patterns) but did not complete the final section (perceived access change, well-being, and demographics). All 393 respondents were included in analyses where they provided data; survey responses were deidentified before analysis. Participants were provided the option of entering a prize draw alongside the survey.

Ethical Considerations

This study was reviewed in March 2026 by the BRANY (Biomedical Research Alliance of New York) independent Institutional Review Board and determined to be exempt under category 4(ii) (File # 26-081-2393). These data were collected during routine product operations from users who had consented to the use of their data for research, and the deidentified dataset was analyzed under this exemption. The survey invitation described an anonymous, voluntary survey whose aggregate results would inform product and policy work (see email invitation text in Multimedia Appendix 2). As this study involved community-based UK adults rather than NHS patients or records, it fell outside the UK Health Research Authority's NHS Research Ethics Committee system. All data processing complied with UK General Data Protection Regulation and the Data Protection Act 2018.

Measures

Overview

The survey comprised 12 items assessing five domains: (1) support sources since losing access to Ash, (2) general-purpose AI use patterns, (3) perceived change in access to support, (4) subjective well-being, and (5) demographics. Items were developed by the research team to capture the specific phenomenon of interest, namely, where users turn when a purpose-built mental health AI tool becomes unavailable.

As the survey comprised single-item and multiple-response measures of behavior and self-perception rather than multi-item reflective scales of latent constructs, internal-consistency reliability (eg, Cronbach α) and discriminant-validity indices were not calculable; each item was intended as a direct indicator of the behavior or experience it names. The full instrument, including all item stems and response options, is provided in Multimedia Appendix 2.

Support Sources

Respondents were first asked, "Since Ash/Slingshot stopped being available in the United Kingdom, where have you turned for emotional or mental health support?" Respondents could select all that apply from 11 options: general-purpose AI tools (eg, ChatGPT [OpenAI], Claude [Anthropic], Gemini [Google LLC], and Copilot [Microsoft Corp]); other mental health or well-being apps; NHS services (general practitioner, NHS Talking Therapies, etc); private therapist/counsellor; friends, family, or partner; support groups or community groups; workplace support/employee assistance program; online forums or social media; books, podcasts, or self-help programs; "I haven't sought support since"; and other (free text). A follow-up item asked respondents to identify which single source they had relied on most.

General-Purpose AI Use Patterns

Four items assessed AI use among all respondents. Frequency of use for emotional or mental health support was assessed on a 7-point scale (daily to never). For those endorsing

XSL•FO
RenderX

general-purpose AI use for emotional or mental health support, 3 follow-up questions were asked: (1) The role in the respondent's life, assessed on a 5-point scale (main source of support to occasional curiosity); (2) primary uses of AI for mental health, assessed via a multiselect item ("select up to 3") with options including venting or feeling heard; advice or problem-solving; coping tools; relationship or communication help; stress/anxiety/sleep support; and journaling or reflection prompts; (3) motivations for choosing AI, assessed via a separate multiselect item with options including free or low cost, instant access, felt more helpful than alternatives, more private, easier than NHS or human support, didn't want something "medical," and "other" options.

Perceived Access Change

Respondents rated how their access to mental health support had changed since losing access to Ash on a 5-point scale (much better to much worse).

Well-Being

A single item assessed general well-being over the past month on a 5-point scale (much better than usual to much worse than usual).

Open-Ended Response

One free-text item asked, "Is there anything you're using now that works better—or worse—than Ash did for you?"

Demographics

Age range (6 categories from 18-24 to 65+ years) and UK region (England, Scotland, Wales, Northern Ireland, and prefer not to say).

Data Analysis

Quantitative Analysis

Descriptive statistics (frequencies and percentages) were computed for all structured items. For multiselect items, percentages reflect the proportion of all respondents who endorsed each option. Denominators vary slightly across items due to partial completion and are reported where relevant. Analyses were done in Python 3.10 using pandas. All proportions are reported to one decimal place as percentages with numerators and denominators, accompanied by Wilson score 95% CIs; qualitative code frequencies are reported as counts and percentages of the 272 analyzable free-text responses. Consistent with this study's descriptive aims, no null-hypothesis significance testing was conducted.

Qualitative Analysis

Free-text responses were analyzed using codebook-based qualitative content analysis, with the codebook developed through a hybrid inductive-deductive process [26]. Of 351 free-text responses, 272 contained sufficient content for analysis (>5 characters, excluding single-word or uninformative entries). The lead author, a licensed clinical psychologist, first read all responses and inductively identified recurring patterns, which were discussed and refined with the authorship team and organized into a codebook of 15 nonmutually exclusive codes across five domains: (1) evaluation of general-purpose AI as a substitute, (2) support gap and disengagement, (3) emotional response to loss, (4) valued features of a purpose-built tool, and (5) coping strategies adopted. The full codebook, including code definitions, inclusion and exclusion rules, and anchor examples for different codes, is provided in Multimedia Appendix 3. Each code was then operationalized as a set of transparent keyword and phrase patterns (regular expressions). Anthropic's Opus 4.6 was used to assist in drafting candidate patterns from the code definitions; all patterns were reviewed, edited, and approved by the lead author, and the classification step itself was fully deterministic (rule-based rather than model-based), such that identical inputs yield identical codes; no generative model was involved in assigning codes to responses. Patterns were refined over 3 coding passes. After each pass, the lead author manually coded those that remained uncoded, also reviewing all responses to correct misclassifications, either by refining the shared patterns or by direct reclassification. The 24 direct reclassifications are individually documented, with rationale, in this study's audit records and summarized in Multimedia Appendix 3. The final coded dataset was reviewed by the full authorship team for face validity. Of the 272 responses, 270 (99.3%) were coded to at least one theme; the remaining 2 lacked sufficient specificity for classification and are described in Multimedia Appendix 3. Coding was performed by a single coder, and interrater reliability statistics were therefore not computed. Representative quotations were selected to illustrate each theme. The codebook, deterministic classification rules, and a summary of every manual reclassification are publicly available; because the free-text responses are not publicly shared to protect participant privacy, response-level reproduction is limited by data availability.

Reflexivity and Coder Roles

Coding was led by the first author, a licensed clinical psychologist with research expertise in digital mental health employed by Slingshot AI, the developer of Ash, at the time of the analysis; 1 coauthor (KPK) is an academic researcher unaffiliated with the company. The authorship team recognizes that our proximity to the tool under study could shape codebook construction and interpretation, particularly given that respondents were former users of a withdrawn product; however, we attempted to mitigate this risk in part by including an independent academic author who provided input into the iterative development of the codebook and coding decisions. Three additional features of the design help mitigate risk of bias: (1) the codebook includes codes capturing unfavorable evaluations of Ash and favorable evaluations of general-purpose alternatives, both of which are reported in full; (2) code assignment was deterministic rather than interpretive; and (3) all coding decisions are independently reproducible from the shared analysis materials.

Results

Sample Characteristics

Three hundred ninety-three former Ash users responded to the survey (response rate: 5.3%, 393/7415). Of the 363 (92.4%) users providing demographic data, 30.3% (110/363) were aged 25-34 years, 25.6% (93/363) were 35-44 years, and 16.5%

XSL•FO
RenderX

(60/363) were 45-54 years, with 12.1% (44/363) aged 18-24 years and 14.9% (54/363) aged 55 years or older. The regional distribution was broadly representative of the UK population, with 87.3% (317/363) of respondents based in England, 6.3% (23/363) in Scotland, 4.4% (16/363) in Wales, and 0.6% (2/363) in Northern Ireland (Table 1). Respondents were generally more engaged users (median of 10 sessions, IQR 4-27 sessions) than nonrespondents (median of 2 sessions, IQR 1-6 sessions); the geographic distribution (ie, UK region) of users did not significantly differ between respondents and nonrespondents.

Table 1. Sample demographics (n=363). Demographics were completed by 363 of 393 (92.4%) respondents.

Characteristic	Values
Age range (years), n (%)	
18-24	44 (12.1)
25-34	110 (30.3)
35-44	93 (25.6)
45-54	60 (16.5)
55-64	41 (11.3)
65+	13 (3.6)
Prefer not to say	2 (0.6)
UK region, n (%)	
England	317 (87.3)
Scotland	23 (6.3)
Wales	16 (4.4)
Northern Ireland	2 (0.6)
Prefer not to say	5 (1.4)

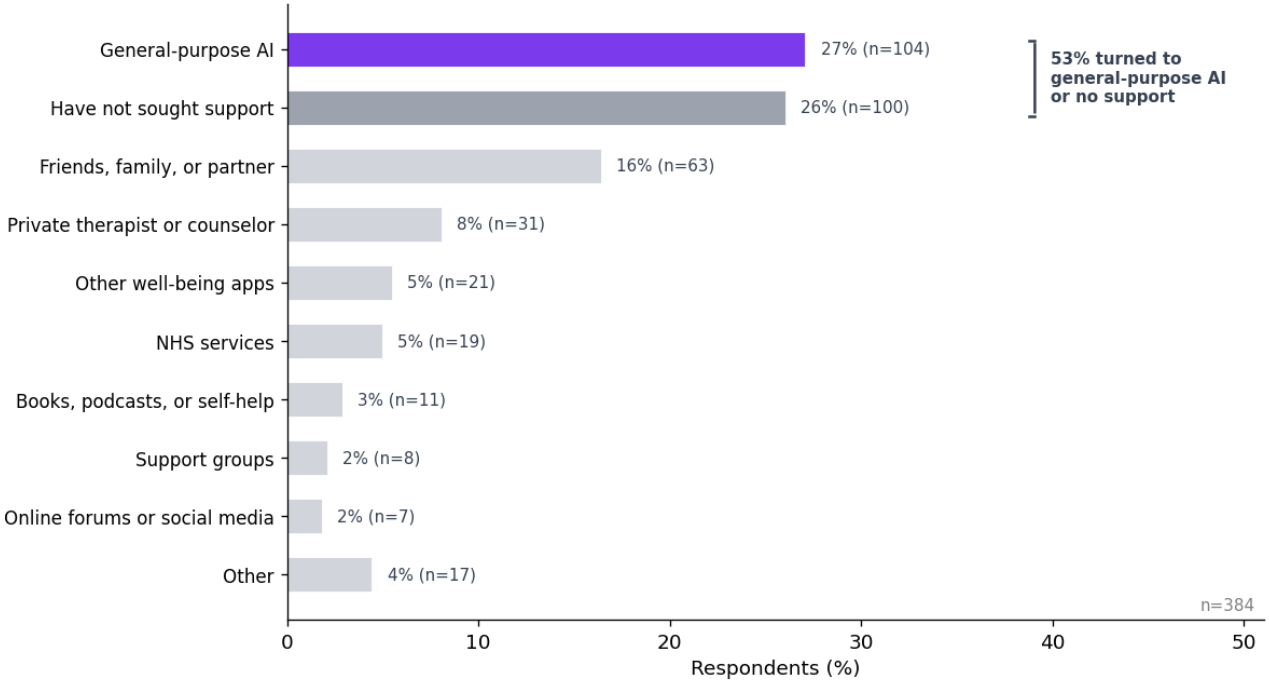
Support Sources Following Service Withdrawal

Table 2 presents the sources of support respondents reported turning to since Ash became unavailable (n=389 answering this multiselect item). General-purpose AI tools (eg, ChatGPT, Claude, and Gemini) were the most endorsed option, selected by 40.4% (157/389) of respondents (95% CI 35.6-45.3). This was followed by friends, family, or partner (131/389, 33.7%; 95% CI 29.2-38.5) and "I haven't sought support since" (117/389, 30.1%; 95% CI 25.7-34.8). Notably, only 16.5% (64/389; 95% CI 13.1-20.5) reported turning to a private therapist or counselor, and 14.9% (58/389; 95% CI 11.7-18.8) to NHS services.

Table 2. Support sources since Ash became unavailable. "Selected (multi)" reflects all-that-apply responses (n=389 answering). "Primary" reflects the single source relied on most (n=384 answering); percentages use each column's denominator.

Support source	Selected (multi, n=389), n (%)	Primary (n=384), n (%)
General-purpose AI tools	157 (40.4)	104 (27.1)
Friends, family, or partner	131 (33.7)	63 (16.4)
"I haven't sought support since"	117 (30.1)	100 (26)
Other mental health or well-being apps	69 (17.7)	21 (5.5)
Private therapist or counselor	64 (16.5)	31 (8.1)
Books, podcasts, or self-help	62 (15.9)	11 (2.9)
NHS[a] services	58 (14.9)	19 (4.9)
Online forums or social media	33 (8.5)	7 (1.8)
Support groups	21 (5.4)	8 (2.1)
Workplace support or EAP[b]	12 (3.1)	0 (0)
Other	27 (6.9)	17 (4.4)

[a]NHS: National Health Service.



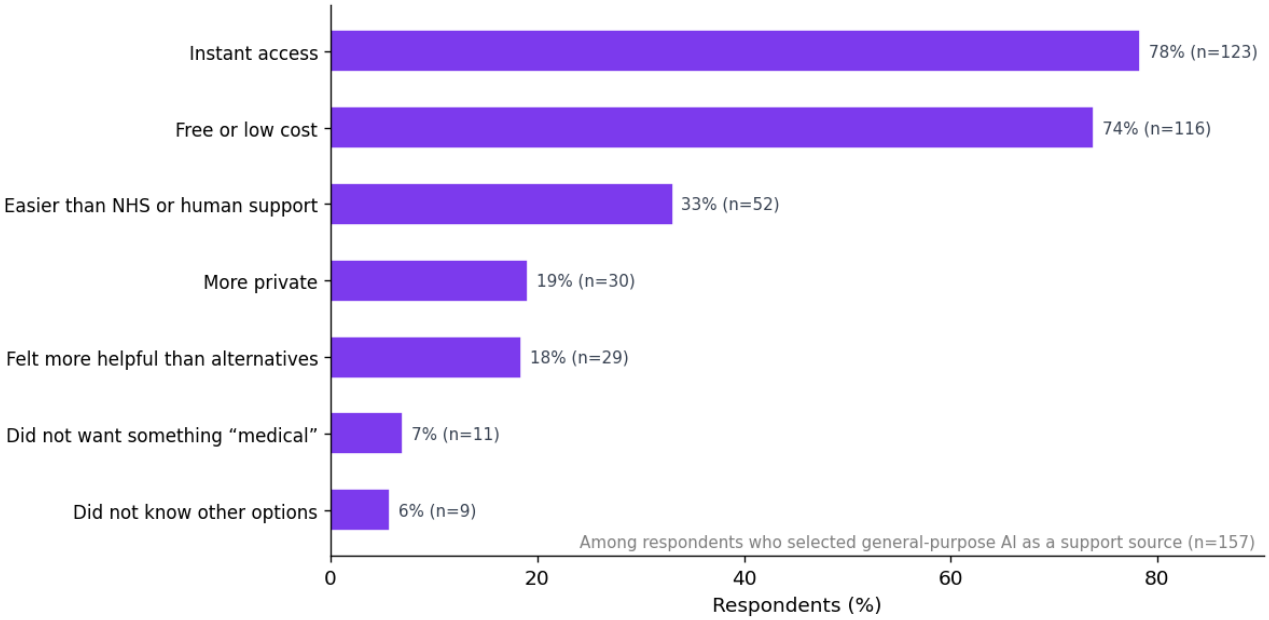
[b]EAP: employee assistance program.

When asked to identify their single most relied-upon source (Figure 1), general-purpose AI tools remained the most common response (27.1%, 104/384; 95% CI 22.9-31.7), followed closely by "I haven't sought support since" (26%, 100/384; 95% CI

XSL•FO
RenderX

21.9-30.7; note that 4.9% (19/389) of participants selected "I haven't sought support since" alongside other response options) and friends, family, or partner (16.4%, 63/384; 95% CI 13.0-20.4). Fewer respondents reported using NHS services (4.9%, 19/384; 95% CI 3.2-7.6) or a private therapist (8.1%, 31/384; 95% CI 5.7-11.2) as their primary resource.

Figure 1. Primary source of support since Ash became unavailable (n=384). Purple bar indicates general-purpose AI tools and the dark gray bar indicates respondents who have not sought support. NHS: National Health Service.



General-Purpose AI Use Patterns

In the subset of participants who identified general-purpose AI as one of their sources of mental health support (n=157), 154 responded to a question asking about their usage patterns. Use was frequent: 78.6% (121/154; 95% CI 71.4-84.3) used it weekly or more, with 24.7% (38/154; 95% CI 18.5-32.0) reporting daily use. In terms of how AI mental health support fits into their lives (n=152 responding), 31.6% (48/152; 95% CI 24.7-39.3) described it as their main source of support, 43.4% (66/152; 95% CI 35.8-51.4) as one of several sources, 14.5% (22/152; 95% CI 9.8-20.9) as a backup when nothing else was available, and 9.9% (15/152; 95% CI 6.1-15.6) used it occasionally or out of curiosity. The most commonly reported use cases (multiselect; percentages of all 157) were advice or problem-solving (77.1%, 121/157; 95% CI 69.9-83.0), venting or feeling heard (54.8%, 86/157; 95% CI 47.0-62.4), coping tools such as grounding or cognitive reframing (36.9%, 58/157; 95% CI 29.8-44.7), relationship or communication help (35%, 55/157; 95% CI 28.0-42.8), and stress, anxiety, or sleep support (22.9%, 36/157; 95% CI 17.0-30.1). The primary motivations for choosing general-purpose AI (Figure 2) were instant access (78.3%, 123/157; 95% CI 71.3-84.1) and cost (73.9%, 116/157; 95% CI 66.5-80.1), followed by ease relative to NHS or human support (33.1%, 52/157; 95% CI 26.2-40.8), privacy (19.1%, 30/157; 95% CI 13.7-26.0), and perceived helpfulness compared to alternatives (18.5%, 29/157; 95% CI 13.2-25.3). Only 7% (11/157; 95% CI 4.0-12.1) cited not wanting something "medical" as a motivation.

XSL•FO
RenderX

Figure 2. Motivations for choosing general-purpose AI tools for emotional support among respondents who endorsed general-purpose AI as a support source (n=157). Respondents could select up to 3 options. NHS: National Health Service.

Perceived Change in Access to Support

Two items assessed perceived impact on well-being and access to support on an exploratory basis. Of the 364 who answered, 60.2% (219/364; 95% CI 55.1-65.1) reported that their access to mental health support had worsened since losing access to Ash, with 30.8% (112/364; 95% CI 26.2-35.7) reporting it was "much worse" and 29.4% (107/364; 95% CI 25.0-34.3) "a bit worse." No change was reported by 31.6% (115/364; 95% CI 27.0-36.5), and 8.2% (30/364; 95% CI 5.8-11.5) reported improvement (a bit better: 4.7%, 17/364; 95% CI 2.9-7.4; much better: 3.6%, 13/364; 95% CI 2.1-6.0). The impact was most pronounced among the 26% (100/384; 95% CI 21.9-30.7) of respondents who had not sought any support since, 88 of whom answered this item: in this subgroup, 80.7% (71/88; 95% CI 71.2-87.6) reported worse access, including 56.8% (50/88; 95% CI 46.4-66.7) who rated it "much worse" and 23.9% (21/88; 95% CI 16.2-33.7) "a bit worse." The remaining respondents in this subgroup reported no change (10.2%, 9/88; 95% CI 5.5-18.3) or improvement (9.1%, 8/88; 95% CI 4.7-16.9; a bit better: 2.3%, 2/88,; much better: 6.8%, 6/88).

Current Well-Being

Among 363 who answered, 41.9% (152/363; 95% CI 36.9-47.0) reported that their general well-being over the past month had been worse than usual (slightly worse: 30.6%, 111/363; 95% CI 26.1-35.5; much worse: 11.3%, 41/363; 95% CI 8.4-15.0), while 25.9% (94/363; 95% CI 21.7-30.6) reported feeling better than usual (slightly better: 18.7%, 68/363; 95% CI 15.1-23.1; much better: 7.2%, 26/363; 95% CI 4.9-10.3) and 32.2% (117/363; 95% CI 27.6-37.2) reported no change. Among respondents who had not sought any support since losing access, the proportion reporting worse-than-usual well-being rose to 56.8% (50/88; 95% CI 46.4-66.7). In this subgroup, 37.5% (33/88; 95% CI 28.1-47.9) reported feeling slightly worse and 19.3% (17/88; 95% CI 12.4-28.8) much worse than usual, while 28.4% (25/88; 95% CI 20.0-38.6) reported no change and 14.8% (13/88; 95% CI 8.8-23.7) felt better than usual (slightly better: 12.5%, 11/88; much better: 2/88, 2.3%).

Demand for Purpose-Built Well-Being AI

When asked whether they would use Ash again if it were available in the United Kingdom under a clear well-being framework, 89.3% (325/364) of those who answered (95% CI 85.7-92.1) said they were very likely (68.4%, 249/364; 95% CI 63.5-73.0) or somewhat likely (20.9%, 76/364; 95% CI 17.0-25.3) to do so. A total of 8.2% (30/364; 95% CI 5.8-11.5) said they were not sure, and 2.5% (9/364; 95% CI 1.3-4.6) said they were unlikely to return.

Qualitative Findings

Overview

Of 272 free-text responses analyzed, 270 (99.3%) were coded to at least one substantive theme. The codebook comprised 5 domains encompassing 15 individual codes, with responses frequently spanning multiple themes (Table 3). Percentages reflect code frequencies and are not intended as population prevalence estimates.

XSL•FO
RenderX

Table 3. Content analysis of free-text responses (n=272). Codes are nonmutually exclusive; individual responses could be assigned to multiple themes. Percentages reflect the proportion of the 272 analyzable responses. Two (0.7%) responses were too ambiguous for reliable classification.

Theme	Values, n (%)
Evaluation of AI tools	
Inferior to Ash	62 (22.8)
Adequate or comparable	43 (15.8)
Critique of Ash	9 (3.3)
Support gap and disengagement	
No adequate replacement found	92 (33.8)
Human support preferred but inaccessible	12 (4.4)
NHS[a] access barriers referenced	8 (2.9)
Emotional response to loss	
Distress at losing access	43 (15.8)
Valued features of a purpose-built tool	
Insights and reflections valued	20 (7.4)
Memory and conversational continuity	19 (7)
Privacy, trust, and safety valued	9 (3.3)
24/7 on-demand availability valued	8 (2.9)
Coping strategies adopted	
Self-managing or informal coping	61 (22.4)
Switched to other well-being app	37 (13.6)
Accessing a human professional	36 (13.2)
VPN[b] workaround to maintain access	8 (2.9)

[b]VPN: virtual private network.

Evaluation of General-Purpose AI as Substitute

The most commonly discussed topic was users' experience with general-purpose AI after losing Ash. A total of 22.8% (62/272) of coded responses described these tools as inferior, citing lack of conversational memory, generic rather than personalized responses, a tendency to validate rather than constructively challenge, and the absence of structured reflective features. As 1 respondent noted: "With ChatGPT it's difficult because it doesn't have memory and can't ask 'how did that thing go last week?'—it feels less personable and it does feel like AI compared to Ash." A smaller group (15.8%, 43/272) found general-purpose AI comparable or acceptable: "ChatGPT. It works about the same. It seems to cut more to the point, which I like but can't always remember the back story which is a draw back." Several respondents (3.3%, 9/272) preferred the directive style of general-purpose AI, critiquing Ash's repetitive conversational patterns and difficulty reaching a resolution: "Ash kept asking me questions non-stop and felt like there was never a resolution to things."

Support Gap and Disengagement

Overall, 33.8% (92/272) of coded responses reported finding no suitable alternative to Ash. This was compounded by structural barriers: 4.4% (12/272) expressed a preference for human support but cited cost or inaccessibility, and 2.9% (8/272) specifically referenced NHS waiting times. Sample responses included the following: "There is nothing I can use. Other NHS-authorised apps do not cater for my needs" and "Bottling things up as I have no one to talk to."

Emotional Response to Loss

A total of 15.8% (43/272) of coded responses expressed notable emotional distress at losing access to Ash, using language such as "gutted," "devastated," and "don't know what I would do without it."

Valued Features of a Purpose-Built Tool

Across several overlapping codes, respondents identified features that distinguished Ash from general-purpose alternatives: memory and conversational continuity across sessions (7% of coded responses, 19/272), structured insights and reflections (7.4%, 20/272), 24/7 on-demand availability (2.9%, 8/272), and the privacy and trust associated with a purpose-built, evidence-informed tool (3.3%, 9/272). While some of these features (eg, 24/7 availability and privacy) also characterize general-purpose AI, respondents emphasized that they found value in the combination of purpose-built design, conversational memory, and structured reflective features with Ash. In other words, the distinction was not accessibility alone,

XSL•FO
RenderX

but the perceived safety and intentionality behind a purpose-built tool. One respondent captured several of these dimensions: "Ash's killer feature was its weekly reflections. It has an amazing ability to see beyond the specifics of our conversations to the broader themes and challenges. Which is something Claude and ChatGPT don't do that I've been missing a lot!" Another noted the trust dimension: "Other AI tools don't feel safe due to news about suicides related to their usage. Ash was the only trustworthy app for me."

Coping Strategies Adopted

Among coded responses, the most frequently coded theme overall was self-managing through informal means (22.4%, 61/272), including journaling, exercise, meditation, and leaning on friends or family. A total of 13.6% (37/272) participants described having switched to another well-being app, and 13.2% (36/272) participants were accessing a human professional—often noting it as a complement rather than a replacement. Furthermore, 2.9% (8/272) participants reported using a virtual private network to maintain access to Ash.

Discussion

Principal Findings

To our knowledge, this study provides the first empirical evidence of where users go when access to a purpose-built AI well-being tool is disrupted. For 53% (204/384) of respondents, the answer was general-purpose, unregulated AI (27%, 104/384), or nothing (26%, 100/384). Fewer reported seeking professional care from the NHS (5%, 19/384) or a private therapist (8%, 31/384) as their primary resource. These findings suggest that the self-reported use of formal, human-delivered mental health services may be relatively uncommon in the wake of access disruptions to purpose-built AI well-being tools; most former users of Ash reported turning to general-purpose alternatives or having a gap in care. Users who reported turning to general-purpose AI did so frequently but instrumentally, primarily for instant access and low cost rather than perceived superiority; most reported that their access to support had worsened and over 40% (152/363) reported worse-than-usual well-being; and in open-ended responses they generally characterized general-purpose AI as an inferior substitute for a purpose-built tool. These findings matter because AI regulation is evolving rapidly and carries real-world consequences: here, there was voluntary withdrawal in the context of regulatory uncertainty by the makers of a purpose-built model while leaving general-purpose models untouched, an asymmetry that our data suggest may carry measurable costs for the people it affects.

Comparison With Prior Work

Prior work has documented the rising adoption of general-purpose AI for emotional support [2,3], evaluated the efficacy and safety of commercially available purpose-built tools [15,20-22,24], and assessed the capabilities and risks of general-purpose chatbots in controlled or observational settings [4,5]; none has examined the real-world impact of regulatory policy on help-seeking behavior among former users of a purpose-built AI for mental health. Our findings suggest that, in the wake of such policy, high usage of traditional health care is not observed; for most, there is reliance on the very general-purpose tools whose safety limitations this literature has documented [4-6,22], or no support at all. These patterns reflect an empirical instance of the disruption the NASSS framework locates outside the user-technology relationship [14], and of the "missing middle" left underserved [13].

Our quantitative and qualitative findings converge on a central point: the care usage reported by respondents appears more consistent with constrained choice than with preference, with motivations centering on access and cost rather than perceived superiority. Three mechanisms appeared to underlie this substitution: logistical barriers to formal care, psychological barriers rooted in stigma and prior negative experiences with services, and the specific design affordances of a purpose-built tool that general-purpose AI generally did not replicate. The dominant motivations for turning to general-purpose AI for mental health after losing access to Ash (instant access or cost-effectiveness) reflected logistical barriers to professional care, rather than enthusiasm for AI as a modality: nearly a third cited "easier than NHS or human support," and fewer than 1 in 5 felt general-purpose AI was more helpful than alternatives. These reflect the choices of people navigating an access gap rather than exercising a preference. Users who tried ChatGPT or Claude as substitutes largely described them as lacking the qualities of a support relationship built with clinical intent: a system that remembered what they had shared across sessions, that surfaced patterns they could not see themselves, and that challenged their thinking rather than simply validating it. Users described how general-purpose AI could respond in the moment but often struggled to track a trajectory or push back. Notably, in open-text responses, the distinction respondents drew was not between AI and human support, but between a tool designed for psychological care and one repurposed for it.

It is also noteworthy that 3.3% (9/272) of free-text responses specifically raised trust and safety concerns about general-purpose AI, with some referencing news reports about suicides linked to chatbot use. This concern is particularly salient in a regulatory context where purpose-built tools face greater scrutiny than general-purpose alternatives. Recent research has documented a range of safety concerns with general-purpose AI for mental health: an analysis of real user interactions found that mental health crises were apparent in a nonnegligible minority of conversations, with companion AIs often unable to recognize or respond appropriately to signs of distress [4]. Emerging case reports have described phenomena including emotional dependency, reinforcement of delusional beliefs, and dangerous behavioral escalation [6]. A systematic review evaluating general-purpose generative AI chatbots for mental health found that while these tools show promise for psychoeducation and symptom monitoring, their diagnostic accuracy, cultural competence, and safety in crises remain limited [5]. These concerns especially apply to general-purpose platforms that may lack the crisis escalation protocols, boundary management, and safety architecture central to tools explicitly designed for well-being.

The 26% (100/384) of respondents who reported not having sought any support since losing access to Ash warrant particular attention. This group reported the worst outcomes across all

XSL•FO
RenderX

measures: 81% (71/88) said their access to support had gotten worse (57%, 50/88 “much worse”), and 57% (50/88) reported worse-than-usual well-being over the past month. These individuals did not report using NHS services, did not find a private therapist, and did not turn to ChatGPT. They simply stopped seeking support. This population is likely invisible to policymakers and health systems: they do not appear in NHS referral statistics, are not captured by app marketplace data, and were not redirected to any alternative service. In their free-text responses, this subgroup of respondents described cost barriers, negative experiences with NHS services, and an unwillingness to start over with a tool they did not trust. The clinical significance of an abrupt loss of a trusted support tool for people managing everyday emotional difficulties, many of whom may lack other accessible options, deserves further investigation. While cost and access are important factors, our past research suggests that stigma and broken trust with human services also explain meaningful variance in AI help-seeking behavior [27].

These substitution patterns are consistent with the NASSS framework’s account of how regulatory withdrawal of a health technology cascades across domains [14], and with the “missing middle” literature documenting the persistent gap between primary and specialist mental health care [13]. While the present study did not assess clinical severity, the finding that so few users reported seeking professional care despite ongoing need suggests a population for whom viable alternatives simply did not exist.

Limitations

Several limitations should be considered when interpreting these findings. First, the sample comprises former users of a specific product who were sufficiently engaged to respond to a survey and significantly more engaged than the average user; selection bias likely inflates positive sentiment toward Ash, particularly given the low response rate (5.3%, 393/7415). The 89.3% (325/364) intent-to-return figure, in particular, should be interpreted in this context. Second, all outcomes are self-reported and cross-sectional; we cannot establish causal relationships between service withdrawal and changes in well-being or access. For example, it is possible that users turned to tools such as general-purpose AI not because of service disruption, but rather because of factors such as preference and brand familiarity, insufficient differentiation of the purpose-built tool, or absence of clinical need among some users. Third, the single-item well-being measure lacks the psychometric properties of validated instruments and provides only a coarse assessment. Given these limitations, our findings from former users of a single product in a single country may not generalize to other tools or health systems. In addition, the qualitative coding was AI-assisted and refined through 3 rounds of human review but was not subjected to a formal intercoder reliability analysis. We also did not assess clinical severity and therefore cannot determine what proportion of respondents had needs warranting professional care. Finally, as the developer of the withdrawn product, Slingshot AI has a financial and reputational interest in these findings; we have attempted to mitigate this through transparent reporting of all results, including critiques of Ash and transparency around the subset of users who found general-purpose AI adequate.

Where possible, future research should follow users prospectively rather than cross-sectionally, to understand whether the access and well-being decrements observed here persist, worsen, or resolve. Incorporating validated clinical measures could help clarify how many displaced users had needs that warranted professional care, and comparison cohorts (eg, with users of other tools or users of the same tool in jurisdictions where access was uninterrupted) could help isolate the effect of service withdrawal itself. Replication beyond a single product and country is needed to establish how far these patterns generalize.

Conclusion

Among the 5.3% (393/7415) of invited former users who responded to a survey after a purpose-built AI well-being tool was voluntarily removed from the UK market, general-purpose AI and no support were the 2 most frequently reported primary sources of care. These findings suggest that regulatory frameworks for AI well-being tools should account for the real-world care usage behavior observed in the wake of disrupted access to purpose-built products. They should also weigh a central asymmetry: the same regimes that constrain purpose-built tools typically leave the general-purpose AI platforms that users turn to next unregulated, so restricting the former may, paradoxically, increase exposure to the latter. Users are not waiting for regulatory clarity to seek emotional support through AI, and the alternatives they find may offer fewer safeguards than the tools they lost.

Acknowledgments

We thank the former Ash users who opted in to research participation and made this work possible. Generative AI was used in 2 ways in this work. As described in the Methods section, AI-assisted keyword-pattern matching supported the thematic coding of free-text responses; all coding was reviewed and refined over 3 rounds by the authors, who take responsibility for the final classification. In addition, the authors used a generative AI tool to assist with language editing and formatting during this paper’s preparation. The authors reviewed and verified all content and are fully responsible for this paper.

Funding

This study was supported by grants from the National Institute of Mental Health (R34MH128410 [KPK]; K01MH131898 [KPK]) and Slingshot AI. External funders had no role in study design, data collection and analysis, decision to publish, or preparation

Abstract

Background: Frailty is prevalent among hospitalized patients and is associated with increased risk of complications, prolonged hospitalization, higher mortality, and health care costs. Existing frailty screening tools, including the Clinical Frailty Scale (CFS) and Hospital Frailty Risk Score (HFRS), have limitations related to subjectivity, resource intensity, or reliance on retrospective data, limiting their use in routine acute care. Early identification of frailty is critical to support targeted interventions and resource allocation, yet scalable approaches for predicting frailty early during hospital admission remain limited.

Objective: This paper evaluates whether routinely collected electronic medical record (EMR) data available within the first 72 hours of admission can be used to predict frailty in hospitalized patients.

Methods: A retrospective cohort study was conducted using routinely collected EMR data from the Royal Adelaide Hospital (RAH), including overnight admissions with a length of stay of at least 72 hours between July 2023 and December 2024. Frailty was defined using the HFRS (score >4). Predictors were derived from EMR data available within 72 hours of admission, including demographics, medications, laboratory results, nursing assessments, and medical and allied health consult orders. Data were split into training (21,436/26,824, 80%) and test (5388/26,824, 20%) sets. Multiple machine learning models were trained, with the F_2-score as the primary optimization metric. Model performance was evaluated using the F_2-score, recall, area under the receiver operating characteristic curve (AUROC), calibration, and clinical utility analyses.

Results: This study included 26,824 admissions, of whom 9427 (35%) were classified as frail. The final XGBoost (XGB) model achieved an F_2-score of 0.755 (95% CI 0.741-0.768), an AUROC of 0.777 (95% CI 0.764-0.790), and a recall of 0.873 (95% CI 0.857-0.887) on the test dataset, with good calibration and an expected-to-observed ratio close to 1 (0.996, 95% CI 0.963-1.028). Key predictors included polypharmacy, laboratory results (including creatinine, albumin, and sodium), allied health consult orders, and nursing assessment data. Model performance was lower at 24 hours postadmission and improved by discharge.

Conclusions: An EMR-based frailty prediction model using data available at 72 hours postadmission can identify patients with frailty early in their hospital stay, supporting targeted interventions and operational planning. Reduced performance in Indigenous patients highlights the need for culturally validated frailty indices and ongoing evaluation of equity in predictive modeling.

Introduction

Frailty in Hospitalized Patients

Patients with frailty admitted to hospital are at an increased risk of poorer outcomes, including an increased risk of hospital-acquired complications, prolonged length of stay, and higher mortality [1]. Although several validated frailty screening and assessment tools exist, frailty remains underrecognized in acute care for various reasons, including resource constraints and a lack of hospital protocols [2,3]. Early identification of frailty in the hospital setting enables targeted interventions that

XSL•FO
RenderX

can improve patient outcomes and optimize resource allocation [3]. Frailty disproportionately affects certain segments of the population, including Indigenous Australians and patients with lower socioeconomic status [4,5].

The Clinical Frailty Scale (CFS) is a commonly used tool to screen for frailty; however, it relies on clinician judgment, making it subjective and resource-intensive for screening large numbers of patients [6]. The Hospital Frailty Risk Score (HFRS) [7] can be derived from ICD-10-AM (International Statistical Classification of Diseases and Related Health Problems, Tenth Revision, Australian Modification) diagnosis codes within the electronic medical record (EMR); however, as these codes are generated after discharge, the score cannot be used for early frailty identification during hospitalization.

Many frailty models are derived from diagnosis codes; however, other approaches have incorporated routinely collected clinical data, such as laboratory test results [8]. Nursing and allied health (AH) documentation are rich sources of structured data, providing insight into patients' health and functional status, but remain underused in predictive modeling and risk stratification. Diagnoses, demographic characteristics, medications, laboratory results, procedures, and vital signs data are the most common types of structured EMR data used in frailty prediction models [9]. Nursing documentation includes assessments of mobility, malnutrition, and activities of daily living (ADLs), which are associated with frailty [10].

Methodological Foundation

This study builds on the EMR data model and methodological approach developed by Bills et al [11], who examined whether routinely collected EMR data could be used to characterize hospital demand, care complexity, and resource use in a public quaternary teaching hospital in South Australia. In that work, hospital admissions were classified into 4 patient flow streams reflecting differing patterns of operational complexity and resource use. Of these, flow stream 3 represented a heterogeneous cohort of patients with intermediate complexity who required input from multiple disciplines and accounted for a substantial proportion of bed use, 18.6% of total admissions. Frailty is an important contributor to complexity within this cohort, given its association with functional vulnerability, prolonged hospital stays, and the need for coordinated multidisciplinary care. This study extends this EMR-based methodological framework to the related task of early frailty prediction, using routinely collected structured data available within 72 hours of admission.

Need for Early and Scalable Frailty Identification

Currently, no validated frailty index can be readily calculated across an entire hospital early in a patient's admission. This study aimed to develop and internally validate a frailty prediction model using routinely collected EMR data available within 72 hours of admission. The model could enable the early identification of patients with frailty for targeted clinical interventions, operational planning, and resource allocation.

Key Objectives

Key objectives were to build a robust frailty prediction model based on the data available 72 hours after hospital admission, identify important predictors of frailty, and evaluate the model's performance at 24 hours after admission and at discharge.

Methods

This study was conducted and reported in accordance with the TRIPOD-AI (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis-AI) guidelines for clinical prediction models using machine learning (ML) methods.

Ethical Considerations

Approval was granted by the Central Adelaide Local Health Network (CALHN) Human Research Ethics Review Committee (2024/HRE00225), with a waiver of individual consent due to the retrospective nature and scale of the cohort. Access to EMR data was authorized by the data custodian, and data handling complied with relevant governance and privacy legislation. Data were deidentified at extraction to meet confidentiality and ethical considerations. The manuscript and supplementary materials contain no identifiable patient images. Participants did not receive any compensation for participation in the study as it involved a retrospective analysis of routinely collected data.

Study Population

The Royal Adelaide Hospital (RAH) is an 812-bed principal referral hospital within the CALHN, providing several specialized statewide services for South Australia [12]. The study used data from the statewide EMR database, which served as the data source for model development and validation. All admissions between July 1, 2023, and December 30, 2024, were extracted.

Of 103,258 admissions during the study period, admissions with a length of stay less than 72 hours were excluded. This included day-only elective surgical admissions, which were not eligible because they did not meet the minimum 72-hour length-of-stay criterion. Patients younger than 18 years were also excluded. Overnight elective surgical admissions with a length of stay of at least 72 hours remained eligible for inclusion (26,824). The final study cohort comprised 26,824 admissions from 20,667 unique patients. Of these patients, 3862 (19%) had multiple eligible admissions during the study period. Direct age-stratified frailty rates were calculated to compare frailty between Indigenous and non-Indigenous populations.

The EMR was used as a data source because of its comprehensive capture of inpatient data, including documentation from multiple disciplines, including administrative, medical, nursing, and AH.

Use of a common statewide EMR may support generalizability and implementation of the modeling approach at other South Australian public hospitals; however, the cohort was drawn from a single quaternary hospital and requires external validation before broader generalizability can be established.

RenderX

Data Extraction

Data were extracted from the EMR database. Extraction logic was based on hospital admission identifiers, admission and discharge timestamps, and clinical documentation tables relevant to laboratory, medication, nursing, and consult order data. Extracted data were deidentified prior to analysis. Data underwent initial validation to confirm completeness and consistency with source records, and duplicate or implausible entries (eg, negative timestamps or null admission identifiers) were excluded. Each hospital admission was treated as an independent entity, and only the first 72 hours of data from each admission were used to derive predictor variables. Separate indicator sets were derived for the primary analysis of 72 hours and the alternate 24 hours and discharge time points for evaluation.

Data Processing

Data processing and analysis were conducted using Python (version 3.12.3). HFRS scores were generated for each visit using ICD-10-AM codes assigned after discharge, characterizing visits as frail (HFRS >4; intermediate or high risk) or not frail (HFRS <5; low risk), which was used as the outcome variable for model training. ICD-10-AM codes are standardized and used across all public hospitals in South Australia, so they are generated consistently across demographic groups. The HFRS, derived from these codes, ensures consistent outcome assessment across sociodemographic groups in this dataset.

Categorical variables were one-hot encoded using *OneHotEncoder* from scikit-learn (version 1.4.2), which converts categorical variables into a binary format, with each category represented by a separate column with values of 0 or 1. Missing values were replaced with an "unknown" category during the one-hot encoding process to avoid arbitrary assignment. Mean imputation was used to handle missing numeric values under the assumption of missing at random, and the numeric variables were subsequently scaled using *StandardScaler* from scikit-learn. Data quality checks including profiling for missing values were conducted, with variables with high missingness (threshold >30% missing) being excluded as model predictors to reduce the risk of unreliable model estimates. The variables excluded based on missingness were previous clinical service admitted under, previous length of stay, MRI in the first 72 hours, and falls history. Model preprocessing was relatively consistent across demographic groups, suggesting that missingness was likely random.

Sample Size Calculation

When developing a multivariate prediction model, the sample size must be sufficient to ensure reliable estimation, considering both the number of admissions and outcome events in relation to the number of predictors included [13]. The minimum sample size was calculated using the *pmsampsize* function from the R package *pmsampsize* developed by Joie Ensor (version 1.1.3) for binary prediction model development. The sample size was determined to be 1451, with a minimum of 508 events (patients with frailty), based on the 40 input parameters generated from data processing, a frailty prevalence of 35% (9,427/26,824) from the dataset, and an anticipated C-statistic of 0.78. The anticipated C-statistic was based on a recent hospital-admission frailty prediction study by Chou et al [14], which used routinely available hospital clinical data to train supervised ML models for identifying frailty in older inpatients with acute illness. The final cohort size substantially exceeded the calculated minimum, ensuring sufficient power to reliably address the research question.

Modeling Approach

Potential model predictors were identified through clinician workshops and frailty risk factors from the literature [8,15]. Predictors were categorized into 5 groups: medication-related, laboratory test results, AH and medical consult orders, nursing assessment scores, and demographics. All predictors were derived from data available within 72 hours of hospital admission. A complete list of model predictors is available in Multimedia Appendix 1.

The 72-hour prediction window was selected to balance clinical actionability with data completeness. Although earlier prediction may allow more time for clinical intervention, key predictors such as laboratory results and AH and nursing assessments are less consistently available in the first 24 hours than demographic variables. By 72 hours, these multidisciplinary EMR data are more complete while still being available early enough to support targeted interventions during the admission.

As patients could have multiple admissions during the period, the data were split at the patient level to avoid data leakage from the same patient appearing in both the training and test datasets. The data were split into 80% (21,436/26,824) training and 20% (9427/26,824) test datasets using *train_test_split* from scikit-learn. All model training, model selection, threshold tuning, and reported performance metrics were generated using this patient-level split.

Four classification models were trained to predict the HFRS frailty grouping at discharge based on data available within 72 hours of hospital admission, including XGBoost (XGB), random forest, logistic regression, and support vector machine (SVM) models. These models were chosen based on their established use in prior ML frailty modeling studies [16]. The random forest, logistic regression, and SVM models were all from the scikit-learn library, and the *XGBClassifier* from the XGB library (version 3.1.1) was used to train the XGB model. The F_2-score was chosen as the objective function for hyperparameter and threshold tuning. The F_2-score, which weights recall higher than precision, was chosen to prioritize identifying patients with frailty while still maintaining reasonable precision in model predictions. Hyperparameter tuning was performed using cross-validation with the *GridSearchCV* function from scikit-learn on the training dataset. Predicted probabilities were generated using *predict_proba* from scikit-learn. The final 72-hour XGB model and selected classification threshold were then applied without retraining to predictor sets reconstructed using data available at 24 hours after admission and at discharge. These analyses were used to assess how model performance varied according to the amount of clinical information available at different stages of admission.

XSL•FO
RenderX

Threshold Sensitivity Testing

A threshold sensitivity analysis was performed on the 72-hour training data to select the final classification threshold. F_2-score, recall, and precision were assessed across thresholds from 0.10 to 0.50 on the training data. The final classification threshold was based on the optimal F_2-score, which is consistent with the study aim of prioritizing frailty detection while limiting false positives. The selected threshold was then applied to the 72-hour training and test datasets and to the 24-hour and discharge predictor sets without further threshold tuning.

Model Assessment

Model performance was assessed using discrimination, classification, and calibration metrics. The F_2-score was selected as the primary evaluation metric because it weights recall higher than precision, consistent with the aim of minimizing missed frailty cases in an imbalanced dataset. The scikit-learn package was the source of all evaluation functions, unless otherwise specified. Receiver operator curves (ROCs) were generated for the training and test datasets using *roc_curve*, and area under the receiver operating characteristic curve (AUROC) was calculated using *roc_auc_score*. Classification metrics included F_2-score, recall, precision, specificity, positive predictive value (PPV), and negative predictive value (NPV). Overall model performance was assessed using the Brier score, and calibration was assessed using the ratio of the expected number of cases predicted by the frailty model to the observed number of cases (expected-to-observed [E/O] ratios).

Bootstrapped 95% CIs were calculated for F_2-score, recall, precision, specificity, AUROC, Brier score, and E/O ratios to quantify uncertainty around point estimates. The same evaluation metrics were calculated for the primary 72-hour test dataset and for the 24-hour and discharge predictor sets to compare model performance across admission time points. Subgroup analyses were performed by sex and Indigenous status to evaluate model bias across demographic groups.

The final prediction model comprised a preprocessing pipeline and an XGB classifier implemented in Python (version 3.12.3) using the scikit-learn and XGB libraries. Owing to ethics, governance, and data security restrictions associated with the underlying EMR data, the full model object and analytical code are not publicly available. The analytical code, preprocessing pipeline specifications, and model artifacts may be made available upon reasonable request, subject to approvals.

Feature Importance

Feature importance was then assessed for the final 72-hour XGB model using Shapley additive explanations (SHAP) values generated by *TreeExplainer* in the SHAP library (version 0.46) to assess how each variable contributes to the overall performance of the model [17]. XGB was the final chosen model due to its superior performance and interpretable feature importance. Interpretable features are particularly important in health care, where explainability can increase end-user trust [18].

Clinical Utility Analysis

Clinical utility was assessed using standard decision curve analysis in the test dataset. Decision curve analysis was used to estimate the net benefit of using the final XGB model to identify patients at increased risk of frailty across threshold probabilities from 0.10 to 0.50. The analysis used predicted probabilities from the final XGB model without recalibration. Net benefit was compared with the default strategies of treating all patients as frail and treating no patients as frail. In this context, a positive model prediction was interpreted as identifying a patient for potential frailty-related clinical review or intervention, although a specific implementation pathway was not prespecified.

Net benefit was calculated as the proportion of true positives minus the proportion of false positives weighted by the odds of the threshold probability. The selected operating threshold of 0.20 was not clinically prespecified; it was selected from threshold sensitivity testing to prioritize the F_2-score while limiting false-positive classifications. Results at this threshold were therefore interpreted as performance at the selected statistical operating point rather than as evidence of an established clinical decision threshold. Uncertainty in net benefit estimates was quantified using 1000 nonparametric bootstrap resamples at the admission level, with 95% CIs derived from the bootstrap distribution.

Results

Study Population

The flow of patient exclusions is shown in Figure 1. The characteristics of the study population are detailed in Table 1. Age-stratified frailty rates differed between Indigenous and non-Indigenous patients (Table 2). In non-Indigenous patients, frailty increased progressively with age, rising from 19% (249/1289) in those aged 18 to 30 years to 54% (774/1431) in those aged 91 years and older. In Indigenous patients, frailty rates did not increase consistently across age groups, although the interpretation of older age groups is limited by small denominators. The highest observed frailty rate was in Indigenous patients aged 81 to 90 years (11/17, 65%), while rates were lower in those aged 71 to 80 years (35/121, 29%) and 91 years and over (1/3, 33%). These findings indicate different observed age-frailty profiles between Indigenous and non-Indigenous patients in the study cohort, with estimates in older Indigenous age groups likely to be unstable.

Modeling Approach

The development and test datasets were broadly similar with respect to demographics, frailty prevalence, and key predictor distributions (Table 3).

The best model parameters derived from hyperparameter tuning are shown in Table 4. F_2-score optimization resulted in the best parameters being model__colsample_bytree=0.8, model__learning_rate=0.1, model__max_depth=5, model__n_estimators=200, and model__subsample=0.8.

Table . Comparison of development and evaluation datasets.

Characteristic	Training	Test
Admissions, n	21,436	5388
Frail, n (%)	7541 (35)	1886 (35)
Age (years), mean (SD)	66.0 (18.7)	65.4 (18.7)
Female, n (%)	9511 (44)	2271 (42)
Indigenous status, n (%)	1443 (7)	406 (8)

model__learning_rate	0.1
model__max_depth	5
model__n_estimators	200
model__subsample	0.8

XGB showed the strongest overall performance across the four candidate models, as shown in Table 5. Discrimination was similar across models, with AUROC values ranging from 0.755 (95% CI 0.741 - 0.769) for random forest to 0.777 (95% CI 0.764-0.790) for XGB. XGB had the highest F_2-score (0.755, 95% CI 0.741 - 0.768), substantially exceeding logistic regression (0.492, 95% CI 0.470 - 0.512), random forest (0.421, 95% CI 0.400 - 0.443), and SVM (0.486, 95% CI 0.464 - 0.507). Recall was also highest for XGB (0.873, 95% CI 0.857 - 0.887), compared with 0.463 (95% CI 0.441 - 0.484) for logistic regression, 0.385 (95% CI 0.365 - 0.408) for random forest, and 0.455 (95% CI 0.433 - 0.476) for SVM. This indicates that XGB identified a substantially greater proportion of patients with frailty and was less likely to miss frailty cases.

XSL•FO
RenderX

Brier score was lowest for XGB (0.181, 95% CI 0.175 - 0.186), although differences between models were small. XGB was therefore selected as the final model for subsequent evaluation.

Table . Performance of candidate machine learning models for frailty prediction on the test dataset.

Model	F_2-score (95% CI)	Recall (95% CI)	AUROC[a] (95% CI)	Brier score (95% CI)
Logistic regression	0.492 (0.470 - 0.512)	0.463 (0.441 - 0.484)	0.768 (0.755 - 0.781)	0.183 (0.178 - 0.189)
Random forest	0.421 (0.400 - 0.443)	0.385 (0.365 - 0.408)	0.755 (0.741 - 0.769)	0.189 (0.185 - 0.193)
SVM[b]	0.486 (0.464 - 0.507)	0.455 (0.433 - 0.476)	0.760 (0.746 - 0.774)	0.186 (0.180 - 0.192)
XGB[c]	0.755 (0.741 - 0.768)	0.873 (0.857 - 0.887)	0.777 (0.764 - 0.790)	0.181 (0.175 - 0.186)

[a]AUROC: area under the receiver operating characteristic curve.

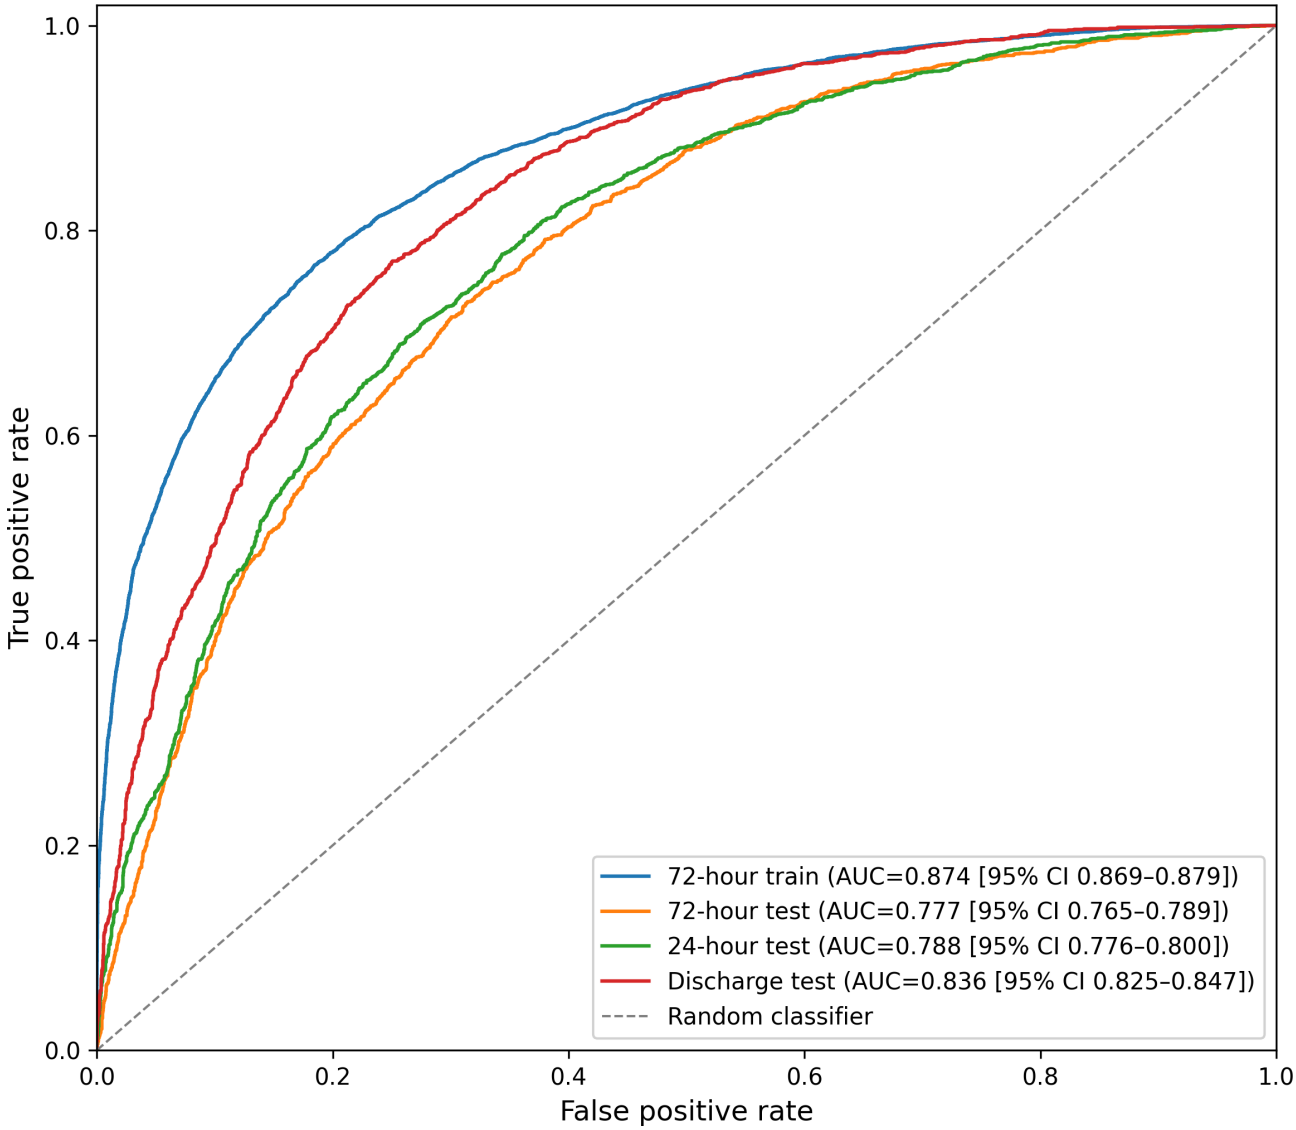
[b]SVM: support vector machine.

[c]XGB: XGBoost.

Threshold Sensitivity Testing

Threshold sensitivity testing showed the expected trade-off between recall and precision as the classification threshold increased (Table 6). Lower thresholds produced higher recall but lower precision and specificity, while higher thresholds improved precision and specificity at the cost of missed frailty cases. The threshold of 0.20 was selected for the final model, as it had the best F_2-score of 0.802 (95% CI 0.796 - 0.808). This threshold was consistent with the study objective of prioritizing frailty detection while retaining moderate precision (0.519, 95% CI 0.510 - 0.528) and specificity (0.533, 95% CI 0.525 - 0.541).

Table . Threshold sensitivity analysis for the final XGBoost frailty prediction model.



Threshold	F_2-score (95% CI)	Recall (95% CI)	Precision (95% CI)	Specificity (95% CI)	Predicted positive, n	Predicted negative, n
0.1	0.774 (0.768 - 0.779)	0.985 (0.982 - 0.988)	0.416 (0.408 - 0.423)	0.250 (0.243 - 0.257)	17,850	3586
0.15	0.795 (0.789 - 0.800)	0.962 (0.958 - 0.966)	0.469 (0.461 - 0.477)	0.410 (0.402 - 0.418)	15,454	5982
0.2	0.802 (0.796 - 0.808)	0.928 (0.922 - 0.934)	0.519 (0.510 - 0.528)	0.533 (0.525 - 0.541)	13,488	7948
0.25	0.798 (0.791 - 0.804)	0.889 (0.882 - 0.896)	0.566 (0.557 - 0.574)	0.630 (0.621 - 0.637)	11,851	9585
0.3	0.787 (0.780 - 0.794)	0.848 (0.839 - 0.856)	0.611 (0.602 - 0.620)	0.707 (0.700 - 0.715)	10,458	10,978
0.35	0.771 (0.763 - 0.779)	0.805 (0.796 - 0.815)	0.658 (0.648 - 0.668)	0.773 (0.766 - 0.780)	9225	12,211
0.4	0.741 (0.732 - 0.750)	0.751 (0.741 - 0.761)	0.703 (0.693 - 0.713)	0.828 (0.822 - 0.835)	8049	13,387
0.45	0.704 (0.694 - 0.713)	0.694 (0.684 - 0.705)	0.747 (0.737 - 0.757)	0.872 (0.867 - 0.878)	7005	14,431
0.5	0.664 (0.653 - 0.674)	0.638 (0.626 - 0.649)	0.792 (0.782 - 0.803)	0.909 (0.905 - 0.914)	6068	15,368

Model Assessment

The ROCs shown in Figure 2, generated for the test and training datasets, showed good discrimination between the classes, with an AUROC for the training dataset of 0.874 (95% CI 0.869 - 0.879). The AUROC for the test dataset was 0.777 (95% CI 0.764 - 0.790), which still indicates reasonable discrimination.

XSL•FO
RenderX

Figure 2. Receiver operator curves for training, test, 24-hour validation, and discharge validation datasets. AUC: area under the receiver operating characteristic curve.

Model discrimination and classification performance across training, test, 24-hour, and discharge datasets is shown in Table 7. The F_2-score was 0.802 (95% CI 0.796 - 0.808) for the training dataset and 0.755 (95% CI 0.741 - 0.768) for the test dataset, with corresponding recall values of 0.928 (95% CI 0.922 - 0.934) and 0.873 (95% CI 0.857 - 0.887), respectively. Specificity was similar between the training and test datasets at 0.533 (95% CI 0.525 - 0.541) and 0.511 (95% CI 0.493 - 0.528), respectively. PPV was moderate in both datasets (0.519, 95% CI 0.510 - 0.528 and 0.490, 95% CI 0.473 - 0.506), while NPV remained high (0.932, 95% CI 0.926 - 0.937 and 0.882, 95% CI 0.867 - 0.895). These results indicate that the model retained high sensitivity for frailty detection, with a lower probability of false-negative classification than false-positive classification.

XSL•FO
RenderX

Table . Discrimination and classification performance of the final XGBoost frailty prediction model across prediction time points.

Dataset	F_2-score (95% CI)	Recall (95% CI)	AUROC[a] (95% CI)	Specificity (95% CI)	PPV[b] (95% CI)	NPV[c] (95% CI)[c]
Training	0.802 (0.796 - 0.808)	0.928 (0.922 - 0.934)	0.874 (0.869 - 0.879)	0.533 (0.525 - 0.541)	0.519 (0.510 - 0.528)	0.932 (0.926 - 0.937)
Test	0.755 (0.741 - 0.768)	0.873 (0.857 - 0.887)	0.777 (0.764 - 0.790)	0.511 (0.493 - 0.528)	0.490 (0.473 - 0.506)	0.882 (0.867 - 0.895)
24-hour test	0.742 (0.725 - 0.756)	0.827 (0.809 - 0.844)	0.785 (0.772 - 0.797)	0.597 (0.581 - 0.612)	0.525 (0.507 - 0.541)	0.865 (0.851 - 0.879)
Discharge test	0.796 (0.785 - 0.806)	0.957 (0.947 - 0.965)	0.835 (0.824 - 0.846)	0.433 (0.416 - 0.450)	0.476 (0.460 - 0.492)	0.949 (0.938 - 0.960)

[a]AUROC: area under the receiver operating characteristic curve.

[b]PPV: positive predictive value.

[c]NPV: negative predictive value.

Calibration was acceptable for both the training and test datasets, with E/O ratios close to 1.0 and CIs crossing 1.0 (Table 8). As shown in Table 8, the training dataset showed slight overestimation (E/O ratio 1.000, 95% CI 0.986 - 1.015), while the test dataset showed slight underestimation (E/O ratio 0.996, 95% CI 0.963 - 1.028). The calibration plot for the test dataset is shown in Figure 3. The Brier score was 0.136 (95% CI 0.134 - 0.139) for the training dataset and 0.181 (95% CI 0.175 - 0.186) for the test dataset, supporting reasonable overall probability accuracy.

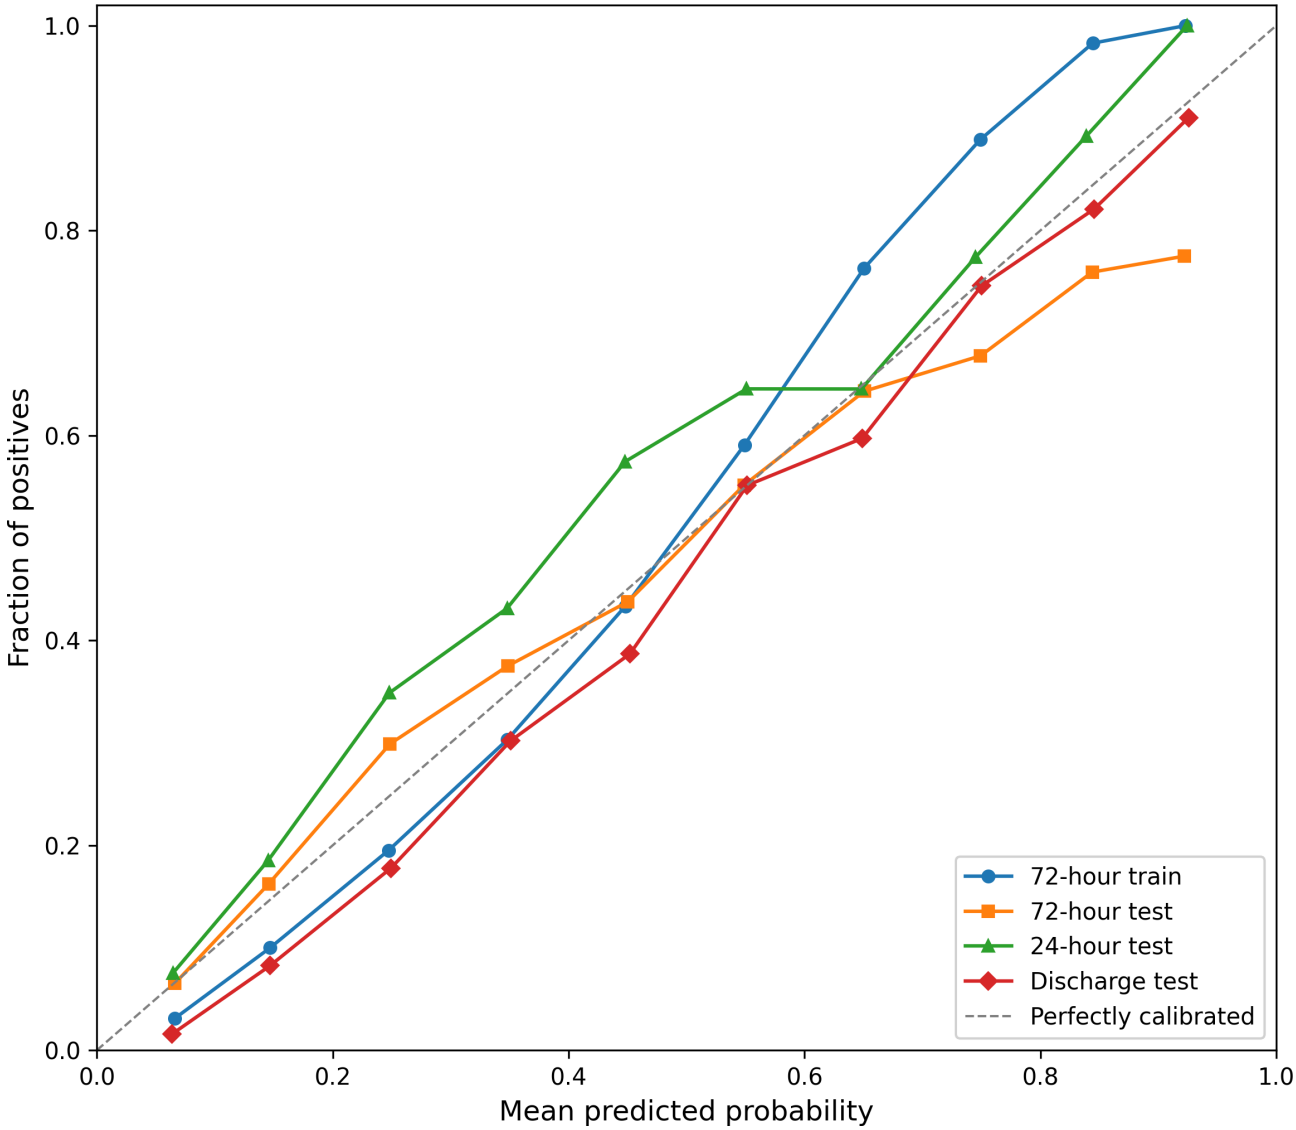


Table . Calibration and overall performance of the final XGBoost frailty prediction model across prediction time points.

Dataset	Brier score (95% CI)	E/O ratio[a] (95% CI)[a]
Training	0.136 (0.134 - 0.139)	1.000 (0.986 - 1.015)
Test	0.181 (0.175 - 0.186)	0.996 (0.963 - 1.028)
24-hour test	0.181 (0.175 - 0.187)	0.826 (0.801 - 0.852)
Discharge test	0.158 (0.153 - 0.163)	1.123 (1.092 - 1.157)

RenderX

Figure 3. Calibration curves for the train, test, 24-hour validation, and discharge validation datasets.

At 24 hours, the F_2-score and recall were lower than in the 72-hour test dataset (0.742, 95% CI 0.725 - 0.756 and 0.827, 95% CI 0.809 - 0.844), although specificity and PPV were higher (0.597, 95% CI 0.581 - 0.612 and 0.525, 95% CI 0.507 - 0.541). NPV remained high at 0.865 (95% CI 0.851 - 0.879). The 24-hour model underestimated frailty, with an E/O ratio of 0.826 (95% CI 0.801 - 0.852). At discharge, recall increased to 0.957 (95% CI 0.947 - 0.965) and NPV to 0.949 (95% CI 0.938 - 0.960), but specificity decreased to 0.433 (95% CI 0.416 - 0.450) and PPV to 0.476 (95% CI 0.460 - 0.492), reflecting more positive classifications. The discharge model overestimated frailty, with an E/O ratio of 1.123 (95% CI 1.092 - 1.157).

Model discrimination and classification performance metrics across sex and Indigenous status are shown in Table 9. Female participants had slightly higher F_2-score and recall values (0.769, 95% CI 0.749 - 0.788 and 0.887, 95% CI 0.865 - 0.909) compared with male participants (0.744, 95% CI 0.726 - 0.764 and 0.862, 95% CI 0.842 - 0.883). Male participants demonstrated higher specificity (0.533, 95% CI 0.511 - 0.555 vs 0.477, 95% CI 0.450 - 0.504) and NPV (0.885, 95% CI 0.868 - 0.903 vs 0.876, 95% CI 0.854 - 0.900), whereas female participants had higher PPV (0.502, 95% CI 0.477 - 0.527 vs 0.480, 0.458 - 0.503). AUROC was marginally lower in female participants (0.771, 95% CI 0.753 - 0.790 vs 0.780, 95% CI 0.765 - 0.797), with a higher Brier score (0.187, 95% CI 0.179 - 0.196 vs 0.176, 95% CI 0.169 - 0.183; Tables 9 and 10). Calibration was acceptable for both groups, with E/O ratios close to 1.0 and CIs crossing 1.0, indicating slight underestimation in female participants (0.981, 95% CI 0.935 - 1.031) and slight overestimation in male participants (1.007, 95% CI 0.965 - 1.050; Table 10).

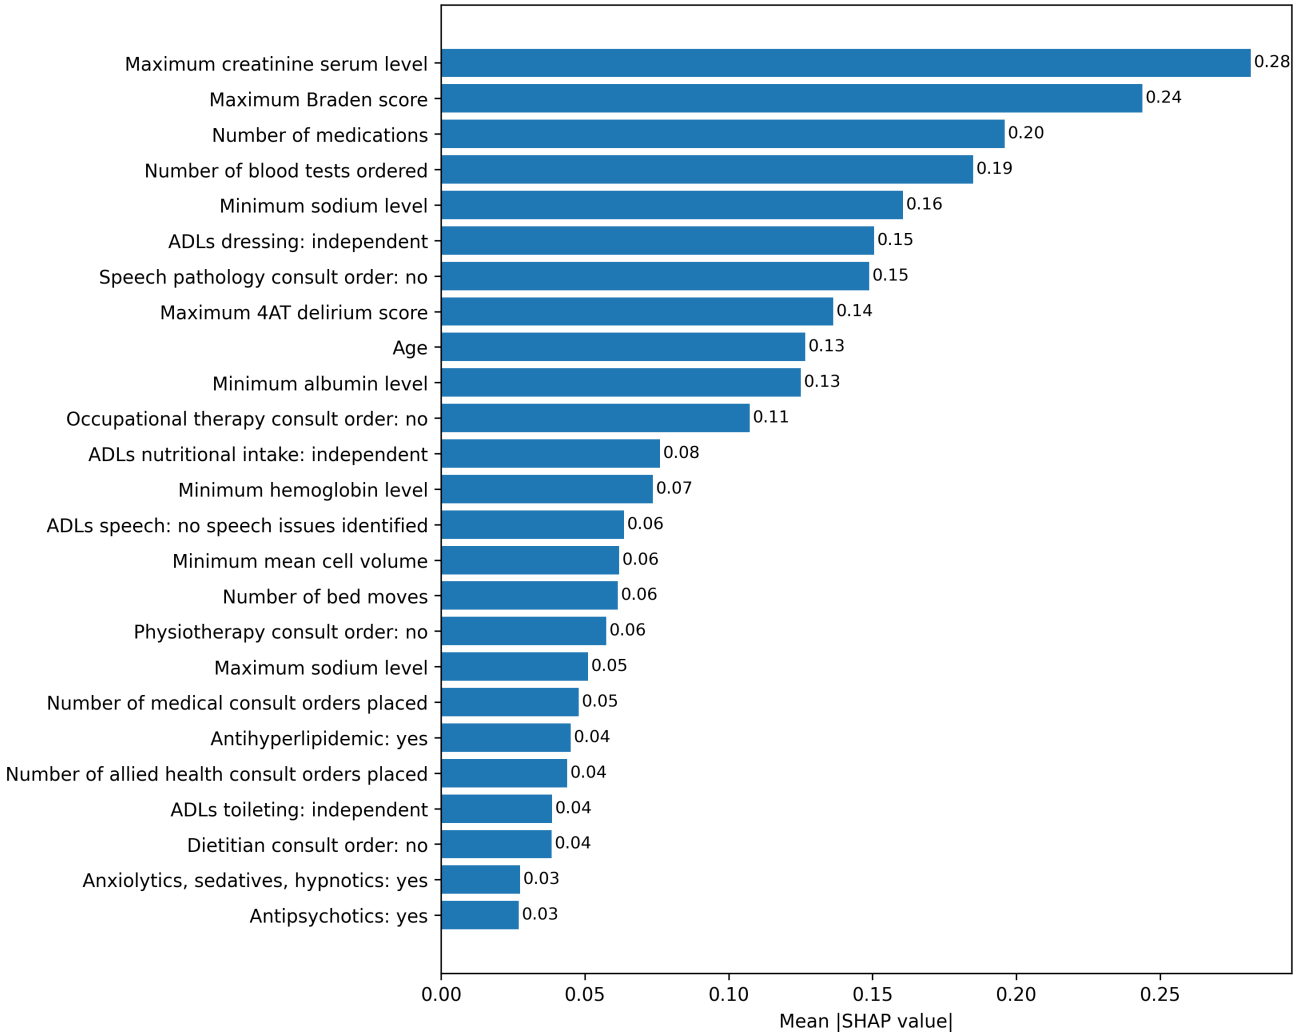
Table . Calibration and overall performance of the final XGBoost frailty prediction model by subgroup.

Subgroup	Brier score (95% CI)	E/O ratio[a] (95% CI)
Female	0.187 (0.179 - 0.196)	0.981 (0.935 - 1.031)
Male	0.176 (0.169 - 0.183)	1.007 (0.965 - 1.050)
Indigenous	0.152 (0.132 - 0.172)	1.009 (0.885 - 1.168)
Non-Indigenous	0.183 (0.177 - 0.189)	0.995 (0.961 - 1.026)

[a]E/O ratio: expected-to-observed ratio.

Patients who identified as Indigenous had a lower F_2-score (0.723, 95% CI 0.664 - 0.776) and recall (0.848, 95% CI 0.784 - 0.911) compared to patients who identified as non-Indigenous (F_2-score 0.757, 95% CI 0.743 - 0.770, recall 0.874, 95% CI 0.860 - 0.890). Specificity was higher in Indigenous patients (0.612, 95% CI 0.558 - 0.668 vs 0.501, 95% CI 0.485 - 0.518), with lower PPV (0.455, 95% CI 0.389 - 0.520 vs 0.492, 95% CI 0.476 - 0.510) and higher NPV (0.914, 95% CI 0.874 - 0.949 vs 0.878, 95% CI 0.864 - 0.893). AUROC was higher for Indigenous patients (0.798, 95% CI 0.749 - 0.846 vs 0.774, 95% CI 0.761 - 0.787), while the Brier score was lower (0.152, 95% CI 0.132 - 0.172 vs 0.183, 95% CI 0.177 - 0.189), suggesting better overall probability accuracy despite poorer threshold-dependent classification performance. These findings highlight that probability-based measures and threshold-dependent classification metrics may provide different perspectives on model performance across subgroups.



As shown in Table 10, calibration was acceptable in both groups, with E/O ratios close to 1.0 and overlapping CIs (0.995, 95% CI 0.961 - 1.026 vs 1.009, 95% CI 0.885 - 1.168).

Feature Importance

Figure 4 shows the 25 most important features determined by mean absolute SHAP values. The maximum serum creatinine level was the most important feature, followed by the maximum Braden pressure injury score and number of medications. This was followed by the number of blood tests ordered, minimum sodium level, whether a speech pathology consult order was placed, and independence in dressing as an ADL.

Clinical Utility Analysis

Decision curve analysis showed that the final XGB model provided positive net benefit across all evaluated threshold probabilities from 0.10 to 0.50 (Table 11; Figure 5). The model exceeded the treat-all strategy from a threshold probability of 0.10, indicating greater clinical utility than applying frailty-related clinical review or intervention to all patients across the evaluated threshold range.

At the operating threshold of 0.20, the model achieved a net benefit of 0.224 (95% CI 0.210 - 0.237). This corresponded to identifying 62% (n=3360) of admissions for potential frailty-related clinical review or intervention and a net reduction of 37.5 interventions per 100 patients compared with a treat-all strategy. Net benefit decreased as the threshold probability increased, from 0.282 at a threshold of 0.10 to 0.081 at a threshold of 0.50, while the proportion of admissions identified for review or intervention decreased from 82.9% (n=4469) to 27.9% (n=1505).

These findings suggest that the model may provide clinical utility for prioritizing frailty-related review among hospitalized patients, particularly where the acceptable threshold for action is between 0.10 and 0.30. Because no clinical risk threshold or implementation pathway was prespecified, results should be interpreted as evidence of potential utility rather than as a definitive clinical decision rule.

Table . Decision curve analysis of the final XGBoost frailty prediction model.

Threshold	Net benefit[a] (95% CI)	Admissions identified for review[b] (N=5388), n (%)	Net reduction per 100 admissions
0.1	0.282 (0.269 - 0.294)	4469 (83)	16.6
0.15	0.253 (0.240 - 0.267)	3858 (72)	27.7
0.2	0.224 (0.210 - 0.237)	3360 (62)	37.5
0.25	0.197 (0.183 - 0.211)	2966 (55)	44.7
0.3	0.168 (0.154 - 0.182)	2614 (49)	51.2
0.35	0.142 (0.128 - 0.156)	2328 (43)	56.5
0.4	0.123 (0.109 - 0.137)	2028 (38)	62
0.45	0.100 (0.086 - 0.113)	1757 (33)	67.5
0.5	0.081 (0.068 - 0.095)	1505 (28)	72.1

[a]Net benefit was estimated using decision curve analysis on the test dataset.

[b]Admissions identified for review refers to admissions classified as positive at each threshold probability.

Figure 5. Clinical utility of the final XGBoost frailty prediction model using decision curve analysis.

Discussion

Principal Findings

This study aimed to develop and internally validate a frailty prediction model for hospital inpatients using routinely collected EMR data available within 72 hours of admission. The final XGB model demonstrated good discrimination (F_2-score 0.755, 95% CI 0.741 - 0.768; recall 0.873, 95% CI 0.857 - 0.887) and calibration on the test dataset. Key predictors included polypharmacy, laboratory results (creatinine, albumin, and sodium), AH consult orders, and nursing assessment data. Model

XSL•FO
RenderX

performance improved as more clinical information became available during admission but was reduced for Indigenous patients, potentially highlighting limitations of the HFRS in this subgroup. These findings indicate that early frailty prediction using routine EMR data is feasible and may inform both clinical decision-making and operational planning, though further external validation and attention to equity are required.

The performance of the present model was broadly comparable to previously published frailty prediction models. Chou et al [14] developed a ML frailty detection model using 21 variables and a 6-month hospital data window, reporting an AUROC of 0.811, compared with an AUROC of 0.777 (95% CI 0.764 - 0.790) in this study. Differences in performance should be interpreted in the context of substantial methodological variation, including the prediction time horizon, outcome definition, and predictor set. A complementary frailty prediction model developed by Blanes Selva et al [19] achieved an AUROC of 0.89, although that study focused on frailty and mortality prediction to support palliative care assessment and is therefore not directly comparable to acute inpatient frailty screening. Similarly, Zhang et al [20] reported AUROC values ranging from 0.76 to 0.77 using community survey data rather than routinely collected hospital EMR data. Collectively, these findings suggest that the performance of the current model is within the range reported in the literature despite the challenges of early inpatient prediction using data available within 72 hours of admission.

Interpretation of Key Predictors

The variable importance results confirm known frailty predictors from the literature. Polypharmacy was a key predictor, and the presence of specific medications linked to frailty in the literature was also a key predictor [15]. Laboratory test results for creatinine, albumin, sodium, and the number of blood tests ordered were strong predictors. These specific laboratory tests were derived from the Frailty Index Laboratory Data frailty index, reinforcing the importance of biochemical markers in predicting frailty [8]. AH consult orders emerged as important and previously untested predictors.

The prominence of predictors such as specific medications and abnormal laboratory test results is likely attributable to their direct association with the specific diagnoses underpinning the HFRS score, which was used as the outcome variable. This creates the potential for criterion contamination, whereby the model may partially learn patterns associated with future diagnostic coding and disease burden rather than the broader multidimensional construct of frailty itself. While this does not negate the model's ability to identify patients likely to receive a frailty classification based on the HFRS, it does mean that model performance should be interpreted as prediction of an HFRS-defined frailty outcome, rather than direct measurement of biological or functional frailty.

Previous research has demonstrated that frailty and multimorbidity are closely related but distinct constructs, with substantial overlap among hospitalized older adults [21]. Consequently, models trained to predict HFRS may identify broader patterns of clinical vulnerability, disease burden, and health care complexity in addition to frailty itself. This may help explain the importance of predictors reflecting multidisciplinary care involvement, polypharmacy, laboratory abnormalities, and health care use within the present model. These findings should therefore be interpreted as predictors of an HFRS-defined frailty phenotype rather than as direct measures of physical or biological frailty alone.

Value of Multidisciplinary EMR Data for Frailty Prediction

The number of AH consult orders and the presence of specific consult orders, such as speech pathology, occupational therapy, and physiotherapy, were among the strongest predictors of frailty, features not previously identified in frailty prediction models, to our knowledge. This finding suggests that requiring early AH referrals during hospital stay indicates an increased risk of frailty. To our knowledge, our study is the first to demonstrate an association between early AH involvement and frailty risk. Nursing assessment–related variables, including those related to ADL assessments, Braden pressure injury scores, and delirium and cognitive impairment 4-item assessment test scores, were also important predictors. The strong contribution of both nursing-related and AH-related predictors highlights the potential untapped value of multidisciplinary data for frailty and broader health care–related predictive models.

Timing of Prediction During a Hospital Admission

At 72 hours post admission, the model identified a high proportion of patients with frailty, with high recall (0.873, 95% CI 0.857 - 0.887), an AUROC of 0.777 (95% CI 0.764 - 0.790), and a F_2-score of 0.755 (95% CI 0.741 - 0.768) on the test dataset. The model had good calibration, with an E/O ratio close to 1 (0.996, 95% CI 0.963 - 1.028), indicating that the predicted risk probabilities aligned well with observed frailty rates. The model's performance demonstrates that frailty risk can be reliably estimated early in the hospital stay, using routinely available EMR data, enabling hospital-wide identification of patients at risk of frailty.

Model performance varied across time points according to the amount of clinical data available. Using only data available at 24 hours after admission, the model's performance declined (F_2-score 0.742, 95% CI 0.725 - 0.756; recall 0.827, 95% CI 0.809 - 0.844), consistent with limited data completeness early in the admission. By discharge, when clinical documentation was more comprehensive, the model's performance improved (AUROC 0.835, 95% CI 0.824 - 0.846; F_2-score 0.796, 95% CI 0.785 - 0.806). This increase in model performance over time supports the conclusion that frailty prediction improves as more clinical data become available. The 72-hour time point provided a pragmatic balance between earlier clinical actionability and greater availability of multidisciplinary data.

Subgroup Performance and Equity Considerations

Subgroup analysis identified differences in observed frailty rates and model performance by Indigenous status. Overall, Indigenous patients had a lower observed frailty rate than non-Indigenous patients in this cohort (n=531, 29% vs n=8700, 36%), which contrasts with published evidence that frailty is more prevalent among First Nations populations [4]. This

XSL•FO
RenderX

difference should be interpreted in the context of differing age distributions and smaller denominators for Indigenous patients, particularly in older age groups. Age-stratified analysis showed similar frailty rates in some younger age bands, with higher frailty among Indigenous patients in the 31 to 40 years (95/346, 28% vs 273/1390, 20%), 51 to 60 years (132/410, 32% vs 924/3255, 28%), 61 to 70 years (117/338, 35% vs 1531/4702, 33%), and 81 to 90 years age groups (11/17, 65% vs 2297/4757, 48%). However, frailty rates were lower among Indigenous patients aged 71 to 80 years (35/121, 29% vs 2180/5609, 39%) and 91 years and older (1/3, 33% vs 774/1431, 54%). These findings indicate that the lower overall frailty rate among Indigenous patients may reflect age structure and limited data, rather than a lower underlying burden of frailty.

Model performance was lower for Indigenous patients than non-Indigenous patients on the F_2-score (0.723, 95% CI 0.664 - 0.776 vs 0.757, 95% CI 0.743 - 0.770) and recall (0.848, 95% CI 0.784 - 0.911 vs 0.874, 95% CI 0.860 - 0.890), indicating more missed frailty cases in this subgroup. The AUROC was higher for Indigenous patients (0.798, 95% CI 0.749 - 0.846 vs 0.774, 95% CI 0.761 - 0.787), while the Brier score was lower (0.152, 95% CI 0.132 - 0.172 vs 0.183, 95% CI 0.177 - 0.189), suggesting that poorer threshold-dependent classification performance occurred despite comparable or better discrimination and overall probability accuracy. The observation that Indigenous patients had a lower Brier score despite lower recall and F_2-score illustrates the importance of considering multiple model performance measures when evaluating subgroup performance. Unlike recall and F_2-score, which depend on a selected classification threshold, the Brier score evaluates the accuracy of predicted probabilities across all patients. The lower observed frailty prevalence among Indigenous patients in this cohort (n=531, 29% vs n=8700, 36%) may have contributed to lower average predicted probabilities and consequently lower Brier scores, despite poorer threshold-dependent performance. Similar patterns can occur when outcome prevalence differs between groups, highlighting that probability-based measures, discrimination measures, and threshold-dependent classification metrics capture different aspects of predictive performance and should be interpreted together rather than in isolation.

This pattern may reflect differences in frailty prevalence, calibration, threshold suitability, or limitations of the HFRS outcome definition in this population. The HFRS was developed using data from UK hospitals and has not been validated for Indigenous Australians [7]. In addition, *ICD-10*-AM diagnostic patterns used to derive the HFRS may not fully capture frailty-related health in Indigenous patients. These findings support the need for culturally validated frailty measures, subgroup calibration, and external validation in larger Indigenous cohorts.

Model performance was broadly similar between sexes, with only small differences observed across discrimination, classification, and calibration metrics.

Clinical and Operational Implications

At the selected operating threshold of 0.20, 3360 (62%) admissions were classified as positive for frailty risk. The threshold was intentionally selected to prioritize sensitivity, identifying 87% (1647/1886) of patients with frailty while maintaining a PPV of 49% (1647/3361). Consequently, approximately half of flagged patients would ultimately be classified as frail according to HFRS, while 62% (3360) of admissions would be flagged for review by the model. These trade-offs may be acceptable where the objective is early identification of patients for multidisciplinary frailty assessment rather than definitive diagnosis, although the optimal threshold is likely to depend on local clinical resources and service capacity.

Decision curve analysis demonstrated positive net benefit across all evaluated thresholds, suggesting that use of the model may provide greater clinical utility than reviewing all patients. At the selected threshold of 0.20, 62% (n=3360) of admissions would be identified for potential review. Decision curve analysis estimated a net reduction of 37.5 reviews avoided per 100 admissions compared with a treat-all strategy, after accounting for the trade-off between true-positive and false-positive classifications. These findings suggest that the model may improve targeting of frailty-related review compared with reviewing all patients, particularly where the acceptable intervention threshold lies between 0.10 and 0.30.

Implementation of the model would require consideration of incomplete or unavailable predictor data. During model development, missing categorical values were assigned to an “unknown” category, and missing numeric values were imputed using the training-set mean. In practice, delayed laboratory results, incomplete nursing assessments, or unavailable consult order data could affect prediction accuracy. Operational deployment would, therefore, require ongoing monitoring of data completeness and periodic evaluation of model performance when key predictor variables are missing or recorded outside expected time frames.

The intended use of the model would be as a decision support tool integrated within or alongside the EMR. Predictions would be generated automatically from routinely collected data, without requiring manual data entry by end users. Clinical interpretation and any subsequent intervention would remain the responsibility of treating clinicians and multidisciplinary teams. No specialist expertise in ML would be required of end users; however, appropriate training would be needed to support interpretation of model outputs and integration into existing clinical workflows.

Limitations of the Study

Key limitations include generalizability and potential subgroup biases. The model was trained only at a single tertiary hospital (RAH), which may limit its generalizability and increase the risk of overfitting, as health care use patterns vary by site.

An increased sample size of Indigenous patients and additional training variables could allow for the development of a model that has better performance for Indigenous patients; however, the lack of a validated frailty index for Indigenous patients

XSL•FO
RenderX

makes identifying frailty in Indigenous patients challenging. The incorporation of bias mitigation strategies, such as subgroup calibration, could also potentially improve model performance for Indigenous patients.

A further limitation relates to the use of HFRS as the reference standard. The HFRS was derived from postdischarge ICD-10-AM codes and therefore reflects documented diagnostic burden rather than direct clinical assessment of frailty. Because some predictor variables, particularly laboratory test results and medication use patterns, are associated with diagnoses that contribute to the HFRS calculation, a degree of criterion contamination may exist. Consequently, the model may partially predict future diagnostic coding patterns rather than frailty as a distinct clinical syndrome. Although HFRS is a validated and widely used frailty measure, it may not fully capture functional, cognitive, and social dimensions of frailty that are typically assessed through clinician-administered tools such as the CFS. Future studies should evaluate model performance against alternative frailty measures and prospective clinical assessments.

As HFRS is derived from diagnostic coding data, the outcome may capture broader constructs, including multimorbidity and clinical complexity, in addition to frailty. These constructs frequently overlap in hospitalized patients and may contribute to model performance. Future studies should evaluate model performance against prospective clinical frailty assessments to better distinguish frailty from related dimensions of patient vulnerability and health care complexity.

Data quality is often a challenge when working with EMR data, as it is part of an operational system designed to deliver patient care, not for data analysis. Incomplete and variable-quality data are limitations of this study. Integration of the model into a clinical workflow is a potential future direction, which would require consultation with clinicians. Validation against prospectively collected clinical frailty assessments would also help determine whether the model is identifying frailty itself or predicting the diagnostic burden captured by HFRS.

This study was limited to model development and internal validation. Evaluation of real-world implementation, including alert presentation, workflow integration, clinician acceptance, alert burden, intervention pathways, and patient outcomes, was outside the scope of the current study and should be assessed in prospective implementation studies. Future work should evaluate how model outputs can be incorporated into multidisciplinary frailty pathways and determine the optimal balance between sensitivity, specificity, and service capacity.

Conclusions

This study developed and validated a frailty prediction model for hospital inpatients using routinely collected EMR data available within 72 hours of admission. The model demonstrated good discrimination (F_2-score of 0.755, 95% CI 0.741 - 0.768), high recall (0.873, 95% CI 0.857 - 0.887), and reasonable calibration on the test dataset, with E/O ratios close to 1 (0.996, 95% CI 0.963 - 1.028), supporting its utility for early frailty identification. Key predictors included polypharmacy, laboratory results (including creatinine, albumin, and sodium), AH consult orders, and nursing assessment data, highlighting the value of multidisciplinary EMR data for frailty risk stratification. Model performance was robust at 72 hours, lower at 24 hours postadmission, and improved further by discharge, indicating that predictive accuracy increases as more data becomes available during a patient's admission.

Subgroup analysis revealed lower model performance for Indigenous patients, likely reflecting limitations of the HFRS as a frailty score in this population and highlighting the need for culturally validated frailty indices. No substantial differences in model performance were observed between sexes. These findings reinforce the importance of ongoing evaluation of model fairness and subgroup validity.

Future research should prioritize external validation across diverse hospital settings and patient populations to assess generalizability and mitigate overfitting. The development of frailty indices validated for Indigenous Australians and other underrepresented groups is needed to address equity gaps. Integration of the model into clinical workflows, with real-time EMR implementation and clinician engagement, will be essential for translation into practice. Ongoing monitoring for bias and periodic recalibration are recommended to ensure sustained model performance and fairness.

Abstract

Background: Schizophrenia is a severe mental disorder characterized by high disability and relapse rates, posing significant challenges to public safety and community-based mental health management.

Objective: This study aimed to develop and validate a model for identifying hospitalization-related severe relapse risk among individuals with schizophrenia and to determine the key factors associated with this risk.

Methods: A total of 44,804 electronic records of community-managed individuals with schizophrenia were extracted from an information management system between January 1, 2022, and December 31, 2023. The dataset included demographic information, clinical records, interview data, policy support, and management indicators to construct a comprehensive feature system. A Light Gradient Boosting Machine (LightGBM) machine learning algorithm was used for model development, with cost-sensitive learning applied to address class imbalance. Model interpretability was enhanced using Shapley additive explanations (SHAP) to identify the most influential predictors of relapse risk.

Results: After screening, a total of 39,818 community-dwelling individuals with schizophrenia were included in this study, of whom 3717 (9.33%) experienced hospitalization-related severe relapse. The dataset was randomly divided using stratified sampling into a training set (n=31,854, 80%) and an independent test set (n=7964, 20%). Among the 6 machine learning models evaluated, LightGBM showed leading and balanced performance, yielding an area under the receiver operating characteristic curve of 0.95, an area under the precision–recall curve of 0.79, a relapse-class recall of 0.77, a precision of 0.71, and an F_1-score of 0.74 in the independent test set. SHAP-based interpretability analysis identified medication persistence (23.30%), specialist recommendation: medication adherence training (19.74%), number of follow-ups (7.38%), age (3.72%), and educational attainment (3.58%) as the most influential predictors. Higher hospitalization-related severe relapse risk was generally associated with interrupted or refused medication use, more frequent follow-ups, younger age, and higher educational attainment, whereas sustained medication use, better occupational functioning and productive work, greater social participation, and better social functioning were associated with lower predicted risk.

Conclusions: This study developed a hospitalization-related severe relapse risk identification model that integrates multidimensional factors reflecting the clinical and functional complexity of schizophrenia. The findings provide an evidence-based foundation for risk identification, targeted intervention, and the optimization of community mental health services to reduce hospitalization-related severe relapse risk and support long-term recovery.

Introduction

Schizophrenia is a major global public health concern characterized by multidimensional impairments in perception, cognition, and emotion [1]. According to the Global Burden of Disease (GBD) Study 2019, an estimated 23.6 million people worldwide are affected by schizophrenia [2], with an increasing incidence over time [3]. Its high relapse rate severely compromises functional recovery and poses substantial challenges to long-term disease management, particularly within community-based mental health systems [4-6], further threatening the safety and well-being of families and communities [7].

The early identification and prediction of relapse have long been priorities in schizophrenia research [8-10]. Previous studies have reported that factors such as medication adherence, substance misuse, insight [11], exposure to stressful life events [12], social support, employment status [13], sleep quality [8], and adverse drug reactions [14] are closely associated with relapse [15]. Although electronic health records (EHRs) hold great potential for relapse or rehospitalization prediction, several limitations persist [16]. Relapse is widely recognized as the result of complex interactions among biological, psychological, and social factors, yet systematic investigations within community-based rehabilitation settings remain scarce. In practice, most patients with schizophrenia rely primarily on long-term community follow-up for disease management. However, existing studies often rely on data from single medical institutions with limited sample sizes, restricting their ability to reflect the real-world disease trajectory. Additionally, data collection methods vary across settings, and some variables depend on subjective assessments, which may weaken model generalizability and external validity.

While machine learning techniques offer advantages over traditional statistical methods in handling high-dimensional, complex real-world data and in distinguishing relapse from nonrelapse cases [17], existing models still face limitations in robustness and scalability [13,18,19]. In community mental health systems, predictive models must not only achieve high accuracy but also demonstrate interpretability and operational feasibility, enabling frontline practitioners to derive actionable intervention insights.

To address these gaps, this study developed an information management system (IMS) dataset encompassing community rehabilitation institutions across Shanghai and including 39,818 individuals with schizophrenia. The dataset integrates clinical diagnostic information, demographic characteristics, and community follow-up records, providing a comprehensive representation of relapse-related risk characteristics in real-world community mental health management settings. Furthermore, explainable machine learning techniques were used to improve predictive performance while elucidating the relative contributions of different risk factors to model predictions. The aim of this study was to develop a decision-support tool that can be integrated into community mental health service workflows to support risk identification and timely intervention, thereby providing empirical evidence for the monitoring of hospitalization-related severe relapse risk among individuals with schizophrenia in community settings.

Methods

Study Design and Setting

This study was based on the IMS for community-based rehabilitation of patients with schizophrenia, developed and maintained by the Shanghai Mental Health Center; the system continuously monitors and records patients' rehabilitation data across 16 districts. Patients experiencing acute or severe psychotic episodes were admitted to psychiatric hospitals for inpatient treatment, while those in clinically stable phases were transferred to home-based and community-based rehabilitation programs. Within these community rehabilitation centers, psychiatrists at outpatient clinics were responsible for recording and uploading follow-up information to the IMS. Additionally, family members or other informal caregivers were invited to participate in the evaluation process, providing supplementary observations of patients' behavior and daily functioning, thereby contributing to the establishment of a unified and comprehensive IMS database.

Sampling Strategy and Participants

A stratified cluster sampling strategy was adopted to select participants for this study. First, based on the level of urbanization, the 16 administrative districts of Shanghai were categorized into 3 tiers: central urban districts, semicentral suburban districts, and suburban districts, which served as the sampling framework. Following the principle of cluster sampling, Huangpu District and Yangpu District were selected from the central urban tier, Pudong New Area from the semicentral suburban tier, and Baoshan, Minhang, and Jiading Districts from the suburban tier. All individuals with schizophrenia who had follow-up records in the Shanghai Mental Health Information System between January 2022 and December 2023 within the selected districts were included in the initial sample (n=44,804). Participants were then screened according to predefined inclusion and exclusion criteria.

The inclusion criteria were as follows: (1) officially registered in the Shanghai Mental Health IMS; (2) aged 18 years or older; and (3) diagnosed with schizophrenia according to the *International Classification of Diseases, Tenth Revision (ICD-10)* criteria. The exclusion criteria were as follows: deceased individuals, those who had migrated outside Shanghai during the data collection period, long-term inpatients, and individuals younger than 18 years. After applying these criteria, a total of 39,818 patients were retained for subsequent modeling and analysis.

During feature selection, personal identifiers (eg, patient name, hospital name, and rehabilitation site), time-dependent variables irrelevant to the prediction task (eg, follow-up date and record creation time), and potential data leakage variables (eg, residential address and name of attending psychiatrist) were excluded. Each patient record contained structured information, including demographic characteristics, clinician-rated diagnostic data, social interaction indicators, and treatment-related management details. Additionally, unstructured text fields

XSL•FO
RenderX

documented behavioral observations, participation in rehabilitation programs, and individualized recommendations from psychiatric specialists.

In this study, relapse was operationally defined as a patient's transfer from community-based rehabilitation to a psychiatric hospital for inpatient treatment due to acute exacerbation or deterioration of psychotic symptoms [20]. Hospitalizations related to physical comorbidities or nonpsychiatric causes were excluded. Only hospital admissions that psychiatrists determined to be acute psychotic relapse events were classified as relapse cases. If such a transfer occurred during the observation period, the patient was labeled as a positive (relapse) case; otherwise, the patient was classified as a negative (nonrelapse) case.

For relapse cases, data from the last follow-up prior to hospitalization were used as predictive variables for subsequent relapse outcomes. For nonrelapse cases, data from the most recent follow-up were selected as predictive variables, and the absence of relapse during the subsequent observation period was used as the outcome label. This approach ensured temporal precedence of predictors relative to outcomes, thereby preventing bias from potential data leakage.

Because the original IMS database could contain multiple follow-up records for the same patient, the analysis dataset was constructed at the patient level before model development. Each patient was restricted to 1 predefined index record. For patients who experienced hospitalization-related severe relapse, the index record was defined as the last community follow-up record before hospitalization due to acute exacerbation or deterioration of psychotic symptoms. For patients without hospitalization-related severe relapse during the observation period, the index record was defined as the last valid community follow-up record during the observation period. After this procedure, each patient contributed only one record to the final analysis dataset.

Feature Construction

The initial feature pool comprised 52 candidate variables, spanning five thematic domains: (1) sociodemographic characteristics; (2) clinical diagnosis and medical history; (3) medication management and follow-up; (4) rehabilitation participation; and (5) rehabilitation interventions and specialist recommendations. During data preprocessing, variables with more than 50% missing values were excluded [21]. Prior to feature selection, a variance thresholding approach was applied to remove variables with negligible predictive utility. Specifically, features with zero variance and near-zero variance (ie, nonzero occurrence rate below 0.1%) were eliminated. After preprocessing, 41 features were retained for model training (Table 1). These features were subsequently organized into 5 major domains (Multimedia Appendix 1), as summarized in Table 1.

Table . Summary of feature categories.

Domain	Variables
(1) Sociodemographic characteristics	Age; sex; educational attainment; marital status; long-term bedridden status or loss of mobility; family supervision status; participation in community rehabilitation services; number of follow-ups
(2) Clinical diagnosis and medical history	Antipsychotic treatment status; reason for untreated status; recent stressful events; social functioning assessment; insight into illness; history of violent or disruptive behavior; mode of illness onset; past medical history; disability severity level
(3) Medication management and follow-up	Medication persistence; medication administration pattern; medication adherence; timeliness of clinical follow-up
(4) Rehabilitation participation	Social participation; sleep quality; dietary status; personal self-care ability; household functioning; occupational functioning and productive work; acquisition of new knowledge and skills; interpersonal social interaction
(5) Rehabilitation interventions and specialist recommendations	Rehabilitation intervention (daily living and vocational skills); rehabilitation intervention (vocational training); rehabilitation intervention (learning ability); rehabilitation intervention (social interaction); other rehabilitation interventions; specialist recommendation: treatment adjustment; specialist recommendation: vocational rehabilitation training; specialist recommendation: symptom monitoring training; specialist recommendation: learning skills training; specialist recommendation: social skills training; specialist recommendation: daily living skills training; specialist recommendation: medication adherence training

Ethical Considerations

This study was based on the analysis of routinely collected community follow-up data, with all personally identifiable information removed prior to analysis. The Ethics Committee of the Shanghai Mental Health Center approved this study (institutional review board registration number: IORG0002202; Federalwide Assurance number: FWA00003065).

Statistical Analysis and Model Training

Statistical Analysis

Baseline statistical analyses were performed using SPSS Statistics software (version 26.0; IBM Corp). For categorical variables, chi-square tests were conducted to examine group differences in variable distributions across relapse statuses. For multiple-response categorical variables, multiple-response

XSL•FO
RenderX

analyses were applied to calculate the frequency of each response option, followed by between-group comparisons. For continuous variables with skewed distributions or those violating the assumption of normality, nonparametric tests were used. Specifically, independent-samples *t*-tests or Mann-Whitney *U* tests were used for comparisons between 2 groups, whereas Kruskal-Wallis H tests were used for comparisons involving more than 2 groups. All statistical tests were 2-tailed, and a *P* value <.05 was considered statistically significant.

Model Training

In the present study, the original dataset exhibited severe class imbalance, with a ratio of approximately 10:1 between the majority (nonrelapse) and minority (relapse) classes. Such an extreme imbalance can cause conventional classifiers to exhibit strong bias toward the majority class, thereby achieving deceptively high overall accuracy but extremely poor recall for the minority class—resulting in suboptimal identification of relapse cases and limited generalizability.

A stratified random sampling strategy was applied to split the dataset into a training set (31,854/39,818, 80%) and an independent test set (7964/39,818, 20.0%), ensuring that the relapse-to-nonrelapse ratio remained consistent across both subsets. All feature selection and hyperparameter optimization procedures were strictly confined to the training set to prevent information leakage. Final model performance was evaluated exclusively on the held-out test set to ensure an unbiased assessment [22]. Class imbalance was addressed using cost-sensitive learning. For tree-based gradient boosting models (Light Gradient Boosting Machine [LightGBM] and extreme gradient boosting [XGBoost]), scale_pos_weight was applied. For random forest (RF), support vector machine (SVM), and logistic regression (LR), class_weight was used. For adaptive boosting (AdaBoost), sample weights (sample_weight) were assigned. Higher misclassification costs were assigned to the minority class (relapse), and all weighting parameters were jointly optimized with other hyperparameters through 5-fold stratified cross-validation and grid search. This strategy improves minority-class sensitivity without altering the true class distribution of the test set.

Missing-value handling was implemented according to model capabilities. LightGBM and XGBoost support native missing-value processing by learning an optimal routing direction for missing observations at each tree split; therefore, original missing values were retained without imputation. For the 4 models that do not support native missing values (RF, AdaBoost, SVM, and LR), median imputation was performed using statistics estimated exclusively from the training set. For SVM and LR, feature standardization was subsequently applied, with the scaler fitted only on the training set and then applied to the test set, thereby preventing any information leakage.

A total of 14 variables contained missing values, with missingness rates ranging from 0.6% to 17.2%. Under this framework, all samples retained their natural missing-data patterns and were handled through the native mechanisms of tree-based models whenever possible. Finally, model-derived feature importance was examined as part of the model interpretation process, and Shapley additive explanations (SHAP) analysis was subsequently used to quantify feature contributions to the final LightGBM model [23].

Exploratory Temporal Robustness Check

An exploratory temporal robustness check was conducted according to the calendar year of the retained patient-level index record. Using the same modeling pipeline as in the primary random 80/20 split analysis, the LightGBM model was trained on the 2022 index-record cohort and evaluated on the 2023 index-record cohort. Because the calendar year of the retained index record was partly influenced by the index-record selection rule, this analysis was prespecified as an exploratory robustness check rather than as a conventional independent temporal validation. For patients without hospitalization-related severe relapse, the retained index record was the last valid follow-up record during the observation period, whereas for relapse cases, the retained index record was the last follow-up before hospitalization. Therefore, the calendar-year split was not fully independent of outcome status.

Model Implementation and Optimization

The machine learning models were implemented in Python 3.10 using LightGBM (version 3.3.5). In this study, 6 widely used machine learning algorithms were evaluated, including LightGBM, RF, AdaBoost, SVM, LR, and XGBoost.

Hyperparameter optimization was performed using GridSearchCV with 5-fold stratified cross-validation, using area under the receiver operating characteristic curve (ROC-AUC) as the optimization metric. Class imbalance was addressed through cost-sensitive learning rather than resampling. Specifically, gradient boosting models (LightGBM and XGBoost) used the scale_pos_weight parameter, while RF, SVM, and LR used class_weight, and AdaBoost incorporated class-dependent sample weights (sample_weight). The hyperparameter search spaces and the corresponding optimal configurations for all models are provided in Multimedia Appendix 2.

SHAP Analysis

To enhance the clinical interpretability of the model, SHAP analysis was performed on the final trained LightGBM model to quantify the direction and magnitude of each feature's contribution to the predicted outcome.

SHAP values are derived from Shapley values in cooperative game theory and provide both local explanations at the individual patient level and global feature importance at the cohort level.

In the SHAP summary plot, each point represents an individual patient. The x-axis indicates the SHAP value, which reflects the contribution of a given feature to the model output. Positive SHAP values indicate an increased predicted risk of relapse, whereas negative values indicate a lower predicted risk. Features are ranked according to their mean absolute SHAP values, with those at the top of the plot exerting a greater overall influence on model predictions.

Results

Baseline Characteristics of the Included Patients

The baseline characteristics of community-dwelling patients with schizophrenia showed that the median age was 60 (IQR 47 - 69) years, and 53.2% (21,170/39,818) of the participants were female. Among the 39,818 individuals included in this study, 3717 (9.3%) experienced relapse, while 36,101 (90.7%) did not.

Between-group comparisons indicated that patients in the relapse group were significantly younger than those in the nonrelapse group (z=−20.78, *P*<.001). Regarding educational attainment, a significantly higher proportion of patients with a college education or above was observed in the relapse group (839/3717, 22.6%) compared with the nonrelapse group (χ^2_2=98.73, *P*<.001). In terms of marital status, the proportion of unmarried patients was higher in the relapse group (2054/3717, 55.3%) than in the nonrelapse group (15,234/36,101, 42.2%; χ^2_2=339.34, *P*<.001; Table 2). The detailed data provided in Multimedia Appendix 1.

Table . Demographic and baseline characteristics of patients by relapse status.

Variable	Nonrelapse (n=36,101)	Relapse (n=3717)	Total (N=39,818)	Statistic	*P* value

Model Development and Performance

To systematically evaluate risk factors associated with relapse in schizophrenia and their relative importance, multiple machine learning models were constructed and compared, including LightGBM, AdaBoost, XGBoost, SVM, LR, and RF.

Given that nonrelapse cases were dominant in the dataset, relying solely on overall accuracy and weighted metrics (weighted recall, weighted precision, and weighted F_1-score) may be biased toward the majority class. Therefore, this study additionally focused on relapse-class-specific performance and macroaveraged metrics (macro recall, macro precision, and macro F_1-score) to more objectively evaluate model performance under class imbalance conditions.

Among the 6 models evaluated, the 2 gradient boosting models (LightGBM and XGBoost) achieved the best overall performance, both attaining ROC-AUC values of approximately 0.95 and substantially outperforming LR (ROC-AUC=0.85). These findings suggest that boosting-based models are more capable of capturing the complex nonlinear relationships and high-dimensional interactions present in community mental health EHRs (Figure 1). LightGBM demonstrated the best overall performance, achieving an ROC-AUC of 0.95, an area under the precision–recall curve (PR-AUC) of 0.79, a relapse-class recall of 0.77, a precision of 0.71, and an F_1-score of 0.74. The optimal hyperparameter configuration was learning_rate=0.1, max_depth=13, n_estimators=100, num_leaves=31, and scale_pos_weight=3.

Figure 1. Performance evaluation of the hospitalization-related severe relapse risk identification model. (A) Receiver operating characteristic curve illustrating the model's overall ability to discriminate between relapse and nonrelapse patients. (B) Precision-recall curve assessing the model's performance in identifying the minority class (relapse patients), particularly in terms of precision and recall. (C) Confusion matrix of the Light Gradient Boosting Machine (LightGBM) model, showing the number of correctly classified nonrelapse (stable) and relapse patients. AdaBoost: adaptive boosting; FPR: false positive rate; SVM: support vector machine; TPR: true positive rate; XGBoost: extreme gradient boosting.

XSL•FO
RenderX

Notably, the models exhibited a clear sensitivity–precision trade-off in identifying relapse cases. AdaBoost and SVM achieved relatively high relapse-class recall values of 0.80 and 0.82, respectively, indicating greater sensitivity in detecting relapse cases. However, their precision values were comparatively low, at 0.49 and 0.56, respectively, suggesting a higher number of false-positive predictions. XGBoost showed overall performance highly comparable to that of LightGBM, with similar accuracy, macro F_1-score, relapse-class recall, relapse-class precision, relapse-class F_1-score, and ROC-AUC (Table 3). However, the PR-AUC of XGBoost was slightly lower than that of LightGBM. Considering that PR-AUC is particularly informative under class imbalance, and that LightGBM maintained a favorable balance between relapse-class recall and precision, LightGBM was retained as the primary model for subsequent interpretability and sensitivity analyses.

In addition to discrimination performance, model calibration was evaluated using calibration curves and Brier scores. The unweighted baseline model achieved a Brier score of 0.036, indicating good agreement between predicted probabilities and observed outcomes. The cost-sensitive LightGBM model yielded a slightly higher Brier score of 0.040. Although cost-sensitive learning improved relapse detection performance, a modest reduction in calibration was observed, reflecting the inherent trade-off between sensitivity and probability calibration (Multimedia Appendix 2).

Model Interpretability

The SHAP-based interpretability analysis identified the key predictors contributing to model predictions, ranked according to their relative importance (Figure 2). Among all features, medication persistence contributed the most to model prediction, accounting for 23.30% of the total feature importance, suggesting that medication-management information was an important predictive signal. The next most influential predictors were specialist recommendation: medication adherence training (19.74%), number of follow-ups (7.38%), and age (3.72%), indicating that these variables were closely related to the relapse risk patterns captured by the model. Other important predictors included educational attainment (3.58%), occupational functioning and productive work (3.11%), family supervision status (2.94%), and social functioning assessment (2.80%). The SHAP summary plot further showed the direction of associations between these features and model-predicted risk. Overall, refusal of medication, intermittent medication use, or poorer medication persistence during disease management, as well as a greater number of follow-ups, were generally associated with higher model-predicted risk. Although the number of follow-ups did not show a significant univariate between-group difference in the baseline comparison, its SHAP contribution reflects its conditional contribution to model prediction after accounting for other clinical, medication-management, and functional variables. In addition, younger age and higher educational attainment were generally associated with higher predicted risk. Poorer occupational functioning and productive work, specialist recommendation: treatment adjustment, higher disability severity level, and lower social participation were also associated with increased predicted risk.

Exploratory Temporal Robustness Check

In the exploratory temporal robustness check, the LightGBM model was trained on the 2022 index-record cohort and evaluated on the 2023 index-record cohort using the same modeling pipeline as in the primary random 80/20 split analysis. The 2022 index-record cohort included 9028 patients, with a hospitalization-related severe relapse prevalence of approximately 19.7%. The 2023 index-record cohort included 30,790 patients, with a relapse prevalence of 6.3%. Among the 30,790 patients in the 2023 cohort, 21,566 had retained index records in the fourth quarter of 2023.

The model achieved a ROC-AUC of 0.93 and a PR-AUC of 0.62 in the 2023 index-record cohort, compared with 0.95 and 0.79, respectively, in the primary random 80/20 split analysis. At the default threshold of 0.50, relapse-class recall, precision, and F_1-score were 0.56, 0.63, and 0.60, respectively. When the decision threshold selected from the 2022 training cohort was applied, relapse-class recall increased to 0.61, with a precision of 0.60 and an F_1-score of 0.61.

These results suggest that the model retained discrimination when applied to records indexed in the subsequent calendar year. However, because the calendar year of the retained index record was partly influenced by the index-record selection rule, this analysis should be interpreted as an exploratory temporal robustness check (Table 4) rather than as evidence of conventional independent temporal validation. The lower PR-AUC and threshold-dependent performance in the 2023 cohort may partly reflect differences in relapse prevalence, case mix, and the index-record selection rule. Further details on quarter-wise performance and relapse prevalence are provided in Multimedia Appendix 2.

Discussion

Main Findings

Using large-scale, real-world community rehabilitation data from 39,818 individuals with schizophrenia recorded in the IMS, this study developed a hospitalization-related severe relapse risk identification model for community mental health management settings. The primary purpose of the model is not to provide precise predictions of relapse within a predefined future time window. Rather, it aims to use information routinely collected during community follow-up visits to dynamically identify patients who may have entered a high-risk trajectory and are more likely to require hospitalization-related intervention. Therefore, the model is intended to support risk screening, risk stratification, and early intervention within community mental health services.

The model integrated multidimensional information, including behavioral characteristics, functional status, interpersonal relationships, and community support, and used LightGBM together with SHAP-based interpretability analysis to identify key risk factors. The results indicated that medication persistence, specialist recommendation: medication adherence training, number of follow-ups, and age were among the most influential predictors of hospitalization-related severe relapse risk. In addition, educational attainment, occupational functioning and productive work, and social functioning assessment also demonstrated substantial importance, suggesting that functional recovery and social adaptation are closely associated with the risk patterns identified by the model [24].

Global feature importance analysis further highlighted the central role of medication management–related factors. Among them, medication persistence and specialist recommendation: medication adherence training were the 2 most influential predictors, while medication adherence also ranked among the key features. SHAP distribution plots showed that sustained medication use and good medication adherence were generally associated with lower risk, whereas intermittent medication use or refusal to take medication was more frequently associated with higher risk. These findings suggest that medication management–related factors play a critical role in the identification of hospitalization-related severe relapse risk. Previous studies have widely recognized medication nonadherence as one of the most important predictors of schizophrenia relapse [15,25], and medication education and supervision are typically associated with improved adherence and lower relapse rates [14,24]. Overall, the findings of this study are generally consistent with existing evidence. However, it is noteworthy that the proportion of patients recorded as having “regular medication adherence” was higher in the relapse group than in the nonrelapse group. For patients with more severe illness or higher relapse risk, community physicians and family members may implement stricter supervision and management, making these patients more likely to be documented as having “regular medication adherence” in follow-up records. In addition, this study found that better occupational functioning and productive work, better social functioning assessment, and better social participation were associated with lower model-predicted risk. This finding is consistent with previous research on social skills training, which has shown that social skills training and functional rehabilitation are typically associated with better social functioning, self-efficacy, and clinical stability [26,27]. Furthermore, Chen et al [28] found that higher levels of social participation are generally associated with lower levels of psychosocial stress and fewer social withdrawal behaviors [29,30].

Other Findings

Some findings in this study were inconsistent with previous literature. Higher educational attainment was associated with higher model-predicted relapse risk. One possible explanation is that patients with higher education levels may exhibit greater sensitivity to diagnostic labeling and social stigma, which may

XSL•FO
RenderX

in turn be reflected in different illness perceptions and treatment attitudes during long-term management. This finding suggests that, in community rehabilitation settings, in addition to symptom control, greater attention should be paid to psychological adaptation, illness perception, and social support among higher-functioning patients. Future longitudinal studies are warranted to further explore the relationship between educational level, social functioning, and long-term disease management [31]. Higher disability severity was associated with higher model-predicted risk. This finding may be explained by patients' current functional status, including impairments in self-care and social participation. Such functional impairments may increase perceived stigma and reduce self-esteem, thereby increasing patients' vulnerability to relapse [32].

The present study also observed that younger age was associated with higher model-predicted relapse risk. Consistent with previous studies, younger patients or those with early-onset schizophrenia tend to have higher relapse rates and poorer long-term outcomes. On one hand, patients in the early stages of the illness often show more pronounced symptom instability and lower treatment stability. On the other hand, younger patients more frequently experience treatment discontinuation, loss to follow-up, and less stabilized social functioning. These characteristics have also been associated with higher relapse risk in previous research. In addition, younger patients are often in the process of establishing social roles, and greater pressures related to education, employment, and social adaptation may further complicate disease management [33].

Finally, a higher number of follow-ups was associated with higher model-predicted relapse risk. This finding may reflect the "high-risk intensive follow-up" pattern in community mental health management, whereby patients with unstable conditions, a frequent relapse history, or higher clinical risk receive more intensive community follow-up and health management. Therefore, higher follow-up frequency may reflect not only health care usage intensity but also indirectly indicate underlying disease severity and relapse risk.

Overall, dynamic management information within community mental health service systems may provide important complementary signals for relapse risk identification, further highlighting the potential use of machine learning models based on community EHRs in chronic mental disorder management.

Model Performance and Clinical Utility

In this study, LightGBM showed leading and balanced performance among the 6 evaluated models, with an ROC-AUC of 0.95, a PR-AUC of 0.79, a relapse-class recall of 0.77, a precision of 0.71, and an F_1-score of 0.74 on the independent test set. These results suggest that the model had good discriminative ability and performed reasonably well in identifying patients at risk of hospitalization-related severe relapse under a highly imbalanced outcome distribution. However, model performance should not be interpreted solely on the basis of ROC-AUC or overall accuracy. In community mental health management, the balance between sensitivity and precision is particularly important. A relapse-class recall of 0.77 indicates that the model identified approximately 77% of hospitalization-related severe relapse cases, while approximately 23% of such cases were not detected. Meanwhile, a precision of 0.71 suggests that most patients classified as high risk subsequently experienced hospitalization-related severe relapse, although false-positive alerts remained present. This trade-off has practical implications for community-based risk management. Lowering the decision threshold may improve the detection of high-risk patients, but it would also increase false-positive alerts, leading to additional follow-up visits, referral assessments, and intervention-related resource use. Conversely, using a stricter threshold may improve precision and reduce unnecessary alerts, but at the cost of missing more patients who may later require hospitalization-related intervention. Therefore, the model is better understood as a risk stratification and decision-support tool rather than a standalone screening instrument or a replacement for clinical judgment.

In community practice, the predicted risk score may be used to support follow-up prioritization and resource allocation. For example, patients with higher predicted risk may be considered for more frequent community follow-up, timely psychiatric reassessment, multidisciplinary review, or individualized management strategies addressing medication management, social functioning, family supervision, and rehabilitation participation. However, the model should not be used to automatically determine treatment adjustment, referral, or hospitalization. Final decisions should remain clinician-led and should integrate the predicted risk score with clinical assessment, patient history, family support, current mental state, and local service resources.

In addition, the slightly higher Brier score observed in the cost-sensitive LightGBM model indicates that improved relapse detection may be accompanied by a modest reduction in probability calibration. Thus, the predicted scores should be interpreted primarily as relative risk indicators for prioritizing community management, rather than as fully calibrated individual probabilities. Future studies should further optimize decision thresholds according to specific service scenarios, available community resources, and an acceptable false-positive burden, and should evaluate calibration and clinical utility before broader implementation.

The exploratory temporal robustness check further suggests that the model retained good discriminative performance when applied to a future cohort within the same community mental health management system. However, temporal robustness should be distinguished from external generalizability. Because all data in this study were derived from the Shanghai community mental health management system, model performance may still be influenced by local follow-up protocols, hospitalization referral criteria, documentation practices, patient characteristics, and community rehabilitation resources. Before broader implementation, the model should be externally validated using independent datasets from different geographic regions, health care systems, and community mental health service settings.

Finally, if the model is integrated into routine community mental health practice, its performance and calibration should be periodically monitored. As community management practices, follow-up routines, patient composition, service resources, and relapse prevalence evolve over time, recalibration or model

XSL•FO
RenderX

updating may be required to maintain the model's long-term applicability and clinical decision-support value.

Limitations

Several limitations should be acknowledged. First, this study did not use a fully standardized prediction window. For relapse cases, predictors were extracted from the last follow-up assessment before hospitalization; therefore, the model should be interpreted as a tool for identifying hospitalization-related severe relapse risk in real-world community management, rather than as a prognostic model for predicting relapse within a fixed future time horizon. Future studies should incorporate predefined prediction windows, longitudinal sequential data, and time-to-event modeling to evaluate earlier relapse risk detection. Second, the outcome was defined as hospitalization-related severe relapse, namely, psychiatric hospitalization due to acute exacerbation or deterioration of psychotic symptoms. This definition provides an objective and clinically meaningful end point, but it may not capture milder symptom exacerbations managed through outpatient care, medication adjustment, or intensified community follow-up. Third, generalizability remains limited because all data were derived from the Shanghai community mental health management system. Although the exploratory temporal robustness check using the 2022 and 2023 index-record cohorts suggested temporal robustness, the calendar year of the retained index record was partly influenced by outcome status because the index record was selected differently for nonrelapse and relapse patients. Model performance may also be affected by local follow-up protocols, hospitalization referral criteria, documentation practices, and related contextual factors. Future studies should prospectively validate the model in independently assembled cohorts or external datasets and consider periodic recalibration before broader implementation. In addition, some predictors, including specialist recommendations, medication-management variables, and follow-up-related variables, may partly reflect community management intensity or clinicians' responses to perceived instability rather than patient-level risk factors alone. These variables should therefore be interpreted cautiously. The main analysis used integer encoding for categorical variables, which may impose artificial ordering on nominal variables, particularly for distance-based and linear comparator models. Future studies should consider one-hot encoding or model-native categorical feature handling to minimize the potential influence of encoding choices. Finally, several optimal hyperparameters were located at the boundary of the predefined search grid, suggesting that the search space may not have fully covered all potentially optimal parameter combinations. Therefore, the performance of each model should be interpreted as the performance achieved under the predefined tuning protocol rather than as the theoretical upper-bound performance of the algorithm. Future studies may use broader search ranges, random search, or Bayesian optimization for more exhaustive hyperparameter optimization.

Conclusions

Based on IMS data for community mental health services, this study developed a hospitalization-related severe relapse risk identification model for individuals with schizophrenia and used LightGBM in combination with SHAP analysis to enhance model interpretability. The study integrated multidimensional variables related to patient behavioral characteristics, social functioning, community management, and rehabilitation, and analyzed community follow-up records from 39,818 patients. The results showed that medication persistence, educational attainment, specialist recommendation for medication adherence training, age, and follow-up management were among the most influential predictors in the model. Specifically, sustained medication use and better occupational functioning and productive work were generally associated with lower predicted relapse risk, whereas higher educational attainment, high disability level, and younger age were more frequently associated with higher predicted relapse risk. Among the machine learning models evaluated, LightGBM demonstrated the leading and balanced performance in identifying relapse cases, suggesting that EHR-based machine learning approaches may provide a promising tool for the identification of hospitalization-related severe relapse risk in community mental health management settings.

Abstract

Background: Liposuction is widely performed to remove localized fat deposits and improve body contour, yet individualized prediction of postoperative outcomes remains challenging. Existing machine learning (ML) studies have largely focused on single-outcome prediction, with limited attention to the interdependence between postoperative body weight and circumferential size.

Objective: This study aimed to develop and validate a chained multioutput ML framework to jointly predict postoperative body weight and circumferential size after liposuction using a large multicenter cohort from the 365mc network.

Methods: We analyzed a multicenter cohort of 7804 individuals who underwent liposuction in 2024 at 20 obesity specialty clinics in the 365mc network across South Korea. Using 15 predictors, we compared 8 individual ML models, an automated ML approach, 2 ensemble approaches, and chained multioutput regression models for predicting postoperative body weight and circumferential size. Models were developed using 5-fold cross-validation and evaluated on an independent test set. Performance was assessed using the coefficient of determination (R^2), root mean square error (RMSE), mean absolute error (MAE), and mean absolute percentage error (MAPE), and feature importance was evaluated using Shapley additive explanation (SHAP) values. The selected model was integrated into a web-based clinical decision support system (CDSS).

Results: A total of 7804 individuals who underwent liposuction were included; of these, 7612 (97.54%) were female. The chained extra trees regressor model with a weight-to-size prediction order achieved an R^2 of 0.98, an RMSE of 2.36, an MAE of 1.24, and a MAPE of 2.19. The SHAP analysis identified preoperative weight as the main predictor of postoperative body weight and preoperative size and liposuction-related factors as key predictors of postoperative circumferential size. The final model was integrated into a web-based CDSS (365mc AI platform).

Conclusions: We developed and validated a chained multioutput regression model to predict postoperative body weight and circumferential size after liposuction. Integrated into a web-based CDSS, the model may support patient-specific preoperative counseling and surgical planning.

Introduction

Liposuction is a widely performed cosmetic surgical procedure to remove localized fat deposits and enhance body contours [1]. The International Society of Aesthetic Plastic Surgery reported more than 5.1 million body contouring operations, including liposuction, in 2023, placing it among the 5 most frequent cosmetic surgeries worldwide [2]. As liposuction cases increase, patients increasingly seek individualized predictions of their postoperative results, whereas clinicians require comprehensive preoperative profiles to support data-driven surgical decision-making [3].

Despite these advances, postoperative outcomes after liposuction remain difficult to predict because they are influenced by patient-specific, anthropometric, and procedural factors. Recent machine learning (ML) studies have used patient-level data and ensemble methods to improve prediction of surgical or anthropometric outcomes [4-6]. However, evidence remains limited for liposuction-specific postoperative prediction using large multicenter datasets, and many studies have focused on single outcomes rather than modeling related targets together. As summarized in Table S1 in Multimedia Appendix 1, prior liposuction-related prediction studies were largely limited to single-center cohorts, single-outcome models, or algorithms that did not explicitly account for dependencies between correlated postoperative outcomes. To our knowledge, no previous study has jointly modeled postoperative body weight and circumferential size using a multicenter dataset of this scale.

Postoperative body weight and circumferential size are closely related outcomes after liposuction. Predicting them independently may overlook the relationship between overall weight change and local body-contour change. Previous multioutput learning studies have shown that when response variables are correlated or clinically dependent, chained regression models can be useful because they use the prediction of one target as additional information for another [7,8]. This structure allows the model to capture intertarget dependencies that may not be reflected in separate single-output models [9]. On the basis of this rationale, we developed a chained multioutput regression model to jointly predict postoperative body weight and circumferential size.

Therefore, this study aimed to develop and validate a chained multioutput ML framework to predict postoperative body weight and circumferential size in individuals undergoing liposuction. Using a large multicenter dataset from 20 obesity specialty hospitals in the 365mc network in South Korea, we evaluated a range of algorithms, including chained multioutput models, to jointly predict postoperative body weight and circumferential size while accounting for the relationship between these outcomes. The best-performing configuration was subsequently integrated into a web-based clinical decision support system (CDSS), enabling its use for preoperative planning and individualized patient counseling in clinical practice.

Methods

Patient and Data Collection

We analyzed anonymized, deidentified data from a multicenter cohort comprising individuals who underwent liposuction in 2024 across 20 obesity specialty clinics in the 365mc network in South Korea [10]. A comprehensive dataset was constructed from patients who underwent procedures at these clinics throughout 2024, totaling 8064 individuals. To ensure data integrity for model development, patients with incomplete records regarding the liposuction site or postoperative outcomes were excluded. After data preprocessing, the final cohort included 7804 patients. A detailed flowchart of the data processing is shown in Figure S1 in Multimedia Appendix 1.

Ethical Considerations

The research protocol was approved by the institutional review board of Kyung Hee University (KHUH 2024–04–002). The requirement for informed consent was waived by the board, as deidentified data were used for all analyses. This study was conducted in accordance with the principles outlined in the Declaration of Helsinki. The Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis statement was followed to guide the design, analysis, and reporting of this study [11].

Multicenter Liposuction Cohort

The multicenter liposuction cohort included individuals aged ≥17 years who underwent liposuction between 1 January and 31 December 2024 at 20 obesity specialty clinics in the 365mc network in South Korea. Clinical records from these branches were consolidated into a single dataset and randomly partitioned into training, validation, and test subsets for model development. The ML model was developed to simultaneously predict 2 primary postoperative outcomes: body weight and site-specific circumference, using preoperative variables [12]. Participants' weight and the dimensions of the treated site were measured preoperatively and again at a mean of 3.82 (SD 2.24) weeks after liposuction with a bioelectrical-impedance analyzer; all measurements were obtained with the InBody 370S (InBody Co) [13]. Only patients with complete paired preoperative and postoperative anthropometric and bioelectrical data were included in the final analysis.

Model Variables

To develop a multioutput ML-based model for predicting postoperative outcomes after liposuction, we used the following 15 features: sex (male or female), age (continuous), height (continuous), preoperative body weight (continuous), BMI (continuous), preoperative size (continuous), liposuction technique (local anesthetic minimally invasive liposuction [LAMS] or conventional surgical liposuction), liposuction site (abdomen, arms, back, buttocks, calves, flanks, or thighs), skeletal muscle mass (continuous), body fat mass (continuous), total body water (continuous), fat-free mass (continuous), body protein (continuous), body mineral content (continuous), and

XSL•FO
RenderX

waist-to-hip ratio (continuous). Detailed descriptions of the variables are provided in Table S2 in Multimedia Appendix 1.

Preprocessing

The dataset was randomly split into training and test sets in a 7:3 ratio. The test set was used only for final model evaluation and was not accessed during training or internal validation. Missing values were handled using multiple imputation by chained equations. Continuous variables were winsorized to reduce the influence of outliers [14], and z-score standardization was then performed using the mean and SD estimated from the training set, which were subsequently applied to the test set [15]. Feature selection was performed using least absolute shrinkage and selection operator (LASSO) regularization, with detailed procedures provided in Multimedia Appendix 1 and the selected features shown in Figure S2 in Multimedia Appendix 1. The correlation matrix of the resulting feature set is shown in Figure S3 in Multimedia Appendix 1 [16,17].

ML Algorithms

We established a multioutput ML framework to predict postoperative body weight and circumferential size using preoperative profiles from the 365mc network. The candidate algorithms included tree-based ensemble models, including the random forest regressor and extra trees regressor; boosting-based models, including gradient boosting regressor (GBR), histogram-based GBR (HGBR), and adaptive boosting (AdaBoost) regressor; and a kernel-based model, support vector regressor [18,19]. The Tree-Based Pipeline Optimization Tool (TPOT; Epistasis Lab) was also evaluated as an automated ML approach [20]. Ensemble strategies, including the voting regressor and stacking regressor, were applied to combine predictions from multiple base learners [21]. For multioutput prediction, a regressor chain framework was implemented to model the dependency between postoperative body weight and circumferential size. The principles and key formulas of the algorithms used in this study are provided in Table S3 in Multimedia Appendix 1. To characterize the variability and distribution of the target variables, descriptive statistics were calculated separately for the training and test sets and are presented in Table S4 in Multimedia Appendix 1. All models were optimized using grid search [22], and the final hyperparameters are summarized in Table S5 in Multimedia Appendix 1.

Multioutput Regression Model

Multioutput learning was used to jointly predict 2 related postoperative outcomes, postoperative body weight and circumferential size, from the same selected input features [23,24]; let x denote the predictor vector for a given patient, and let y=(y1, y2) denote the target outcomes. We implemented a wrapper-based regressor chain using the extra trees regressor as the base estimator, allowing the prediction of the first target to inform the second target [8]. In the forward chain, postoperative body weight was predicted first and then used as an additional feature to estimate circumferential size:

$$[y\hat{}1=f1(x)][y\hat{}2=f2(x,y\hat{}1)]$$

In the reverse chain, the order of the 2 targets was swapped. Both chain directions were evaluated to assess the influence of target ordering on model performance. The overall objective was to minimize the joint prediction error across both outcomes:

$$L=1N\sum i=1N[\ell(yi1,y\hat{}i1)+\ell(yi2,y\hat{}i2)]$$

The extra trees regressor with the forward chain order was selected as the final multioutput prediction model based on its overall predictive performance.

Model Training and Evaluation

Model performance was evaluated using 5-fold cross-validation on the training set, as described in Multimedia Appendix 1. Predictive performance was assessed using the coefficient of determination (R^2), root mean square error (RMSE), mean absolute error (MAE), and mean absolute percentage error (MAPE), with their definitions and formulas summarized in Table 1 [25]. Higher R^2 values and lower RMSE, MAE, and MAPE values indicated better performance. Model selection prioritized R^2, with RMSE used as a secondary criterion among models with comparable R^2 values; MAE and MAPE were additionally considered to provide a comprehensive assessment of predictive performance. Model interpretability was assessed using Shapley additive explanations (SHAP) values [26], and an ablation analysis was performed by sequentially removing the most influential predictors and evaluating the resulting changes in performance [27]. All analyses were conducted in Python (version 3.10.17; Python Software Foundation), NumPy (version 1.26.4; NumFOCUS), Pandas (version 1.5.3; NumFOCUS), Matplotlib (version 3.10.1; NumFOCUS), and Scikit-learn (version 1.6.1; NumFOCUS) [28].

Table . Four statistical metrics used for performance assessment of algorithm methods in this research.

Metrics	Description
$R^2=1-\sum i=1n(Actuali-Predictedi)2\sum i=1n(Actuali-Actualavg)2$	Coefficient of determination
$MSE=1n\sum i=1n(Actuali-Predictedi)2$	Mean squared error
$RMSE=1n\sum i=1n(Actuali-Predictedi)2$	Root mean squared error
$MAE=1n\sum i=1n\lvert Actuali-Predictedi\rvert$	Mean absolute error
$MAPE=100\%n\sum i=1n\lvert Actuali-PredictediActuali\rvert$	Mean absolute percentage error

Statistical Analysis

To evaluate the reliability of the model's continuous predictions, agreement with the observed postoperative measurements was assessed using the Bland-Altman methodology [29]. For each patient, the difference between the predicted and observed values was plotted against their mean, and the overall mean difference

XSL•FO
RenderX

together with the 95% limits of agreement (LoA) based on the SD was derived. Separate analyses were performed for postoperative body weight and circumferential size. To assess model robustness across different patient populations, subgroup analyses were performed according to sex and age group (Table S7 in Multimedia Appendix 1). To facilitate clinical adoption, an AI-driven, web-based CDSS was subsequently developed, enabling surgeons to input preoperative data and receive real-time predictions of postoperative body weight and circumferential size outcomes at the point of care [30].

Results

Study Population

The multicenter 365mc cohort comprised 8064 patients who underwent liposuction between January 1, 2024, and December 31, 2024, at 20 obesity specialty hospitals in the 365mc network in South Korea. After excluding 3.2% (260/8064) incomplete records, 96.8% (7804/8064) eligible participants were included in the final analysis, as shown in Figure S1 in Multimedia Appendix 1. The excluded records included 3.2% (249/7804) records with missing postoperative body weight or treated-site circumference, 0.1% (8/7804) records with missing surgical-site information, and 0.04% (3/7804) records with missing sex information. Baseline characteristics are summarized in Table 2. The cohort included 7612 (97.54%) female participants and 192 (2.46%) male participants. The mean age was 35.3 (SD 8.6) years, and the mean BMI was 24.0 (SD 3.9) kg/m^2.

Table . Baseline characteristics of patients who underwent liposuction at a single branch within the 20-branch 365mc liposuction hospital network in South Korea, used to develop a multioutput machine learning model for predicting postoperative body weight and circumferential size (N=7804).

Variables	Participants
Sex, n (%)	
Male	192 (2.46)
Female	7612 (97.54)
Age (years), mean (SD)	35.25 (8.57)
Height (cm), mean (SD)	161.91 (5.35)
Preoperative weight (kg), mean (SD)	63.06 (11.38)
BMI (kg/m^2), mean (SD)	23.99 (3.87)
Preoperative size (cm), mean (SD)	57.92 (25.82)
Liposuction technique, n (%)	
Local anesthetic minimally invasive liposuction	6832 (87.54)
Surgery	972 (12.46)
Liposuction site, n (%)	
Abdomen	1888 (24.19)

Model Performance

Table 3 summarizes the performance of all candidate ML models and approaches, evaluated using R^2, RMSE, MAE, and MAPE. Using 15 predictors, we compared 8 individual ML models, an automated ML approach, 2 ensemble approaches, and chained multioutput regression models for predicting postoperative body weight and circumferential size. In the 5-fold cross-validation of the training dataset, the chained extra trees regressor with a forward prediction order showed the best overall performance across all evaluation metrics, with an R^2 of 0.986 (95% CI 0.983-0.988), an RMSE of 1.916 (95% CI 1.680-2.151), an MAE of 1.042 (95% CI 1.006-1.078), and a MAPE of 1.839 (95% CI 1.765-1.913). The stacked model using the extra trees regressor and random forest regressor showed comparable performance, with an R^2 of 0.985 (95% CI 0.983-0.988), an RMSE of 1.932 (95% CI 1.684-2.179), an MAE of 1.052 (95% CI 1.020-1.085), and a MAPE of 1.859 (95% CI 1.763-1.925).

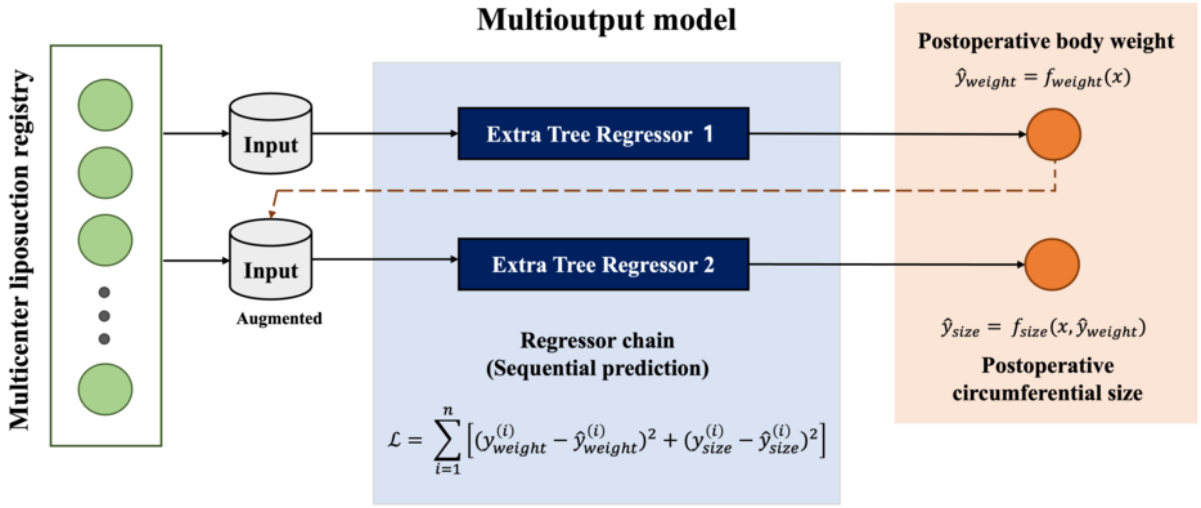
[b]TPOT: Tree-Based Pipeline Optimization Tool; TPOT indicates a genetic programming–based automated machine learning framework.

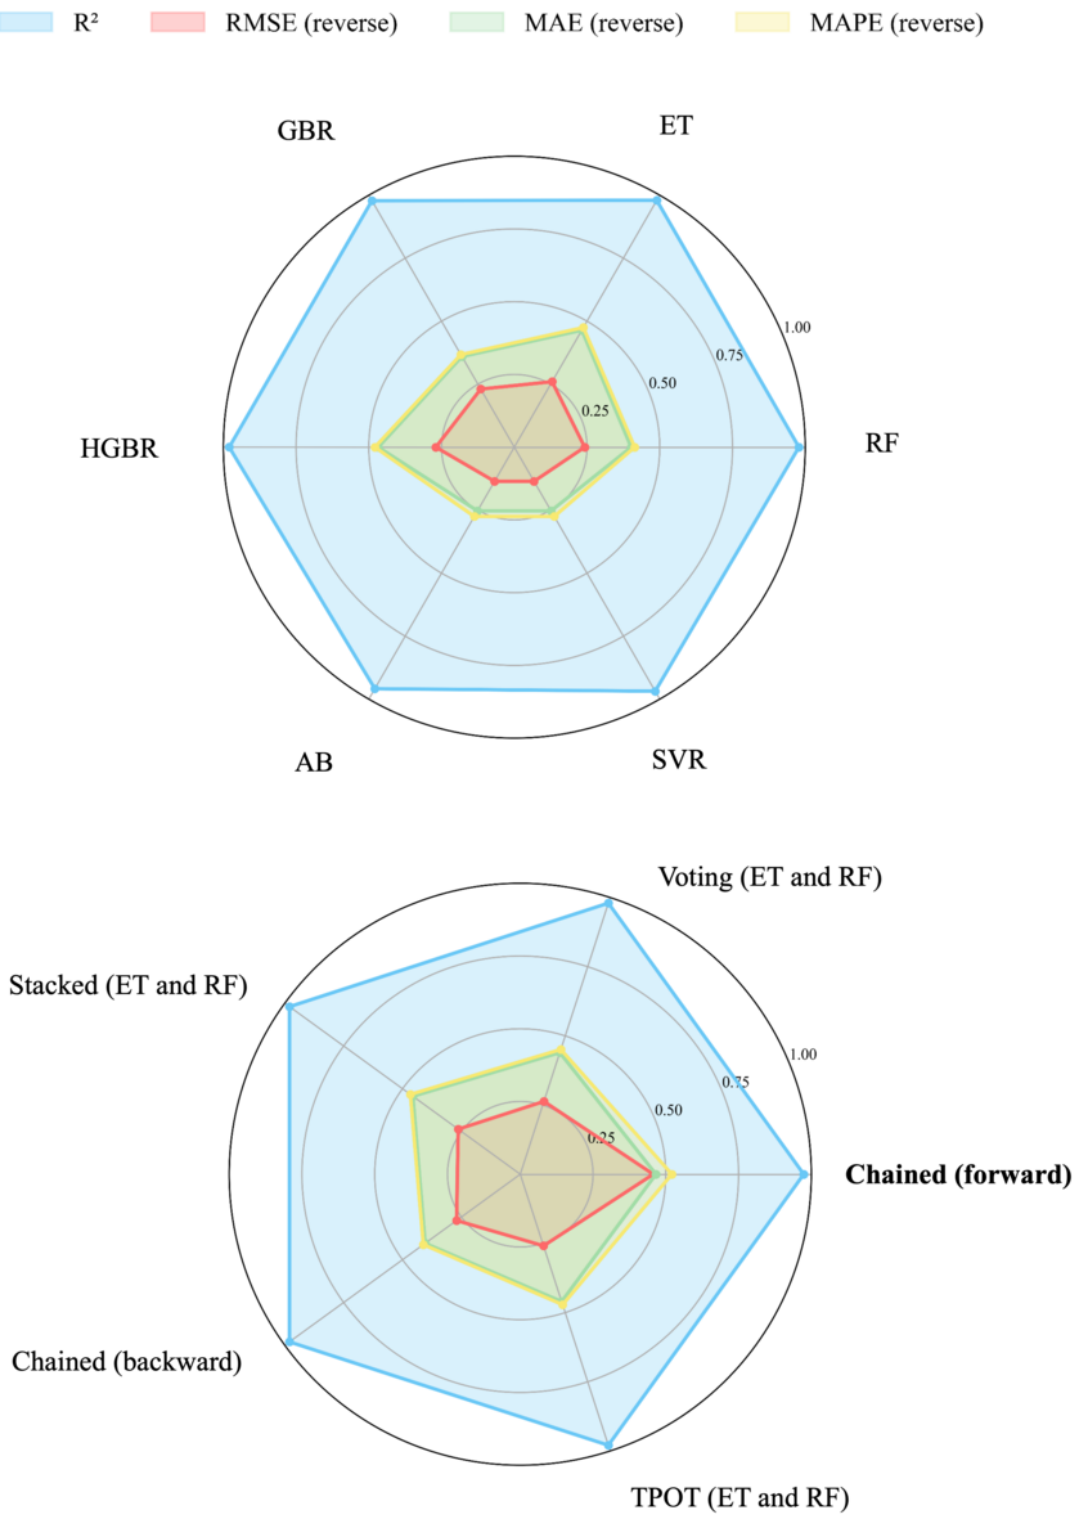
[c]This stacking ensemble used extra trees regressor and random forest regressor as base learners, with ridge regressor as the meta-learner.



[d]The regressor chain using the extra trees regressor was implemented as a multioutput regression model, predicting postoperative body weight first, followed by size.

[e]Italicized data indicate the best performance.

[f]The regressor chain using the extra trees regressor was implemented as a multioutput regression model, predicting postoperative circumferential size first, followed by weight.



In the independent test dataset, the chained extra trees regressor with a forward prediction order achieved an R^2 of 0.980, an RMSE of 2.356, an MAE of 1.242, and a MAPE of 2.199. Among the models achieving the highest R^2 of 0.980, this model had the lowest RMSE and was therefore selected as the final model based on the model-selection criteria. HGBR showed comparable performance, with an R^2 of 0.980, an RMSE of 2.359, and an MAE of 1.110. The architecture of the selected chained multioutput regression model is illustrated in Figures 1 and 2. To further evaluate predictive reliability, Bland-Altman analyses stratified by surgical site are presented in Figure 3.

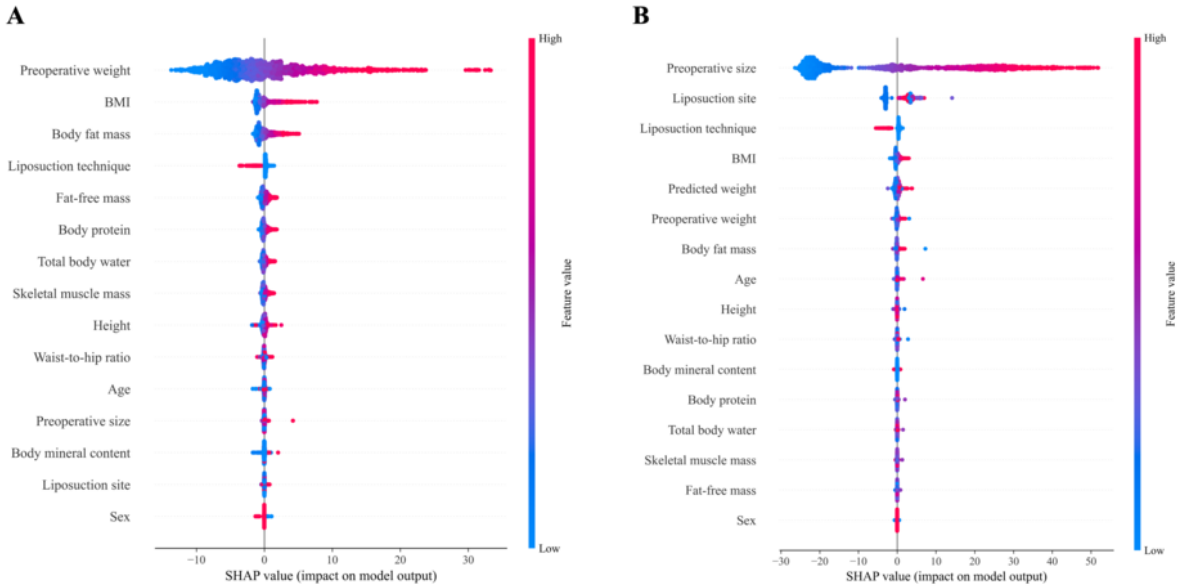

Figure 3. Bland-Altman plots for our proposed model between observed and predicted postoperative body weight and circumferential size across different liposuction sites. Each point represents a patient, color-coded by surgical site. The shaded regions indicate the mean difference and 95% limits of agreement (SD 1.96).

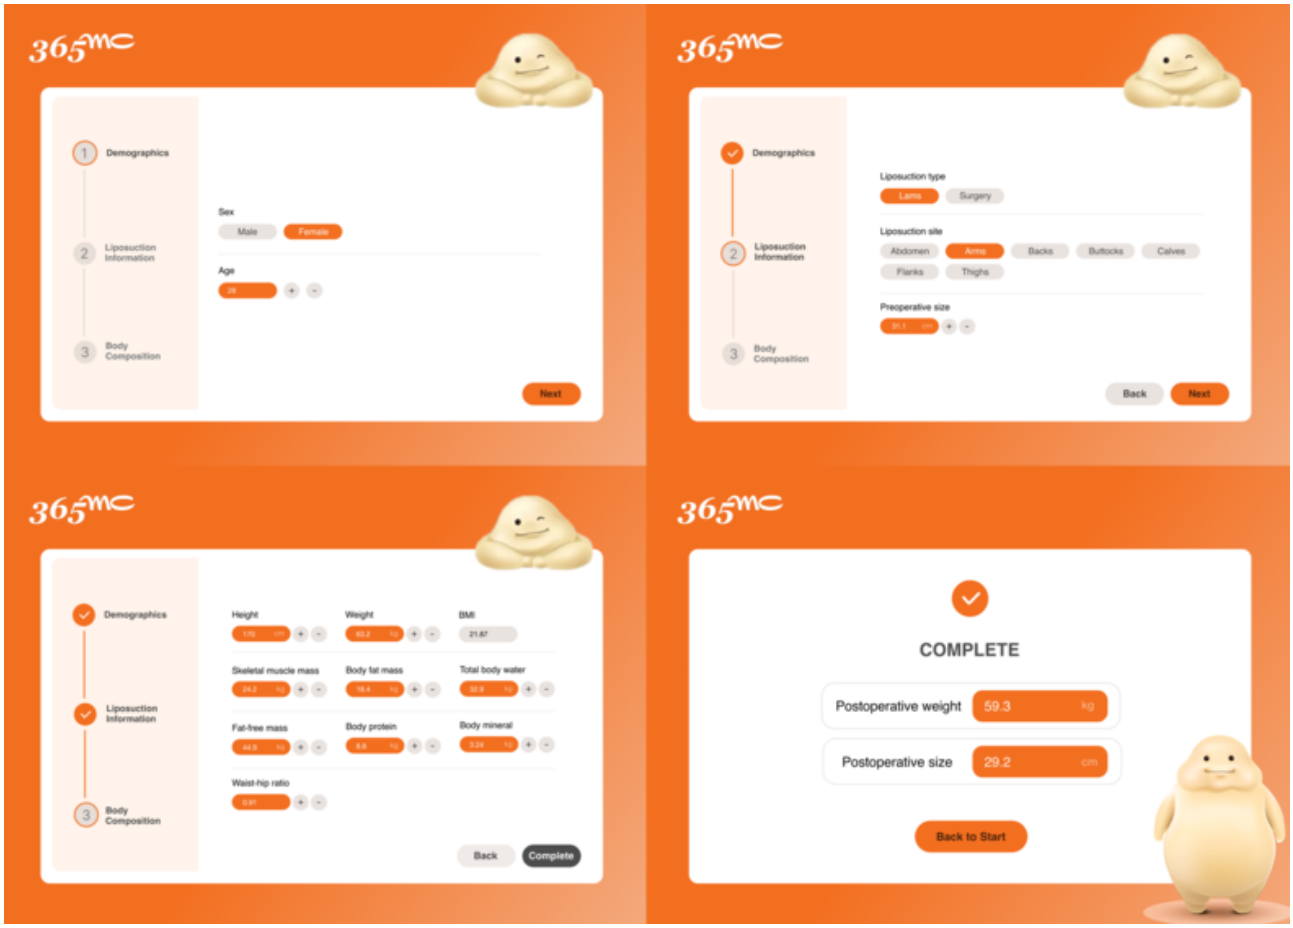
Feature Importance Based on SHAP Values

Figure 4 displays SHAP summary plots for the chained multioutput model. Figure 4A illustrates the first regressor, which predicts postoperative body weight, confirming that preoperative weight and related clinical variables exert the greatest influence on the output. Figure 4B depicts the second regressor, which incorporates the predicted postoperative body weight from the first stage as an additional feature when estimating postoperative circumferential size. In this second stage, the predicted weight becomes an important predictor alongside preoperative circumferential size, liposuction site, and surgical technique.

Figure 4. Shapley additive explanation (SHAP) values for the proposed regressor chain model for postoperative outcomes prediction. (A) First regressor predicting postoperative body weight and (B) second regressor predicting postoperative circumferential size, incorporating both original features and the predicted weight from the first regressor.

Ablation Study

To quantify the marginal contribution of each key feature, we performed an ablation analysis by sequentially removing 4 influential features: preoperative size, liposuction site, liposuction technique, and BMI. Model performance was then reassessed after each feature removal. The exclusion of preoperative size resulted in the largest performance decrease, with R^2 decreasing from 0.980 to 0.975 and error metrics increasing from 2.356 to 2.868 for RMSE, from 1.242 to 1.419 for MAE, and from 2.199% to 2.445% for MAPE. Despite this decrease, the model maintained strong predictive performance, suggesting that the overall prediction framework was robust to the removal of individual features. Full results of the ablation analysis are provided in Table S6 in Multimedia Appendix 1.



Web-Based CDSS

To facilitate clinical implementation, we deployed the chained multioutput model as a web-based CDSS accessible (365mc AI

XSL•FO
RenderX

platform [31]). The platform guides the user through 3 sequential input screens that capture demographic details, operative variables, and body composition measurements, after which it instantly returns personalized forecasts of postoperative body weight and circumferential size. Figure 5 illustrates the interface, showing the stepwise data-entry process and the final results page. All information entered by the user is transmitted over an encrypted connection and is automatically deleted once the prediction is generated, ensuring that no personally identifying data are retained or stored on the server.

Discussion

Key Findings

This study developed and validated a chained multioutput ML model that jointly predicts postoperative body weight and circumferential size using 15 predictors from a multicenter liposuction cohort across 20 obesity specialty clinics in the 365mc network. Among the benchmarked single-output, automated ML, ensemble, and chained approaches, the chained extra trees regressor achieved the best performance (R^2=0.980, RMSE=2.356), supporting the value of explicitly modeling the dependency between these two clinically related outcomes. In this structure, postoperative body weight was predicted first and then used to estimate postoperative circumferential size, underscoring the conditional relationship between the two outcomes. Feature-importance analysis showed that preoperative weight was the main predictor of postoperative body weight, whereas preoperative size, liposuction-related factors, and the predicted weight estimate most strongly influenced postoperative circumferential size. The model was implemented as a web-based CDSS, supporting its potential for preoperative planning and individualized patient counseling.

Plausible Mechanism and Comparison With Previous Studies

This study proposed a chained multitarget regression model to jointly predict postoperative body weight and circumferential size after liposuction. These two outcomes are clinically related, and predicting them separately may fail to capture the dependency between overall weight change and local body-contour change [10,32]. Unlike previous single-target approaches, our model used the prediction of one outcome as additional information for predicting the other. This structure allowed the model to reflect the conditional relationship between postoperative body weight and circumferential size, which is important for surgical planning, objective outcome assessment, and patient counseling [33]. SHAP analysis further supported this relationship by showing that the predicted postoperative body weight contributed meaningfully to the prediction of postoperative circumferential size [34].

From a methodological perspective, direct single-output regression models and chained regression models have different strengths. Direct models are simple and useful when target outcomes are relatively independent, but they may not capture dependencies between clinically related outcomes [7]. In

XSL•FO
RenderX

contrast, chained regression models use the prediction of one target as additional information for another, allowing them to reflect intertarget relationships [7,8]. In this study, postoperative body weight and circumferential size were considered clinically related outcomes after liposuction, and the chained extra trees regressor achieved the best overall performance, suggesting that modeling this dependency was appropriate for our prediction task. However, because predictions in subsequent steps depend on those made in the preceding steps, careful validation of the prediction order and model robustness is required [35].

Ensemble approaches also showed strong performance, with voting providing stable averaged predictions and stacking allowing a meta-model to combine base learners more flexibly [36,37]. However, more complex models, including stacking and chained regression, require careful validation because their performance may depend on the dataset structure, target relationships, and prediction order. Therefore, although our findings support the usefulness of the chained multioutput approach, future studies should further evaluate different chaining orders and validate the model in external datasets to confirm its generalizability and robustness.

Clinical and Policy Implementation

Building on these methodological and ML modeling advances, we deployed our proposed chained multioutput model as a web-based CDSS that simultaneously forecasts postoperative body weight and circumferential size while leveraging individual patient profiles. By presenting key features including the surgical site, technique, and conditional relationship between outcomes, the system may enhance personalized preoperative counseling and surgical planning [38]. Explicit modeling and communication of the interdependence between outcomes further bolster interpretability and may increase clinician and patient trust, underscoring the need for prospective evaluation of how these explanatory elements affect decision quality, patient satisfaction, and adherence to recommended care [39].

Limitations

Despite promising performance, this study has several limitations. First, the proposed model was developed using a retrospective cohort from a single high-volume liposuction network in South Korea, and the study population was predominantly young Asian women with a relatively low BMI [40]. These characteristics may restrict the external validity of the findings when applied to other ethnicities, anatomical surgical sites, or clinical settings. Second, reliance on existing medical records introduces potential selection bias and missing data; although records with critical omissions were excluded, residual confounding and incomplete capture of relevant variables cannot be excluded [41]. Third, although the model effectively leverages the conditional dependence between postoperative circumferential size and body weight, it does not explicitly characterize higher-order interactions among other preoperative factors such as age, sex, and body composition, which could further enhance predictive performance. Finally, the surgical-site information was based on a single, operator-designated representative region, and definitions or granularity of those regions may vary across institutions, limiting the generalizability of findings related to procedural localization. Prospective validation in multicenter and more diverse populations, including assessments across finer anatomical subregions and evaluation of the stability of key predictive features, is needed to confirm and extend these results.

Conclusions

This study developed and validated a chained multioutput regression model to predict postoperative body weight and circumferential size using 15 predictors from a multicenter liposuction cohort across 20 obesity specialty clinics in the 365mc network. The model accounted for the dependency between the two postoperative outcomes and was implemented as a web-based CDSS. The key findings are as follows:

- The extra trees regressor–based chained multioutput regression model achieved an R^2 of 0.980 and an RMSE of 2.356 and was selected as the final model based on its high R^2 value and favorable RMSE value among models with comparable R^2 values.
- Predicting postoperative body weight first and then using it to estimate circumferential size captured the conditional relationship between the two outcomes.
- Feature-importance analysis identified preoperative weight as the main predictor of postoperative body weight, while preoperative size and liposuction-related factors were most influential in predicting postoperative circumferential size.

Acknowledgments

This research was supported by the 20 obesity specialty hospitals affiliated with the 365mc network (South Korea). No generative AI tools were used in the preparation, analysis, or writing of this manuscript.

Funding

This research was supported by the Ministry of Science and Information and Communication Technology (grants RS-2023-00262002 and IITP-2026-RS-2024-00438239) and the Ministry of Health and Welfare (grant RS-2025-02220492), Republic of Korea. The funders played no role in the study design, data collection, data analysis, data interpretation, or manuscript writing.

Abstract

Background: Traditional Chinese medicine (TCM) constitution is a structured health state taxonomy used in preventive care, but its relationship with routinely collected health examination data, disease-related markers, and longitudinal change remains difficult to interpret in clinical informatics settings.

Objective: This study aimed to develop and evaluate a longitudinal clinical informatics framework for characterizing TCM constitution as a computable, explainable, record-based phenotype using routine health examination records.

Methods: We conducted a retrospective longitudinal analysis of 47,417 examination-constitution records from 11,355 older adults examined between 2017 and 2026. Baseline analyses used the first available record per participant, and longitudinal analyses used 32,648 pairs of adjacent annual visits. The framework included bidirectional disease-constitution mapping, nonoverlapping multimarker burden modeling, lagged next-visit association models, constitution-state transition analysis, and temporal evaluation of routine examination–based label prediction models. Additional sensitivity analyses evaluated participant overlap across calendar-year splits, participant-disjoint temporal evaluation, BMI-only and BMI-plus-waist baselines, exclusion of anthropometric predictors, adiposity adjustment of longitudinal models, and new-onset and persistence outcomes.

Results: Phlegm-dampness showed the clearest record-based signature and was associated with higher cardiometabolic marker burden than balanced constitution (incidence rate ratio 1.65, 95% CI 1.60 - 1.70). In lagged models, its associations with a subsequent abdominal ultrasound abnormality flag and cardiometabolic risk clustering persisted after BMI adjustment, whereas associations with diabetes-related markers, proteinuria, dyslipidemia, and glucose abnormalities were substantially attenuated. Of 11,355 participants, 8122 appeared in at least 2 original calendar-year splits. In a participant-disjoint temporal sensitivity analysis with 1054 new test participants, extreme gradient boosting (XGBoost) identified phlegm-dampness label presence with an area under the receiver operating characteristic curve of 0.927 (95% CI 0.912 - 0.941). A BMI-only model achieved 0.923 (95% CI 0.907 - 0.938), whereas XGBoost without anthropometric predictors achieved 0.685 (95% CI 0.653 - 0.717).

Conclusions: Routine health examination data captured a reproducible, predominantly adiposity-centered phlegm-dampness label phenotype in this cohort of older adults. High discrimination was retained in participant-disjoint evaluation but was nearly matched by the BMI-only model, and several longitudinal associations were explained by adiposity. The models should therefore be interpreted as decision-support and communication aids for an existing constitution assessment process and not as stand-alone diagnostic systems or comprehensive classifiers of TCM constitution.

Introduction

Clinical informatics increasingly depends on the ability to reuse routinely collected health data to construct interpretable phenotypes for prevention, risk stratification, decision support, and patient-centered communication. Electronic health record phenotyping has made substantial progress in deriving computable disease definitions from structured and unstructured clinical data [1]. Informatics research has also emphasized the need for next-generation phenotype representations that can handle longitudinal, heterogeneous, and multidimensional clinical data [2]. Transportable phenotype algorithms and shared phenotype knowledge bases further illustrate how clinical concepts can be made reproducible across settings [3].

The challenge is broader than conventional disease phenotyping. Health systems often contain locally meaningful categories, patient-reported patterns, functional taxonomies, and culturally embedded health state classifications that are not fully represented by diagnosis codes. Digital phenotyping was initially popularized as moment-by-moment quantification of individual-level human phenotype using data from personal digital devices [4]. Subsequent work has emphasized purpose, quality, safety, and interpretability rather than data volume alone [5]. In this study, we used digital phenotyping in the narrower clinical informatics sense of computationally characterizing an existing health state label from longitudinal routine records; we do not imply continuous or passive behavioral sensing. We used label prediction for models that reproduce an existing recorded constitution label and longitudinal association for models relating current constitution to subsequent recorded marker status. Neither term denotes a stand-alone diagnosis.

Traditional Chinese medicine (TCM) constitution is one such structured health state taxonomy. The constitution framework has been discussed as a basis for individualized and preventive health management in Chinese medicine [6]. Constitution assessment is widely used in China to describe relatively stable yet modifiable patterns of physiological and functional status, commonly grouped into balanced constitution and several biased constitution types, including phlegm-dampness, yang-deficiency, qi-deficiency, and yin-deficiency. The Constitution in Chinese Medicine Questionnaire has been psychometrically validated in Chinese-speaking populations [7], and short-form and Cantonese versions have been evaluated for health management and older adult populations [8,9].

Previous clinical and epidemiological studies have linked constitution patterns, particularly phlegm-dampness, with metabolic syndrome, cardiometabolic risk, and diabetes-related conditions [10,11]. However, much of this evidence remains cross-sectional, condition specific, or focused on conventional association testing. Two practical clinical informatics questions remain insufficiently answered. First, among people with recorded disease histories or examination abnormalities, which constitution patterns are overrepresented? Second, among people with a given constitution pattern, which disease-related markers are currently present or subsequently recorded? These questions matter because patients and clinicians often need bidirectional explanations: what a disease or marker may imply about constitution, and what a constitution label may imply about prevention and follow-up.

Therefore, the relevance of TCM constitution in clinical informatics is not limited to traditional medicine. Constitution can be viewed as a structured health state taxonomy that captures patient-level heterogeneity through a culturally specific lens. If such a taxonomy can be mapped, tracked, and predicted using routine examination data, it may provide a model for studying other non-Western, patient-reported, or locally embedded health classifications. This requires moving beyond single-marker correlation analysis. A computable constitution phenotype should have measurable clinical content, longitudinal behavior, temporal generalizability, model interpretability, and transparent uncertainty. It should also be evaluated using more than discrimination metrics alone because a high area under the receiver operating characteristic curve (AUC) does not guarantee calibration [12] and apparent discrimination does not by itself establish clinical usefulness [13].

In this study, we developed a longitudinal clinical informatics framework for TCM constitution using routine health examination records of older adults. We treated constitution as a structured health state phenotype rather than as a clinical diagnosis. The framework combines bidirectional disease-constitution mapping, multimarker burden modeling, lagged longitudinal association modeling, constitution state transition analysis, and temporally evaluated label prediction from routine examination variables. To align model evaluation with clinical informatics expectations, we incorporated explainable machine learning, calibration assessment, decision curve analysis, sensitivity analysis for unmeasured confounding, and exploratory uncertainty quantification. Our aim was not to deploy an autonomous diagnostic model but to test whether routine examination data can characterize a culturally embedded health taxonomy as an interpretable, reproducible, and longitudinally informative record-based phenotype.

Methods

Study Design and Data Source

We conducted a retrospective longitudinal analysis of routine health examination records linked with TCM constitution assessments. The records were collected from residents of 2 communities in Deyang City who underwent routine health examinations between February 22, 2017, and March 30, 2026. The baseline analytic cohort had an observed age range of 64 to 104 years. Each record included demographic information, anthropometric measurements, blood pressure, routine biochemical and hematologic measurements, urine test results, selected examination findings, recorded disease history fields, and TCM constitution labels. These records arose from routine community health management rather than protocol-driven research recruitment.

The analysis was designed to address 3 complementary questions. First, we mapped how recorded diseases and examination-derived disease-related markers were distributed across constitution patterns. Second, we assessed whether baseline and current constitution states were associated with

XSL•FO
RenderX

concurrent and next-visit disease or disease marker burden. Third, we evaluated whether routine health examination variables could be used to predict constitution states without using the TCM constitution questionnaire items.

The study size was determined by all eligible routine examination–constitution records available in the source database during the study period; no a priori sample size calculation was performed because the study was retrospective and record based. Reporting was informed by the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidance for observational studies [14] and RECORD (Reporting of Studies Conducted Using Observational Routinely Collected Health Data) guidance for studies using routinely collected health data [15].

Ethical Considerations

The study used routinely collected health examination and TCM constitution assessment records. The study protocol was reviewed and approved by the Medical Ethics Committee of the Affiliated Hospital of Chengdu University of Traditional Chinese Medicine (approval 2021KL-055). Written informed consent was obtained from participants before inclusion in the routine health examination and constitution assessment database. Analyses were conducted on deidentified records. Publicly released outputs were restricted to analysis code, data dictionaries, aggregate tables, figures, and synthetic demonstration data; participant-level records were not released because they contain sensitive health information.

Data Cleaning and Variable Harmonization

Raw variables were harmonized into a reproducible analytic data frame. Examination dates were parsed as calendar dates, and examination year was derived from the examination date. Numeric values were extracted from raw fields, and values outside prespecified plausible ranges were set to missing. Bilateral blood pressure measurements were summarized as mean systolic and diastolic blood pressure for continuous analyses and as maximum systolic and diastolic blood pressure for high blood pressure classification. Estimated glomerular filtration rate (eGFR) was calculated from serum creatinine, age, and sex using the 2021 Chronic Kidney Disease Epidemiology Collaboration creatinine equation.

For repeated record analyses, all records with a valid participant identifier, examination date, and constitution label were retained. For baseline descriptive analyses, the first available record per participant was used. For longitudinal analyses, adjacent records for the same participant were paired if the interval between examinations was 180 to 730 days, creating an adjacent annual visit design.

For regression-based association analyses, records were included when the outcome, constitution exposure, and required covariates for the relevant model were nonmissing. For prediction models, missing continuous predictors were imputed using the median within the training pipeline, and missing categorical predictors were encoded as a separate missing category.

TCM Constitution Assessment and Grouping

Constitution was assessed using the national 33-item Older Adult TCM Constitution Scale, which was incorporated into China's basic public health service specifications for primary care–based health management of older adults in 2013 [16]. Each item is scored from 1 to 5. Each of the 8 biased constitution types is represented by 4 items: a summed score of 11 or higher indicates that constitution, a score of 9 to 10 indicates a tendency toward it, and a score of 8 or lower indicates its absence. Balanced constitution is assessed using 5 items, of which 4 are reverse scored. A balanced constitution summed score of 17 or higher together with scores of 8 or lower for all 8 biased types indicates balanced constitution. When this definite criterion is not met, the same balanced constitution summed score together with scores of 10 or lower for all 8 biased types indicates a tendency toward balanced constitution. Other score combinations do not meet the balanced constitution criterion. Notably, the standardized phlegm-dampness subscale includes an item scored from BMI categories and an item scored from waist circumference categories.

The routine assessment system automatically applied the standardized rules to calculate constitution scores and generate preliminary classifications. A clinician then reviewed and confirmed the resulting constitution labels. The analytic export retained responses to the 33 items, separate determination fields for all 9 constitution types, an original constitution label field, and a corrected constitution label field. It did not retain assessor identity or a detailed audit trail showing whether and how preliminary classifications changed during clinical confirmation. We therefore analyzed the clinician-confirmed corrected labels recorded in routine practice rather than rerunning the scoring algorithm from individual items.

The recorded labels included balanced constitution (Pinghe), qi-deficiency, yang-deficiency, yin-deficiency, phlegm-dampness, dampness-heat, blood stasis, qi-stagnation, and special diathesis. Multiple labels could be stored in one record. For mutually exclusive descriptive and association analyses, the first-listed label was used as a reproducible primary label convention; the source export did not document whether the first position represented the highest score, clinical dominance, or procedural priority. Primary labels were grouped into balanced, phlegm-dampness, yang-deficiency, qi-deficiency, yin-deficiency, and other biased constitutions. The category other biased constitutions combined dampness-heat, blood stasis, qi-stagnation, and special diathesis because of sparse counts and was interpreted descriptively only.

Balanced constitution was used as the reference group in constitution-to-marker and longitudinal association models. For label prediction, 2 binary targets were defined: any biased primary label vs a balanced primary label and phlegm-dampness appearing anywhere among the recorded labels vs all other records. Thus, the phlegm-dampness prediction target was not restricted to the first-listed label.

XSL•FO
RenderX

Recorded Diseases and Examination-Derived Risk Markers

Recorded disease history fields were analyzed as recorded diseases rather than adjudicated clinical diagnoses. Disease history fields included cerebrovascular disease, kidney disease, heart disease, vascular disease, eye disease, neurological disease, and other system disease. Examination-derived disease-related markers included electrocardiogram (ECG) abnormality flag, abdominal ultrasound abnormality flag, urine protein trace or positive, urine glucose trace or positive, urine occult blood trace or positive, liver enzyme elevation, anemia, kidney impairment or proteinuria, diabetes-related markers, and cardiometabolic risk clustering. The analytic export contained structured ECG and abdominal ultrasound interpretation codes only; code 1 was harmonized as normal and code 2 as abnormal. It did not retain free-text interpretations or specific abnormalities such as arrhythmia, fatty liver, gallstones, cysts, or masses. These broad fields were therefore treated as heterogeneous screening flags rather than disease diagnoses.

Overweight was defined as BMI ≥24 kg/m^2 and obesity as BMI ≥28 kg/m^2. High blood pressure was defined as systolic blood pressure ≥140 mm Hg or diastolic blood pressure ≥90 mm Hg. Fasting glucose thresholds were defined as ≥6.1 mmol/L and ≥7.0 mmol/L. High triglycerides were defined as triglycerides ≥1.7 mmol/L, high total cholesterol as total cholesterol ≥5.2 mmol/L, high low-density lipoprotein cholesterol (LDL-C) as LDL-C ≥3.4 mmol/L, and low high-density lipoprotein cholesterol (HDL-C) as HDL-C <1.0 mmol/L. Any dyslipidemia was defined as any abnormality in triglycerides, total cholesterol, LDL-C, or HDL-C. Kidney impairment or proteinuria was defined as eGFR<60 mL/min/1.73 m^2 or urine protein trace or positive. Diabetes-related marker was defined as fasting glucose ≥7.0 mmol/L or urine glucose trace or positive. Liver enzyme elevation was defined as alanine aminotransferase (ALT) >40 U/L or aspartate aminotransferase (AST) >40 U/L. Anemia was defined as hemoglobin<130 g/L for men and<120 g/L for women. Cardiometabolic risk clustering was defined as at least 2 positive markers among obesity, high blood pressure, fasting glucose ≥6.1 mmol/L, and any dyslipidemia, requiring at least 2 available component markers.

Baseline Descriptive Analysis

Baseline characteristics were summarized using the first available record for each participant. Continuous variables were reported as mean (SD), and binary variables were reported as number (percentage). Differences across constitution groups were assessed using Kruskal-Wallis tests for continuous variables and chi-square tests for binary variables. Standardized mean differences vs balanced constitution were calculated to assess the magnitude of between-group imbalance.

Bidirectional Disease-Constitution Mapping

We performed a bidirectional mapping analysis to answer 2 clinically different questions. The disease-to-constitution analysis estimated, among participants with each recorded disease or examination-derived marker, the proportion belonging to each constitution group. This analysis was intended to answer the patient-facing question: given a disease or marker abnormality, which constitution patterns are most common?

Additionally, we calculated enrichment ratios by comparing the case-specific constitution proportion with the baseline constitution distribution. For example, the phlegm-dampness enrichment ratio for a disease or disease marker was calculated as the percentage of primary phlegm-dampness constitution among cases divided by the percentage of primary phlegm-dampness constitution in the baseline cohort.

The constitution-to-disease analysis addressed the reverse question: given a constitution pattern, which recorded diseases or examination-derived markers are more frequent? For each biased constitution group, age- and sex-adjusted logistic regression models were fitted with balanced constitution as the reference group. Results were reported as odds ratios and 95% CIs. False discovery rate correction was applied across tested associations.

Constitution-Wide Phenome Association Analysis

To complement the focused disease mapping analyses, we performed a constitution-wide phenome association analysis across routine biochemical, hematologic, anthropometric, and binary risk marker outcomes. For continuous outcomes, values were standardized and modeled using linear regression. For binary outcomes, logistic regression was used. Models compared each biased constitution group with balanced constitution and adjusted for age, sex, and examination year. Because participants could contribute repeated records, robust SEs clustered by participant were used. This analysis was used primarily for heat map visualization and hypothesis generation rather than for causal inference.

Multimarker Burden Modeling

To summarize overall clinical burden beyond individual binary markers, we constructed 3 marker burden scores at baseline: recorded disease burden, cardiometabolic marker burden, and examination-derived marker burden. For each participant, the number of positive markers was divided by the number of nonmissing eligible markers. The recorded disease burden included recorded cerebrovascular, kidney, heart, vascular, eye, and neurological disease fields. The cardiometabolic marker burden included obesity, high blood pressure, fasting glucose ≥6.1 mmol/L, high triglycerides, high LDL-C, low HDL-C, and eGFR<60 mL/min/1.73 m^2. In the revised examination-derived burden, all components were mutually nonoverlapping: high blood pressure, fasting glucose ≥7.0 mmol/L, any dyslipidemia, ECG abnormality flag, an abdominal ultrasound abnormality flag, proteinuria, glycosuria, hematuria, liver enzyme elevation, anemia, and eGFR<60 mL/min/1.73 m^2. The earlier composite component kidney impairment or proteinuria was removed so that proteinuria would not be counted twice.

Constitution-specific burden associations were estimated using robust Poisson regression with the log number of available markers as an offset. Models were adjusted for age and sex. Results were reported as incidence rate ratios relative to balanced constitution.

XSL•FO
RenderX

Lagged Longitudinal Risk Modeling

For longitudinal analyses, pairs of adjacent annual visits were used to evaluate associations between current constitution and subsequent disease-related marker status. For each current biased constitution group, analyses were restricted to records with either balanced constitution or the target biased constitution at the current visit. Logistic regression models were fitted for next-visit outcome status, with the target constitution indicator as the exposure. Models were adjusted for current status of the same outcome, current age, sex, follow-up interval in years, and current examination year. Robust SEs clustered by participant were used to account for repeated observations. These models estimated subsequent status conditional on current status; they were not interpreted as causal effects or confirmed disease development.

New-onset analyses were restricted to visit pairs in which the marker was normal or absent at the current visit, and persistence analyses were restricted to pairs in which the marker was positive at the current visit. Recurrence was not analyzed because it requires at least 3 appropriately spaced observations and a prespecified remission interval. For the main phlegm-dampness outcomes, additional sensitivity models adjusted for current BMI, current waist circumference, and both measures together to distinguish associations that persisted from those explained by body size. False discovery rate correction was applied across the original longitudinal association tests; the additional adiposity-adjusted models were interpreted as sensitivity analyses.

Constitution State Transition Analysis

Constitution state dynamics were described using pairs of adjacent annual visits. A transition matrix was constructed by cross-tabulating the current constitution group against the next-visit constitution group. The crude change rate was defined as the proportion of adjacent pairs in which the next constitution group differed from the current constitution group.

We then modeled the predictors of 2 clinically interpretable transitions: transition from balanced constitution to any biased constitution and transition from phlegm-dampness constitution to balanced constitution. Candidate predictors included age, BMI, waist circumference, systolic blood pressure, diastolic blood pressure, fasting glucose, triglycerides, HDL-C, LDL-C, ALT, creatinine, eGFR, and hemoglobin. Continuous predictors were standardized, and logistic regression models estimated ORs per SD increment. Models were adjusted for age when age was not the predictor, sex, follow-up interval, and current examination year; robust SEs clustered by participant were used.

Temporal Validation of Digital Constitution Prediction Models

We developed routine examination–based prediction models for 2 constitution screening tasks: any biased constitution vs balanced constitution and phlegm-dampness label presence vs all other records. TCM questionnaire items were not included as predictors. Candidate predictors included age, height, weight, waist circumference, BMI, mean systolic and diastolic blood pressure, hemoglobin, white blood cell count, platelet count, fasting glucose, ALT, AST, total bilirubin, creatinine, urea, eGFR, total cholesterol, triglycerides, LDL-C, HDL-C, lifestyle variables, self-rated health and function fields, cognitive and emotional assessment fields, and recorded disease history fields.

The original calendar-year evaluation used 2017 - 2023 records for model training, 2024 records for threshold selection, and 2025 - 2026 records for testing. Because participants could contribute records in more than 1 period, this design was interpreted as future record prediction within a recurring examination cohort rather than as independent validation. We quantified participant overlap across all 3 periods. As an additional sensitivity analysis, we then implemented a participant-disjoint temporal evaluation based on each participant's first entry into the entire cohort: participants first observed in 2017 - 2023 were assigned to training, those first observed in 2024 to validation, and those first observed in 2025 - 2026 to testing. The first eligible labeled record per participant was used within each disjoint split, and no participant appeared in more than 1 split.

The evaluation was aligned with the Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis (TRIPOD) principles [17] and the updated TRIPOD + AI guidance [18]. Two modeling strategies were compared: penalized logistic regression and XGBoost. Classification thresholds were selected in the validation set by maximizing balanced accuracy and applied unchanged to the test set. We additionally fitted BMI-only and BMI-plus-waist logistic regression baselines and repeated the full models after removing height, weight, waist circumference, and BMI. Test set AUC, precision-recall AUC (PR-AUC), and Brier score were accompanied by 95% percentile bootstrap CIs in the participant-disjoint analysis.

Model discrimination and classification performance were evaluated using AUC, average precision (PR-AUC), balanced accuracy, F_1-score, precision, recall, specificity, confusion matrix counts, and Brier score. The evaluation strategy was designed to reduce avoidable prediction model bias and applicability concerns emphasized in Prediction Model Risk of Bias Assessment Tool (PROBAST) + AI [19]. As a sensitivity analysis, all anthropometric variables directly related to body size and adiposity (height, weight, waist circumference, and BMI) were removed, and models were refit using the same temporal validation framework.

Explainability, Calibration, Decision Curve Analysis, and Uncertainty Quantification

For the XGBoost models, Shapley additive explanations (SHAP) analysis was performed on a sample of temporal test records to estimate the mean absolute contribution of each predictor to model output [20]. Feature importance was summarized using mean absolute SHAP values.

Calibration was assessed in the temporal test set using deciles of predicted probability, Brier score, calibration intercept, calibration slope, 10-bin expected calibration error, and integrated absolute calibration error. Decision curve analysis was performed across prespecified threshold probabilities to estimate model net benefit relative to treat-all and treat-none strategies.

XSL•FO
RenderX

As exploratory uncertainty quantification, split conformal set prediction was applied to XGBoost model probabilities using the 2024 validation set as the calibration set and the 2025 - 2026 temporal test set as the evaluation set. Conformal prediction provides a distribution-free framework for prediction sets under exchangeability assumptions [21]. Clinical applications still require caution because temporal shift can undermine nominal coverage [22]. Because the temporal test period showed a distribution shift, conformal results were interpreted as temporal stress test summaries rather than as guaranteed clinical coverage estimates.

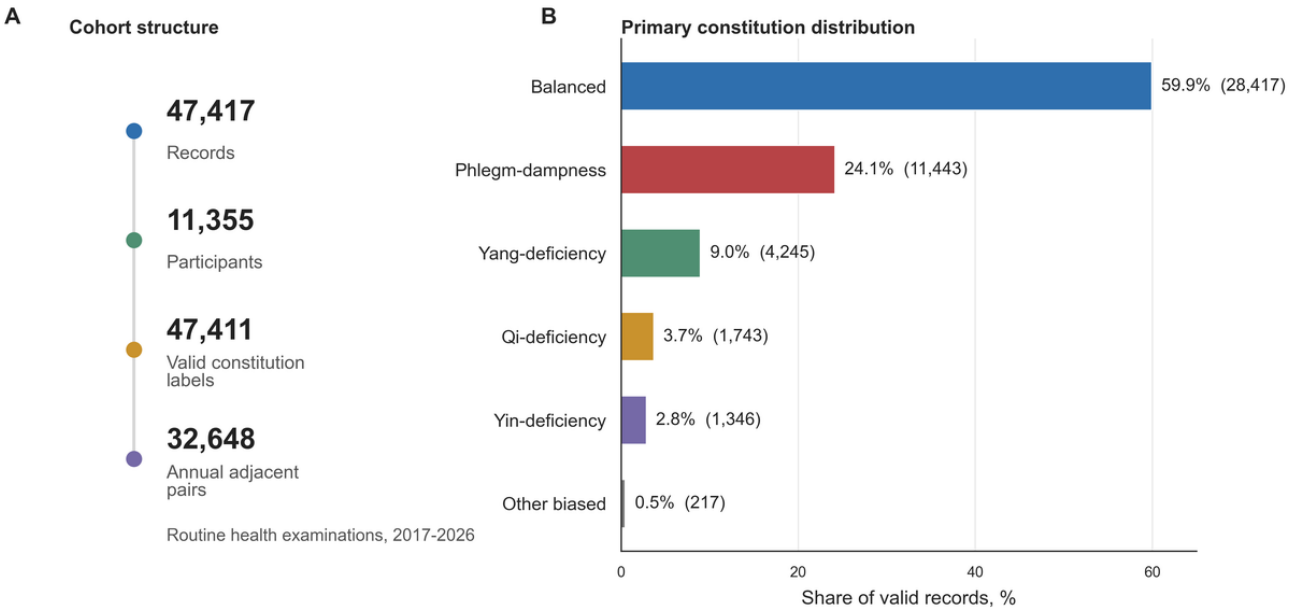
Quantitative Sensitivity and Subgroup Analyses

For selected longitudinal associations, E-values were calculated to quantify the minimum strength of association that an unmeasured confounder would need to have with both the constitution exposure and next-visit outcome, conditional on measured covariates, to explain away the observed association [23]. E-values were reported for the point estimate and for the confidence limit closest to the null.

The main phlegm-dampness associations were repeated by sex and by age group using the cohort median age as the cut point. Interaction terms were tested to evaluate whether the association between the phlegm-dampness constitution and key outcomes differed by sex or age group. Medication names were present in 42.3% of records, but a blank field could not be distinguished from no medication use, and drug names were not standardized for the source database. Medication was therefore not included as a covariate; its incomplete ascertainment was treated as a source of residual confounding.

Reproducibility

All data cleaning, statistical analyses, prediction modeling, and figure generation were implemented using reproducible scripts. Main analysis outputs were saved as structured CSV tables, and publication figures were exported as vector files (PDF/scalable vector graphics [SVG]) and high-resolution bitmap files (PNG/TIFF). The raw Microsoft Excel workbook was not modified during analysis. For public reproducibility, the repository package contains executable scripts, environment specifications, a file manifest, data dictionaries, aggregate result tables, submission-oriented figure files, and synthetic demonstration data that reproduce the expected feature schema without exposing participant-level records.



Results

Study Population and Digital Phenotyping Framework

The source workbook contained 47,417 examination-constitution records from 11,355 unique older adults between February 22, 2017, and March 30, 2026. Constitution labels were available for 47,411 records, with only 6 records missing constitution information. The median number of records per participant was 4 (IQR 2-6, maximum 11), and 9134 participants had at least 2 records.

Across all valid records, balanced constitution (Pinghe) accounted for 28,417 of 47,417 records (59.9%), followed by phlegm-dampness constitution (11,443/47,417; 24.1%), yang-deficiency constitution (4,245/47,417; 9.0%), qi-deficiency constitution (1,743/47,417; 3.7%), yin-deficiency constitution (1,346/47,417; 2.8%), and other biased constitutions (217/47,417; 0.5%). The baseline descriptive analysis used the first available record for each participant (n=11,354). In this baseline cohort, 7786 participants had balanced constitution, 2215 had phlegm-dampness constitution, 699 had yang-deficiency constitution, 316 had qi-deficiency constitution, 311 had yin-deficiency constitution, and 27 had other biased constitutions. Because the other biased constitutions group was extremely small, its estimates were treated as descriptive only. Annual lagged analyses included 32,648 adjacent record pairs with an interval of 180 to 730 days; the median follow-up interval was 363 (IQR 348 - 383) days (Figure 1).

Figure 1. Study cohort and constitution distribution. (A) Overview of the routine health examination cohort; (B) the distribution of primary traditional Chinese medicine constitution groups.

XSL•FO
RenderX

The overall analytic framework treated TCM constitution as a structured health state phenotype rather than as a diagnosis. We used routine examination data to construct bidirectional disease-constitution maps, multimarker burden models, subsequent status association models, transition models, and temporally evaluated label prediction models.

Baseline Characteristics by Constitution Group

In the baseline cohort, phlegm-dampness constitution showed a distinct adiposity-centered cardiometabolic profile (Table 1). Mean BMI was 28.34 (SD 2.59) in the phlegm-dampness constitution group compared with 23.65 (SD 2.74) in the balanced constitution group, and mean waist circumference was 94.02 (SD 6.79) vs 81.01 (SD 7.04) cm. Overweight was present in 2175 of 2215 (98.2%) participants with phlegm-dampness constitution compared with 3473 of 7784 (44.6%) participants with balanced constitution; the corresponding proportions for obesity were 49.9% (1106/2215) and 5.3% (410/7784) for participants with phlegm-dampness constitution and balanced constitution, respectively.

[a]Continuous variables are presented as mean (SD); n=available observations. Binary variables are presented as events/available observations (%).

[b]SMD: standardized mean difference.

[c]Not applicable.

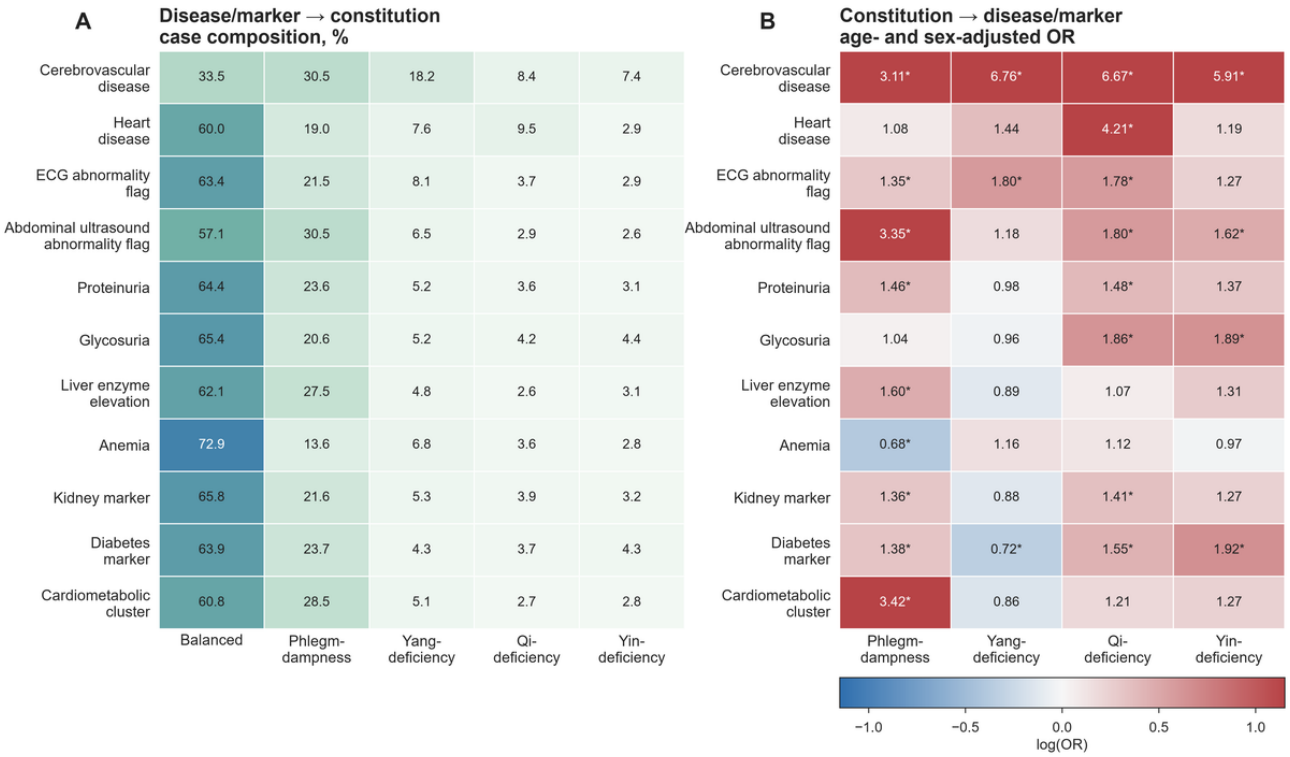
[d]BP: blood pressure.

[e]HDL-C: high-density lipoprotein cholesterol.

[f]LDL-C: low-density lipoprotein cholesterol.

[g]FPG: fasting plasma glucose.

[h]eGFR: estimated glomerular filtration rate.



Phlegm-dampness constitution was also characterized by higher cardiometabolic marker burden. High blood pressure was observed in 1449 of 2215 (65.4%) participants in the phlegm-dampness group vs 4001 of 7785 (51.4%) participants in the balanced group. Fasting glucose ≥6.1 mmol/L was present in 743 of 2208 (33.7%) vs 1904 of 7758 (24.5%) participants with the phlegm-dampness constitution and balanced constitution, respectively, and high triglycerides were present in 975 of 2201 (44.3%) vs 2226 of 7752 (28.7%) participants with the phlegm-dampness constitution and balanced constitution, respectively.

Bidirectional Disease-Constitution Mapping

We first examined the patient-facing question of which constitution patterns were common among participants with recorded diseases or disease-related examination markers. Several disease or disease marker groups showed a higher proportion of biased constitution overall and a higher proportion of primary phlegm-dampness constitution (Figure 2, panel A). Among participants with an abdominal ultrasound abnormality flag, biased constitution accounted for 42.9% (2284/5323), and primary phlegm-dampness constitution accounted for 30.6% (1626/5323) (enrichment ratio vs baseline 1.57). Among participants with recorded cerebrovascular disease, biased constitution accounted for 66.5% (135/203), and primary phlegm-dampness constitution accounted for 30.5% (62/203) (enrichment ratio 1.57). Among participants with cardiometabolic risk clustering, biased constitution accounted for 39.2% (2253/5744), and primary phlegm-dampness constitution accounted for 28.5% (1635/5744) (enrichment ratio 1.46). Primary phlegm-dampness constitution was also enriched among participants with liver enzyme elevation, diabetes-related markers, urine protein trace or positive, kidney impairment or proteinuria, and an ECG abnormality flag.

Figure 2. Bidirectional constitution-disease map at baseline. (A) Constitution composition among participants with each recorded disease or examination-derived marker; (B) age- and sex-adjusted odds ratios relative to balanced constitution. Cell labels show percentages or odds ratios; * indicates a false discovery rate of q<0.05. ECG: electrocardiogram; OR: odds ratio.

Next, we examined the reverse question of which recorded diseases or disease-related markers were more common in each constitution group compared with balanced constitution, adjusted for age and sex (Figure 2 panel B; Table 2). Phlegm-dampness constitution was strongly associated with cardiometabolic markers and an abdominal ultrasound abnormality flag. Compared with balanced constitution, phlegm-dampness constitution was associated with cardiometabolic risk clustering (OR 3.42, 95% CI 3.07 - 3.80), an abdominal ultrasound abnormality flag (OR 3.35, 95% CI 2.98 - 3.76), liver enzyme elevation (OR 1.60, 95% CI 1.38 - 1.84), diabetes-related markers (OR 1.38, 95% CI 1.22 - 1.56), and kidney impairment or proteinuria (OR 1.36, 95% CI 1.21 - 1.53).

Table . Baseline associations of constitutions with diseases and disease-related markers.[a]

Outcome	Phlegm-dampness	Yang-deficiency	Qi-deficiency	Yin-deficiency
Recorded cerebrovascular disease	3.11 (2.18 - 4.42)*	6.76 (4.48 - 10.21)*	6.67 (3.84 - 11.58)*	5.91 (3.33 - 10.47)*
Recorded heart disease	1.08 (0.65 - 1.81)	1.44 (0.68 - 3.02)	4.21 (2.12 - 8.34)*	1.19 (0.37 - 3.81)
ECG[b] abnormality flag	1.35 (1.22 - 1.49)*	1.80 (1.54 - 2.10)*	1.78 (1.42 - 2.24)*	1.27 (1.01 - 1.61)
Abdominal ultrasound abnormality flag	3.35 (2.98 - 3.76)*	1.18 (1.00 - 1.40)	1.80 (1.37 - 2.36)*	1.62 (1.22 - 2.14)*
Liver enzyme elevation	1.60 (1.38 - 1.84)*	0.89 (0.67 - 1.18)	1.07 (0.73 - 1.58)	1.31 (0.92 - 1.88)
Diabetes-related marker	1.38 (1.22 - 1.56)*	0.72 (0.56 - 0.91)*	1.55 (1.18 - 2.04)*	1.92 (1.47 - 2.49)*
Kidney impairment or proteinuria	1.36 (1.21 - 1.53)*	0.88 (0.71 - 1.08)	1.41 (1.09 - 1.82)*	1.27 (0.96 - 1.67)
Cardiometabolic risk cluster	3.42 (3.07 - 3.80)*	0.86 (0.73 - 1.00)	1.21 (0.96 - 1.52)	1.27 (1.01 - 1.59)

[a]Values are age- and sex-adjusted odds ratios (95% CIs) for each biased constitution group relative to balanced constitution. * indicates a false discovery rate-adjusted q value <0.05.

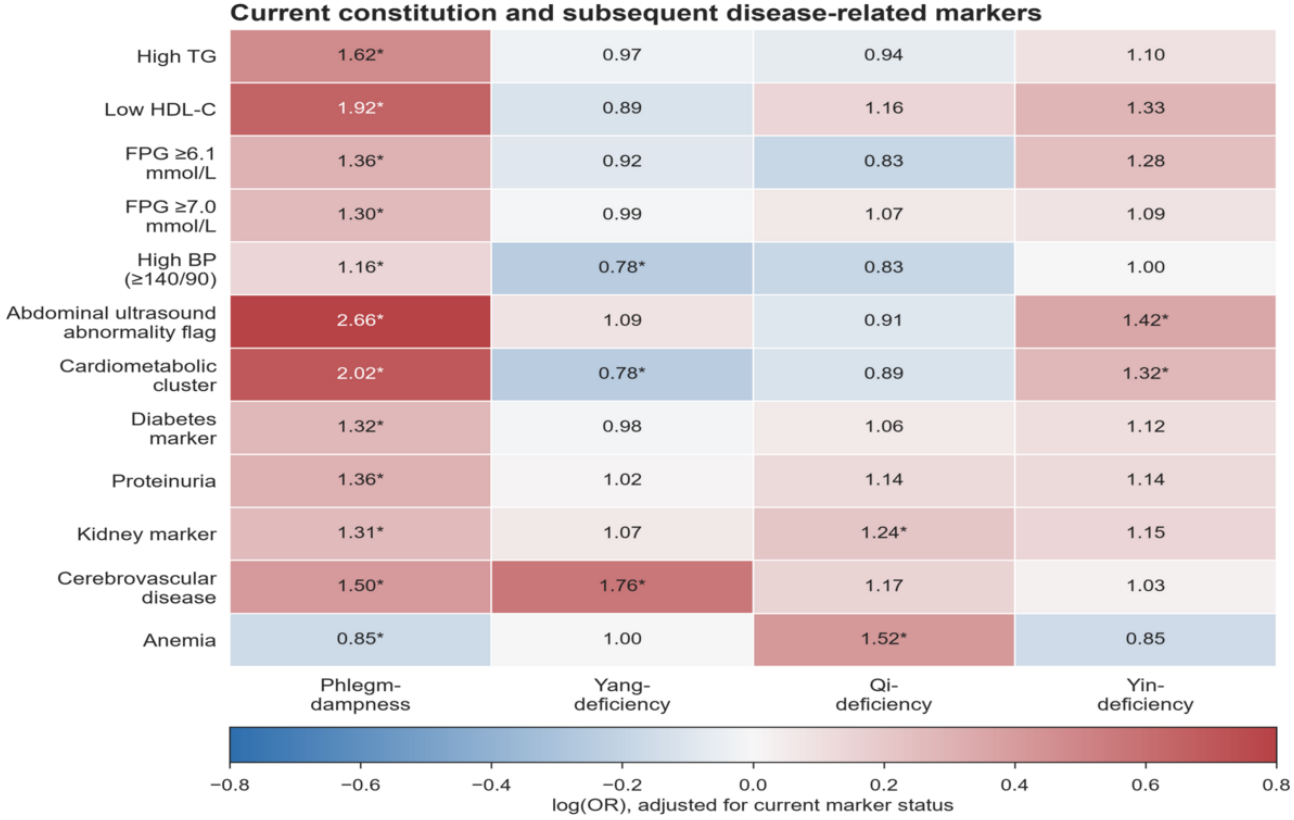
[b]ECG: electrocardiogram.

Recorded cerebrovascular disease showed a broader pattern across biased constitutions. Compared with balanced constitution, the odds of recorded cerebrovascular disease were higher for phlegm-dampness constitution (OR 3.11, 95% CI 2.18 - 4.42), yang-deficiency constitution (OR 6.76, 95% CI 4.48 - 10.21), qi-deficiency constitution (OR 6.67, 95% CI 3.84 - 11.58), and yin-deficiency constitution (OR 5.91, 95% CI 3.33 - 10.47). An ECG abnormality flag was also more

XSL•FO
RenderX

common in phlegm-dampness, yang-deficiency, and qi-deficiency constitutions. Compared with balanced constitution, Yin-deficiency constitution showed a stronger association with diabetes-related markers than balanced constitution (OR 1.92, 95% CI 1.47 - 2.49). while qi-deficiency constitution showed higher odds of recorded heart disease (OR 4.21, 95% CI 2.12 - 8.34) and kidney impairment or proteinuria (OR 1.41, 95% CI 1.09 - 1.82).

Multimarker Burden Modeling



To move beyond single-marker associations, we summarized recorded disease burden, cardiometabolic marker burden, and examination-derived marker burden. Compared with balanced constitution, phlegm-dampness constitution was associated with a higher cardiometabolic marker burden (incidence rate ratio [IRR] 1.65, 95% CI 1.60 - 1.70), corrected nonoverlapping examination–derived marker burden (IRR 1.23, 95% CI 1.20 - 1.25), and recorded disease burden (IRR 1.38, 95% CI 1.10 - 1.72) after adjustment for age and sex.

Other biased constitutions showed a different burden profile. Recorded disease burden was higher in yang-deficiency constitution (IRR 2.07, 95% CI 1.54 - 2.78), qi-deficiency constitution (IRR 2.77, 95% CI 1.93 - 4.00), and yin-deficiency constitution (IRR 2.33, 95% CI 1.49 - 3.62), whereas the cardiometabolic marker burden was most prominent for phlegm-dampness constitution.

Longitudinal Constitution-to-Risk Associations

In lagged annual analyses, current constitution was associated with marker status at the next visit after adjustment for the current status of the same marker, age, sex, examination year, and follow-up interval (Figure 3; Table 3). Compared with balanced constitution, current phlegm-dampness constitution was associated with a subsequent abdominal ultrasound abnormality flag (OR 2.66, 95% CI 2.46 - 2.88), cardiometabolic risk clustering (OR 2.02, 95% CI 1.88 - 2.17), diabetes-related markers (OR 1.32, 95% CI 1.20 - 1.45), urine protein trace or positive (OR 1.36, 95% CI 1.26 - 1.48), kidney impairment or proteinuria (OR 1.31, 95% CI 1.21 - 1.41), and recorded cerebrovascular disease (OR 1.50, 95% CI 1.29 - 1.75). These estimates describe associations with subsequent recorded status and do not establish new disease development.

Figure 3. Current constitution and subsequent disease-related markers. Models were adjusted for age, sex, follow-up interval, and current marker status. Cell labels show percentages or odds ratios; * indicates a false discovery rate of q<0.05. BP: blood pressure; FPG: fasting plasma glucose; HDL-C: high-density lipoprotein cholesterol; OR: odds ratio; TG: triglycerides.

[a]Values are odds ratios (95% CIs) adjusted for age, sex, examination year, follow-up interval, and current status of the same marker. * indicates a false discovery rate-adjusted q value <0.05.

[b]HDL-C: high-density lipoprotein cholesterol.

[c]FPG: fasting plasma glucose.

[d]BP: blood pressure.

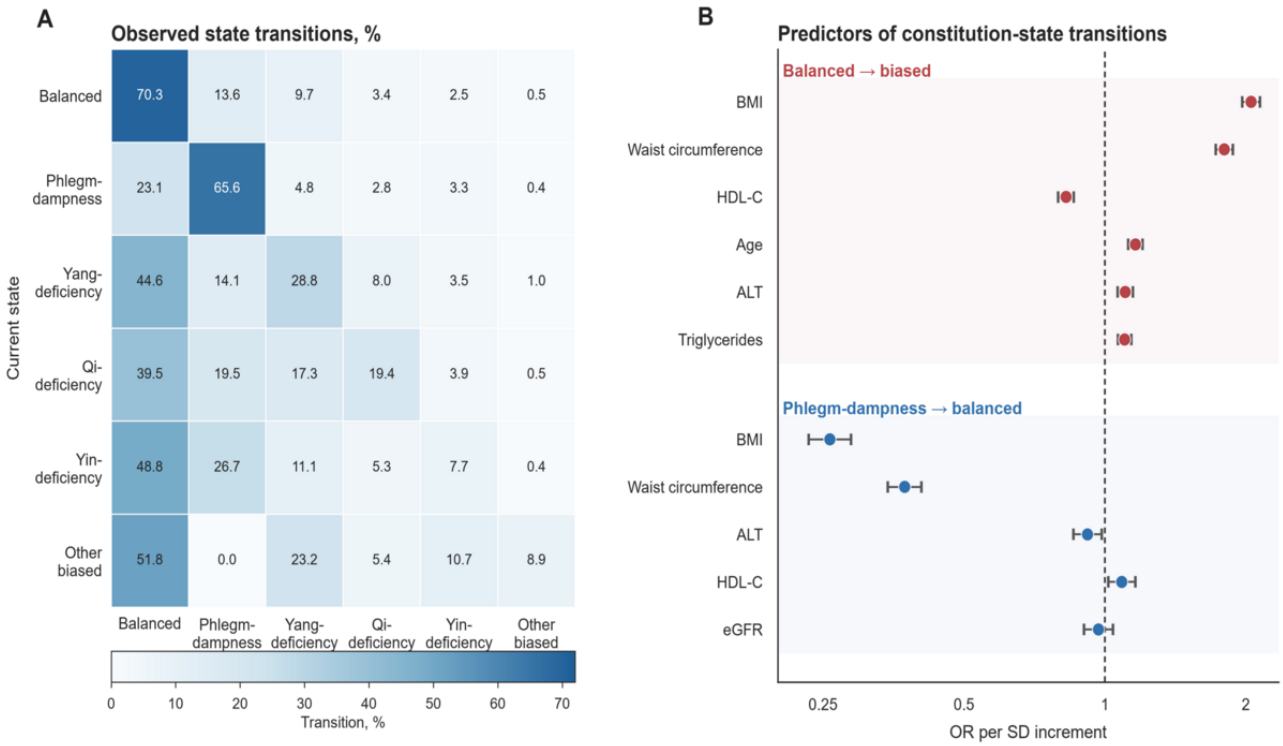
[e]eGFR: estimated glomerular filtration rate.

Among biochemical risk markers, current phlegm-dampness was associated with subsequent high triglycerides (OR 1.62, 95% CI 1.51 - 1.73), low HDL-C (OR 1.92, 95% CI 1.64 - 2.25), fasting glucose ≥6.1 mmol/L (OR 1.36, 95% CI 1.26 - 1.46), fasting glucose ≥7.0 mmol/L (OR 1.30, 95% CI 1.19 - 1.43), any dyslipidemia (OR 1.20, 95% CI 1.12 - 1.29), and high blood pressure (OR 1.16, 95% CI 1.08 - 1.23).

Additional adiposity adjustment materially changed interpretation. After BMI adjustment, associations remained for a subsequent abdominal ultrasound abnormality flag (OR 1.46, 95% CI 1.33 - 1.61) and cardiometabolic risk clustering (OR 1.19, 95% CI 1.09 - 1.30). In contrast, associations with diabetes-related markers (OR 1.04, 95% CI 0.92 - 1.18), proteinuria (OR 1.09, 95% CI 0.98 - 1.20), kidney impairment or proteinuria (OR 1.07, 95% CI 0.97 - 1.17), any dyslipidemia (OR 1.07, 95% CI 0.98 - 1.17), and fasting glucose ≥6.1 mmol/L (OR 1.04, 95% CI 0.94 - 1.15) were attenuated to include the null. New-onset analyses showed the same pattern: BMI-adjusted associations persisted for a new abdominal ultrasound abnormality flag (OR 1.43, 95% CI 1.24 - 1.66) and new cardiometabolic risk clustering (OR 1.21, 95% CI 1.06 - 1.38), whereas the other reviewed outcomes did not remain statistically distinguishable from the null. Waist circumference–adjusted models produced similar conclusions. Persistence analyses are reported separately from new-onset analyses in Multimedia Appendix 1.

Other constitution-specific longitudinal patterns were also observed. Yang-deficiency constitution was associated with subsequent recorded cerebrovascular disease (OR 1.76, 95% CI 1.40 - 2.22) but was inversely associated with subsequent cardiometabolic risk clustering (OR 0.78, 95% CI 0.69 - 0.88). Qi-deficiency constitution was associated with subsequent anemia (OR 1.52, 95% CI 1.23 - 1.88) and eGFR <60 mL/min/1.73 m^2 (OR 1.60, 95% CI 1.24 - 2.06).

E-value analysis was used as a quantitative sensitivity analysis for selected longitudinal associations. The strongest robustness signals were observed for associations of phlegm-dampness constitution with a subsequent abdominal ultrasound abnormality flag (OR 2.66, 95% CI 2.46 - 2.88; E-value for the confidence limit closest to the null=4.36), cardiometabolic risk clustering (OR 2.02, 95% CI 1.88 - 2.17; E-value=3.17), low HDL-C (OR 1.92, 95% CI 1.64 - 2.25; E-value=2.66), and high triglycerides (OR 1.62, 95% CI 1.51 - 1.73; E-value=2.38). For the association between yang-deficiency constitution and subsequent recorded cerebrovascular disease, the corresponding E-value was 2.15. These sensitivity estimates do not establish causality but quantify how strong an unmeasured confounder would need to be to fully explain away each observed association.



Constitution State Transitions

Adjacent constitution state transitions showed that constitution was not a fixed label (Figure 4, panel A). Across adjacent

XSL•FO
RenderX

observed records, the crude constitution group change rate was 35.6% (12833/36057). Among records initially classified as balanced constitution, 70.3% (17181/24424) remained balanced at the next observed visit, while 13.6% (3322/24424) transitioned to phlegm-dampness, 9.7% (2364/24424) to yang-deficiency, 3.4% (826/24424) to qi-deficiency, and 2.5% (601/24424) to yin-deficiency. Among records initially classified as phlegm-dampness, 65.6% (5260/8019) remained phlegm-dampness, and 23.1% (1850/8019) transitioned to balanced constitution.

Figure 4. Constitution-state transition dynamics. (A) The adjacent state transition matrix; (B) presents standardized predictors of selected transitions. ALT: alanine aminotransferase; eGFR: estimated glomerular filtration rate; HDL-C: high-density lipoprotein cholesterol; OR: odds ratio.

Baseline adiposity and metabolic markers were associated with subsequent constitution state transitions (Figure 4, panel B). Among individuals with balanced constitution, higher BMI (OR 2.05 per SD, 95% CI 1.96 - 2.14), larger waist circumference (OR 1.80 per SD, 95% CI 1.72 - 1.88), older age (OR 1.16 per SD, 95% CI 1.12 - 1.20), higher triglycerides (OR 1.10 per SD, 95% CI 1.07 - 1.14), higher ALT (OR 1.11 per SD, 95% CI 1.06 - 1.15), and higher fasting glucose (OR 1.06 per SD, 95% CI 1.03 - 1.10) were associated with transition to biased constitution, whereas higher HDL-C was protective (OR 0.83 per SD, 95% CI 0.79 - 0.86). Among individuals with phlegm-dampness constitution, higher BMI (OR 0.26 per SD, 95% CI 0.23 - 0.29) and larger waist circumference (OR 0.37 per SD, 95% CI 0.34 - 0.41) were associated with lower odds of returning to balanced constitution.

Digital Constitution Prediction, Explainability, Calibration, and Utility

Finally, we evaluated whether routine examination variables could identify recorded constitution labels without using the 33 assessment items. In the original record-level temporal evaluation, XGBoost achieved an AUC of 0.935 and PR-AUC of 0.898 for phlegm-dampness label presence, while the broader biased-vs-balanced task showed moderate discrimination (XGBoost AUC, 0.733). However, 6694 participants overlapped between training and validation, 6382 between training and testing, and 6558 between validation and testing; 8122 of 11,355 participants appeared in at least 2 periods. We therefore interpret these results as future record prediction within a recurring cohort rather than as independent temporal validation.

In the participant-disjoint temporal sensitivity analysis, the training, validation, and test sets contained 9219, 1081, and 1054 participants, respectively. For phlegm-dampness label presence, full-model XGBoost achieved an AUC of 0.927 (95% CI 0.912 - 0.941), a PR-AUC of 0.881, and a Brier score of 0.123. Full logistic regression achieved an AUC of 0.924 (95% CI 0.909 - 0.938). A BMI-only logistic model achieved an AUC of 0.923 (95% CI 0.907 - 0.938), and adding waist circumference did not improve discrimination (AUC 0.918, 95% CI 0.903 - 0.933). Without anthropometric predictors, XGBoost AUC decreased to 0.685 (95% CI 0.653 - 0.717). The corresponding participant-disjoint biased-vs-balanced XGBoost AUC was 0.739 (95% CI 0.708 - 0.768). These results show that participant overlap did not explain the high phlegm-dampness discrimination, but BMI alone captured nearly all of that discrimination. The results of participant-disjoint temporal evaluation are summarized in Table 4.

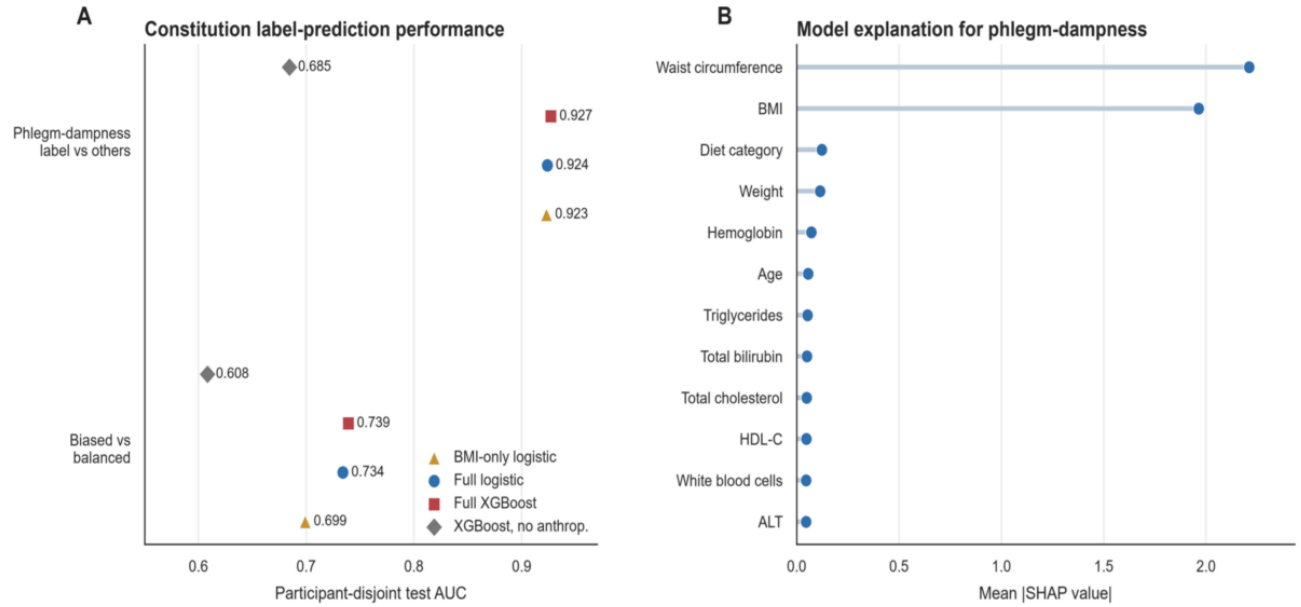
XGBoost	0.685 (0.653 - 0.717)	0.527	0.238	1054	376

[a]No participant appeared in more than 1 split.

[b]AUC: area under the receiver operating characteristic curve.



[c]PR-AUC: area under the precision-recall curve.

[d]XGBoost: extreme gradient boosting.

SHAP-based interpretation of the original XGBoost phlegm-dampness model identified waist circumference and BMI as the dominant predictors, followed by body weight, hemoglobin, age, triglycerides, total bilirubin, total cholesterol, HDL-C, white blood cell count, ALT, creatinine, LDL-C, and diastolic blood pressure (Figure 5, panel B). Together with the BMI-only and no-anthropometry comparisons, this indicates that the model primarily reproduces an adiposity-centered component of the recorded phlegm-dampness label rather than a comprehensive constitution construct.

XSL•FO
RenderX

Figure 5. Constitution label prediction and model explanation. (A) Participant-disjoint temporal evaluation; (B) presents mean absolute Shapley additive explanations (SHAP) values for the original temporal extreme gradient boosting (XGBoost) phlegm-dampness label prediction model and excludes traditional Chinese medicine (TCM) assessment items. ALT: alanine aminotransferase; anthrop.: anthropometry; AUC: area under the receiver operating characteristic curve; HDL-C: high-density lipoprotein cholesterol.

Calibration analyses showed that the phlegm-dampness prediction task was more stable than the broad biased-vs-balanced task under temporal validation (Multimedia Appendix 2). For phlegm-dampness prediction, the XGBoost model had a temporal test Brier score of 0.120, 10-bin expected calibration error of 0.085, and calibration slope of 0.65; the logistic regression model had a Brier score of 0.118, expected calibration error of 0.073, and calibration slope of 0.78. By contrast, the broad biased-vs-balanced task showed weaker calibration, reflecting temporal distribution shift in the 2025 - 2026 test period.

Decision curve analysis suggested potential utility for the phlegm-dampness model across clinically plausible threshold probabilities. For the XGBoost phlegm-dampness model, net benefit exceeded both treat-all and treat-none strategies from threshold probabilities of 0.20 to 0.50, with a net benefit of 0.301 at a threshold of 0.20, 0.277 at a threshold of 0.30, 0.251 at a threshold of 0.40, and 0.228 at a threshold of 0.50. The broad biased-vs-balanced model showed less favorable decision curve behavior because of temporal changes in event prevalence.

Exploratory split-conformal summaries further highlighted the temporal stress imposed by the 2025 - 2026 test period. For the XGBoost phlegm-dampness model, the nominal 90% set prediction procedure achieved empirical coverage of 0.83 with an average set size of 0.98 in the temporal test set. For the broader biased-vs-balanced task, empirical coverage was 0.70 with an average set size of 1.29. These results are best interpreted as exploratory uncertainty quantification under temporal shift rather than guaranteed clinical coverage. Supplementary tables for disease-to-constitution enrichment, burden score definitions, burden models, E-value sensitivity analysis, subgroup and interaction analyses, prediction sensitivity analysis, conformal uncertainty, variable missingness, and disease marker missingness are provided in Multimedia Appendix 3.

Discussion

Principal Findings

In this longitudinal analysis of 47,417 examination-constitution records of 11,355 older adults, we found that TCM constitution labels could be characterized as record-based phenotypes using routine health examination data. Phlegm-dampness constitution showed the clearest and most reproducible signal. At baseline, it was characterized by higher BMI, larger waist circumference, more frequent obesity, higher blood pressure, higher fasting glucose, and higher triglycerides than balanced constitution. In multimarker burden models, phlegm-dampness constitution was associated with substantially higher cardiometabolic marker burden and higher corrected, nonoverlapping examination-derived marker burden. In lagged annual models, current phlegm-dampness was associated with multiple subsequent marker states after adjustment for the current status of the same marker and other covariates; however, most glucose, lipid, kidney, and proteinuria associations attenuated after adiposity adjustment.

The findings also showed that constitution is dynamic rather than a fixed label. More than one-third of adjacent annual visit pairs changed constitution group, and adiposity-related markers were strongly associated with transitions. Among participants currently classified as balanced constitution, higher BMI and larger waist circumference were associated with transition to biased constitution. Among participants with phlegm-dampness constitution, higher BMI and larger waist circumference were associated with lower odds of returning to balanced constitution. These results support a longitudinal interpretation of constitution as a modifiable health state phenotype linked to body composition and metabolic status.

The label prediction analysis provided a complementary perspective. High discrimination persisted after enforcing

XSL•FO
RenderX

complete participant separation, showing that overlap did not account for model performance. However, BMI alone nearly matched the full model, and performance fell markedly without anthropometric variables. The evidence therefore supports a reproducible adiposity-centered phlegm-dampness label phenotype and not a broad classifier that captures the complete TCM constitution construct.

Contribution to Clinical Informatics

A central contribution of this study is methodological. We did not attempt to prove that a traditional taxonomy is equivalent to biomedical disease categories. Instead, we asked which measurable components of an existing culturally embedded label could be recovered from routine records, how those labels changed over time, and where the limits of prediction became visible. This framing preserves the local classification while subjecting it to reproducible data-driven characterization and explicit boundary testing.

This approach extends prior electronic health record phenotyping work, which has often focused on deriving disease labels from structured and unstructured clinical data [1]. It also aligns with efforts to make phenotype algorithms portable and transparent across clinical datasets [3]. Here, the target was not a conventional disease diagnosis but a health state taxonomy used in preventive care. The same logic could be applied to other culturally specific, functional, behavioral, or patient-centered classifications. The key requirement is not that the taxonomy originate from biomedicine but that it can be linked transparently to observable data, longitudinal outcomes, and uncertainty-aware prediction.

Interpretation of Phlegm-Dampness as a Cardiometabolic Digital Phenotype

Among the constitution groups, phlegm-dampness had the strongest record-based signature. Its association with obesity, waist circumference, dyslipidemia, glucose abnormalities, and abdominal ultrasound flags is consistent with previous studies linking phlegm-dampness constitution with metabolic syndrome and cardiometabolic risk [10]. This anthropometric signal is partly expected because the standardized older adult scale directly incorporates BMI and waist-circumference categories into the phlegm-dampness score [16]. Therefore, the high AUC of a model containing those same measurements cannot be interpreted as independent validation of the full phlegm-dampness construct. The additional sensitivity analyses substantially narrowed interpretation: BMI alone produced almost the same discrimination as the full model, whereas model performance fell markedly after anthropometric variables were removed. Adiposity adjustment also explained most longitudinal associations with glucose, lipids, and kidney-related markers. Associations with subsequent abdominal ultrasound abnormality and cardiometabolic risk clustering persisted but were attenuated. Thus, the evidence identifies an adiposity-centered recorded phenotype with limited additional cardiometabolic information rather than a general digital representation of phlegm-dampness.

This distinction is important for interpreting the contribution of the prediction models. The close performance of the BMI-only model indicates that the strongest recoverable signal for the recorded phlegm-dampness label was largely captured by a simple anthropometric measure, whereas the decline after removing anthropometric variables indicates that body-size information was central to model performance. This finding does not invalidate the broader TCM constitution construct. Rather, it defines the information content of the operational phenotype that could be reconstructed from this routine examination dataset. The study therefore contributes not only a predictive framework but also an empirical assessment of construct boundaries and incremental predictive value. In practical terms, the recorded phenotype may support risk communication and hypothesis generation, but it should not be interpreted as an independent diagnostic classifier or as evidence that phlegm-dampness has a causal effect on metabolic disease.

These findings suggest that phlegm-dampness may function as an adiposity-centered cardiometabolic phenotype within this older adult examination cohort. However, this interpretation should remain descriptive rather than causal. The constitution label and several risk markers were measured in routine practice rather than under a prospective experimental protocol. The observed associations may reflect shared upstream determinants, including body composition, diet, activity, socioeconomic factors, medication use, comorbidities, and health care use. E-value analyses quantified the strength of unmeasured confounding that would be required to explain selected longitudinal associations, but they do not eliminate the possibility of residual confounding [23].

Why Bidirectional Mapping Matters for Patients and Clinicians

The bidirectional analysis addresses a practical communication gap. Patients may ask 2 different questions: “Given my disease or examination abnormality, which constitution pattern is common?” and “Given my constitution, which health problems should I pay attention to?” These questions are not statistically identical. Disease-to-constitution mapping showed which constitution patterns were overrepresented among people with specific recorded diseases or examination-derived markers. Constitution-to-disease modeling estimated the adjusted association between a constitution state and each marker relative to balanced constitution.

This bidirectional framing may make constitution research more interpretable to clinicians and patients outside TCM. It also reduces the risk of presenting constitution as a single-direction causal exposure. For clinical informatics applications, such mapping could support patient-facing explanations, preventive counseling, and hypothesis generation. For example, a decision support interface could use the disease-to-constitution map to contextualize a patient’s abnormal ultrasound or metabolic markers, while using the constitution-to-risk map to highlight follow-up priorities. Such applications would require prospective evaluation before clinical use.

Model Evaluation Beyond AUC

The phlegm-dampness label prediction model achieved high temporal test discrimination, but the broader evaluation showed why AUC alone is insufficient. Calibration analyses suggested

XSL•FO
RenderX

that model probabilities were not perfectly calibrated under temporal shift, and the broad biased-vs-balanced model showed weaker calibration than the phlegm-dampness model. Decision curve analysis suggested potential net benefit for phlegm-dampness label prediction across the evaluated threshold probabilities, but this retrospective analysis does not establish clinical effectiveness. Exploratory conformal summaries further demonstrated that uncertainty behavior differed across tasks when the model was evaluated in a later calendar period.

These findings align with broader concerns in clinical prediction and artificial intelligence evaluation. Prediction models can appear accurate in one setting yet perform differently when prevalence, measurement practices, population characteristics, or care pathways change [24]. Transparent reporting is therefore essential when prediction models are developed from routine clinical data [17]. For clinical informatics tools, calibration is especially important because users may interpret model outputs as actionable probabilities rather than simple risk rankings [12]. Decision curve analysis provides a complementary view of potential clinical utility, but it cannot replace prospective implementation evaluation [13]. Our results therefore support the feasibility of digital constitution phenotyping while emphasizing that deployment would require prospective validation, workflow integration, and monitoring for temporal drift.

Privacy-Preserving Reproducibility and Deployment Boundary

This study illustrates a common tension in clinical informatics research: the data most relevant for phenotyping often cannot be fully open because they contain sensitive health information. Algorithmic governance discussions have emphasized that transparency must be balanced with privacy, accountability, and contextual risk [25]. We addressed this tension by separating reproducible code and aggregate evidence from restricted participant-level data. The public package contains scripts, data dictionaries, aggregate output tables, figure-generation workflows, a file manifest, and synthetic demonstration data, while the original workbook and individual-level derived analysis frames remain restricted. This approach is consistent with the findable, accessible, interoperable, reusable (FAIR) data management principles in that reusable metadata and analytic outputs are shared even when individual-level data cannot be open [26].

The same privacy-aware framing is important for implementation. Adaptive mobile health design work has shown that patient-facing systems require explicit workflows, adaptation logic, usability assessment, and carefully defined deployment boundaries rather than a prediction model alone [27]. Our models are therefore best viewed as research prototypes for decision support and communication. They should not replace clinician assessment or the original TCM constitution assessment, and any patient-facing use would require prospective workflow evaluation, local recalibration, and clear explanation of uncertainty.

Strengths

This study has several strengths. It used a large longitudinal routine examination dataset with repeated constitution assessments, separated recorded diseases from examination-derived marker flags, used bidirectional mapping, and evaluated constitution state transitions. The additional analyses also quantified participant overlap, added a strictly participant-disjoint temporal evaluation, compared the full model against simple adiposity baselines, separated new onset from persistence, adjusted longitudinal associations for adiposity, and corrected overlapping burden components. These additions make both performance and limitations more transparent.

Limitations

Several limitations should be considered. First, this observational study cannot establish causal effects of constitution on disease. Adjustment for current marker status does not eliminate residual confounding from disease severity, treatment, repeated measurements, or health care use. Second, the standardized older adult scale explicitly includes BMI and waist circumference in phlegm-dampness scoring. Therefore, strong performance of anthropometry-based models partly reflects criterion overlap rather than independent recovery of constitution from unrelated biomarkers. Although the system automatically calculated scores and the resulting labels were confirmed by a clinician, the analytic export did not preserve assessor identity or a detailed correction audit trail. We could not quantify how often preliminary classifications changed during confirmation or evaluate between-assessor variation. Third, participants were residents of 2 communities in Deyang City undergoing routine health examinations; generalizability to other regions, recruitment settings, and age groups requires external validation. Fourth, ECG and abdominal ultrasound were available only as heterogeneous structured normal or abnormal flags; specific findings and free-text interpretations were unavailable. Fifth, medication names were recorded in only 42.3% of records, and blanks could not be distinguished from no medication use, preventing reliable adjustment. Socioeconomic status, detailed lifestyle intensity, and adjudicated diagnoses were also unavailable. Sixth, the original calendar-year evaluation included repeated participants across periods. Participant-disjoint sensitivity analysis reduced this bias but remains an internal validation within the same source cohort. Seventh, BMI alone nearly matched the full phlegm-dampness model, and most longitudinal cardiometabolic associations attenuated after adiposity adjustment. Because BMI, waist circumference, and the constitution label share information by design, residual construct overlap and collinearity are unavoidable in models that include anthropometry. Accordingly, adiposity adjustment in this study evaluates statistical incremental value rather than causal mediation or equivalence between phlegm-dampness constitution and adiposity. The model should therefore not be interpreted as a comprehensive constitution classifier. Eighth, the other biased constitutions group was too small for stable inference. Finally, recurrence was not evaluated, and subgroup analyses did not constitute a full fairness audit.

XSL•FO
RenderX

Future Work

Future studies should validate this digital phenotyping framework in independent cohorts, younger age groups, different regions, and other clinical and health examination settings. Prospective studies are needed to determine whether digital constitution phenotyping improves preventive counseling, risk communication, or follow-up adherence. Model development should incorporate external validation, calibration updating, subgroup performance assessment, fairness analysis, and human-centered evaluation, consistent with broader recommendations for health equity in machine learning [28]. If digital constitution tools are deployed, they should be presented as decision support and communication aids rather than stand-alone diagnostic systems. Future research should also examine whether longitudinal changes in body composition, lifestyle, medication use, and metabolic markers precede constitution transitions or whether constitution changes mainly reflect concurrent health state reassessment.

Conclusions

Routine health examination data captured a reproducible, predominantly adiposity-centered phlegm-dampness label phenotype in this older adult cohort. Strong discrimination persisted in participant-disjoint evaluation but was nearly matched by BMI alone, and several longitudinal associations were explained by adiposity. The framework is useful for transparent characterization of an existing culturally embedded health state label, but it does not establish a stand-alone diagnostic system or a comprehensive digital classifier of TCM constitution.

The authors thank the staff involved in routine health examination data collection and traditional Chinese medicine constitution assessment.

Generative AI Use

The authors declare that no AI tools, including but not limited to large language models (eg, ChatGPT, Claude, or Gemini), AI writing assistants, or automated text-generation software, were used in the writing, editing, or preparation of this manuscript. All text, data analysis, figures, and interpretations were generated solely by the authors without AI assistance.

Funding

This work was supported by the National Key Research and Development Program of China (Construction and demonstration application of a traditional Chinese medicine service model for the psychosomatic health of older adults; grant 2020YFC2003104). The funder had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Data Availability

The analysis code, data dictionary, aggregate result tables, figure-generation scripts, file manifest, and synthetic demonstration data are available in a public repository [29]. Because the source dataset contains participant-level health examination records from older adults and includes potentially identifiable clinical information, individual-level data cannot be shared publicly. Qualified researchers may request access to the deidentified participant-level analytic dataset from the corresponding author; data access is subject to institutional approval, data use agreement, ethics approval where applicable, and relevant privacy regulations.

Authors' Contributions

YH and MC conceptualized the study. YH, GD, LK, HQ, LX, YD, and XC contributed to data curation and investigation. YH, DD, FW, MZ, and MC contributed to methodology. YH performed the formal analysis and visualization. MC acquired funding and supervised the project together with FW and MZ. YH drafted the manuscript. All authors reviewed and edited the manuscript and approved the final version for submission.

Abstract

Background: Colorectal polyps are a major source of precancerous lesions in colorectal cancer (CRC). In many population-based screening programs, a major challenge is the efficient triage of high-risk individuals for diagnostic colonoscopy amid limited endoscopic resources.

Objective: To enrich current screening frameworks, we aimed to develop an accessible, noninvasive risk stratification tool to serve as a digital triage mechanism for colorectal polyps using machine learning (ML) and routinely collected data in China.

Methods: We conducted a cross-sectional study in Wenzhou, China. A total of 4108 individuals (aged 50 - 74 y) who were referred for and accepted colonoscopy following an initial population-based risk assessment (questionnaire and fecal test) between May and November 2021 were included. The dataset was split into training and validation sets, and the synthetic minority oversampling technique (SMOTE) was applied only to the training dataset to address class imbalance. Twenty-one noninvasive predictors (lifestyle, dietary, clinical symptoms, and family history) were selected using the Boruta algorithm and least absolute shrinkage and selection operator (LASSO) regression. Nine ML models were evaluated, with the Shapley Additive Explanations (SHAP) method and local interpretable model–agnostic explanations (LIME) used for model interpretability and feature ranking.

Results: Among the 9 ML algorithms evaluated, XGBoost (Extreme Gradient Boosting) achieved the highest area under the receiver operating characteristic curve of 0.672, while LightGBM (Light Gradient Boosting Machine) was identified as the optimal model for clinical triage due to its superior recall (0.6503), a key metric for minimizing missed lesions in community screenings. SHAP analysis identified current smoking status, sex, and family history of colorectal polyps as the most influential factors. Notably, the model captured significant nonlinear risk thresholds, such as an age of 50 years and a BMI of 25 kg/m^2, providing a more granular risk profile than traditional linear models.

Conclusions: This study provides a scalable, interpretable triage tool to complement existing 2-step CRC screening protocols. By leveraging only noninvasive variables, the LightGBM model enables prioritized referral for colonoscopy, offering a resource-efficient strategy to optimize CRC prevention in resource-limited settings.

Introduction

Colorectal cancer (CRC) remains one of the most common and preventable malignancies worldwide. In 2020, it accounted for approximately 1.9 million new cases and over 930,000 deaths globally, with incidence rates continuing to rise in many transitioning countries [1]. Colorectal polyps are abnormal growths arising from the mucosal lining of the colon and rectum; adenomatous and serrated polyps represent the earliest morphologically recognizable precursors in the adenoma-carcinoma sequence [2]. Numerous studies have demonstrated that early detection and removal of these precancerous polyps significantly reduce both CRC incidence and mortality [3,4]. Despite this evidence, CRC incidence and

XSL•FO
RenderX

mortality rates have not declined substantially in many regions over recent decades, possibly because most precancerous polyps are asymptomatic and therefore remain undetected until advanced stages are reached.

Numerous approaches have emerged for the early detection of colorectal polyps, such as fecal occult blood testing, urinary metabolomics, and computed tomographic colonography [5-7]. Despite these advances, colonoscopy remains the gold standard for definitive diagnosis [8]. Nevertheless, the invasiveness of colonoscopy, coupled with potential complications including bleeding, perforation, and postprocedural pain, together with its substantial cost, restricts its application as a population-wide screening tool [5,9,10]. Given these limitations, a more practical screening strategy is needed: noninvasive, cost-effective tests for the asymptomatic general population, with colonoscopy reserved for those with positive screening results.

The development of colorectal polyps results from a complex interplay of genetic, metabolic, environmental, and lifestyle factors [11-13]. Traditional predictive models, most commonly logistic regression (LR), often oversimplify this multifactorial etiology because of their assumptions of linearity and feature independence. These constraints of traditional models highlight the need for flexible, data-driven approaches like machine learning (ML) that can capture nonlinear relationships and population-specific risk profiles [14]. In recent years, ML has been extensively applied to the diagnosis of colorectal polyps using colonoscopy images and computed tomographic colonography [15]; however, its potential in optimizing the initial triage stage of population-based screening remains underexplored.

Population-based screening programs, which primarily target middle-aged and older adults, typically follow a 2-step protocol: an initial risk assessment (often via simple questionnaires and fecal tests) followed by referral for colonoscopy. However, these programs frequently face resource constraints and limited endoscopic capacity [16]. A major challenge in this setting is the low "yield" of colonoscopies and the difficulty in prioritizing individuals among the large pool of "high-risk" candidates identified by traditional tools. ML excels at uncovering subtle, nonlinear relationships in multidimensional data, where traditional statistical methods often fall short [17]. Consequently, ML holds great promise for refining these screening frameworks by building more accurate risk stratification tools, thereby providing a digital triage mechanism to pinpoint individuals with the highest probability of harboring polyps for prioritized colonoscopy referral.

This study aimed to develop and assess the performance of ML-based risk prediction models for colorectal polyps to enrich existing population-based screening programs. By using readily available, noninvasive data, we sought to provide a cost-effective strategy to precisely stratify risk within the screened population and guide selective, prioritized referral for colonoscopy. This approach is particularly intended to optimize resource allocation and improve screening efficiency in resource-limited settings.

Methods

Data Sources and Study Participants

This study was conducted within a population-based CRC screening program targeting residents aged 50 to 74 years in Zhejiang Province, China [18]. Data were collected from all 12 administrative districts and counties of Wenzhou between May and November 2021. This multicenter recruitment strategy allowed for the inclusion of a diverse study population from both highly urbanized city centers and semiurban and rural regional areas, reflecting a wide spectrum of socioeconomic statuses and lifestyle patterns.

The program followed a systematic 2-step triage protocol. All enrolled residents underwent a primary risk assessment consisting of a simple risk evaluation questionnaire and a fecal immunochemical test. Individuals identified as "high-risk" by the questionnaire or those with a positive fecal immunochemical test result were subsequently referred for colonoscopy. Our study focused on those who underwent the full procedure to ensure diagnostic gold-standard confirmation.

Of the 276,395 individuals initially enrolled in the program, 257,481 did not undergo colonoscopy and were excluded. This high exclusion rate was attributed to several factors, including individuals not being identified as "high-risk" during the initial screening or declining colonoscopy due to anxiety regarding the invasive procedure or logistical inconvenience. Among the remaining 18,914 participants who completed colonoscopy, 12,094 were diagnosed with colorectal polyps, while 6820 did not. Cases were defined as individuals with newly diagnosed, histologically confirmed colorectal polyps who were aged 50 to 74 years and had no history of gastrointestinal surgery, chemotherapy, radiotherapy, or other gut-related treatments. Controls were individuals aged 50 to 74 years with a normal colonoscopy (no colorectal polyps detected). Participants were further excluded if they had a history of any malignancy, precancerous gastrointestinal lesions, hereditary CRC syndromes (eg, Lynch syndrome or familial adenomatous polyposis), inflammatory bowel disease, severe comorbidities (eg, serious psychiatric disorders or advanced cardiopulmonary disease), or incomplete data on key variables. After applying these criteria, the final study dataset consisted of 4108 participants: 816 cases with colorectal polyps and 3292 controls without colorectal polyps.

Data Extraction

Potential predictors of colorectal polyps were selected based on an extensive literature review, clinical expert consultation, and practical feasibility in population-based screening settings [19,20]. All selected variables could be easily obtained through routine questionnaires and basic physical examinations in daily clinical practice. Data were collected once during the screening program and categorized as follows: (1) sociodemographic and lifestyle factors, including age, sex, education level, marital status, smoking status, alcohol consumption, physical activity, family history of cancer (FHC) and/or family history of colorectal polyps (FHPs), and history of colonoscopy (HCS); (2) comorbidities and medication use, including hypertension, diabetes mellitus, gout, hyperlipidemia, use of nonsteroidal

XSL•FO
RenderX

anti-inflammatory drugs, and anticoagulant therapy; (3) clinical symptoms and anthropometric measurements, including unexplained weight loss, hematochezia, abdominal pain, abdominal distension, palpable abdominal mass, abnormal bowel habits, iron-deficiency anemia, BMI, and waist circumference; and (4) dietary habits, including consumption of vegetables, fruits, white meat, red meat, processed meat, pickled foods, fried foods, whole grains, and legumes. Variables were incorporated into the models based on their raw distribution to minimize information loss. Sociodemographic and clinical factors were treated as binary or continuous where appropriate. Notably, adequate physical activity was dichotomized based on the frequency of moderate-to-vigorous intensity exercise, with more than 3 times per week defined as “adequate” and less than 3 times per week as “inadequate.” Secondhand smoking was defined as a binary variable based on self-reported exposure (“yes” or “no”). Medical history, medication use, and symptoms were all dichotomized as “yes” or “no.” Detailed variable definitions and units are summarized in Table 1.

Data Preparation

Several issues were present in the raw data, including missing values, outliers, and class imbalance, all of which could substantially affect the construction and performance of colorectal polyp risk prediction models. Missing values were rare, ranging from 0% to 3.5% across all variables. To ensure the appropriateness of our handling method, the Little missing completely at random test was conducted, which yielded a nonsignificant result (*P*=.37), indicating that the data were missing completely at random. Consequently, we performed complete-case analysis by excluding any records with missing values. Outliers were defined as values greater than or less than 1.5 times the IQR beyond the upper or lower quartile. We replaced these outliers with the 1st or 99th quantile values, thereby ensuring that extreme outliers did not disproportionately influence feature selection and model training, particularly for regularization-based algorithms [21].

The dataset exhibited marked class imbalance, with the majority of participants having no colorectal polyps, which could bias models toward negative predictions. To address this, we applied the synthetic minority oversampling technique (SMOTE) only to the training dataset after train-test splitting at an 80:20 ratio. SMOTE generates synthetic examples of the minority class (cases) by interpolating between each minority instance and its k-nearest neighbors until class balance is achieved [22]. Because oversampling was performed within the training dataset and conducted on a secure internal network, there was no risk of data leakage.

Feature Selection

Candidate features for the colorectal polyp risk stratification model exhibited considerable heterogeneity in scale and clinical relevance. To reduce model complexity, enhance training efficiency, and improve interpretability, a systematic feature-selection pipeline was implemented. Relevant clinical experts were first consulted to prioritize variables with established or plausible associations with colorectal polyps. All subsequent feature-selection procedures were conducted exclusively on the training dataset after splitting. Subsequently, 2 complementary data-driven methods were applied: (1) least absolute shrinkage and selection operator (LASSO) regression embedded within a 10-fold cross-validation framework, which shrinks coefficients of irrelevant predictors to exactly zero through L1 regularization [15], and (2) the Boruta algorithm, a random forest (RF)–based wrapper that identifies truly important features by comparing their importance (*z*-scores) against iteratively generated shadow features, effectively capturing nonlinear relationships and interactions [23]. Features confirmed as important by either LASSO or Boruta were then evaluated for multicollinearity using Spearman correlation analysis; when the absolute correlation coefficient exceeded 0.8, only the variable with greater clinical interpretability or a stronger univariate association was retained.

Construction of a Colorectal Polyp Risk Stratification Model

Nine well-established ML algorithms were used to develop the colorectal polyp risk stratification models. LR applies the logistic function for binary classification but can overfit with high-dimensional data [24]. Support vector machine constructs

XSL•FO
RenderX

optimal separating hyperplanes by maximizing the margin between classes [25]. Gaussian naive Bayes relies on Bayes' theorem with the assumption of conditional independence among features. The multilayer perceptron addresses linearly inseparable problems by stacking multiple layers of neurons with nonlinear activation functions [26]. Decision tree recursively partitions the feature space, with internal nodes representing feature-based decisions and leaf nodes denoting final class predictions [27]. RF, Extreme Gradient Boosting (XGBoost), Light Gradient Boosting Machine (LightGBM), and categorical boosting (CatBoost) are ensemble methods that aggregate numerous decision trees. While RF uses bagging with random feature selection, the boosting-based algorithms (XGBoost, LightGBM, and CatBoost) use sequential gradient boosting with advanced regularization. Specifically, LightGBM uses gradient-based 1-side sampling and exclusive feature bundling to accelerate training and handle high-dimensional screening data, whereas CatBoost offers native handling of categorical variables, making these ensemble approaches collectively highly effective in complex medical prediction tasks [28]. To optimize hyperparameters and prevent overfitting, 10-fold cross-validation was performed on the training dataset, using 9 folds for training and 1 fold for validation in each iteration.

Performance Assessment of a Colorectal Polyp Risk Stratification Model

The independent validation dataset, comprising 20% of the total dataset, was used for final model performance evaluation. Models were assessed across 3 key dimensions: discrimination, calibration, and clinical utility. Discrimination was evaluated using accuracy, sensitivity (recall), specificity, positive predictive value, negative predictive value, F_1-score, and Brier score. The area under the receiver operating characteristic curve was calculated for each model, with 95% CIs estimated using the DeLong method. To further evaluate model performance under class imbalance, precision-recall curves were generated, and the average precision (AP) was calculated. AP provides a more robust measure of a model's ability to identify true positive cases by summarizing the trade-off between precision and recall across various thresholds. Calibration performance was examined through calibration plots and quantified using Brier scores. Clinical usefulness and net benefit across a range of risk thresholds were assessed via decision curve analysis. This comprehensive evaluation framework ensured a robust assessment of both statistical performance and real-world clinical applicability [29].

Feature Importance and Results Interpretation

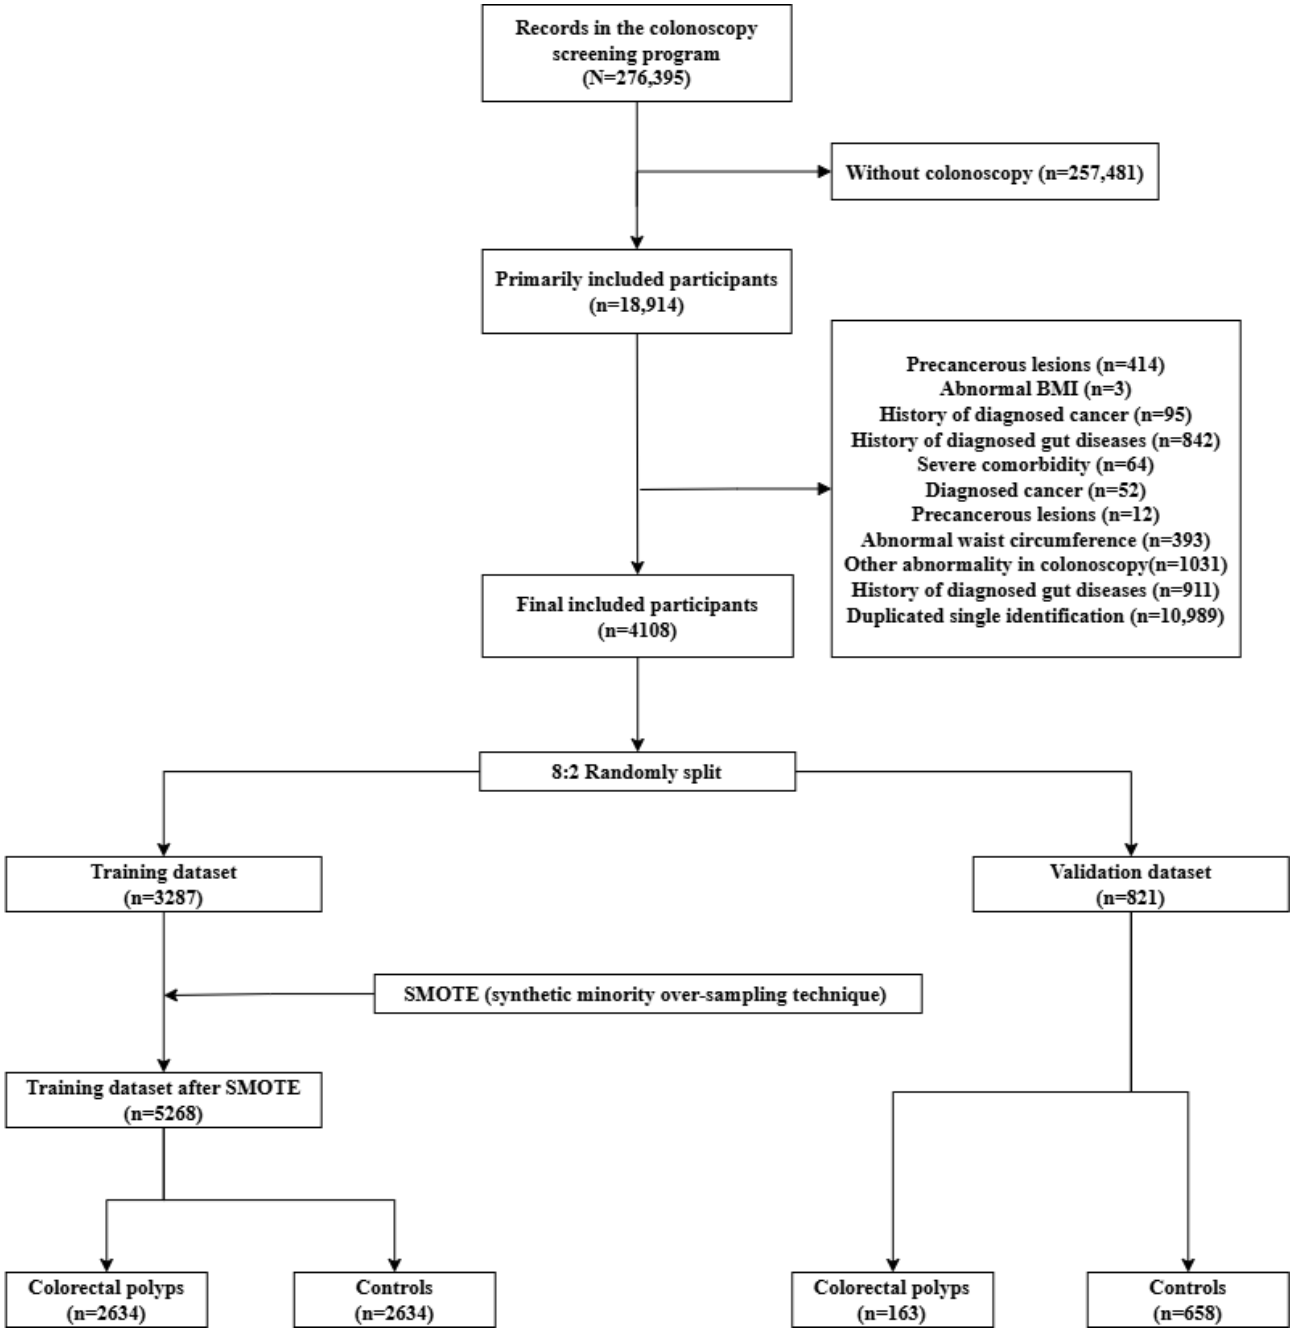
ML models are frequently criticized as "black boxes" owing to their complexity and lack of transparency. To address this limitation and enhance clinical trust, we applied the Shapley Additive Explanations (SHAP) framework to the best-performing model [30]. SHAP, grounded in cooperative game theory, provides consistent and locally accurate feature-attribution values that can be aggregated for both global and local interpretability for virtually any ML algorithm. Global model behavior was elucidated through SHAP summary plots, which rank features by their overall impact on model output and illustrate the direction and magnitude of each feature's effect across the entire dataset. Local interpretability for individual predictions was complemented by local interpretable model–agnostic explanations (LIME), which approximates the complex model locally with an interpretable surrogate to explain specific predictions. Additionally, SHAP dependence plots for the 3 most influential features and those displaying potential nonlinear patterns in the summary plot were generated to visualize interaction effects between each feature and the model's risk prediction [31].

Statistical Analysis

Descriptive statistics were presented as mean (SD) or median with IQR for continuous variables, depending on the data distribution, and as frequencies with percentages for categorical variables. To mitigate excessive sparsity, low-frequency categories were merged when clinically appropriate. Between-group comparisons were performed using the 2-tailed Student *t* test, Wilcoxon rank-sum test, or chi-square test, as appropriate. A 2-sided $P<.05$ was considered statistically significant. All data processing, statistical analyses, and ML modeling were conducted using R software (version 4.4.1; R Foundation for Statistical Computing) [32].

Ethical Considerations

All participants provided written informed consent. The study procedures were carried out in accordance with the Declaration of Helsinki. Ethics approval was obtained from the Ethics Committee of Zhejiang Cancer Hospital (IRB-2023 - 464).



Results

Baseline Characteristics of Included Participants

A total of 4108 participants were included in the final analysis (816 cases with colorectal polyps and 3292 controls). The participant selection process is illustrated in Figure 1. The baseline characteristics of the study population are summarized in Table 1. The median age of all participants was 62 (IQR 55 - 67) years, with 1799 out of 4108 participants (43.8%) being male. In the case group, the median age was 63 (IQR 56 - 68) years and 460 out of 816 (56.4%) participants were male, whereas the control group had a median age of 61 (IQR 55 - 67) years and 1399 out of 3292 (42.5%) participants were male. Apart from age and sex, participants in the 2 groups were largely comparable across most sociodemographic, clinical, and lifestyle variables. Details of the colorectal polyp composition in the case group are provided in Multimedia Appendix 1.

Feature Selection and SMOTE Implementation

A total of 36 candidate predictors were initially considered based on a literature review and consultation with clinical experts before data splitting. LASSO regression with 10-fold cross-validation was first performed for feature selection and regularization. Using the 1 SE rule, the optimal λ of 0.0046 was selected, retaining 18 informative features with nonzero coefficients (Figure 2 and Multimedia Appendix 2). Independently, the Boruta algorithm confirmed the importance of multiple features and rejected 24 variables as unimportant (Figure 3). Features identified as important by either LASSO or Boruta (n=21) were carried forward. These comprised FHP, FHC, HCS, age, sex, BMI, waist circumference, current smoking, secondhand smoke exposure, alcohol consumption, educational attainment, marital status, intake frequency of fried food, pickled food, white meat, and red meat, as well as gout, diabetes, hypertension, hematochezia, and unexplained weight loss. Spearman correlation analysis among these 21 features revealed no pair with an absolute correlation coefficient greater than 0.8 (Multimedia Appendix 3). Consequently, all 21 variables were retained for the final ML model development and evaluation. After applying SMOTE, the training dataset (case-to-control ratio=653:3287, 19.86% before balancing) was perfectly balanced, with 2643 cases and 2643 controls, respectively (Figure 1).

Comparison of Constructed Prediction Models

The 9 ML models were trained on a balanced dataset and evaluated on an independent validation dataset (n=821). XGBoost and LightGBM emerged as the top-performing models. In Figure 4A to C, XGBoost achieved the highest area under the receiver operating characteristic curve of 0.672 (95% CI 0.623 - 0.722) and a higher AP of 0.430 (Multimedia Appendix 4). LightGBM, while having a slightly lower AUC, demonstrated the highest clinical sensitivity, correctly identifying 106 out of 163 cases (Multimedia Appendix 5). This trade-off between precision and recall makes LightGBM particularly valuable for minimizing missed lesions in population-based screening. Decision curve analysis further confirmed that these ensemble models maintained a consistent positive net benefit across a broad range of threshold probabilities (Figure 4D). Calibration performance was assessed via calibration plots (Multimedia Appendix 6). Most models, including XGBoost and LightGBM, exhibited favorable calibration in the low-to-moderate risk range (predicted probability <0.5), with Brier scores consistently below 0.25. While fluctuations were observed in the high-probability zones due to limited sample density, the overall alignment with the ideal diagonal line indicates reliable probability estimates for clinical triage. In conclusion, XGBoost and LightGBM are recommended as the preferred models for clinical risk stratification. The optimal probability cutoffs were derived from the validation dataset. Individuals with risk scores exceeding these thresholds (XGBoost: 0.2432; LightGBM: 0.1395) are recommended for prioritized diagnostic colonoscopy to optimize the detection of precancerous lesions in resource-limited settings.

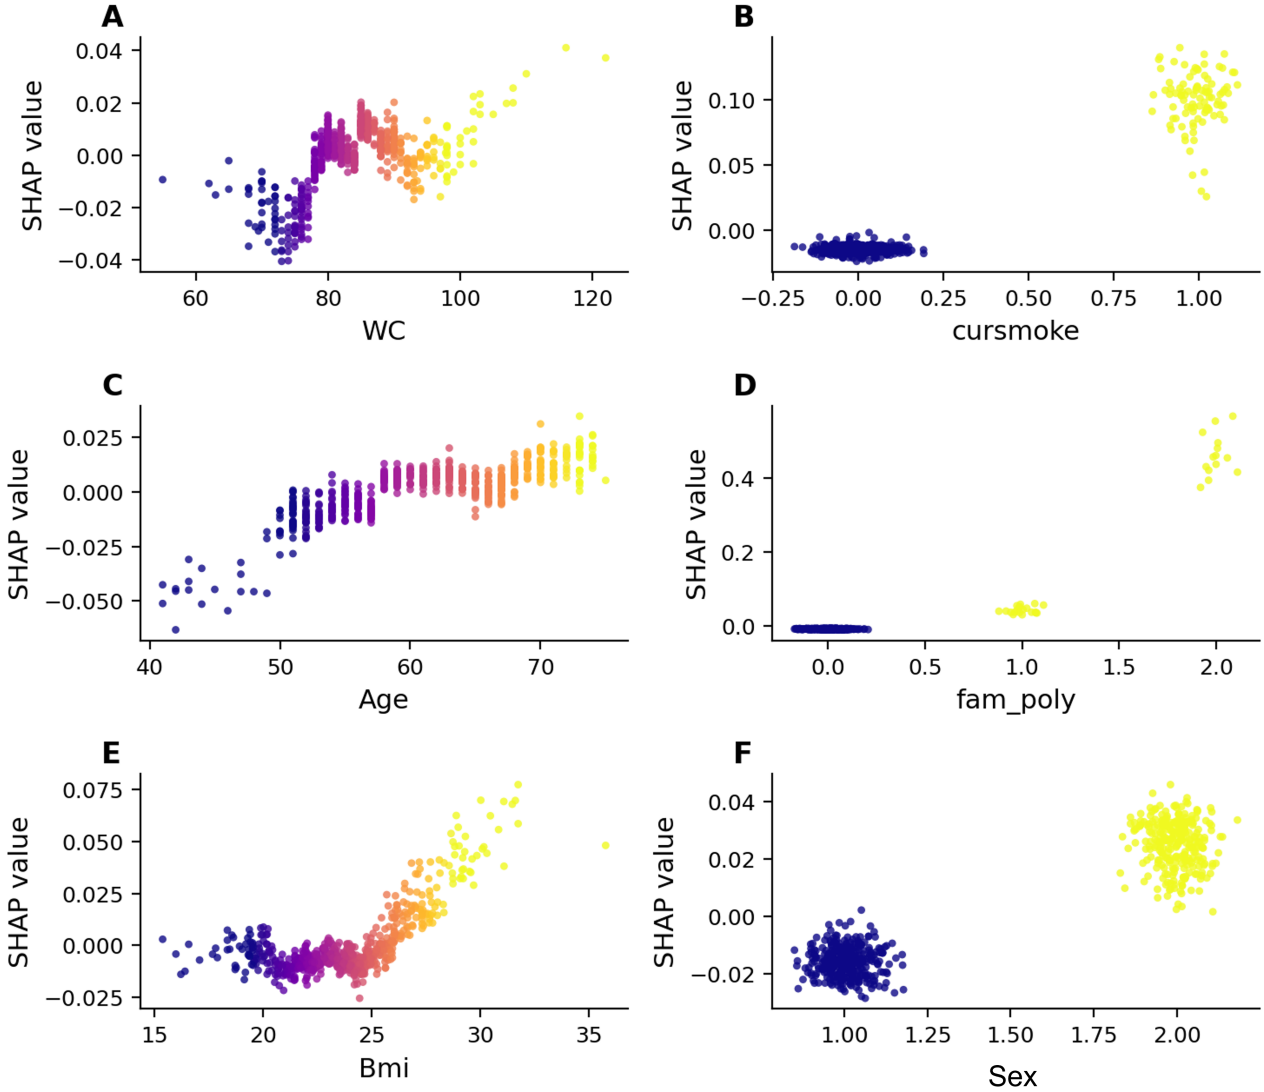
Figure 4. Multidimensional evaluation of machine learning (ML) models for colorectal polyp risk stratification: (A) receiver operating characteristic (ROC) curves; (B) bubble chart comparison of comprehensive performance metrics; (C) precision-recall (PR) curves with average precision (AP) values; a higher area under the PR curve (closer to the top-right corner) indicates superior predictive performance; (D) decision curve analysis (DCA). The red curves represent the ML models; the gray line represents "screen-all," and the horizontal dashed line represents "screen-none." Models with higher net benefit (further above the gray and dashed lines) provide greater clinical value for triage. AUC: area under the curve; CatBoost: categorical boosting; DT: decision tree; LightGBM: Light Gradient Boosting Machine; LR: logistic regression; MLP: multilayer perceptron; NB: naive Bayes; RF: random forest; SVM: support vector machine; XGBoost: Extreme Gradient Boosting.

Feature Importance and Interpretation With the SHAP and LIME Methods

To elucidate the biological and lifestyle-related drivers behind the model's predictions, we performed global and local interpretability analyses using SHAP and LIME, specifically focusing on the LightGBM model, given its optimal sensitivity for triage screening. Figure 5A presents the global feature importance based on the mean absolute SHAP values. Current smoking status (cursmoke), sex, and a family history of polyps (fam_poly) emerged as the most influential predictors, followed by socioeconomic and anthropometric factors such as education level (Edu) and BMI. The SHAP beeswarm plot (Figure 5B) details the direction and magnitude of these effects across the validation dataset. Notably, the beeswarm distribution for waist circumference, age, and BMI suggested potentially nonlinear relationships with the risk of colorectal polyps, as evidenced by the nonuniform spread of their SHAP values.



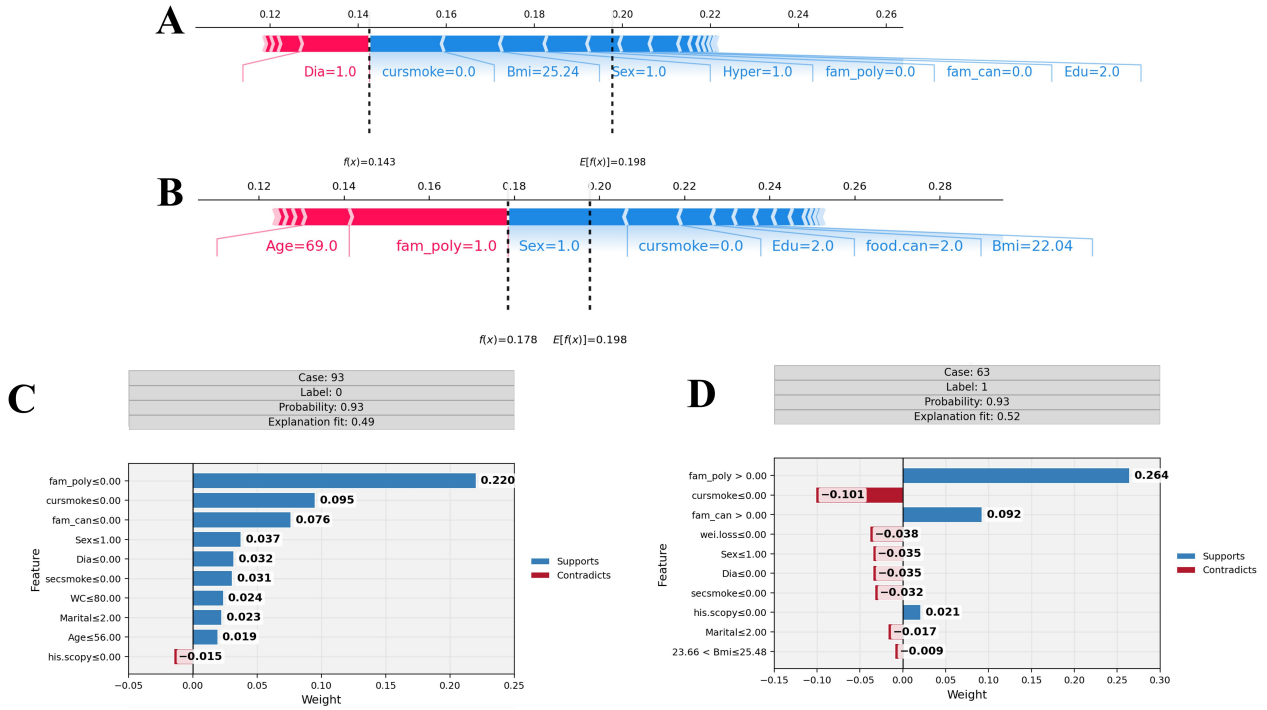
XSL•FO
RenderX

A higher mean SHAP value indicates a greater influence on the prediction. (B) SHAP beeswarm plot. Each dot represents an individual in the validation set. Dots to the right of the zero line indicate an increased risk, while those to the left indicate a protective effect. WC: waist circumference.

XSL•FO
RenderX

To further dissect the specific impact of key predictors on colorectal polyp risk, SHAP partial dependence plots were generated for 6 prioritized variables (Figure 6). These plots illustrate the nonlinear trajectories and threshold effects captured by the LightGBM model. For continuous variables, waist circumference exhibited a distinct inflection point at approximately 85 cm, beyond which the SHAP values decreased sharply and nearly linearly (Figure 6A). Similarly, age demonstrated a clear threshold effect at 50 years; while the risk remained below the baseline for younger participants, it increased monotonically thereafter, reinforcing the clinical rationale for intensified screening in the 50 years and older age group (Figure 6C). BMI showed a comparable trend, with the contribution to risk transitioning from protective to causative as BMI exceeded the 25 kg/m² threshold (Figure 6E). Regarding categorical factors, the model captured consistently elevated risks for males (Figure 6F) and current smokers (Figure 6B). Notably, family history of polyps showed the highest magnitude of impact among all categorical features, with a positive history contributing the strongest positive deviation in predicted risk scores (Figure 6D).

Figure 6. Shapley Additive Explanations (SHAP) method partial dependence plots for key predictors of colorectal polyps. (A,C,E) Continuous variables (waist circumference, age, and BMI); (B,D,F) Categorical and binary variables (current smoking status, family history of polyps, and sex).



To visualize the "push and pull" of individual risk factors, we used SHAP force plots to decompose the prediction process for representative participants (Figure 7A and B). For a low-risk individual (Figure 7A), the final prediction ($f[x]$=0.143) was driven below the overall baseline ($E[f(x)]$=0.198) primarily by the absence of family history (fam_poly=0.0) and nonsmoking status (cursmoke=0.0), which successfully counteracted the risk elevation from diabetes (Dia=1.0). In contrast, for a high-risk individual (Figure 7B), advanced age (69 y) and family history (fam_poly=1.0) served as the dominant forces pushing the risk score toward a positive diagnosis. These visualizations demonstrate how LightGBM integrates disparate clinical signals into a unified risk score.

We further used LIME to validate the model's decision-making logic through localized linear approximations (Figure 7C and D). For Case 93 (Figure 7C), the model achieved a high-confidence prediction (probability=0.93) for the control, citing the absence of family history as the primary supportive evidence, while identifying the absence of colonoscopy as the only contradictory evidence. Conversely, for Case 63 (Figure 7D), despite certain lifestyle factors acting as contradictory

XSL•FO
RenderX

evidence (eg, nonsmoking), the synergistic weight of family history of colorectal polyps (fam_poly=1.0) and cancer (fam_can=1.0) was sufficient to trigger a high-risk alert (probability=0.93). The consistent alignment between SHAP's global-to-local logic and LIME's local attribution enhances the clinical reliability of the model.

Figure 7. Individualized model interpretability via Shapley Additive Explanations (SHAP) method force plots and local interpretable model–agnostic explanations (LIME) local explanations. (A,B) SHAP force plots for a low-risk ($f[x]$=0.143) and a high-risk ($f[x]$=0.178) individual, where red and blue arrows represent risk-increasing and risk-decreasing effects, respectively. (C,D) LIME feature attribution plots for Case 93 (control) and Case 63 (case).

Discussion

Principal Findings

In this study, we developed and validated 9 ML models to enhance the initial risk stratification stage of the current population-based CRC screening framework. Using a large-scale screening dataset from Wenzhou, China, our results demonstrated that ML models, particularly the LightGBM algorithm, can effectively refine colorectal polyp risk assessment in individuals aged 50 to 74 years. By prioritizing a high recall (0.6503), our model ensures a robust "digital filter" that minimizes the risk of missed diagnoses during initial triage. Notably, our models achieved strong predictive utility by fully using the variables already collected during the initial screening phase. This suggests that the proposed ML approach can serve as a precision-driven triage tool, potentially improving the "yield" and cost-effectiveness of subsequent colonoscopies compared to traditional risk assessment methods.

Compared with previously published prescreening models, our LightGBM model showed substantially better discrimination. An electronic health record (EHR)–based AdaBoost model reported an AUC of 0.687 and sensitivity of 0.635, which is comparable to our results; however, such models are often limited by the incomplete capture of lifestyle and family history data in clinical databases [15]. A genetic risk score (GRS)–augmented LR model in a Caucasian cohort reached an AUC of 0.666, but required costly genotyping and had uncertain generalizability to Asian populations [33]. While some questionnaire- or nomogram-based models have reported AUCs ranging from 0.68 to 0.75, our model, achieving an AUC of 0.6724 and a superior sensitivity of 0.6503, offers a more streamlined approach by using only essential variables collected during the initial screening phase [34,35]. The robust performance of our LightGBM model is likely attributable to its ability to capture complex, nonlinear interactions and higher-order combinations among risk factors, such as the threshold effects of waist circumference and age identified in SHAP analysis. Unlike traditional LR and nomograms, this gradient-boosting framework effectively models these dependencies, providing a high-recall "digital triage" that is both cost-effective and specifically optimized for the East Asian population.

A distinguishing feature of our study is the deliberate prioritization of recall (0.6503) over precision in a screening context, where missing a polyp carries far greater clinical consequences than referring a low-risk individual for colonoscopy [36]. This recall is considerably higher than the 0.635 reported for the EHR-based model and provides a significant safety margin for population-level triage [15]. While our sensitivity does not yet reach the levels of intraprocedural computer-aided detection systems (0.90 - 0.96), it is achieved noninvasively and at negligible cost using only baseline screening data [37-39]. Substantial studies have demonstrated that early detection of precancerous lesions through screening significantly reduces the burden of CRC [40,41]. By enabling targeted referral of truly high-risk individuals using a simple questionnaire that can be deployed at scale, our LightGBM

XSL•FO
RenderX

model offers an efficient, equitable, and immediately implementable solution. This approach can dramatically improve the yield of limited colonoscopy resources, thereby maximizing the population-level impact of CRC screening programs in China and similar resource-constrained settings.

The clinical utility of our LightGBM model is underpinned by its capacity to prioritize and interpret multidimensional risk factors. SHAP analysis revealed that the model's predictive power is primarily driven by current smoking, sex, and family history of colorectal polyps (FHP). Extensive evidence links cigarette smoking to an elevated risk of various polyp subtypes, including sessile serrated and hyperplastic polyps [42-44]. Notably, smoking cessation for over 20 years can reduce the risk to levels comparable to never-smokers [45], likely because tobacco-induced BRAF (B-Raf Proto-Oncogene, Serine/Threonine Kinase) mutations, a key mechanistic pathway, are primarily implicated in the serrated neoplasia sequence [46]. In terms of sex, males consistently have a higher prevalence of colorectal adenomas, advanced adenomas, and high-risk polyps than women in large screening cohorts [47,48]. Sex differences in colorectal polyp risk likely arise from interactions between sex steroids, body fat distribution, and adipokines, immune and inflammatory pathways, and sex-specific gut microbiota profiles [49,50]. Furthermore, FHP emerged as a critical predictor, a factor often absent or incomplete in prior models. Numerous studies confirm that FHP significantly increases the risk of colorectal polyps, particularly for early-onset cases or when multiple first-degree relatives are affected [51]. Inherited germline variants, such as mutations in DNA mismatch repair genes (eg, MSH3 and MLH3), are believed to underlie this predisposition [52]. Overall, the SHAP dependence plots (Figure 6B, D, and F) for these 3 factors also support the findings from most of the literature, in which males, current smokers, and those with a family history of colorectal polyps have the highest SHAP values.

While these categorical factors establish a significant risk baseline, the LightGBM model's superior performance also stems from its ability to decipher complex, nonlinear effects within continuous clinical metrics. The following section details specific thresholds for BMI, waist circumference, and age, which provide a more granular risk profile than traditional linear assessments. Although BMI emerged as a stronger global predictor in our SHAP importance ranking, waist circumference provides critical localized insights into central obesity, which is often a more potent driver of colorectal neoplasia [53]. Notably, in Asian populations, individuals with a normal BMI but elevated waist circumference (90 - 102 cm for men; 80 - 88 cm for women) exhibit the highest risk of colorectal polyps [54]. This aligns closely with the nonlinear threshold of approximately 85 cm observed in our SHAP dependence analysis, a finding likely influenced by the predominance of female participants in our study sample. Similarly, BMI displayed a distinct nonlinear pattern, with a marked risk inflection point at 25 kg/m^2. This threshold is consistent with international evidence from Australian, African American, and Iranian populations, where a BMI exceeding 25 kg/m^2 consistently correlates with higher colorectal polyp prevalence [55-57]. The biological mechanisms for both indicators likely involve chronic inflammation and gut microbiota dysbiosis [58,59]. For instance, obesity-related inflammation can promote DNA mismatch repair defects and microsatellite instability, pathways particularly relevant to serrated polyps [60]. Furthermore, the higher abundance of *Fusobacterium nucleatum* in obese individuals is more strongly associated with serrated than with conventional pathways [61]. In addition to metabolic factors, age is a well-established primary risk factor for colorectal polyps and most chronic diseases. Epidemiological evidence consistently shows that the prevalence of colorectal polyps rises markedly after age 50, a pattern mirrored by the threshold at approximately 50 years in our SHAP analysis [62]. The underlying mechanism is thought to involve the progressive accumulation of somatic DNA mutations with aging, notably in the adenomatous polyposis coli gene, which initiates the classic adenoma-carcinoma sequence [63]. By integrating these nonlinear age and metabolic signatures, our model effectively captures the complex physiological transitions that define individual risk.

To bridge the gap between algorithmic prediction and clinical action, we used SHAP force plots as the primary tool for individual risk communication, supplemented by LIME for local validation. The force plot provides a transparent "risk balance sheet," visualizing how specific predictors quantifiably push the individual's risk score from the overall baseline toward a high-probability threshold. For instance, when triaging the high-risk individual in Figure 7B, the clinician can use the force plot to demonstrate that while certain factors might be protective, the combined "force" of being 69 years old and having a history of colorectal polyps necessitates an immediate colonoscopy. By replacing generic screening guidelines with this individualized, evidence-based visualization, our approach facilitates more nuanced patient-physician dialogue, builds clinical trust, and helps overcome patient reluctance in population-based settings.

Strengths and Limitations

The strengths of our study are highlighted by several key aspects. First, our model was designed and validated within the context of a real-world, population-based screening program. Unlike studies relying on symptomatic hospital data, we exclusively used variables routinely collected during initial screening. This ensures that the tool is perfectly aligned with its intended deployment as a precolonoscopy triage mechanism. Second, we used a rigorous and reproducible modeling pipeline. Feature selection combined LASSO regression with the Boruta algorithm to balance interpretability and data-driven relevance. By using advanced ensemble algorithms like LightGBM, our approach effectively captured complex nonlinear interactions and clinical thresholds (eg, for age and BMI) that traditional LR cannot model, resulting in superior clinical utility. Third, this study addresses a critical clinical bottleneck: limited endoscopic resources. By prioritizing high recall, our model provides a resource-efficient strategy to ensure that truly "high-risk" individuals are fast-tracked for colonoscopy, thereby minimizing missed diagnoses and optimizing the efficiency of existing screening frameworks.

XSL•FO
RenderX

Despite these contributions, several limitations should be acknowledged. First, our models were developed using cross-sectional data from a single-center screening program in southeastern China, which may limit generalizability to other regions or ethnicities. Risk factor profiles vary geographically; for instance, dietary patterns and lifestyle stressors differ significantly between urban and rural populations [16,64]. External validation in diverse populations is therefore essential to confirm the robustness of our identified nonlinear thresholds, such as the BMI of 25 kg/m^2 inflection point. Second, we did not stratify predictions by histopathological subtypes (eg, conventional adenomas vs sessile serrated lesions), which have distinct malignant potential. Future iterations using larger longitudinal datasets, aimed at specifically differentiating advanced neoplasia from nonadvanced lesions, are needed. Additionally, GRSs were not incorporated. While GRS can enhance predictive performance [33], our focus was on maintaining a zero-cost, high-accessibility tool for community-based triage. Lastly, although we provided interpretability through SHAP and LIME, the cross-sectional nature of the study precludes definitive causal inferences. Future longitudinal research is warranted to validate the biological trajectories identified by our ML framework.

Conclusions

In conclusion, this study explored several ML models to enrich the current population-based CRC screening protocol. By using only noninvasive, routinely collected clinical and lifestyle variables, the XGBoost and LightGBM models achieved the best discriminative performance, while the latter excelled in recall, which is important in the screening context. These models function as a sophisticated “digital triage tool” that can be seamlessly integrated into the initial assessment phase of mass screening. By identifying truly high-risk individuals among asymptomatic populations, this approach supports a more efficient allocation of limited colonoscopy resources, potentially reducing the burden on health care systems. This study provides a scalable, data-driven solution to bridge the gap between initial risk assessment and definitive diagnostic intervention.

Abstract

Background: Neonatal sepsis remains a major cause of neonatal morbidity and mortality in low- and middle-income countries (LMICs). Early diagnosis is challenging because of nonspecific clinical manifestations and delays in laboratory confirmation. Machine learning (ML) approaches using structured electronic health record (EHR) data may improve early risk stratification in neonatal intensive care units (NICUs).

Objective: This study aimed to evaluate ML models for predicting culture-confirmed neonatal sepsis among neonates admitted to a tertiary NICU in Jordan, with the objective of addressing diagnostic gaps in resource-limited settings. Specifically, we aimed to identify key predictors through feature importance analysis, evaluate model performance with class-imbalanced data, and propose strategies to improve interpretability and generalizability in LMICs.

Methods: A retrospective cohort study was conducted using structured EHRs of 3274 neonates admitted to a tertiary NICU in Jordan between 2018 and 2024. Neonates who underwent blood culture testing were included. The dataset was divided into training (n=2619, 80%) and testing (n=655, 20%) subsets using stratified sampling. Three ML models—Extreme Gradient Boosting (XGBoost), decision trees, and neural networks—were trained using clinical, laboratory, and demographic variables. Class imbalance was addressed using the synthetic minority oversampling technique (SMOTE) applied to the training dataset. Model performance was evaluated using accuracy, sensitivity, specificity, and the area under the receiver operating characteristic curve (AUC).

Results: Among 3274 neonates included in the study, the XGBoost model demonstrated the best predictive performance on the independent test set (n=655, 20%), achieving an accuracy of 94% (616/655 correct predictions, 95% CI 92% to 96%), sensitivity of 98% (95/97 sepsis cases correctly identified, 95% CI 96% to 99%), and an AUC of 0.98 (95% CI 0.97 to 0.99). Decision trees provided interpretable classification rules with moderate performance, whereas neural networks showed lower discriminative ability, with an AUC of 0.81 (95% CI 0.78 to 0.84). Important predictive features included C-reactive protein, platelet count, and gestational age.

Conclusions: XGBoost demonstrated strong predictive performance in this retrospective cohort, supporting its potential as a foundation for future prospective clinical decision support tools. External validation and prospective studies are required before clinical implementation.

Introduction

Neonatal sepsis (NS) remains a major contributor to neonatal mortality worldwide, causing approximately 550,000 deaths per year (15% of neonatal deaths) in low- and middle-income countries (LMICs) [1,2]. Preterm neonates and those with low birth weight are particularly vulnerable due to immature immune systems and prolonged exposure to invasive procedures [3]. Early prediction and detection of sepsis are critical for improving outcomes; however, challenges arise from nonspecific clinical presentations; delays in conventional diagnostics such as blood cultures; and the limited reliability of biomarkers, including C-reactive protein (CRP), procalcitonin, and complete blood count [3-7]. The increasing prevalence of multidrug-resistant organisms further complicates treatment, emphasizing the need for innovative tools to optimize antibiotic use and address antimicrobial resistance (AMR) [8].

Machine learning (ML) has emerged as a promising approach for early sepsis prediction by integrating clinical, laboratory, and electronic health record (EHR) data [9-13]. Algorithms such as Extreme Gradient Boosting (XGBoost) and neural networks can detect complex patterns in large datasets, enabling rapid risk assessment and potential early intervention [12-14]. Challenges such as class imbalance, where nonsepsis cases dominate datasets, can reduce model sensitivity, while overfitting may limit generalizability in single-center cohorts [15-17]. Techniques including the synthetic minority oversampling technique (SMOTE) and regularization address these issues but remain underexplored in LMIC contexts [4,18,19].

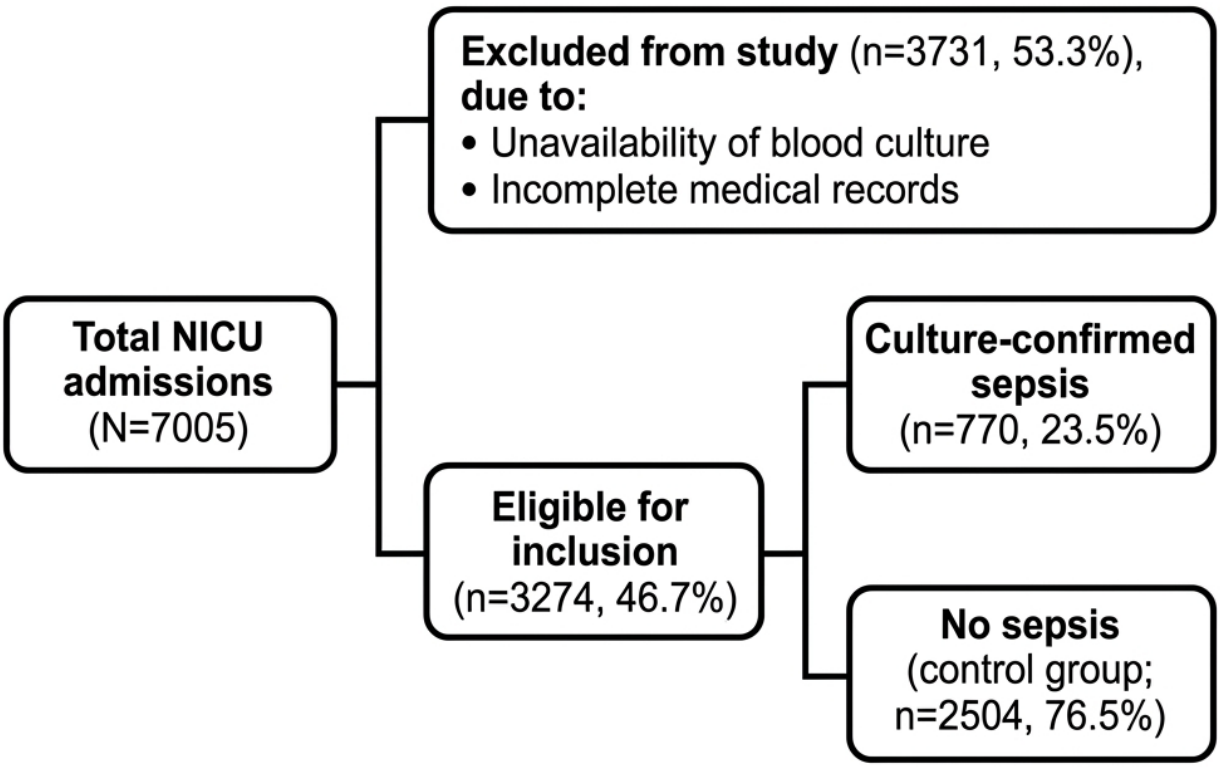
Previous studies have primarily focused on high-income countries [19-22], with limited evidence from regions such as Jordan, where resource constraints and unique epidemiological profiles necessitate context-specific approaches [3]. Emerging research in other LMICs has begun to address this gap, with ML models for NS showing promise in diverse settings, including India [23], Uganda [24], and Ethiopia [25]. In this context, this study aimed to evaluate ML models for predicting culture-confirmed NS in a Jordanian tertiary neonatal intensive care unit (NICU), addressing key diagnostic challenges in resource-limited settings. Specifically, we aimed to identify important predictors through feature importance analysis, assess model performance in the presence of class-imbalanced data, and explore strategies to enhance interpretability and generalizability in LMIC contexts. To support these objectives, we implemented an adaptable framework integrating SMOTE with XGBoost, providing a reproducible approach for early sepsis detection and future multicenter validation.

Methods

Ethical Considerations

The data used in this study were originally collected for a prior investigation on trends in NS organisms and antimicrobial sensitivity (Institutional Review Board of Jordan University [IRB] approval 10/2023/16360). For this secondary analysis, deidentified datasets were repurposed to predict NS using ML. All procedures adhered to international and national ethical standards, including the Declaration of Helsinki. Data were anonymized and accessible only to the research team. Because the study involved retrospective records without direct patient contact, a waiver of informed consent was approved by the Scientific Research Ethics Committee University of Jordan, School of Medicine (IRB 787/2023/76; renewal 4531/2025/67).

Study Design and Population



A retrospective cohort study was conducted at the 34-bed NICU of Jordan University Hospital, which admits approximately 1000 neonates annually. Between October 2018 and April 2024, 7005 neonates were admitted. Of these 7005 neonates, 3731 (53.3%) were excluded due to unavailability of blood culture data, leaving 3274 (46.7%) eligible for inclusion in the 3 predictive ML models for NS evaluation. Among the 3274 included cohort, 770 (23.5%) had culture-confirmed sepsis. Figure 1 shows the cohort flow diagram.

The eligibility criteria and definition of sepsis used to determine inclusion and classify the study population were as follows:

- Inclusion criteria: neonates aged <28 days at admission who had blood cultures collected and complete clinical, laboratory, and demographic data were included in the study.
- Exclusion criteria: neonates with incomplete records or no blood culture data were considered ineligible and therefore excluded from the study.
- Sepsis definition: sepsis status was classified based on the presence or absence of culture-confirmed sepsis, with sepsis=1 indicating culture-confirmed sepsis and sepsis=0 indicating no clinical or laboratory evidence of sepsis.

XSL•FO
RenderX

Figure 1. Flow diagram of participant selection. NICU: neonatal intensive care unit.

Data Sources and Categories

Data were extracted from the NICU EHR system and included the following variables:

- Demographics: including birth weight, gestational age (GA), delivery mode, APGAR (appearance, pulse, grimace, activity, and respiration) scores at 1 and 5 minutes, sex, and exclusive breastfeeding
- Clinical indicators: including prolonged rupture of membranes (PROM), respiratory distress, and neonatal resuscitation
- Laboratory variables: including blood culture, CRP, white blood cell (WBC) count, absolute neutrophil count, neutrophil-to-lymphocyte ratio, platelet count (PLT), and hemoglobin
- Procedural data: including central venous catheter placement, invasive ventilation, surgery, blood transfusion, lumbar puncture, and chest tube insertion

A complete description of all predictor variables, including definitions, measurement units, timing, and transformations applied, is provided in Table S1 in Multimedia Appendix 1.

Preprocessing Steps

The dataset of 3274 neonates was randomly divided into training and testing sets using stratified sampling to preserve the original sepsis class distribution (23.5% sepsis in both subsets), with a training set comprising 2619 (80%) neonates and a testing set comprising 655 (20%) neonates.

Handling Missing Data

Missing values were imputed using the mean for continuous variables and the mode for categorical variables to provide a

XSL•FO
RenderX

consistent preprocessing framework across all evaluated ML models. This deterministic approach was selected to ensure reproducibility and comparability between algorithms. However, we acknowledge that missingness in routinely collected clinical data is frequently informative rather than completely random. Consequently, simple imputation may not fully capture the underlying data-generating mechanisms and may influence predictive performance. More sophisticated approaches, such as multiple imputation, model-based imputation, or missingness-aware ML algorithms, should be evaluated in future studies [9,17].

Normalization

Continuous variables were scaled using minimum-maximum normalization (0-1) to ensure a uniform feature range [9,17].

Categorical Encoding

Categorical variables (eg, mode of delivery and sex) were 1-hot encoded to enable integration with tree-based and neural network algorithms.

Temporal Alignment

To minimize temporal leakage, all predictor variables included in model development were restricted to information available at or before the time of blood culture sampling, which represented the prediction time point. For procedural variables (eg, central line insertion, intubation, and catheter-related procedures), the EHR contained temporal indicators (date [DD/MM/YYYY] and time [HH:MM]) specifying whether the procedure occurred before sample collection. Only procedures documented before blood culture sampling were eligible for inclusion in the predictive models. Variables occurring after the prediction time, such as exclusive breastfeeding at discharge, were excluded from model development and retained only for descriptive analyses.

Demographic and Clinical Characteristics

Overview

Baseline demographic and clinical characteristics of the cohort are summarized in Table S2 in Multimedia Appendix 2. In the cohort of 3247 neonates, 1334 (40.7%) were female, and 1940 (59.3%) were male, with a mean postnatal age at sampling of 4.88 (SD 9.9) days and a mean GA of 35.53 (SD 3.4) weeks. Exclusive breastfeeding was reported in 1574 (48.1%) neonates, and PROMs (>18 hours) occurred in 443 (13.5%) cases.

Birth Weight Distribution

The distribution of 3274 neonates according to birth weight category was as follows:

- Extremely low birth weight (<1000 g): 109 (3.3%) neonates
- Very low birth weight (1000-1500 g): 229 (7%) neonates
- Low birth weight (1500-2500 g): 1084 (33.1%) neonates
- Normal birth weight (2500-4000 g): 1793 (54.8%) neonates
- High birth weight (>4000 g): 56 (1.7%) neonates

Delivery and Clinical Outcomes

The mean APGAR scores were 7.58 (SD 1.25) at 1 minute and 8.84 (SD 0.69) at 5 minutes. In the cohort of 3274 cases, delivery was by cesarean section in 2399 (73.3%) cases and by vaginal delivery in 875 (26.7%) cases. Clinical interventions included intubation in 296 (9%) neonates, umbilical venous catheter placement in 392 (12%) neonates, central line placement in 30 (0.9%) neonates, blood transfusion in 323 (9.9%) neonates, cardiopulmonary resuscitation in 135 (4.1%) neonates, and surgery in 179 (5.5%) neonates. Mortality occurred in 171 (5.2%) neonates.

ML Models

Overview and Workflow

Three ML models—XGBoost (version 2.1.0; XGBoost Developers, 2024), neural networks, and decision trees—were applied to predict culture-confirmed NS. The modeling workflow included feature selection, class imbalance handling, and overfitting mitigation to ensure robust and reproducible predictions.

Feature Selection

XGBoost was used for recursive feature elimination and feature importance analysis to identify predictors critical to NS [17,19].

Addressing Class Imbalance

The dataset showed a strong imbalance between nonsepsis (majority) and sepsis (minority) cases. To mitigate this imbalance, the following approaches were used: oversampling, in which the minority class (sepsis=1) was oversampled using SMOTE, applied only to training folds during model training; and class weights, in which the loss functions in XGBoost and neural networks incorporated class weights to improve sensitivity to the minority class without biasing overall predictions [18,19].

Overfitting Mitigation

XGBoost

Overfitting in XGBoost was mitigated using L1 (reg_alpha) and L2 (reg_lambda) regularization, with the maximum tree depth limited to 5.

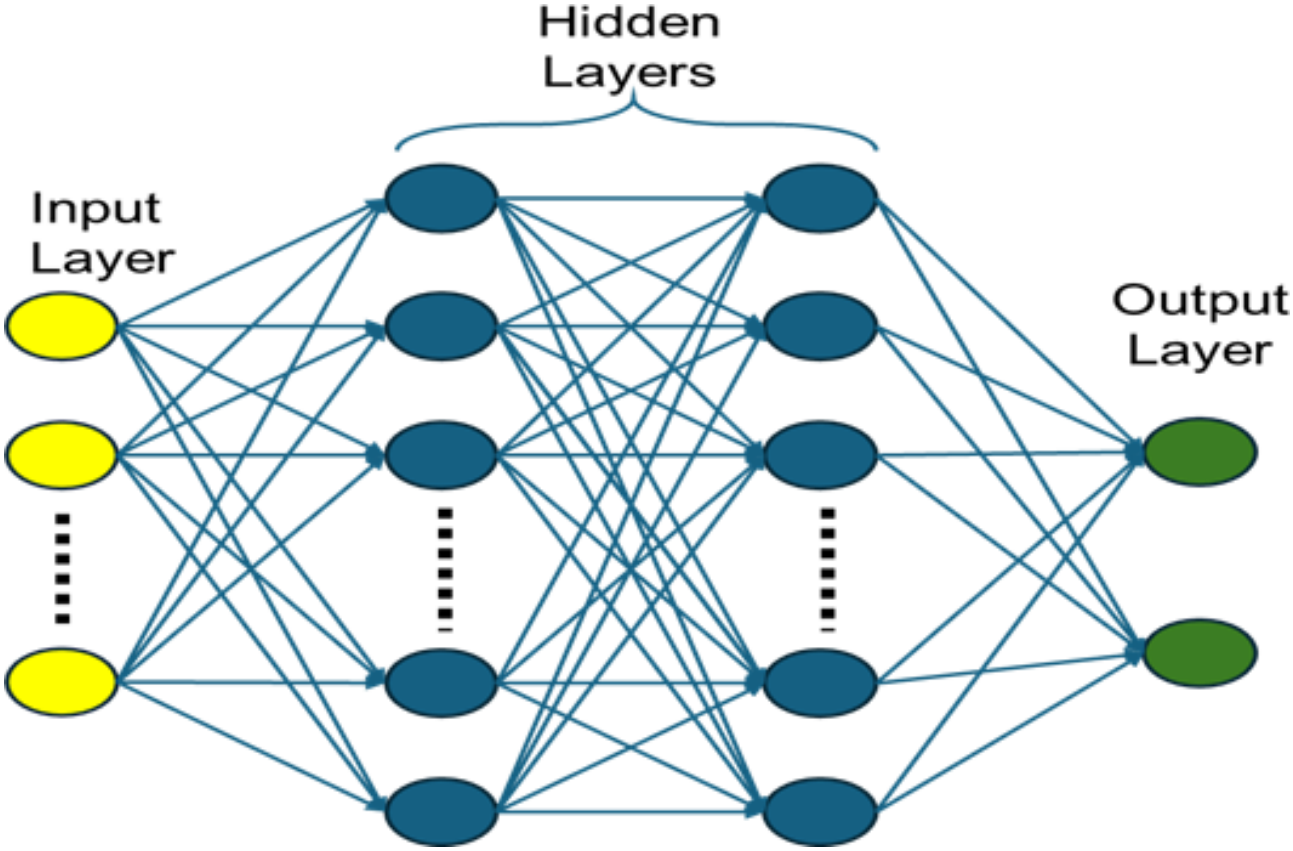
Neural Network

Overfitting in the neural network was mitigated using a multilayer perceptron (MLP) with 2 hidden layers of 100 neurons each, rectified linear unit (ReLU) activation, L2 regularization, early stopping, and feature scaling.

Decision Trees

Overfitting in the decision tree models was mitigated by limiting the maximum depth to 5, setting the minimum samples per split to 10, and setting the minimum number of samples per leaf to 5.

XGBoost



XGBoost is an implementation of gradient-boosted decision trees that builds multiple trees sequentially, where each subsequent tree corrects the errors of the previous tree. The model incorporates L1 and L2 regularization to prevent overfitting. Refer to Multimedia Appendix 3 for the complete mathematical formulation, including the regularized objective function and regularization terms.

XSL•FO
RenderX

Neural Network

The neural network used in this study is an MLP classifier with an input layer, 2 hidden layers of 100 neurons each using ReLU activation, and an output layer for binary classification. The model was optimized using the Adam optimizer. Refer to Multimedia Appendix 3 for the mathematical formulation of neuron activation and loss functions. Figure 2 shows the neural network architecture.

Figure 2. Two-hidden-layer multilayer perceptron architecture for neonatal sepsis, with rectified linear unit activation.

Decision Tree

The decision tree classifier splits data at each node based on criteria that maximize information gain or minimize Gini impurity. Tree depth was limited to 5, with minimum samples per split of 10 and minimum samples per leaf of 5 to prevent overfitting. Refer to Multimedia Appendix 3 for the mathematical formulations of Gini impurity and information gain.

Evaluation of Model Performance

For XGBoost, 95% CIs for accuracy, recall (sensitivity), and specificity were calculated using the Wilson score method, while area under the receiver operating characteristic curve (AUC) CIs were estimated using the DeLong method. For the neural network and decision tree models, all performance metric CIs (accuracy, sensitivity, specificity, precision, recall, F_1-score, and AUC) were estimated using bootstrap resampling with 1000 iterations.

Results

Feature Importance

The feature importance analysis was obtained from the XGBoost algorithm. Table 1 presents the contribution of each feature to predicting sepsis, ranked by their respective *F* scores. The *F* score indicates how many times a feature is used to perform a data split across all decision trees in the XGBoost model. Features with higher *F* scores are more frequently chosen for partitioning, exerting a greater impact on the model's predictions, while features with lower *F* scores have less influence.

XSL•FO
RenderX

Table . Feature importance and their *F* scores derived from the Extreme Gradient Boosting (XGBoost) model for neonatal sepsis prediction.

Features	*F* scores
C-reactive protein (mg/L)	826.0
Platelets count (×10 /L)	641.0
Hemoglobin (g/dL)	561.0
White blood cell count (×10 /L)	497.0
Neutrophils (%)	416.0
Gestational age (wks)	395.0
Absolute neutrophils count (×10 /L)	391.0
Lymphocyte (%)	387.0
Red blood cell count (×10^{12}/L)	347.0
Neutrophil-to-lymphocyte ratio	250.0
APGAR[a] at 1 minute	196.0
Duration of umbilical venous catheterization (days)	151.0
Age at intubation (days)	141.0
Mode of delivery	82.0
Exclusive breastfeeding at discharge[b]	78.0
Patient age at admission (days)	69.0
Umbilical line age (days)	56.0
Sex	52.0
APGAR at 5 minutes	43.0
Age at central line insertion (days)	36.0
Low birth weight	33.0
Very low birth weight	28.0
Surgical procedure	25.0
Extremely low birth weight	22.0
Normal birth weight	22.0
Prolonged rupture of membranes	21.0
Umbilical venous catheter	18.0
Intervention	16.0
Intubation in relation to blood culture sampling	12.0
Chest tube	9.0
Hepatitis B vaccine	1.0
Central line insertion in relation to blood culture sampling	1.0
Blood transfusions	0.0

[a]APGAR: appearance, pulse, grimace, activity, and respiration.

[b]Exclusive breastfeeding at discharge was included in model-derived feature importance only. It is not a clinically valid predictor for real-time sepsis prediction because it was not temporally available. No causal or clinical inference should be made from this variable.

The most significant predictors of sepsis included CRP (*F* score=826.0), PLT (*F* score=641.0), hemoglobin (*F* score=561.0), and GA (*F* score=395.0). Moderately influential predictors were WBC count (*F* score=497.0) and neutrophil percentage (*F* score=416.0), with elevated neutrophils being strongly associated with bacterial invasion, consistent with the pathophysiology of sepsis. The APGAR score at 1 minute (*F* score=196.0) correlated with perinatal stress, such as hypoxia or trauma, highlighting birth complications as a potentially modifiable risk factor.

Exclusive breastfeeding at discharge (*F* score=78.0) appeared in the feature importance analysis derived from the trained XGBoost model; however, it is not temporally available at the time of prediction and therefore is not a clinically valid predictor for real-time sepsis detection.

XSL•FO
RenderX

In contrast, central line insertion and chest tube interventions had much lower *F* scores, suggesting a smaller role in model decisions. This analysis highlights which clinical parameters are most vital for predicting NS.

Overall Model Performance

All 3 ML models were evaluated for their ability to predict NS. XGBoost showed the best accuracy and discriminatory power, followed by the decision tree and neural network models. Across models, the incorporation of class imbalance handling, feature selection, and overfitting mitigation contributed to improved sensitivity for minority sepsis cases while maintaining balanced performance for the majority class. The overall trends suggest that tree-based models, particularly gradient boosting, may be better suited for structured neonatal EHR data, while neural networks demonstrated moderate performance likely limited by dataset size and hyperparameter sensitivity.

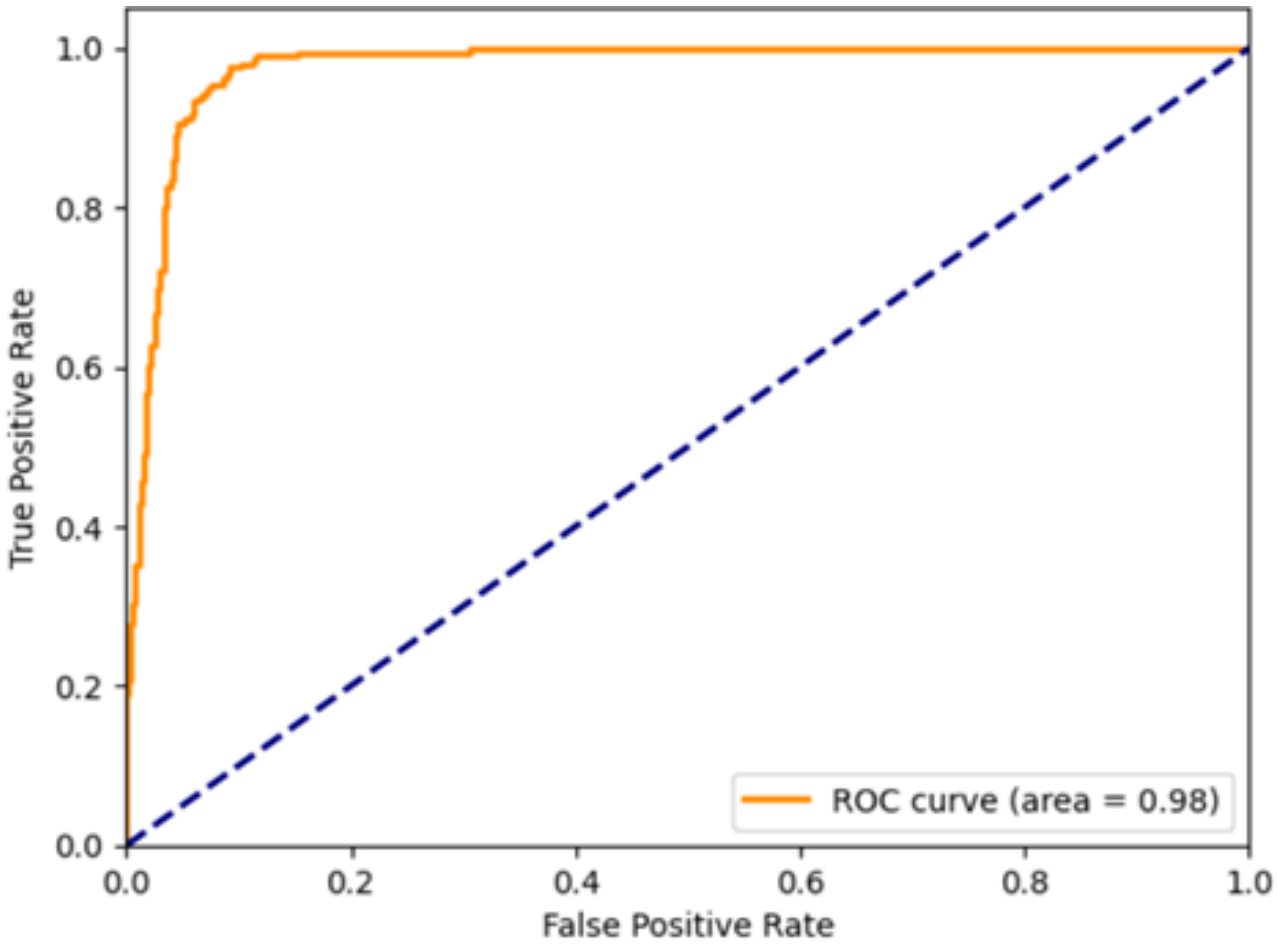
The results are summarized in Table 2. Each model offered unique strengths and trade-offs regarding accuracy, recall, and precision, reflecting its suitability for this specific task.

Table . Comparative performance metrics of machine learning models for neonatal sepsis prediction[a].

Models	Accuracy, % (95% CI)	Precision	Recall (95% CI)	F_1-score	AUC[b] (95% CI)
Extreme Gradient Boosting	94 (92-96)	0.91	0.98 (0.96-0.99)	0.94	0.98 (0.97-0.99)
Neural network	75 (71-78)	0.74	0.73 (0.69-0.76)	0.74	0.81 (0.78-0.84)
Decision tree	80 (77-83)	0.77	0.84 (0.81-0.87)	0.80	0.86 (0.83-0.89)

[a]All metrics were calculated on the independent test set (N=655).

[b]AUC: area under the receiver operating characteristic curve.



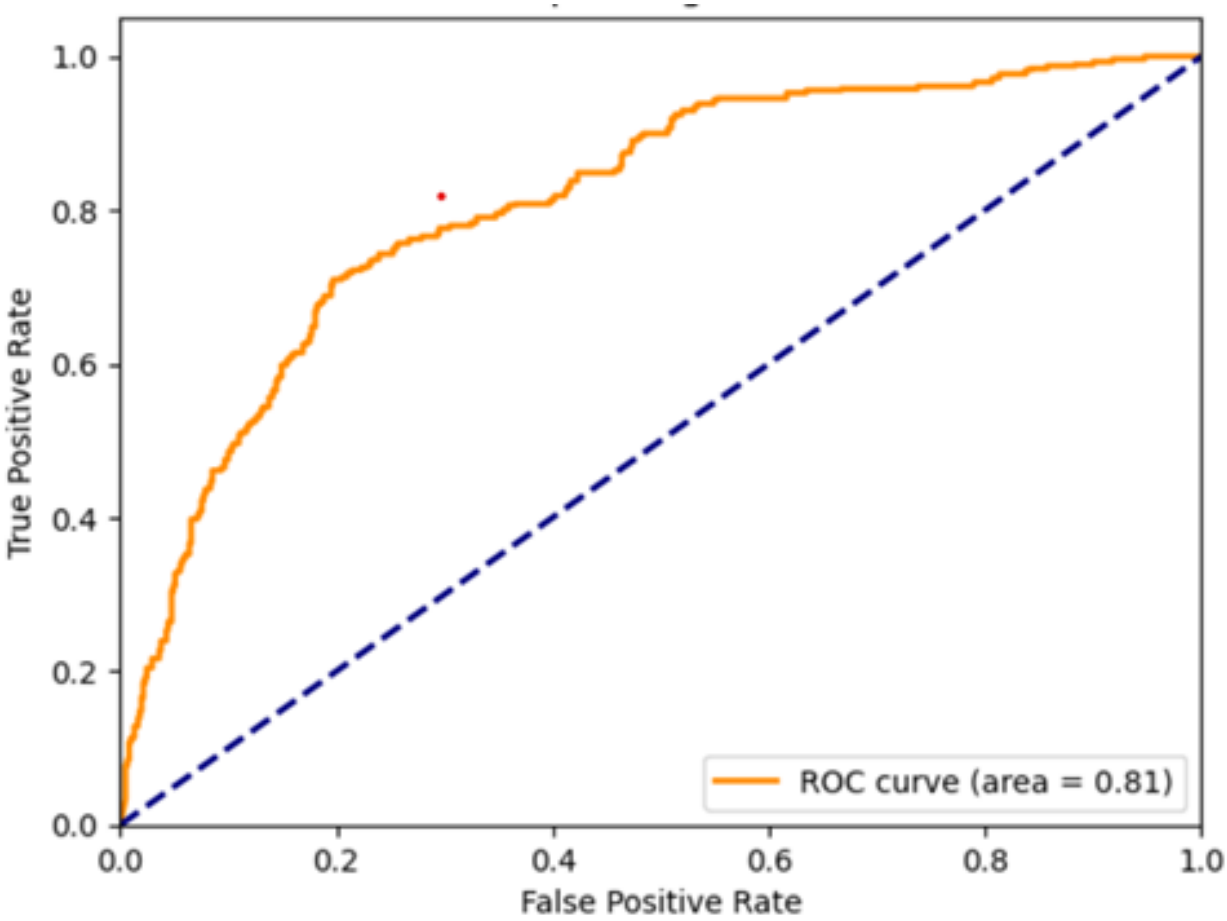
XGBoost Performance

XGBoost demonstrated superior performance among the 3 models. It achieved a mean cross-validation accuracy of 93.7% (SD 1.2%) and a test accuracy of 94% (95% CI 92%-96%; 616/655, 94% correct predictions), making it the most effective model for this task. For sepsis=0, precision was 0.98 (95% CI 0.96-0.99) and recall was 0.91 (95% CI 0.88-0.93), while for sepsis=1, precision was 0.91 (95% CI 0.88-0.93) and recall was 0.98 (95/97, 98% sepsis cases, 95% CI 0.96 to –0.99). The F_1-score for both classes was 0.94, reflecting a strong balance between precision and recall.

Figure 3 shows the receiver operating characteristic (ROC) curve for XGBoost, with an AUC of 0.98 (95% CI 0.97-0.99), indicating excellent discriminatory power. The curve rises steeply near the y-axis, demonstrating the model's ability to correctly classify positive cases while maintaining a minimal false-positive rate. Its proximity to the upper-left corner emphasizes high sensitivity and specificity. These results underscore XGBoost's robustness in handling structured and imbalanced datasets. Its incorporation of class weights and regularization enables a focus on minority classes without compromising overall accuracy, and minimal variation in cross-validation scores confirms stability and generalization capability.

XSL•FO
RenderX

Figure 3. Receiver operating characteristic (ROC) curve for the Extreme Gradient Boosting (XGBoost) model demonstrating high discriminatory power.

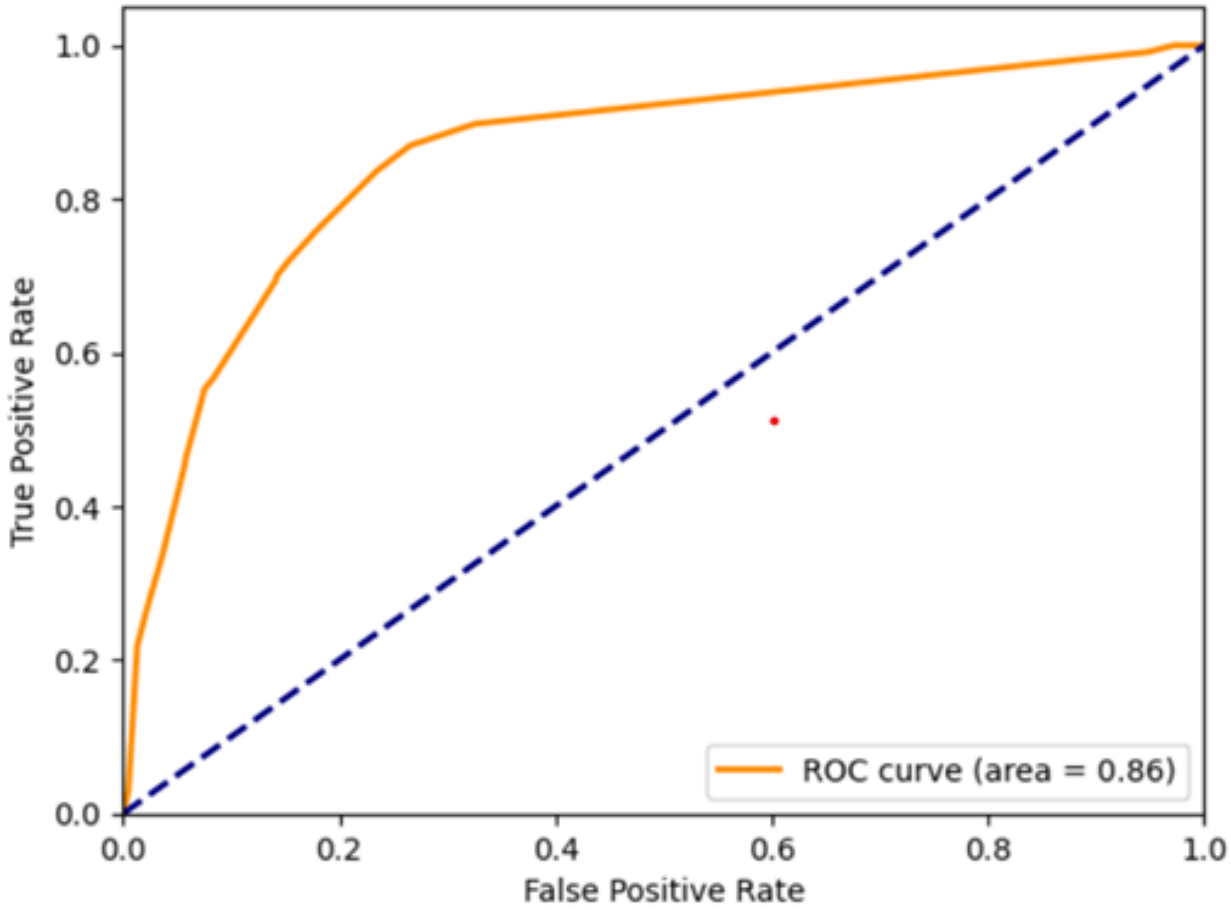


Neural Network Performance

The neural network model, despite its flexibility in modeling complex relationships, underperformed compared to XGBoost. It achieved a test accuracy of 75% (95% CI 71%-78%; 491/655, 75% correct predictions). For sepsis=0, precision was 0.76 (95% CI 0.73-0.79) and recall was 0.77 (95% CI 0.74-0.80). For sepsis=1, precision was 0.74 (95% CI 0.71-0.77) and recall was 0.73 (71/97, 73% sepsis cases, 95% CI 0.70 to –0.76). Figure 4 shows the ROC curve for the neural network, with an AUC of 0.81 (95% CI 0.78-0.84). The curve demonstrates a good, although not perfect, ability to discriminate between positive and negative cases. Its upward trajectory reflects the model's capacity to achieve a high true-positive rate while maintaining a moderate false-positive rate, although deviations from the upper-left corner indicate some misclassification. The lower performance likely stems from the limited dataset size, the neural network's sensitivity to hyperparameters, and the structured nature of the data, which tree-based models such as XGBoost handle more efficiently. Despite these limitations, the neural network demonstrated reasonable predictive capability and could potentially improve with hyperparameter tuning, feature scaling, or a larger dataset.

XSL•FO
RenderX

Figure 4. Receiver operating characteristic (ROC) curve for the neural network model in neonatal sepsis prediction.



Decision Tree Performance

Decision trees are inherently interpretable, making them valuable in clinical applications where understanding model decisions is critical. Pruning techniques, including limiting tree depth and controlling the minimum number of samples per split and leaf, mitigated overfitting and ensured generalization.

The decision tree achieved a mean cross-validation accuracy of 79.1% and a test accuracy of 80% (95% CI 77%-83%; 524/655, 80% correct predictions). Precision and recall were relatively balanced across both classes. For sepsis=0, precision was 0.83 (95% CI 0.80-0.86) and recall was 0.77 (95% CI 0.74-0.80), while for sepsis=1, precision was 0.77 (95% CI 0.74-0.80) and recall was 0.84 (81/97, 84% sepsis cases, 95% CI 0.81 to –0.87). The F_1-score was 0.80 for both classes. Figure 5 shows the ROC curve, with an AUC of 0.86 (95% CI 0.83-0.89), reflecting good discriminative performance. The curve demonstrates the model's ability to correctly identify positive cases, although a moderate false-positive rate is observed. Although its performance was lower than that of XGBoost, the decision tree provides an interpretable and clinically useful alternative for NS prediction.

Discussion

In this retrospective cohort study of 3274 neonates in a Jordanian tertiary NICU, the XGBoost ML model achieved excellent discrimination for culture-confirmed NS, with an accuracy of 94% (616/655 correct predictions, 95% CI 92%-96%), a sensitivity of 98% (95/97 sepsis cases, 95% CI 96%-99%), a specificity of 91% (508/558 nonsepsis cases, 95% CI 89%-93%), and an AUC of 0.98 (95% CI 0.97-0.99), outperforming neural networks (AUC 0.81, 95% CI 0.78-0.84) and decision trees (AUC 0.86, 95% CI 0.83-0.89).

Model Performance and Clinical Implications

This study highlights the transformative potential of ML for NS prediction, especially in resource-constrained settings. XGBoost emerged as the top-performing model, achieving consistent performance across all folds with a mean accuracy of 93.7% (SD 1.2%), a mean AUC of 0.98 (SD 0.01), and a mean sensitivity of 0.97 (SD 0.02). Minimal fold-wise variance confirmed strong generalizability, with better performance than neural networks (AUC 0.81, 95% CI 0.78-0.84) and decision trees (AUC 0.86, 95% CI 0.83-0.89).

These findings align with prior studies identifying gradient-boosting algorithms as particularly well-suited for structured medical data due to their robustness against class imbalance and capacity for regularization [19,22]. A recent systematic review also identified ensemble methods such as XGBoost among the top-performing models, despite heterogeneity in study designs and outcomes [26]. Our model (AUC 0.98) compares favorably with LMIC-based studies, including a regression nomogram from Ethiopia (AUC 0.81) [25] and an electronic medical record–based model from Uganda with moderate performance [24]. Together, these findings suggest that gradient boosting may outperform traditional regression approaches in LMIC settings, although external validation remains necessary.

Feature importance analysis further reinforced clinical relevance, with CRP, PLT, and GA identified as top predictors, consistent with established biomarkers for early sepsis detection [3,18].

Decision trees, while slightly less accurate (accuracy 80%, 95% CI 77%-83%; AUC 0.86, 95% CI 0.83-0.89), provided interpretable decision pathways that may support clinical decision-making and bridge the gap between algorithmic outputs and bedside practice [22].

Addressing Methodological Challenges

Class imbalance, a pervasive issue in medical ML, was mitigated using SMOTE oversampling and class-weighted loss functions, improving sensitivity to sepsis cases (recall 0.98, 95% CI 0.96 - 0.99) without compromising specificity [17,18]. Overfitting risks were addressed via L1/L2 regularization in XGBoost and neural networks, alongside constrained tree depth in decision trees [17,19]. Cross-validation ensured internal generalizability, although the single-center, retrospective design limits external validity. Collectively, these strategies may

XSL•FO
RenderX

enhance model reliability and adhere to best practices for ML implementation in LMICs [15,20-26].

Strengths

This study demonstrates high diagnostic accuracy, with XGBoost achieving an AUC of 0.98 (95% CI 0.97-0.99), surpassing conventional biomarker-based approaches and enabling timely identification of NS. The model effectively identifies actionable predictors, including CRP, PLT, and GA, which align with clinical workflows and support targeted monitoring. Additionally, the study effectively addressed class imbalance using SMOTE and class-weighted loss functions, improving detection of sepsis cases without compromising performance for the majority class. Collectively, these methodological innovations may enhance the robustness and clinical relevance of the predictive framework for LMIC neonatal populations.

Limitations

The retrospective, single-center design may introduce selection bias and limits generalizability to other NICU settings or populations. The analysis was restricted to culture-positive cases, which may exclude culture-negative sepsis, limiting the ability to predict sepsis in its earliest stages. The timing of feature availability relative to sepsis onset is also uncertain, which may impact true early prediction. Although temporal constraints were applied to all procedural variables included in the predictive models, some laboratory and intervention-related variables may still partially reflect clinician-driven diagnostic or treatment decisions rather than purely biological manifestations of NS. Consequently, feature importance should be interpreted as reflecting predictive utility within the study cohort rather than causal relationships. Although cross-validation reduces overfitting, external validation in multicenter prospective cohorts is necessary to confirm model performance. Exclusive breastfeeding at discharge was included only in descriptive analyses and feature importance. It was not available at the time of prediction and is not a clinically valid predictor for real-time sepsis detection due to temporal misalignment. An additional limitation relates to missing data handling. Although mean and mode imputation provided a simple and consistent preprocessing strategy across all ML models, this approach assumes that missing values can be adequately represented by measures of central tendency. Because missingness in EHRs is often informative and not completely at random, the present results should be interpreted with this limitation in mind. Future studies should investigate advanced imputation techniques, such as multiple imputation, missing-indicator approaches, sensitivity analyses under different missingness assumptions, and missingness-aware learning methods, to evaluate their impact on predictive performance and model robustness. Finally, algorithmic transparency and data privacy considerations could influence clinical trust and adoption, highlighting the need for interpretability tools and secure integration into EHR systems.

Future Directions

Prospective multicenter validation is essential to ensure the robustness and generalizability of the models across diverse geographic and demographic neonatal cohorts. Recent comprehensive reviews have highlighted both the potential and the challenges of implementing AI for NS in resource-limited settings, emphasizing the need for context-specific solutions and robust external validation [27]. Integrating AMR data into ML frameworks could optimize antibiotic stewardship and support clinical decision-making in LMIC settings. Region-specific model tuning, using localized datasets and tailored algorithms, could enhance predictive accuracy and applicability for neonatal populations with unique epidemiological characteristics. Furthermore, the adoption of interpretability tools such as Shapley Additive Explanations (SHAP) or Local Interpretable Model-Agnostic Explanations (LIME) can improve clinician trust, facilitate integration into EHR systems, and support transparent, actionable insights for bedside decision-making. These interpretability considerations align with recommendations from recent scoping reviews, which emphasize that clinician trust and model transparency are critical barriers to real-world implementation of ML for NS [28].

Conclusions

This study represents the first ML-driven approach tailored to NS prediction in Jordan, addressing diagnostic gaps and highlighting the need for region-specific models in LMICs. Our findings demonstrate that ML models, particularly XGBoost, can integrate heterogeneous clinical, laboratory, and demographic data to provide actionable predictions, potentially enabling earlier interventions and improved neonatal outcomes. Although challenges such as class imbalance, data limitations, and ethical considerations remain, methodological innovations in regularization, oversampling, and interpretability may enhance model reliability and usability. Future work should focus on prospective multicenter validation, incorporation of AMR patterns, and equitable model deployment to support clinical decision-making and reduce neonatal mortality in resource-limited settings.

Acknowledgments

The authors extend their gratitude to Mrs Safa Al Momani from the Information Technology department and Mr Khader Al Zaben from the Department of Statistics at Jordan University Hospital for their invaluable assistance in facilitating access to data from the electronic health record system. All authors declare that they had insufficient funding to support the open access publication of this manuscript, including from affiliated organizations or institutions, funding agencies, or other organizations. JMIR Publications provided article processing fee (APF) support for the publication of this article. The APF support was approved for #02 geobased-LMIC. The authors also declare that generative AI technology (ChatGPT-4.0; OpenAI) was used exclusively to enhance readability and language clarity during manuscript preparation. Specifically, it assisted with grammar and syntax

Abstract

Background: Sepsis-induced coagulopathy (SIC) is a common and severe complication in patients with sepsis, characterized by microvascular thrombosis, systemic endothelial damage, and markedly increased short-term mortality. Existing traditional clinical risk scoring systems demonstrate limited accuracy and fail to capture complex, nonlinear physiological interactions, underscoring the urgent need for advanced prognostic tools.

Objective: The objective of this study was to develop and validate an interpretable machine learning (ML) model using large-scale, multicenter databases to predict early mortality in intensive care unit (ICU) patients with SIC and to evaluate its predictive performance and clinical utility compared with traditional clinical risk scores.

Methods: The study retrospectively analyzed clinical data of patients with SIC from the Medical Information Mart for Intensive Care IV (MIMIC-IV), the eICU Collaborative Research Database (eICU-CRD), and Tianjin Medical University General Hospital. Feature selection was performed using LASSO (least absolute shrinkage and selection operator) regression, the Boruta algorithm, and recursive feature elimination with cross-validation, combined with multivariable logistic regression. Twelve ML algorithms were trained and compared with 4 traditional clinical scoring systems (Sequential Organ Failure Assessment, Acute Physiology and Chronic Health Evaluation II, Simplified Acute Physiology Score II, and Oxford Acute Severity of Illness Score) to predict 28-day mortality after ICU admission. Model discrimination, calibration, and clinical utility were assessed using the area under the curve (AUC), calibration curves, and decision curve analysis. Furthermore, Shapley additive explanations (SHAP) values were used to ensure model interpretability and to identify individual pathophysiological drivers.

Results: A total of 7980 (66.3%) patients with SIC from the MIMIC-IV database, 3815 (31.7%) from the eICU-CRD database, and 235 (2.0%) from Tianjin Medical University General Hospital were included in the study. Ten independent predictors were identified to construct the model. The XGBoost (extreme gradient boosting) model performed the best, with an AUC of 0.899 (95% CI 0.889 - 0.909) in the internal validation set and 0.882 and 0.904 in the 2 external validation sets, significantly outperforming traditional scoring systems and demonstrating higher clinical net benefit. SHAP analysis identified that the top 5 critical features were anion gap, red blood cell distribution width, lactate, total bilirubin, and age. Furthermore, an easy-to-use online tool, SIC Predict Streamlit, was developed based on this model to enable clinicians to quickly assess patient risk.

Conclusions: The ML model developed in this study demonstrated superior accuracy, robustness, and generalizability in predicting early mortality in patients with SIC. The model outperformed traditional clinical scoring tools, and the findings provide valuable insights for prognostic assessment and the individualized management of patients with SIC.

Introduction

Sepsis is a clinical syndrome associated with severe infection, characterized by life-threatening organ dysfunction resulting from a dysregulated host response to infection [1]. According to the Global Burden of Disease Study, the global age-standardized incidence rate of sepsis in 2017 was 677.5 (535.7 - 876.1) cases per 100,000 population (0.7%). Sepsis-related deaths account for approximately 20% of all global deaths, making it one of the leading threats to human life [2]. Sepsis-induced coagulopathy (SIC) is characterized by vascular endothelial injury and coagulation dysfunction induced by sepsis [3]. Globally, SIC occurs in 24.0% to 60.0% of patients with sepsis; if not managed properly, it may progress to disseminated intravascular coagulation, increasing the mortality rate by up to 2-fold [4,5].

In 2017, the International Society on Thrombosis and Haemostasis (ISTH) established specific criteria and a scoring system for SIC, which primarily evaluates the condition based on the degree of thrombocytopenia, the international normalized ratio (INR), and the Sequential Organ Failure Assessment (SOFA) score. SIC is defined as a total score ≥4, and patients with a score of ≥4 have a mortality rate exceeding 30% [6,7]. These studies highlight the importance of identifying high-risk populations for SIC and implementing timely interventions. Currently, developing effective tools to accurately assess the prognosis of SIC and dynamically optimize treatment strategies has become an urgent priority for clinicians.

The development of machine learning (ML) has opened up new opportunities for clinical medical research [8]. Compared to traditional statistical models, such as logistic regression or Cox proportional hazards models, ML techniques have demonstrated superior performance in disease prediction and prognosis [9,10]. However, there remains significant room for improvement in the existing studies regarding the application of ML to predict outcomes in SIC [11-13]. These studies exhibit specific methodological limitations and suboptimal predictive performance. Specifically, models developed by Lu et al [11] and Liu et al [13] achieved moderate area under the curve (AUC) values (0.81 and 0.795, respectively) but were constrained by single-center designs and a complete lack of external validation. Although Zhou et al [12] developed an externally validated extreme gradient boosting (XGBoost) model with an internal AUC of 0.828, their study lacked essential clinical utility assessments, such as decision curve analysis (DCA), to confirm actual clinical net benefit. In light of these limitations, this study aims to construct a novel prediction model to improve predictive accuracy and enhance the overall reliability and robustness of the research findings.

Therefore, the primary aim of this study is to develop and validate a high-performance, interpretable ML model for the early prediction of 28-day mortality in patients with SIC. We leveraged and compared 12 different ML algorithms using diverse, large-scale multicenter datasets, including the Medical Information Mart for Intensive Care IV (MIMIC-IV), the eICU Collaborative Research Database (eICU-CRD), and electronic medical records from Tianjin Medical University General Hospital. We hypothesize that optimized ML algorithms can effectively capture the complex, nonlinear pathophysiological trajectories of SIC, thereby significantly outperforming traditional clinical risk assessment models—such as SOFA, Acute Physiology and Chronic Health Evaluation II (APACHE II), Simplified Acute Physiology Score II (SAPS II), and Oxford Acute Severity of Illness Score (OASIS)—in prognostic accuracy. Additionally, Shapley additive explanations (SHAP) was used to visualize feature contributions, thereby enhancing the model's transparency and providing clinicians with actionable insights to guide early, individualized interventions and optimize clinical resource allocation [14].

Methods

Study Design

This study was conducted and reported in strict accordance with the Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis for Artificial Intelligence (TRIPOD+AI) 2024 guidelines (Checklist 1).

Data Source

A multicenter retrospective study was conducted using deidentified data from the MIMIC-IV (v3.1) database [15], the eICU-CRD (v2.0) database [16], and the emergency intensive care unit (EICU) data from Tianjin Medical University General Hospital. The MIMIC-IV database includes hospitalization records from 2008 to 2019 at the Beth Israel Deaconess Medical Center in Boston, Massachusetts. It contains data from over 65,000 intensive care unit (ICU) admissions and more than 200,000 emergency department visits. The eICU-CRD is a multicenter database containing data on over 200,000 ICU admissions across the United States between 2014 and 2015. One of the authors, JS, completed the Collaborative Institutional Training Initiative program (Certification Number: 64628900), signed the data use agreement, and obtained access to both the MIMIC-IV and eICU-CRD databases. Additionally, patients with SIC admitted to the EICU of Tianjin Medical University General Hospital between October 2021 and December 2023 with complete data were retrospectively included as an external validation cohort.

Ethical Considerations

This study was approved by the Ethics Committee of Tianjin Medical University General Hospital (approval number: IRB2023-YX-045 - 01). Written informed consent was waived due to the retrospective nature of the study.

Participants

Patients were included if they met the following criteria: (1) first-time ICU admission (patients with previous ICU stays and potential prior SIC episodes were systematically excluded from the analysis), and (2) patients with sepsis who were diagnosed with SIC within 24 hours of ICU admission. Sepsis was defined according to the Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3), which includes patients with confirmed or suspected infection and a SOFA total score ≥2 [1]. Suspected infection was defined as the administration of antibiotics within 3 days of culture specimen collection. SIC

XSL•FO
RenderX

was defined according to the ISTH criteria [6]. The diagnosis of SIC in patients with sepsis was established based on the best clinical and laboratory values (including platelet count and INR) obtained within the first 24 hours after ICU admission, ensuring rigorous patient selection. Detailed diagnostic criteria for SIC are provided in Table S1 in Multimedia Appendix 1.

The exclusion criteria were as follows: (1) age less than 18 years; (2) ICU length of stay less than 24 hours; (3) receipt of anticoagulation therapy prior to ICU admission; (4) history of primary coagulation disorders, hemophilia, or immune thrombocytopenia; (5) history of malignancy; (6) history of cirrhosis; (7) pregnancy; and (8) missing clinical data or incomplete laboratory records.

Variable Extraction

PostgreSQL (version 17.6; PostgreSQL Global Development Group) and R (version 4.5.1; R Foundation for Statistical Computing) were used for data extraction and processing. Data extracted from the MIMIC-IV database included the following: (1) demographic characteristics: age, gender, height, and weight; (2) vital signs: heart rate, respiratory rate, temperature, oxygen saturation (SpO_2), noninvasive systolic and diastolic blood pressure, and mean arterial pressure; (3) clinical risk assessment models: SOFA [17], APACHE II [18], SAPS II [19], and OASIS [20]; (4) laboratory tests: lymphocytes, white blood cells, hemoglobin, platelet count, red blood cell distribution width (RDW), neutrophils, albumin, anion gap (AG), total calcium, potassium, sodium, glucose, lactate, D-dimer, functional fibrinogen, INR, prothrombin time, partial thromboplastin time (PTT), alanine aminotransferase, aspartate aminotransferase (AST), total bilirubin, creatinine, blood urea nitrogen (BUN), C-reactive protein, and bicarbonate; (5) comorbidities determined by *International Classification of Diseases, Ninth Revision* and *International Classification of Diseases, Tenth Revision* diagnostic codes: pneumonia, stroke, chronic kidney disease, type 2 diabetes, heart failure, myocardial infarction, and coronary heart disease; (6) interventions: mechanical ventilation, continuous renal replacement therapy, fluid intake, vasopressors, glucocorticoids, and antibiotics; and (7) outcomes: 28-day mortality after ICU admission and in-hospital mortality. For vital signs and laboratory tests, data within 24 hours prior to ICU admission were included. If multiple measurements were available, the mean value was used. The primary outcome of this study was 28-day mortality after ICU admission. Patients without a death record within 28 days of ICU admission were considered survivors.

Feature Engineering

Feature engineering was performed in three steps:

First step was identification and handling of missing values. The R package "VIM" was used to identify missing values. To minimize bias caused by missing data, variables with more than 30% missing values were excluded. The percentage of missing values in the database is shown in Table S2 in Multimedia Appendix 1. Missing data imputation was performed using multiple imputation (MI) via the R package *mice*. Crucially, to prevent potential data leakage, imputation was conducted strictly after data splitting. The imputation models were trained exclusively on the training set and subsequently applied to the internal validation set. Furthermore, given the distinct clinical environments and potential differences in missingness mechanisms, the external validation datasets (the eICU-CRD and the Tianjin Medical University General Hospital cohort) were imputed independently. We evaluated 3 methods: predictive mean matching, classification and regression trees (CART), and random forest (RF). The CART algorithm was identified as the optimal method due to its superior convergence and distributional consistency. Standard MI typically requires pooling models via Rubin rules; however, this is computationally prohibitive and clinically impractical for complex, nonlinear ML algorithms like XGBoost. Therefore, as a widely adopted pragmatic approach in predictive modeling, the CART imputation was repeated 10 times to account for imputation uncertainty. The 10 resulting complete datasets were then aggregated into a single robust dataset by calculating the mean for continuous variables and the mode for categorical variables, which was subsequently used for model training and validation.

Second step was handling of outliers. Given the presence of equipment artifacts and data entry errors inherent in large electronic health records, a rigorous data cleaning procedure was implemented prior to analysis. We established clinically plausible physiological ranges for continuous variables based on clinical domain expertise. Values falling outside these physiologically possible ranges were defined as artifactual errors and were converted to missing values prior to imputation. However, extreme values that remained within biologically plausible limits were intentionally retained, as they reflect genuine severe pathological states in critically ill patients. For example, in the context of severe sepsis and systemic hypoperfusion, profound hyperlactatemia (eg, lactate >15 mmol/L) or severely elevated transaminases (eg, AST >1000 U/L) are true manifestations of severe metabolic derangement and ischemic hepatitis (shock liver), rather than measurement errors [21]. This strategy ensures data integrity while preserving valuable high-risk prognostic signals.

Third step was feature selection for model construction. The final feature set for the ML models was selected based on the training set using LASSO (least absolute shrinkage and selection operator) regression, the Boruta algorithm, RF-based recursive feature elimination with cross-validation (RFECV), and multivariable logistic regression. While simpler single-method strategies exist, clinical datasets are often noisy and highly collinear. Therefore, we adopted a multimethod ensemble approach to overcome the intrinsic biases of individual algorithms. Specifically, LASSO regression introduces L1 regularization into the objective function, selecting features and reducing dimensionality by shrinking coefficients, retaining features with significant contributions, and eliminating redundant ones [22]. The Boruta algorithm identifies the most important features by comparing the *Z*-value of each feature with that of the "shadow features" [23]. Recursive feature elimination (RFE), acting as a greedy algorithm, ranks and selects features based on their importance through iterative training, combined with 10-fold cross-validation to select clinical variables [24]. Furthermore, 10-fold cross-validation was embedded within both the LASSO and RFECV procedures,

XSL•FO
RenderX

serving as an inherent feature-stability assessment. Prior to final confirmation, the variance inflation factor (VIF) was calculated [25]. A VIF of 1 indicates no multicollinearity; a VIF between 1 and 5 indicates moderate collinearity; a VIF >5 indicates high collinearity; and a VIF >10 indicates severe multicollinearity. Variables exhibiting high collinearity were accordingly removed. The features commonly selected across methods were finally evaluated using a multivariable logistic regression model to adjust for confounding effects and confirm them as statistically independent risk factors for the prognosis of SIC.

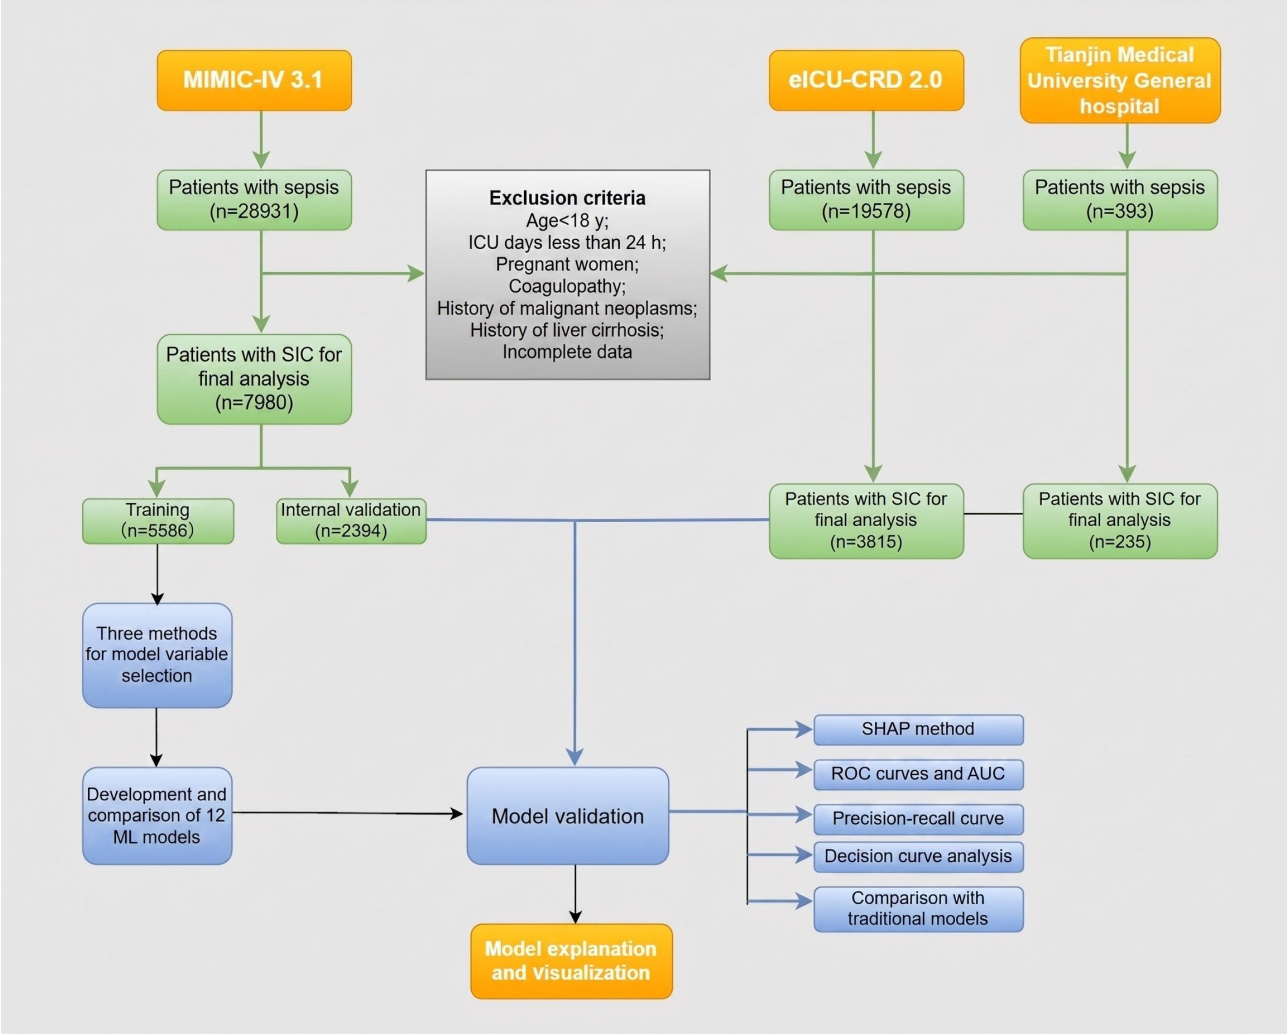
Statistical Analysis

The Shapiro-Wilk test was used to assess the normality of continuous variables. Continuous variables conforming to a normal distribution were expressed as mean (SD), while those with a nonnormal distribution were expressed as median (IQR). Categorical variables were presented as counts and percentages. For comparisons of continuous variables between groups, a 2-tailed independent sample *t* test was used if the assumption of normality was met; otherwise, the Wilcoxon rank-sum test was applied. Pearson chi-square (χ^2) test was used for categorical variables, while Fisher exact test was used when the expected frequency was <1 or the total sample size was <40. All statistical tests and calculations were performed using Python (version 3.11; Python Software Foundation) and the R package "tableone." All charts were generated using the R package "ggplot2." A *P* value <.05 was considered statistically significant.

Model Development and Comparison

The MIMIC-IV database was randomly split into a training set (5586/7980, 70%) and an internal validation set (2394/7980, 30%). Ten features were used to construct the task-specific models. Stratified sampling was performed using the R package "createDataPartition" to ensure a balanced distribution of the original outcomes between the 2 subsets. A total of 12 ML algorithms were used to construct the models, including logistic regression, support vector machine, decision tree (DT), gradient boosting decision tree, light gradient boosting machine, categorical boosting, RF, naive Bayes, k-nearest neighbors, adaptive boosting, XGBoost, and artificial neural network. To comprehensively evaluate the models, we used a multidimensional assessment strategy. Initially, fundamental classification metrics, including AUC, sensitivity, specificity, accuracy, false negative rate (FNR), false positive rate (FPR), and F_1-score, were calculated. Furthermore, considering the potential class imbalance, the precision-recall curve was adopted [26]. To assess clinical utility and reliability, calibration curves were used to evaluate the model's calibration, and DCA was performed using the R package "rmda" to quantify the clinical net benefit [27].

To enhance the reliability and robustness of the models, both internal and external validations were performed. The internal validation set was derived from the MIMIC-IV database. Two independent datasets were used for external validation: the eICU-CRD database as external validation set I and the Tianjin Medical University General Hospital database as external validation set II. To address the class imbalance issue that could significantly distort performance metrics, the synthetic minority oversampling technique was applied during model training [28]. The SHAP algorithm was used to interpret the predictions of the ML models by calculating the SHAP value for each feature, quantifying their contributions to the prediction outcomes, and identifying critical features that influence model decisions [29]. Subsequently, univariate and multivariable logistic regression and regression-based prediction models were used to compare the ML model with 4 commonly used clinical risk assessment models (SOFA, APACHE II, SAPS II, and OASIS) in the internal validation set and in external validation set I. External validation set II served as an independent dataset that more closely resembled real-world clinical scenarios and was used to further validate the clinical applicability of the optimal model. Furthermore, to assess internal consistency and mitigate the risk of overfitting, 10-fold cross-validation was applied during the training phase for the prognostic models.



Results

Baseline Characteristics

As shown in Figure 1, from an initial cohort of 28,931 patients with sepsis in the MIMIC-IV database, 20,951 (72.4%) were excluded and 7980 (27.6%) were included; of 19,578 patients with sepsis in the eICU-CRD database, 15,763 (80.5%) were excluded and 3815 (19.5%) were included; and of 393 patients with sepsis from Tianjin Medical University General Hospital, 158 (40.2%) were excluded and 235 (59.8%) were included. In total, 12,030 patients with SIC were analyzed across the 3 cohorts, comprising 7980 (66.3%), 3815 (31.7%), and 235 (2.0%) patients, respectively. Table 1 summarizes the baseline demographic and clinical characteristics of the MIMIC-IV cohort, with a focus on 28-day mortality as the primary outcome and in-hospital mortality as the secondary outcome. Among these participants, 6015 survived (75.4%) and 1965 died (24.6%). The overall extent of missing data is presented in Table S2 in Multimedia Appendix 1. Clinical data for the 2 external validation cohorts are provided in Tables S3 and S4 in Multimedia Appendix 1.

The optimal ML algorithm was identified as “cart,” selected based on the convergence and consistency of the distribution between imputed and observed values. This process was repeated 10 times, and the mean of the results was used to impute missing data for further analysis.

Variable Selection

The initial selection of these 41 candidate variables was comprehensively determined based on a literature review of previous prognostic studies on sepsis and coagulopathy, established clinical guidelines, and the routine availability of these variables in the ICU. Specifically, demographic characteristics, vital signs, interventions, and laboratory parameters were included as they have been widely validated as crucial predictors of mortality in patients with sepsis [30-32]. The RFE method combined with 10-fold cross-validation was used for preliminary screening, retaining 39 variables associated with the risk of short-term mortality (Figure 2A). The Boruta algorithm selected 34 variables classified as “Confirmed”; the results of the Boruta-based feature selection are illustrated in Figure 2B. Subsequently, LASSO coefficient analysis was performed. By minimizing binomial deviance through 10-fold cross-validation, the optimal lambda value (lambda.1se=0.0136) was determined, identifying 19 variables with nonzero coefficients (Figure 2C). Figure 2D shows the cross-validation curve for LASSO regression, demonstrating the binomial deviance across different lambda values. The feature subset was determined by the intersection of the 3 selection methods (Figure 2E). Finally, multivariable logistic regression analysis identified 10 variables significantly associated with the outcome, including AG, RDW, lactate, total bilirubin, age, BUN, SpO_2, PTT, heart rate, and vasopressors (Table S5 in Multimedia Appendix 1). All variables remained independently predictive after adjustment. VIF analysis showed no significant multicollinearity among the variables (Table S6 in Multimedia Appendix 1).

Model Development and Validation

Based on the identified features, 12 ML models were developed to predict the prognosis of patients with SIC. The AUC, accuracy, recall, F_1-score, specificity, FPR, and FNR were calculated to comprehensively evaluate the models. Based on these evaluations, the XGBoost model demonstrated the best performance. In the internal validation cohort, the XGBoost model achieved an area under the receiver operating characteristic curve (AUROC) of 0.899 (95% CI 0.889 - 0.909), with accuracy, F_1-score, and specificity of 0.818, 0.819, and 0.817, respectively (Table 2 and Figure 3). The confusion matrix revealed 1628 true negatives (TNs), 196 true positives (TPs), 402 false negatives (FNs), and 168 false positives (FPs) regarding 28-day mortality (Figure 4A). The model's performance was further validated using external validation sets I and II. In external validation set I, the AUROC was 0.882 (95% CI 0.867 - 0.897), and the model's accuracy, F_1-score, and specificity were 0.805, 0.803, and 0.813, respectively (Table S7 in Multimedia Appendix 1). The confusion matrix showed 2264 TNs, 372 TPs, 316 FNs, and 863 FPs (Figure 4B). External validation set II assessed the clinical applicability of the model, with an AUROC of 0.904 (95% CI 0.846 - 0.962), with accuracy, F_1-score, and specificity of 0.815, 0.811, and 0.818, respectively (Table S7 in Multimedia Appendix 1). The confusion matrix indicated 158 TN, 13 TP, 29 FN, and 30 FP (Figure 4C). Finally, the 12 models were used to evaluate in-hospital mortality in patients with SIC within the internal validation cohort. The results showed that the XGBoost model continued to perform excellently, with an AUROC (95% CI) of 0.963 (0.958 - 0.968; Table S8 in Multimedia Appendix 1), further confirming the model's predictive accuracy for the prognosis of SIC.

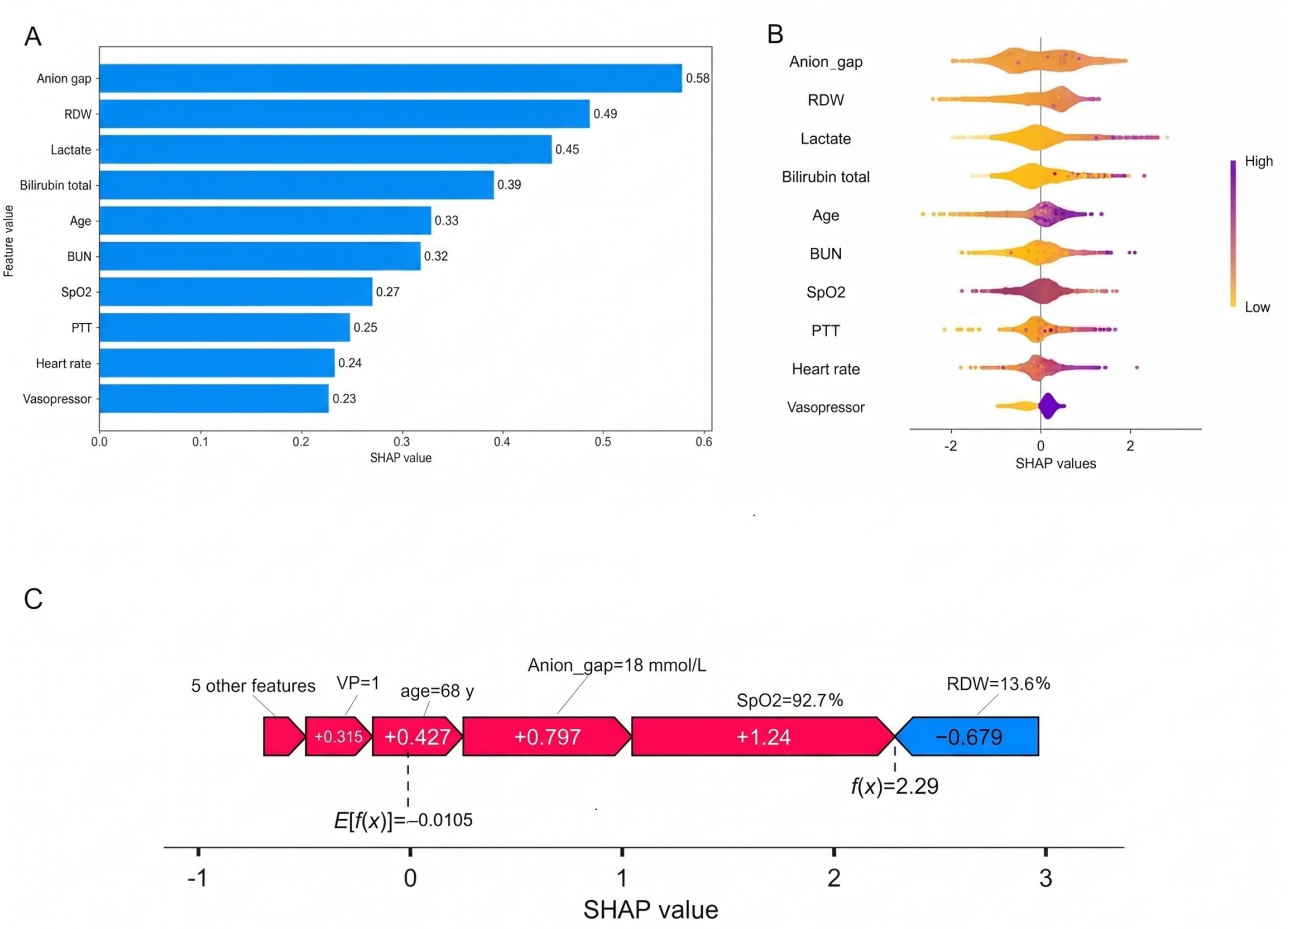
Figure 4. Confusion matrices for predicting 28-day mortality across different cohorts. (A) Internal validation set. (B) External validation set I. (C) External validation set II. The x-axis represents the predicted outcome, and the y-axis represents the actual outcome. The diagonal elements represent correct predictions (true negatives and true positives), while the off-diagonal elements represent misclassifications. Darker colors indicate a higher number of patients.



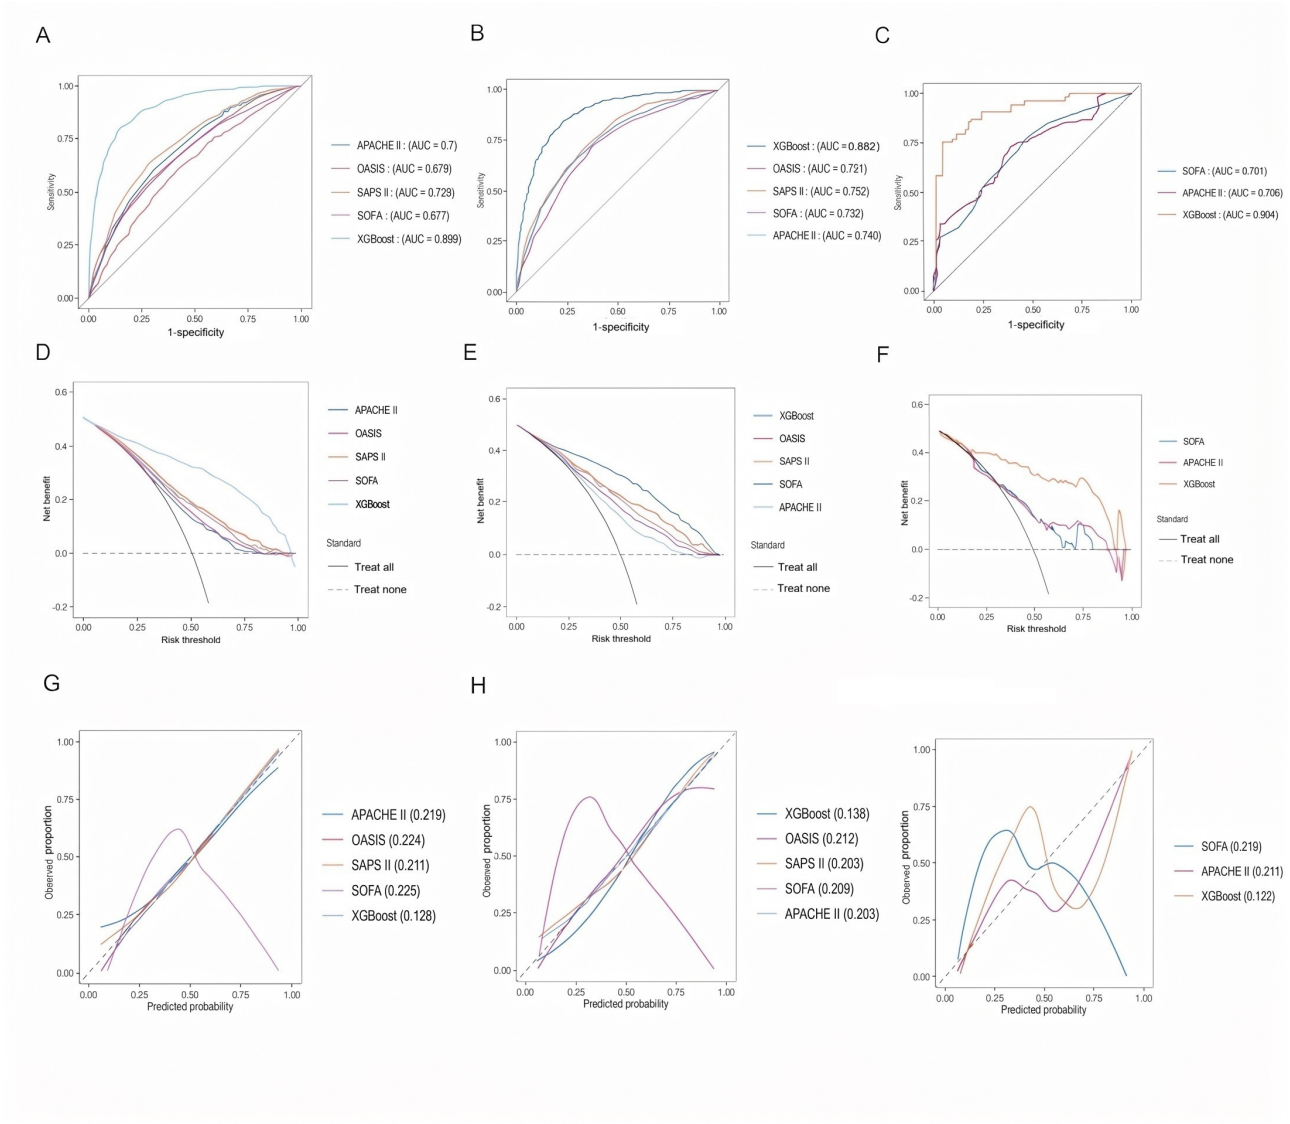
Furthermore, to assess the robustness and generalizability of the XGBoost model, 10-fold cross-validation was performed to examine its predictive efficacy. Detailed performance metrics and ROC curve results (Table S9 and Figure S1 in Multimedia Appendix 1) indicated that the constructed model exhibited favorable robustness and generalizability, with no signs of overfitting or underfitting.

To enhance the interpretability of the model, the SHAP method was used to quantify the contribution of each input feature to the model's predictions. The importance scores of the 10 features used in the XGBoost model were calculated to identify critical factors (Figure 5A and B). The position on the y-axis implicitly indicates the ranking of feature importance, while the x-axis represents the relationship between feature values and their corresponding SHAP values. For instance, the SHAP values for advanced age were generally greater than zero, indicating that the risk of mortality in patients with SIC increases with age. Furthermore, feature importance results based on absolute SHAP values revealed that the top 5 risk features for SIC were AG, RDW, lactate, total bilirubin, and age. Specifically, the analysis revealed a consistent positive correlation for the top 5 key predictors: higher levels of AG, elevated RDW, increased lactate concentrations, higher total bilirubin, and advanced age were all robustly associated with an increased predicted risk of 28-day mortality. For this specific patient, SHAP results indicated that the critical threshold values for predicting the probability of poor prognosis were AG=18

XSL•FO
RenderX

mmol/L, RDW=13.6%, SpO_2=92.7%, and age=68 years (Figure 5C).

Figure 5. Visualization of feature importance and model interpretation using Shapley additive explanations (SHAP). (A) Bar plot illustrating the mean absolute SHAP values, ranking the top 10 features by their global importance in the XGBoost model. (B) SHAP summary plot. Each dot represents a single patient sample. The position on the x-axis indicates the SHAP value (impact on model output), while the color gradient represents the feature value (purple color indicates high values, and yellow color indicates low values). Positive SHAP values suggest an increased risk of mortality. (C) SHAP force plot for an individual patient case. Red arrows represent features that increase the prediction score (higher risk), while blue arrows represent features that decrease the score (lower risk). The length of the arrow reflects the magnitude of the feature's contribution. BUN: blood urea nitrogen; PTT: partial thromboplastin time; RDW: red blood cell distribution width; SpO_2: oxygen saturation; vp: vasopressor.



Model Comparison

The performance of the XGBoost model was compared with that of 4 clinical risk assessment models using the internal validation set. The XGBoost model demonstrated the best discriminative ability (AUC=0.899) (Figure 6A). Univariate logistic regression analysis revealed statistically significant odds ratios (ORs) for all models, with the XGBoost model exhibiting the largest effect size (OR 47.96, 95% CI 37.43 - 61.81; P<.001). Multivariable regression analysis indicated significant predictive associations for the adjusted XGBoost model (OR 31.45, 95% CI 24.05 - 41.35; P<.001), SAPS II, and OASIS, with the XGBoost model maintaining the strongest prognostic relationship (Table S10 in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 6. Performance comparison and clinical utility assessment of the XGBoost model vs traditional clinical risk assessment models. (A-C) Receiver operating characteristic curves comparing the discriminative ability of the XGBoost model with APACHE II, OASIS, SAPS II, and SOFA scores. (A) Internal validation set. (B) External validation set I. (C) External validation set II. (D-F) Decision curve analyses illustrating the clinical net benefit at different threshold probabilities. (D) Internal validation set. (E) External validation set I. (F) External validation set II. The black line represents the strategy of treating all patients, while the horizontal dashed line represents treating none. (G-I) Calibration plots assessing the agreement between predicted probabilities and observed outcomes. (G) Internal validation set. (H) External validation set I. (I) External validation set II. The diagonal dotted line represents ideal calibration. APACHE II: Acute Physiology and Chronic Health Evaluation II; AUC: area under the curve; OASIS: Oxford Acute Severity of Illness Score; SAPS II: Simplified Acute Physiology Score II; SOFA: Sequential Organ Failure Assessment; XGBoost: extreme gradient boosting.

The same analysis was repeated using external validation set I, and the XGBoost model consistently demonstrated the best predictive accuracy for 28-day mortality (AUC=0.882; Figure 6B). Univariate logistic regression analysis indicated that all models were statistically significant, with the XGBoost model retaining the most significant risk association (OR 77.47, 95% CI 54.98 - 110.57; *P*<.001). Following multivariable adjustment, the XGBoost model (OR 52.05, 95% CI 36.23 - 75.70; *P*<.001), SAPS II, OASIS, and APACHE II maintained significant prognostic associations, further confirming the robust predictive capability of the XGBoost model (Table S11 in Multimedia Appendix 1). Analysis of the external validation set II further assessed the model's robust clinical adaptability (AUC=0.904; Figure 6C). Consistent with previous findings, logistic regression in this cohort revealed that the XGBoost model maintained an exceptionally strong association with mortality in both univariate (OR 122.34, 95% CI 30.21 - 649.17; *P*<.001) and multivariable analyses (OR 113.88, 95% CI 24.32 - 762.29; *P*<.001). In contrast, traditional scores showed limited predictive value in multivariable analysis (Table S12 in Multimedia Appendix 1).

Clinical Utility

To objectively evaluate the clinical utility of the ML models in predicting 28-day mortality, calibration plots were generated using the bootstrap method, and DCA was performed for each model in the internal validation set and in 2 external validation sets. The DCA results indicated the net benefit of model-guided interventions across various threshold probabilities. A high net benefit indicates that using the model to trigger aggressive therapies, such as intensive fluid resuscitation, improves overall patient outcomes compared to treating all patients or none

XSL•FO
RenderX

(Figure 6D-F). Calibration curve analysis demonstrated that the XGBoost model maintained high consistency between predicted probabilities and actual outcomes. This accuracy builds physician trust for individual risk stratification (Figure 6G-I). Considering the potential application of our model in future clinical practice, a user-friendly web-based tool, SIC Predict Streamlit, was developed [33]. This tool enables medical professionals to easily input key patient parameters to rapidly assess the mortality risk associated with SIC, thereby improving clinical resource utilization.

Discussion

Principal Findings

In this study, we developed and validated SIC clinical prognosis prediction models based on 12 ML algorithms using 3 independent databases. The performance of each model was evaluated using AUROC, accuracy, recall, F_1-score, and specificity, identifying the XGBoost model as having the optimal performance. This model exhibited excellent discriminative ability and robustness in both internal and external validation sets, significantly outperforming traditional risk assessment tools (SOFA, APACHE II, SAPS II, and OASIS). Clinically, by translating these robust algorithms into an accessible online calculator, this study provides a highly interpretable decision support tool that enables frontline clinicians to achieve early risk stratification, guide timely individualized interventions, and optimize the allocation of intensive care resources.

SIC is a common and fatal complication in patients with sepsis, characterized by a vicious cycle of microvascular thrombosis and organ perfusion failure. The occurrence and severity of SIC are independently associated with in-hospital mortality [4,34]. Although the ISTH criteria provide a framework for identifying SIC, existing clinical scoring systems have inherent limitations in dynamic and individualized prognostic assessment [35,36]. Most of these models are based on linear assumptions, making it difficult to capture the highly nonlinear processes of physiological compensation and decompensation in SIC. In contrast, advanced ML algorithms, particularly tree-based ensemble methods such as XGBoost, are inherently designed to overcome these analytical bottlenecks. Unlike simpler linear models (eg, logistic regression), XGBoost iteratively constructs multiple DTs to minimize prediction errors, allowing it to automatically capture complex, higher-order interactions among diverse clinical variables [37]. This makes XGBoost exceptionally well-suited for modeling the intricate, multisystem pathophysiological cascades of SIC, thereby offering a more precise and individualized prognostic evaluation.

To enhance the robustness and reliability of the model and eliminate irrelevant or highly collinear features, feature selection was performed using the following 3 methods: LASSO regression, the Boruta algorithm, and RFECV. This process identified 10 independent predictors associated with the prognosis of SIC. Furthermore, to enhance interpretability and facilitate clinical adoption, we implemented SHAP to visualize feature contributions and elucidate the decision-making process of the model [38]. SHAP importance analysis revealed that the top 5 key features were AG, RDW, lactate, total bilirubin, and age. These indicators reflect the body's metabolic status, organ function, and physiological reserve capacity and are closely correlated with the pathophysiological mechanisms of SIC.

AG is a crucial indicator for assessing acid-base balance and is commonly associated with metabolic acidosis [39]. Previous studies have shown that for each 1 mmol/L increase in AG, the risk of mortality can increase by 5% to 10% [40]. In patients with SIC, elevated AG suggests severe tissue hypoperfusion, cellular metabolic dysfunction, and multiple organ failure, serving as a comprehensive marker of disease severity. These represent the core pathological processes of sepsis-induced coagulation disorders. Sepsis leads to microcirculatory dysfunction, increasing the accumulation of acidic metabolites such as lactate, thereby widening the AG. A high AG not only indicates metabolic acidosis but is also associated with inflammatory cascades and coagulation activation, which further exacerbate endothelial injury and thrombosis, leading to a worse prognosis.

RDW reflects the heterogeneity of red blood cell size; its elevation is closely related to inflammatory responses, oxidative stress, and malnutrition [41]. In SIC, a persistent inflammatory state suppresses bone marrow function and shortens red blood cell lifespan, leading to increased RDW. This may worsen prognosis by affecting microcirculation and exacerbating coagulation abnormalities (such as platelet activation and fibrin deposition), reflecting the chronicity and systemic inflammatory burden of sepsis [42-44].

Lactate is a direct marker of tissue hypoxia and anaerobic metabolism [45]. Microcirculatory dysfunction and tissue hypoperfusion lead to increased lactate production and decreased clearance. Hyperlactatemia not only suggests circulatory failure but is also associated with the progression of coagulation dysfunction, including endothelial cell activation and thrombosis, ultimately leading to organ failure [46]. Sepsis-induced liver injury (such as ischemic hepatitis or inflammatory cytokine storms) causes bilirubin metabolism disorders, further aggravating coagulation abnormalities. This correlates with multiple organ failure, forming a vicious cycle [47].

Advanced age reduces physiological reserve and enhances a prothrombotic state; older patients are more prone to coagulation activation and endothelial dysfunction, resulting in worsened prognosis [48]. For older patients with SIC, clinical decision-making should be more prudent, necessitating a balance between treatment benefits and risks to formulate individualized treatment plans.

Beyond physiological interpretation, individualized SHAP force plots provide actionable bedside insights. Traditional models merely output a mortality probability. In contrast, SHAP explicitly identifies patient-specific pathophysiological drivers. For example, a high SHAP value for lactate directly alerts physicians to severe tissue hypoxia. This insight promptly guides targeted resuscitation strategies, including fluid optimization and vasopressor adjustments. Ultimately, SHAP transforms static predictions into dynamic guides for personalized critical care.

XSL•FO
RenderX

By integrating large-scale multicenter databases, this study compared the XGBoost model with various ML algorithms and traditional clinical risk prediction models (including SOFA, APACHE II, SAPS II, and OASIS). Both internal and external validation cohorts confirmed the superior predictive capability of the XGBoost model for early mortality. DCA and calibration curves further validated the model's clinical utility and predictive calibration. Compared with other models, the XGBoost model exhibited the widest range of clinically reasonable risk-threshold probabilities and the highest net benefit. Traditional scoring systems are static, weight-based additive systems, whereas ensemble learning models like XGBoost can iteratively learn higher-order interactions among complex features through boosting techniques. For instance, the model may capture synergistic effects between advanced age and delayed lactate clearance or between high bilirubin levels and coagulation disorders, which are nonlinear relationships that traditional statistical models struggle to represent effectively. Furthermore, we did not settle for merely providing a predictive tool with a high AUC; instead, we comprehensively screened for the optimal model using multiple performance metrics. Furthermore, multiple feature selection methods were used to ensure the robustness and biological plausibility of the selected variables. This approach effectively reduced model complexity and the risk of overfitting, ensuring that the model focused on the most biologically significant features. As a result, it provides an efficient and interpretable decision support tool for the prognostic evaluation of SIC.

However, this study has several potential limitations. First, as a retrospective cohort study, it may be subject to selection bias and information bias, and causal relationships cannot be established. Future prospective studies are required to further validate model performance. Second, the model's predictions are based on data obtained within the first 24 hours of ICU admission, without considering the dynamic evolution of the disease. Future research could develop dynamic prediction models incorporating time-series data to facilitate continuous risk assessment. Specifically, advanced deep learning architectures designed for sequential data hold great potential. Using models such as recurrent neural networks, long short-term memory networks, or transformers could enable the dynamic tracking of patient trajectories. Integrating these methodologies will facilitate continuous, real-time risk assessment and further improve prognostic accuracy. Third, although data from multiple centers were included, they were primarily from the United States and China, and the model's performance in other ethnicities and regional populations remains unclear. Additionally, the relatively small sample size of external validation set II (n=235) may affect statistical power and the assessment of generalizability, necessitating further validation. Finally, due to data availability limitations, certain potentially important predictors (such as imaging features and genetic markers) were not included in the model, which may have restricted its predictive performance. Therefore, further validation using prospective, multicenter, and large-scale patient datasets will provide more robust evidence for the XGBoost model's effectiveness and generalizability.

Conclusions

This study developed and validated ML models based on large-scale multicenter databases for predicting early mortality in patients with SIC, demonstrating significant improvement over traditional clinical risk assessment tools across all metrics. SHAP analysis further confirmed the model's interpretability. The findings provide a valuable reference for the prognostic assessment and individualized management of patients with SIC.

Acknowledgments

The authors appreciate the important contributions of all participants in this study. Special thanks are extended to the team at the Laboratory for Computational Physiology at the Massachusetts Institute of Technology for maintaining the eICU Collaborative Research Database and Medical Information Mart for Intensive Care IV databases. The manuscript was edited and refined using the Gemini generative AI tool. This tool was used solely for language enhancement and manuscript polishing, ensuring clarity and coherence in the presentation of the research findings. The authors maintain full responsibility for the content and accuracy of the manuscript.

Funding

This study was funded by the Key Discipline (Specialty) Construction Project of the Tianjin Municipal Health Commission (TJYXZDXK-3 - 009C). The funders had no role in the study design, data collection, data analysis, or writing of the report.

Data Availability

The Medical Information Mart for Intensive Care IV (version 3.1) and eICU Collaborative Research Database (version 2.0) datasets used in this study are publicly available via the PhysioNet platform [49], subject to completion of the necessary data use agreements and relevant training. The dataset from Tianjin Medical University General Hospital is not currently publicly available due to institutional and patient privacy concerns. However, qualified researchers may submit a reasonable request to the corresponding author to gain access to this dataset.

Authors' Contributions

JS, JW, and SS conceived and designed the study. JS, JL, and SF were responsible for data collection, data analysis, and model construction. Y Dong, Y Ding, and DC performed data visualization. JS and Y Dong wrote the initial draft of the manuscript. SS and Y Dong reviewed and revised the manuscript. All authors participated in the review and editing of the manuscript.

Conflicts of Interest

None declared.

Multimedia Appendix 1
Sepsis-induced coagulopathy diagnostic criteria, missing data distributions, baseline patient characteristics, feature selection and collinearity diagnostics, and comprehensive performance metrics of predictive models across internal and external validation cohorts.

Abstract

Background: Postoperative nausea and vomiting are common complications after anesthesia. However, vomiting represents a clinically distinct and objectively measurable endpoint.

Objective: This study aimed to develop and internally validate predictive models for postoperative vomiting within 24 hours using structured perioperative data and unstructured clinical text, while introducing a structured framework that separates feature construction from interpretability using large language models (LLMs).

Methods: We analyzed 33,460 anesthesia records from a single center (2019 - 2022). Two temporally defined prediction tasks were constructed to reflect real-world clinical decision-making and prevent information leakage: a preoperative model using variables available before anesthesia induction, and a perioperative model using variables available up to the end of surgery. Structured data were modeled using machine learning algorithms (logistic regression, Extreme Gradient Boosting, Light Gradient Boosting Machine [LightGBM]). Unstructured clinical text was incorporated through a deterministic, concept-driven preprocessing pipeline, where LLMs were used solely for normalization (temperature=0) without feature generation, followed by rule-based concept mapping and feature encoding. Post hoc interpretability was further supported using an LLM-based Question Answering Chain module. Model performance was evaluated using receiver operating characteristic-area under the curve (AUC), precision-recall AUC, calibration metrics, and threshold-based operating characteristics. Classification thresholds were selected using the Youden J statistic, and all metrics were reported with 95% CIs derived from bootstrap resampling. Decision curve analysis was performed to assess clinical utility.

Results: A total of 33,460 surgical procedures were included, of which 3607 (10.8%) experienced postoperative vomiting within 24 hours. In the preoperative task, LightGBM achieved an AUC of 0.729 (95% CI 0.706 - 0.749), compared with 0.610 (95% CI 0.588 - 0.632) for the Apfel score. In the end-of-surgery task, LightGBM achieved an AUC of 0.735 (95% CI 0.714 - 0.757). At the Youden-optimal threshold, the negative predictive value exceeded 0.95 across all models. Decision curve analysis demonstrated positive net benefit across clinically relevant threshold probabilities. Incorporating text-derived features provided modest improvements, while LLM-based explanation modules generated structured, natural-language explanations intended to enhance interpretability without substantially improving predictive performance.

Conclusions: Machine learning models can effectively predict postoperative vomiting within 24 hours using perioperative data. The proposed framework demonstrates that LLMs can be integrated in a controlled and reproducible manner—restricted to deterministic normalization and post hoc reasoning—to generate natural-language explanations intended to enhance the interpretability of model predictions, without introducing information leakage or altering predictive modeling. As no formal clinician-based evaluation was conducted, this interpretability benefit cannot yet be objectively confirmed, and the generated explanations should be regarded as a useful interpretability aid to be validated in future clinician-centered studies. External, multicenter validation is required before broader clinical applicability can be assumed.

Introduction

Background

In clinical medicine, anesthesia is a fundamental component across a wide range of procedures. However, it is associated with several postoperative complications, among which postoperative nausea and vomiting (PONV) remains one of the most common and clinically significant. PONV can disrupt recovery, increase the risk of secondary complications, prolong hospitalization, and negatively impact patients' perceived quality of life [1].

Accurate identification and stratification of PONV risk factors are essential for guiding preventive strategies. The overall incidence of PONV is estimated at 27.7%, underscoring its clinical importance [2]. Traditional risk assessment approaches primarily rely on static patient characteristics, such as sex, age, smoking status, and prior history of PONV or motion sickness [3,4]. However, these factors alone may be insufficient to capture the complexity of perioperative risk.

Although PONV includes both nausea and vomiting, these outcomes differ in mechanisms and clinical implications. Therefore, this study focuses specifically on postoperative vomiting within 24 hours (POV 24h) as a clearly defined and objectively measurable endpoint. Existing prediction tools, such as Apfel's simplified risk score, report moderate accuracy (55% - 80%) [5], but are largely based on fixed patient characteristics and do not account for the temporal availability of perioperative information [6]. As a result, their applicability in real-time clinical decision-making remains limited.

Despite these advances, current prediction models face several key methodological limitations. First, most models do not explicitly distinguish between variables available at different clinical time points, potentially introducing information leakage by incorporating variables not available at the intended prediction time point, thereby limiting real-world clinical deployment. Second, perioperative factors—such as intraoperative physiological changes and anesthetic exposure—are often underrepresented despite their clinical relevance. Third, unstructured clinical text, including medical history and procedural notes, is rarely incorporated into predictive modeling due to integration challenges.

To address these gaps, we propose a temporally structured prediction framework that separates preoperative and perioperative modeling tasks. In addition, we explore the use of large language models (LLMs) in a structured framework that separates feature construction from interpretability to transform unstructured clinical text into structured representations and to support post hoc clinical reasoning, with the primary goal of generating structured explanations and supporting transparent post hoc review, rather than substantially improving predictive performance.

To evaluate this framework, we conducted a large-scale study using 33,460 anesthesia records, incorporating both structured (eg, physiological parameters, surgical, and anesthetic information) and unstructured data (eg, medical history and procedural notes). The objective of this study was to develop and internally validate predictive models for POV 24h. Two models were constructed based on the availability of clinical data: a preoperative model using variables available before anesthesia induction, and a perioperative model using variables available up to the end of surgery. Furthermore, we investigated whether LLM-based processing of unstructured clinical text could be performed while maintaining methodological rigor and supporting clinically grounded reasoning.

Related Works

To overcome the limitations of conventional models, recent studies have increasingly turned to machine learning (ML) and deep learning (DL) techniques for PONV prediction [7]. These methods are well-suited for analyzing high-dimensional clinical datasets and capturing complex, nonlinear relationships that often elude traditional statistical models [8,9]. Although most prior studies focus on the composite outcome of PONV, vomiting can be assessed as a distinct and clinically measurable postoperative outcome within a defined time frame [10]. Therefore, this study specifically focuses on POV 24h.

Among these approaches, gradient boosting models like LightGBM (Light Gradient Boosting Machine) have been widely used to identify key PONV predictors and assist anesthesiologists in postoperative risk evaluation [11]. Common predictors highlighted across ML studies include sex, smoking status, type of surgical procedure, and use of opioids [12]. DL further advances prediction by modeling intricate interactions among features, with comparative analyses showing that algorithms such as logistic regression, support vector classifiers (SVCs), and AdaBoost frequently outperform traditional scoring systems [13]. Notably, TabNet, a DL architecture tailored for tabular data, leverages instance-level feature selection and attention mechanisms to improve efficiency and model transparency [14].

Despite these advances, the opaque nature of many ML and DL models presents a barrier to clinical adoption. To address this, explainable AI (XAI) techniques such as Shapley Additive Explanations (SHAP) have been introduced to illuminate the decision-making process of complex models. SHAP enables clinicians to assess the influence of individual features on prediction outcomes [15-17]. For instance, Jiang et al [18] demonstrated that incorporating traditional Chinese medicine (TCM) metrics alongside glycosylated hemoglobin levels substantially enhanced the interpretability of ML models in diabetic neuropathy. Similarly, in PONV research, SHAP has revealed previously unrecognized high-dimensional risk factors linked to delayed but clinically significant postoperative nausea and vomiting (CIPONV) [19].

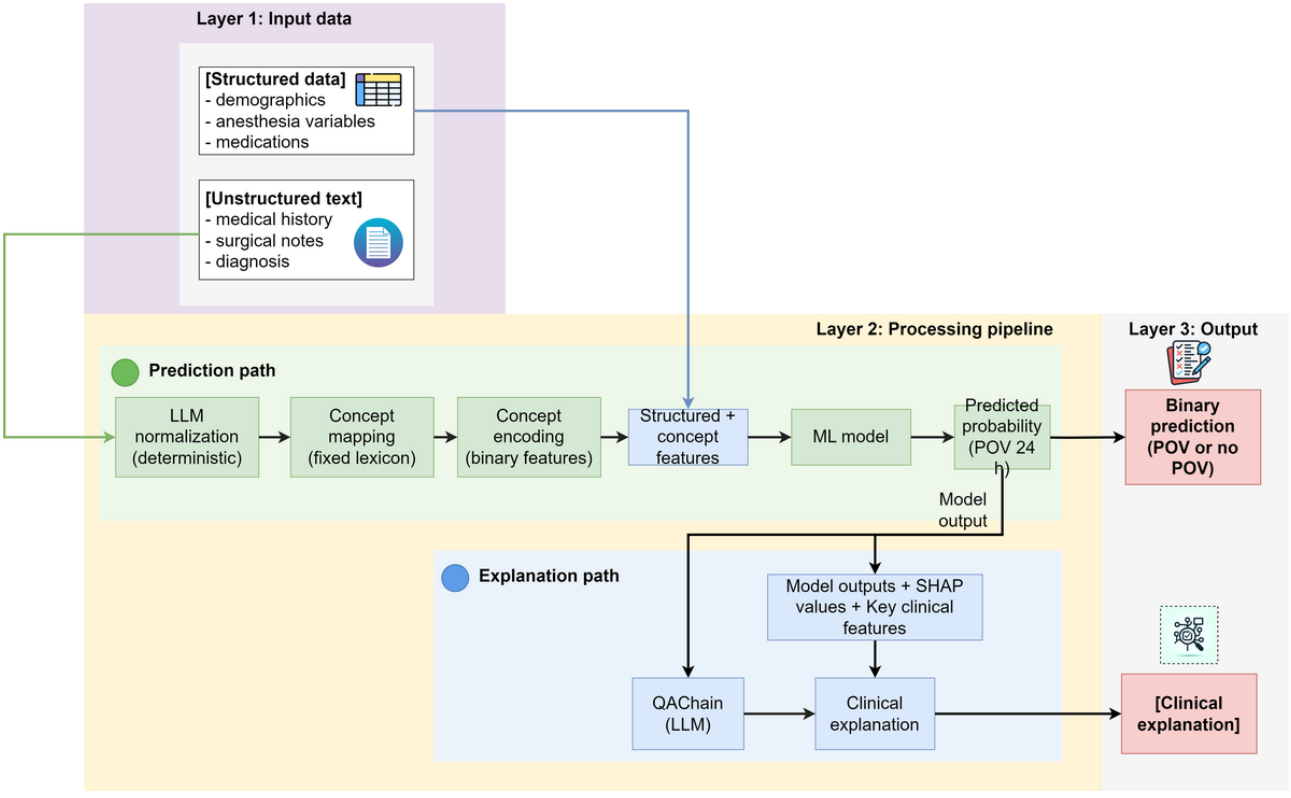
Preoperative assessment and optimization have long been recognized as critical components in surgical care [20,21]. More recently, LLMs such as ChatGPT have been increasingly explored as tools to enhance the interpretability and usage of unstructured clinical text. LLMs have shown promise in preoperative evaluations and have even demonstrated alignment with expert consensus on pharmacologic strategies for PONV management [22-24]. However, current LLM implementations tend to function independently of structured patient data and often overlook patient-specific factors such as age, sex, and clinical history [22,24-26].

Past PONV research has laid a strong foundation for risk factor identification, offering essential insights for future feature engineering and data preprocessing efforts [27,28]. Nonetheless, in today's fast-paced clinical environments, real-time decision-making is increasingly entrusted to frontline providers. Moreover, ML and DL systems should serve as enhancements to, and not replacements for, human clinical decision-making, especially in real-time environments where clinicians must rapidly interpret patient data [29].

Recent studies emphasize that beyond predictive performance, model interpretability and calibration are critical for clinical deployment. For instance, explainable tree-based models such as ExtraTrees have shown that even models with moderate discrimination require careful evaluation of calibration and feature contributions before clinical adoption, highlighting the importance of aligning model outputs with real-world clinical distributions and decision thresholds [30]. In addition, systematic reviews of clinical AI applications have identified persistent challenges in interpretability, bias, and insufficient validation, particularly in surgical and perioperative decision-making [31]. These concerns further underscore the need for greater transparency and trust in AI systems, as emphasized in broader discussions on AI deployment [32,33].



Taken together, future research should not only focus on improving predictive accuracy but also prioritize interpretable modeling, robust validation (including calibration), and transparency-aware model design, thereby fostering greater clinician confidence and facilitating real-world implementation.

Methods

Overview

We propose a clinically grounded framework for predicting POV 24h using ML, deep learning (DL), and LLMs. The framework comprises three core modules: data preprocessing, model development, and interpretability analysis (Figure 1). Traditional ML and DL models serve as predictive baselines, while LLM-based techniques support the structured transformation of unstructured clinical data and support post hoc interpretation within the modeling framework.

Figure 1. Proposed framework for predicting postoperative vomiting within 24 hours (POV 24h). The framework integrates modules for data preprocessing, model construction, and interpretability analysis. Traditional machine learning (ML) and deep learning (DL) methods serve as predictive baselines, while large language model (LLM)-based techniques support the structured representation of unstructured clinical data and generate post hoc explanations of model predictions. DL: deep learning; LLM: large-language model; ML: machine learning; POV: postoperative vomiting; QA: question answer.

The primary endpoint was POV 24h, excluding nausea-only events. For each surgical case, multiple postoperative interviews were aggregated at the surgery level. A case was labeled positive (1) if any documented vomiting event occurred within 24 hours,

XSL•FO
RenderX

and negative (0) if all available interviews indicated no vomiting. Surgeries without a valid 24-hour follow-up were excluded from the main analysis.

To reflect real-world clinical decision-making, we defined two prediction tasks based on the timing of feature availability: (1) a preoperative model using variables available before anesthesia induction, and (2) a perioperative model using variables available up to the end of surgery. Only variables available prior to each prediction time point were included in model training. Postoperative variables were excluded from all prediction models. To minimize the risk of temporal leakage, all variables were classified according to temporal availability prior to model construction (Multimedia Appendix 1). Variables unavailable at the intended prediction time point were excluded from the corresponding prediction task.

Ethical Considerations

This retrospective study was approved by the Institutional Review Board of Kaohsiung Medical University Hospital (approval number: KMUHIRB-E(I)-20200040). The requirement for informed consent was waived due to the deidentified and retrospective nature of the data. The study was conducted in accordance with the principles of the Declaration of Helsinki.

The dataset was obtained from the hospital's electronic medical records system. Data collection and processing were conducted following institutional review board (IRB) approval (IRB No: KMUHIRB-E(I)-20200040).

Structured Data Preprocessing

The dataset used in this study was obtained from a collaborating medical center and comprises both structured and unstructured data. Structured data includes physiological measurements, anesthetic information, and surgical procedure types. Unstructured data consists of narrative text, such as patient medical history and surgical records.

Structured data preprocessing was performed to ensure data quality and consistency prior to model development. An important characteristic of this dataset is that the hospital information system encodes the absence of an event or measurement as a value of 0 rather than as a conventional missing value (not a number [NaN]). For example, an intraoperative drug dosage of 0 indicates that the drug was not administered, and an airway-equipment size of 0 indicates that the corresponding procedure was not performed. Consequently, the structured feature set contained no conventional missing (NaN) values: across all 78 perioperative model features and the full study cohort (n=33,460), the NaN rate was 0%. A median- and mode-imputation step (for numeric and categorical variables, respectively) was nonetheless retained within the unified modeling pipeline as a safeguard for prospective deployment, where sporadic true missing values may occur; in the present study dataset this step was not triggered because no NaN values were present. All preprocessing procedures were refitted independently within each training fold before being applied to the corresponding validation data, ensuring that any imputation parameters would be derived exclusively from training data and preventing information leakage.

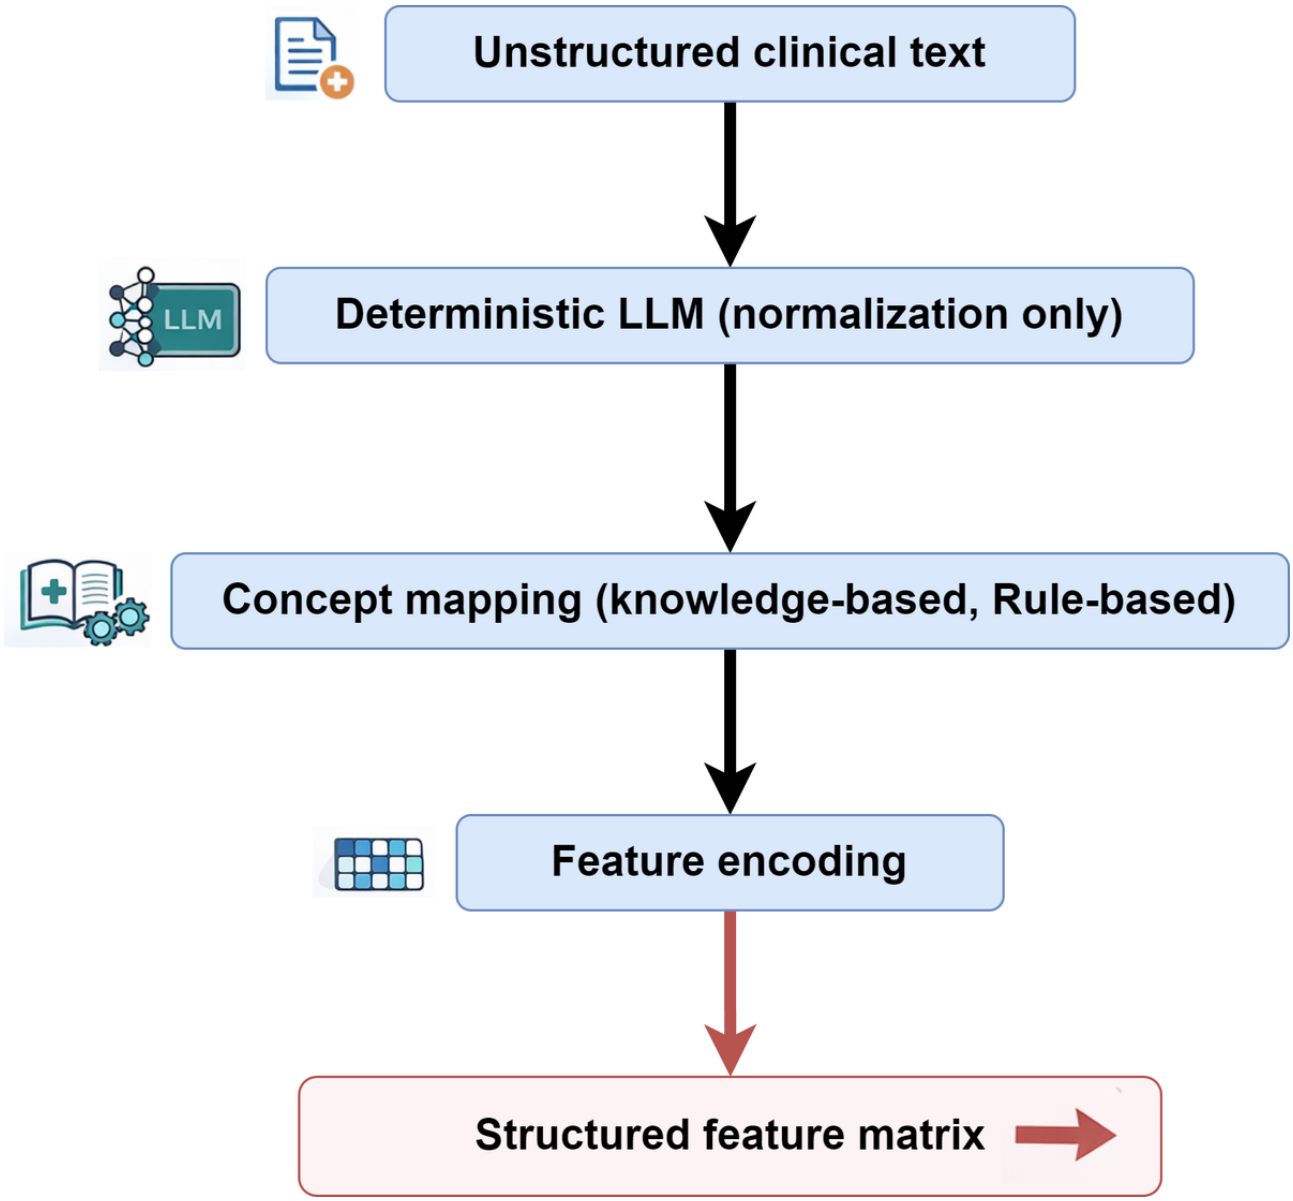
It is therefore important to distinguish these structurally coded zeros from genuine missing data. To characterize their distribution, we summarized the per-variable zero rate across the cohort. Most numeric features were near-completely recorded, whereas a small number of procedure-specific measurements (eg, airway-equipment sizes and selected intraoperative drug dosages) showed high zero rates that reflect non-performance of the corresponding procedure rather than missing information. A detailed per-variable zero-rate summary is provided as a supplementary file (Multimedia Appendix 2). Alternative imputation strategies, including K-Nearest Neighbors (KNN) imputation, were explored during preliminary assessment but did not materially affect downstream model performance and were therefore not adopted in the primary pipeline.

Extreme values were handled using percentile-based capping to reduce the influence of outliers while preserving clinically meaningful variation. Antiemetic administration was retained as a perioperative variable rather than excluded. As this variable may reflect clinicians' responses to perceived risk and thus introduce potential confounding, prediction tasks were explicitly defined based on temporal availability, with variables included only when available at the time of prediction. The potential confounding effect of this variable was considered during the interpretation of model performance.

The study protocol was reviewed and approved by the Institutional Review Board (IRB) of Kaohsiung Medical University Hospital (approval number: KMUHIRB-E(I)-20200040). All data used for analysis were fully deidentified in accordance with institutional data protection and ethical standards. Direct identifiers (eg, patient names, national identification numbers, and dates of birth) were completely removed. For indirect identifiers (eg, admission time, hospital stay, and diagnosis codes), data masking or generalization techniques were applied to minimize the risk of reidentification.

Unstructured Text Data Preprocessing

LLM-based methods for unstructured clinical text processing were implemented using a fixed model version with deterministic settings (temperature=0) to ensure reproducibility. All inputs to the LLM were strictly limited to deidentified text. Direct identifiers (eg, patient names, identification numbers, and exact dates) were completely removed prior to processing. When a commercial API was used, only deidentified text was transmitted through secure, encrypted channels in accordance with institutional data governance policies. No direct identifiers or personally identifiable information were transferred to external services. Alternatively, LLM processing could be conducted within a controlled or self-hosted environment. This design supports reproducible and secure use of LLM technologies within the clinical data pipeline while maintaining compliance with data protection regulations.



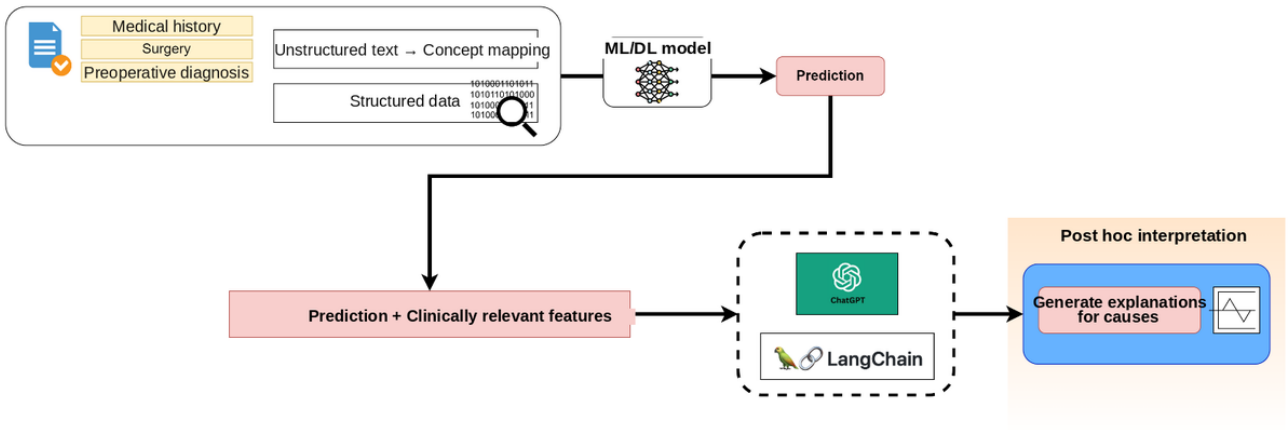
Handling unstructured clinical text requires approaches beyond conventional categorical encoding. We implemented a concept-based framework in which narrative text was normalized and mapped to predefined clinical concepts using LLM-assisted semantic standardization. Ordinal encoding was

XSL•FO
RenderX

applied separately to ordered categorical variables, such as American Society of Anesthesiologists (ASA) physical status, by assigning ranked numerical values, enabling machine learning models to capture ordinal relationships effectively. However, more complex narrative text requires semantic interpretation that cannot be fully represented through predefined ordinal or categorical structures alone.

To extract clinically meaningful signals from medical history, surgical notes, and diagnostic descriptions, we implemented a keyword-based feature construction approach guided by predefined clinical concepts derived from prior literature and domain knowledge. The LLM was used solely to standardize semantically related expressions (eg, synonyms and linguistic variations) into consistent representations aligned with predefined clinical concepts. The identified concepts were subsequently mapped to structured features using a predefined scoring scheme, ensuring consistent and reproducible feature construction. The overall preprocessing pipeline for unstructured clinical text is illustrated in Figure 2.

Figure 2. Clinical data preprocessing framework for unstructured text.



Beyond keyword-based feature construction, we further incorporated Question Answering (QA) Chain, an LLM-based framework built on LangChain, as a post hoc explanation module to support clinical interpretation of model outputs. QAChain operates after model prediction by leveraging structured inputs, including model outputs and derived clinical features, to generate context-aware explanations. With a deterministic setting (temperature=0), the model produces consistent, structured explanations aligned with clinical reasoning and grounded in patient context.

For example, it may generate: “The patient received high-dose opioids and underwent prolonged general anesthesia, both of which contribute significantly to PONV risk.” Such outputs provide interpretable narratives that connect model predictions with clinically relevant factors. The QAChain-based explanation process is illustrated in Figure 3. The full prompt template, system instructions, and configuration details are provided in Multimedia Appendix 3 to ensure reproducibility and transparency.

XSL•FO
RenderX

Figure 3. QAChain-based post hoc explanation framework. The QAChain module generates structured, natural-language explanations based on model predictions and input features. This module is used solely for interpretability purposes and does not participate in model training, feature construction, or prediction. DL: deep learning; ML: machine learning. QAChain: Question Answering Chain.

Model Development

We developed predictive models for POV 24h using a temporally structured dual-task framework aligned with clinical decision-making. Two independent prediction tasks were constructed to prevent information leakage: (1) a preoperative model using variables available before anesthesia induction, and (2) a perioperative model using variables available up to the end of surgery. Only features available prior to each prediction time point were included in the corresponding model.

For structured data, three ML algorithms were implemented: logistic regression, LightGBM, and XGBoost (Extreme Gradient Boosting). Logistic regression served as an interpretable baseline model, while gradient boosting models (LightGBM and XGBoost) were used as primary predictive approaches due to their strong performance on tabular clinical data and their ability to capture nonlinear relationships and feature interactions.

Unstructured clinical text features derived from the preprocessing pipeline were incorporated into the model as structured inputs using a predefined keyword-based scoring system. This approach enabled integration of clinically relevant information from narrative data while maintaining methodological rigor and preventing information leakage.

Model training and evaluation were conducted under a temporal split design to simulate real-world deployment, in which models trained on earlier data were evaluated on unseen future cases. Model performance was assessed using discrimination (receiver operating characteristic–area under the curve and precision-recall-area under the curve), calibration (Brier score and calibration plots), and clinically relevant operating metrics. Classification thresholds were selected using Youden's J statistic, and decision curve analysis was performed to evaluate clinical utility. All performance metrics were reported with 95% CIs derived from bootstrap resampling.

Interpretability Analysis

To enhance transparency and support clinical interpretability, we incorporated both model-based and LLM-assisted explanation approaches. First, model-level interpretability was assessed using SHAP. SHAP values were used to quantify the contribution of individual features to model predictions and to derive global feature importance rankings based on the mean absolute SHAP values across samples. These analyses enabled the identification of key predictors associated with POV 24h.

Second, the keyword-based scoring system provided interpretable representations of unstructured clinical text, enabling examination of text-derived risk factors within the model.

Finally, we implemented QAChain, an LLM-based post hoc explanation module, to generate context-aware natural-language interpretations of model outputs. QAChain was configured with deterministic settings (temperature=0) to ensure reproducibility. Importantly, this module was not used for predictive modeling, but solely to provide human-readable explanations aligned with clinical reasoning.

Together, these approaches provide complementary perspectives on model behavior by combining quantitative feature attribution with qualitative explanation, thereby supporting clinical understanding and potential real-world application.

Results

Dataset

The study population consisted of patients who underwent anesthesia for surgical procedures at Kaohsiung Medical University Hospital between July 2019 and September 2022. The initial dataset included 79,919 anesthesia records comprising 127 variables and 95,304 postoperative interview records comprising 81 variables. These datasets were merged at the surgery level using a unique surgery identifier, resulting in a combined dataset with 208 variables.

Cohort construction was performed based on predefined inclusion and exclusion criteria to ensure data quality and clinical consistency. Patients younger than 18 years, duplicate records, and cases with invalid or inconsistent timestamps were excluded. Patients with an ASA physical status of 5 or 6 were also excluded due to their extreme clinical risk profiles. In addition, cases without valid postoperative follow-up within 24 hours were excluded from the primary analysis. The cohort selection process is illustrated in Figure 4. (Multimedia Appendix 4)

XSL•FO
RenderX

Figure 4. Cohort selection flow diagram.ASA: American Society of Anesthesiologists; POV: postoperative vomiting;

XSL•FO
RenderX

Prophylactic antiemetic use was retained as a variable and further examined through sensitivity and subgroup analyses. After cohort construction, the final study population consisted of 33,460 surgical cases. Among these, 3607 cases (10.8%) experienced postoperative vomiting within 24 hours (POV 24h), while 29,853 cases (89.2%) did not.

The primary endpoint was defined as POV 24h. For each surgical case, postoperative interview records across multiple time windows were aggregated at the surgery level. A case was labeled as positive if vomiting occurred at any time within the 24-hour postoperative period.

Given the class imbalance in POV 24h outcomes, model evaluation focused on metrics that reflect both discrimination and clinical relevance, including receiver operating characteristic – area under the curve, precision-recall area under the curve, and operating characteristics such as sensitivity and positive predictive value.

Model Performance

We evaluated three ML models (logistic regression, LightGBM, and XGBoost) for POV 24h. Logistic regression served as an interpretable baseline, while LightGBM and XGBoost were used to capture nonlinear relationships and feature interactions in tabular clinical data. The Apfel score was included as a clinical reference baseline.

All models were evaluated using a temporal split protocol, in which models were trained on earlier cases and tested on subsequent, unseen cases. Two prediction settings were defined according to clinical workflow: a preoperative model (using variables available before anesthesia induction) and a perioperative model (using variables available up to the end of surgery).

Table 1 summarizes model performance using only structured variables. Across both prediction settings, discrimination was consistent across model families. Gradient boosting models generally achieved slightly higher receiver operating characteristic-area under the curve and precision-recall-area under the curve than logistic regression, while logistic regression showed lower Brier scores, indicating better calibrated probability estimates. The receiver operating characteristic curves for the preoperative and perioperative prediction models are shown in Figure 5, demonstrating similar discrimination performance across the two settings, with only a marginal improvement when perioperative variables were included.

Table . Model performance using structured variables only Bootstrap-based 95% CIs (BCa, 1000 resamples) are reported for machine learning models.

Prediction task and model	ROC-AUC[a,b] (95% CI)	PR-AUC[c] (95% CI)	F_1-score (95% CI)	Brier score (95% CI)
Preoperative				
Apfel score	0.606	0.122	0.040	0.097
Logistic regression	0.717 (0.695 to 0.739)	0.205 (0.176 to 0.230)	0.217 (0.180 to 0.251)	0.090 (0.086 to 0.094)

Figure 5. ROC curve comparison for preoperative and perioperative POV prediction models. AUC: area under the curve; POV: postoperative vomiting; ROC: receiver operating characteristic.

The transition from preoperative to perioperative prediction yielded only marginal improvements in discrimination metrics. Notably, changes in threshold-dependent metrics such as F_1-score were inconsistent across models, reflecting differences in operating characteristics rather than overall predictive capability. This suggests that a substantial proportion of predictive information is already available prior to anesthesia induction, with intraoperative variables providing limited incremental value in overall model discrimination.

The relatively small performance differences between model types further indicate that, under the current feature set, model selection plays a secondary role compared to the availability and timing of clinical information. The Apfel score, a rule-based clinical model based on four binary predictors, showed lower discrimination and F_1-scores than ML models.

Calibration curves for both preoperative and perioperative models are presented in Figure 6. Overall, predicted probabilities showed reasonable agreement with observed event rates, although some deviation from perfect calibration was observed at higher predicted risk levels. This is consistent with the Brier score results reported in Table 1, which show that logistic regression demonstrated slightly better calibration performance. Clinical performance metrics at the Youden-optimal threshold are summarized in Table 2. The between-model differences in calibration carry practical implications for the intended clinical use. Because the framework is intended to support selective antiemetic prophylaxis—where action depends on whether a patient's estimated risk exceeds an institution-specific threshold—well-calibrated probabilities are as important as discrimination. Logistic regression produced the lowest Brier scores and the closest agreement between predicted and observed risk, whereas the gradient boosting models, despite marginally higher discrimination, tended to overestimate risk at the highest predicted-probability levels. This suggests that, when absolute risk estimates rather than rank ordering alone are used to guide prophylaxis, either the better-calibrated logistic regression model or a post hoc recalibration of the gradient boosting models (eg, Platt scaling or isotonic regression) would be preferable.

LightGBM	0.50	0.593	0.762	0.195	0.951	0.355
XGBoost	0.44	0.664	0.683	0.169	0.954	0.347

[a]PPV: positive predictive value.

[b]NPV: negative predictive value.

[c]LightGBM: Light Gradient Boosting Machine.

[d]XGBoost: Extreme Gradient Boosting.

We further evaluated the contribution of unstructured clinical text by incorporating deterministic text-derived scores as structured model inputs. Table 3 presents model performance after including text-derived features. Across models, the inclusion of text-derived features resulted in modest changes in discrimination metrics, with slight improvements observed in several model and task settings. The magnitude of improvement was limited, indicating that structured perioperative variables account for the majority of the predictive signal.

XSL•FO
RenderX

Table . Model performance with text-derived features Bootstrap-based 95% CIs (bias-corrected and accelerated [BCa], 1000 resamples) are reported for machine learning models.

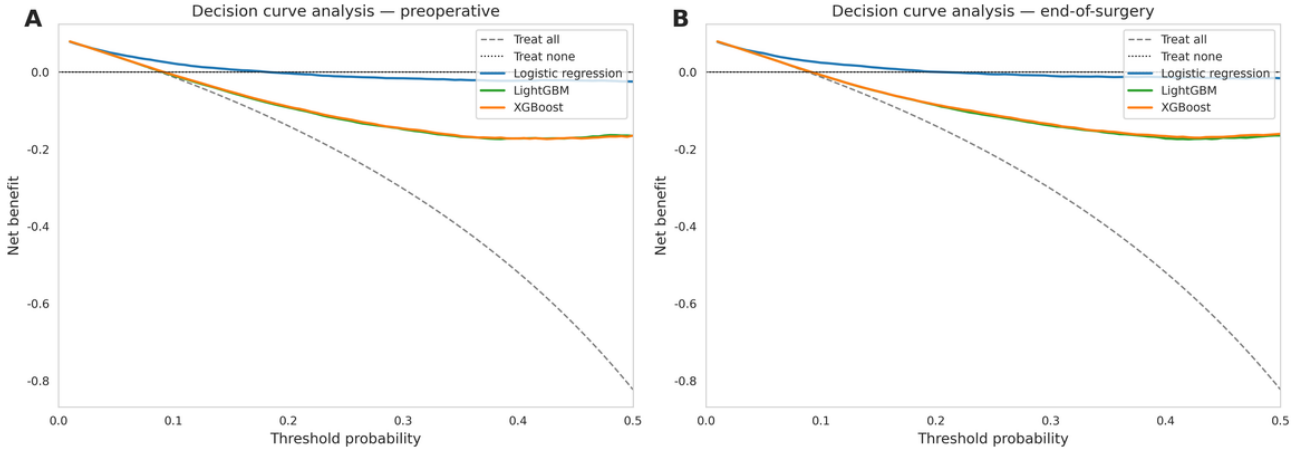
[a]ROC: receiver operating characteristic.

[b]AUC: area under the curve.

[c]PR: precision-recall.

[d]LightGBM: Light Gradient Boosting Machine.



[e]XGBoost: Extreme Gradient Boosting.

Text-derived features appear to provide complementary information, enriching the representation of clinical context without substantially altering overall model performance.

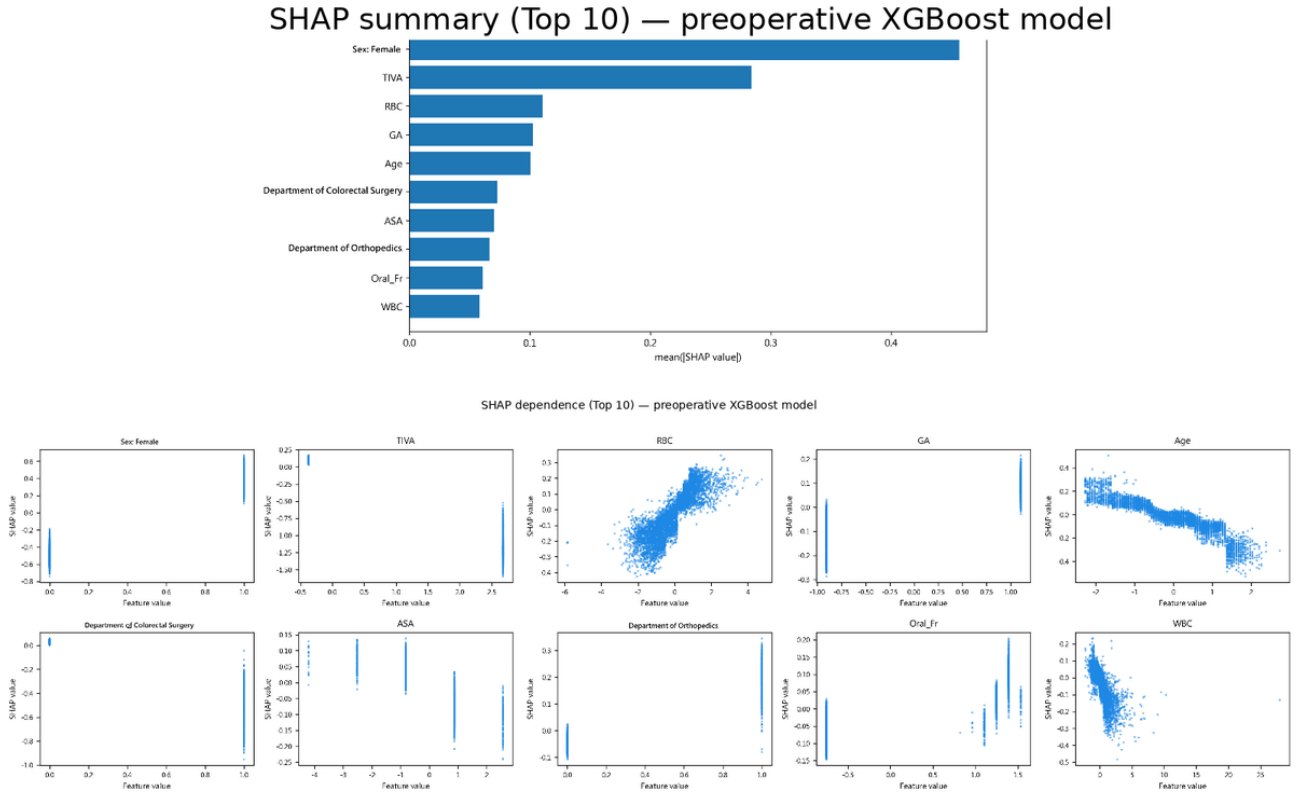
Decision Curve Analysis

Decision curve analysis was performed to evaluate the predictive models' clinical utility across a range of threshold probabilities (Figure 7). For both preoperative and perioperative prediction tasks, the machine learning models demonstrated positive net benefit across clinically relevant threshold probabilities, supporting the potential value of model-guided selective prophylaxis strategies compared with treat-all or treat-none approaches.

Figure 7. Decision curve analysis preoperative and perioperative postoperative vomiting (POV) prediction models. (A) Preoperative prediction models. (B) End-of-surgery prediction models. Net benefit is plotted against threshold probability for logistic regression, LightGBM, and XGBoost models, along with treat-all and treat-none reference strategies. LightGBM: Light Gradient Boosting Machine; XGBoost: Extreme Gradient Boosting.

Interpretability Analysis

To enhance transparency and support clinical interpretation, we adopted a multi-level interpretability approach integrating model-based feature attribution, text-derived feature representation, and LLM-assisted explanation. SHAP was used to quantify feature contributions at the model level, the deterministic keyword-based scoring system provided traceability for unstructured clinical text, and QAChain generated context-aware, human-readable explanations of model predictions. Together, these approaches offer complementary insights into model behavior and support clinically meaningful interpretation.



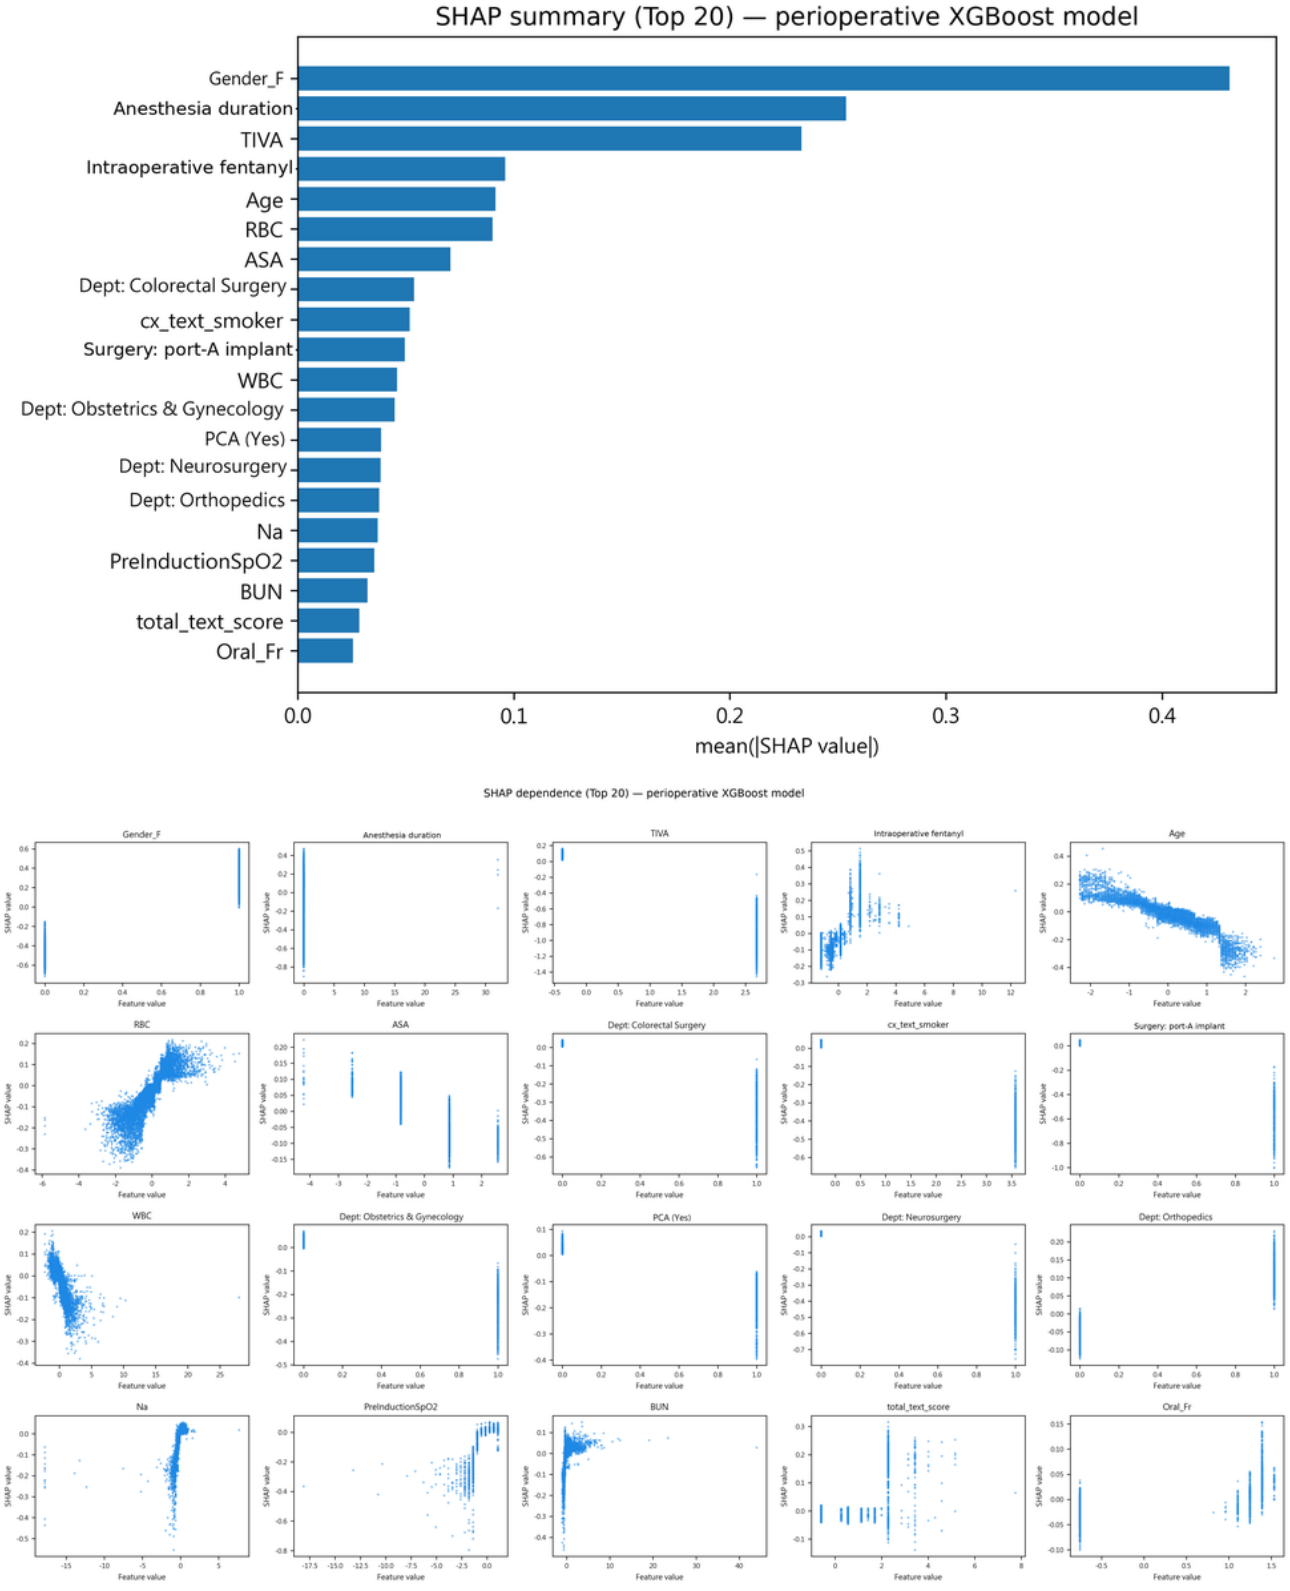
SHAP Analysis

To interpret the model's internal decision-making mechanism, SHAP analysis was performed on the XGBoost model, which achieved the best overall predictive performance. Figure 8 presents the combined SHAP summary and dependence plots for the preoperative model. The summary plot ranks features according to their global importance based on mean absolute SHAP values, while the dependence plots further illustrate the

XSL•FO
RenderX

direction and magnitude of each feature's effect on the predicted PONV risk.

Figure 8. Combined SHAP summary and dependence plots for the XGBoost preoperative model. The summary bar plot displays global feature importance based on mean absolute SHAP values, while the dependence plots illustrate the direction and magnitude of each feature's effect on prediction outcomes. Female sex, red blood cells (RBC), and general anesthesia are associated with increased predicted postoperative nausea and vomiting (PONV) risk, whereas total intravenous anesthesia (TIVA) shows a strong protective effect. Age demonstrates an inverse relationship with risk. Other variables, such as American Society of Anesthesiologists (ASA) status and surgical specialties, exhibit more complex patterns. GA: general anesthesia: PONV: postoperative nausea and vomiting: RBC: red blood cells: SHAP: Shapley Additive Explanations: TIVA: total intravenous anesthesia: WBC: white blood cells; XGBoost: Extreme Gradient Boosting.



The most influential features include female sex, total intravenous anesthesia (TIVA), red blood cells, general anesthesia, age, ASA status, and selected surgical specialties. Among these, several variables exhibit clear, clinically meaningful directional patterns. Female sex shows a strong positive association with predicted PONV risk, with consistently higher SHAP values observed in female patients. In contrast, TIVA exhibits a substantial protective effect, with markedly negative SHAP values indicating reduced predicted risk. Age demonstrates an inverse relationship, where younger patients are associated with higher predicted risk, as reflected by decreasing SHAP values with increasing age.

Continuous variables, such as red blood cells, show a positive trend, indicating that higher values are associated with a higher predicted risk. Similarly, general anesthesia is associated with higher prediction outputs compared to nongeneral anesthesia approaches. Other variables, including ASA status and surgical specialties, exhibit more complex or nonlinear patterns, suggesting potential interactions or confounding effects within the model. These features contribute to prediction but require cautious interpretation.

Overall, the SHAP analysis indicates that demographic characteristics, anesthetic strategies, and perioperative physiological variables jointly drive model predictions, with several features demonstrating consistent and interpretable directional effects aligned with clinical knowledge. Similar patterns were observed in the perioperative model (Figure 9), with additional contributions from intraoperative variables such as anesthesia duration and opioid use.

XSL•FO
RenderX

Figure 9. SHAP summary and dependence plots for the perioperative XGBoost model. The summary plot (top) presents the global importance of features ranked by mean absolute SHAP values, while the dependence plots (bottom) illustrate the relationship between feature values and their contributions to model predictions. Key predictors include sex, anesthesia duration, TIVA, opioid use (fentanyl), age, and laboratory variables. Text-derived features, including concept-based indicators (eg, cx_text_smoker) and procedure-specific features (eg, port-a-catheter implantation), also contribute to model predictions, although their influence is smaller compared to primary clinical variables. BUN: blood urea nitrogen; PCA: patient-controlled analgesia; RBC: red blood cells; SHAP: Shapley Additive Explanations; TIVA: total intravenous anesthesia; WBC: white blood cells; XGBoost: Extreme Gradient Boosting.

A structured summary of the top features, including their direction and clinical interpretation, is provided in Table 4.

XSL•FO
RenderX

Table . Summary of top SHAP features with direction and clinical interpretation.

Feature	Direction	Clinical interpretation
Preoperative model		
Female sex	↑	Strong established risk factor for PONV[a]
TIVA[b]	↓	Protective compared to general anesthesia
RBC[c]	↑	May reflect physiological status; associated with increased risk
GA[d]	↑	Known to increase PONV risk vs non-GA
Age	↓	Younger patients have higher risk
Colorectal surgery	↑	Procedure-related risk variation
ASA[e]	Nonlinear	Reflects overall health; nonlinear effect
Orthopedic surgery	Nonlinear	Procedure-specific variation
Oral_Fr	↑	Airway-related procedural factor
WBC[f]	↓	Weak or indirect association
Perioperative model		
Female sex	↑	Strong risk factor
Anesthesia duration	↑	Longer exposure increases risk
TIVA[b]	↓	Protective anesthetic strategy
Fentanyl (intraop)	↑	Opioid-related risk increase
Age	↓	Younger patients at higher risk
RBC[c]	↑	Physiological association
ASA	Nonlinear	Reflects baseline health
Smoking (text-derived)	↓	Smoking paradox (known effect)
Surgery type (colorectal)	↑	Procedure-related risk
Total_text_score	↑	Aggregated clinical context

[a]PONV: postoperative nausea and vomiting.

[b]TIVA: total intravenous anesthesia.

[c]RBC: red blood cell.

[d]GA: general anesthesia.

[e]ASA: American Society of Anesthesiologists.

[f]WBC: white blood cell.

Text-Derived Feature Analysis

To connect the preprocessing pipeline with model interpretability, we examined how text-derived features constructed from LLM-assisted normalization and concept-based mapping contribute to model predictions.

The LLM was applied to selected unstructured clinical text fields, including medical history descriptions, surgical notes, and diagnostic narratives. These fields contain heterogeneous linguistic expressions, such as synonyms, abbreviations, and mixed-language representations, which cannot be reliably standardized using simple rule-based methods. Using a deterministic configuration (temperature=0), the LLM was employed to normalize semantically equivalent expressions into consistent representations aligned with predefined clinical concepts (eg, smoking status, prior PONV, and laparoscopic procedures). Importantly, the LLM was not used to generate new features or discover additional concepts, and no outcome-related information was used in this process. Only text fields available prior to the prediction time point were included, ensuring temporal consistency and preventing information leakage.

Clinically relevant concepts were predefined based on established literature and domain knowledge. Following normalization, clinical narratives were mapped to structured features using deterministic and rule-based procedures. Three types of text-derived features were constructed: (1) concept-based binary indicators (cx_text_*), representing the presence or absence of clinically meaningful conditions; (2) aggregated scoring features (eg, history_score, surgery_score, diagnosis_score, and total_text_score), derived from predefined weighting schemes; and (3) count-based features based on keyword frequency. While all final features are constructed

XSL•FO
RenderX

deterministically, the LLM enhances the consistency and robustness of concept extraction from unstructured text.

Within the XGBoost model, SHAP analysis (Figure 9) shows that text-derived contributions are concentrated in a small number of concept-based features. In particular, cx_text_smoker and cx_text_ponv_history show substantially higher contributions than most other text-derived features, indicating that clinically meaningful concept indicators account for the majority of the text-derived signal in the model. In comparison, composite scoring variables (eg, history_score, surgery_score, diagnosis_score) show relatively limited contribution, while total_text_score provides a moderate but secondary contribution.

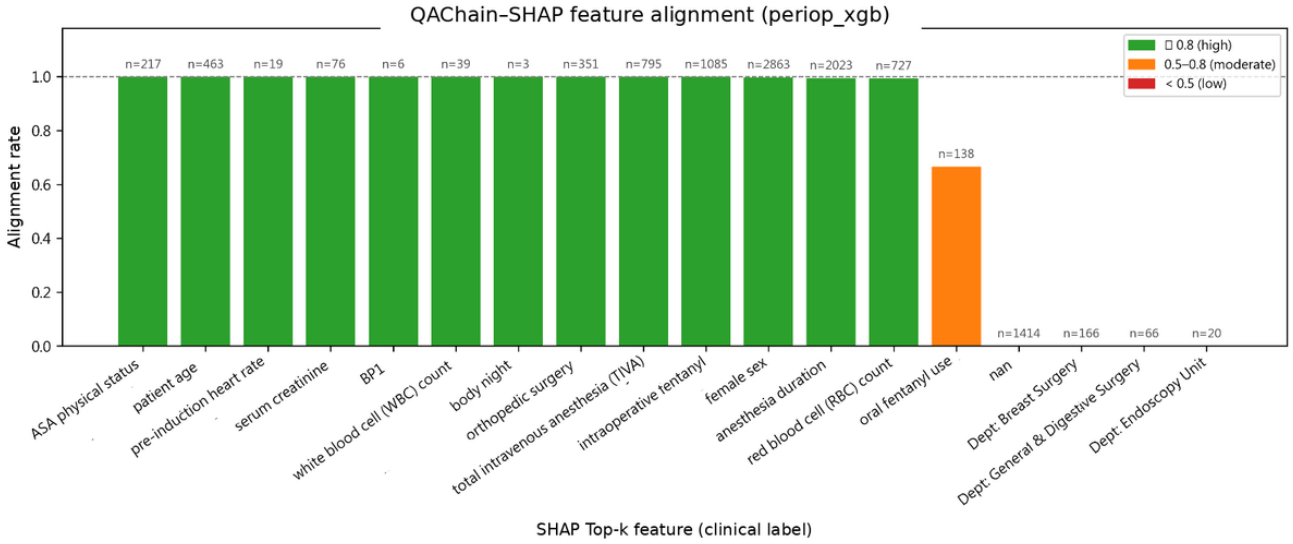
In addition to concept-based features, certain procedure-specific text-derived features (eg, port-a-catheter implantation) also appear among the top contributors, reflecting localized clinical patterns captured from surgical narratives that are not fully represented by predefined concept categories.

To further examine how the model uses different representations of clinical text, we grouped text-derived features into concept-based, aggregated-score, and count-based categories and visualized their SHAP contributions (Figure 9). This analysis shows that the model primarily relies on concept-based indicators, with aggregated- and count-based representations playing a secondary role.

Overall, these findings indicate that LLM-assisted semantic normalization enables consistent extraction of clinically meaningful concepts, which the model subsequently leverages as structured features. This design supports integrating unstructured clinical text into predictive modeling while preserving interpretability and reproducibility. Additional supporting analyses of text-derived features, including concept hit rates, postoperative vomiting rate comparisons, signal strength, the coverage funnel, and concept-level statistics, are provided in (Multimedia Appendix 5).

QAChain Reasoning Analysis

To evaluate the interpretability and reliability of the proposed framework, we conducted a comprehensive analysis of QAChain, an LLM-based post hoc explanation module that generates context-aware, human-readable interpretations of model predictions.



At the case level, QAChain consistently produced clinically meaningful explanations aligned with patient-specific risk profiles. For high-risk cases, explanations frequently emphasized well-established risk factors such as opioid exposure (eg, intraoperative fentanyl), prolonged anesthesia duration, and general anesthesia. For instance, explanations often highlighted that high-dose opioid administration and extended anesthesia duration jointly contribute to increased PONV risk. In contrast, for low-risk cases, QAChain tended to emphasize protective or mitigating factors, such as the use of TIVA and shorter procedural duration. For intermediate or borderline cases, QAChain generated balanced explanations that incorporated both risk-enhancing and risk-reducing factors, reflecting nuanced and context-sensitive reasoning.

To quantitatively assess whether QAChain explanations align with model behavior, we evaluated their alignment with SHAP-based feature attributions, which serve as a proxy for model-derived feature importance. Specifically, for each case, the top-k features ranked by SHAP values were compared with the features explicitly referenced in the corresponding QAChain explanation. Alignment was defined as the proportion of SHAP top-k features that were mentioned in the generated explanation.

As illustrated in Figure 10, QAChain explanations show high consistency with model-derived feature importance at the surface level. Most clinically relevant features—such as intraoperative fentanyl, TIVA, anesthesia duration, patient age, and female sex—are frequently reflected in QAChain explanations, achieving near-perfect alignment rates (≈99% - 100%). For example, high-frequency features such as female sex (n=2863) and anesthesia duration (n=2023) exhibit alignment rates above 99%, indicating that QAChain reliably captures dominant predictive signals even in large-scale clinical data.

XSL•FO
RenderX

Figure 10. Feature-level alignment between QAChain explanations and SHAP attributions (perioperative XGBoost model). Each bar represents the proportion of cases in which a SHAP top-k feature is explicitly referenced in the corresponding QAChain-generated explanation. Numbers above bars indicate feature occurrence frequency. Most clinically relevant features align nearly perfectly, demonstrating that QAChain explanations are strongly grounded in model-derived feature importance. ASA: American Society of Anesthesiologists; SHAP: Shapley Additive Explanations; TIVA: total intravenous anesthesia; RBC: red blood cell; XGBoost: Extreme Gradient Boosting.

However, this alignment metric captures lexical feature mention rather than direct causal faithfulness. Therefore, the results should be interpreted as surface-form concordance between QAChain explanations and SHAP-derived feature importance, rather than definitive evidence of full mechanistic fidelity. Features with lower alignment, such as oral fentanyl use, likely reflect semantic abstraction, where QAChain generalizes specific variables into broader clinical concepts (eg, opioid exposure) rather than consistently preserving fine-grained distinctions. Additionally, variables such as missing values (“nan”) and categorical surgical department labels are rarely mentioned, suggesting that QAChain selectively prioritizes clinically interpretable and semantically meaningful features in its natural-language explanations.

Overall, these findings indicate that QAChain produces stable, clinically coherent explanations that are meaningfully related to model attributions, while allowing semantic abstraction and human-readable reasoning.

To ensure reproducibility, QAChain was configured with deterministic settings (temperature=0), resulting in highly consistent outputs across repeated runs with identical inputs. Furthermore, QAChain explanations were generated from structured, engineered features derived from the modeling pipeline, without direct access to raw unstructured text or outcome variables. This design reduces the risk of information leakage and helps ensure that explanations remain aligned with the model’s input space.

Collectively, these findings indicate that QAChain produces stable explanations that are internally consistent with model-derived signals and are intended to enhance the interpretability of model predictions. Because no formal clinician-based evaluation was performed, this interpretability benefit cannot be objectively confirmed at this stage; the explanations should therefore be regarded as a useful interpretability reference to be validated in future clinician-centered studies.

Discussion

This study developed and internally validated a temporally structured clinical decision-support framework for POV 24h using ML and LLM-assisted interpretability methods. The results show that model performance was comparable across algorithms, with gradient boosting models demonstrating slightly higher discrimination and logistic regression showing better calibration. Most predictive information was already available before anesthesia induction, suggesting that clinically actionable risk stratification may be feasible during preoperative assessment and could support earlier prophylaxis planning and perioperative risk management. The limited incremental gain from perioperative variables suggests that a substantial proportion of clinically relevant risk information is already available before surgery. In addition, text-derived features contributed limited but consistent improvements, suggesting a complementary role. Finally, integrating SHAP-based attribution and LLM-based explanation enabled a multi-level interpretability framework that supports a clinically meaningful understanding of model predictions.

Building upon these findings, this study provides a deeper analysis of a temporally structured framework for POV 24h, integrating structured clinical variables, text-derived features, and multi-level interpretability methods.

The inclusion of text-derived features yielded consistent but limited performance gains, suggesting that unstructured clinical text provides complementary rather than dominant predictive signals. Importantly, the proposed LLM-assisted preprocessing approach enables consistent extraction of clinically meaningful concepts from heterogeneous narrative data while preserving interpretability and reproducibility.

From an interpretability perspective, combining SHAP-based feature attribution with QAChain-generated explanations provides a multi-level view of model behavior. SHAP offers

XSL•FO
RenderX

quantitative insight into feature contributions, while QAChain translates these signals into human-readable clinical narratives. The alignment analysis suggests that QAChain explanations are meaningfully related to dominant model signals, though the evaluation is based on lexical features and does not establish full causal faithfulness. Instead, QAChain can be interpreted as a translation layer that bridges structured feature attribution and clinically interpretable reasoning. We note that this characterizes the explanations generated by the framework; the extent to which they enhance clinician interpretability or usability remains to be confirmed through future clinician-based evaluation.

These findings position the proposed framework as a practical approach for enhancing the interpretability of clinical machine learning systems through multi-level explanation, without relying on a single explanation modality. Because a formal clinician-based evaluation was not conducted, the magnitude of this interpretability benefit could not be objectively quantified in the present study and remains to be confirmed through future clinician-centered evaluation.

Importantly, the role of LLMs in this framework should be interpreted as a deliberate design choice rather than a strategy aimed at maximizing predictive performance. While the inclusion of text-derived features resulted in only modest improvements, this reflects the dominance of structured perioperative variables in this prediction task rather than a limitation of the approach.

Instead, LLMs were intentionally constrained to deterministic semantic normalization and post hoc explanation rather than being used as autonomous predictive generators, thereby minimizing the risk of introducing additional predictive signal or potential information leakage. Under this design, QAChain functions as a translation layer that converts model-derived feature attributions into clinically interpretable narratives, rather than acting as an independent predictive component.

This design aligns with emerging directions in clinical AI, where interpretability, transparency, and alignment with clinical reasoning are increasingly recognized as essential for real-world deployment. From this perspective, the limited performance gain associated with LLM integration should be interpreted as evidence that explanations intended to enhance interpretability can be generated without compromising model validity, with the magnitude of this interpretability benefit remaining to be confirmed through future clinician-based evaluation.

Several limitations should be noted. First, the alignment analysis between QAChain explanations and SHAP features is based on surface-form matching, which may not fully capture semantic equivalence or causal reasoning. Second, QAChain explanations are generated using a fixed prompt and deterministic settings, which may limit variability but do not guarantee true interpretive fidelity. Third, this study is based on retrospective data from a single medical center, which limits external generalizability. Multicenter validation of POV prediction models is inherently challenging due to the heterogeneity of institutional anesthesia practices, antiemetic protocols, and postoperative interview procedures across sites, which can substantially alter both feature distributions and outcome definitions. Furthermore, standardized multi-center data sharing in perioperative research remains limited by privacy regulations and the absence of unified electronic health record schemas. These structural barriers make single-center development studies a common and accepted starting point in this domain. External validation in independent, multi-center cohorts nevertheless remains an essential prerequisite before broader clinical applicability of the proposed models can be assumed, and we caution against generalizing the present single-center findings to other settings without such validation. In addition, the clinical usefulness of QAChain-generated explanations was not formally evaluated by clinicians in this study. Conducting a prospective clinician assessment requires a dedicated deployment environment and institutional review board approval beyond the scope of the current retrospective study. The alignment analysis between QAChain explanations and SHAP attributions provides an objective proxy for consistency, but this does not substitute for human-centered evaluation. Clinician-based usability studies are therefore explicitly identified as a priority for future research.

Conclusion

This study presents a temporally structured framework for POV 24h that integrates structured clinical variables, text-derived features, and multilevel interpretability methods. By explicitly separating preoperative and perioperative prediction tasks, the framework reflects real-world clinical decision-making and avoids information leakage.

The results show that predictive performance is largely driven by structured clinical variables available before anesthesia induction, with intraoperative variables and text-derived features providing complementary but limited additional contributions. These findings highlight the importance of early-stage risk stratification and suggest that most predictive information is already available before surgery.

From an interpretability perspective, the proposed framework combines SHAP-based feature attribution with QAChain-generated explanations to provide both quantitative and human-readable insights into model behavior. Rather than serving as a standalone explanation method, QAChain functions as a translation layer that converts structured feature contributions into clinically interpretable narratives. The observed alignment between QAChain explanations and model-derived feature importance indicates meaningful consistency with dominant predictive signals, while allowing for semantic abstraction and contextual reasoning. This consistency supports the intended interpretability contribution of the explanations, although it does not by itself constitute an objective, clinician-based validation of interpretability or usability.

Overall, this work demonstrates a practical, transparent approach to integrating machine learning and large language models into clinical prediction tasks. By bridging structured modeling and natural-language explanation, the proposed framework provides multi-level explanations intended to enhance interpretability and support more transparent clinical decision-making. Because clinician-based evaluation was beyond the scope of this study, this interpretability benefit should be regarded as a promising reference rather than an objectively validated outcome, and warrants confirmation in future clinician-centered studies.

XSL•FO
RenderX

Before broader clinical adoption can be considered, the models also require prospective, multi-center external validation; the present results should therefore be regarded as evidence of internal feasibility rather than established clinical applicability.

Abstract

Background: Overactive bladder (OAB) is a prevalent condition, particularly among women, characterized by urinary urgency, often accompanied by frequency and nocturia. Traditional risk prediction methods for OAB are limited, as they fail to fully integrate multidimensional risk factors, including female reproductive history. Machine learning offers potential for enhanced predictive accuracy by using large-scale datasets like the National Health and Nutrition Examination Survey (NHANES).

Objective: This study aimed to develop and validate a machine learning–based model to predict OAB risk in women, incorporating reproductive and sociodemographic factors, and to identify key predictors using interpretable methods.

Methods: This retrospective observational study analyzed data from 7884 participants across 4 consecutive cycles (2011 - 2018) of the National Health and Nutrition Examination Survey. LASSO (least absolute shrinkage and selection operator) regression and univariate and multivariate logistic regression analyses were applied to identify key variables in the training set. Fourteen variables were selected via LASSO regression for model construction, among which age, BMI, ratio of family income to poverty threshold (PIR), age at menarche, and number of vaginal deliveries were identified as the most significant clinical predictors. The SHAP (Shapley Additive Explanations) method interpreted the optimal model, and restricted cubic spline (RCS) curves were used for dose-response analysis.

Results: Five variables were identified as significant predictors. Among the 11 ML models, random forest (RF) demonstrated the highest predictive performance. The random forest model achieved an AUROC (area under the receiver operating characteristic curve) of 0.8536 (95% CI 0.8435 - 0.8638) in the training set and 0.6999 (95% CI 0.6768 - 0.7212) in the test set, indicating moderate predictive capability. SHAP analysis identified age, BMI, and the number of vaginal deliveries as the top 3 contributors to OAB risk. Both RCS and SHAP analyses revealed a positive association of age and BMI with OAB risk and a negative association with PIR. Additionally, RCS showed that the risk of OAB was higher with an earlier age at menarche and a greater number of vaginal deliveries.

Conclusions: Integrating ML with SHAP interpretability provides a robust predictive tool for OAB, facilitating early identification and clinical management.

KEYWORDS

overactive bladder; women; machine learning; predictive modeling; National Health and Nutrition Examination Survey; NHANES; cross-sectional study

Introduction

Overactive bladder (OAB) is characterized by urinary urgency with or without urinary incontinence in the absence of urinary tract infection or other pathology [1]. It is frequently accompanied by increased daytime urinary frequency and nocturia. OAB is estimated to affect millions of people worldwide and is more prevalent in women than in men [2,3]. Despite the high prevalence of OAB, accurate prediction of OAB risk remains a challenge. Traditional methods rely heavily on clinical symptoms and a basic physical examination, often failing to fully consider all influencing factors. Understanding the risk factors associated with OAB, especially in the context of women's health, is crucial for developing effective prevention and management strategies.

Previously, the majority of research on OAB mainly focused on other related factors, such as BMI [4], diabetes [5,6], and inflammatory indicators [7,8]. However, research on female reproductive factors remains insufficient and represents a significant research gap. Previous studies have shown that

XSL•FO
RenderX

gender-specific differences exist in the structure and function of the innervation of the female urethra and bladder, which may lead to bladder hypersensitivity and detrusor overactivity [9]. In terms of hormonal levels, fluctuations in estrogen are closely associated with the onset and severity of OAB symptoms [10]. In particular, women in perimenopause experience a sharp change in estrogen levels, significantly increasing their risk of developing OAB [11]. Furthermore, during pregnancy, significant changes occur in the structure and function of the pelvic floor, which is likely to be a key trigger for the onset of OAB [12].

To address this gap, this study focuses specifically on underinvestigated female reproductive factors (such as age at menarche, number of pregnancies, menopausal status, etc) using machine learning (ML) approaches. The ability of ML to analyze large-scale, complex data; extract underlying patterns; and construct accurate predictive models significantly improves the efficiency and accuracy of disease prediction compared to traditional statistical methods. Compared with previous studies that had limitations such as a small number of participants and regional or local biases, our research used the National Health and Nutrition Examination Survey (NHANES) database, which is based on national population survey data in the United States. The NHANES database covers a wide range of populations and has excellent representativeness, enabling it to comprehensively reflect the health conditions and reproductive characteristics of women of different ages, races, and regions, thus providing a solid data foundation for accurately constructing a risk prediction model for female OAB. By integrating multidimensional reproductive-related variables, this study aims to establish a comprehensive and accurate risk prediction model for OAB, with the goal of identifying high-risk female populations at an early stage and providing a basis for formulating personalized prevention and intervention strategies.

Methods

Ethical Considerations

All procedures of the National Health and Nutrition Examination Survey (NHANES) involving human participants, materials, or data were conducted in accordance with the Declaration of Helsinki and approved by the National Center for Health Statistics (NCHS) Ethics Review Board (Protocol #2011-17). Written informed consent was obtained from all participants. The study did not require clinical trial registration, and the survey data are publicly accessible for researchers and data users worldwide [13].

Data Source and Study Population

The Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis with Artificial Intelligence (TRIPOD+AI) guidelines (Checklist 1) were adhered to in the conduct of this study [14]. The NHANES, a nationwide survey using a stratified, multistage sampling process, provided the data for this investigation, assessing the nutritional and medical conditions of individuals across all age groups in the United States. The NHANES, established by the NCHS, is a comprehensive national survey designed to evaluate the nutritional status and overall health of the US population. The study's design and data collection methods were reviewed and approved by the NCHS Ethics Review Board. Comprehensive information regarding ethical approval can be found on the Centers for Disease Control and Prevention website. Data from 4 consecutive survey cycles (2011 - 2018) were analyzed for OAB.

OAB Assessment

Urgency urinary incontinence and nocturia are the principal symptoms of OAB, which is a prevalent clinical condition in the field of urology. OAB symptoms in the population were systematically evaluated using the renal disease-urology questionnaire from NHANES, and the Overactive Bladder Symptom Score was used to quantify the severity of OAB symptoms. Urgency urinary incontinence and nocturia are among the multiple symptoms taken into account by the Overactive Bladder Symptom Score [15], a reliable assessment tool, and are translated into a specific score. According to the scoring results, patients are regarded as having OAB when their total score reaches 3 points or higher (Figure S5 in Multimedia Appendix 1).

Covariate Assessment

Aiming to explore the risk factors associated with female OAB, female reproductive history—an integral part of women's lives—was integrated as a research variable in this study. Variables were obtained with the assistance of the reproductive health questionnaire. The reproductive health questionnaire comprised menstrual history, pregnancy history, use of birth control pills, and other relevant reproductive aspects. At the mobile examination center, the questionnaire was administered by trained interviewers through the Computer Assisted Personal Interview system. Among these variables, age at menarche was the response furnished by the participants to the query: "At what age did the first menstrual period occur?" Normal menstrual status was the response to the question, "Did you have regular periods in the past 12 months?" (Yes/No). A positive response (Yes) denoted the occurrence of normal menstruation during the past 12 months, whereas a negative response (No) indicated its absence. The number of vaginal deliveries was the response to the question: "How many vaginal deliveries have you had?" Contraceptive use was the response to the question, "Have you ever taken birth control pills?" (Yes/No). Pregnancy diabetes diagnosis was the response to the question, "During pregnancy, were you informed that you had diabetes?" (Yes/No).

Furthermore, drawing on databases and clinical expertise, a host of additional variables were incorporated in relation to diverse modules within NHANES (Table S3 in Multimedia Appendix 1), including demographic details (age, race, ratio of family income to poverty threshold [PIR], and education), laboratory examination outcomes (white blood cell count, lymphocyte count, monocyte count, platelet count, neutrophil count, and glycohemoglobin), questionnaire-derived data (smoking, alcohol, and physical activity), and physical examination metrics (BMI, systolic blood pressure [SBP], and diastolic blood pressure).

Data Preprocessing

Variables with more than 30% missing data were excluded. Subsequently, k-nearest neighbor (KNN) imputation was performed using the R package DMwR2. The parameters were set as follows: K=15, with the mode for categorical variables specified as meth="most" and the mean used for continuous variables. Furthermore, a comparison between the data before and after imputation was carried out (Multimedia Appendix 1), and the results demonstrated that no statistically significant difference was caused by the imputation (P>.05). The missing data rates for all analyzed variables were relatively low, uniformly remaining below 10% (ranging from 0% to 9.5%), ensuring the validity of subsequent KNN imputation. In addition, the correlation analysis of all continuous variables was performed using correlation heat maps. It was deemed that a significant correlation existed between variables with a correlation coefficient greater than 0.7, and those variables were deleted. All categorical variables were factorized before modeling, and for multiclass variables, dummy variables were set up. To maintain the continuity of the data, no classification was imposed on the continuous variables.

Selection of Variables

Given that high-dimensional data tend to complicate ML algorithm performance, before model construction, LASSO (least absolute shrinkage and selection operator) regression [16], a method that involves selecting variables and reducing model complexity through parameter tuning to mitigate the risk of overfitting, was used on the training set. This approach uses the parameter λ to regulate model complexity, ultimately resulting in a model with fewer variables. The LASSO regression was implemented to identify the most critical factors for model inclusion. To determine the optimal λ, 10-fold cross-validation was performed, with the minimum λ value used for variable selection. The SHAP (Shapley Additive Explanations) values of the top 5 variables were investigated to ascertain the dose-response association between independent risk variables and OAB. These values were evaluated using a restricted cubic spline (RCS) function. Additionally, univariable and multivariable logistic regression (LR) models were used to explore the association between the variables and OAB, with odds ratios and 95% CIs calculated in the training set. Finally, variables that were non-zero coefficients in the LASSO regression were selected for constructing the ML model.

Model Development

To predict the risk of OAB in women, we trained 11 ML models: LR, ridge regression, support vector machine, elastic net, eXtreme gradient boosting (XGBoost), random forest (RF), light gradient boosting machine, KNN, decision tree, multilayer perceptron, and naive Bayes. To ensure optimal performance and reliability, we tuned hyperparameters using Bayesian optimization combined with 5-fold cross-validation, selecting the best model configuration based on generalization performance across different hyperparameter settings. Model performance was comprehensively evaluated using more than 10 metrics, including area under the receiver operating characteristic curve (AUROC), precision, F_1-score, recall, accuracy, area under the precision-recall (PR) curve, and decision curve analysis. Finally, the model that showed the best and most robust performance on the test set was selected as the final prediction model, and its interpretability was analyzed using SHAP values.

Model Interpretability

It is difficult to explain ML models. The "black box" problem is solved by the SHAP method, a game theory–based approach that prioritizes the significance of input features and provides an explanation for the output of the prediction model. The SHAP technique increases the model's interpretability and transparency by determining each feature's contribution to the prediction outcomes while offering both local and global explanations [17]. The SHAP technique, which gives each variable a corresponding attribution value (SHAP value), was used to clarify the final model with the highest effectiveness. These SHAP values quantify each feature's effect on prediction accuracy. A SHAP summary plot was created to show each feature's contribution to the model. Furthermore, SHAP interaction analysis was performed to explore the pairwise interactions among the main variables, thereby revealing how the effect of one variable on the prediction depends on the value of another.

Statistical Analysis

In the baseline analyses, the Shapiro-Wilk test was used to assess the normality of continuous variables. To compare continuous variables that exhibited a normal distribution, the Student t test was used. These variables were presented in the form of mean (SD). For the comparison of continuous data featuring skewed distributions, either the Kruskal-Wallis H test or the Mann-Whitney U test was used. Such data were presented as medians along with IQRs. The chi-square test was applied to compare categorical variables. These variables were presented as numbers in conjunction with percentages. Additionally, dose-response relationships for all continuous variables in the ML models were analyzed using RCS curves. All statistical analyses were executed using R version 4.4.2. The development of all ML models was facilitated by the R package "tidymodels." A 2-tailed P-value less than .05 was considered statistically significant.

Results

Patient Characteristics

A total of 7884 participants were enrolled in the study, from a total of 39,156 individuals, comprising a training set (70%, n=5519) and a test set (30%, n=2365; Figure 1). As illustrated in Table 1, significant differences were identified in most variables between the OAB and non-OAB groups within the training set (P<.05). For example, it was found that patients with OAB exhibited an advanced age (61 y as opposed to 47 y in the training set and test set) and possessed a relatively higher BMI (30.7 kg/m^2 compared to 28.0 kg/m^2 in the training set and 31.1 kg/m^2 compared to 28.2 kg/m^2 in the test set). Notably, the OAB group exhibited higher blood pressure values and a larger proportion of individuals with "normal menstruation" marked as "No," which may reflect the older age of patients with OAB.

Model Variable Selection

As shown in Figures 2A and 2B, LASSO regression was performed to select robust risk factors. Fourteen variables—age, marital status, PIR, smoke, physical activity, age at menarche, normal menstrual status, number of vaginal deliveries, contraceptive use, pregnancy diabetes, diabetes, glycohemoglobin, BMI, and SBP—demonstrated significant statistical associations and retained non-zero coefficients in the LASSO model. These 14 variables were, therefore, all included in the construction of the ML model. In addition, as presented in Table 2, univariate and multivariate LR analyses were conducted to further characterize the associations between each variable and OAB, providing complementary interpretability.

XSL•FO
RenderX

Figure 2. Results of the LASSO (least absolute shrinkage and selection operator) method for variable selection. (A) LASSO coefficient curves for 22 variables. Coefficients are plotted on the y-axis, and log(λ) is shown on the x-axis. As log(λ) increases, the tuning parameter strengthens, shrinking the absolute magnitude of coefficients toward zero, which leads to their elimination. (B) Ten-fold cross-validation with the minimum criterion selected the optimal λ value. The relationship between log(λ) and partial likelihood deviance (binomial deviance) is shown. Dashed vertical lines indicate the minimum mean squared error (MSE) and 1 SD from the minimum MSE (1-SE criterion), defining the optimal λ. Seven predictor variables corresponding to the log(λ) value with the minimum MSE were retained.

Model Explanation

Five cycles of 5-fold internal cross-validation were performed to train 11 ML models. To rigorously determine the most robust predictive architecture, a comprehensive benchmark was conducted across multiple clinical validation dimensions, including discriminative power, clinical net benefit, and calibration alignment (Figure 3). As illustrated in Figures 3A and 3B, the performance metrics of all 11 algorithms were systematically compared. In terms of discriminative ability, the ROC analysis revealed that the RF model achieved the highest predictive performance, with an AUROC of 0.8536 (95% CI 0.8435 - 0.8638) on the training set (Figure 3C) and 0.6999 (95% CI 0.6768 - 0.7212) on the test set (Figure 3D). This superior performance of the RF model was further corroborated by the PR curves, yielding a top-tier area under the PR curve of 0.7409 on the training set (Figure 3I) and 0.5031 on the test set (Figure 3J). Concurrently, the XGBoost model demonstrated highly competitive and stable diagnostic performance, securing a test set AUROC of 0.6879 (95% CI 0.6652 - 0.7105).

Beyond statistical classification accuracy, decision curve analysis was introduced to evaluate the clinical use of the developed algorithms. Across a wide range of threshold probabilities, both the RF and XGBoost models consistently demonstrated superior net benefits over the “treat-all” or “treat-none” reference strategies in both datasets, establishing their pragmatic value for clinical decision-making (Figures 3E and 3F). Furthermore, urological calibration curves were plotted to examine the concordance between the predicted risk scores and the actual observed OAB outcomes. As shown in Figure 3G and H, the calibration trajectories for the primary models (RF and XGBoost) closely adhered to the 45-degree ideal line.

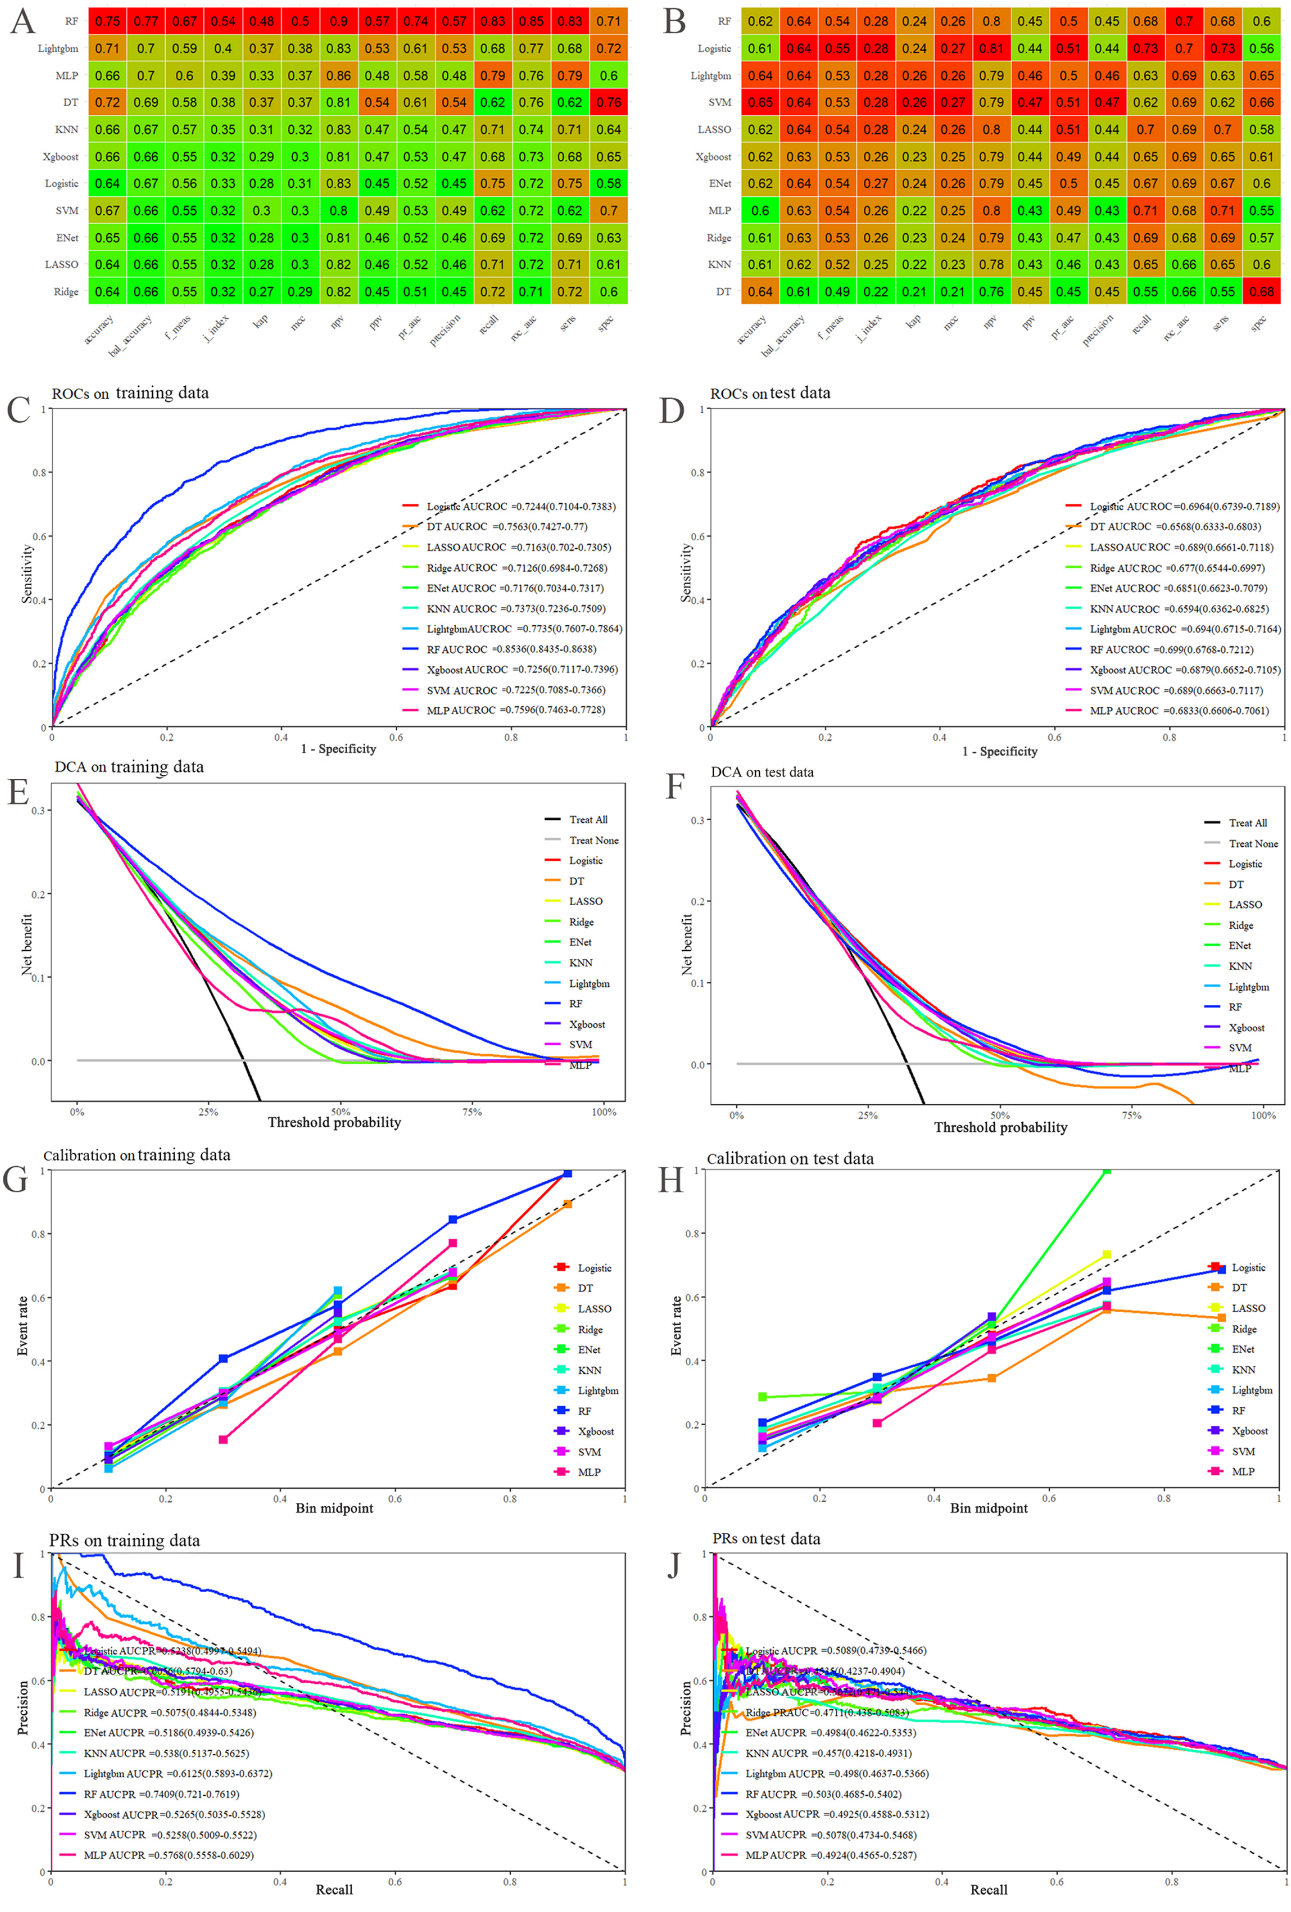
RenderX

The RF model's output was interpreted using the SHAP approach, which computed each variable's influence on the prediction. This interpretable approach provides 2 types of explanations: a local explanation at the individual level and an overall explanation of the model at the characteristic level. As depicted in the SHAP beeswarm plot (Figure 4A), the global feature importance and the direction of their impact were summarized in descending order of their mean absolute SHAP values: age, BMI, number of vaginal deliveries, SBP, glycohemoglobin, PIR, and age at menarche. Higher values of age, BMI, SBP, and number of vaginal deliveries, along with lower values of PIR, contributed to an increased probability of OAB in the prediction model.



To closely inspect the model's decision-making process at the individual level, a SHAP waterfall plot (Figure 4B) illustrates the quantitative contribution of each variable for a representative patient (predicted probability=0.150, baseline=0.243). In this clinical case, a BMI level of 19.7 (–0.118) kg/m^2 contributed the most significant negative effect to the prediction, while an age of 73 (+0.0884) years, glycohemoglobin of 6.0 (+0.0242), and SBP of 115 (+0.0194) mm Hg pushed the model outcome toward higher OAB risk.

Furthermore, to capture the exact dose-response trends and the continuous distribution of features, SHAP dependence plots were constructed for key continuous variables (Figure 4C). These scatter plots demonstrate how the SHAP values vary across different ranges of each risk factor, color-coded by the actual OAB status, thereby visually uncovering the potential nonlinear interactions within the prediction model.

Dose-Response Relationship

As shown in Figure 5, the dose-response relationship analysis was conducted on the top 5 variables ranked with the assistance of RCS. The analysis revealed nonlinear relationships between BMI, number of vaginal deliveries, and OAB (*P*-overall <.05; *P*-nonlinear <.05). Furthermore, it was observed that when BMI values exceeded 33.659 kg/m² and the number of vaginal deliveries exceeded 0, the risk of OAB increased rapidly. Linear relationships were identified between age, age at menarche, PIR, and OAB (*P*-overall <.05; *P*-nonlinear >.05). It was observed that when the female age exceeded 58 years, the risk of developing OAB increased significantly. Additionally, it was observed that for females under the age of 13 years, earlier menstruation was associated with an elevated risk of OAB, which gradually decreased with increasing age. Furthermore, it was observed that when PIR was less than 3.299, it was identified as a risk factor for OAB, and the risk increased concomitantly with decreasing PIR.

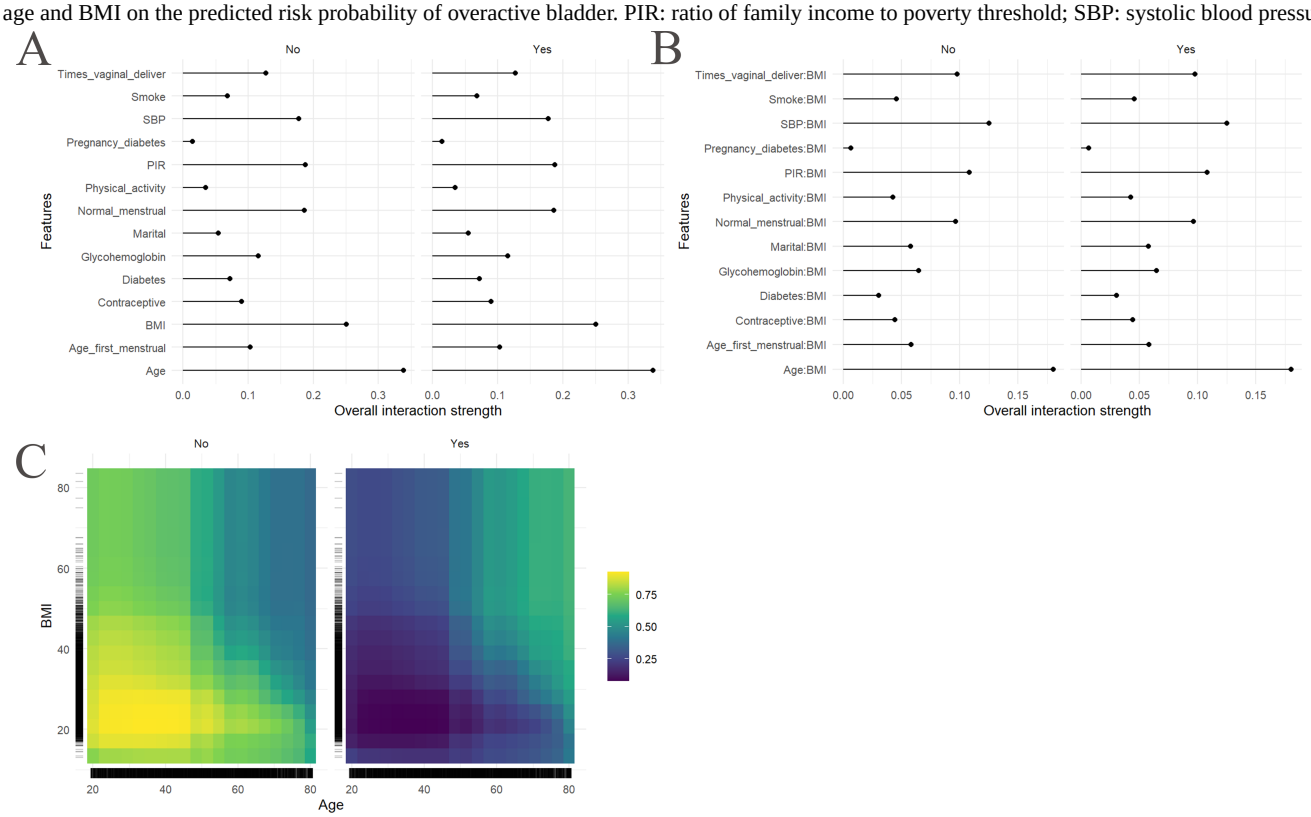
The nonlinear correlations between each continuous variable and overactive bladder (OAB) are depicted in these figures. (A) Age, (B) BMI, (C) age at menarche, (D) ratio of family income to poverty threshold (PIR), and (E) number of vaginal deliveries are among the specific continuous variables. lshap: L-shaped association; OR: odds ratio; ushap: U-shaped association.



Interaction Analysis

To further explore the potential nonlinear relationships and synergy among the predictors, a formal feature interaction analysis based on Friedman *H*-statistic was performed using the most influential variables from the final model (Figure 6). As illustrated in Figure 6A, the overall interaction strength of each feature with all other variables was quantified and stratified by urological subgroups (No vs Yes). Notably, age and BMI exhibited the highest overall interaction strengths, followed closely by PIR, number of vaginal deliveries, and normal menstrual cycle, indicating that these major risk factors do not act in isolation but possess substantial joint compounding effects on OAB manifestation.

Furthermore, since BMI was identified as a paramount driver with high connectivity, we evaluated the specific pairwise interaction strengths between BMI and all other remaining features (Figure 6B). The pairwise analysis revealed that the interaction between age and BMI (age:BMI) yielded the most pronounced synergistic effect, followed by SBP:BMI and PIR:BMI. To visually and intuitively decode this top-ranking interaction, a 2-way partial dependence plot was constructed to illustrate the joint effect of age and BMI on the predicted OAB risk matrix (Figure 6C). The heatmap demonstrates that the predicted probability of OAB peaks sharply within the combined stratum of advanced age and elevated BMI, providing strong statistical evidence of their nonlinear synergistic acceleration in OAB pathogenesis.

(A) Overall interaction strength representing the total nonlinear interaction profile of each individual feature with all other variables, stratified by urological cohorts (No vs Yes); (B) pairwise interaction strength specifically evaluating the synergistic combinations between BMI and other clinical predictors; (C) 2-way partial dependence heatmap illustrating the joint synergistic effect of age and BMI on the predicted risk probability of overactive bladder. PIR: ratio of family income to poverty threshold; SBP: systolic blood pressure.

Discussion

Principal Findings

In a pioneering attempt, the potential risk factors of OAB in female participants were predicted using NHANES data combined with ML techniques. Furthermore, particular attention was paid to the influence of female reproductive factors on OAB. The findings from our comprehensive suite of univariate and multivariate LR analyses, along with LASSO, RCS, and ML methodologies, unanimously demonstrated a pronounced correlation between age, BMI, PIR, age at menarche onset, the frequency of vaginal deliveries, and the increased risk of OAB, aligning with prior research findings.

Extensive investigations have revealed that the incidence rate of OAB among females increases after the age of 40 to 50 years, corresponding with the onset of menopause [18,19]. A causal relationship has been postulated, proposing that the depletion of sex hormones during menopause may predispose women to OAB [18], a finding that aligns with our results. The findings suggest that the risk of developing OAB increases for female participants over the age of 58 years. This discrepancy with prior studies may stem from differences in study populations and sample characteristics. Obesity, a well-established critical risk factor for OAB, has garnered extensive validation. A study of 206 overweight female participants found that individuals with a body fat percentage exceeding 32% had a 95% higher risk of OAB compared to those with a body fat percentage at or below 32% [20]. A prospective study found that overweight women had a 5.8-fold increased risk of severe OAB, while obese women showed an 18.6-fold increase compared to those with a normal BMI [21]. The RCS analysis of the BMI-OAB relationship was conducted, and the results indicated that the risk of OAB increased proportionally with higher BMI. Of particular interest is the observation that, upon attaining a BMI value of 33.659 kg/m², the odds ratio transitioned from a subunity value to a value that exceeded unity. This clinical threshold of 33.659 kg/m² falls into the class II obesity category, suggesting a nonlinear cumulative effect where the bladder's compensatory mechanisms are overwhelmed beyond this level. From a biological plausibility perspective, this sharp increase in risk may be explained by critical changes in mechanical and metabolic stresses. The occurrence of OAB may be caused by mechanical factors related to obesity, such as increased abdominal and bladder pressure [22]. Additionally, leptin secreted by visceral adipose tissue and inflammatory cytokines may lead to noradrenergic sympathetic activity and urothelial stimulation, which could be associated with the development of OAB [22,23].

Additionally, PIR serves as a proxy for the economic deprivation level of the study participants. This study found that PIR was a significant factor in precipitating OAB occurrence. When PIR was below 3.299, an inverse relationship was observed: lower PIR values corresponded to a higher likelihood of OAB, consistent with earlier findings [24,25]. This inverse relationship suggests that economic constraints may delay diagnosis and exacerbate symptoms. As reported, Medicare for individuals with OAB in the United States were more than 2.5 times higher than for those without OAB [26].

XSL•FO
RenderX

Previous studies have examined the relationship between age at menarche and urinary incontinence, but a gap remains in the existing literature regarding age at menarche and OAB. We undertook a pioneering study to investigate this relationship. The findings of this investigation revealed that earlier age of menarche onset was concomitant with an elevated risk of OAB manifestation. The risk of OAB decreased as the age at menarche exceeded 13 years. Studies have reported that early puberty onset leads to prolonged estrogen exposure, affecting hormonal sensitivity in the bladder and pelvic floor tissues, and influencing detrusor stability [27]. Furthermore, an earlier age at menarche is significantly associated with a higher risk of obesity in adulthood [28], and obesity is a known major risk factor for OAB. Vaginal delivery has been shown to increase the risk of OAB, peaking 5 years after the first delivery [29-31]. Our research findings have corroborated this observation, and the outcomes of our RCS-based analysis have indicated that the risk of OAB progressively escalates when the delivery count surpasses zero. To better understand this association, several interconnected pathophysiological mechanisms must be considered. First, vaginal childbirth can lead to significant neuromuscular injury, particularly mechanical stretching or compression of the pudendal nerve during the second stage of labor. This partial denervation of the pelvic floor muscles and detrusor can result in altered bladder sensations and subsequent detrusor overactivity due to axonal degeneration [32]. Second, connective tissue trauma plays a vital role. Mechanical distension during labor can lacerate or overstretch the pelvic organ support systems, such as the endopelvic fascia and levator ani muscle complex [33]. This collagen disruption compromises pelvic structural support, altering the anatomical position of the bladder neck and predisposing it to hypermobility, which can trigger involuntary detrusor contractions. Lastly, the prolonged mechanical compression of the fetal head against the vaginal wall can induce focal ischemia-reperfusion injury in the bladder and pelvic floor tissues [34]. The subsequent generation of reactive oxygen species and chronic inflammatory cytokines can lead to urothelium denudation and detrusor instability, further aggravating OAB symptoms.

Clinically, the primary predictors and synergies highlighted by our models underscore that OAB is a multifactorial disorder driven by interconnected mechanical (vaginal deliveries) and metabolic (BMI, glycohemoglobin) pathways. Consequently, rather than adopting a generalized approach, clinicians should leverage these risk profiles to implement phenotype-specific management, combining targeted pelvic floor rehabilitation with strict metabolic counseling to optimize preventive urological care.

This study has several strengths: first, this is the first study to predict OAB risk using the NHANES database. We used multiple methodologies (univariate or multivariate LR, RCS, and 11 ML frameworks) to analyze risk factors for OAB, focusing on female reproductive factors. Second, the data supporting this research were procured from the NHANES database, which contains exceptionally comprehensive population data, including demographic specifics and physical examination particulars. The RF model, demonstrating superior predictive performance, achieved an AUROC of 0.8536 in the training set and 0.6999 in the testing set. This model evidences a robust predictive capability. Although the RF model (testing AUROC=0.6999) and the highly competitive XGBoost model (testing AUROC=0.6879) developed in this study have not reached an excellent level (AUROC >0.8), their performance is better than the traditional LR model and shows a moderate and robust discriminative ability. This suggests that the model can be integrated into clinical and public health practices as a tool for preliminary screening or risk stratification. For example, in community health screening or gynecological or urological outpatient clinics, a simple questionnaire (collecting age, BMI, income status, age at menarche, and delivery history) can be used to quickly calculate the OAB risk score for female participants. For individuals identified as high-risk, more detailed evaluations (such as voiding diaries or urological tests) can be recommended, thereby achieving early warning and targeted interventions to avoid symptom worsening. For women of reproductive age, this model can also be used for preconception or prenatal counseling to inform them of the potential long-term bladder health risks of multiple vaginal deliveries.

This study has several limitations that warrant consideration. First, the retrospective observational design, based on NHANES data, precludes establishing causality between identified risk factors (eg, age, BMI, age at menarche, etc) and OAB, as reverse causality—such as OAB symptoms influencing lifestyle factors like BMI—cannot be excluded, potentially leading to ambiguous interpretations of risk factor associations. Longitudinal cohort studies tracking these variables over time could clarify temporal relationships and confirm causality. Second, reliance on self-reported NHANES questionnaires introduces recall bias, particularly for variables like age at menarche, which may result in misclassification and attenuate or exaggerate associations with OAB, thus compromising result reliability. Future studies could incorporate objective measures, such as medical records or validated diagnostic tools, to enhance data accuracy. Finally, the absence of environmental (eg, occupational exposure) and genetic data limits our ability to account for potential confounders or modifiers of OAB risk, such as lifestyle factors influencing BMI or genetic predispositions affecting bladder function, potentially leading to an incomplete risk profile. While these limitations exist, they also point to valuable directions for future improvement. To enhance the model's performance, future studies could first incorporate richer predictors, such as detailed pelvic floor electrophysiological data, bladder ultrasound parameters, genetic markers related to connective tissue metabolism, and specific quality of life or behavioral psychology data. Additionally, exploring more advanced urological algorithms and ensemble strategies, such as using deep learning to process complex feature interactions or adopting stacking techniques for model fusion, could further optimize prediction. Finally, conducting external validation in independent cohorts across different geographical and ethnic populations remains essential to verify the model's generalizability. Integrating detailed lifestyle questionnaires and genetic profiling, such as genome-wide association studies, in future research could provide a more comprehensive understanding of OAB etiology.

RenderX

Conclusions

In this study, age, BMI, PIR, age at menarche, and the number of vaginal deliveries were identified as significant risk factors for OAB. The RF model demonstrated good predictive accuracy and practical clinical applicability, serving as a noninvasive, cost-effective tool for early screening and risk stratification in community health and primary outpatient settings.

Acknowledgments

The authors respectfully thank all the participants for their selfless dedication and effort, as well as the National Health and Nutrition Examination Survey (NHANES) for providing critical data. No generative AI tools were used at any stage in the preparation of this manuscript.

Funding

The authors declare no financial support was received for this work.

Authors' Contributions

GH and SL conceptualized and designed the research approach. GH conducted the data analysis and interpretation, and drafted the initial manuscript. SL provided critical revisions to the manuscript. All authors reviewed and approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Sepsis-associated acute kidney injury (SA-AKI) is a frequent and life-threatening complication of sepsis. While the static lactate-to-albumin ratio (LAR) has prognostic value, its dynamic temporal evolution during early resuscitation and its utility for guiding clinical risk stratification remain underexplored.

Objective: The aim of the study is to identify distinct dynamic trajectories of LAR, evaluate their independent associations with adverse clinical outcomes, and construct a practical prognostic nomogram for patients with SA-AKI.

Methods: Data were extracted from the Medical Information Mart for Intensive Care IV database, including adult patients with SA-AKI and ≥ 3 lactate and albumin measurements within the first 72 hours of intensive care unit admission. A multicenter external validation cohort was assembled from 5 tertiary hospitals in Beijing, China. Group-based trajectory modeling identified distinct LAR trajectories. The primary outcome was 28-day mortality; secondary outcomes included 90-day mortality and continuous renal replacement therapy initiation. Trajectory-outcome associations were assessed using multivariable Cox and logistic regression models. Robustness was examined using restricted cubic splines, inverse probability of treatment weighting, weight truncation, doubly robust estimation, and subgroup analyses. Incremental predictive value beyond single baseline LAR was quantified, and a trajectory-integrated nomogram was developed and externally validated.

Results: Among the 615 patients in the primary cohort, 3 LAR trajectories were identified: trajectory 1 (low-stable type), trajectory 2 (rapid-clearance type), and trajectory 3 (delayed-clearance type). In adjusted multivariable models, trajectory 3 (vs trajectory 1) was independently associated with increased 28-day mortality risk (hazard ratio 1.63, 95% CI 1.00 - 2.64; *P*=.0496), 90-day mortality (hazard ratio 1.72, 95% CI 1.14 - 2.60; *P*=.01), and continuous renal replacement therapy initiation (odds ratio 3.40, 95% CI 1.64 - 7.15; *P*=.001). Conversely, the mortality risk for trajectory 2 did not differ significantly from trajectory 1. Sensitivity analyses supported these findings, although trajectory 3 associations attenuated in inverse probability of treatment weighting–weighted analyses. Incorporating trajectories improved predictive accuracy over single baseline LAR (continuous net reclassification improvement 0.170, integrated discrimination improvement 0.023; both *P*=.01). In the external validation cohort (n=508), 3 analogous trajectories were identified. Trajectory 3 consistently conferred a higher mortality risk across both cohorts, whereas trajectory 2 was significantly associated with 28-day mortality only in validation. The nomogram exhibited modest discrimination in the external cohort (concordance index=0.612), acceptable calibration, and potential utility as a supplementary bedside risk stratification tool.

Conclusions: Dynamic LAR trajectories are independently associated with 28- and 90-day mortality in SA-AKI. The delayed-clearance trajectory identifies a specific high-risk phenotype, suggesting that longitudinal LAR monitoring and the constructed nomogram may support early risk stratification and inform clinical decision-making.

Introduction

Sepsis-associated acute kidney injury (SA-AKI) is a frequent and devastating complication in critically ill patients, associated with increased risks of chronic kidney disease, cardiovascular events, and mortality [1]. The pathophysiology of SA-AKI is multifactorial, involving microcirculatory dysfunction, metabolic reprogramming, immune and inflammatory dysregulation, and tubular epithelial injury and impaired repair [2,3]. Current management focuses on early recognition, antimicrobial therapy, appropriate fluid resuscitation, vasopressor support, and initiation of renal replacement therapy when indicated for severe cases [4,5]. Traditional functional markers, such as serum creatinine and urine output, demonstrate low sensitivity and significant lag for early detection of SA-AKI. Therefore, identifying novel biomarkers for early diagnosis and prognostic assessment in SA-AKI remains crucial. Consistent with this concept, the Acute Disease Quality Initiative 23 Consensus Conference emphasized that acute kidney injury (AKI) risk assessment should move beyond traditional functional indices alone and incorporate additional biologically informative markers to improve early risk prediction [6].

The prognostic impact of inflammatory mediators, endothelial injury markers, and metabolic indicators in SA-AKI has been widely investigated. Lactate, a byproduct of anaerobic metabolism, serves as a biomarker reflecting tissue hypoperfusion and impaired oxygen use [7]. Elevated lactate levels have been associated with poor outcomes and markedly increased mortality in patients with septic shock [8]. However, as a single metabolic marker, lactate is influenced by multiple factors, including medications (eg, metformin and long-acting β-blockers), vasoactive therapy, and hepatic or renal dysfunction [9-12]. Albumin, the most abundant plasma protein, maintains colloid osmotic pressure, facilitates hormone and drug transport, acts as a pH buffer, and serves as a negative acute-phase reactant, decreasing during inflammation or stress [13]. Recent studies have demonstrated that hypoalbuminemia significantly increases both short-term and long-term mortality in patients with sepsis, serving as a prognostic biomarker [14,15]. In addition, hypoalbuminemia has been shown to be associated with worse outcomes in patients with SA-AKI [16]. However, similar to lactate levels, albumin levels are susceptible to multiple factors, including chronic underlying diseases, nutritional status, hepatic function, and changes in capillary permeability [17]. Thus, using lactate or albumin alone as a prognostic marker has limitations.

The lactate-to-albumin ratio (LAR) integrates information on tissue hypoperfusion (lactate) and nutritional or inflammatory status (albumin) and has attracted increasing attention as a prognostic marker in sepsis. Several studies have shown that LAR performs better than either lactate or albumin alone in predicting short-term and long-term mortality, as well as severe outcomes such as the need for renal replacement therapy or mechanical ventilation [18,19]. Moreover, LAR has been identified as an early biomarker for SA-AKI, outperforming traditional severity scores and laboratory parameters in predicting adverse outcomes and serving as an independent risk factor for short-term mortality [20,21]. These findings suggest that LAR may serve as a simple and emerging prognostic biomarker for SA-AKI with practical value in early risk prediction. However, it must be recognized that the development and progression of SA-AKI represent a continuously evolving pathophysiological process. Most existing studies are limited to evaluating LAR at a single time point, such as at admission or diagnosis, making it difficult to capture its dynamic evolution during the early phase of critical illness and resuscitation. Therefore, dynamically monitoring the trajectory of LAR may more accurately reflect the progression of SA-AKI, potentially offering incremental prognostic value over static baseline measurements. Nevertheless, clinical studies in this area remain scarce, and practical tools integrating these dynamic patterns for bedside decision-making are currently lacking.

Group-based trajectory modeling (GBTM), a type of finite mixture modeling or latent class trajectory modeling, is a statistical approach used to identify latent phenotypes with similar longitudinal patterns [22]. GBTM enables the identification of distinct trajectories of clinical or biological markers over time, often improving outcome prediction compared with single-point measurements [23]. The Medical Information Mart for Intensive Care IV (MIMIC-IV) database provides comprehensive clinical data on critically ill patients, offering a valuable resource for such analyses [24]. Based on the MIMIC-IV (version 2.2) database and supplemented by an external multicenter validation cohort, this study applied GBTM to characterize dynamic LAR trajectories among patients with SA-AKI and to examine their associations with clinical outcomes. Furthermore, we aimed to systematically quantify the incremental predictive value of these dynamic trajectories compared with a single baseline LAR and to construct and externally validate a clinical prognostic nomogram, ultimately providing a practical tool to improve early risk stratification in critically ill populations. The reporting of this cohort study complies with the STROCSS (Strengthening the Reporting of Cohort, Cross-Sectional and Case-Control Studies in Surgery) 2025 guidelines [25].

Methods

Data Source and Study Design

Data for this study were obtained from the MIMIC-IV (version 2.2) database [24], which contains deidentified information from over 50,000 intensive care unit (ICU) admissions at the Beth Israel Deaconess Medical Center between 2008 and 2019. The database includes detailed records of demographics, laboratory tests, medications, surgical procedures, and survival outcomes. This study involved an external validation cohort derived from a multicenter, prospective observational cohort study conducted between June 2023 and October 2025 at 5 tertiary hospitals in Beijing, China (Peking Union Medical College Hospital, Beijing Shijitan Hospital, Beijing Jishuitan Hospital, Beijing Hospital, and Beijing Chaoyang Hospital). The inclusion and exclusion criteria for the external validation cohort were identical to those applied to the MIMIC-IV cohort.

This cohort study included only patients with SA-AKI from the MIMIC-IV (version 2.2) database who met the following criteria: first hospital admission, first ICU admission, ICU length

XSL•FO
RenderX

of stay ≥72 hours, age ≥18 years, a confirmed diagnosis of SA-AKI on the day of ICU admission, and availability of lactate and albumin measurements at least 3 times within the predefined 0-, 24-, 48-, and 72-hour time windows following ICU admission. SA-AKI was defined according to established criteria [1], requiring both Sepsis-3.0 criteria (presence of infection with Sequential Organ Failure Assessment [SOFA] score ≥2) and AKI diagnostic criteria (meeting Kidney Disease Improving Global Outcomes [KDIGO] criteria). To clarify the temporal sequence, the Sepsis-3.0 criteria had to be met concurrently with or prior to the KDIGO criteria, with AKI occurring within 7 days of sepsis onset. Exclusion criteria included: (1) end-stage renal disease or dialysis dependence, (2) pregnancy or lactation, (3) AIDS, (4) patients with burns, (5) end-stage malignancy, and (6) patients with organ transplants.

Ethical Considerations

This study used data from 2 separate cohorts, adhering strictly to privacy and confidentiality protocols, with no financial compensation provided to participants and no identifiable information or images included in this paper. For the primary analysis, the use of the preanonymized and deidentified MIMIC-IV database was approved by the institutional review boards of the Massachusetts Institute of Technology and Beth Israel Deaconess Medical Center. Individual informed consent was waived for this secondary analysis under the HIPAA (Health Insurance Portability and Accountability Act) Safe Harbor provision, and investigators accessed the data after obtaining Collaborative Institutional Training Initiative certification (certificate 57230846). The external prospective validation cohort, registered with the Chinese Clinical Trial Registry (ChiCTR2300074175), was reviewed and approved by the ethics committees of Peking Union Medical College Hospital (approval K3148, I-22PJ1104), Beijing Shijitan Hospital (IIT2023-007-002), Beijing Jishuitan Hospital (K2023-195-00), Beijing Hospital (2023BJYYEC-150‐01), and Beijing Chaoyang Hospital (2025-Ke-869). For this validation cohort, written informed consent was obtained from all patients or their legally authorized representatives prior to data collection, and all extracted data were strictly anonymized and stored on secure, encrypted servers.

Data Extraction

Based on the inclusion and exclusion criteria, data were extracted using Navicat Premium 15 through Structured Query Language queries, yielding a total of 615 patients with SA-AKI in the MIMIC-IV (version 2.2) database. The external validation cohort ultimately included 508 eligible patients with SA-AKI. Baseline variables, including severity scoring systems (Acute Physiology and Chronic Health Evaluation III [APACHE III], Simplified Acute Physiology Score II [SAPS II], and SOFA) and therapeutic interventions (broad-spectrum antibiotic use and binary vasopressor use), were rigorously defined as data documented exclusively within the first 24 hours of ICU admission. For continuous renal replacement therapy (CRRT), only a binary indicator of whether CRRT was initiated at any time during the ICU stay was available, without the exact timestamp of initiation. Therefore, CRRT was treated as a postadmission clinical event variable rather than a baseline covariate. The analytical handling and associated temporal limitations of the CRRT outcome are detailed in the Statistical Analysis and Strengths and Limitations sections, respectively.

To minimize bias caused by inconsistent sampling times, lactate and albumin values were standardized using a time-window approach in which 4 reference points were defined at 0, 24, 48, and 72 hours after ICU admission, and each point allowed a ±12-hour collection window. To address potential overlapping boundaries at 12, 36, and 60 hours, an explicit data-handling rule was applied: if multiple laboratory values were drawn within a window or fell exactly on an overlapping boundary, the measurement recorded closest to the exact reference hour (0, 24, 48, or 72 hours) was selected. Only patients with both lactate and albumin values available in at least 3 distinct windows were included in the final cohort. Prior to trajectory modeling, continuous variables, including LAR, were winsorized at the 1st and 99th percentiles to mitigate the influence of extreme outliers.

Data collected in this study included demographic information (age, sex, race, and BMI), vital signs (temperature, heart rate, respiratory rate, oxygen saturation, systolic blood pressure, diastolic blood pressure, and mean arterial pressure), laboratory parameters (white blood cell [WBC] count, platelet count, hemoglobin, hematocrit, lymphocytes, monocytes, neutrophils, glucose, serum creatinine, blood urea nitrogen, anion gap [AG], bicarbonate [HCO_3^-], sodium [Na^+], potassium [K^+], calcium [Ca^{2+}], chloride [Cl], international normalized ratio [INR], prothrombin time [PT], activated partial thromboplastin time, alanine aminotransferase [ALT], alkaline phosphatase, aspartate aminotransferase [AST], total bilirubin [TBIL], and lactate dehydrogenase), ICU scoring systems (APACHE III, SAPS II, SOFA, and Charlson Comorbidity Index), comorbidities (hypertension, diabetes mellitus, coronary artery disease, heart failure [HF], chronic obstructive pulmonary disease, and liver disease [including cirrhosis and liver failure]), therapeutic interventions (vasopressor use, mechanical ventilation, CRRT, broad-spectrum antibiotic use, exogenous albumin administration, and fluid resuscitation [≥30 mL/kg]), and outcome indicators (hospital and ICU length of stay, in-hospital, 28-day, and 90-day mortality).

The primary exposure variable was the dynamic trajectory of the LAR during ICU stay, derived from serial measurements of lactate and albumin.

Follow-Up and Outcomes

The primary outcome was 28-day all-cause mortality. The secondary outcomes included 90-day all-cause mortality and CRRT initiation. For both the Medical Information Mart for Intensive Care (MIMIC) and external hospital cohorts, follow-up began at ICU admission in this study. All 28- and 90-day mortality outcomes were calculated from this index time. Patients who were discharged alive and had no subsequent death records were considered alive for the corresponding follow-up window, and no additional adjustments were made for the date of hospital discharge.

XSL•FO
RenderX

Statistical Analysis

LAR was calculated based on lactate and albumin measurements at the 4 time windows. In the MIMIC-IV cohort, the proportions of missing LAR values at 0, 24, 48, and 72 hours were 5.85% (36/615), 10.73% (66/615), 11.71% (72/615), and 14.96% (92/615), respectively. Corresponding proportions in the external validation cohort were 11.42% (58/508), 7.48% (38/508), 5.12% (26/508), and 13.19% (67/508). To handle missing data at later time points (partly due to early death or ICU discharge), GBTM was performed using the R package *lcmm* [26]. Within this framework, missing repeated measures were statistically managed using full information maximum likelihood. This method allows all available data points to inform the model without removing patients with incomplete trajectories, thereby reducing potential bias from incomplete repeated measurements. Trajectory modeling used cubic polynomial functions for LAR trajectories, and models with 1 to 7 classes were fitted to select the optimal number of classes. The optimal model was determined based on comprehensive evaluation using the following criteria [27]: (1) Bayesian information criterion and Akaike information criterion, with lower values indicating better fit; (2) average posterior probability (AvgPostProb) >0.7 to ensure classification reliability; (3) minimum sample proportion for each trajectory group not less than 5% - 10%; (4) entropy >0.7 indicating good between-group discrimination; and (5) clinical interpretability of the model.

Baseline covariates with missing rates ≥20% were excluded, whereas missing values in the remaining baseline covariates were imputed using multiple imputation with the random forest algorithm implemented via the *mice* package in R. The normality of continuous variables was assessed using the Shapiro-Wilk test. Normally distributed variables were expressed as mean (SD) and compared using one-way ANOVA, whereas nonnormally distributed variables were expressed as median (IQR) and compared using the Kruskal-Wallis test. Categorical variables were presented as counts (%) and compared using the chi-square test or Fisher exact test, as appropriate.

Survival analyses were performed using Kaplan-Meier curves and multivariable Cox proportional hazards models to examine associations between LAR trajectory classes and mortality. To address confounding by artificial clearance mechanisms while maintaining the clinical simplicity of the prognostic tools, exogenous albumin administration was strictly adjusted as a baseline fixed covariate in the mortality models. CRRT was not included as a covariate in the mortality models and was analyzed separately as a secondary outcome. CRRT initiation was treated as the dependent variable in this analysis. Due to the lack of precise initiation timing, this analysis was not intended to infer time-sequenced causal effects and should be interpreted as an association. Covariates for multivariable models were predefined based on clinical rationale and core interventions highlighted during peer review. Three stepwise models were constructed: model A (unadjusted), model B (partially adjusted for key clinical interventions altering LAR and hemodynamics: baseline liver disease, exogenous albumin administration, and fluid resuscitation target ≥30 mL/kg), and Model C (fully adjusted). For 28- and 90-day mortality outcomes, model C further adjusted for APACHE III score, AKI stage, HF, and vasopressor use. For CRRT initiation, multivariable logistic regression was used, with model C additionally adjusting for model B covariates plus AKI stage, SOFA score, vasopressor use, and AG. Furthermore, the variance inflation factor for all included covariates across these models was confirmed to be < 5, indicating the absence of significant multicollinearity. Restricted cubic spline (RCS) analyses were applied to explore potential nonlinear relationships between LAR values at each time point and 28-day mortality. Subgroup analyses were performed to identify potential effect modifiers in the association between LAR trajectories and both 28- and 90-day mortality among patients with SA-AKI, with results visualized using the *forestploter* R package.

To test the robustness of results, inverse probability of treatment weighting (IPTW) and truncated weight sensitivity analyses were conducted to control for confounding bias [28]. Additionally, a doubly robust (DR) model was constructed using weighted data to evaluate the association between LAR trajectory classes and 28-day mortality, with weighted Kaplan-Meier survival curves plotted for visualization.

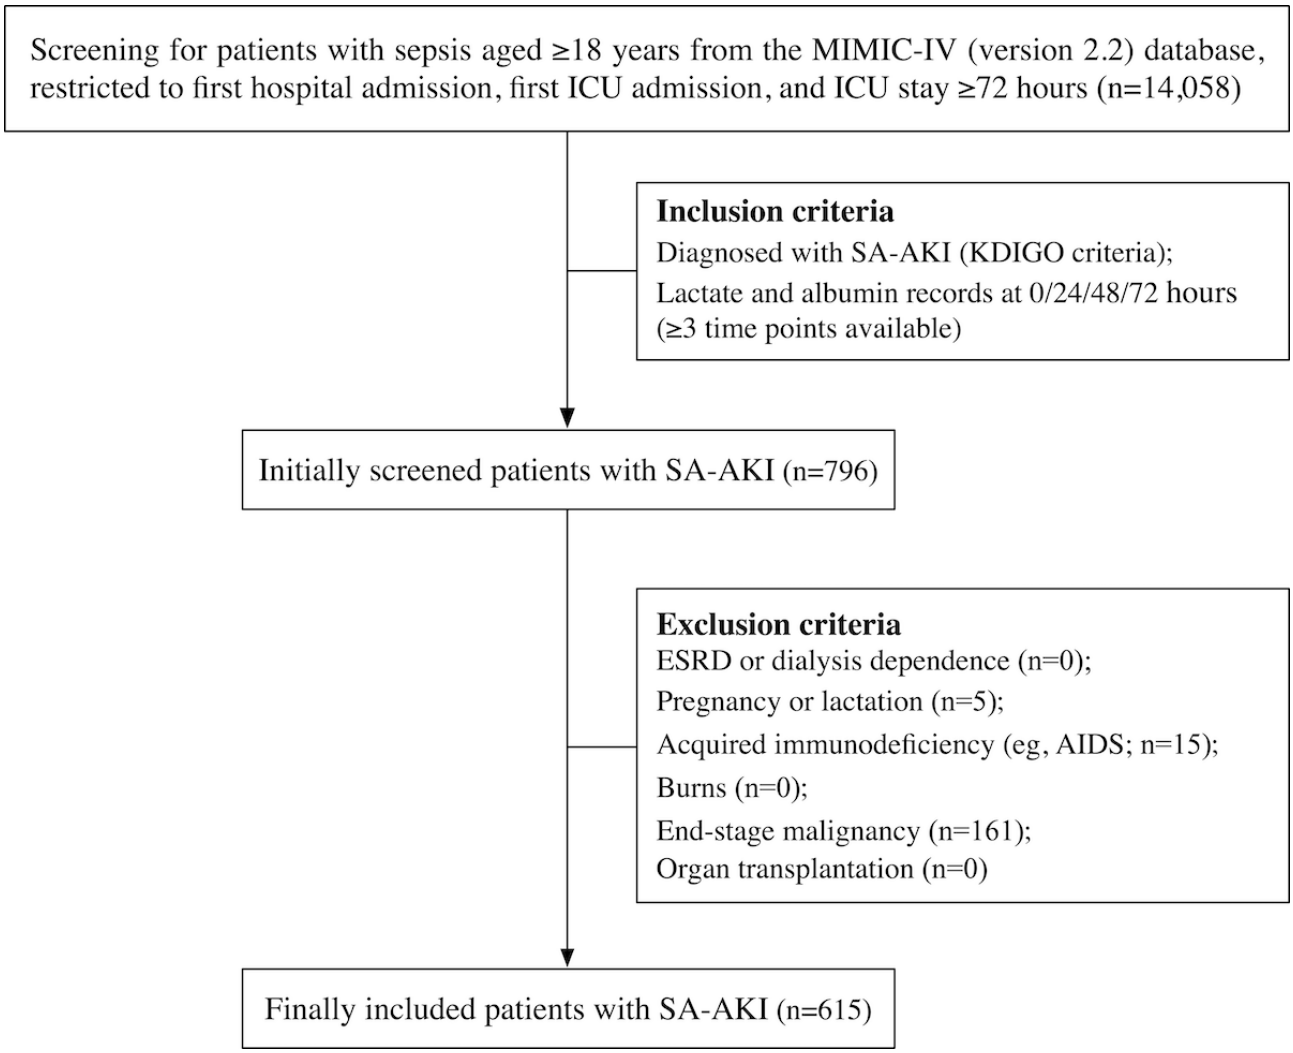
For external validation, the GBTM method was used to classify LAR trajectories. Multivariable Cox regression assessed the association between trajectory groups and 28-day mortality, while multivariable logistic regression evaluated their relationship with CRRT. Because APACHE III was not available in the prospective cohort (APACHE II was collected instead; Table S3 in Multimedia Appendix 1), and several primary-cohort covariates (baseline liver disease, exogenous albumin administration, and fluid resuscitation volume) were unavailable, the validation-cohort models were adjusted using routinely available variables (age, SOFA score, AKI stage, and vasopressor use) rather than the primary-cohort adjustment set. This approach assessed the reproducibility of the trajectory classification.

To further quantify the incremental predictive value of the dynamic trajectory model, we systematically compared it against a baseline model using only the single admission LAR (LAR at 0 hour). The improvement in predictive performance for both 28- and 90-day mortality was assessed using Harrell's concordance index (C-index), continuous net reclassification improvement (NRI), and integrated discrimination improvement (IDI).

To facilitate bedside decision-making, a prognostic nomogram was constructed by integrating the LAR trajectory classes with the core predefined covariates. The predictive performance and clinical applicability of this tool were rigorously evaluated in both the derivation and external validation cohorts. Discrimination was quantified using the C-index, while calibration curves were plotted to assess the agreement between predicted and observed survival probabilities. Furthermore, decision curve analysis and clinical impact curves were generated to evaluate the clinical net benefit and utility at varying threshold probabilities. Finally, patients in the external validation cohort were stratified into distinct risk groups based on their total nomogram scores, and Kaplan-Meier survival curves were used to validate the model's risk stratification

XSL•FO
RenderX

capacity. These predictive modeling and clinical utility analyses were primarily conducted using the *rms* and *rmda* R packages.



All analyses were performed using R software (version 4.5.1; R Foundation for Statistical Computing), and a 2-tailed *P* value <.05 was considered statistically significant.

Results

LAR Trajectory Phenotypes in Patients With SA-AKI

Figure 1 shows the study flowchart. Of the 14,058 adult patients who were admitted to the ICU for the first time and stayed for more than 72 hours, 615 patients with SA-AKI met the inclusion criteria and were included in the GBTM analysis. To mitigate the influence of extreme values, LAR data were winsorized at the 1st and 99th percentiles prior to modeling (Figure S1 in Multimedia Appendix 1).

Figure 1. Flowchart of the patient selection process. ESRD: end-stage renal disease; ICU: intensive care unit; KDIGO: Kidney Disease Improving Global Outcomes; MIMIC-IV: Medical Information Mart for Intensive Care IV; SA-AKI: sepsis-associated acute kidney injury.

The model fitting results for 1 to 7 trajectory classes are presented in Table 1 and Figure 2B. A 3-class model was ultimately selected as optimal. Although the 3-class model did not yield the lowest Akaike information criterion or Bayesian information criterion values, it exhibited the highest AvgPostProb, satisfactory entropy, a minimum class proportion >10%, and excellent clinical interpretability. As illustrated in Figure 2A, 3 distinct trajectories of LAR were identified. Trajectory 1 (low-stable type) was characterized by consistently low LAR levels with minimal fluctuation over time. Trajectory 2 (rapid-clearance type) showed markedly elevated baseline LAR levels that decreased rapidly, reflecting an effective and swift clearance of lactate following initial resuscitation, before gradually rising again. Trajectory 3 (delayed-clearance type) exhibited an early increase, indicating an initial failure of lactate clearance and continuous metabolic accumulation, followed by a gradual decline in LAR levels. These findings highlight substantial heterogeneity in LAR evolution among patients with SA-AKI, delineating 3 distinct and clinically meaningful trajectory patterns.

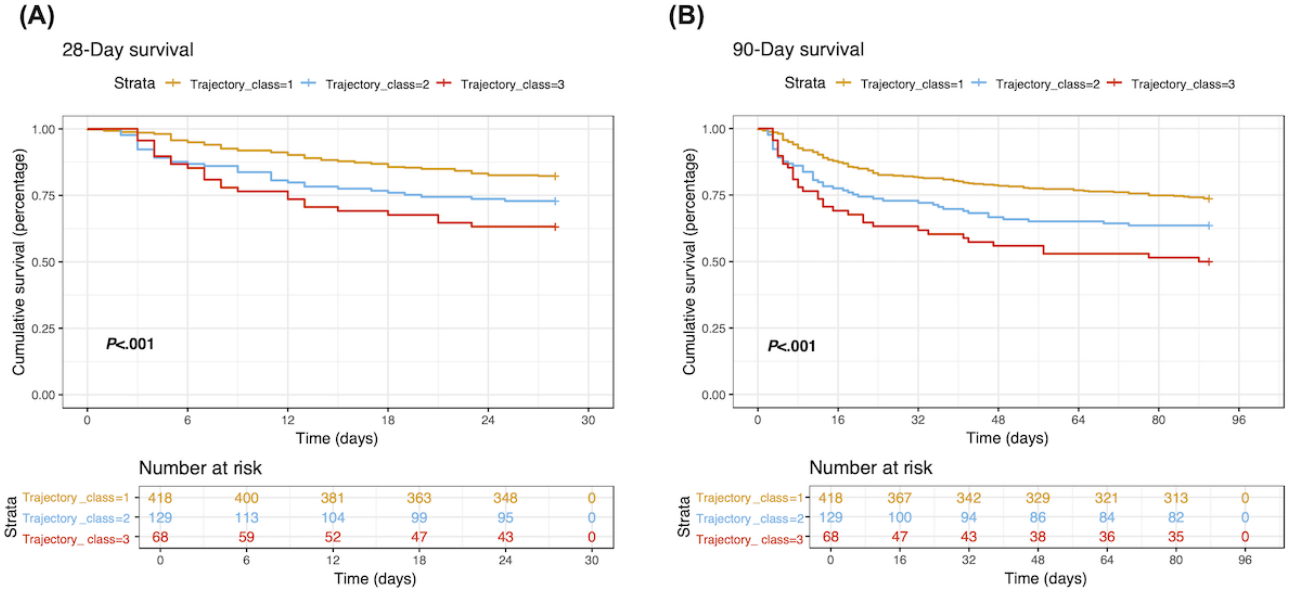
Baseline Characteristics

The 615 included patients were divided into 3 trajectory groups: trajectory 1 (n=418, 67.97%), trajectory 2 (n=129, 20.97%), and trajectory 3 (n=68, 11.06%). Table 2 compares baseline characteristics of patients across the 3 LAR trajectory types. The 3 groups showed no statistically significant differences in age, sex, race, or the prevalence of preexisting liver disease (*P*>.05). SOFA scores were lowest in trajectory 1, while trajectories 2 and 3 were comparably higher. Clinically, trajectory 3 patients presented with higher BMI and faster heart rates. Laboratory findings revealed lower WBC and lymphocyte counts, HCO_3^-, and Ca^{2+}, alongside higher AG and lactate dehydrogenase levels. In addition, significantly elevated APACHE III and SAPS II scores in trajectory 3 reflected more pronounced systemic inflammation and organ dysfunction. Furthermore, trajectory 3 had the highest proportion of AKI stage 3 and CRRT initiation, with significantly increased vasopressor use. Consistent with their profound hemodynamic instability, a substantially greater proportion of patients in trajectory 3 required aggressive early fluid resuscitation (≥30 mL/kg; 51/68, 75%; *P*<.001) and exogenous albumin administration (30/68, 44.12%; *P*=.03). Trajectory 2 (rapid-clearance type) patients had lower platelet counts, hemoglobin, hematocrit, and monocyte levels, while PT, INR, ALT, AST, and TBIL were higher, suggesting potential acute hepatic dysfunction despite no significant difference in baseline liver disease history. In contrast, trajectory 1 patients showed relatively higher temperature, WBC count, blood urea nitrogen levels, and HF prevalence, but overall milder clinical severity.

Regarding clinical outcomes, no significant difference was observed in overall hospital length of stay among these 3 groups. However, trajectory 3 patients had longer ICU stays and significantly higher in-hospital, 28-day, and 90-day mortality rates compared with the other 2 groups (all *P*<.05).



Association Between LAR Trajectories and Outcome Variables

Kaplan-Meier survival curves across LAR trajectory groups are shown in Figure 3. Trajectory 3 exhibited the lowest survival probability among these 3 patient groups (28-day mortality: *P*<.001; 90-day mortality: *P*<.001; Figure 3A and B). Consistent with these survival trends, multivariable logistic regression analysis revealed that trajectory 3 was also associated with a significantly increased risk of in-hospital mortality (OR 1.81,

XSL•FO
RenderX

95% CI 1.07 - 3.13; *P*=.03) after adjusting for baseline liver disease, exogenous albumin administration, and fluid resuscitation target (≥30 mL/kg), whereas the risk for trajectory 2 did not differ significantly from the reference group (Table S1 in Multimedia Appendix 1).

Figure 3. Kaplan-Meier survival analysis for all-cause mortality among each LAR trajectory. Kaplan-Meier curves of (A) 28-day and (B) 90-day all-cause mortality stratified by LAR trajectories. LAR: lactate-to-albumin ratio.

To evaluate the independent association between LAR trajectories and clinical outcomes, we constructed 3 progressive multivariable regression models (Table 3 and Figure 4A and C). In the unadjusted analysis (model A) and the partially adjusted analysis (model B, which accounted for baseline liver disease and early resuscitation interventions), both trajectories 2 and 3 remained significantly associated with increased risks of 28-day mortality, 90-day mortality, and CRRT initiation compared to trajectory 1.

However, after further adjusting for overall disease severity and organ dysfunction indicators (model C), the trajectory-outcome associations diverged: trajectory 3, but not trajectory 2, remained an independent risk factor for these adverse outcomes. Specifically, using trajectory 1 as the reference, trajectory 3 was independently associated with a 1.63-fold higher risk of 28-day mortality (hazard ratio [HR] 1.63, 95% CI 1.00 - 2.64; *P*=.0496) and a 1.72-fold higher risk of 90-day mortality (HR 1.72, 95% CI 1.14 - 2.60; *P*=.01). Conversely, the mortality risk for trajectory 2 (rapid-clearance type) did not differ significantly from trajectory 1 in the fully adjusted model (28-day: HR 1.30, 95% CI 0.85 - 1.97; *P*=.22; 90-day: HR 1.25, 95% CI 0.88 - 1.78; *P*=.22). Consistent findings were observed for the CRRT initiation; multivariable logistic regression (model C) demonstrated that trajectory 3 patients had a substantially higher risk of requiring CRRT (odds ratio [OR] 3.40, 95% CI 1.64 - 7.15; *P*=.001), whereas trajectory 2 was not independently associated with increased CRRT use (OR 0.92, 95% CI 0.53 - 1.58; *P*=.77).

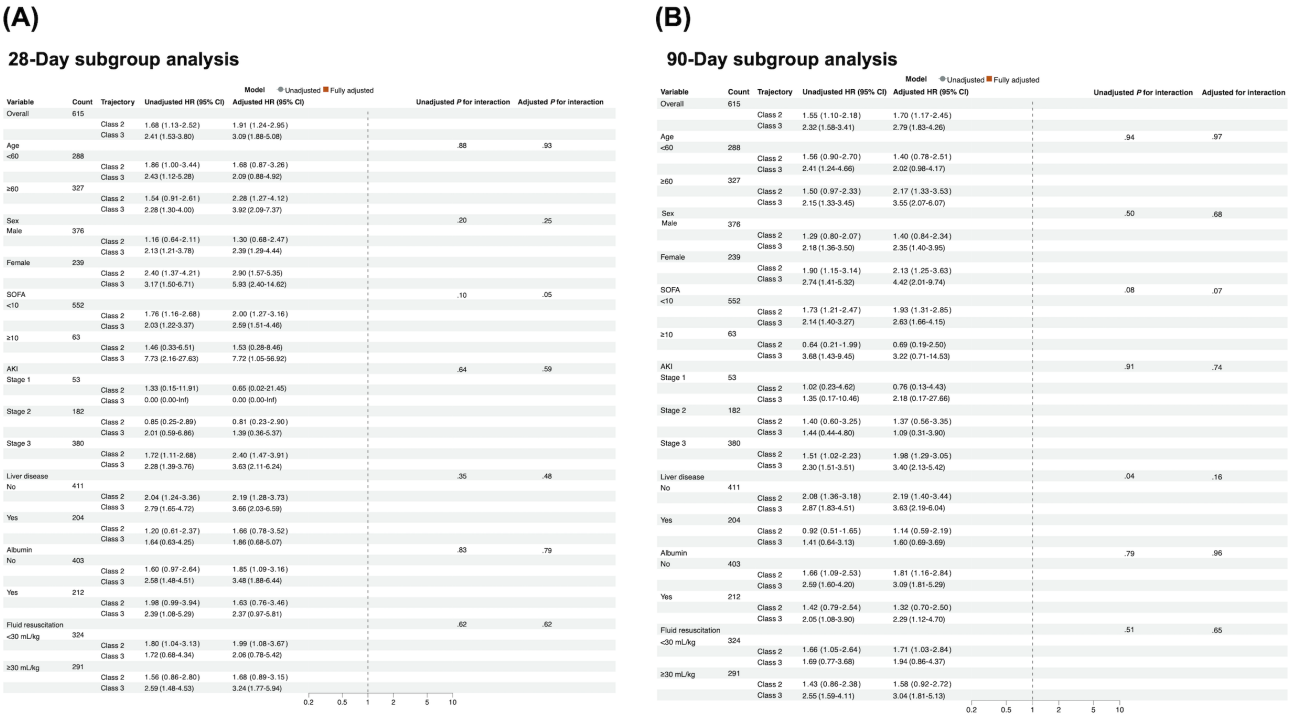
(C) Multivariable Cox regression analysis of 90-day mortality across 3 progressive models. (D) Incremental predictive value of the trajectory model for 90-day mortality. C-index: concordance index.



RCS and Subgroup Analysis

RCS models were used to explore the nonlinear association between LAR and 28-day mortality in patients with SA-AKI (Figure S2 in Multimedia Appendix 1). A significant nonlinear relationship was observed at all 4 time points (0, 24, 48, and 72 hours; all $P<.05$). Notably, the mortality risk gradients steepened progressively at later time intervals (24 - 72 hours) compared with the baseline (0 hours). These temporal dynamics demonstrate that a persistently elevated LAR confers a disproportionately higher mortality hazard, underscoring the prognostic superiority of serial assessments over a single admission value.

Figure 5 presents the subgroup analyses evaluating the association between LAR trajectory classes and 28-day (Figure 5A) as well as 90-day mortality (Figure 5B). Patients were stratified by clinically relevant baseline characteristics and early interventions, including age, sex, SOFA score, AKI stage, liver disease, exogenous albumin administration, and fluid resuscitation volume (≥30 mL/kg). No significant interactions were detected across any of the predefined strata (all P for interaction >.05), demonstrating that the prognostic impact of the LAR trajectories was consistent across diverse clinical subpopulations. Crucially, in alignment with our primary multivariable analysis, the fully adjusted forest plots confirmed that trajectory 3 (delayed-clearance type) maintained a consistent and independent association with higher mortality risk across most subgroups. Conversely, the mortality risk associated with trajectory 2 was largely attenuated and lost statistical significance upon full adjustment within these strata.

XSL•FO
RenderX

Figure 5. Subgroup analyses of the associations between LAR trajectories and mortality. (A) Forest plot of subgroup analysis for 28-day mortality. (B) Forest plot of subgroup analysis for 90-day mortality. Both unadjusted and fully adjusted HRs are presented, with *P* values for interaction indicating no significant effect modification across strata. AKI: acute kidney injury; HR: hazard ratio; LAR: lactate-to-albumin ratio; SOFA: Sequential Organ Failure Assessment.

Sensitivity Analyses

After applying IPTW based on multinomial propensity scores, the absolute standardized mean differences for all covariates were substantially reduced to <0.1 (indicated by the dashed line), demonstrating excellent covariate balance and successful mitigation of baseline confounding across the LAR trajectory groups (Figure 6A).

As shown in Table 4, the weighted Cox regression (untruncated) revealed that the mortality risk for trajectory 2 did not differ significantly from trajectory 1 (HR 1.19, 95% CI 0.75 - 1.88; *P*=.45), while trajectory 3 exhibited a trend toward higher risk (HR 1.95, 95% CI 0.93 - 4.09; *P*=.08). After trimming extreme weights at the 1st and 99th percentiles to reduce the influence of extreme values, the results remained consistent, yielding HRs of 1.20 and 1.79 for trajectories 2 and 3, respectively.

To rigorously account for any residual confounding, a DR Cox model was used (IPTW+covariate adjustment). In this DR model, trajectory 3 remained significantly and independently associated with higher 28-day mortality (HR 2.09, 95% CI 1.03 - 4.24; *P*=.04), whereas trajectory 2 maintained no significant association (HR 1.24, 95% CI 0.79 - 1.95; *P*=.34). These findings are visually corroborated by the IPTW-adjusted Kaplan-Meier survival curves (Figure 6B), where trajectory 3 continues to exhibit the lowest survival probability. However, in the IPTW-weighted analyses (both untruncated and truncated), the association for trajectory 3 was attenuated and did not reach statistical significance (*P*=.08 and *P*=.07, respectively), and statistical significance was only observed in the DR model. Given that the primary fully adjusted estimate was also borderline (HR 1.63, 95% CI 1.00 - 2.64), these results indicate that the estimated effect for trajectory 3 is sensitive to the analytical framework. Accordingly, these findings should be interpreted as supportive but not conclusive evidence of an independent association.

Figure 6. Sensitivity analyses evaluating the robustness of LAR trajectories using IPTW and a doubly robust model. (A) Covariate balance before (unadjusted) and after (adjusted) IPTW. The dashed line indicates an absolute standardized mean difference of 0.1, showing excellent balance across covariates. (B) IPTW-adjusted Kaplan-Meier survival curves and the adjusted HR derived from the doubly robust model for 28-day mortality. AKI: acute kidney injury; APACHE III: Acute Physiology and Chronic Health Evaluation III; HF: heart failure; HR: hazard ratio; IPTW: inverse probability of treatment weighting; LAR: lactate-to-albumin ratio; PT: prothrombin time; WBC: white blood cell.

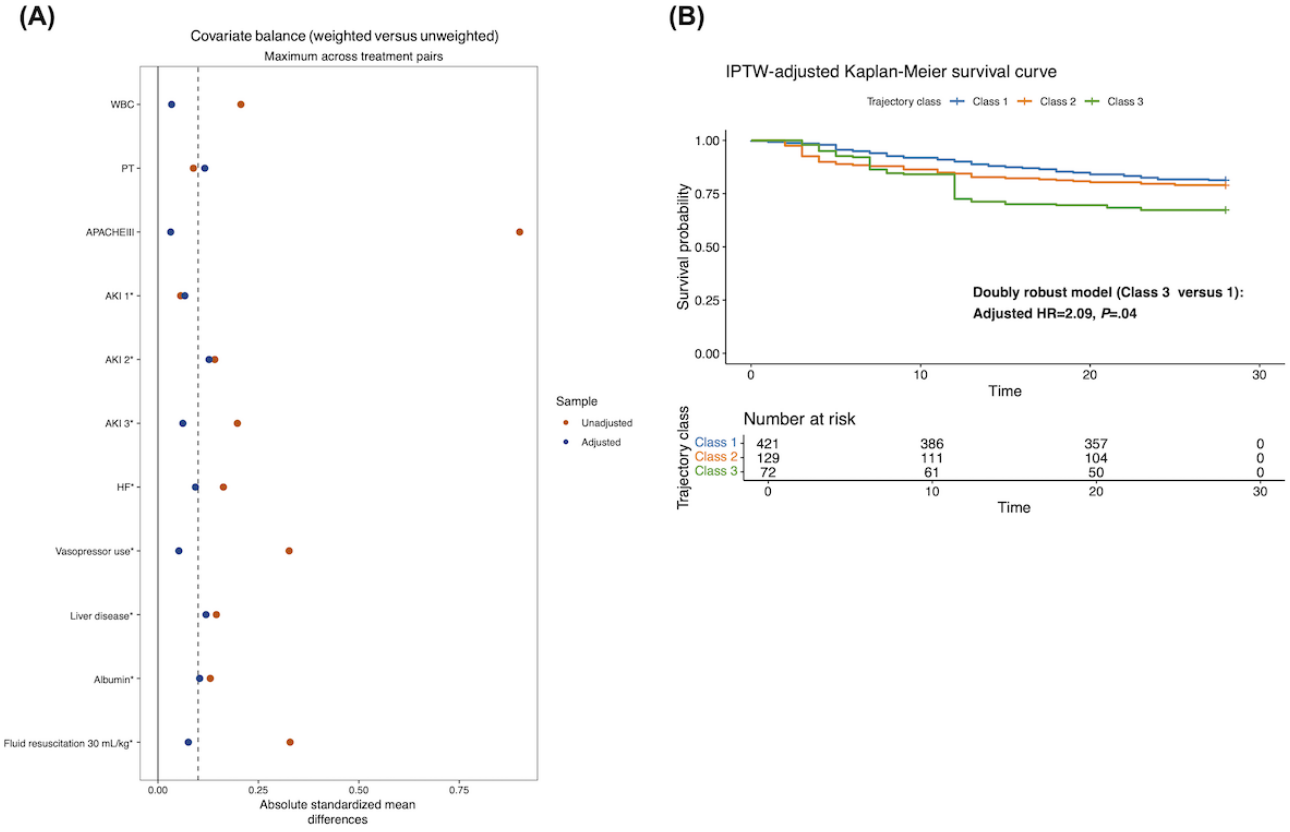

Table . Association between lactate-to-albumin ratio trajectory classes and 28-day mortality after IPTW[a] and double robust adjustment.

Model and comparison vs trajectory 1	HR[b] (95% CI)	*P* value	Concordance	Weighted method
IPTW-Cox (untruncated)			0.553	Stabilized weights
Trajectory 2	1.19 (0.75 - 1.88)	.45		
Trajectory 3	1.95 (0.93 - 4.09)	.08		
IPTW-Cox (truncated)			0.545	Truncated weights (1st-99th percentile)
Trajectory 2	1.20 (0.76 - 1.88)	.44		
Trajectory 3	1.79 (0.95 - 3.39)	.07		
Double robust Cox model			0.685	IPTW+covariate adjustment
Trajectory 2	1.24 (0.79 - 1.95)	.34		
Trajectory 3	2.09 (1.03 - 4.24)	.04		

[a]IPTW: inverse probability of treatment weighting.

[b]HR: hazard ratio.

External Validation Results

In the external validation cohort (n=508), 3 distinct LAR trajectory patterns were identified, with time-course patterns consistent with those observed in the MIMIC-IV cohort. These included trajectory 1 (low-stable type), trajectory 2 (rapid-clearance type), and trajectory 3 (delayed-clearance type; Figure 7A and Table S2 in Multimedia Appendix 1). Patients in trajectory 3 exhibited poorer prognosis, with a significantly higher 28-day mortality rate (Figure 7B). Comparison of baseline characteristics (Table S3 in Multimedia Appendix 1) revealed that trajectory 3 patients exhibited more pronounced inflammation, more severe coagulopathy, greater multiorgan dysfunction, and higher rates of CRRT initiation, in line with the findings from the MIMIC-IV cohort. Multivariable regression analyses were conducted on the validation set to

XSL•FO
RenderX

further assess the relationship between LAR trajectories and clinical outcomes (Table 5). For 28-day mortality, multivariable Cox regression analysis confirmed that trajectory 3 (delayed-clearance type) carried the highest mortality risk, demonstrating a 2.86-fold increase compared with trajectory 1 (HR 2.86, 95% CI 1.57 - 5.22; *P*<.001). In this validation cohort, trajectory 2 was also significantly associated with an elevated risk of 28-day mortality (HR 2.49, 95% CI 1.35 - 4.59; *P*=.003). Cross-cohort analyses revealed that trajectory 2 patients from the validation cohort were more critically ill at baseline than their MIMIC-IV counterparts, with higher SOFA scores and more frequent vasopressor use (Table S4 in Multimedia Appendix 1). Conversely, multivariable logistic regression analysis revealed that the LAR trajectory type did not independently predict the initiation of CRRT in the validation set. While patients in trajectory 3 (OR 1.89, 95% CI 0.79 - 4.76; *P*=.16) and trajectory 2 (OR 1.62, 95% CI 0.71 - 3.68; *P*=.25) showed a clinical tendency toward requiring CRRT, neither association reached statistical significance.

Incremental Predictive Value and External Validation of the Clinical Nomogram

To evaluate whether dynamic LAR trajectories offer superior prognostic utility compared with a single baseline measurement, we assessed their incremental predictive value using C-index, continuous NRI, and IDI (Table 6 and Figure 4B and D). For 28-day mortality, integrating the LAR trajectory class into the baseline model significantly improved its discriminative ability (C-index increased from 0.579 to 0.618; *P*=.03). This enhancement was further supported by a continuous NRI of 0.170 (*P*=.01) and an IDI of 0.023 (*P*=.01), indicating that the trajectory model correctly reclassified a substantial proportion of patients. Consistent improvements in predictive accuracy were similarly observed for 90-day mortality (Table 6). These findings strongly suggest that the temporal evolution of LAR provides critical prognostic information beyond what a single admission value can offer.

Table . Incremental predictive value of dynamic LAR[a] trajectories compared to single baseline LAR.

Predictive model[b]	C-index[c]	*P* value[d]	Continuous NRI[e] (95% CI)	*P* value	IDI[f] (95% CI)	*P* value

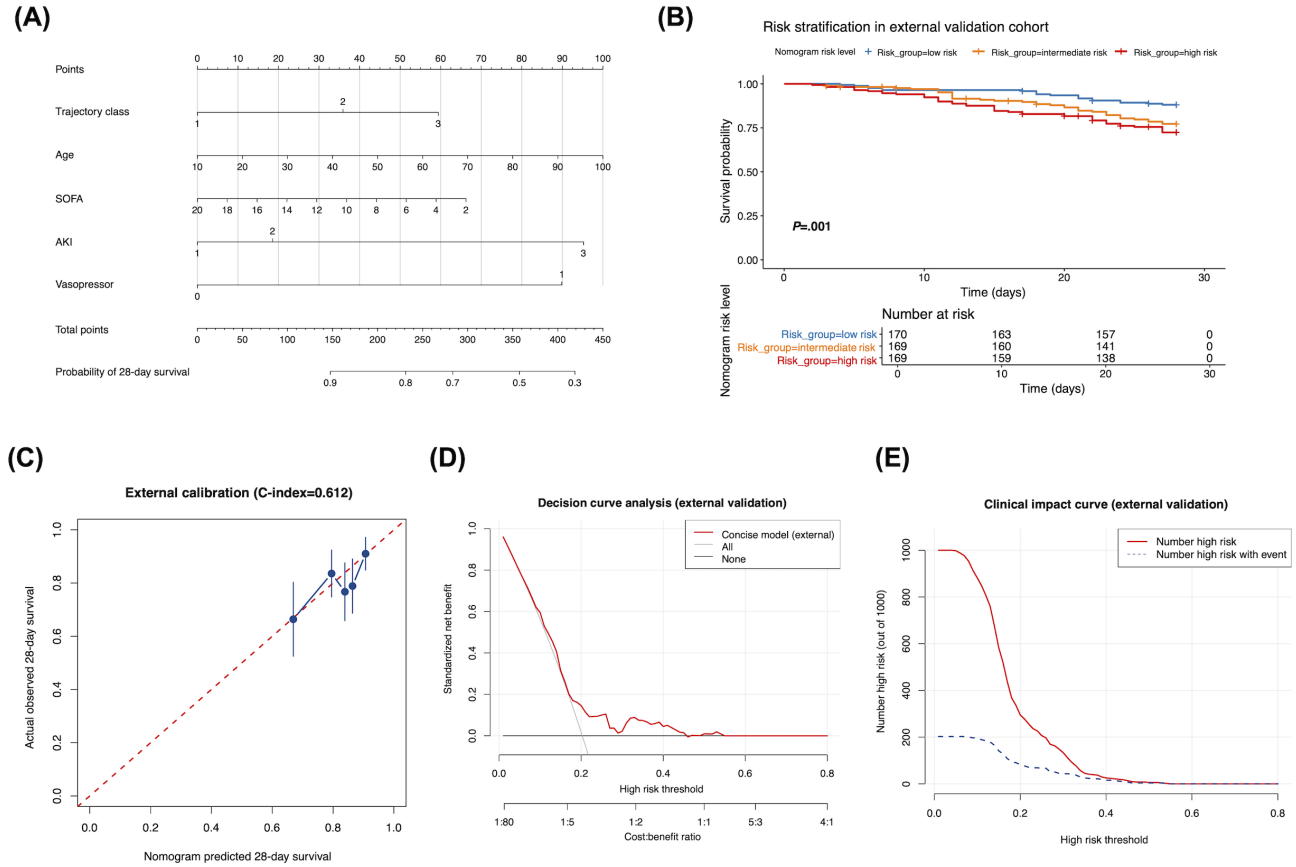
[f]IDI: integrated discrimination improvement.



[g]Not applicable.

To translate these findings into a practical bedside tool, we constructed a prognostic nomogram for predicting 28-day survival. As illustrated in Figure 8A, the nomogram incorporates the LAR trajectory class alongside standard clinical predictors: age, SOFA score, AKI stage, and vasopressor use. The clinical reliability and generalizability of this model were subsequently evaluated in an independent multicenter validation cohort from tertiary hospitals in Beijing. Additionally, a web-based dynamic prognostic calculator with a user-friendly interface is available to facilitate bedside risk assessment (Figure S3 in Multimedia Appendix 1).

Applying the nomogram to the external validation cohort allowed for effective risk stratification. Patients were stratified into low-, intermediate-, and high-risk groups, with Kaplan-Meier analysis showing statistically detectable separation in survival probabilities among the 3 strata (*P*=.001; Figure 8B). The nomogram exhibited satisfactory discrimination in the external cohort with a C-index of 0.612, and the calibration curve showed favorable concordance between the nomogram-predicted and actual observed 28-day survival probabilities (Figure 8C). Furthermore, decision curve analysis confirmed that the concise model yielded a positive standardized net benefit across a wide range of high-risk thresholds, outperforming the “treat-all” and “treat-none” strategies (Figure 8D). The clinical impact curve additionally suggested the model’s practical utility in accurately identifying high-risk individuals in a real-world clinical setting, primarily functioning as a supplementary tool for bedside risk stratification rather than a standalone predictive model (Figure 8E).

Discussion

Principal Findings

In this derivation and multicenter trajectory-based study of patients with SA-AKI, we identified 3 distinct early LAR trajectories and demonstrated that the delayed-clearance trajectory (trajectory 3) was independently associated with 28- and 90-day mortality. Importantly, dynamic LAR trajectories provided incremental prognostic value beyond single baseline LAR, and the trajectory-integrated nomogram showed reproducible risk stratification in an external validation cohort. These findings suggest that the temporal evolution of LAR, rather than its baseline value alone, may better capture the dynamic pathophysiology of SA-AKI. Although the overall trajectory shapes identified in the external validation cohort were analogous to those in the MIMIC-IV cohort, substantial differences in trajectory distribution were evident. Specifically, the proportion of patients assigned to the low-stable trajectory increased from 67.97% in the MIMIC cohort to 87.4% in the validation cohort, whereas the rapid-clearance and delayed-clearance trajectories became less frequent (6.9% and 5.7%, respectively). These findings indicate that while the trajectory framework itself was reproducible, the prevalence of individual trajectory classes varied substantially across cohorts. Several factors may contribute to this distributional shift, including differences in patient case-mix, health care system structures, ICU admission thresholds, local resuscitation practices, and the timing of ICU admission relative to sepsis onset.

Pathophysiological Insights Into LAR Trajectories

Multiple studies have demonstrated that LAR is closely associated with mortality in SA-AKI and may serve as an emerging composite biomarker with significant value in assessing disease severity and prognosis in critically ill patients [17,29,30]. However, LAR changes with SA-AKI disease progression and may serve as a “dynamic marker” of disease evolution. A study from Athens measured LAR both at sepsis diagnosis and 1 week later, demonstrating that LAR was associated with sepsis severity and mortality in both early and late disease stages [19]. Research by Shadvar et al [31] showed that LAR at 6 hours after septic shock onset had high predictive value for mortality, with the area under the receiver operating characteristic curve reaching 91.7%. Consequently, dynamic monitoring of LAR is crucial for assessing septic shock. Nevertheless, the longitudinal trajectory of LAR during the course of SA-AKI and its association with clinical outcomes has not been fully elucidated. Thus, systematically evaluating the dynamic changes of LAR holds significant clinical value for predicting the prognosis of SA-AKI. Furthermore, existing research indicates that most AKI cases resolve within 72 hours, with persistent severe AKI defined as progression from AKI

XSL•FO
RenderX

stage 2‐3 (KDIGO classification) to stage 3 persisting ≥72 hours [32], highlighting the importance of early SA-AKI management. Therefore, it is reasonable that this study selected the 72-hour time window after SA-AKI onset to analyze LAR dynamic changes.

In this study, we identified 3 LAR dynamic trajectory classes: trajectory 1 (low-stable type), trajectory 2 (rapid-clearance type), and trajectory 3 (delayed-clearance type). Among these, trajectory 1 had the lowest overall critical illness scores and best outcomes, representing a "low-risk stable trajectory" group with consistently low LAR values (<1). Trajectory 3 had the most severe disease course, complicated by metabolic acidosis, renal function deterioration, and circulatory deterioration, with markedly higher critical illness scores, more pronounced multiorgan dysfunction, the highest subsequent CRRT initiation, and the highest 28- and 90-day mortality rates (P<.05). Furthermore, Kaplan-Meier survival analysis and multivariable Cox regression suggested an association between trajectory 3 and 28-day mortality in patients with SA-AKI. RCS and subgroup analyses were directionally consistent. However, in IPTW-weighted models, the association was attenuated and no longer statistically significant; significance was only observed under DR adjustment. Consequently, this finding appears sensitive to the analytical approach and should be interpreted with caution. Trajectory 2 presented with markedly elevated baseline LAR, initially mimicking a critically ill state, but experienced a rapid decline. This pattern may reflect preserved physiologic reserve, quick restoration of tissue perfusion, and a favorable biochemical response to early resuscitation. In contrast, trajectory 3 showed a more prolonged metabolic disturbance. Consistent with established pathophysiological mechanisms of persistent hyperlactatemia and severe systemic inflammation in sepsis [33], this delayed-clearance phenotype likely reflects a "refractory" state driven by underlying microcirculatory shunting, mitochondrial dysfunction, and impaired hepatic clearance. These patients may initially appear hemodynamically stabilized; yet, the delayed clearance signals an ongoing, insidious cellular hypoxia that ultimately drives progressive organ damage. The successful reproduction of these trajectory models in the multicenter validation cohort supports their external validity, despite cohort-level variations in class distribution and effect sizes. These results indicate that the dynamic trajectory of LAR may serve as a prognostic indicator in patients with SA-AKI, potentially facilitating early identification of high-risk individuals and supporting the development of individualized therapeutic strategies to slow disease progression and improve clinical outcomes.

Clinical Actionability and Bedside Translation

Prior studies have reported markedly different optimal cutoff values for LAR. For example, Bou Chebl et al [34] identified thresholds of 1.22 for sepsis and 1.47 for septic shock in an emergency department population, whereas Zhu et al [35] found that LAR ≥1.49 independently predicted in-hospital and ICU mortality among critically ill patients with AKI. In another study, Wang and Yu [30] determined a cutoff value of LAR ≥0.95 associated with increased mortality in SA-AKI. These inconsistencies are likely attributable to differences in study populations, sample sizes, and timing of LAR measurement. Our study overcomes the inherent limitations of these static cutoffs by demonstrating the substantial incremental predictive value of dynamic trajectories. Integrating the trajectory class significantly improved model discrimination (C-index) and reclassification (NRI and IDI) compared to a single baseline LAR. Although statistically significant, the improvement in model discrimination was numerically modest (absolute C-index of approximately 0.61). This performance is consistent with existing ICU prognostic scores, which typically report C-indices between 0.60 and 0.70 [36,37]. Given the multifactorial nature of SA-AKI, no single biomarker can fully capture outcome heterogeneity. In this context, LAR trajectories may provide additional phenotypic information that helps refine bedside risk stratification and identify patients at higher risk of adverse outcomes when interpreted alongside established clinical scores. Furthermore, our RCS analysis highlighted a potential therapeutic time window. Because mortality risk curves steepened progressively at 24 and 48 hours compared to the 0-hour baseline, we suggest that the 24- to 48-hour window may represent an important period for clinical reassessment. If LAR fails to decline during this time, it warrants a thorough evaluation of hemodynamic adequacy, tissue perfusion, metabolic status, and evolving organ dysfunction, rather than relying on apparent macrocirculatory stabilization alone. While formal trajectory classification requires 72 hours of data, early LAR dynamics may provide clinically relevant information before trajectory assignment is possible. A stagnant or rising LAR during the first 24 to 48 hours may signal inadequate physiological recovery and warrants close reassessment, as these patients may ultimately be classified into the delayed-clearance trajectory. Because the externally validated nomogram relies on the complete 72-hour LAR profile, it functions as a day-3 prognostic tool rather than a real-time resuscitation guide. It is designed to reflect the cumulative physiological response to early treatment and inform subsequent risk stratification.

Trajectory 2 (rapid-clearance type) was particularly noteworthy in this study. Patients in this group exhibited marked hepatic dysfunction, evidenced by significant elevations in PT, INR, ALT, AST, and TBIL, suggesting concurrent or evolving liver injury. From a pathophysiological standpoint, hepatic dysfunction may exert a dual influence on LAR, as impaired hepatic metabolism and clearance of lactate lead to lactate accumulation [38], while reduced albumin synthesis reflects both malnutrition and hepatic synthetic failure [39]. Consequently, LAR levels in this group may be artifactually elevated. These findings highlight the importance of interpreting dynamic LAR changes in conjunction with hepatic function, given the potential bias introduced by liver injury. Notably, previous research has shown that LAR retains prognostic value for mortality even among patients with sepsis and cirrhosis [40], underscoring its robustness and clinical applicability under complex pathophysiologic conditions. Crucially, after rigorous multivariable adjustment for disease severity, baseline liver disease, and early resuscitation interventions (such as fluid volume ≥30 mL/kg and exogenous albumin), the mortality risk associated with trajectory 2 was attenuated and lost statistical significance. This suggests that the initially elevated risk in trajectory 2 may be largely mitigated by appropriate standard care. Although this interpretation may account for the findings

XSL•FO
RenderX

observed in the MIMIC cohort, a different pattern was observed in the external validation cohort. After full adjustment, trajectory 2 remained significantly associated with 28-day mortality in the validation cohort, whereas no independent association was observed in the derivation cohort. Compared with patients assigned to trajectory 2 in the MIMIC-IV cohort, those in the validation cohort were older and had higher illness severity at baseline, including higher SOFA scores and more frequent vasopressor use (Table S4 in Multimedia Appendix 1). These differences suggest that patients sharing a similar LAR trajectory pattern may represent distinct clinical phenotypes across health care settings. Furthermore, exogenous albumin administration was not available in the prospective cohort, which may partly account for differences in the observed performance of trajectory 2 between cohorts. While the trajectory framework itself was reproducible, the apparent prognostic separation between classes is likely influenced by case-mix differences and variation in covariate availability. In contrast, trajectory 3 showed an association with mortality in the primary and DR models, although results were not consistent across IPTW-weighted analyses. Given the marginal significance of the primary estimate (HR 1.63, 95% CI 1.00 - 2.64) and attenuation in IPTW models, the stability of this association should be interpreted with caution. Nevertheless, the directionality of the effect remained consistent across models, suggesting a persistent signal of increased mortality risk in the delayed-clearance phenotype, despite standard fluid or albumin resuscitation. These findings suggest that conventional interventions may be insufficient to fully overcome the profound underlying pathophysiological derangements in this specific subgroup, underscoring the need for vigilant monitoring and the exploration of individualized or intensified therapeutic strategies.

In this study, the CRRT initiation was defined as a secondary end point. In the MIMIC cohort, multivariable logistic regression analysis showed that only trajectory 3 was independently associated with CRRT initiation, whereas trajectory 2 was not. Patients in trajectory 3 exhibited markedly higher AG, lower HCO_3^- levels, a greater proportion of KDIGO stage 3 AKI, and higher vasopressor requirements, indicating that they were more likely to meet CRRT initiation criteria. In contrast, patients in trajectory 2 tended to present with hepatic dysfunction and a relatively lower proportion of KDIGO stage 3 AKI than those in trajectory 3. For them, the clinical benefits of CRRT appear to be limited. However, in our external validation cohort, this association did not reach statistical significance. These findings indicate that the optimal timing of CRRT initiation in SA-AKI remains uncertain [41] and that LAR trajectories alone may be insufficient to guide decisions regarding CRRT. Clinical assessment, metabolic derangements, and multiorgan function should be jointly considered when determining CRRT initiation.

Implications for Future Clinical Trials

Beyond guiding individualized bedside management, identification of the delayed-clearance LAR trajectory may also have important implications for future clinical trial design. Previous pharmacologic trials in SA-AKI have frequently failed, in part because of the substantial clinical heterogeneity of septic populations. Enrolling low-risk patients who are likely to recover with standard care alone, such as those in trajectory 1 or trajectory 2, may dilute the true treatment effect of investigational interventions. Prognostic enrichment [42] based on dynamic LAR trajectories could allow future randomized controlled trials to selectively enroll patients with a high-risk delayed-clearance phenotype who respond poorly to conventional treatment. Such a targeted enrollment strategy may improve statistical power and more accurately define the clinical value of novel metabolic-modulating therapies or extracorporeal organ support strategies.

Strengths and Limitations

The major strengths of this study include the use of longitudinal trajectory modeling, comprehensive sensitivity analyses, comparison with single baseline LAR, and consistent external validation in a prospective multicenter cohort. Nevertheless, this study has several limitations. First, as a single-center study based on the MIMIC database, while validated by a multicenter prospective cohort, the findings may not be generalizable to community hospitals. Second, due to the lack of precise timestamps, CRRT could not be treated as a time-varying exposure. In patients who initiated CRRT early, subsequent LAR measurements may have reflected, in part, machine-driven solute clearance rather than purely physiological lactate handling. Consequently, the observed trajectory patterns may have been influenced by treatment effects in addition to the underlying disease process. Furthermore, because trajectory classification requires 72 hours of data, CRRT may be initiated before this window is completed, introducing temporal ambiguity into the secondary outcome analysis. This analysis should therefore be interpreted as an observational association rather than a causal effect. Third, in the multicenter external validation cohort (collected between June 2023 and October 2025), routine COVID-19 nucleic acid testing was no longer widely implemented in the postpandemic era. Consequently, specific data on COVID-19 infection status were largely unmeasured. Despite this potential unmeasured confounding regarding viral etiology, the trajectory model and nomogram retained modest discrimination (C-index 0.612) while showing acceptable calibration and positive net clinical benefit in this cohort, suggesting its generalizability across different clinical settings. Fourth, although multiple adjustment strategies such as multivariable modeling, IPTW, and DR estimation were used to minimize confounding bias, residual confounders may still exist. Specifically, the external validation cohort lacked data on baseline liver disease, exogenous albumin administration, and fluid resuscitation volume, resulting in a different adjustment set between cohorts. The absence of exogenous albumin data is particularly relevant, as it acts as an unmeasured confounder that may influence the observed prognostic performance of trajectory 2. This external validation represents a pragmatic assessment under real-world data constraints rather than a fully harmonized replication. Finally, the ascertainment of 90-day mortality in the primary MIMIC-IV cohort relied on hospital records and linked mortality data available within the database. Patients discharged alive without subsequent recorded death events were assumed to be alive at 90 days. As MIMIC-IV may not capture all out-of-hospital deaths, this approach could introduce ascertainment bias and potentially underestimate

XSL•FO
RenderX

long-term mortality. Therefore, the 90-day mortality findings should be interpreted with appropriate caution. Addressing these limitations will help to clarify the clinical implications of LAR trajectories for prognostic assessment in patients with SA-AKI.

Conclusions

This study identified distinct dynamic trajectories of the LAR in patients with SA-AKI. The findings demonstrated that temporal LAR trajectories were associated with both 28- and 90-day mortality, with the "delayed-clearance" pattern conferring the highest risk. Furthermore, this trajectory was associated with CRRT initiation in the primary cohort. Dynamic LAR trajectories may serve as consistent composite biomarkers for characterizing disease progression and prognosis in SA-AKI, providing significant incremental predictive value over static baseline measurements. Failure of LAR clearance within the early 24- to 48-hour window may help identify patients who warrant closer monitoring and reassessment of perfusion, metabolic status, renal dysfunction, and overall therapeutic strategy. Ultimately, the externally validated trajectory-integrated nomogram may serve as a supplementary tool for bedside risk stratification, rather than a standalone predictive model.

Abstract

Background: The maintenance and progression of pregnancy rely on immune homeostasis at the maternal-fetal interface. However, pregnancy complicated by autoimmune abnormalities can disrupt this balance and significantly increase the risk of adverse pregnancy outcomes (APOs).

Objective: This study aimed to (1) develop an interpretable predictive tool for APOs in patients with immune abnormalities and (2) interpret the models using Shapley additive explanations (SHAP) values.

Methods: This study retrospectively analyzed clinical data from 288 patients with autoimmune abnormalities at Yichang Central People's Hospital between 2019 and 2024. Feature selection was performed using both the Boruta algorithm and Least Absolute Shrinkage and Selection Operator regression to identify optimal predictive factors associated with APOs. Nine machine learning models were developed and subsequently underwent a comprehensive comparative evaluation of their predictive performance, leading to the identification of the optimal predictive model. SHAP values were generated to provide interpretable insights into model predictions.

Results: A total of 288 patients were included in the study, 124 (43.06%) of whom had APOs. The extreme gradient boosting algorithm was shown to be the optimal model after a comparison of 9 different models utilizing various metrics. The SHAP analysis showed that crown-rump length at 6^{+0} to 8^{+6} weeks, the number of other drugs, the number of complications during pregnancy, gestational sac volume at 6^{+0} to 8^{+6} weeks, and yolk sac diameter change at 6^{+0} to 8^{+6} weeks were the key predictive factors affecting APOs.

Conclusions: The study developed an interpretable predictive tool for APOs in patients with immune abnormalities, which may assist clinicians in making early intervention decisions.

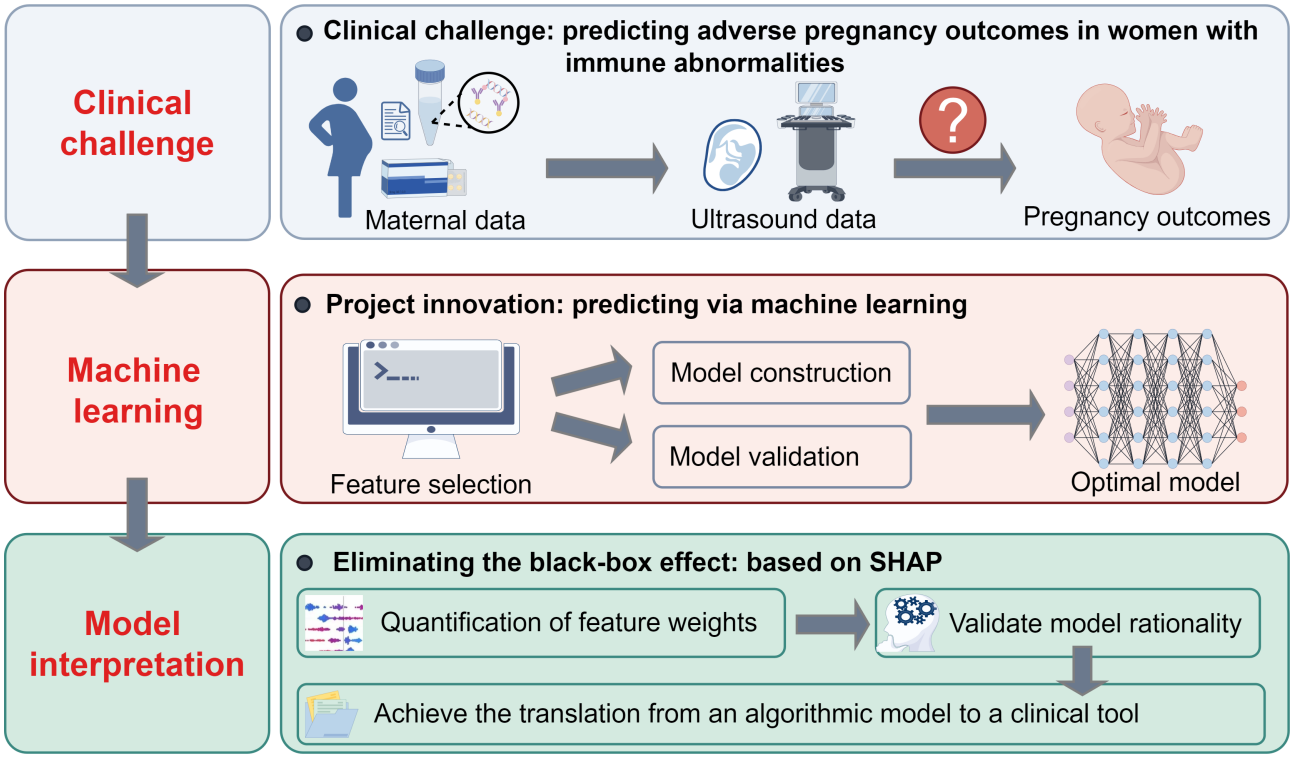
machine learning; ML; ultrasound features; immune abnormalities; pregnancy outcomes

Introduction

When a woman becomes pregnant, the symptoms of autoimmune conditions may improve, worsen, or remain unchanged depending on her specific condition, and such conditions may complicate pregnancy as antibodies produced by the mother can enter the fetal system during development—for example, anti-Ro/SSA antibodies crossing the placenta and impacting the development of the fetal heart [1]. Prior studies have shown that systemic autoimmune conditions are associated with higher risks of adverse pregnancy outcomes (APOs), including spontaneous abortion, preeclampsia or eclampsia, intrauterine growth restriction, and stillbirth [2]. Moreover, reproductive failure in women has been associated with the presence of autoantibodies, including antiphospholipid antibodies and antinuclear antibodies, even in the absence of autoimmune diseases [3]. Hence, it is crucial to develop a prognostic diagnostic model for pregnant women with immune abnormalities or autoimmune diseases, which can predict the risk of subsequent APOs in the first trimester, so as to assist doctors in diagnosing and making informed decisions on timely immunosuppressive or anticoagulant therapy.

XSL•FO
RenderX



Clinical data have been collected and analyzed to identify risk factors for APOs and establish early predictive models. In a prospective study, Moyle et al [4] discovered that in pregnant individuals with antiphospholipid antibodies, with or without systemic lupus erythematosus, anti-β2 glycoprotein-I domain 1 and antiphosphatidylserine-prothrombin IgG are significant independent predictors of APOs and are strongly associated with lupus anticoagulant. Reis et al [5] constructed separate logistic regression models for outcomes, including gestational loss, preterm delivery, fetal growth restriction (FGR), and preeclampsia, and analyzed the predictors for each model. By synthesizing the results of these models, it was found that lupus flares during pregnancy were the most significant predictors of APOs. Prior studies predominantly developed predictive models based on baseline maternal information, previous manifestations, biochemical biomarkers, and medication use, while largely overlooking the predictive value of sonographic parameters for pregnancy outcomes. Gad et al [6] found that yolk sac size abnormalities serve as a reliable early predictor of pregnancy loss, detectable prior to fetal morphological assessment by ultrasound. Zhang et al [7] conducted a study to investigate whether the presence of endometrial cavity fluid (ECF) in infertile patients scheduled to undergo in vitro fertilization or intracytoplasmic sperm injection was associated with pregnancy outcomes. They found that the presence of ECF is an indicator of APOs, even when the fluid measures less than 3.5 mm in the anteroposterior dimension. Xu et al [8] investigated the association between crown-rump length (CRL) during the first trimester of pregnancy and neonatal outcomes. CRL was positively associated with birth length, birth weight, incidence of large-for-gestational-age infants, and preterm birth, while negatively associated with the incidence of small-for-gestational-age infants and neonatal intensive care unit admission. Although prenatal ultrasonography is integral to routine antenatal care, research into its value for predicting APOs in pregnancies with maternal autoimmune diseases and abnormal immune antibody profiles is markedly lacking. Notably, no systematic reviews or meta-analyses have synthesized the predictive value of sonographic parameters in this high-risk population, nor are there any validated, condition-specific predictive models integrating ultrasound markers with maternal immunological profiles to predict the risk of adverse outcomes. This paucity of consolidated evidence and dedicated clinical tools impedes the development of targeted antenatal surveillance protocols.

Current studies predominantly rely on conventional logistic regression models for predicting APOs. However, this methodology is inherently limited by its statistical assumptions, including linearity and observation independence requirements, which constrain the analysis to predefined predictor-outcome relationships while failing to capture complex nonlinear interactions. These limitations substantially compromise the models' clinical predictive performance [9]. In contrast, machine learning (ML) has emerged as a powerful alternative, demonstrating superior performance in clinical outcome predictions. In contrast to conventional approaches, ML is capable of managing intricate interactions and nonlinear associations, which has contributed to its growing adoption in clinical research. In this field, the outcomes under investigation frequently rely on complex relationships among numerous factors [10]. Although ML models attain high levels of accuracy, the impact of individual variables on these models often remains unclear. This lack of transparency hinders the application of ML in clinical practice [11]. Shapley additive explanations (SHAP), a cutting-edge development aimed at enhancing the interpretability of tree-based models, utilizes a game theory–inspired approach. It consolidates the local contributions of individual features to account for the model's overall performance on a global level. This method is regarded as more effective than other global approximation techniques. Moreover, the algorithm not only quantifies the importance of features throughout the model but also sheds light on how each feature functions in particular predictive outcomes [12].

Therefore, this study innovatively integrates first-trimester sonographic parameters with comprehensive clinical data to develop an ML-based predictive model for the early and precise risk assessment of APOs in patients with positive immune markers or diagnosed autoimmune diseases, enhances the clinical utility of the established model by employing SHAP analytical methods for model interpretability visualization, and further facilitates clinicians' accurate identification of high-risk populations and timely clinical intervention through this interpretable ML framework. The graphical abstract is presented in Figure 1.

Ethical Considerations

This retrospective study was approved by the Ethics Committee of The First College of Clinical Medical Science, China Three Gorges University & Yichang Central People's Hospital (approval number 2024-335-01) with a waiver of informed consent. The study was conducted in strict accordance with the requirements of the Declaration of Helsinki. All patient data were anonymized, access was limited to research team members only, and all data were handled in strict confidence to prevent any information disclosure. No compensation was provided to the participants.

Data Acquisition

This retrospective study analyzed data from all first-trimester patients with positive immunological marker tests or a diagnosis of autoimmune diseases in the Obstetrics and Rheumatology departments of The First College of Clinical Medical Science of China Three Gorges University between January 2019 and October 2024. This study enrolled women aged 18 to 45 years with singleton pregnancies at 6^{+0} to 8^{+6} weeks of gestation (with gestational age correction when indicated), as confirmed by first-trimester ultrasonography, all of whom completed first-trimester immunological marker testing. To preserve data quality, patient records containing missing or anomalous data were excluded from the study. The stringent inclusion and exclusion criteria applied in this research were designed to guarantee the completeness and dependability of information pertaining to the included cases, thereby establishing a high-caliber database for assessing the risk of APOs in patients with autoimmune disorders. The inclusion criteria were as follows: (1) underwent first-trimester ultrasound and serological testing for autoimmune diseases, (2) age between 18 and 45 years, (3) history of autoimmune disease or abnormal autoimmune antibody levels, (4) singleton intrauterine pregnancy, (5) regular medication adherence as prescribed by physicians, and (6) availability of pregnancy outcome data. The exclusion criteria were as follows: (1) twin pregnancy patient, (2) noncompliance with the prescribed treatment plan, (3) lack of follow-up data on pregnancy outcomes, and (4) missing pregnancy details. Of the 364 patients retrieved from the electronic medical record system, 288 patients were enrolled in this study.

Research Variables

To mitigate the impact of invalid variables on model calculations, the identification of scientifically legitimate variables is essential. By integrating ultrasound-specific domain knowledge and retrieving literature on predictive factors in PubMed, the following 39 research variables with potential discriminative ability were screened out: basic characteristics (age, number of previous miscarriages, and history of rheumatic immune disease), number of complications during pregnancy, abnormal antibody values, medication during pregnancy (which

XSL•FO
RenderX

included the number of medications used, hydroxychloroquine, glucocorticoids, low-molecular-weight heparin, compound aspirin, progestogens, intravenous immunoglobulin, cyclosporine A, and the number of other drugs), and ultrasound measurement values at 6^{+0} to 8^{+6} weeks of gestation (yolk sac diameter change, gestational sac volume [GSV], CRL, and ECF).

This study employed APOs as the primary outcome variable, defined as the occurrence of any one of the following: miscarriage, preterm birth, biochemical pregnancy, low birth weight, fetal arrhythmia, neonatal asphyxia, or stillbirth [13].

Feature Selection

To remove the impact of scale differences between variables and enhance the performance of the model and the comparability between features, the data were standardized using the *z* score standardization method, which is a commonly used and widely applied approach. During the data standardization process, the following coding criteria were implemented for yolk sac diameter: code 0, which indicates yolk sac diameter within a normal reference range (3 - 6 mm); code 1, which signifies yolk sac enlargement (>6 mm); and code –1, which denotes yolk sac absence (nonvisualization on ultrasonography).

We employed a dual-feature selection approach combining the Least Absolute Shrinkage and Selection Operator (LASSO) regression and the Boruta algorithm to identify robust predictors associated with APOs. Using scikit-learn's LassoCV in Python, we automatically selected the optimal regularization parameter alpha (λ_min) that minimizes the cross-validated mean squared error and then applied the 1 SE rule to determine a more conservative α value (λ_1se), yielding a sparser model and retaining features with nonzero coefficients from both models. Concurrently, we implemented the Boruta algorithm in Python using the Boruta-py package (maintained by Daniel Homola). The algorithm iteratively compares variable importance against randomly generated shadow features using a random forest (RF) classifier to identify statistically significant predictors [14]. This process continued until either feature importance rankings stabilized or a maximum of 100 iterations was reached. The final feature set comprised only those variables consistently selected by both LASSO and the Boruta algorithm, ensuring high-confidence predictors of APOs risk.

Model Construction and Evaluation Metrics

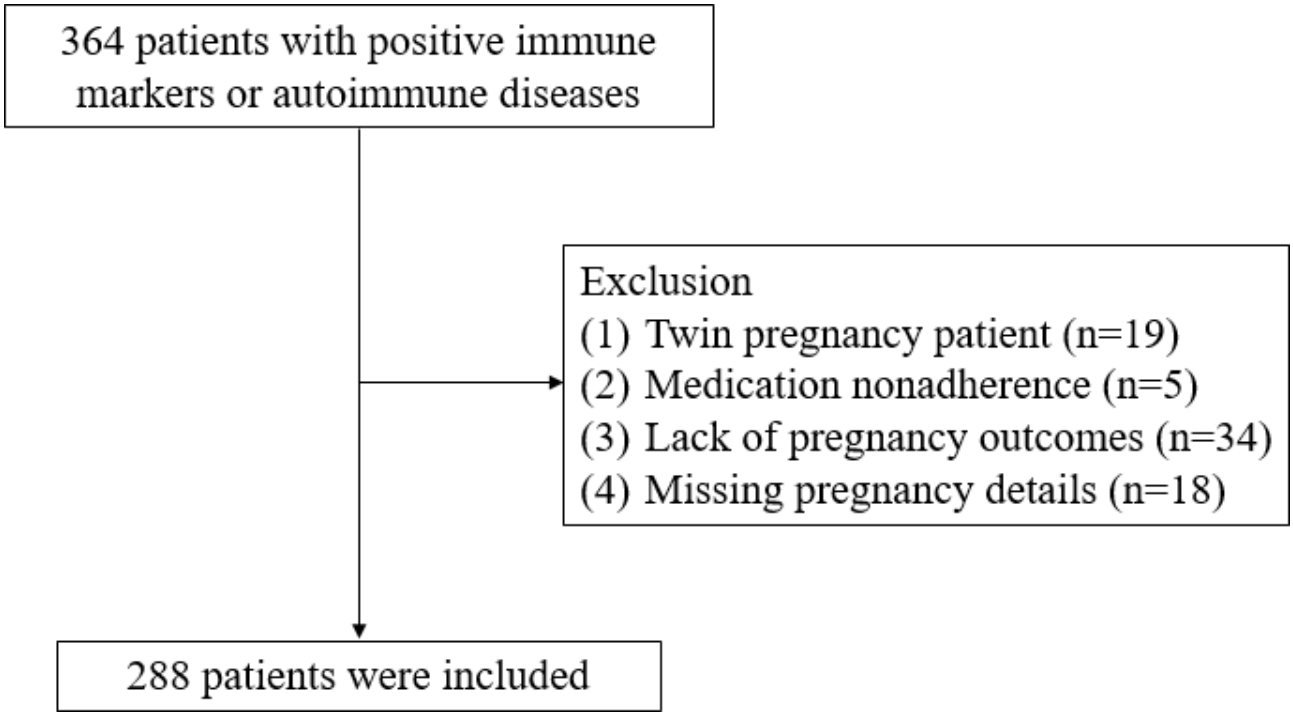
We utilized 70% of the data for training the model through random sampling, reserving the remaining 30% for testing the model's performance. Based on the features selected by Boruta and LASSO in the previous section, we developed 9 predictive models using artificial neural network (ANN), decision tree, extra tree, gradient boosting machine, k-nearest neighbor, light gradient boosting machine, RF, support vector machine, and extreme gradient boosting (XGBoost) algorithm. The Python scikit-learn library (version 1.3.0; originally created by David Cournapeau et al) was used to build the ML models. A combination of grid search with 5-fold cross-validation was employed to optimize the model's hyperparameters. The predictive models were built on the training set, and the test set was validated on the best model. The bootstrap method was implemented with 1000 replications to derive the CI of the area under the receiver operating characteristic curve (AUC), accuracy, specificity, and F_1-score for both the test and training sets. Given that our model's primary objective is to accurately detect positive samples, often known as APOs, our main focus was on maximizing the recall value. Furthermore, we also generated the precision-recall curve and the area under the precision-recall curve (AUPRC) for each model.

SHAP Model Interpretation

SHAP is a technique used to interpret predictions from complex ML models, especially those with numerous features [15]. It provides both cohort and patient-level insights by quantifying each feature's contribution to predictions. To assess global feature importance, we aggregated and averaged the absolute SHAP values across all patients, where higher values indicate greater predictive influence. The SHAP summary plot visualizes feature importance and directional effects, where each point represents the SHAP value for an individual patient. The color gradient indicates relative feature values, with red corresponding to high values and blue to low values. The SHAP decision plot visualizes the relationship between individual patients' feature-level contributions and the corresponding model predictions. By analyzing the trajectory patterns of the curves, we can observe feature-specific effects across different patients and quantitatively assess how each feature drives the final prediction outcomes. Dependence plots further elucidate how specific features influence the model output. The SHAP method was implemented in Python using SHAP version 0.47.2.

Statistical Analysis

Statistical analyses were conducted using R (version 4.3.0) (R Core Team), with ML model development performed using scikit-learn in Python 3.12.7. Normality assessments were performed for continuous variables. Variables conforming to a normal distribution were represented as mean (SD) and analyzed using the *t* test. Nonnormally distributed data were presented as median (IQR; Q_1 -Q_3) and were compared using the Mann-Whitney *U* test. Categorical data were expressed as frequencies and percentages (n, %) and analyzed using the χ^2 test or Fisher exact test. A *P* value of <.05 was considered to denote statistical significance.



Results

Clinical Characteristics of Patients

A total of 288 patients were included in the study, divided into the No-APO group (n=164) and APO group (n=124). Among APO cases, the spectrum of adverse outcomes included 76 (26.39%) miscarriages, 22 (7.64%) preterm births, 17 (4.51%) biochemical pregnancies, 10 (3.45%) low birth weight, 3 (1.04%) fetal arrhythmia, 2 (0.07%) neonatal asphyxia, and 2 (0.07%) stillbirth. Some cases had 2 of the aforementioned adverse outcomes. The mean age of the patients was 31.04 (SD 5.37) years. A total of 177 (61.46%) patients were found to have autoimmune diseases. A comprehensive flowchart illustrating the inclusion and exclusion criteria is presented in Figure 3.

XSL•FO
RenderX

Figure 3. Specifics of the patient inclusion and exclusion processes.

Feature Selection

Participants were randomly allocated to either the training set (201/288, 70%) or the test set (87/288, 30%). Statistical analysis revealed no significant differences between the 2 groups (Table 1). Boruta is a feature selection algorithm rooted in the RF classifier. It works by repeatedly contrasting the importance of each variable with that of randomly permuted attributes to pinpoint variables with significant relevance. The selection results of the Boruta algorithm are summarized in Figure 4A. Variables having the box plot in green show that all predictors are important. If boxplots are in red, it shows they are rejected. If the box plots are in yellow, it indicates that they are tentative. The following features were associated with the risk of APOs: GSV at 6^{+0} to 8^{+6} weeks, number of medications used, number of complications during pregnancy, number of other drugs, yolk sac diameter change at 6^{+0} to 8^{+6} weeks, and CRL at 6^{+0} to 8^{+6} weeks. In addition, LASSO regression functions as a shrinkage estimation technique that achieves variable selection and complexity adjustment by constructing an optimization objective function that includes penalty terms. In this study, LASSO regression was utilized to identify characteristic factors such as GSV at 6^{+0} to 8^{+6} weeks, CRL at 6^{+0} to 8^{+6} weeks, ECF at 6^{+0} to 8^{+6} weeks, yolk sac diameter change at 6^{+0} to 8^{+6} weeks, anti-cardiolipin antibody, anti-topoisomerase I antibody, anti-Sjögren syndrome antigen A/Ro52 antibody, anti-mitochondrial antibody M2, anti-histidyl-tRNA synthetase antibody, proliferating cell nuclear antigen antibody, polymyositis-scleroderma antibody, anti-centromere protein B antibody, anti-histone antibody, small nuclear ribonucleoprotein Sm D1, age, number of complications during pregnancy, hydroxychloroquine, intravenous immunoglobulin, cyclosporine A, and number of other drugs (Figure 4B and C). Through a comparative analysis of LASSO regression and the Boruta algorithm for feature selection, we identified their commonly selected feature subset. These selected features were ultimately utilized in the construction of the model and consisted of GSV at 6^{+0} to 8^{+6} weeks, yolk sac diameter change at 6^{+0} to 8^{+6} weeks, CRL at 6^{+0} to 8^{+6} weeks, number of complications during pregnancy, and number of other drugs (Figure 4D). Using these 5 variables, we developed 9 ML models to predict the risk of APOs in individuals with positive immune markers or diagnosed autoimmune diseases.

Model Construction and Evaluation

In this study, 9 different ML techniques were used to establish the model: ANN, decision tree, extra tree, gradient boosting machine, k-nearest neighbor, light gradient boosting machine, RF, support vector machine, and XGBoost. The performance of the 9 models in terms of AUC and AUPRC for both the training cohort and the test cohort is displayed in Figure 5. The accuracy, specificity, recall, and F_1-score are compared in Table 2. Out of the 9 models, the ANN, RF, and XGBoost models demonstrated superior AUC performance (ANN: 0.915, 95% CI 0.876 - 0.946; RF: 0.865, 95% CI 0.815 - 0.907; XGBoost: 0.850, 95% CI 0.791 - 0.907). The AUPRC was used to further compare the performances of the ML models because the AUPRC is an evaluation metric focused on positive class performance, which quantifies the overall trade-off between precision and recall, providing a critical performance indicator for cost-sensitive tasks. In both the training and test sets, the XGBoost model demonstrated balanced performance in AUPRC, with values of 0.858 (95% CI 0.796 - 0.907) in the training set and 0.801 (95% CI 0.692 - 0.894) in the test set. Additionally, the model maintained high recall across both datasets, indicating its stable discriminative efficacy and clinical utility in the detection of the target disease. Therefore, a downstream analysis was performed using the XGBoost model.

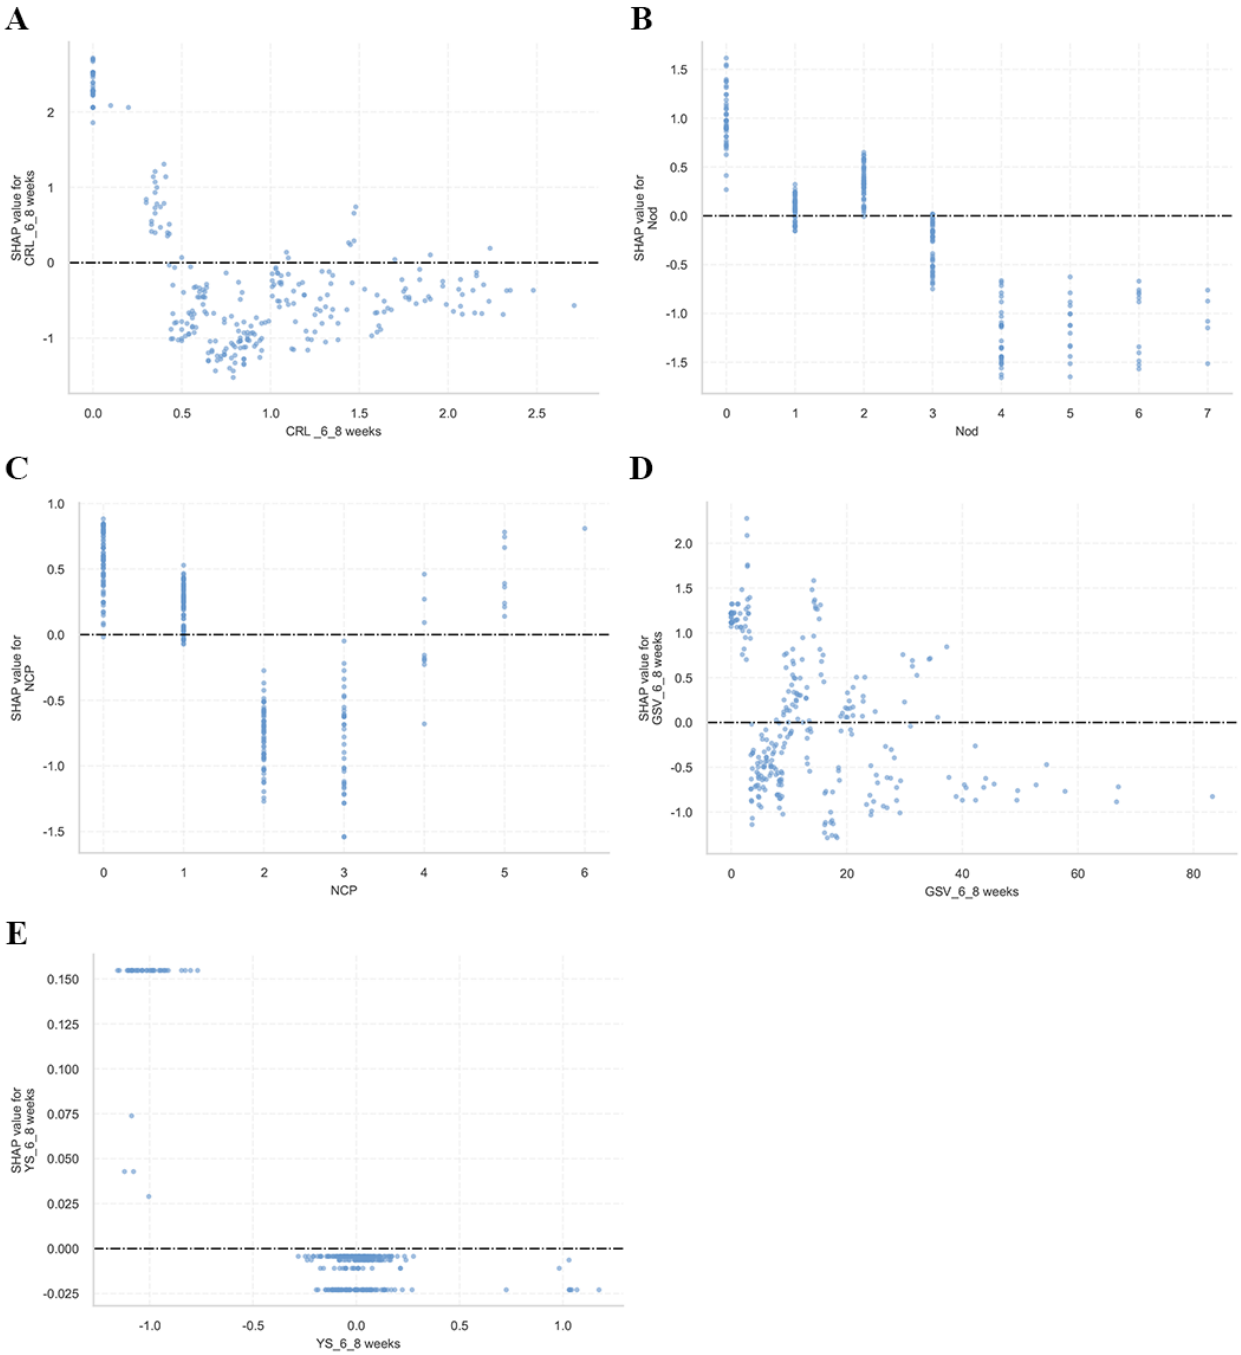
SHAP Model Interpretation

The SHAP feature importance for the XGBoost model is shown in Figure 6A. The features assessed are arranged in descending order according to their mean absolute SHAP values, which reflect the degree of their impact on the model's predictions. The specific ranking is as follows: CRL at 6^{+0} to 8^{+6} weeks, number of other drugs, number of complications during pregnancy, GSV at 6^{+0} to 8^{+6} weeks, and yolk sac diameter change. The SHAP summary plot of the XGBoost model shows the impact of features on the prediction model (Figure 6B). Based on the prediction model, a higher SHAP value of a feature indicates a greater likelihood of APOs. For example, patients with smaller GSV at 6^{+0} to 8^{+6} weeks are more likely to experience APOs compared to those with larger volumes during pregnancy. Moreover, the SHAP decision plot visually delineates the contribution of each clinical feature to individualized predictive outcomes. Through ANOVA trends in feature contribution values, the distinct differential impact patterns of specific clinical variables across different patients can be reliably identified (Figure 6C).

XSL•FO
RenderX

Figure 6. Variable contribution to the model by Shapley additive explanations (SHAP) values. (A) SHAP bar chart and (B) SHAP summary plot Each dot represents a SHAP value for a feature per patient. The x-axis is the SHAP value; color, from red to blue, indicates feature values from high to low. (C) SHAP decision plot. CRL-6 - 8 weeks: crown-rump length at 6^{+0} to 8^{+6} weeks; GSV-6 - 8 weeks: gestational sac volume at 6^{+0} to 8^{+6} weeks; NCP: number of complications during pregnancy; Nod: number of other drugs; YS-6 - 8 weeks: yolk sac diameter change at 6^{+0} to 8^{+6} weeks.

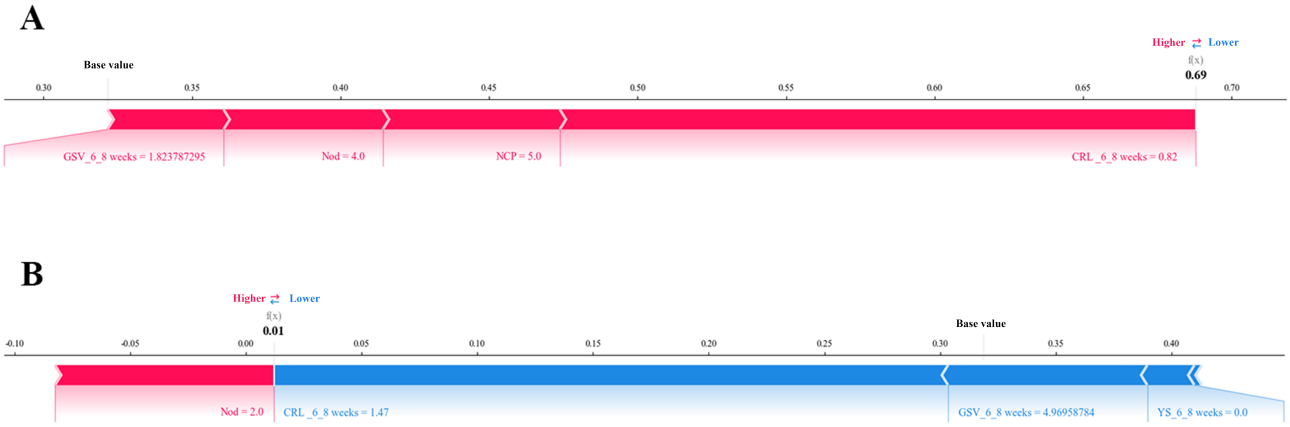


Additionally, the SHAP dependence plot illustrates how a feature influences the predictive outcomes of the XGBoost model (Figure 7). Patients with decreased CRL at 6^{+0} to 8^{+6} weeks and the number of other drugs (decrease in the x-axis value) were associated with a higher SHAP value, indicating a higher likelihood of APOs (increase in the y-axis value). Additionally, a larger GSV at 6^{+0} to 8^{+6} weeks was associated with lower SHAP values, suggesting a reduced likelihood of

XSL•FO
RenderX

APOs. Conversely, the absence of a yolk sac during the same gestational period correlated with higher SHAP values, indicating a significantly elevated risk.

Figure 7. Shapley additive explanations (SHAP) dependence plots of model features: (A) CRL-6 - 8weeks: crown-rump length at 6^{+0} to 8^{+6} weeks; (B) Nod: number of other drugs; (C) NCP: number of complications during pregnancy; (D) GSV-6 - 8 weeks: gestational sac volume at 6^{+0} to 8^{+6} weeks; (E) YS-6 - 8 weeks: yolk sac diameter change at 6^{+0} to 8^{+6} weeks. The y-axis shows features' SHAP values; the x-axis displays specific feature values. Each dot represents a patient's feature-specific SHAP value, with values above 0 indicating heightened adverse pregnancy outcome (APO) risk.



Explanation of the ML Model at the Patient Level

To evaluate the contributions of features for individual patients using the XGBoost model, we applied the SHAP method to explain the individual predictions for 2 patients. The color represents the contributions of each feature, with red being positive and blue being negative. The length of the color bar represents the contribution strength. For patient A, who was in the "true positive" group, the XGBoost model predicted a 69% probability of APOs (Figure 8A). For patient B, who was in the "true negative" group, the XGBoost model predicted a 1% probability of APOs (Figure 8B).

XSL•FO
RenderX

Figure 8. Shapley additive explanations (SHAP) force plot of (A) patient A (true positive) and (B) patient B (true negative). The color represents the contributions of each feature, with red being positive and blue being negative. The length of the color bar represents the contribution strength. CRL-6 - 8weeks: crown-rump length at 6^{+0} to 8^{+6} weeks; GSV-6 - 8 weeks: gestational sac volume at 6^{+0} to 8^{+6} weeks; NCP: number of complications during pregnancy; Nod: number of other drugs; YS-6 - 8 weeks: yolk sac diameter change at 6^{+0} to 8^{+6} weeks (code 0 indicates yolk sac diameter within the normal reference range; code 1 signifies yolk sac enlargement; code −1 denotes yolk sac absence).

Patient A, a 27-year-old female with a positive antinuclear antibody, was clinically diagnosed with antiphospholipid syndrome complicated by thrombotic predisposition. Transvaginal ultrasonography during early pregnancy (6^{+0} to 8^{+6} weeks of gestation) demonstrated the following parameters: CRL 0.82 cm, GSV 1.82 cm³, with normal yolk sac morphology. The pregnancy was complicated by multiple comorbidities, including gestational diabetes mellitus, hypothyroidism, anemia, and hypoproteinemia. Despite active symptomatic supportive therapy and standardized pregnancy-preserving interventions, the pregnancy ultimately resulted in preterm delivery.

Patient B, a 28-year-old female with a positive SS-B/La antibody (without confirmed autoimmune disease), during early pregnancy (6^{+0} to 8^{+6} weeks), underwent a transvaginal ultrasound that showed parameters consistent with gestational age: CRL 1.47 cm, GSV 4.97 cm³, and normal yolk sac morphology. The patient reported the use of 2 additional medication categories during pregnancy.

Discussion

Principal Findings

This study focuses on using ML models to predict APOs in patients with abnormal immune indices or autoimmune diseases during early pregnancy. We evaluated 9 ML methods for prediction, with the XGBoost model demonstrating the highest performance. Additionally, we utilized the SHAP approach to explore interpretations of the XGBoost model. The most important features were the CRL at 6^{+0} to 8^{+6} weeks, number of other drugs, number of complications during pregnancy, GSV at 6^{+0} to 8^{+6} weeks, and yolk sac diameter change at 6^{+0} to 8^{+6} weeks.

In previous clinical studies, variables predominantly focused on clinical demographic characteristics, clinical history, baseline clinical and laboratory indices, as well as medication and disease activity markers but overlooked the impact of first-trimester ultrasound parameters on APOs. Fazzari et al [16] developed multiple predictive models incorporating 41 clinical parameters (including lupus serological markers, antiphospholipid antibody assays, disease activity indices, etc) obtained during early gestation to assess APOs in systemic lupus erythematosus patients. The comparative analysis demonstrated that the Super Learner ensemble learning model achieved optimal predictive performance, with an AUC of 0.77. Jiang et al [17] utilized mean arterial pressure, prepregnancy hypertension, positive aCL-IgM, 24-hour urinary protein, serum albumin, history of hematological diseases, and serum uric acid, achieving an AUC of 0.975 (95% CI 0.958 - 0.992) in a single-center sample of 587 cases. However, substantial evidence indicates that first-trimester ultrasound parameters, such as yolk sac diameter, GSV, and CRL, are significantly associated with APOs. Building upon this foundation, Pavanya et al [18,19] have demonstrated the value of both traditional and novel assessments. Their work not only identified key birthweight-related factors, including CRL and nuchal translucency thickness, but also developed an explainable artificial intelligence model that predicts early FGR by quantifying fetal movements from routine first-trimester ultrasound scans. The accurate measurement of foundational biometrics, such as CRL and nuchal translucency, serves as the critical baseline for such integrated risk assessment. Roelants et al [20] conducted a study with a sample size of 918 patients, utilizing virtual reality software on 3D ultrasound scans to measure CRL and embryonic volume (EV) at 7, 9, and 11 weeks of gestation. The study found that larger embryonic CRL and EV are associated with lower odds of adverse birth outcomes, especially small for gestational age (SGA).

We constructed a predictive model utilizing ML techniques that integrate sonographic parameters. Among the models developed, the XGBoost model yielded an AUC of 0.850 (95% CI 0.791 - 0.907) and an AUPRC of 0.858 (95% CI 0.796 - 0.907). In the test dataset, the XGBoost model also surpassed other ML models, achieving an AUC of 0.802 (95% CI 0.704 - 0.895) and an AUPRC of 0.801 (95% CI 0.692 - 0.894). For the purpose of interpreting our XGBoost model, we employed SHAP summary plots and dependence plots to identify the predictive factors of APOs, whereas SHAP force plots were used to analyze individual patient cases. The SHAP results showed that CRL at 6^{+0} to 8^{+6} weeks, number of other drugs,

XSL•FO
RenderX

number of complications during pregnancy, GSV at 6^{+0} to 8^{+6} weeks, and yolk sac diameter change, which can be easily evaluated in clinical practice, are important features for the ML model to predict APOs.

Several sonographic parameters have been reported as possible predictors of APOs. For instance, EV has been associated with miscarriage and SGA outcomes and is also linked to maternal risk factors, such as smoking and vitamin B12 levels [21]. More specifically, an SGA GSV is a significant sonographic predictor of miscarriage, likely resulting from impaired placentation [22]. The first-trimester CRL is a well-established predictor: a small CRL (<10th percentile) significantly increases the risk of delivering an SGA neonate and preterm birth before 34 weeks, whereas a large CRL (≥90th percentile) is strongly associated with large-for-gestational-age outcomes [23]. Indeed, its association with birth weight is so strong that a small first-trimester CRL is a key indicator for subsequent low birth weight [24]. Notably, the SHAP dependence plot shows the effect of sonographic parameters on the XGBoost prediction. The yolk sac acts as the primary route of exchange between the human embryo and the mother before placental circulation is established. The yolk sac is a critical landmark that identifies a true gestational sac. In fact, it is the first conceptional structure that is usually visualized by transvaginal sonography when a gestational sac measures above 8 mm [25]. There have been conflicting results regarding the yolk sac. Some have suggested that the yolk sac diameter is not significantly associated with miscarriage [26], but others have demonstrated that the absence of a yolk sac or a small yolk sac is a significant predictor of miscarriage [27]. Our results demonstrate that the absence of a yolk sac is associated with an increased risk of APOs, a finding that corroborates previous research observations. Previous studies have highlighted that comorbidities during pregnancy, such as hypertensive disorders of pregnancy in the setting of chronic hypertension, are associated with the highest odds of serious consequences on the pregnant person and neonate [28]. Consequently, there exists a positive correlation between the number of antenatal comorbidities and the risk of APOs. However, our study found that APOs were associated with either ≤1 or >5 pregnancy complications, whereas the increased use of other medications was inversely correlated with APOs risk. Although clinical practice generally suggests that a higher burden of comorbidities portends a poorer prognosis, our data demonstrated that APO risk was significantly reduced in cases with 2 to 3 obstetric complications, as well as with the increased use of pregnancy complication–related medications and tocolytic agents. This observation may be explained by enhanced clinical management in high-risk pregnancies, including more intensive prenatal monitoring, optimized therapeutic interventions, and stricter medication supervision. Furthermore, potential confounding factors, including disease-disease interactions and the study's limited sample size, may have contributed to model overfitting, potentially affecting outcome prediction accuracy.

Limitation of the Study

This study has some limitations. First, the single-center design of this study may introduce selection bias, as the sample representativeness could be compromised by institution-specific clinical protocols that may influence data generation. Multicenter validation with diverse patient populations is required to enhance model generalizability. Second, APOs are a composite outcome, and each subtype (such as miscarriage, fetal growth restriction, and preterm birth) may have unique predictors. Future studies could develop subtype-specific prediction models and compare differences in feature importance. Third, the homogeneity of the validation data (originating from 1 institution) poses a threat to external validity. Prospective validation in independent, diverse cohorts is needed to assess performance across broader clinical spectra and populations.

Conclusions

ML models utilizing easily available clinical data and sonographic parameters can predict APOs in individuals with positive immune markers or diagnosed autoimmune diseases during early pregnancy. The SHAP method offers clinically interpretable explanations for ML predictions, identifying patient-specific risk factors underlying APOs through intuitive visualizations. These insights directly support personalized obstetric counseling and facilitate targeted clinical interventions to mitigate pregnancy risks.

Abstract

Background: Echocardiography is a fundamental imaging modality for the diagnosis of heart disease (HD), but its interpretation remains operator-dependent and lacks standardized, data-driven decision support. Although artificial intelligence has improved image-based diagnosis, the added value and interpretability of integrating routinely collected electronic medical records (EMRs) with echocardiogram (ECHO) for large-scale screening remain underexplored.

Objective: This study aims to develop an explainable artificial intelligence framework that integrates multimodal data, including ECHO images and EMRs, with derived temporal and clinical features, to enhance the screening and interpretability of heart disease diagnosis.

Methods: In this retrospective single-center study, we analyzed 26,936 patients with linked ECHO and EMR records (1470 with clinically confirmed HD and 25,466 without). We constructed cross-sectional EMR features (demographics, comorbidities, and registration history) and extracted view-specific image features with a simplified Inception-v3 backbone. Five modality-specific feature vectors (4 imaging views + EMR) were concatenated and input to an extreme gradient boosting classifier within a patient-level stratified 5-fold cross-validation framework. To mitigate class imbalance during training, non-HD cases in the training folds were randomly downsampled to a 1:3 HD:non-HD ratio; held-out test folds preserved the original prevalence. Post hoc explainability was provided via Grad-CAM heatmaps for images and Shapley additive explanations analysis for EMR features.

Results: For the primary binary task (presence vs absence of HD), the multimodal model achieved an AUC of 0.8147 (SD 0.009) on held-out test folds, compared with 0.7785 (SD 0.014) for the image-only baseline, and 0.7343 (SD 0.009) for the EMR-only baseline. At the clinically selected decision threshold, sensitivity, specificity, positive predictive value, and negative predictive value were 84.6% (SD 1.6%), 72.4% (SD 2%), 15% (SD 2.3%), 98.8% (SD 0.3%) for the multimodal model, versus 82.3% (SD 1.9%), 73.5% (SD 2%), 15.2% (SD 2.1%), 98.6% (SD 0.3%) (image-only), and 77.5% (SD 2.1%), 67% (SD 2.3%), 11.9% (SD 1.7%), 98.1% (SD 0.4%) (EMR-only). Grad-CAM visualizations qualitatively highlighted anatomically and physiologically meaningful regions (eg, valvular structures and abnormal flow jets), while Shapley additive explanations analysis identified age, registration years, sex, and hypertension among the top EMR contributors—findings that align with established cardiovascular risk factors.

Conclusions: Integrating echocardiographic images and EMR data in an explainable multimodal framework yields improved and clinically plausible screening performance for heart disease. Future work should focus on external multicenter validation, quantitative assessment of visual explanations against expert annotations, and prospective studies assessing clinical use and workflow integration.

Introduction

Heart disease (HD) continues to be one of the leading causes of morbidity and mortality worldwide, placing a substantial burden on both public health systems and individual quality of life [1]. Early identification and risk stratification remain essential for improving clinical outcomes [2]. Transthoracic echocardiography (ECHO) is regarded as the primary imaging modality for noninvasive cardiac evaluation because of its accessibility, safety, and cost-effectiveness. Despite its widespread use, ECHO interpretation is inherently operator-dependent, and diagnostic accuracy varies with clinical expertise, institutional workflow, and patient-specific factors [3]. These challenges underscore the need for standardized, data-driven decision-support tools that can enhance the consistency and accuracy of ECHO-based diagnosis.

Traditional cardiovascular risk prediction models and classical machine learning (ML) approaches have been applied to assist HD assessment [4,5]. However, such models typically rely on handcrafted features, limited physiological assumptions, or population-specific parameters, which restrict their generalizability in diverse clinical environments [6-10]. Moreover, these models often treat imaging and clinical variables independently, overlooking the potential complementary value of integrating the 2 modalities [11].

Recent advancements in deep learning have greatly expanded the capabilities of automated ECHO analysis, enabling applications such as view classification, cardiac chamber quantification, functional assessment, and disease detection [12-20]. While these imaging-based artificial intelligence (AI) models have demonstrated promising results, most rely solely on pixel-level information and do not incorporate routinely collected electronic medical records (EMRs), which contain valuable demographic, temporal, and comorbidity-related data pertinent to cardiac risk prediction [21,22]. Several multimodal approaches have been explored, but existing studies are often limited by small sample sizes, dataset heterogeneity, incomplete fusion strategies, or insufficient evaluation protocols [23-39]. Furthermore, explainability remains a major barrier to clinical implementation: many prior models provide limited insight into how predictions are derived, reducing their transparency and acceptance among clinicians.

Despite growing interest in multimodal learning, there remains a notable gap: no prior large-scale study has developed and rigorously evaluated an explainable framework that fuses 4-view transthoracic ECHO with structured EMR features for comprehensive HD screening. Existing works typically lack patient-level validation across large real-world cohorts, rely on single-modality inputs, or provide inadequate interpretability. These limitations hinder their practical deployment in clinical decision support.

To address these gaps, this study makes three key contributions:

1. We propose a novel explainable multimodal AI framework that integrates ECHO images from 4 standard views with structured EMR-derived features, leveraging complementary information from both modalities for enhanced HD screening.
2. We perform large-scale, patient-level stratified 5-fold cross-validation on a real-world clinical cohort of 26,936 individuals (1470 with HD and 25,466 without), ensuring robust performance assessment under realistic class imbalance and eliminating patient-level data leakage.
3. We incorporate modality-specific interpretability, combining Grad-CAM for visualizing image-based attention patterns with Shapley additive explanations (SHAP) analysis for quantifying EMR feature contributions. This dual-level explainability provides clinically meaningful insights and increases transparency, supporting future integration into routine diagnostic workflows.

Overall, this study advances the development of clinically informed multimodal diagnostic models by unifying echocardiographic and EMR data in an interpretable framework. The results demonstrate the potential of explainable AI to enhance screening accuracy, reduce operator dependency, and strengthen clinician trust in machine-assisted cardiac assessment.

Methods

Material

The EMRs data includes a total of 27,398 individuals, out of which 26,936 individuals have corresponding ECHO imaging data, and 462 individuals do not have corresponding ECHO imaging data. All EMR data were recorded prior to the last ECHO examination. The index date was defined as each patient's last echocardiographic examination. EMR variables were extracted from the entire history prior to (and including) the index date. Binary clinical history and symptom variables (eg, hypertension, diabetes mellitus [DM], atrial fibrillation [AF], and chest tightness or pain [Cpain]) were coded as 1 if ever recorded before the index date and 0 otherwise (including absence of documentation). Among the 26,936 individuals with corresponding ECHO imaging, 1470 individuals have HD, and 25,466 individuals do not have HD. HD labels were identified from the EMRs using either free-text discharge diagnoses or the corresponding ICD-10 codes. HD in this context refers to both structural and functional abnormalities of the heart, encompassing conditions such as congenital heart defects, rheumatic and pulmonary HDs, nonischemic cardiomyopathy, and valvular disorders involving the mitral, tricuspid, aortic, and pulmonary valves. It also includes ventricular hypertrophy, heart failure, hypertensive HD, as well as septal anomalies like ventricular and atrial septal defects. HD refers to structural and functional disorders of the heart, broadly categorized into 3 types. The first category pertains to valvular and hemodynamic abnormalities, such as congenital heart defects, rheumatic heart conditions, and diseases affecting the heart valves. The second category includes disorders related to ventricular structure and function, including pulmonary HD, nonischemic cardiomyopathy, and hypertensive cardiac conditions. The third type is heart failure.

The field list of the EMRs is shown in Table 1, and the distribution and numbers of patients with HD subtypes in the study cohort are shown in Table 2. For Table 2, HD subtypes

XSL•FO
RenderX

were counted in a non–mutually exclusive manner because multiple subtypes can be recorded for the same patient within a category. For the multiclass (3-class and 4-class) tasks, we used the top-level category as the ground-truth label, and these categories were constructed to be mutually exclusive at the patient level (ie, no patient had diagnoses spanning more than one category).

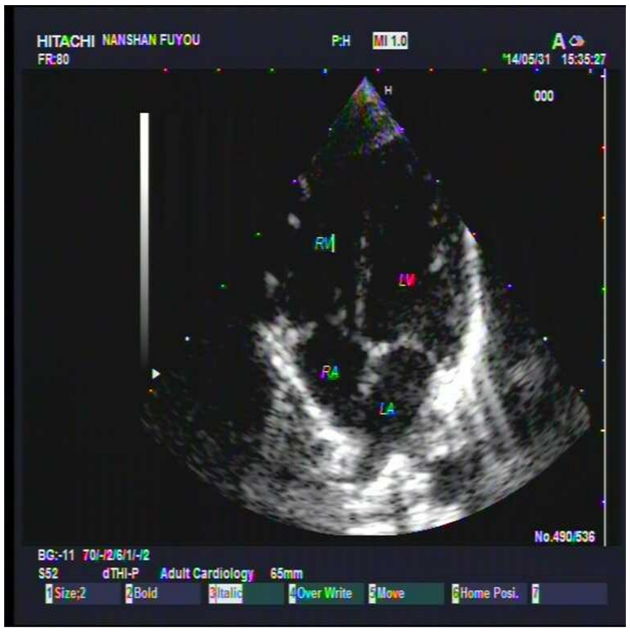
Table . Explanation of the EMRs[a] data fields used in this study. This table summarizes the EMR variables extracted from a retrospective single-center cohort of individuals undergoing routine transthoracic echocardiographic examinations for heart disease screening at a medical institution in China.

List of fields	Explanation	Notes
Pid	Resident personal identification	Consistent with the Pid in cardiac ECHO[b] and can be correlated
HTN	Hypertension	0 No 1 Yes
DM	Diabetes	0 No 1 Yes
Hlipid	Hyperlipidemia	0 No 1 Yes
Huric	Hyperuricemia	0 No 1 Yes
AR	Arrhythmias	Tachycardia, bradycardia, asystole, conduction block, and flutter
AF	Atrial fibrillation	0 No 1 Yes
PB	Premature beat	Atrial premature beats, ventricular premature beats, and sinus premature beats
Cpain	Chest tightness or pain	0 No 1 Yes
Hache	Headache or dizziness	0 No 1 Yes
Sex_code	Gender code	0 male and 1 female
Date_of_birth	Date of birth	—
Reg_date	Image examination registration date	Reg_date

[a]EMRs: electronic medical records.

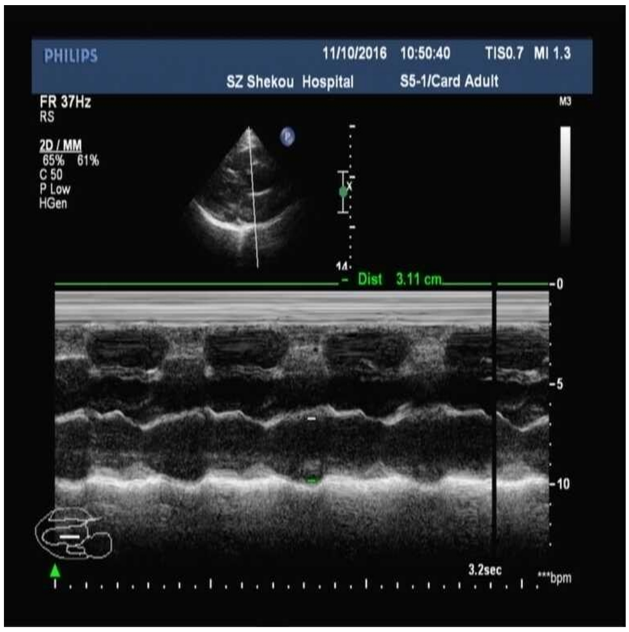
[b]ECHO: echocardiogram.

Table . Distribution and numbers of patients with heart disease subtypes in the study cohort.



Disease category	Subtype	Number of patients, n
Abnormalities of heart valves and blood flow	Congenital HD[a]	451
	Rheumatic HD	193
	Valvular HD	340
Ventricular abnormalities	Pulmonary HD	66
	Cardiomyopathy	283
	Hypertensive HD	43
Heart failure	Heart failure	181

[a]HD: heart disease.



The ECHO imaging data comprises 27,398 individuals, with a total of 32,111 ECHO examinations and 530,569 images. Among the 27,398 individuals, 26,936 individuals have corresponding EMR data, and 462 individuals do not have corresponding EMR data. The field list for the ECHO imaging data is detailed in the following table. The ECHO imaging data can be divided into 4 categories, as shown in Figure 1, namely 2D echocardiography, M-mode echocardiography, color Doppler, and spectral Doppler.

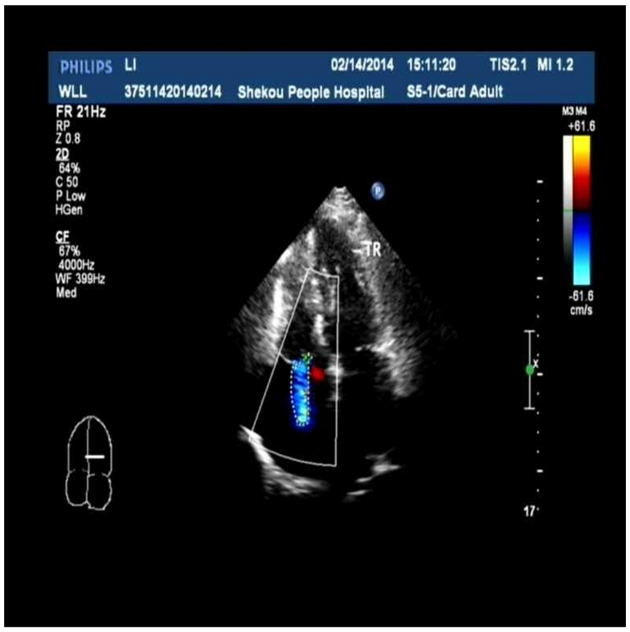

Figure 1. The four main categories of echocardiogram images in this study. Examples are shown from a retrospective single-center cohort of individuals undergoing routine cardiac examinations at a medical institution in China. The four panels illustrate the main echocardiographic modalities analyzed in this work: (A) 2D echocardiography, (B) M-mode echocardiography, (C) color Doppler imaging, and (D) spectral Doppler imaging, which together provide structural and blood-flow information for automated heart disease screening.

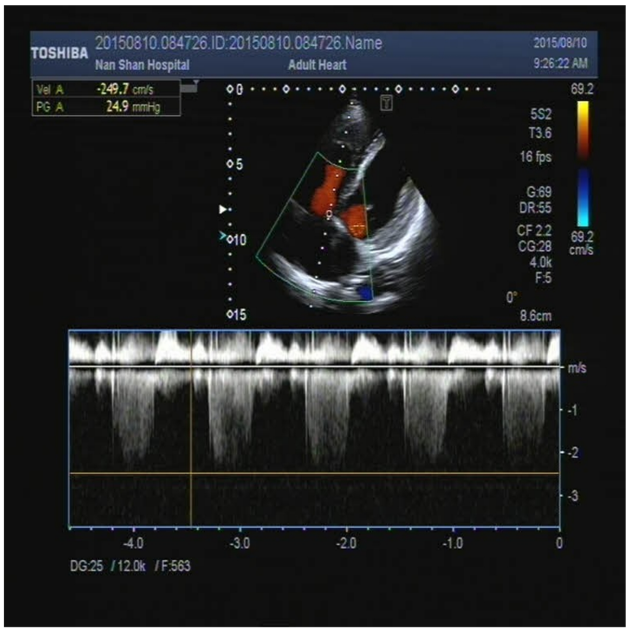


(A) 2D echocardiography

(B) M-mode echocardiography

(C) Color Doppler

(D) Spectral Doppler

Ethical Considerations

Data used in this study were obtained from Huazhong University of Science and Technology Union Hospital (Nanshan Hospital), China. Medical imaging data and EMRs were extracted from the hospital Picture Archiving and Communication System and Hospital Information System, respectively, and were linked across systems for patients with the same Pid. This study was conducted as a retrospective analysis of routinely collected clinical data. Given that all medical records and echocardiogram images were acquired during standard clinical procedures and fully anonymized prior to analysis, a waiver of written informed consent was granted in accordance with Clause 32 of the World Medical Association's Declaration of Helsinki. The study protocol received approval from the Institutional Review Board of the Shenzhen Institute of Advanced Technology, Chinese Academy of Sciences (Approval No. SIAT-IRB-151115-H0084).

All direct personal identifiers (eg, name, medical record number, contact information, and exact dates of birth) were removed or

XSL•FO
RenderX

replaced with study-specific codes before data extraction, and the de-identified dataset was stored on secure servers with access restricted to authorized investigators only. As this work involved secondary analysis of existing de-identified records and required no additional visits or interventions, participants did not receive any financial or other compensation. All echocardiographic images and example screenshots presented in the manuscript and Multimedia Appendix 1 were carefully inspected to ensure that no individual patient can be identified; any potentially identifying overlays present in the original images were masked or removed prior to inclusion.

Algorithm

The aim of this study is to classify HD through the multimodal fusion of EMRs and medical imaging data. Specifically, we preprocess the EMRs and medical imaging data and then feed the processed data into a multimodal model for training. It's worth noting that our multimodal framework is implemented as a staged pipeline, where the image encoder and the downstream fusion, classifier components are trained sequentially rather than jointly. For the imaging input, we use a simplified version of Inception_V3 with specific layers removed. Specifically, our model follows the canonical Inception-V3 network in the stem, Inception-A, BC, and reduction blocks, but removes the last 2 Inception Module C blocks in the final grid. Apart from this truncation and the adaptation of the final fully connected layer to match the number of target classes, all convolutional kernel sizes, strides, and filter numbers are kept identical to the original Inception-V3 implementation. Our model architecture incorporates 3 standard Inception modules operating at a 35×35 resolution, each with 288 filters. A grid reduction operation subsequently compresses this to a 17×17 resolution with 768 filters. The output dimension of each module serves as the input to the following one. To preserve spatial dimensions, zero-padding is applied to convolutional layers that maintain grid size, including those within non-downsampling Inception modules; other layers, particularly those performing downsampling, omit padding. The simplified Inception-V3 network was trained using the Adam optimizer with an initial learning rate of 0.001 and binary cross-entropy loss, using a mini-batch size of 32. Input echocardiogram frames were resized to 299×299×3 to match the network input. Training was run for up to 1024 epochs with early stopping based on the validation loss (patience=10 epochs), and the model achieving the lowest validation loss on the validation set was selected for evaluation. Unless otherwise specified, all other optimization hyperparameters followed the default settings of the TensorFlow Keras implementation of Inception-V3 and Adam.

For each image type, we use a pretrained Inception-v3 network as the initialization point. Fine-tuning this model, rather than training from scratch, significantly improves efficiency and convergence. The Inception-v3 model, originally trained on the ImageNet dataset—which classifies over a million natural images into 1000 categories—is adopted here via transfer learning. A streamlined version of Inception-v3 is used for feature extraction, where selected inception blocks are removed to simplify the network. This simplification was motivated by the moderate size of our dataset and preliminary experiments, in which the full-depth Inception-V3 showed signs of overfitting without improving validation performance, whereas the truncated variant achieved comparable discrimination with fewer parameters and reduced training time. For each of the 4 echocardiographic views (2D, M-mode, color Doppler, and spectral Doppler), the simplified Inception-v3 backbone processes the input images and outputs a fixed-length feature vector, denoted as f(2D),f(M),f(CD) and f(SD), respectively. The EMR modality is represented by a 12-dimensional vector f(EMR) containing the normalized clinical variables described in Table 1 (for example, hypertension, diabetes, hyperlipidemia, age, and registration years). Feature fusion is implemented as intermediate (feature-level) fusion by concatenating these five modality-specific feature vectors into a single fused representation:

$$z=[f(2D);f(M);f(CD);f(SD);f(EMR)]$$

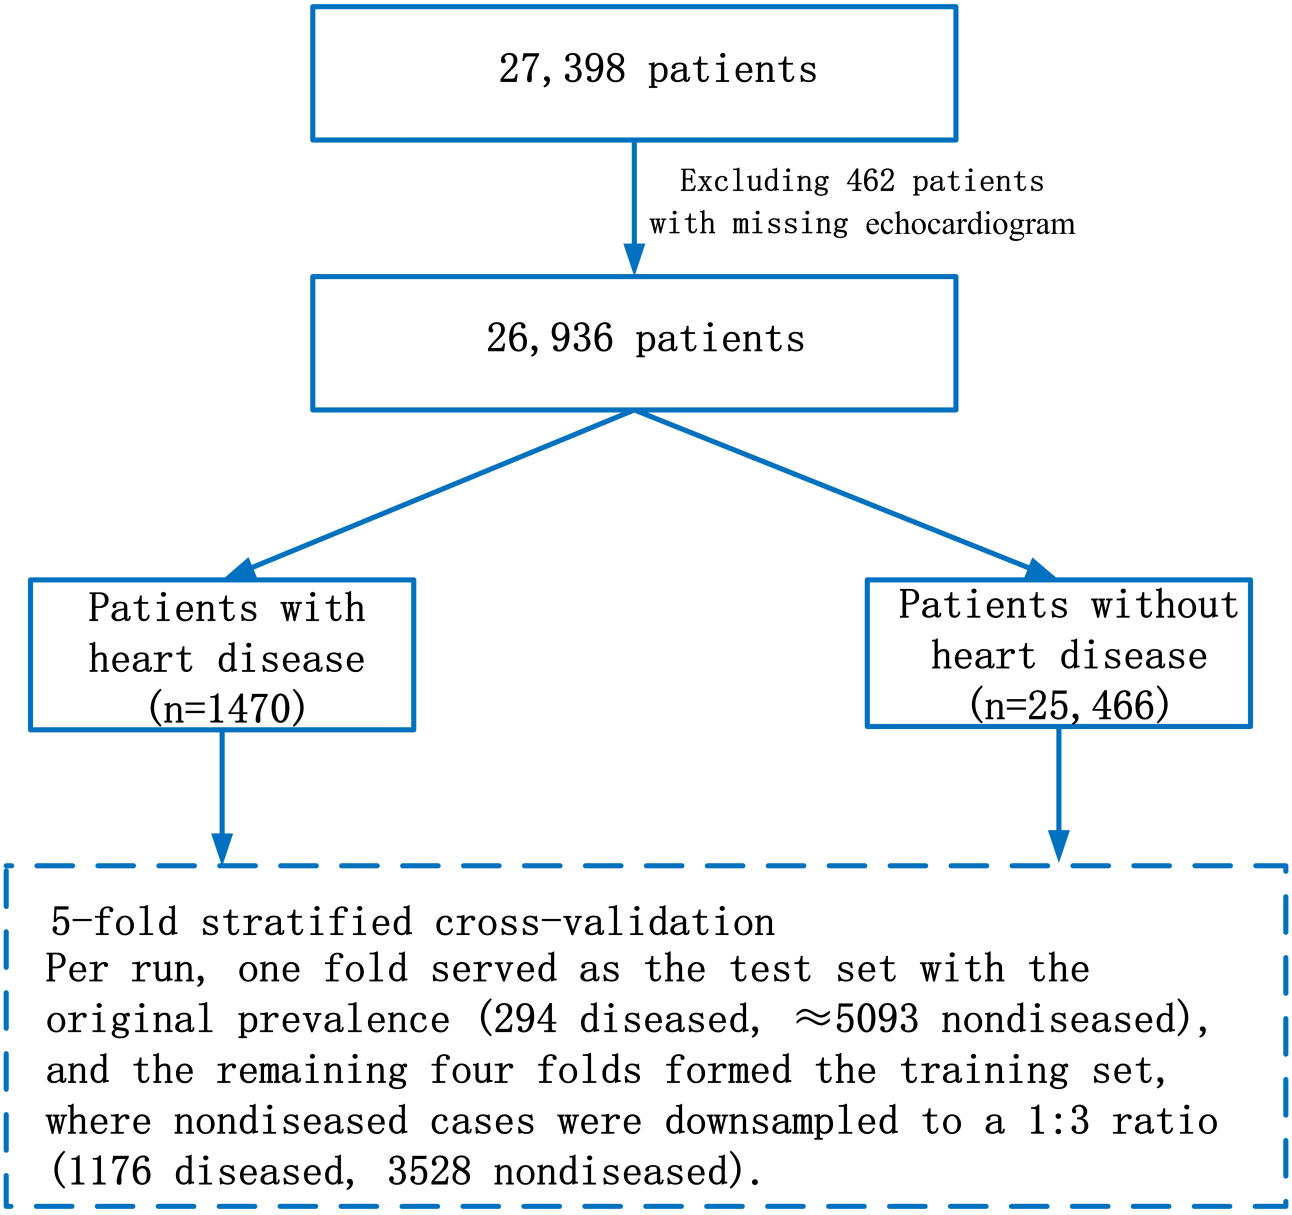
The fused feature vector z is used as the input to an extreme gradient boosting (XGBoost) classifier. Specifically, we first train and fine-tune the simplified Inception-v3 backbones to obtain fixed-length image embeddings. These embeddings are then concatenated with EMR features to train the XGBoost classifier; during XGBoost training, the image backbone is kept fixed (ie, no joint backpropagation across modules). The main hyperparameters were set as follows: learning rate (eta)=0.01, maximum tree depth=4, evaluation metric = "AUC," subsample ratio=0.75, column sampling rate for each tree (colsample_bytree)=0.75, number of threads=8, random seed=42, and silent mode enabled. All other hyperparameters used the default values of the XGBoost library. For binary classification tasks, we use XGBoost with a logistic ("binary: logistic") objective to obtain the probability of HD. For multiclass tasks with C classes, we use the "multi:softprob" objective to produce a C-dimensional probability vector, and the predicted class is obtained arg maxcPc. All reported receiver operating characteristic curves and area under the receiver operating characteristic curve (AUC) values are computed from these XGBoost output probabilities.

Experimental Setup

Experimental Environment

All experiments were conducted using TensorFlow (version 2.3.1), a widely adopted deep learning framework, on a system running the Windows Server 2012 operating system. The computational environment consisted of a high-performance server featuring 8-core Intel Xeon E5-2690 V4 CPUs and 64 GB of RAM. Additionally, the server was equipped with an NVIDIA Tesla P100 GPU with 16 GB of dedicated memory to accelerate model training. Python 3.6 was used as the primary programming language throughout the implementation.

Experimental Framework



To rigorously evaluate performance and avoid data leakage, we adopted a patient-level stratified 5-fold cross-validation scheme on the entire cohort of 26,936 individuals (1470 with HD and 25,466 without HD) as shown in Figure 2. All patients were randomly partitioned into 5 nonoverlapping folds of approximately equal size while preserving the original, imbalanced prevalence of HD; thus, each fold contained 294

XSL•FO
RenderX

patients with HD and approximately 5093 patients without HD. In each cross-validation iteration, one fold was held out as the test set (294 diseased and ≈5093 nondiseased individuals), and the remaining 4 folds were combined as the training set (1176 diseased and ≈20,372 nondiseased individuals). To address class imbalance during model training, we retained all 1176 diseased cases in the training set and randomly downsampled the nondiseased cases to 3528, yielding a 1:3 ratio of diseased to nondiseased individuals in the training subset. The held-out test fold was never resampled—no down-sampling, up-sampling, or other resampling techniques were applied—so that the evaluation always reflected the real-world prevalence. For each patient in the held-out test fold, 5 4-view inputs were generated by repeated random sampling from that patient's image pool, and the model output one probability for each sampled 4-view set. These 5 probabilities were then averaged to obtain the final patient-level prediction used for evaluation. Model hyperparameters were tuned on the training data using early stopping based on performance on an internal validation subset of the training folds [39], and all performance metrics, including the AUC, were computed on each untouched test fold and then averaged across the 5 folds. In contrast, for the multiclass and subtype-specific experiments, no over-sampling or downsampling was applied across heart disease subtypes. Models for these tasks were trained and evaluated on the natural, imbalanced distribution of subtypes within each fold.

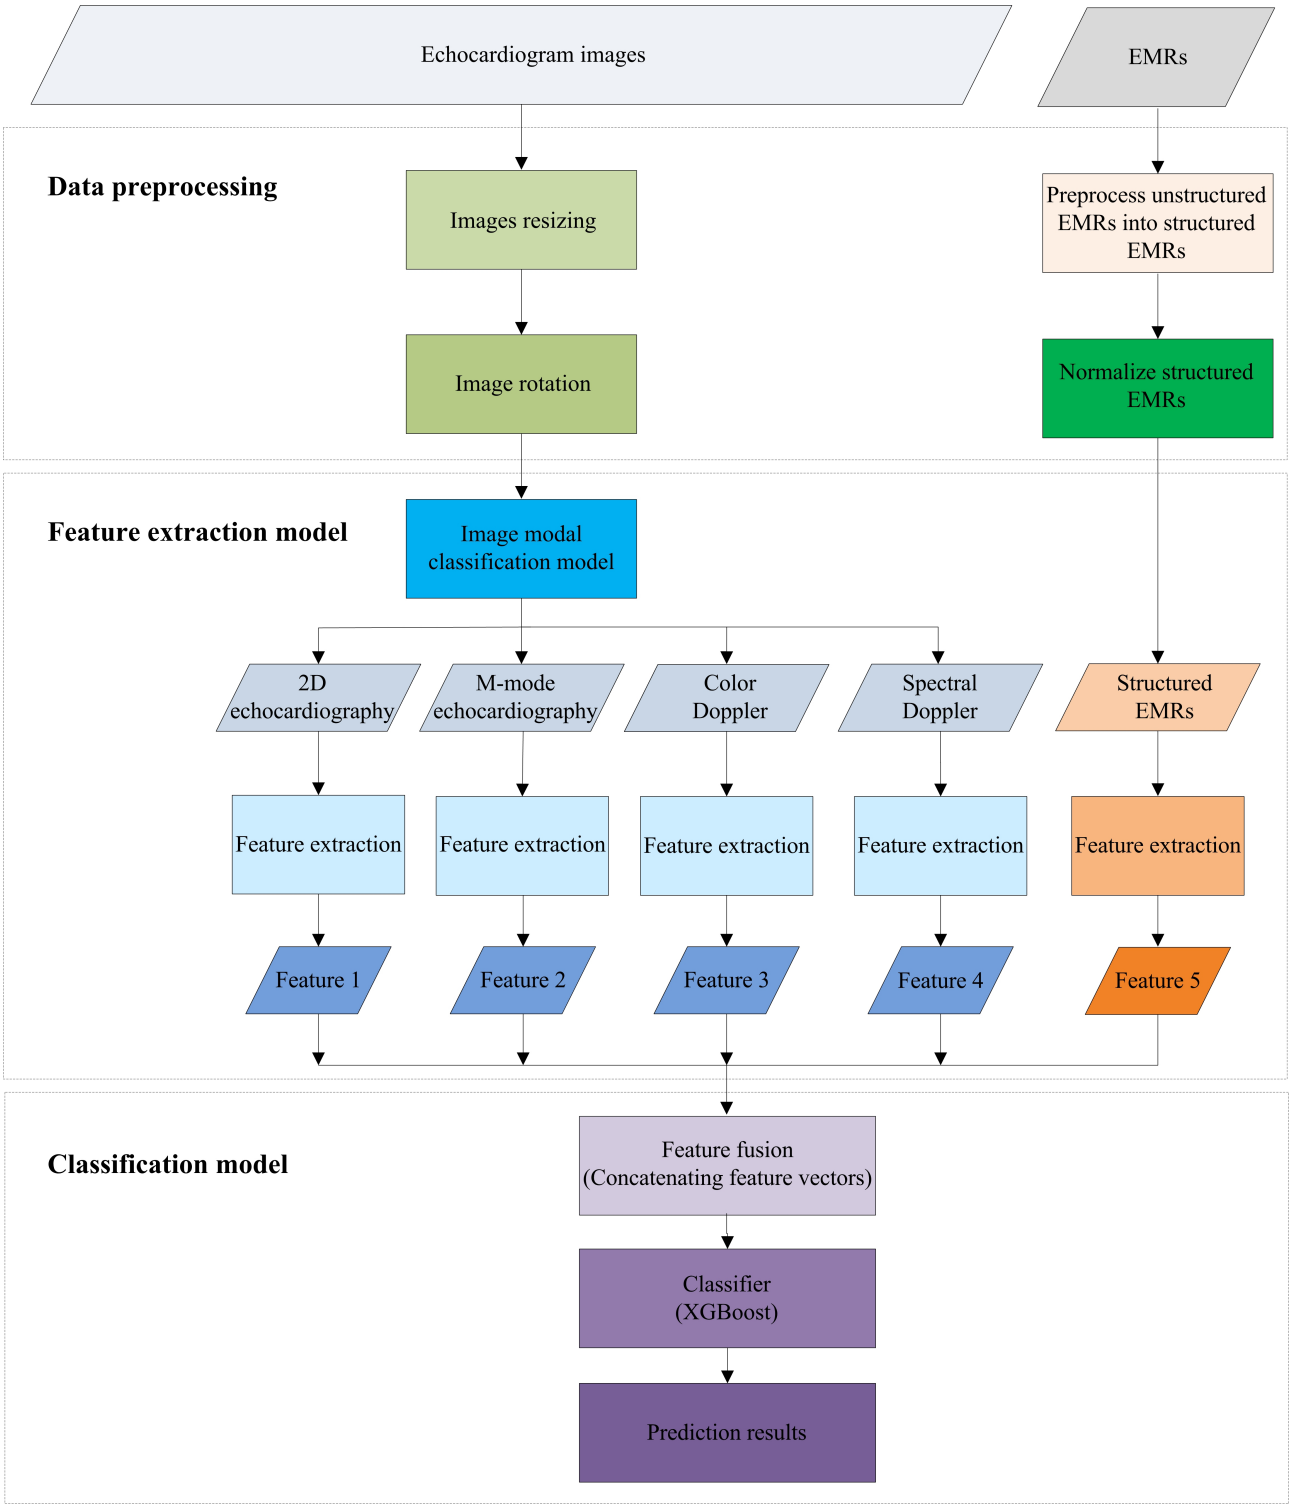


Figure 3 provides a detailed schematic of the experimental framework.

Figure 2. Patient selection flowchart. The flowchart illustrates the selection of 26,936 individuals with paired echocardiogram images and electronic medical records, including 1470 patients with heart disease and 25,466 individuals without HD, from the initial dataset. This entire cohort was used for patient-level stratified 5-fold cross-validation.

RenderX

Figure 3. Experimental framework of multimodal classification of heart disease. Four echocardiographic views (2D, M-mode, color Doppler, and spectral Doppler) are processed by simplified Inception-v3 branches to obtain view-specific feature vectors, and electronic medical records are represented by a 12-dimensional clinical feature vector. These five feature vectors are concatenated into a single fused representation, which is then fed into an Extreme Gradient Boosting classifier to produce the final prediction. EMR: electronic medical record; XGBoost: extreme gradient boosting.

The EMRs include 10 structured fields, which are hypertension, DM, hyperlipidemia, hyperuricemia, AR, AF, premature beat, Cpain, Hache, Sex_code, as well as 2 unstructured fields, which are Date_of_birth and Reg_date. For the unstructured field "Date_of_birth" (birthdate), we calculated the difference between it and the date of the last ECHO examination to derive a new field called "age." For the unstructured field "Reg_date," which represents the registration date of the first hospital visit, we calculated the difference between this date and the date of the last ECHO examination to obtain a new field called "registration years." Next, we performed normalization on the final 12 EMR fields, scaling them to a range between 0 and 1.

Each patient's ECHO image contains 4 views, and these 4 views are mixed together in the original ECHO image data. Initially, we manually classified 2000 ECHO images into 4 view

XSL•FO
RenderX

categories. Subsequently, we used this classification result as the training data to develop an AI model based on Inception_V3 for classifying the 4 views. This model is referred to as the ECHO image classifier (UIC). Using the UIC, we classified all ECHO images into their respective 4 views. Due to significant differences between the 4 views, we achieved perfect classification on the annotated test set. This allowed us to effectively separate the ECHO images based on their 4 distinct views. During model training, each input ECHO image is randomly selected from 1 of 4 views. Each person provides up to 16 ECHO images as an image pool, from which 1 image per view is randomly sampled during training to form a 4-view input. During testing and inference, 5 4-view inputs are generated for each patient by repeated random sampling from the same image pool, and the predicted probabilities are averaged to obtain the final patient-level prediction. If a view has fewer than 4 images, subsequent selections from that view will be drawn randomly from previously used images within that view. If a view is completely missing, it is filled with zeros. Notably, all ECHO images fed into the model are resized to 299×299 pixels in advance to fit the model's input requirements. Additionally, for enhanced model stability, each ECHO image undergoes a random rotation of 1 to 10 degrees before being input into the model.

ECHO images from 4 views and EMRs were used as the 5 inputs to the model. After feature extraction, the 5 corresponding feature vectors were concatenated into a single multimodal representation, which was then fed into an XGBoost classifier to predict the presence or absence of heart disease.

Results

Performance of Multimodal Model

We conducted 4 sets of binary classification experiments, including distinguishing between presence or absence of HD, presence or absence of heart valve and blood flow abnormalities, presence or absence of ventricular abnormalities, presence or absence of heart failure. Additionally, we performed 1 set of 3-class classification experiments to differentiate heart valve and blood flow abnormalities, ventricular abnormalities versus heart failure. This 3-class model was trained and evaluated solely on the subset of patients already diagnosed with HD; therefore, no normal or nondisease category is included in this task. From a clinical perspective, this experiment is intended for within-HD coarse phenotyping and triage after disease status has been established, helping prioritize follow-up focus (eg, valvular-focused assessment vs ventricular-function evaluation vs heart-failure–oriented management) and supporting more standardized categorization in clinical workflow. Finally, we conducted 1 set of 4-class classification experiments to distinguish heart valve and blood flow abnormalities, ventricular abnormalities, heart failure versus normal conditions. Detailed view-classifier metrics, per-class multiclass metrics, confusion matrices, precision–recall analysis, and calibration results can be found in Multimedia Appendix 1. These experiments were conducted to comprehensively investigate various aspects of heart health for diagnostic purposes. For all tasks, we evaluated not only our proposed multimodal model but also 2 image-only baseline models, CarpNet and optimized EfficientNetB3 [38]. Both baselines were reimplemented and trained on the same echocardiography dataset as the proposed model and were evaluated under the same patient-level 5-fold stratified cross-validation scheme, using identical train–test folds and echocardiographic inputs to ensure a fair comparison. To assess the effectiveness of the classification models in this study, the main evaluation metric we used is AUC. The receiver operating characteristic curve was generated by plotting the true positive rate against the false positive rate across a range of decision thresholds. In normalized terms, the AUC represents the likelihood that a randomly selected positive instance is assigned a higher score by the classifier than a randomly selected negative instance (under the assumption that positive instances are ranked above negative ones). Consequently, a higher AUC value reflects stronger discriminative ability of the classifier and indicates superior predictive performance of the model. In addition, given the imbalanced nature of the outcome and the intended use as a clinical screening tool, we also report sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) for each model. These metrics are computed at a clinically selected decision threshold (probability cutoff=0.28) on the test dataset. For the 3-class and 4-class tasks, sensitivity, specificity, PPV, and NPV were computed in a one-vs-rest manner for each class, macro-averaged across classes within each held-out test fold, and then summarized as mean± SD across the 5 cross-validation runs. For the binary tasks, all performance metrics were calculated on the held-out test folds and then averaged across the 5 cross-validation runs.

In our study, we conducted 5 sets of binary classification experiments using patient-level stratified 5-fold cross-validation and observed strong overall performance across the binary tasks. Specifically, our model excelled in predicting heart failure with an impressive AUC of 0.9903(SD 0.014), and achieved a substantial AUC of 0.8147 (SD 0.009) in the pivotal task of detecting HD.

Within the 3-class classification experiments, our model demonstrated exceptional performance by effortlessly distinguishing between different subtypes of HDs, achieving an AUC of 0.9914 (SD 0.009). The corresponding macro-averaged threshold-dependent metrics remained high, indicating balanced discrimination across the 3 disease categories.

In the 4-class classification experiments, our model achieved notable AUCs of 0.9298 (SD 0.007) for classifying the 3 subtypes of HD and normal conditions. Because the 4-class task was evaluated by macro-averaging one-vs-rest class-specific metrics under a highly imbalanced class distribution, PPV was lower than sensitivity, whereas specificity remained high across models. The detailed classification results for all binary, 3-class, and 4-class tasks are presented in Table 3.

Ablation Study

As shown in Table 4, we observe that our multimodal model can benefit from all modal data, including EMRs and images. The ablation results show that without any data from the 2 data, the performance of the classification results may decline. The last configuration of Table 4 demonstrates that our method achieves the best overall performance with all classification results.

XSL•FO
RenderX

Table . Ablation study of our proposed multimodal model on HD[a] using different input modalities. The EMRs[b] column corresponds to an EMR-only model implemented with XGBoost[c], the Image column corresponds to an echocardiogram-only CNN[d] model based on the simplified Inception-V3 architecture, and the Ours column corresponds to the joint EMR-image fusion model. AUC[e], sensitivity, specificity, PPV[f], and NPV[g] are reported as mean (SD) across 5-fold cross-validation. For the 3-class and 4-class tasks, sensitivity, specificity, PPV, and NPV were computed in a one-vs-rest manner for each class and macro-averaged across classes within each fold. *P* values are obtained from DeLong's test comparing the AUC of each ablation setting with that of the full multimodal model.

Analysis of Explainability

To interpret the contribution of EMR variables to the XGBoost classifier, we adopted SHAP rather than relying on *F* scores, which may be biased toward variables with high cardinality or frequent tree splits. SHAP provides a unified and theoretically grounded method to quantify the marginal contribution of each feature to the predicted risk of heart disease. Figure 4 presents the SHAP-based global feature importance of the EMR variables. Age exhibits the highest contribution, indicating its dominant role in the model's predictive output. Demographic and cardiovascular risk factors—including sex_code (0.330), hypertension (0.310), and registration years (0.158)—also demonstrate notable influence. Metabolic variables such as hyperlipidemia (0.137) and symptom-related features such as Cpain (0.114) contribute moderately. In contrast, DM, AF, AR, hyperuricemia, Hache, and premature beat show smaller SHAP

XSL•FO
RenderX

values, suggesting weaker but still measurable influence in the examined cohort.

The inherent complexity and opaque decision-making processes of machine learning models—particularly neural networks—frequently hinder the interpretability of their predictions. This lack of transparency presents a significant challenge, particularly in health care, where trust in the decision-making process is paramount. To ensure the reliability and usability of these models, it is vital that their inner workings are not only highly accurate but also interpretable to medical professionals. Fortunately, advancements in data visualization techniques have made it easier to understand these complex models. For instance, heatmaps can now be used to highlight areas of focus in a model's decision-making process, offering clearer insight into how neural networks process data. To interpret the model predictions and visualize which image regions contributed most to the classification, we generated class-discriminative heatmaps using Gradient-weighted Class Activation Mapping (Grad-CAM), as shown in Figure 5. For each echocardiographic view, Grad-CAM was applied to the convolutional feature maps of the simplified Inception-v3 branch corresponding to that view to compute importance weights with respect to the predicted class. The resulting activation maps were then upsampled to the original image resolution and overlaid on the echocardiographic images to highlight regions that were most influential for the model's decision. These heatmaps were used as a qualitative tool to visualize which regions of the input images contributed most to the model's predictions, and were inspected by an experienced cardiologist to assess whether the highlighted areas overlapped with clinically relevant cardiac structures and abnormal flow patterns. Figure 5A presents the heatmap of a patient with valvular heart disease, specifically aortic stenosis. In the 2D echocardiography, our model's attention is focused around the aortic valve, where echo signals are observed. In the color Doppler image, the model highlights a large area of red-blue aliasing. The spectral Doppler image shows an increased blood flow velocity in the left ventricular outflow tract (LVOT). These areas of interest closely align with clinical diagnostic criteria for aortic stenosis. The presence of echoes around the aortic valve suggests possible calcification. The extensive aliasing indicates high-velocity and turbulent flow, which is a typical manifestation of stenosis. Furthermore, the elevated blood flow velocity and the increased peak pressure gradient—characterized by the sharp "dagger-shaped" high-velocity spectral waveform—are classic indicators of aortic stenosis. Figure 5B shows the heatmap of a patient with ventricular abnormality, specifically dilated cardiomyopathy. In the 2D echocardiography, our model focuses on an enlarged left ventricle. The M-mode echocardiography shows that the model attends to a flattened motion pattern of the anterior and posterior walls of the left ventricle, with reduced amplitude. The color Doppler image highlights a mosaic-like turbulent flow region, and the spectral Doppler reveals increased flow velocity. These findings are consistent with clinical features of dilated cardiomyopathy. The left ventricular diameter is measured at 6.95 cm, significantly exceeding the normal upper limit (~5.8 cm, varying slightly by sex), indicating possible dilation. The reduced amplitude of wall motion supports impaired myocardial contractility, suggestive of an underlying myocardial disorder such as dilated cardiomyopathy. The mosaic flow pattern indicates prominent regurgitation, likely due to mitral or tricuspid valve incompetence. This regurgitation may be secondary to annular dilation caused by ventricular enlargement. The peak flow velocity reaches 402 cm/s, with a transvalvular pressure gradient of 65 mmHg, which is characteristic of severe mitral regurgitation commonly observed in dilated cardiomyopathy due to leaflet tethering and annular dilation. The integration of all 4 echocardiographic modalities supports a confident diagnosis of dilated cardiomyopathy. Overall, these Grad-CAM visualizations provide qualitative evidence that the model tends to focus on anatomically and physiologically meaningful regions that clinicians routinely examine when assessing valvular and ventricular abnormalities. However, this analysis remains illustrative and subjective, and we did not perform a formal quantitative comparison with expert-annotated regions or reader studies in this work.

Discussion

Principal Findings

This study presents a multimodal deep learning framework that integrates echocardiographic images and EMRs for comprehensive HD screening. The proposed model demonstrated strong discriminative performance across a range of binary and multiclass classification tasks. Notably, the model achieved an AUC of 0.8147 (SD 0.009) in the critical task of detecting HD presence and an AUC of 0.9903 (SD 0.014) in predicting heart failure, supporting its potential clinical relevance in large-scale check-up settings where echocardiography is routinely acquired. Notably, for heart failure, the EMR-only baseline already achieved strong discrimination (AUC 0.9442, SD 0.011), suggesting that routine clinical variables are highly predictive in this cohort. The multimodal model further improved performance (AUC 0.9903, SD 0.014), but the incremental benefit of adding imaging should be interpreted in light of the additional computational cost and workflow integration required for processing echocardiographic data. The ablation study suggests that the benefit of fusion is task-dependent: combining ECHO and EMR features generally improved performance across endpoints, yet for certain outcomes (eg, heart failure), the image-only model was not statistically distinguishable from the multimodal model (P=.06). This indicates that fusion may offer limited incremental discrimination when 1 modality already captures most predictive signal or when performance approaches a ceiling. Furthermore, visualization techniques such as heatmaps and feature importance rankings enhanced the model's interpretability, highlighting clinically relevant inputs such as age, registration time, and hypertension history. These findings suggest that the proposed multimodal approach can augment HD risk stratification and facilitate early intervention, particularly in settings where echocardiography is already routinely acquired (eg, large-scale check-up programs), so that the primary additional burden is computational inference rather than new data collection.receiver operating characteristic curve

Limitations

Several limitations should be acknowledged.

Class Imbalance

For the primary binary screening task (presence vs absence of HD), we used patient-level stratified 5-fold cross-validation and randomly down-sampled non-HD cases within the training folds to a 1:3 HD: non-HD ratio, while preserving the original prevalence in all held-out test folds. This choice improved training tractability and reduced majority-class dominance, but it inevitably discards a portion of non-HD cases and may underuse negative-class diversity. Data-efficient alternatives (eg, class-weighted loss or focal loss) that retain all non-HD cases may further improve robustness and should be examined in future work. For multiclass and subtype-specific tasks, no oversampling or down-sampling was applied; thus, performance on rare subtypes may be less stable.

Single-Center Retrospective Design

All data were obtained from 1 medical institution in China. Imaging protocols, patient demographics, and clinical workflows may differ across centers; external multicenter validation is required before deployment.

Explainability Validation

Although Grad-CAM and SHAP were used to improve interpretability, the current explainability assessment remains largely qualitative and may be subjective. In particular, the alignment between model-highlighted regions and physiological pathology has not been statistically quantified. We did not collect expert-annotated regions of interest (ROIs) or conduct reader studies; therefore, localization agreement metrics (eg, Intersection-over-Union [IoU] or Dice overlap with radiologist-annotated ROIs) were not measured.

Modeling, Index Date Definition, and EMR Feature Coding Assumptions

EMR information was summarized into cross-sectional features (eg, age and registration years) rather than modeling full longitudinal trajectories. In addition, the "current date" used for feature engineering was defined as the date of the last echocardiographic examination; thus, for patients with multiple visits, the analysis is anchored to the final time point. This may bias the cohort toward later or more established disease and may limit generalizability to early-stage screening settings where only earlier visits are available. In addition, binary clinical history and symptom variables were coded as 1 if documented and 0 otherwise; in retrospective EMRs, documentation may be incomplete (ie, underreporting), so this assumption may introduce systematic bias.

View Classification Generalization

Although the view classifier achieved perfect classification on the annotated test set, real-world echocardiography acquisitions may include off-axis or incomplete views, variable probe positioning, atypical protocols, motion artifacts, and reduced image quality. These factors can introduce view ambiguity (especially between neighboring views) and may lead to misclassification when deployed in routine clinical workflows.

Prospective Use

The model has not yet been evaluated in real-time clinical workflows; prospective studies are needed to assess clinical use and workflow integration.

Future Directions

Future work will focus on external multicenter validation and prospective evaluation in real-world workflows. We will also investigate data-efficient imbalance handling (eg, class-weighted loss and/or focal loss trained on all available non-HD cases) and assess their impact on discrimination, calibration, and robustness. To strengthen explainability, we plan to collect expert-annotated regions of interest (ROIs) for representative pathological patterns and to quantitatively evaluate attention–pathology alignment using localization agreement metrics such as Intersection-over-Union (IoU) and/or Dice overlap, potentially complemented by reader studies. In addition,

XSL•FO
RenderX

we will explore more fine-grained subtype modeling, incorporate longitudinal EMR trajectories, and further improve probability reliability through post-hoc calibration and threshold optimization to balance sensitivity and screening burden in practical deployment.

Conclusions

In this study, we developed a multimodal framework that integrates echocardiography and EMR features for HD screening and category-level classification in large-scale health check-up settings.

Across the primary HD detection task (HD vs non-HD) and subsequent category-level multiclass tasks, the multimodal model achieved favorable discriminative performance and outperformed image-only baselines in our experiments, indicating that combining echocardiography with structured clinical variables can improve screening performance compared with using a single modality.

To support model transparency, we applied Grad-CAM to visualize image regions contributing to predictions and used SHAP to quantify the relative importance of key EMR features, providing complementary qualitative interpretability signals for clinical review.

Acknowledgments

The authors thank the clinicians and sonographers at Huazhong University of Science and Technology Union Hospital (Nanshan Hospital) for their support in data acquisition and interpretation. We also appreciate the assistance of the technical staff at the Shenzhen Institute of Advanced Technology for maintaining the computing environment used in this study. During the preparation of this manuscript, generative AI (ChatGPT) was used only for language editing. The authors reviewed and edited all AI-assisted content and take full responsibility for the final version of the manuscript.

Funding

This work was supported in part by Post-doctoral Foundation Project of Shenzhen Polytechnic University (No.6024331020K), open research fund of Suzhou Key Lab of Multi-modal Data Fusion and Intelligent Healthcare (25SZZD08), the Shenzhen Polytechnic University Research Fund (No. 6023312038K), the Special projects fund in key areas of the Guangdong Provincial Department of Education (2023ZDZX2085) and the National Natural Science Foundation of China under grant (No. U22A2041).

Data Availability

The dataset analyzed during this study are not publicly available due to patient privacy and legislation concerns.

Abstract

Background: Dyslipidemia is a multifactorial and complex condition that warrants investigation through advanced analytical approaches such as machine learning (ML). Few previous ML studies predicting dyslipidemia have been validated across multiple international populations.

Objective: This study aimed to develop an ML model to predict the 5-year incidence of dyslipidemia using routinely collected health examination data. To ensure generalizability, the model was externally validated in populations from South Korea, Japan, and the United Kingdom. Furthermore, the clinical relevance of the model-derived risk was evaluated by examining its association with atherosclerotic outcomes, including acute myocardial infarction and cerebral infarction.

Methods: This study was conducted using 3 independent, large-scale, population-based cohorts. The discovery cohort from South Korea (n=471,650) was used for model training and internal validation, while 2 validation cohorts from Japan (validation A; n=7,255,685) and the United Kingdom (validation B; n=408,725) were used for external validation. We evaluated various ML-based models using 23 features extracted from regular health screening data to predict the new onset of dyslipidemia within 5 years. Shapley Additive Explanations values were calculated to assess feature importance. To ensure the robustness of the proposed ML model, we evaluated the risk of atherothrombotic events (acute myocardial infarction or cerebral infarction) based on the model probability (tertiles; T1, T2, and T3) using a Cox proportional hazards model.

Results: In the discovery cohort, soft-voting ensemble learning with Light Gradient Boosting Machine and categorical boosting exhibited performance metrics of area under the receiver operating characteristic curve (AUROC) of 0.783, precision of 37.9%, and area under the precision-recall curve of 0.469. The model showed moderate discriminatory performance in the external validation cohorts (cohort A: AUROC 0.744; precision 27.2%; and cohort B: AUROC 0.687; precision 5.07%). Shapley Additive Explanations value analysis identified smoking, alcohol intake, and physical activity as the most important features for predicting dyslipidemia. Finally, a higher model probability (T3 vs reference) was pronounced with an increased risk of acute myocardial infarction (adjusted hazard ratio 2.34, 95% CI 1.84‐2.97) and cerebral infarction (adjusted hazard ratio 2.43, 95% CI 2.19‐2.71).

Conclusions: This multinational study developed and validated an ML-based model using routine health checkup data to predict the 5-year risk of new-onset dyslipidemia, which was also associated with atherosclerotic events.

KEYWORDS

atherothrombotic events; dyslipidemia; machine learning; mortality; South Korea; Japan; United Kingdom

Introduction

Dyslipidemia is defined as an abnormal lipid profile, characterized by elevated low-density lipoprotein (LDL) cholesterol or triglycerides or reduced high-density lipoprotein (HDL) cholesterol [1]. This condition is recognized as a significant contributor to the development of numerous health issues, most notably cardiovascular disease [2]. Given its chronic nature, effective management is essential to mitigate associated health risks and reduce the overall health care burden [3]. While dyslipidemia can be diagnosed simply through blood tests, predicting an individual's future risk of developing the condition is challenging. Accurate risk prediction could enable proactive early intervention, thereby controlling its burden. Consequently, there has been increasing interest in using machine learning (ML) to forecast the incidence of dyslipidemia.

However, ML models from previous studies for predicting dyslipidemia have several limitations. Many models focus on single populations, leading to insufficient validation across diverse cohorts [4]. Some models rely on uncommon features, such as genetic markers [5], or predict only specific forms of dyslipidemia, such as familial hypercholesterolemia [6]. Such genetic markers are not readily accessible for widespread application, and dyslipidemia can be diagnosed based on variations in any component of the lipid profile [7]. Consequently, the risk of complications persists regardless of the specific type of lipid abnormality, underscoring the limitations of previous models [8].

Therefore, this study aimed to develop an ML model for predicting the incidence of dyslipidemia within 5 years using readily available routine health examination data. To enhance generalizability, the model was validated across multiple populations in South Korea, Japan, and the United Kingdom. Additionally, we examined whether the model-derived dyslipidemia risk score was associated with subsequent atherothrombotic events as an interpretive analysis of clinical plausibility and alignment with established risk patterns.

Methods

Overview

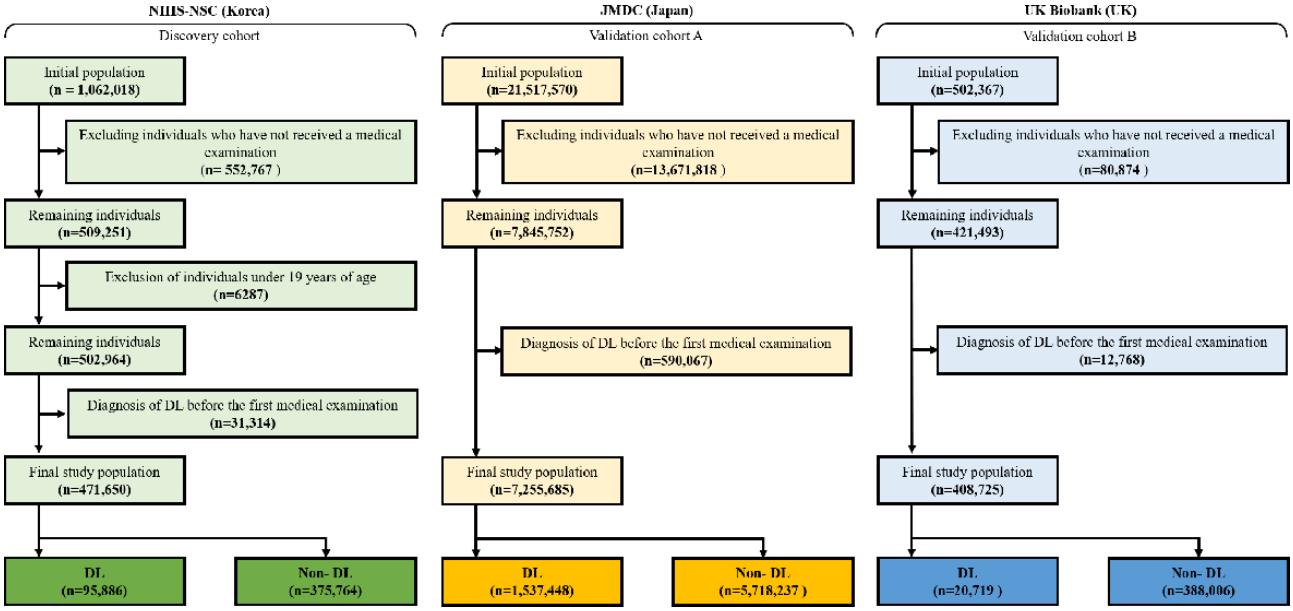
In this study, we developed and validated an ML model to predict dyslipidemia within 5 years based on the initial health screening data from the Korean National Health Insurance Service–National Sample Cohort (NHIS-NSC). Model development was conducted using the Korean cohort, followed by external validation using 2 independent populations: the Japan Medical Data Center (JMDC) cohort in Japan and the UK Biobank in the United Kingdom. This multicohort approach enabled robust assessment of model generalizability across diverse health care systems [9]. To enhance interpretability, we applied explainable artificial intelligence (AI) techniques, including Shapley Additive Explanations (SHAP), to identify key contributing features and elucidate the decision-making process of the models [10]. Additionally, we used Cox proportional hazards regression using the predicted probabilities from the models to assess the longitudinal risk of atherothrombotic events, such as acute myocardial infarction and cerebral infarction, thereby showing the broader clinical plausibility of our framework. This study was conducted and reported in accordance with established Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis (TRIPOD)–AI guidelines for prediction model research (Table S1 in Multimedia Appendix 1).

Data Sources

We used 3 large-scale, population-based cohort datasets to develop and validate an ML model for predicting dyslipidemia. The primary cohort was derived from the NHIS-NSC of South Korea (n=1,062,018), a claim-based cohort. Two external validation cohorts were subsequently used: the JMDC dataset (validation cohort A; n=21,517,570), also a claim-based cohort; and the UK Biobank (validation cohort B; n=502,367), a large-scale population-based prospective cohort [9]. All data used in the analyses were fully deidentified and anonymized prior to access, in compliance with relevant ethical and data protection regulations.

Discovery Cohort

The NHIS-NSC includes 1,062,018 individuals who underwent nationwide health screening between January 1, 2009, and December 31, 2013. This time frame was selected because several predictor variables became newly available and were consistently recorded starting in 2009, and December 31, 2017, was designated as the end point for follow-up. This cohort served as the discovery dataset for development and internal validation of an ML model designed to predict the occurrence of dyslipidemia within 5 years after each participant's baseline health screening. Dyslipidemia was defined based on the presence of *International Classification of Diseases (ICD), 10th revision*, codes E78 in administrative claims data. The ICD-10 system is a globally standardized classification framework developed by the World Health Organization (WHO), ensuring consistent diagnostic coding across countries and health care systems [11]. The index date was designated as the date of each participant's first health screening during the enrollment period. Participants without a dyslipidemia diagnosis during follow-up, including those with less than 5 years of follow-up, were classified as noncases.



Data Preprocessing

As illustrated in Figure 1, we applied the following exclusion criteria: (1) individuals who did not undergo health screening during the study period; (2) individuals younger than 19 years; and (3) individuals with a prior diagnosis of dyslipidemia before their index date, defined as the date of their first health screening. The dataset was split into training and testing sets (7:3) using stratified sampling based on the incident

XSL•FO
RenderX

dyslipidemia outcome variable, and all preprocessing steps were fitted on the training data and applied to the test data. Continuous variables with missing values were imputed using the K-nearest neighbors (KNN) algorithm fitted on the training data and applied to the test data [12]. Categorical variables were not imputed; missing values were treated as a separate "unknown" category. These values were handled as an explicit category rather than as missing data and were retained in the analysis. To address class imbalance, the Synthetic Minority Over-Sampling Technique was applied exclusively within each training fold during cross-validation to prevent information leakage [9]. Synthetic Minority Over-Sampling Technique generates synthetic samples of the minority class by interpolating between existing minority instances, thereby increasing sample diversity without altering the original distribution of the validation or test sets. Finally, all input features were normalized using Min-Max scaling to ensure comparability across variables [10]. Min-Max scaling transforms each feature to a fixed range, typically [0,1], while preserving the original distribution of the data.

Figure 1. Flow diagram of participant selection for the algorithm development and validation cohort study evaluating machine learning–based dyslipidemia prediction. The diagram shows inclusion and exclusion processes applied to adults enrolled in the National Health Insurance Service–National Sample Cohort (NHIS-NSC; South Korea), Japan Medical Data Center (JMDC) claims database (Japan), and UK Biobank (the United Kingdom). DL: dyslipidemia.

Predictor Variables

A total of 23 features were used to predict dyslipidemia within 5 years, encompassing demographic, socioeconomic, clinical, and lifestyle factors. In the demographic and socioeconomic category, sex (male and female), age (years; continuous), region of residence (urban and rural), and household income (low: 0th - 39th percentile, middle: 40th - 79th percentile, and high: 80th - 100th percentile) were included [9]. In the external validation cohorts, income variables were harmonized into this predefined 3-level structure prior to model input to ensure structural consistency across datasets. Clinical measures comprised LDL cholesterol, HDL cholesterol, total cholesterol, triglycerides, aspartate aminotransferase, alanine aminotransferase, γ-glutamyl transpeptidase, waist circumference, systolic blood pressure, diastolic blood pressure, fasting blood glucose, hemoglobin, and BMI. Additionally, lifestyle and medical history factors encompassed smoking status (never, ex, and current); alcohol intake (never, 1 - 2 d/wk, 3 - 4 d/wk, and ≥5 d/wk); physical activity (never, 1 - 2 d/wk, 3 - 4 d/wk, and ≥5 d/wk); and relevant comorbidities, such as a history of hypertension, diabetes, or stroke (Table 1). For variables with structurally different formats across cohorts, predefined mapping rules were applied to ensure consistency. For example, binary physical activity variables were mapped by assigning "no" to "never" and "yes" to ≥1 session per week. Detailed mapping rules are provided in Table S2 in Multimedia Appendix 1.

[c]LDL: low-density lipoprotein.

External Validation Dataset

External validation cohort A (JMDC) included individuals in Japan who underwent health screenings between January 1, 2006, and June 30, 2024. External validation cohort B (UK Biobank) comprised participants from the United Kingdom who enrolled in this prospective cohort between January 1, 2006, and April 30, 2023. For both external cohorts, the prediction target was incident dyslipidemia occurring within 5 years after each participant's baseline health screening, consistent with the discovery cohort. In cohort A, dyslipidemia was defined using the same ICD-10 criteria as in the discovery cohort. In external validation cohort B, dyslipidemia was defined using both ICD-10 and ICD-9 codes (ICD-9: 272) to ensure compatibility with historical records. Consistently, the same exclusion criteria applied to the discovery cohort were used for both validation cohorts, as illustrated in Figure 1 and Tables S3 and S4 in Multimedia Appendix 1. Missing values were imputed using the KNN method, consistent with the preprocessing applied to the discovery dataset [12]. Additionally, all input features in the validation datasets were normalized using the same Min-Max scaling method applied to the training data to ensure consistency in feature distribution.

Model Development and Validation

To predict dyslipidemia within 5 years, we developed and evaluated multiple ML algorithms, including logistic regression, random forest, extreme gradient boosting (XGBoost), adaptive boosting (AdaBoost), Light Gradient Boosting Machine (LightGBM), and categorical boosting (CatBoost) [10,13]. To ensure robust and generalizable model performance, 5-fold cross-validation was used on the training set derived from the discovery cohort during model development. In this approach, the dataset was randomly partitioned into 5 equally sized folds, with each fold serving once as a validation set, while the remaining 4 were used for training. This strategy enabled evaluation across diverse subsamples, thereby reducing the risk of overfitting and improving generalizability. The optimal classification threshold was determined using Youden's J statistic calculated across the 5 cross-validation folds in the discovery cohort only. The final threshold, defined as the mean optimal value across folds, was fixed prior to external validation and subsequently applied unchanged to the internal test set and both external validation cohorts to preserve independence and avoid data leakage. To further enhance overall predictive performance, we performed grid search–based hyperparameter tuning within a cross-validation framework to identify optimal model configurations [10]. During this process, key hyperparameters were tuned using an internal validation split, and an early stopping criterion was applied to prevent overfitting. Among the models tested, a soft-voting ensemble combining CatBoost and LightGBM was selected to improve robustness across heterogeneous multinational datasets by leveraging the complementary strengths of both algorithms [14]. The final optimized hyperparameters for both models are summarized in Table S5 in Multimedia Appendix 1 to facilitate reproducibility. After identifying the optimal hyperparameters through cross-validation, the final model was retrained on the entire training dataset using these parameters, rather than using an ensemble of cross-validation models.

The final models trained on the discovery cohort's training set were subsequently evaluated on the internal test set, as well as on 2 external validation cohorts A and B. This evaluation framework allowed us to assess the generalizability of the models across distinct populations and health care systems. To ensure consistency across cohorts, all predictor variables were harmonized according to the definitions used in the discovery cohort. Model performance was assessed using several metrics, including the area under the receiver operating characteristic curve (AUROC), precision, sensitivity, specificity, accuracy, F_1-score, and the area under the precision-recall curve (AUPRC). Given the class imbalance, precision and AUROC were emphasized as the primary evaluation metrics [10,15]. To obtain 95% CIs for performance metrics, cross-validation procedures were applied in the training dataset. CIs were not

XSL•FO
RenderX

reported for the validation and independent test datasets, as these were evaluated a single time to preserve their role in unbiased model assessment.

Sensitivity Analysis

Two sensitivity analyses were conducted to assess the robustness of the modeling strategy. First, a model excluding baseline lipid measures (LDL cholesterol, HDL cholesterol, triglycerides, and total cholesterol) was developed to evaluate whether model performance was driven by lipid biomarkers directly related to the outcome definition, yielding similar discrimination to the main model. Second, a complete-case sensitivity analysis was additionally conducted by refitting the discovery cohort model using only participants without missing values to assess the impact of imputation. These results collectively support the stability and validity of the preprocessing and modeling procedures.

Calibration and Decision Curve Analysis

Model calibration was evaluated in each cohort by estimating calibration-in-the-large, calibration slope, and the Brier score. Calibration-in-the-large was calculated as the difference between the mean predicted probability and the observed event rate, while calibration slope was estimated by regressing observed outcomes on the logit-transformed predicted probabilities. The Brier score was used to quantify overall prediction error [11]. Calibration plots were generated by comparing observed versus predicted risks across deciles of predicted probability. To assess potential improvements in transportability, simple recalibration was explored by adjusting the model intercept and slope in each external validation cohort while preserving the original predictor coefficients. Discrimination and calibration metrics before and after recalibration were compared to evaluate the impact of cohort-specific recalibration.

Clinical plausibility was further examined using decision curve analysis, which estimates the net benefit of the prediction model across a range of clinically plausible threshold probabilities [11]. Net benefit was compared with default strategies of treating all individuals or treating none, using the predicted 5-year dyslipidemia risk.

Explainable AI

To improve model transparency and interpretability, we applied SHAP values, which quantify the marginal contribution of each feature to individual predictions [10,16]. SHAP values allow both global and local interpretation: the distribution of SHAP values across the population reveals not only the relative importance of features but also the direction of their influence (ie, whether higher values of a feature increase or decrease dyslipidemia risk). Additionally, the average magnitude of SHAP values helps identify the most influential predictors overall, while individual-level SHAP analyses enable a step-by-step understanding of how specific features shape a single prediction [16]. This explainable AI approach transforms the model from a black box into a clinically interpretable tool, highlighting consistent and actionable risk factors. All processes were performed using Python (version 3.11.4; Python Software Foundation). Key libraries from our toolbox included Scikit-learn (version 1.2.2; Scikit-learn development team), NumPy (version 1.24.1; Python Software Foundation), and Pandas (version 1.5.3; Python Software Foundation) for ML tasks and data wrangling.

Statistical Analysis

To evaluate the broader clinical plausibility of the final ML model, the predicted 5-year dyslipidemia probability was used as the primary exposure to assess the risk of diseases with increased incidence associated with dyslipidemia. We acknowledge that associations between the predicted risk score and atherothrombotic outcomes may reflect shared underlying cardiovascular risk factors included in the prediction model. A binary classification threshold, determined using Youden's J statistic during 5-fold cross-validation in the discovery cohort, was applied to define incident dyslipidemia. Individuals with predicted probabilities below this threshold were used as the reference group. Among individuals with predicted probabilities equal to or above the threshold, predicted risks were further categorized into 3 tertiles (T1, T2, and T3). The primary outcomes were acute myocardial infarction (ICD-10: I21; and ICD-9: 410) and cerebral infarction (ICD-10: I63; and ICD-9: 434.01, 434.11). To assess the risk of these outcomes based on predicted dyslipidemia probability, we applied a Cox proportional hazards regression model to estimate adjusted hazard ratios (aHRs) and 95% CIs. The Cox models were sequentially adjusted as follows: model 1 adjusted for age and sex (primary minimally confounded estimate); and model 2 adjusted for age, sex, region, and income (conservative estimate adjusted for key sociodemographic factors). To account for competing risks, we conducted sensitivity analyses using Fine–Gray subdistribution hazard models for acute myocardial infarction and cerebral infarction, treating death as a competing event. Statistical significance was defined as a 2-sided *P* value <.05. All statistical analyses were performed using SAS software (version 9.4; SAS Institute Inc).

Ethical Considerations

The study protocol was approved by the Institutional Review Board of Kyung Hee University. Documentation of the institutional review board approval is provided in Figure S1 in Multimedia Appendix 1. The requirement for informed consent was waived in accordance with relevant ethical guidelines for secondary use of administrative data. All datasets used in this study were fully anonymized or deidentified prior to analysis, and no personally identifiable information was accessible to the investigators. No financial or other compensation was provided to participants for this study. The manuscript and all supplementary materials do not contain any images or information that could enable the identification of individual participants. All studies were conducted following the ethical guidelines and regulations of their respective countries.

Deployment Governance

A model card was developed to document the model's intended purpose, target population, input features, outputs, and key limitations, including circumstances in which the tool should not be used. The web-based app is intended solely for research and educational purposes and is not designed for clinical decision-making, diagnosis, or self-management. User inputs

XSL•FO
RenderX

are processed in real time and are not retained at the individual level, ensuring that no personally identifiable information is stored or recoverable.

To support responsible deployment, a governance framework has been established for postdeployment oversight. The system does not store or log individual-level input data; however, it may record anonymized and aggregated summary statistics (eg, distributions of input features and model outputs) that cannot be linked to any individual user. These aggregated metrics are used exclusively to monitor potential data drift, performance drift, and subgroup-level variation. Model performance and calibration are periodically reviewed, with updates planned on a quarterly basis to maintain reliability and transparency.

Results

Study Population

Among the 1,062,018 participants initially included in the discovery cohort from South Korea, 552,767 individuals who had not undergone regular health screenings and 6287 individuals aged <19 years were excluded. Furthermore, 31,314 individuals with a history of dyslipidemia diagnosis prior to their first health screening were also excluded, resulting in a final discovery cohort of 471,650 participants. Among these participants, 95,886 (20.33%) were identified as patients with dyslipidemia (Figure 1 and Table 1). Variable-wise missingness for the discovery cohorts is summarized in Table S6 in Multimedia Appendix 1, providing an overview of the distribution of incomplete data prior to preprocessing. Similar exclusion criteria were applied to the validation cohorts, resulting in 7,255,685 participants in validation cohort A from Japan and 408,725 participants in validation cohort B from the United Kingdom (Figure 1 and Tables S3 and S4 in Multimedia Appendix 1).

Model Training and Validation

Table 2 presents the results of 5-fold cross-validation of various ML models trained on the discovery cohort from South Korea. LightGBM and CatBoost showed superior performance as single models, particularly regarding AUROC and precision. To further enhance prediction performance, we developed an ensemble model using a soft-voting approach with LightGBM and CatBoost. Detailed hyperparameter configurations for both algorithms are provided in Table S5 in Multimedia Appendix 1 to facilitate reproducibility. This ensemble model exhibited improved performance metrics: AUROC, 0.782 (95% CI 0.782 - 0.783); precision, 37.6% (95% CI 37.0 - 38.1); sensitivity, 74.2% (95% CI 73.0% - 75.5%); specificity, 68.5% (95% CI 67.2 - 69.8); accuracy, 69.6% (95% CI 68.8 - 70.4); balanced accuracy, 71.4% (95% CI 71.2 - 71.5); F_1-score, 49.9% (95% CI 49.6 - 50.1); and AUPRC, 0.464 (95% CI 0.462 - 0.466).

[i]Model with the best performance.

[j]Validation and test datasets were evaluated once without CIs to preserve unbiased assessment.

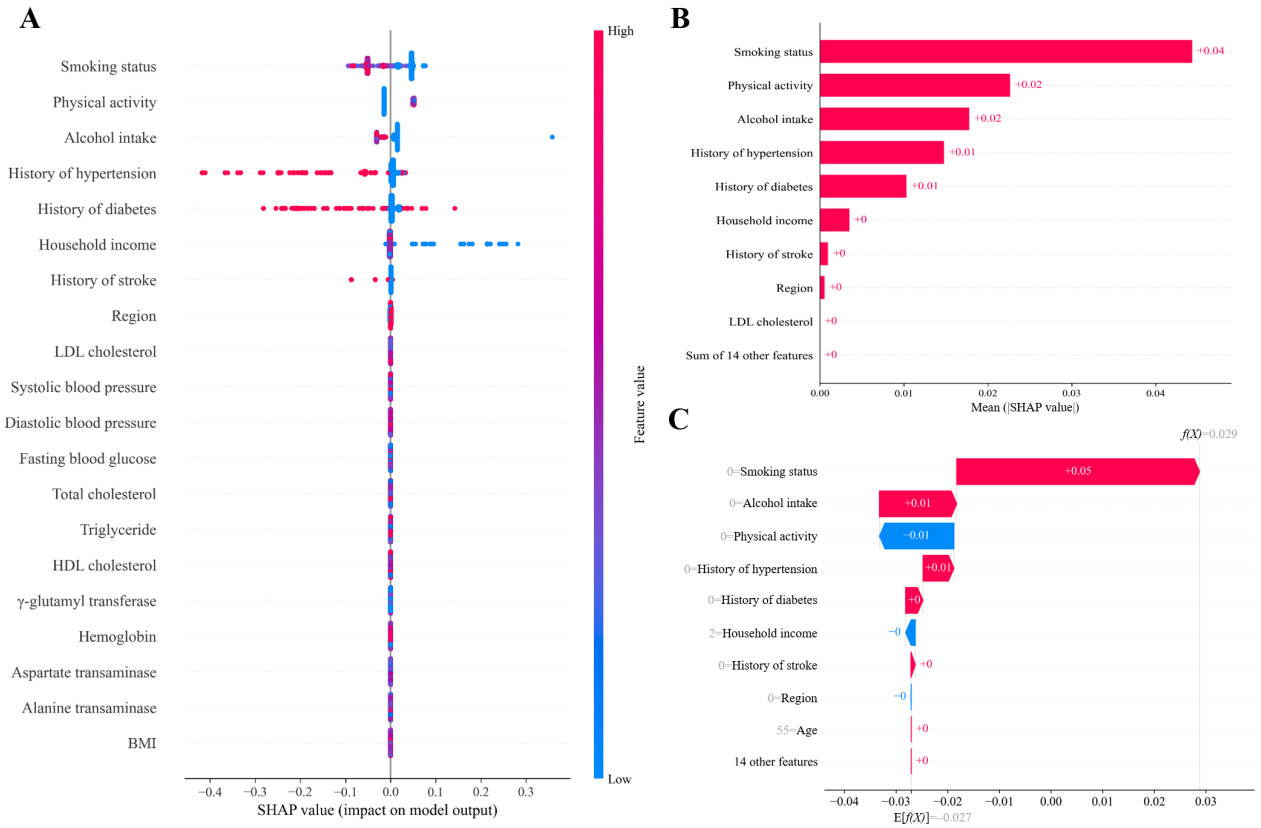
The ensemble model combining LightGBM and CatBoost via a soft-voting approach also indicated the best performance on the test dataset of the discovery cohort from South Korea: AUROC, 0.783; precision, 37.9%; sensitivity, 74.1%; specificity, 69.0%; accuracy, 70.1%; balanced accuracy, 71.6%; F_1-score, 50.2%; and AUPRC, 0.469. The similar performance between the cross-validation and test dataset results suggests minimal overfitting or underfitting of the model.

Performance of the proposed ensemble model on the external validation cohorts from Japan and the United Kingdom is also presented in Table 2. In external validation cohort A (Japan), the model achieved an AUROC of 0.744, a precision of 27.2%, a sensitivity of 81.9%, a specificity of 40.9%, an accuracy of 49.6%, a balanced accuracy of 61.4%, an F_1-score of 40.8%, and an AUPRC of 0.302. In external validation cohort B (UK), the performance metrics were an AUROC of 0.687, a precision of 5.07%, a sensitivity of 79.5%, a specificity of 22.7%, an accuracy of 25.6%, a balanced accuracy of 51.1%, an F_1-score of 9.65%, and an AUPRC of 0.245. Across cohorts from South Korea, Japan, and the United Kingdom, the proposed model showed broadly comparable discriminatory performance in predicting 5-year dyslipidemia incidence using regular health screening data, suggesting a degree of cross-population applicability.

Sensitivity Analysis

As sensitivity analyses, we evaluated the robustness of the model to potential label leakage and missing data handling. First, the model was refitted in the Korean discovery cohort after excluding baseline lipid measurements (LDL cholesterol, HDL cholesterol, triglycerides, and total cholesterol). The lipid-free model showed slightly lower but broadly comparable discrimination to the main model (AUROC 0.767 vs 0.783), suggesting that although lipid biomarkers contributed to predictive performance, the overall model retained reasonable discrimination without them. Second, a complete-case analysis restricted to participants without missing values yielded discrimination similar to that of the imputed analysis (AUROC 0.785 vs 0.783), suggesting that KNN-based imputation did not materially affect model performance. Detailed results are provided in Table S7 in Multimedia Appendix 1.

Calibration and Clinical Plausibility



Across cohorts, the prediction model showed acceptable calibration, with cohort-specific variation in calibration-in-the-large and slope (Table S8 in Multimedia Appendix 1). Calibration-in-the-large values were modestly negative across cohorts, indicating a tendency toward overestimation of absolute risk, while calibration slopes suggested mild overdispersion or underdispersion depending on the cohort. Brier scores remained within an acceptable range, reflecting stable overall predictive accuracy. Calibration plots illustrating observed versus predicted risks are presented in Figure S2 in Multimedia Appendix 1. In the UK cohort, the uncalibrated model showed systematic overestimation of absolute risk, indicating calibration drift. However, simple local recalibration using intercept and slope adjustment substantially improved calibration-in-the-large and calibration slope, while discrimination (AUROC) remained largely unchanged. Recalibration enhanced risk estimation without materially affecting ranking performance. Decision curve analysis showed that the model provided a positive net benefit across a range of clinically relevant threshold probabilities compared with treat-all and treat-none strategies (Figure S3 in Multimedia Appendix 1), supporting its potential utility for risk stratification in preventive care settings.

SHAP Value Analysis

To examine the influence of features used to predict dyslipidemia within 5 years, SHAP values were calculated for the proposed ensemble model combining LightGBM and CatBoost via a soft-voting approach. In this model, smoking had the largest influence on predicting incident dyslipidemia, followed by physical activity and alcohol intake. Histories of hypertension, diabetes, and stroke were also found to be important predictors (Figure 2).

RenderX

Figure 2. Shapley Additive Explanations (SHAP) analysis of feature contributions in the machine learning–based dyslipidemia prediction model. (A) Summary plot of SHAP values showing the impact and direction of each feature. (B) Mean absolute SHAP values across the cohort, identifying the most influential predictors. (C) SHAP decision plot for a representative individual. The consistency of key features across all panels highlights the robustness of model interpretation. HDL: high-density lipoprotein; LDL: low-density lipoprotein.

Risk of Atherothrombotic Events Based on ML-Predicted Probability

Table 3 presents the risk of atherothrombotic events (acute myocardial infarction and cerebral infarction), evaluated based on the model probability in the discovery cohort from South Korea. For acute myocardial infarction, the risk increased significantly from the first tertile of predicted probability (T1: aHR 1.62, 95% CI 1.27 - 2.06), with further increases observed in T2 (aHR 1.74, 95% CI 1.37 - 2.19) and T3 (aHR 2.34, 95% CI 1.84 - 2.97). The risk of cerebral infarction was significantly elevated across all tertiles, showing a graded association with increasing predicted probability (T1: aHR 1.59, 95% CI 1.42 - 1.79; T2: aHR 2.16, 95% CI 1.94 - 2.39; and T3: aHR 2.43, 95% CI 2.19 - 2.71). These findings indicate a trend where higher predicted dyslipidemia probability was associated with an increased risk of these outcomes, for which dyslipidemia is a known risk factor. Results from the Fine–Gray subdistribution hazard models, accounting for death as a competing risk, are presented in Table S9 in Multimedia Appendix 1. Compared with the Cox proportional hazards models, the subdistribution hazard ratios were attenuated or reversed in direction, likely reflecting the influence of competing mortality risk in higher risk groups. This pattern suggests that individuals with higher predicted dyslipidemia risk may also have higher competing mortality risk, which can reduce the probability of observing the cardiovascular outcome in competing risk models.

AI-Driven Web Application

Our final model for predicting incident dyslipidemia within 5 years, based on regular health checkup data, is deployed on our website [17] (Figure S4 in Multimedia Appendix 1). The application collects 23 parameters from regular health screening data to evaluate the probability of incident dyslipidemia. The web application uses encrypted communication protocols (HTTPS), and user-entered information is processed transiently in server memory for real-time risk calculation and deleted immediately after generating results. No individual-level user inputs are stored, logged, or retained, and no personally identifiable information is collected. Aggregated and anonymized summary statistics may be recorded for system monitoring purposes. Access to the hosting environment is restricted to authorized administrators only, and the application is intended solely for research and educational purposes.

Discussion

Key Findings

This study investigated an ML-based approach for predicting dyslipidemia within 5 years using regular health screening data from 3 large-scale population-based cohorts with distinct characteristics (South Korea, Japan, and the United Kingdom). The soft-voting ensemble learning with LightGBM and CatBoost exhibited superior performance (AUROC 0.783 and precision 37.9%). This level of discrimination was observed across cohorts from South Korea, Japan, and the United Kingdom, suggesting that the model retained a degree of ranking ability across populations. Importantly, although discrimination remained acceptable across cohorts, calibration varied substantially, particularly in the UK cohort. Our findings suggest that local recalibration can effectively address this issue, underscoring that recalibration should be considered a necessary step prior to deployment in new health care settings. The proposed model identified smoking, physical activity, and alcohol intake as important features for predicting dyslipidemia incidence. In addition, individuals with higher model probabilities showed elevated risks of atherothrombotic events, including acute myocardial infarction and cerebral infarction.

Plausible Mechanism

The prominent role of lifestyle factors, such as smoking status, physical activity, and alcohol intake, in our model's prediction of incident dyslipidemia is consistent with their well-established impact on lipid metabolism. Smoking contributes to adverse lipid profiles through multiple mechanisms, including the promotion of systemic inflammation, increased oxidative stress, and the dysregulation of enzymes critical to lipoprotein metabolism and clearance [18]. These changes can lead to elevated levels of total cholesterol, LDL cholesterol, and triglycerides, along with reduced HDL cholesterol [19]. Excessive alcohol intake results in increased triglyceride accumulation in the liver and plasma, driven by impaired hepatic fatty acid oxidation and stimulated hepatic lipogenesis and very-low-density lipoprotein synthesis and secretion [20,21]. Conversely, regular physical activity favorably alters lipid profiles by enhancing lipoprotein lipase activity, which promotes efficient triglyceride clearance, and facilitating cholesterol removal from peripheral tissues [22].

Furthermore, the importance of pre-existing conditions, such as hypertension, diabetes, and a history of stroke, as predictors reflects their deep metabolic and pathological interconnections with dyslipidemia. Hypertension and type 2 diabetes, often components of the metabolic syndrome, share underlying mechanisms (eg, insulin resistance and systemic inflammation) that contribute to unfavorable lipid profiles and accelerated

XSL•FO
RenderX

atherosclerosis [19,23]. A history of stroke, indicating established atherosclerosis and often poorly controlled risk factors, suggests ongoing metabolic derangements that predispose individuals to dyslipidemia [24]. Their inclusion as important predictors is biologically plausible, reflecting their established roles in complex metabolic and cardiovascular pathology.

Comparisons With Previous Studies

Previous ML studies predicting dyslipidemia or related conditions have been conducted; however, they have important limitations [4-6,25-28]. These frequently included reliance on single populations with limited sample sizes [4], a focus on specific, narrow forms of dyslipidemia such as familial hypercholesterolemia rather than comprehensive profiles [6,25-27], or the incorporation of data not routinely available, such as genetic markers [5,26,28]. Consequently, their scalability and utility in widespread clinical practice are often constrained.

In contrast, this study developed an ML model using readily accessible clinical indicators derived from routine health screening data. We suggested the model's generalizability through validation in large cohorts from 3 countries. Following an established framework for clinical prediction models [29], model development and validation were performed; however, clinical performance assessment has not yet been conducted, indicating the need for further research. Nevertheless, we observed that a higher predicted probability of incident dyslipidemia was associated with a higher risk of atherothrombotic events for which dyslipidemia is a risk factor. These findings suggest that the model-derived predictions of dyslipidemia are clinically valid, as they show a significant association with the occurrence of atherosclerotic events consistent with established clinical evidence.

Policy Implications

Although dyslipidemia itself may not severely reduce quality of life or pose an immediate risk of death, its critical role as a precursor to atherosclerosis and subsequent occlusive vascular events, such as myocardial infarction and cerebral infarction, which can directly or indirectly lead to mortality, underscores the necessity of early diagnosis and management [30,31]. This necessity highlights the importance of developing effective strategies for early detection and targeted intervention. Accordingly, predictive modeling approaches for dyslipidemia are of significant interest for public health policy and clinical practice.

In response to this need for predictive tools, our study developed an ML model using readily available routine health screening data. This model exhibits the feasibility and clinical plausibility of predicting dyslipidemia within 5 years, enabling the identification of high-risk individuals for targeted early intervention to reduce future disease burden. From a policy perspective, this approach could support population-level risk stratification strategies by integrating model-derived risk scores into existing national health screening programs. Such integration may allow health systems to prioritize preventive counseling, lifestyle modification programs, and follow-up monitoring for individuals at high predicted risk, while avoiding unnecessary interventions in low-risk groups. In clinical guideline development, ML-based risk stratification could complement traditional lipid-based thresholds by incorporating broader cardiometabolic and lifestyle factors, thereby facilitating more personalized and resource-efficient prevention strategies. Furthermore, the use of routinely collected data enhances scalability and feasibility, making this framework particularly relevant for public health planning and implementation across diverse health care settings.

While lipid profile variables (total cholesterol, LDL cholesterol, HDL cholesterol, and triglycerides) were also included to predict the 5-year risk of dyslipidemia, their feature contribution in the model was not prominent. This contrasts with the significant importance of lifestyle factors, such as smoking, alcohol intake, and physical activity, identified by the model. This finding may underscore the necessity of continuous efforts toward lifestyle improvement, rather than complacency based on currently normal lipid profiles.

Limitations

This study has several limitations. First, our reliance on data from regular health screenings meant that potentially important risk factors for dyslipidemia, such as diet, genetic factors, and family history, were not available. Nonetheless, the model's ability to predict dyslipidemia using routinely collected variables supports its potential practicality for large-scale implementation. Second, although the prediction horizon was defined on an individual-specific 5-year basis, calendar time–based internal validation was not performed. In addition, participants without a recorded dyslipidemia diagnosis during follow-up, including those with less than 5 years of follow-up, were classified as noncases. This approach assumes that individuals with truncated follow-up would not have developed dyslipidemia within the full 5-year prediction window, potentially introducing outcome misclassification and censoring-related bias. Consequently, the model's robustness to temporal changes in coding practices, reimbursement policies, or health care use patterns could not be fully evaluated. Third, missing values were handled using KNN imputation and Min-Max scaling; however, these distance-based methods may be sensitive to feature scaling and data distribution, and their influence on model performance cannot be fully excluded. As scaling was applied after KNN imputation, distance calculations during imputation may have been influenced by differences in feature scale. This ordering was chosen to preserve the original data distribution prior to transformation. All preprocessing was performed on the training data to minimize information leakage. Complete-case sensitivity analyses yielded similar results, suggesting that the overall impact is expected to be limited, although some uncertainty may remain. Fourth, dyslipidemia was defined using ICD-10 diagnostic codes extracted from administrative claims data, which may introduce outcome misclassification. Although laboratory measurements such as LDL cholesterol, HDL cholesterol, triglycerides, and total cholesterol were available, they were not incorporated into the outcome definition because longitudinal follow-up laboratory measurements were not consistently available across cohorts within the 5-year prediction window. In addition, laboratory thresholds and treatment practices differ across countries, reducing cross-country

XSL•FO
RenderX

comparability. Using ICD-10 codes provided a standardized framework for outcome definition across Korea, Japan, and the United Kingdom, although differences in national screening practices and treatment thresholds may partly explain calibration differences across cohorts. Fifth, despite efforts to harmonize variables across countries, complete comparability cannot be guaranteed because of differences in health care systems, population characteristics, and data structures. While the model showed broadly comparable discriminatory performance across cohorts from South Korea, Japan, and the United Kingdom, precision was lower in the UK cohort. This likely reflects the substantially lower baseline prevalence of dyslipidemia in the United Kingdom dataset (approximately 5%) compared with the Korean and Japanese cohorts (approximately 20%), together with the use of a fixed classification threshold derived from the Korean discovery cohort. The threshold was fixed across all external validation cohorts to preserve model independence and avoid data-driven optimization. This lower prevalence may partly reflect the characteristics of the UK Biobank, a volunteer-based prospective cohort with a well-documented healthy participant selection bias, as well as potential underascertainment of dyslipidemia due to reliance on diagnostic coding [32]. In contrast, the Korean and Japanese cohorts were based on administrative claims data, which more comprehensively capture routinely managed conditions such as dyslipidemia. As precision is influenced by outcome prevalence, applying the same threshold to populations with different baseline risks may reduce positive predictive value. Cohort-specific recalibration or threshold adjustment may therefore be required before clinical deployment. Sixth, a lipid-free sensitivity analysis yielded a slightly lower AUROC than the full ensemble model (0.767 vs 0.783); however, the absolute difference in discrimination was modest and likely reflects a limited impact on overall model performance. This result should therefore be interpreted cautiously. Seventh, categorical variables were encoded using ordinal representations, which may impose a linear structure across categories. As a result, SHAP values reflect each variable as a single ordered feature and should be interpreted as overall trends rather than category-specific effects. Eighth, although Cox proportional hazards models were used to evaluate associations between predicted dyslipidemia risk and subsequent cardiovascular outcomes, these models estimate cause-specific hazards and do not fully account for competing risks such as death. Sensitivity analyses using Fine–Gray subdistribution hazard models were therefore conducted, treating death as a competing event. Differences between the Cox and Fine–Gray estimates likely reflect the influence of competing mortality risk in higher risk groups, as the 2 approaches quantify distinct epidemiological quantities. This may indicate that individuals with higher predicted dyslipidemia risk also have a greater burden of comorbidities or overall frailty, which could increase mortality before cardiovascular events are observed. Finally, given the observational nature of this study, the associations between predicted dyslipidemia risk and subsequent cardiovascular outcomes should not be interpreted as causal relationships.

Despite these limitations, this study shows the feasibility of using routinely collected health screening data from large-scale population-based cohorts across 3 countries to predict dyslipidemia within 5 years and to explore its potential association with atherothrombotic events.

Conclusions

This study developed an ML-based model for predicting dyslipidemia within 5 years using regular health screening data. The proposed model was evaluated across 3 independent national cohorts (South Korea, Japan, and the United Kingdom). A higher model-derived probability of incident dyslipidemia was significantly associated with the occurrence of atherosclerotic events, indicating alignment with established clinical evidence and supporting its potential clinical applicability. Although the model shows promise, incorporating additional features and validating its application in more diverse populations may further enhance its utility.

Abstract

Background: Early prediction of gestational diabetes mellitus (GDM) is critical for improving maternal health outcomes. However, predictive models are often challenged by limited early-pregnancy samples, severe class imbalance in datasets, and complex interrelationships among clinical features.

Objective: This study aimed to develop and evaluate a unified dual-dimensional enhancement framework integrating data augmentation and feature engineering. By addressing data imbalance and leveraging medical prior knowledge, this framework significantly improves early GDM prediction performance.

Methods: We proposed a framework combining Generative Adversarial Network (GAN)–based data augmentation with large language model–inspired feature engineering. GAN sampling was used to generate clinically plausible synthetic minority class samples to mitigate data imbalance. The large language model was guided to organize features into domains (eg, basic demographics, metabolic syndrome, and core liver biomarkers) and generate higher-order composite features, integrating medical prior knowledge. Machine learning models were subsequently developed, and interpretability analyses were performed using Shapley additive explanations to identify key predictors.

Results: This study used a final analytical cohort of 8214 pregnant women, divided into dataset A comprising 966 out of 5251 (18.4%) participants with GDM, and dataset B comprising 598 out of 2963 (20.2%) participants with GDM. The random forest model enhanced by Tabular Variational Autoencoder–based feature augmentation demonstrated the best performance. On the test dataset, it achieved a recall of 0.7559, an accuracy of 0.8444, and an area under the receiver operating characteristic curve (AUROC) of 0.8873. Statistical evaluation confirmed that the Tabular Variational Autoencoder method significantly outperformed the baseline (Cohen d=2.894; P<.001) and the Conditional Tabular Generative Adversarial Network method (Cohen d=1.637; P=.02) in recall enhancement. Shapley additive explanations analysis identified the following 5 features as the most influential predictors: fasting blood glucose, the composite feature (fasting blood glucose+triglycerides)×prepregnancy BMI, activated partial thromboplastin time, leukocyte count, and neutrophil count.

Conclusions: The proposed dual-dimensional enhancement framework effectively alleviates data limitations and captures complex feature interactions in early GDM prediction. This strategy not only improves model performance, particularly in recall, but also provides interpretable biological evidence to support rapid clinical screening, stratified management, and early intervention in pregnancy.

Introduction

Gestational diabetes mellitus (GDM), defined as glucose intolerance first detected during pregnancy, has a persistently high incidence and typically occurs in the second or third trimester, leading to adverse maternal and fetal outcomes [1]. Women with GDM face increased risks of gestational hypertension, infections, postpartum hemorrhage, preterm birth, and later progression to type 2 diabetes mellitus [2]. However, efficient identification and management remain challenging due to predictive uncertainty [3]. In China, the prevalence of GDM has been reported to reach 24.24%, emphasizing the critical clinical importance of early and precise prediction to enable timely and effective intervention [4]. Although the Oral Glucose Tolerance Test (OGTT) at 24‐28 weeks is the standard diagnostic method, maternal hyperglycemia may already harm the fetus before this stage, and mid-to-late pregnancy interventions often miss the optimal window to prevent irreversible risks [5-7]. Evidence suggests that early assessment between 12 and 14 weeks, and no later than 20 weeks, is optimal, and that lifestyle interventions in early pregnancy can reduce GDM risk [8].

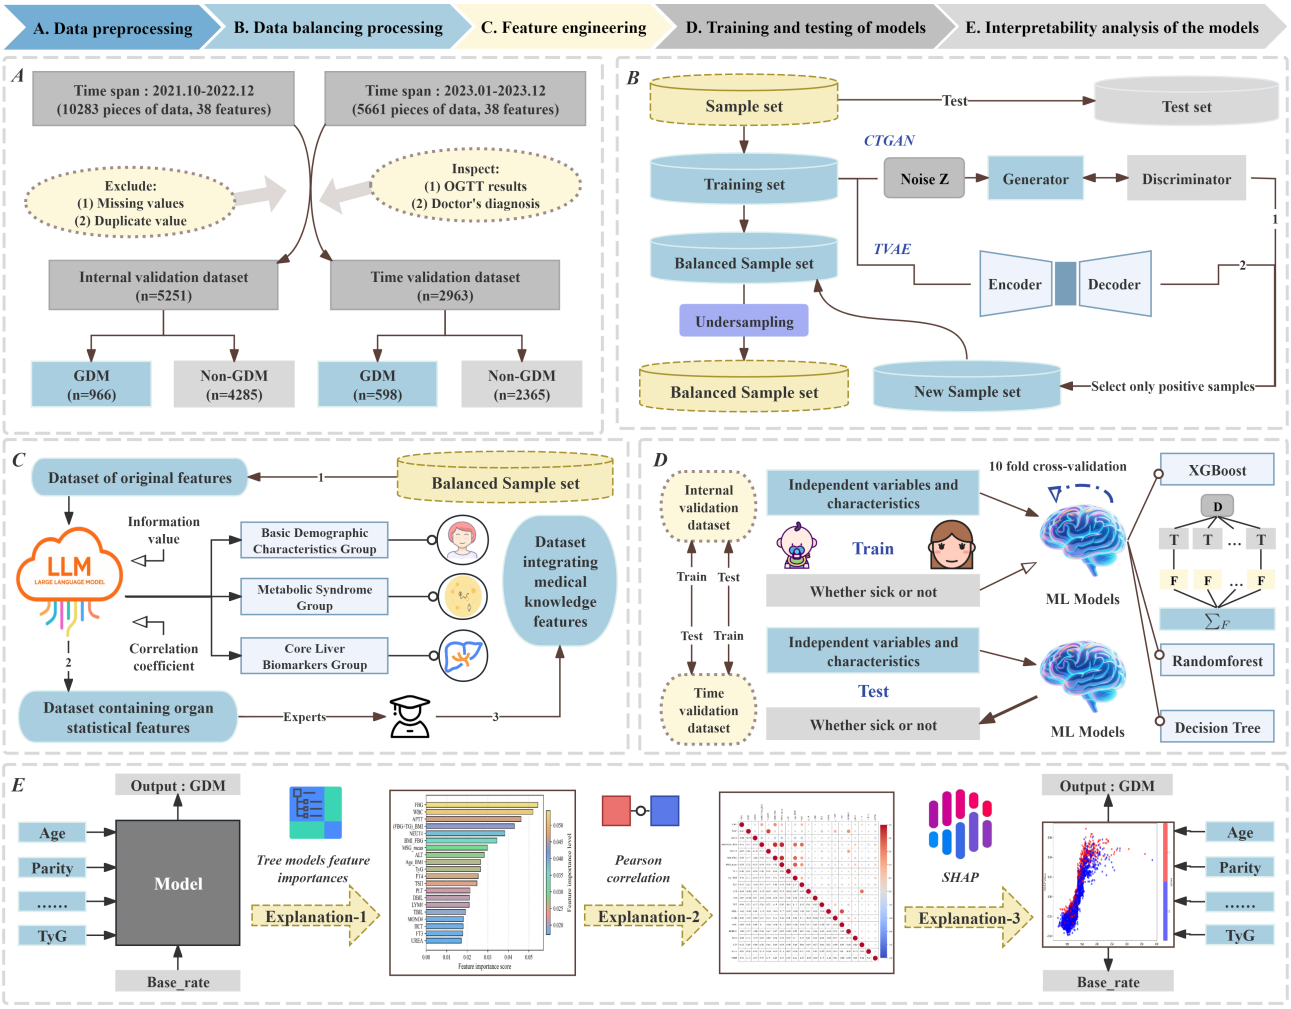
The increasing maturity of machine learning (ML) has promoted its use in early risk prediction and risk stratification in GDM-related clinical scenarios. For example, our previous study applied ML models to predict postpartum dyslipidemia among women with GDM, illustrating the potential value of ML-based approaches in this population [9]. ML models can enable precise screening of high-risk populations and provide in-depth analyses of early-pregnancy risk factors to support timely interventions. Since 2010, related research has grown rapidly, with developed predictive models emphasizing different aspects [10-12]. Wu et al [13] used ML algorithms to develop a GDM risk stratification model for Chinese pregnant women, assessing GDM risk before 16 weeks' gestation. Cooray et al [14] used multivariable regression to integrate multiple indicators and constructed the PeRSonal (Prediction for Risk-Stratified Care for Women with GDM) model, achieving favorable results. Belsti et al [15] compared several ML algorithms, including logistic regression (logit model), k-nearest neighbors, and Gaussian Naïve Bayes, to develop GDM risk prediction models and identified the optimal model for GDM prediction. Zhu et al [16], in a multicenter longitudinal cohort study, validated that steroid hormone indicators used in early- and midtrimester Down syndrome screening can be used to construct GDM prediction models [16]. Lyu et al [17] applied logistic regression to select predictive factors; the final model incorporated 9 clinical and biochemical features and demonstrated good predictive performance in the training cohort.

The early prediction of GDM faces 3 major challenges. First, the scarcity of early-pregnancy data is a core bottleneck limiting model performance, as primary health care institutions often lack complete prenatal testing protocols before 14 weeks' gestation, thereby restricting the acquisition of sufficient high-quality clinical data [18]. Second, severe class imbalance, manifested as a disproportionately low proportion of positive cases, undermines model recall and markedly increases the risk of missed diagnoses among high-risk pregnant women [19]. Third, complex interrelationships exist among clinical indicators across glucose-lipid metabolism, coagulation, and other physiological systems. These complex interactions limit the effectiveness of traditional expert-driven feature engineering, ultimately weakening model generalizability. Collectively, these challenges impede the development of robust, clinically relevant, and generalizable early prediction models for GDM.

To address the aforementioned challenges, this study proposes a unified dual-dimensional enhancement framework, with specific strategies encompassing the following approaches:

1. We introduce a Generative Adversarial Network (GAN)–based data augmentation method to address class imbalance in GDM prediction. Unlike conventional oversampling or undersampling approaches that often sacrifice either accuracy or recall, the proposed method substantially improves recall while maintaining high accuracy.
2. Inspired by large language models (LLMs), we propose a feature enhancement framework that deeply integrates medical prior knowledge with data distribution patterns, thereby further improving predictive performance.
3. We use interpretable analyses grounded in information theory and game theory to investigate model outputs, elucidate and evaluate the decision process of the GDM model, and validate the effectiveness of the feature enhancement framework. This work links model-derived findings with clinical mechanisms underlying GDM.

Our unified framework bridges the semantic gap between purely data-driven algorithms and medical prior knowledge. Traditionally, feature engineering in early GDM prediction relies heavily on highly subjective, manual expert selection. Instead, our study innovatively uses LLMs as knowledge distillers. By feeding raw statistical data distributions into the LLMs, we establish a novel paradigm that translates unstructured pathological knowledge from medical literature into structured, systems biology–guided feature aggregations. Furthermore, the synergy between GAN-based data augmentation and LLM-inspired composite features provides a dual-dimensional enhancement.



Our experimental results demonstrate that the model established using the dual-dimensional enhancement framework, particularly the random forest model enhanced by Tabular Variational Autoencoder–based feature augmentation (TFRFM), achieved the best performance in predicting GDM. The model attained a recall of 0.7559, an accuracy of 0.8444, and an area under the receiver operating characteristic curve (AUROC) of 0.8873, indicating that TFRFM substantially enhances recall without compromising accuracy. This effectively reduces the risk of missed diagnoses among high-risk pregnant women and significantly outperforms conventional sampling methods.

The research workflow is illustrated in Figure 1. The remainder of this paper is organized as follows: the "Methods" section describes the data sources, data preprocessing methods, and the construction and validation of the ML models. The "Results" section presents the evaluation of the ML models and the results of interpretability analyses. "Discussion" section discusses the clinical significance of early-pregnancy laboratory indicators

XSL•FO
RenderX

for GDM prediction and the impact of improved model recall on GDM management. Finally, the "Conclusion" section concludes the study.

Methods

Data Source and Preprocessing

This study enrolled 15,944 singleton pregnant women who delivered at Huizhou First Maternal and Child Health Hospital from October 2021 to December 2023 (10,283 cases in dataset A and 5661 cases in dataset B). These women were aged ≥18 years, underwent blood tests in the first trimester (<14 wk of gestation) and the second trimester (24 - 28 wk of gestation), and completed a 75-g oral glucose tolerance test at 24 - 28 weeks to identify whether they had GDM. Women with a history of diabetes, impaired fasting glucose, prepregnancy lipid-lowering medication use, or miscarriage or induction of labor before 28 weeks of gestation were excluded. The diagnosis of GDM was based on the criteria of the International Association of Diabetes and Pregnancy Study Groups (IADPSG) Consensus Panel, which defines GDM as meeting any of the following: fasting blood glucose (FBG) ≥5.1 mmol/L, 1-hour postload blood glucose ≥10.0 mmol/L, or 2-hour postload blood glucose ≥8.5 mmol/L [20].

The study variables include maternal demographic characteristics such as maternal age, prepregnancy BMI, parity, and gestational weight gain; blood test results during pregnancy and the puerperium, including total cholesterol, triglycerides (TG), OGTT results at 24 - 28 weeks of gestation, blood routine, and coagulation function test results.

The preprocessing was conducted in three steps: (1) integration and cleaning, which involved removing irrelevant indicators and invalid OGTT records; (2) deletion of abnormal zeros and missing values; and (3) deduplication of rows and columns, with row-level deduplication based on IDs and column-level removal of redundant features using Pearson correlation coefficients.

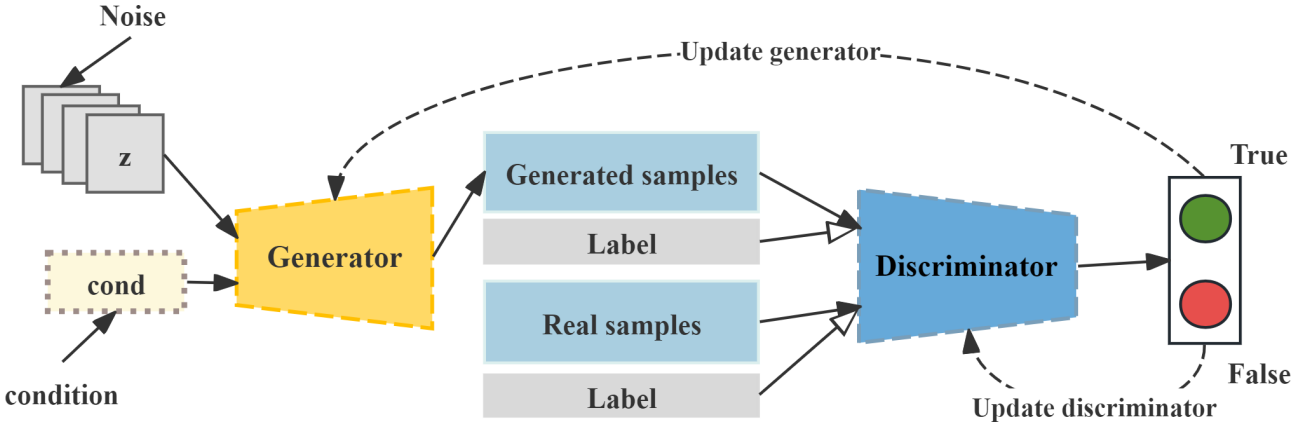
Data Augmentation Strategy Based on GAN Sampling

Clinical data on GDM exhibit a marked class imbalance. Let the original datasets be denoted as DA and DB, and define the imbalance ratio ρ as the ratio of the number of minority class samples to that of majority class samples. In this study, ρA and ρB were 0.23 and 0.25, respectively, indicating a severely imbalanced dataset. Directly using the original datasets for

XSL•FO
RenderX

modeling would lead to insufficient learning of minority class samples, typically manifested as a low recall rate.

To address this issue, 5 data balancing strategies were compared [21]: no resampling (baseline), undersampling, oversampling, Conditional Tabular Generative Adversarial Network (CTGAN), and Tabular Variational Autoencoder (TVAE). An optimized GAN-based minority sample generation approach was proposed to ensure both distributional consistency and clinical plausibility of the generated samples.



Traditional Sampling

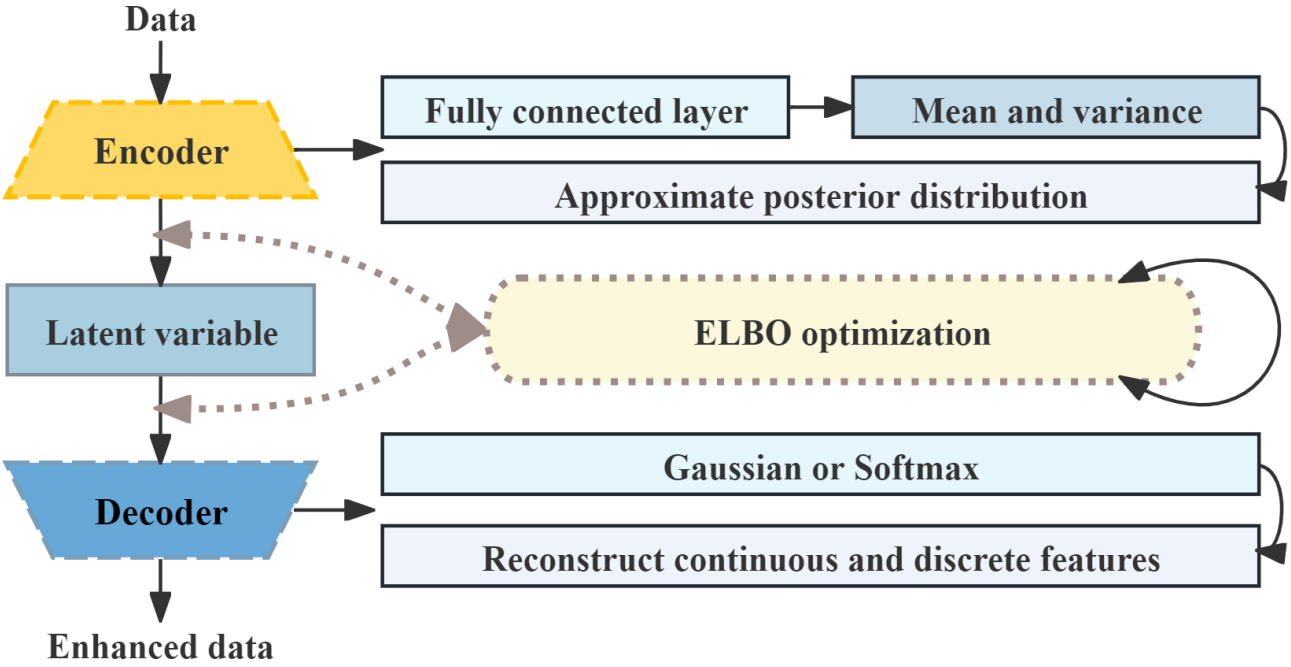
In handling imbalanced datasets, traditional sampling methods primarily alleviate the impact of class imbalance on model performance by adjusting the number of samples in the majority and minority classes. The nonsampling method directly uses the original imbalanced dataset as a baseline control to quantify the impact of imbalance. Undersampling randomly reduces samples from the majority class, which is simple and efficient but may lose key information in the majority class, leading to a decline in the model's generalization ability. The Synthetic Minority Oversampling Technique (SMOTE) algorithm is a classic oversampling method [22]. It generates new samples through linear interpolation within the neighborhood of minority class samples, which is simple and effective. However, its linear assumption may deviate from the true data distribution.

CTGAN

CTGAN is a GAN-based method used to model the distribution of tabular data and extract sample rows from this distribution [23]. As shown in Figure 2, CTGAN introduces a mode-specific normalization method to overcome the problems of non-Gaussian and multimodal distributions, and then trains the generator and discriminator in combination with conditional vectors. The generator takes random noise and class labels as input and outputs synthetic samples; the discriminator distinguishes between real and fake samples under the packed GAN framework, in which multiple samples are jointly evaluated to mitigate mode collapse. The training adopts the Wasserstein generative adversarial network with gradient penalty loss, which incorporates a gradient penalty to alleviate mode collapse, ultimately obtaining minority class samples that are highly consistent with the real distribution.

Figure 2. Conditional Tabular Generative Adversarial Network architecture.

For the CTGAN model, the training configuration was set as follows: epochs=800 and batch_size=250, with a learning rate of 0.0001 applied to both the generator and discriminator. Regarding the network architecture, the generator and discriminator dimensions were both set to (128, 128), the embedding dimension was 64, and the PAC parameter was 5, with GPU acceleration enabled. The training process was completed after 800 epochs, during which the loss curve was recorded for subsequent analysis of training stability.



TVAE

Figure 3 illustrates the network structure of TVAE. Based on the Variational Autoencoder framework, TVAE captures the complex distribution of tabular data by introducing a probabilistic encoding-decoding structure [24]. The encoder maps raw data to a latent Gaussian distribution, and the decoder reconstructs samples from latent variables while modeling continuous and discrete variables separately. The objective function maximizes the Evidence Lower Bound, balancing reconstruction accuracy and distribution approximation to generate minority class samples that are both realistic and diverse.

The detailed training parameters of TVAE are as follows: epochs=450, batch_size=128, and training was performed on GPU; key model parameters included embedding_dim=256, loss_factor=5, l2scale=0.0001, with compression or decompression dimensions of (512, 256, 128) and (128, 256, 512), respectively. The training was terminated after 450 rounds, and the generator loss was recorded every 10 rounds to monitor training stability.

XSL•FO
RenderX

Figure 3. Tabular Variational Autoencoder network structure. ELBO: Evidence Lower Bound.

LLM-Inspired Feature Enhancement Method

A single laboratory indicator contains limited information, while LLMs can automatically extract unstructured pathological knowledge from literature into structured features, breaking through the reliance of traditional feature engineering on expert experience. In this study, information value is used to measure the predictive contribution of each variable to the outcome, and the Pearson correlation coefficient is used to quantify the linear relationship between continuous variables. Both serve as inputs to the LLM, providing an empirical basis for feature selection.

This study uses a systems biology approach, leveraging the knowledge distillation capabilities of LLMs and statistical methods to generate descriptions of pathological mechanisms and recommend associated metrics. Biomarkers are initially grouped based on related organ systems, followed by expert review, optimization, and adjustment of the groupings, thereby constructing feature aggregations guided by medical knowledge. Some features are divided into three distinct subgroups:

1. Basic Demographic Characteristics Group, encompassing maternal age, gravidity, and parity.
2. Metabolic Syndrome Group (MSG), including FBG, prepregnancy BMI, TG, and total cholesterol.
3. Core Liver Biomarkers Group, comprising γ-glutamyl transferase, cholinesterase, and total bilirubin.

The feature grouping process was operationalized as a human-in-the-loop, LLM-guided conceptual framework. Specifically, LLMs were used as interactive knowledge synthesis engines to mine underlying pathophysiological connections from extensive biomedical literature. Rather than acting as a deterministic algorithmic function, the LLMs generated domain-informed hypotheses for feature aggregation. Ultimately, every proposed feature group was verified through its actual predictive performance within our ML models on the clinical dataset.

Each grouping will calculate corresponding statistics, including mean, SD, maximum value, and range. The mean reflects the overall level of the system, SD assesses the coordination of indicators within the group, the maximum value identifies extreme deviations within the group, and the range quantifies the degree of heterogeneity.

Feature combinations create new higher-order features by integrating multiple original or derived features, revealing complex relationships hidden within the data. This study designed 4 composite features to quantify various metabolic risk factors and their synergistic effects before and during early pregnancy. These features are triglycerides glucose index (TyG), age×prepregnancy BMI (Age_BMI), (FBG+TG)×prepregnancy BMI (FBG+TG_BMI), FBG×prepregnancy BMI (BMI_FBG). The TyG is calculated as follows:

$$(1)\text{TyG}=\text{Ln}[\text{TG (mg/dL)}\times\text{FBG (mg/dL)}/2]$$

Predictive Model Construction

This study will focus on tree-based models for predicting GDM. We selected 3 ML algorithms, including decision tree, random forest, and Extreme Gradient Boosting (XGBoost), to develop GDM prediction models.

The decision tree recursively splits data based on the principle of minimizing mean squared error. After reaching preset termination conditions, it outputs predictions using the mean value of leaf nodes [25]. The random forest constructs multiple trees through Bootstrap resampling and randomly selects feature subsets at each node for splitting; it improves stability by averaging the outputs of all trees and estimates generalization error using out-of-bag samples [26]. XGBoost incorporates regularization into the gradient boosting framework, iteratively fits residuals from previous rounds, uses a greedy algorithm to find optimal split points, and gradually accumulates outputs from each tree, thereby reducing overfitting risks and improving accuracy [27]. These models were implemented in Python using the Scikit-learn and XGBoost libraries.

XSL•FO
RenderX

The models were fed with specified features, and hyperparameter tuning was performed using the RandomizedSearchCV method. This method randomly samples 20 hyperparameter combinations from a predefined parameter distribution space, with F_1-score as the optimization target. It uses 10-fold cross-validation to ensure the model's generalization performance and selects the parameter combination with the best evaluation results to train the final model. Unlike GridSearchCV, which attempts all possible parameter combinations, this approach randomly samples a subset of combinations from the parameter space. It significantly reduces search time and computational resource consumption without compromising performance.

Performance Evaluation Metrics

This study aims to predict the occurrence of GDM using ML models and evaluate the models with multiple assessment metrics. The model performance is evaluated through the following metrics: accuracy, recall, precision (positive predictive value), and F_1-score. We also use the AUROC as one of the evaluation metrics. AUROC is used to assess the model's performance across different thresholds. The closer the AUROC value is to 1, the better the predictive model is at distinguishing between individuals with and without GDM.

Interpretable Analysis

The purpose of model interpretability analysis methods is to visualize the reasoning or prediction process of ML models through visual images and other means, helping people intuitively understand why a model makes a certain decision. Especially in the task of predicting GDM, interpreting and verifying the model's prediction results is conducive to clinical diagnosis and decision-making.

Shapley additive explanations (SHAP) analysis, as a model interpretation method based on the game theory framework, enhances the interpretability of ML models systematically by decomposing the model's output results and assigning feature importance scores for specific predictions to each input feature [28]. A positive score indicates that the feature plays a supporting role in the model's prediction results, while a negative score means the feature has an inhibitory effect on the prediction results. With the SHAP method, people can clearly analyze the model's output mechanism, identify the core features that contribute the most to the prediction results, and quantify the direction and extent of the features' influence, ultimately achieving a transparent interpretation of the model's prediction logic [9,29].

Ethical Considerations

This study was approved by the Medical Ethics Committee of Huizhou First Maternal and Child Health Hospital (ethics approval 20240328A14), and all pregnant women signed informed consent forms.

Results

Experimental Setup

Both baseline dataset A and baseline dataset B underwent the same preprocessing procedure. They were used for training CTGAN and TVAE as well as for developing the GDM prediction model. Specifically, baseline dataset A contained 5251 samples, including 966 (18.4%) positive cases, while baseline dataset B contained 2963 samples, including 598 (20.2%) positive cases. To alleviate class imbalance, the study compared 5 strategies: nonsampling, undersampling, SMOTE, CTGAN, and TVAE, with a focus on optimizing the GAN workflow. Specifically, GAN networks were used to model the training dataset and generate new data at a certain proportion; positive samples from the generated new data were merged into the original training dataset for the first data balancing; subsequently, undersampling was applied for the second balancing to ensure complete balance in both quantity and distribution of the dataset.

Both datasets retained 36 original features, including demographic, physiological, and laboratory indicators. Notably, the feature enhancement method was divided into 2 stages: in the first stage, 4 statistical metrics were generated for each of the 3 groups (Basic Demographic Characteristics Group, MSG, and Core Liver Biomarkers Group), resulting in a total of 12 new features; in the second stage, 4 combined features were further constructed to explore nonlinear correlations.

Clinical Rationality of Synthetic Data

To ensure the reliability of synthetic data, this study conducted rigorous validation from 2 dimensions: statistical distribution and clinical plausibility. First, regarding the validity of individual variable values, by verifying whether synthetic features fall within the clinically acceptable range of real data, the results showed that TVAE achieved clinical compliance rates of 0.979 and 0.988 in the full sample and positive samples, respectively, which were significantly higher than those of CTGAN (0.906 and 0.922). Second, in terms of feature correlation consistency, the data structure was evaluated using the mean absolute error of pairwise correlation coefficients. TVAE exhibited mean absolute error values of 0.0325 and 0.0421 in the full sample and positive samples, both lower than CTGAN values of 0.0622 and 0.0685, indicating that TVAE can more effectively preserve the multivariate statistical structure of the original data.

The physiological plausibility of the synthetic samples was rigorously verified through independent blinded evaluations by clinical domain experts. Senior obstetricians independently evaluated a dataset mixed with real and synthetic samples, scoring the clinical plausibility of each sample (on a 1 - 4 scale) and attempting to identify whether samples were real or synthetic. The results indicated that TVAE-generated samples had a higher average plausibility score than CTGAN-generated samples. Moreover, these experts found it difficult to effectively distinguish TVAE synthetic samples from real samples, demonstrating high simulation fidelity. Based on the multidimensional validation results, it is confirmed that synthetic samples generated by TVAE possess both statistical consistency and clinical validity, with data quality superior to that of CTGAN.

XSL•FO
RenderX

Model Results

To ensure the stability and reliability of the prediction models, the evaluation was conducted in 2 phases, with each phase comprising 3 independent assessments: training using only the original features, training with the addition of organ statistical features, and training with the integration of medical knowledge features. In Phase I, dataset A was used as the training set with 10-fold cross-validation to build the prediction models, while dataset B served as the test set for performance evaluation. In Phase II, the roles of the datasets were reversed, with dataset B as the training set and dataset A as the test set.

Table . Evaluation results of models using only original features (Phase I).

[a]AUROC: area under the receiver operating characteristic curve.

[b]XGBoost: Extreme Gradient Boosting.

[c]Baseline: no resampling.

[d]SMOTE: Synthetic Minority Oversampling Technique.

[e]CTGAN: Conditional Tabular Generative Adversarial Network.

[f]TVAE: Tabular Variational Autoencoder.

Tables 1-3 present the evaluation results of models using different features in the first stage. In terms of data augmentation, except for the CTGAN method that only used the original features, models applying augmentation methods all achieved significant improvements in recall compared with the baseline. Models using the undersampling method showed particularly notable gains in recall. In Phase II, the recall of the random forest model reached as high as 0.8344. However, this method tended to show a decline in F_1-score and accuracy compared with the baseline. This conclusion also applies to all evaluations of XGBoost and decision tree models. Models using the TVAE method also achieved remarkable improvements in recall, second only to the undersampling method. In particular, for all evaluations of the XGBoost model, the increase in recall brought by TVAE exceeded that of the SMOTE method. At the same time, TVAE had a weaker negative impact on F_1-score and accuracy than undersampling and could even improve F_1-score in some cases.

Tables 4-6 present the evaluation results of models using different features in the second phase, aimed at verifying the models' generalization capability. It can be observed that the conclusions drawn from Table 1 also apply here. Notably, when comparing the evaluation results of Phase I and Phase II, we found that for the random forest model using the TVAE method, the recall rate in Phase I increased progressively from 0.7157 in assessment I to 0.7508 in assessment II and then to 0.7559 in assessment III. The same trend in recall rate improvement was also observed for the model in Phase II after the introduction of new features.

To validate the effectiveness of the proposed framework combining GAN-based data augmentation with LLM-inspired feature enhancement, this study systematically evaluated the impact of different strategies on model performance using statistical methods. First, a nonparametric Kruskal-Wallis test was conducted to determine whether data augmentation methods and feature enhancement methods produced statistically significant differences in model performance metrics such as accuracy and recall [30]. When the Kruskal-Wallis test indicated significant differences, pairwise comparisons were further performed using the Games-Howell post hoc test to identify which specific augmentation strategies led to superior performance. Meanwhile, Cohen *d* effect size was used to quantify the practical significance of the differences: an effect size of 0.2 - 0.5 indicated a small difference, 0.5 - 0.8 a medium difference, and greater than 0.8 a large difference [31], thereby distinguishing whether statistically significant differences also had practical value.

Table 7 presents the results of the Kruskal-Wallis test. In this test, H denotes the Kruskal-Wallis test statistic, which is used to evaluate whether significant differences exist among multiple independent groups. For data augmentation methods, significant effects were observed on accuracy (P<.001), recall (P<.001), precision (P<.001), and F_1-score (P=.04), with corresponding effect sizes of 0.406, 0.563, 0.457, and 0.147, respectively. Specifically, the effect sizes of accuracy, recall, and precision indicated a strong impact of data augmentation methods, while the effect size of F_1-score suggested a moderate impact. No significant effect of data augmentation methods was observed on AUROC (Kruskal-Wallis H=8.099, P=.09) with a small effect size ($\eta 2$=0.102). In contrast, feature enhancement methods did not have a significant impact on any of the evaluated metrics, and their effect sizes were negligible ($\eta 2 \leq 0.010$).

For the metrics that showed significance in the Kruskal-Wallis test, group differences were further analyzed using the Games-Howell post hoc test. Figure 4 presents the results as a forest plot. Recall is a core metric for GDM prediction, reflecting the model's ability to identify positive cases and avoid missed diagnoses. The recall of TVAE was significantly higher than that of the baseline (0.4454, *P*<.001) and CTGAN (0.5429, *P*=.02), with large effect sizes (Cohen *d*=2.894 and 1.637, respectively), indicating that TVAE-generated samples effectively enhance the model's recognition of positive cases. For accuracy, SMOTE (0.8423) and TVAE (0.7601) did not differ significantly (*P*=.52), but both were significantly higher than undersampling (0.6866, *P*<.01), indicating that generated samples did not compromise overall classification ability.

Traditional oversampling methods, such as SMOTE, demonstrate a clear advantage in rapidly increasing recall. However, their critical weakness lies in generating boundary noise via linear interpolation within the highly nonlinear metabolic feature space, often leading to a disproportionate drop in precision. While CTGAN mitigates this issue, it exhibits limitations when processing continuous, heavily skewed clinical biomarkers. In contrast, the TVAE approach demonstrates a distinct superiority. By modeling a continuous latent Gaussian space, it smoothly reconstructs physiological variables, achieving a superior balance between sensitivity and specificity. Furthermore, when original features are augmented with LLM-inspired composite features, the framework exhibits a remarkable capability in capturing synergistic pathological interactions, which nonlinear tree–based models leverage to build highly robust decision boundaries. The inherent weakness of this dual-enhanced, high-recall strategy is a marginal increase in the false-positive rate. Nevertheless, in the clinical context of early first-trimester screening, the benefit of capturing nearly all true high-risk cases for noninvasive lifestyle intervention significantly outweighs the easily manageable drawback of transient false-positive alerts.

In summary, we consider that the random forest model enhanced by TFRFM represents an effective approach for early-pregnancy prediction of GDM, providing strong support for clinical decision-making. This model demonstrated stable and superior performance across different data augmentation and feature enhancement strategies, showing high accuracy and AUROC. Notably, it effectively improved the identification of positive cases while maintaining a balance between recall and precision, which is critical for the early prediction and precise management of GDM.

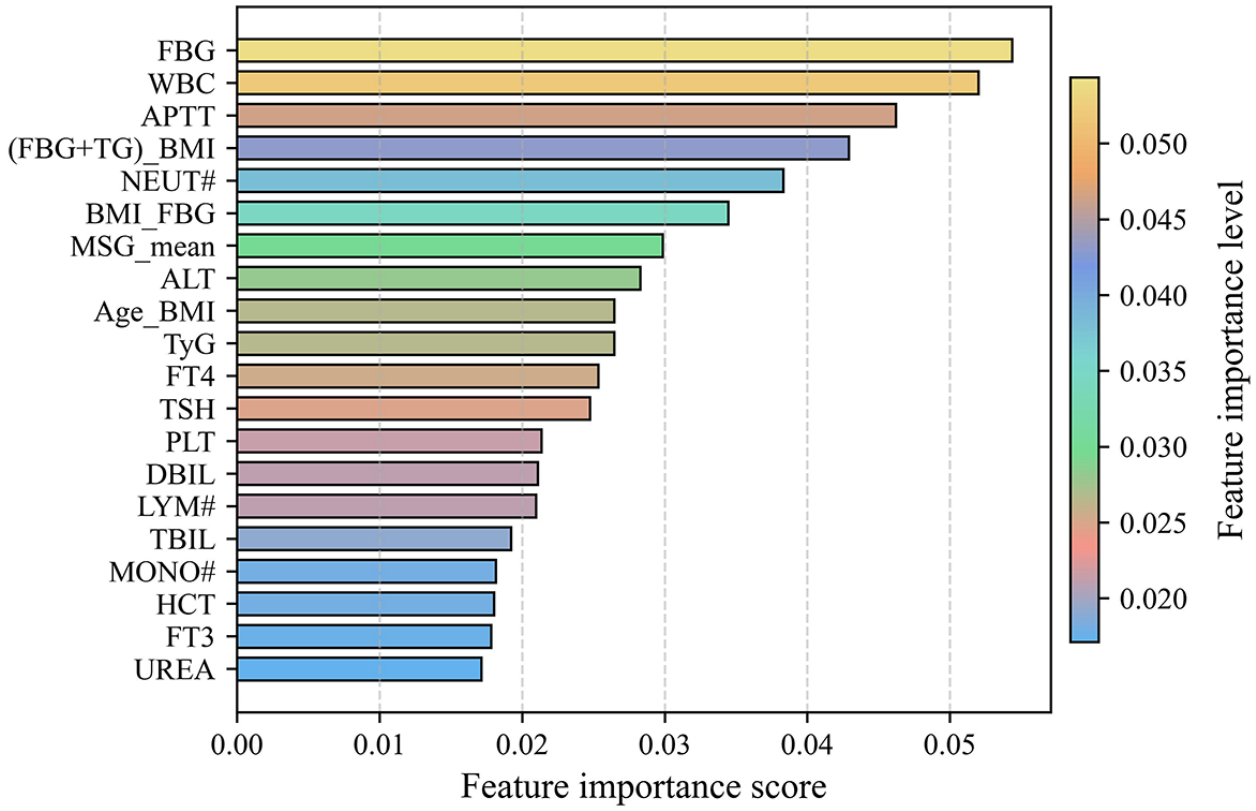
Interpretability Analysis Results: Feature Importance and Correlation Analysis



To investigate the role of features in the model, we conducted feature importance and correlation analyses using the TFRFM. By calculating each feature's contribution to the model's decision-making process, we identified the top 20 features that play a critical role in predicting early-pregnancy GDM. Additionally, correlation analysis was performed on these 20 features to reveal potential relationships and interactions among them.

Figure 5 presents the feature importance analysis of the TFRFM. FBG achieved the highest importance score, followed by white blood cell count (WBC) and activated partial thromboplastin time (APTT), indicating that these features contribute substantially to the model's decision-making process and can be regarded as the most critical predictors of GDM. In addition, the 4 composite features investigated in this study, along with the mean of MSG, were also ranked among the top 20 features, demonstrating their important role in prediction and further validating the effectiveness of integrating medically informed features. Notably, although some traditional indicators such as age, TG, and BMI may not appear prominent when analyzed independently, their contributions become substantial when combined with other features or when potential interfeature correlations are considered. This finding highlights that interactions and relationships among features are also crucial for accurately predicting early-pregnancy GDM.

Figure 6 also presents the correlation analysis among these 20 features. The size of the circles represents the absolute magnitude of the correlation coefficients, and the color gradient corresponds to the direction and strength of the correlations, with red indicating a positive correlation and blue indicating a negative correlation, where darker shades represent stronger associations. The composite feature (FBG+TG)_BMI, ranked fourth in feature importance, exhibited the highest Pearson correlation with GDM, followed by BMI_FBG, Age_BMI, TyG, MSG_mean, FBG, APTT, and WBC, with APTT showing a negative correlation with GDM. These correlation results suggest that the relationships among combined features and their association with GDM may be more complex and informative than analyses of individual features alone. This underscores the importance of considering interfeature interactions and associations when predicting early-pregnancy GDM rather than relying solely on the significance of individual features.

SHAP Analysis Results

SHAP analysis quantifies the contribution of each feature to the model's predictions, providing an intuitive view of feature importance rankings and influence patterns under different methods. In this section, we focus on comparing the SHAP analysis results of the TFRFM, the random forest model enhanced by the TVAE method (TVRFM), and the random forest model trained on baseline data (BLRFM), highlighting the advantages of integrating the TVAE approach with feature enhancement in capturing key predictive factors, stabilizing feature effects, and characterizing feature relationships.

As shown in Figure 7, the top 5 features in terms of average SHAP values for the TFRFM are FBG, APTT, WBC, (FBG+TG)_BMI, and neutrophil (NEUT#), indicating that these are the key drivers for predicting blood glucose levels in the model. In terms of the magnitude of feature impact, FBG has a SHAP range of (–0.10 to 0.125) with a span of 0.225, and WBC has a SHAP range of (−0.125 to 0.10) with the same span of 0.225, showing the greatest fluctuations in prediction influence. This aligns with clinical understanding, where blood glucose (eg, FBG) and inflammatory indicators (eg, WBC) are directly associated with pregnancy risk. Figure 7 clearly shows that the average SHAP values of the top 20 features are all greater than 0, indicating that these features contribute positively to the prediction, and the feature importance ranking aligns well with medical knowledge.

XSL•FO
RenderX

Figure 7. Shapley additive explanations beeswarm plot of the Tabular Variational Autoencoder–based feature augmentation. Age_BMI: age×prepregnancy BMI; ALT: alanine aminotransferase; APTT: activated partial thromboplastin time; AST: aspartate aminotransferase; BDCG_mean: the mean of the basic demographic characteristics group; BMI_FBG: fasting blood glucose×prepregnancy BMI; CLBG_mean: the mean of the core liver biomarkers group; CLBG_range: the range of the core liver biomarkers group; CLBG_std: the standard deviation of the core liver biomarkers group; DBIL: direct bilirubin; FBG: fasting blood glucose; (FBG+TG)_BMI: (fasting blood glucose+triglycerides)×prepregnancy BMI; FT4: free thyroxine; LYM#: lymphocytes; MSG_mean: the mean of the metabolic syndrome group; NEUT#: neutrophil; PLT: platelet count; SHAP: Shapley additive explanations; TSH: thyroid-stimulating hormone; TyG: triglycerides glucose index; WBC: white blood cell count.

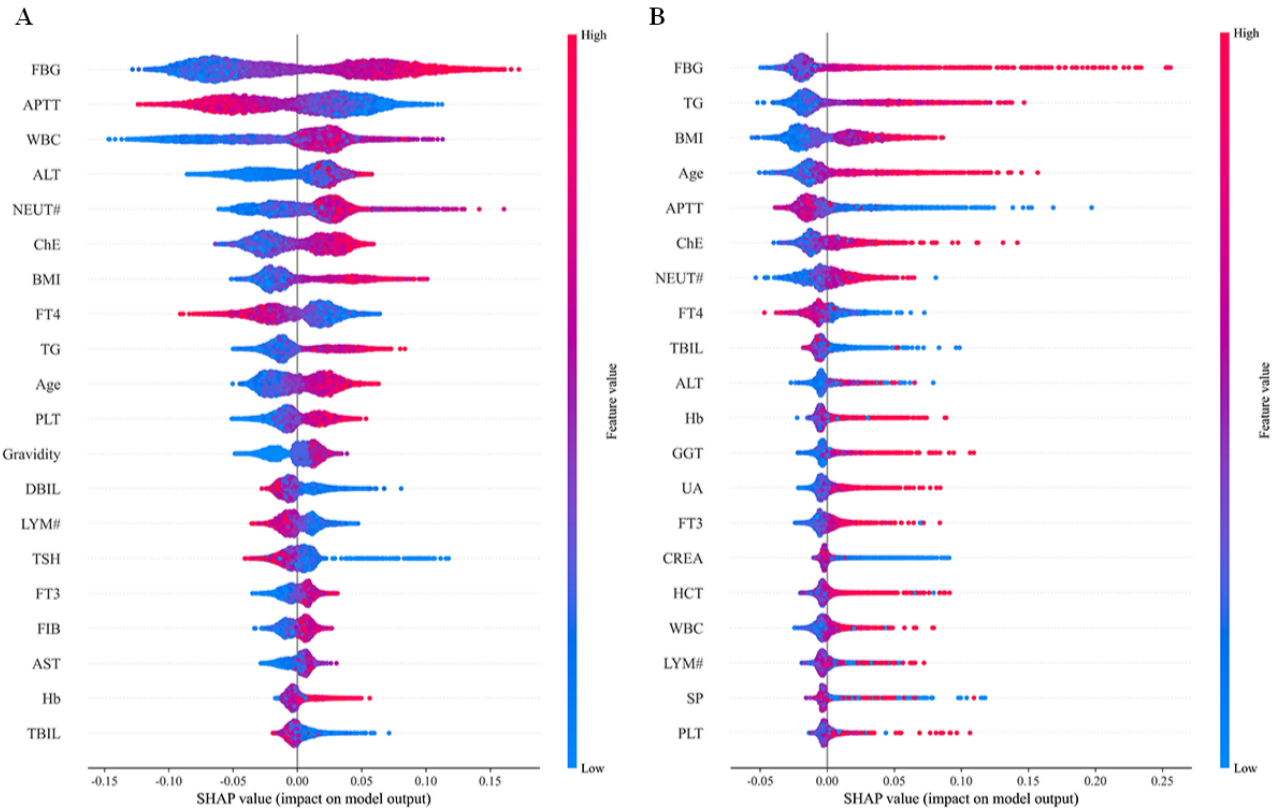

Figure 8 shows the SHAP beeswarm plots for TVRFM and BLRFM. The top 5 features by average SHAP value in TVRFM are FBG, APTT, WBC, ALT, and NEUT#, with an overlap of only 9 out of 20 (45%) with the top 20 features in TFRFM. In TVRFM, the SHAP value range for FBG is 0.3 (−0.125 to 0.175) and for WBC is 0.275 (−0.15 to 0.125), both larger than in TFRFM, indicating greater variability of key feature influence and lower model stability without feature enhancement. In

XSL•FO
RenderX

BLRFM, the top 5 features by average SHAP value are FBG, TG, BMI, age, and APTT, with an overlap of only 7 out of 20 (35%) with the top 20 features in TFRFM. Notably, inflammation-related indicators such as WBC and NEUT# are absent, while age, which has weaker direct clinical relevance, is included. In the baseline model, the SHAP value range for FBG reaches 0.325 (−0.05 to 0.275), exhibiting the largest fluctuation. The scatter points are elongated on the right side of the zero line and concentrated on the left, indicating substantial prediction bias for high-risk pregnant women.

The above findings indicate that the introduction of enhanced features such as (FBG+TG)_BMI strengthens the impact of interactions among physiological indicators, aligning more closely with clinical logic. The SHAP value fluctuations of key features, including FBG and WBC, are reduced, improving the robustness of model predictions. The model also decreases the presence of irregular feature-target relationships, captures linear associations more clearly, and retains the ability to indicate potential nonlinear relationships. In summary, TFRFM, through the combination of feature enhancement and generative modeling, significantly improves the identification of key predictive factors and enhances model stability, providing a more reliable reference for assessing pregnancy-related risks.

ALT: alanine aminotransferase; APTT: activated partial thromboplastin time; AST: aspartate aminotransferase; ChE: cholinesterases; CREA: creatinine; DBIL: direct bilirubin; FBG: fasting blood glucose; FIB: fibrinogen; FT3: free triiodothyronine; FT4: free thyroxine; GCT: γ-glutamyl transferase; Hb: hemoglobin; HCT: hematocrit; LYM#: lymphocytes; NEUT#: neutrophil; PLT: platelet count; SHAP: Shapley additive explanations; SP: systolic pressure; TBIL: total bilirubin; TG: triglycerides; TSH: thyroid-stimulating hormone; TVAE: Tabular Variational Autoencoder; UA: uric acid; WBC: white blood cell count.

Discussion

Principal Findings

The primary finding of this study is that integrating GAN-based data augmentation with LLM-inspired feature enhancement successfully addresses the persistent challenges of class imbalance and complex feature interactions in early-pregnancy GDM prediction. Furthermore, our interpretability analysis revealed that early GDM risk is most strongly driven not only by independent glycemic markers, but by complex metabolic interactions captured through novel composite features, alongside specific inflammatory and coagulation indicators.

Early screening and risk-stratified management of GDM are crucial for reducing the risk of pregnancy-related complications. Effective prediction of GDM in early pregnancy allows for the identification of high-risk pregnant women, enabling clinicians to promptly implement evidence-based interventions. This approach also facilitates the development of precise and individualized management plans tailored to high-risk groups, thereby improving maternal and neonatal health outcomes. Given the profound impact of GDM-related complications on maternal and fetal health, early screening combined with risk-stratified management has become a core component of optimizing GDM interventions [32]. Consequently, exploring earlier and more accurate methods for predicting GDM to enable

XSL•FO
RenderX

timely intervention has emerged as an urgent and critical challenge.

The pathogenesis of GDM involves pancreatic β-cell dysfunction and tissue insulin resistance. The combined indicator of FBG, TG, and BMI, namely the (FBG+TG)_BMI proposed in this study, exhibits a close biological association with insulin resistance. Its underlying mechanism primarily reflects the interplay between dysregulated glucose-lipid metabolism and obesity-related pathophysiological processes. FBG serves as a direct marker of insulin sensitivity, and its elevation indicates increased hepatic glucose output due to hepatic insulin resistance as well as impaired peripheral glucose use. Available studies suggest a biologically plausible link between hyperglycemia and dyslipidemia [33]. Hyperglycemia can trigger reactive oxygen species production in pancreatic β-cells, leading to oxidative stress and cellular dysfunction, thereby exacerbating insulin resistance. On this pathological basis, elevated TG levels directly impair glucose metabolism in muscle tissue and inhibit insulin signaling pathways, further aggravating insulin resistance. Additionally, free fatty acids generated from TG hydrolysis can exert lipotoxic effects, further damaging β-cell function. Consequently, FBG and TG jointly drive the progression of metabolic imbalance, forming a vicious cycle of overlapping glucotoxicity and lipotoxicity. BMI, as a core indicator of obesity, amplifies insulin resistance through ectopic fat deposition, proinflammatory factor release, and endoplasmic reticulum stress. The combined effect of FBG, TG, and BMI comprehensively reflects the metabolic burden by superimposing glucotoxicity, lipotoxicity, and obesity-related states. This synergistic metric captures the complex pathophysiology of insulin resistance more accurately than any single indicator. Accordingly, the composite index (FBG+TG)_BMI may serve as a simple surrogate tool for assessing insulin resistance, particularly suitable for early-pregnancy screening to rapidly identify high-risk individuals, thereby providing a biological basis for risk-stratified management and early intervention.

Clinical studies have shown that pregnant women with GDM often exhibit shortened APTT from early to midpregnancy, which is consistent with a mild hypercoagulable state. For example, in GDM pregnancies, prothrombin time and APTT in early pregnancy are significantly reduced, and multivariate analyses indicate that a shorter APTT is an independent predictor of GDM [34]. Studies examining laboratory data from women at 24 - 28 weeks of gestation also report that the GDM group shows markedly shorter prothrombin time and APTT and higher fibrinogen levels compared with controls [35]. Research on type 2 diabetes has similarly found that overt diabetes is associated with shortened APTT and elevated fibrinogen, suggesting a general thrombotic tendency in diabetes [36].

GDM is characterized by key pathophysiological features, including insulin resistance, pancreatic β-cell dysfunction, and low-grade inflammation, all of which contribute to a procoagulant state. Under diabetic conditions, hyperglycemia and insulin resistance increase the expression of coagulation factors in the intrinsic pathway, such as FXII, FXI, and FVIII, resulting in APTT shortening [37]. In GDM, FXII levels are significantly elevated, and its critical role in activating the intrinsic coagulation pathway helps explain the observed APTT reduction [38].

WBC and NEUT#, as markers of inflammation, are involved in the development of GDM by mediating chronic low-grade inflammatory responses. Pregnant women with GDM often exhibit insulin resistance alongside dysregulated glucose and lipid metabolism. Elevated blood glucose and free fatty acids activate inflammatory signaling pathways. This activation stimulates immune cells, such as neutrophils, to release proinflammatory factors, thereby inducing a systemic low-grade inflammatory state. Neutrophils, being the most abundant leukocyte subset in peripheral blood, can further exacerbate inhibition of insulin signaling and β-cell dysfunction when activated or functionally impaired. Mild elevations of WBC and NEUT# are observed in early pregnancy among patients with GDM, and their levels correlate with the degree of insulin resistance, poor glycemic control, and adverse pregnancy outcomes. These findings suggest that inflammatory markers may not only be concomitant phenomena in GDM pathophysiology but also actively contribute to disease development by amplifying the inflammatory cascade, providing potential biological evidence for early identification of high-risk populations and the development of anti-inflammatory targeted interventions.

The risk probability of developing GDM in pregnant women can be quantitatively estimated using ML models [39]. Given the notable advantage of ML in handling complex, high-dimensional data, several ML-based predictive models have demonstrated superior performance compared with traditional regression models [40]. For instance, Ye and colleagues [41] constructed GDM prediction models using more than 30 ML algorithms, including decision trees and random forests, and compared them with logistic regression models. Their results confirmed the stronger predictive capability of ML approaches and identified TG, FBG, BMI, and hemoglobin A_{1c} as among the most important predictors. Similarly, Belsti et al [15] developed new models based on the internationally validated Monash GDM model using XGBoost and CatBoost classifiers, achieving optimal discrimination performance with AUROC of 0.92 and 0.93, respectively, while decision curve analysis confirmed the highest clinical utility of these models [15]. Furthermore, our findings indicate that the TFRFM model, enhanced through data augmentation and feature augmentation, maximizes early prediction of GDM, demonstrating superior robustness and generalization ability, with an AUROC of 0.8873 and a recall of 0.7559.

Recall is an indicator that measures a model's ability to correctly identify positive cases. An improvement in recall means that the model reduces the risk of missed diagnoses, allowing more pregnant women who truly have GDM to be identified in a timely manner, although this may be accompanied by an increase in false positives. Reducing missed diagnoses directly benefits maternal and neonatal health outcomes, as early prevention or diagnosis of GDM enables pregnant women to receive targeted interventions such as personalized nutritional guidance or blood glucose monitoring, thereby lowering the risks of macrosomia and preterm birth. At the same time,

XSL•FO
RenderX

although the false-positive rate may increase, nonpharmacological interventions such as dietary management and exercise guidance following a misdiagnosis still provide positive health effects. Their potential adverse impacts can be effectively mitigated through standardized OGTT reassessment in midpregnancy. Nonpharmacological interventions, being the foundation of GDM management, can help pregnant women develop healthy lifestyles and reduce metabolic burden even in cases of misdiagnosis [42]. Furthermore, OGTT reassessment in early pregnancy serves as the final diagnostic reference, ensuring that high-risk individuals receive appropriate scientific interventions while minimizing unnecessary medical treatment and reducing the potential impact of misdiagnosis on maternal and neonatal health. Therefore, an increase in recall promotes the transition of GDM stratified management from a reactive to a proactive approach and allows primary health care resources to be optimally allocated to high-risk populations.

It must be acknowledged that the screening and management of GDM largely depend on the available medical resources and the clinical judgment of health care providers. However, primary hospitals often exhibit considerable variability in these aspects, which limits their capacity to prevent and manage GDM and reduces their ability to provide timely and reliable personalized interventions for pregnant women. Furthermore, given that GDM may share underlying pathophysiological mechanisms with other pregnancy-related disorders, exploring the relationships among these conditions and applying the proposed framework combining GAN-based data augmentation with LLM-inspired feature enhancement to develop integrated prediction and management tools for multiple gestational diseases holds promise for further improving maternal and neonatal health outcomes. Additionally, future research should incorporate multicenter and multiethnic cohorts to further rigorously validate the model's generalizability across diverse geographical populations.

Conclusion

This study proposes a framework that combines GAN-based data augmentation with LLM-inspired feature enhancement, effectively addressing data imbalance in GDM datasets and significantly improving model recall. In our experiments, we observed that a random forest model incorporating TVAE and feature enhancement not only increased recall but also maintained high precision, accuracy, and AUROC. The model demonstrated superior overall performance and stability across multiple independent evaluations, highlighting its potential as an effective tool for early-pregnancy GDM prediction. Furthermore, interpretability analysis revealed that FBG, (FBG+TG)_BMI, APTT, WBC, and NEUT# contributed most significantly to GDM prediction. These findings provide important biological evidence to support rapid screening, stratified management, and early intervention for GDM.

The proposed method not only enhances predictive accuracy but also offers new insights into the pathophysiological mechanisms of GDM. By emphasizing interactions among physiological indicators, the model better captures complex relationships within clinical data, which has important implications for guiding clinical practice. In the future, we aim to further optimize this framework and explore its applicability to predicting other pregnancy-related diseases, advancing the prediction and management of gestational disorders and contributing to improved maternal and neonatal health outcomes.

Acknowledgments

We sincerely appreciate the collaboration and assistance of the physicians from the Department of Obstetrics and Gynecology and the Information Department at Huizhou First Maternal and Child Health Care Hospital, Guangdong, China, in collecting maternal medical records for this study.

Generative artificial intelligence (AI) tools were used during both the research and manuscript preparation processes. In this study, large language models were employed as part of the proposed methodological framework to assist in knowledge synthesis and feature grouping for feature engineering. In addition, AI was used to assist with language editing and text refinement for clarity and brevity. All content was subsequently reviewed and edited by the authors to ensure accuracy and appropriateness.

Abstract

Background: Depressive symptoms are linked to nutritional vulnerability and functional decline in aging populations, but their relationships with nutritional risk and lower-extremity physical performance are often examined separately. Tree-based exploratory approaches may provide transparent subgroup characterization.

Objective: This study aimed to examine the cross-sectional associations of depressive symptoms with nutritional risk and lower-extremity physical performance among community-dwelling middle- to older-aged adults and to compare a tree-based exploratory approach with regression-based methods for characterizing depression-related patterns within the study sample.

Methods: This cross-sectional secondary analysis included 1010 community-dwelling adults aged ≥50 years recruited from 1 hospital and 3 community centers in northern Taiwan. Depressive symptoms were assessed using the Geriatric Depression Scale–Short Form (GDS-15). Nutritional status was measured using the Mini Nutritional Assessment–Short Form (MNA-SF), and physical performance was evaluated using the Short Physical Performance Battery (SPPB), gait speed, and the timed up and go (TUG) test. Sociodemographic, lifestyle, and clinical variables were included as covariates. Outcomes were dichotomized using established clinical cutoffs. χ^2 automatic interaction detection (CHAID) decision trees were used as a tree-based exploratory approach for subgroup characterization. Multivariable logistic regression and least absolute shrinkage and selection operator (LASSO) logistic regression models were used for comparison. Model performance was evaluated using the area under the receiver operating characteristic curve (AUC), sensitivity, specificity, and classification accuracy.

Results: Of the 1010 participants, 143 (14.2%) screened positive for depressive symptoms (GDS-15 ≥5). Compared with participants without depressive symptoms, those with depressive symptoms had poorer nutritional status and lower-extremity physical performance, including a higher prevalence of nutritional risk (53/143, 37.1% vs 105/867, 12.1%; *P*<.001), SPPB impairment (53/143, 37.1% vs 118/867, 13.6%; *P*<.001), gait speed impairment (73/143, 51% vs 270/865, 31.2%; *P*<.001), and TUG impairment (25/143, 17.5% vs 55/864, 6.4%; *P*<.001). Across CHAID models, GDS-15 score was consistently selected as the primary splitting variable, while BMI, calf circumference, age, education level, and comorbidity severity provided additional hierarchical refinement of subgroup patterns. In comparative model analyses, LASSO logistic regression analysis had the highest classification performance for the MNA-SF, SPPB, and gait speed outcomes, whereas CHAID provided transparent, rule-based subgroup characterization with acceptable within-sample classification performance. Model performance for TUG was less consistent across approaches.

Conclusions: In this community-based sample of adults aged 50 years and older, depressive symptom severity was associated with nutritional vulnerability and poorer lower-extremity physical performance. CHAID identified hierarchical subgroup patterns linking depressive symptoms, including subthreshold levels, with nutritional and functional vulnerability. Although LASSO logistic regression analysis had higher classification performance, CHAID offered transparent, rule-based subgroup characterization.

Introduction

Depression, nutritional risk, and lower-extremity function are key domains within comprehensive geriatric assessment, as they reflect important medical, psychosocial, and functional dimensions of health, and are routinely considered in geriatric care due to their high prevalence, close interrelationships, and strong associations with disability, frailty, and reduced quality of life [1]. Depression is a common mental health condition and a major public health concern in this population. Depressive symptoms are particularly prevalent among adults aged 50 years and older and have been associated with nutritional vulnerability, accelerated functional decline, and increased premature mortality [2-5]. Malnutrition risk is also common during the transition from midlife to older adulthood, a period often characterized by multimorbidity, retirement-related adjustment, and changing social roles that may weaken psychological resilience and overall health status [6-8]. In addition, greater depressive symptom burden has been shown to have dose-response associations with adverse health outcomes in later life [9]. Decline in lower-extremity physical performance, reflected in slower gait speed and reduced muscle strength, is likewise strongly associated with disability, falls, and progression to frailty among older adults [10-12].

Understanding the mechanisms underlying these associations is important for clinical assessment and intervention. Depressive symptoms may contribute to functional decline through several pathways, including reduced motivation, appetite changes, persistent fatigue, and lower participation in physical and daily activities [8,10,13-15]. These changes may, in turn, accelerate mobility decline and increase vulnerability to social withdrawal and reduced independence. Nutritional status is another important and modifiable determinant of health in aging populations [16]. Poor nutritional intake may lead to loss of muscle mass, sarcopenia, and frailty [15,17], which can further impair gait, balance, and overall physical function [11,18]. From a clinical perspective, depressive symptoms and nutritional vulnerability are both highly relevant because they are potentially modifiable and closely related to mobility outcomes. Together, depression, malnutrition, and impaired physical performance may reinforce one another over time [8,11,19], creating a downward spiral that contributes to disability, frailty, and increased mortality risk [12,13].

Although previous studies have documented associations between depressive symptoms and nutritional risk, depressive symptoms and mobility decline, and nutritional risk and physical performance, these relationships have often been examined separately rather than within an integrated framework in a single community-based sample [13,14,19-21]. Conventional regression approaches have been widely used to characterize such associations, but they may be less well suited to identifying potential nonlinear patterns, interaction structures, and clinically relevant thresholds across multiple correlated factors [22]. In this context, a selected tree-based analytic approach, χ^2 automatic interaction detection (CHAID), may provide complementary value by yielding visually explicit subgroup splits and transparent rule-based patterns for exploratory subgroup characterization [22-25]. In this study, CHAID was used as a transparent exploratory analytic tool rather than as a comprehensive representation of modern interpretable machine learning. However, few studies have applied both a tree-based exploratory approach and conventional regression methods to examine depression-related patterns in nutritional vulnerability and lower-extremity physical performance among community-dwelling middle- to older-aged adults.

Given these considerations, integrating a tree-based exploratory approach with conventional regression methods may provide a more comprehensive understanding of how depressive symptoms relate to nutritional risk and lower-extremity physical performance in community-dwelling middle- to older-aged adults. This study had 2 aims: (1) to examine the cross-sectional associations between depressive symptoms and 2 clinically relevant outcomes, nutritional risk and lower-extremity physical performance, among community-dwelling middle- to older-aged adults and (2) to compare a tree-based exploratory approach with conventional regression methods for characterizing depression-related patterns within the study sample. We hypothesized that greater depressive symptom severity would be associated with higher nutritional risk and poorer lower-extremity physical performance and that the tree-based exploratory approach would provide complementary pattern-based insights beyond regression estimates alone.

Methods

Study Design and Population

We conducted a cross-sectional secondary analysis using data from the Gan Dau Healthy Longevity Plan in Taiwan to examine the associations of depressive symptoms with nutritional risk and lower-extremity physical performance among community-dwelling middle- to older-aged adults. A total of 1010 participants aged 50 years or older were recruited through convenience sampling from 1 hospital and 3 community centers in northern Taiwan between January 2024 and September 2024. Participants were eligible if they were able to communicate in Mandarin or Taiwanese and were able to provide informed consent.

XSL•FO
RenderX

All assessments were completed by trained personnel after written informed consent was obtained. Standardized assessment procedures were used to reduce measurement bias, and all analytic data were fully deidentified to protect participant confidentiality. Sample size was determined by the number of eligible participants in the parent study, and no a priori power calculation was performed. Because participants were recruited through convenience sampling from 1 hospital and 3 community centers, selection bias may have occurred, and the enrolled participants may have been healthier or more motivated than nonparticipants.

Depressive symptoms were assessed using the 15-item Geriatric Depression Scale–Short Form (GDS-15). Nutritional status was assessed using the Mini Nutritional Assessment–Short Form (MNA-SF). Lower-extremity physical performance was assessed using the Short Physical Performance Battery (SPPB), gait speed, and the timed up-and-go (TUG) test. In this analysis, depressive symptom severity was treated as the main explanatory variable, whereas nutritional risk and lower-extremity physical performance were treated as study outcomes. This study was reported in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines.

Ethical Considerations

This study was approved by the Institutional Review Board of Taipei Veterans General Hospital, Taiwan (number 2023-10-001B#1). Written informed consent was obtained from all participants or legally authorized representatives, when necessary, in accordance with the Declaration of Helsinki.

Participant privacy was protected by collecting data anonymously and analyzing the data in aggregate form. No personally identifiable information was reported. The data were stored securely and were accessible only to the research team. Participants did not receive any compensation for participating in this study.

Measures

Depressive Symptoms

Depressive symptoms were assessed using the GDS-15, a validated screening tool widely used in older populations [26]. The abbreviated version of the 30-item GDS was developed by Yesavage and colleagues [27], and the Mandarin Chinese version was culturally adapted by Yeh and colleagues [28]. Each item is answered with Yes or No; total scores range from 0 to 15. A cutoff of ≥5 indicates possible depressive symptoms [29,30].

Nutritional Status

Nutritional status was measured using the MNA-SF, a 6-item tool assessing food intake, weight loss, mobility, psychological stress, neuropsychological problems, and BMI or calf circumference [31,32]. Total scores (0‐14) classify individuals as well-nourished (12-14), at risk (8-11), or malnourished (≤7). The MNA-SF demonstrates strong validity and predictive accuracy in older populations [32-34].

Lower-Extremity Physical Performance

Lower-extremity physical performance was assessed using the SPPB, gait speed, and TUG. The SPPB includes balance tests, a 4-meter usual-pace walk, and a 5-time chair stand, each scored from 0 to 4 for a total score of 0 to 12 [35-37]. Gait speed was measured over 6 meters and expressed in meters per second (m/s) [36]. The TUG evaluates mobility by timing the sequence of standing up, walking 10 feet, turning, returning, and sitting down [38,39].

Covariates

Covariates included demographics (age, sex, marital status, education, living arrangement, economic status), health behaviors (regular exercise, leisure activity, fall history), anthropometrics (BMI, abdominal and calf circumferences), and multimorbidity. Multimorbidity was measured using the Cumulative Illness Rating Scale for Geriatrics (CIRS-G), developed by Linn et al [40] and adapted for older adult populations by Miller et al [41] with a 14-system scoring manual [42]. The CIRS-G total score reflects overall comorbidity burden, and the Severity Index (CIRS-G SI) represents the average severity across organ systems [42,43].

Statistical Analysis

Categorical variables were summarized as n (%), and continuous variables were summarized as median and IQR. Group differences by depression status (GDS-15 score <5 vs ≥5) were examined using the Mann-Whitney *U* test for continuous variables and the χ^2 test or Fisher exact test for categorical variables, as appropriate, with a 2-sided α of .05. Nutritional status was dichotomized as well-nourished (MNA-SF≥12) versus at risk or malnourished (MNA-SF≤11). Impairment thresholds for lower-extremity performance followed established criteria: SPPB≤9, gait speed≤1.0 m/s (6-m walk), and TUG≥12 seconds [38,39]. These binary outcomes were used in all analytic models, including CHAID, logistic regression, and least absolute shrinkage and selection operator (LASSO) logistic regression. Because missingness was <5% for all variables, complete-case analysis was applied; given the low proportion of missing data, the potential impact on the results was considered limited.

The primary exploratory analytic approach used CHAID to identify data-driven thresholds and nonlinear interaction patterns related to impaired nutritional status and lower-extremity physical performance [44,45]. Outcomes were analyzed as binary variables based on the aforementioned clinical cutoffs. Candidate predictors included GDS-15 score, sociodemographic characteristics, lifestyle behaviors, anthropometric measures, and multimorbidity indicators. Predictors were retained in their original scales, and CHAID generated multiway splits using Bonferroni-adjusted χ^2 tests (α=.05). Tree growth was constrained to a maximum depth of 3 levels, with minimum parent and child node sizes of 100 and 50, respectively. For each terminal node, we summarized sample size, class distribution, and misclassification risk. Model evaluation was based on an internal 80% training set and a 20% testing set [46]. Classification accuracy was calculated in both datasets, and the applicability of the training set tree structure to the test set was examined descriptively. Because no cross-validation,

XSL•FO
RenderX

bootstrapping, nor external validation was performed, the reported performance metrics should be interpreted cautiously as preliminary, sample-specific estimates rather than robust indicators of model performance or generalizability.

For comparison with CHAID, we fitted multivariable logistic regression models as conventional regression approaches and LASSO logistic regression models as a penalized alternative to reduce overfitting and improve variable selection. Logistic and LASSO models were used to classify outcome status within the study sample rather than to support causal inference; therefore, the results were interpreted as reflecting association patterns and classification performance rather than causal effects. The same set of candidate predictors used in the CHAID analysis was entered into the logistic and LASSO models to facilitate comparability across analytic approaches. For LASSO logistic regression, the penalty parameter was selected using internal cross-validated deviance within the training set. Classification performance was evaluated separately for each dichotomized outcome—nutritional risk (MNA-SF), impaired SPPB, slow gait speed, and impaired TUG performance—using area under the receiver operating characteristic curve (AUC), sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), accuracy, and F_1 score in the test sets. All analyses were conducted using SPSS version 31 (IBM Corp) and R version 4.4.3. No formal subgroup, interaction, nor sensitivity analyses were conducted.

Results

Participant Characteristics by Depression Status

A total of 1010 community-dwelling adults were included in the study (Table 1). The median age was 68 (IQR 62.7 - 73.0) years, and 757 of 1010 (75%) participants were female. Overall, 143 of 1010 (14.2%) participants screened positive for depressive symptoms, defined as a GDS-15 score ≥5. Because of variable-specific missing data, denominators differed slightly across some analyses.

[h]CIRS-G SI: Cumulative Illness Rating Scale for Geriatrics Severity Index.

Depression status was significantly associated with several sociodemographic characteristics. Educational attainment differed significantly between participants with and without depressive symptoms (χ^2_2=9.42, *P*=.009). Specifically, a higher proportion of participants with depressive symptoms had a junior high school education or below (60/143, 42% vs 253/865, 29.2%), whereas a lower proportion had a college education or above (45/143, 31.5% vs 347/865, 40.1%). Marital status, living arrangement, religious belief, and economic status were also significantly associated with depression status. Compared with participants without depressive symptoms, those with depressive symptoms were more likely to be unmarried (61/143, 42.7% vs 251/865, 29%; χ^2_1=10.68, *P*=.001), to live alone or in an institution (35/143, 24.5% vs 92/865, 10.6%; χ^2_2=21.36, *P*<.001), to report having a religious belief (123/143, 86% vs 670/865, 77.5%; χ^2_1=5.36, *P*=.02), and to report financial stress (87/143, 60.8% vs 393/865, 45.4%; χ^2_1=11.68, *P*<.001). Employment status did not differ significantly between groups (χ^2_1=3.51, *P*=.06).

Regarding lifestyle factors, participants with depressive symptoms were less likely to report regular exercise (92/143, 64.3% vs 741/865, 85.7%; χ^2_1=38.91, *P*<.001) and leisure activities (77/143, 53.8% vs 557/865, 64.4%; χ^2_1=5.85, *P*=.02) and were more likely to report a history of falls (57/143, 39.9% vs 216/865, 25%; χ^2_1=14.14, *P*<.001).

For anthropometric measures, participants with depressive symptoms had a lower median BMI than those without depressive symptoms (23.2, IQR 20.9 - 25.6 vs 24.1, IQR 21.9 - 26.6 kg/m²; *U*=54,700.0, *P*=.03) and a smaller median calf circumference (34.0, IQR 32.0 - 36.2 vs 35.0, IQR 33.0 - 37.4 cm; *U*=50,160.5, *P*<.001), whereas abdominal circumference did not differ significantly between groups (90.0, IQR 83.0 - 97.1 vs 90.0, IQR 84.0 - 96.9 cm; *U*=62,351.5, *P*=.88). Clinical burden also differed significantly by depression status. Participants with depressive symptoms had higher median CIRS-G scores than those without depressive symptoms (9, IQR 6 - 12 vs 5, IQR 2 - 7; *U*=149,099.0, *P*<.001) and higher median CIRS-G SI scores (1.4, IQR 1.1 - 1.6 vs 1.2, IQR 1.0 - 1.4; *U*=181,284.0, *P*<.001).

Associations of Depression Status With Nutritional Risk and Lower-Extremity Physical Performance

As shown in Table 2, the median MNA-SF score was 13 (IQR 12 - 14), and 159 of 1010 (15.8%) participants were classified as at risk of malnutrition or malnourished. Participants with depressive symptoms had poorer nutritional status than those without depressive symptoms, as indicated by lower median MNA-SF scores (12, IQR 11 - 14 vs 14, IQR 12 - 14; *U*=40,275.0, *P*<.001) and a higher proportion classified as at risk of malnutrition or malnourished (53/143, 37.1% vs 105/867, 12.1%; χ^2_1=57.67, *P*<.001).

For lower-extremity physical performance, the median SPPB score was 11 (IQR 10 - 12), and 172 of 1010 (17%) participants met the criteria for impairment. Compared with participants without depressive symptoms, those with depressive symptoms had lower median SPPB scores (10, IQR 9 - 12 vs 12, IQR 10 - 12; *U*=39,722.0, *P*<.001) and were more likely to be classified as impaired (53/143, 37.1% vs 118/867, 13.6%; χ^2_1=50.48, *P*<.001). The median gait speed was 1.1 m/s, and 343 of 1010 (34%) participants were classified as impaired. Participants with depressive symptoms had slower median gait speed than those without depressive symptoms (0.9, IQR 0.8 - 1.2 vs 1.1, IQR 0.9 - 1.3 m/s; *U*=41,132.0, *P*<.001) and were more likely to have impaired gait speed (73/143, 51% vs 270/865, 31.2%; χ^2_1=51.41, *P*<.001). The median TUG time was 8.2 seconds, and 80 of 1010 (7.9%) participants met the impairment threshold. Participants with depressive symptoms had longer median TUG times than those without depressive symptoms (9.3, IQR 7.8 - 11.4 vs 8.1, IQR 7.0 - 9.5 seconds; *U*=78,609.0, *P*<.001) and were more likely to be classified as impaired (25/143, 17.5% vs 55/864, 6.4%; χ^2_1=22.02, *P*<.001). Overall, depressive symptoms were consistently associated with poorer nutritional status and lower-extremity physical performance.

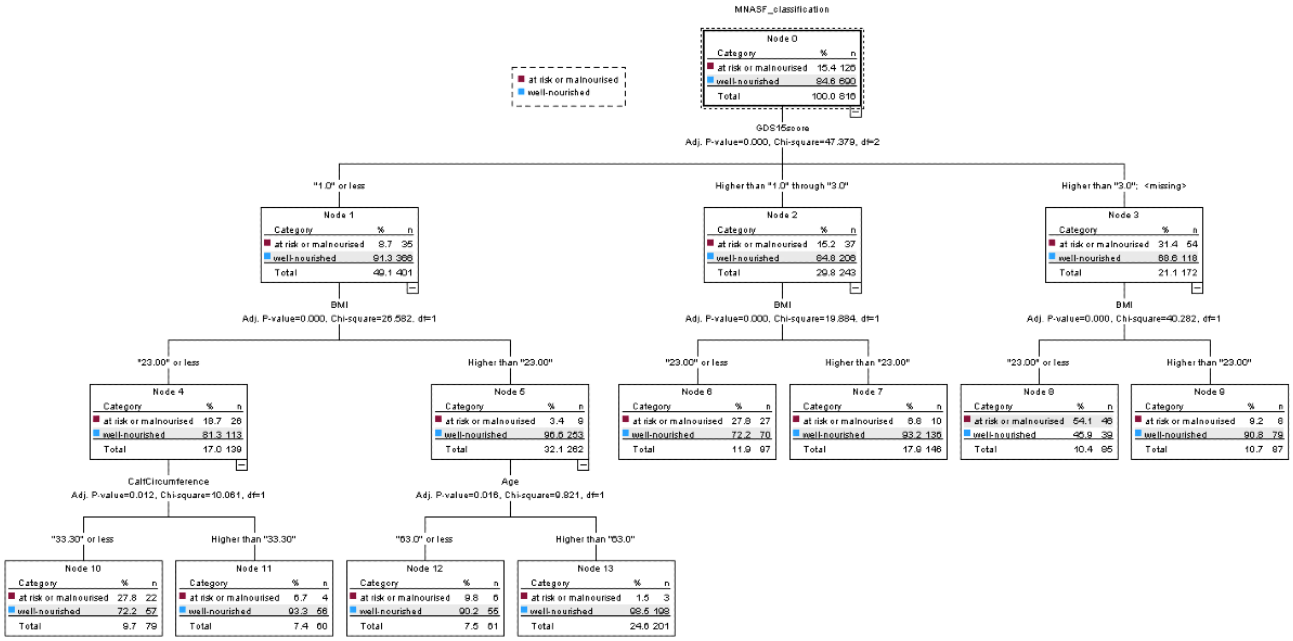
CHAID Decision Tree Analysis for Nutritional Status (MNA-SF)

The CHAID decision tree model for nutritional status based on the MNA-SF is presented in Figure 1. The MNA-SF ranges from 0 to 14, with higher scores indicating better nutritional status and scores ≤11 indicating risk of malnutrition or malnutrition. Nutritional status was modeled as a binary outcome classified as well-nourished versus at risk of malnutrition or malnourished.



Depressive symptom severity, measured using the GDS-15, was identified as the primary splitting variable in the decision tree (*P*<.001). The GDS-15 ranges from 0 to 15, with higher scores indicating greater depressive symptom severity and scores ≥5 indicating clinically relevant depressive symptoms. The model divided participants into 3 depressive symptom groups (≤1, 2 - 3, and ≥4), corresponding to different levels of nutritional vulnerability within the study sample.

Within each depressive symptom stratum, BMI served as the main secondary splitting variable, indicating that anthropometric status further differentiated nutritional status patterns beyond

XSL•FO
RenderX

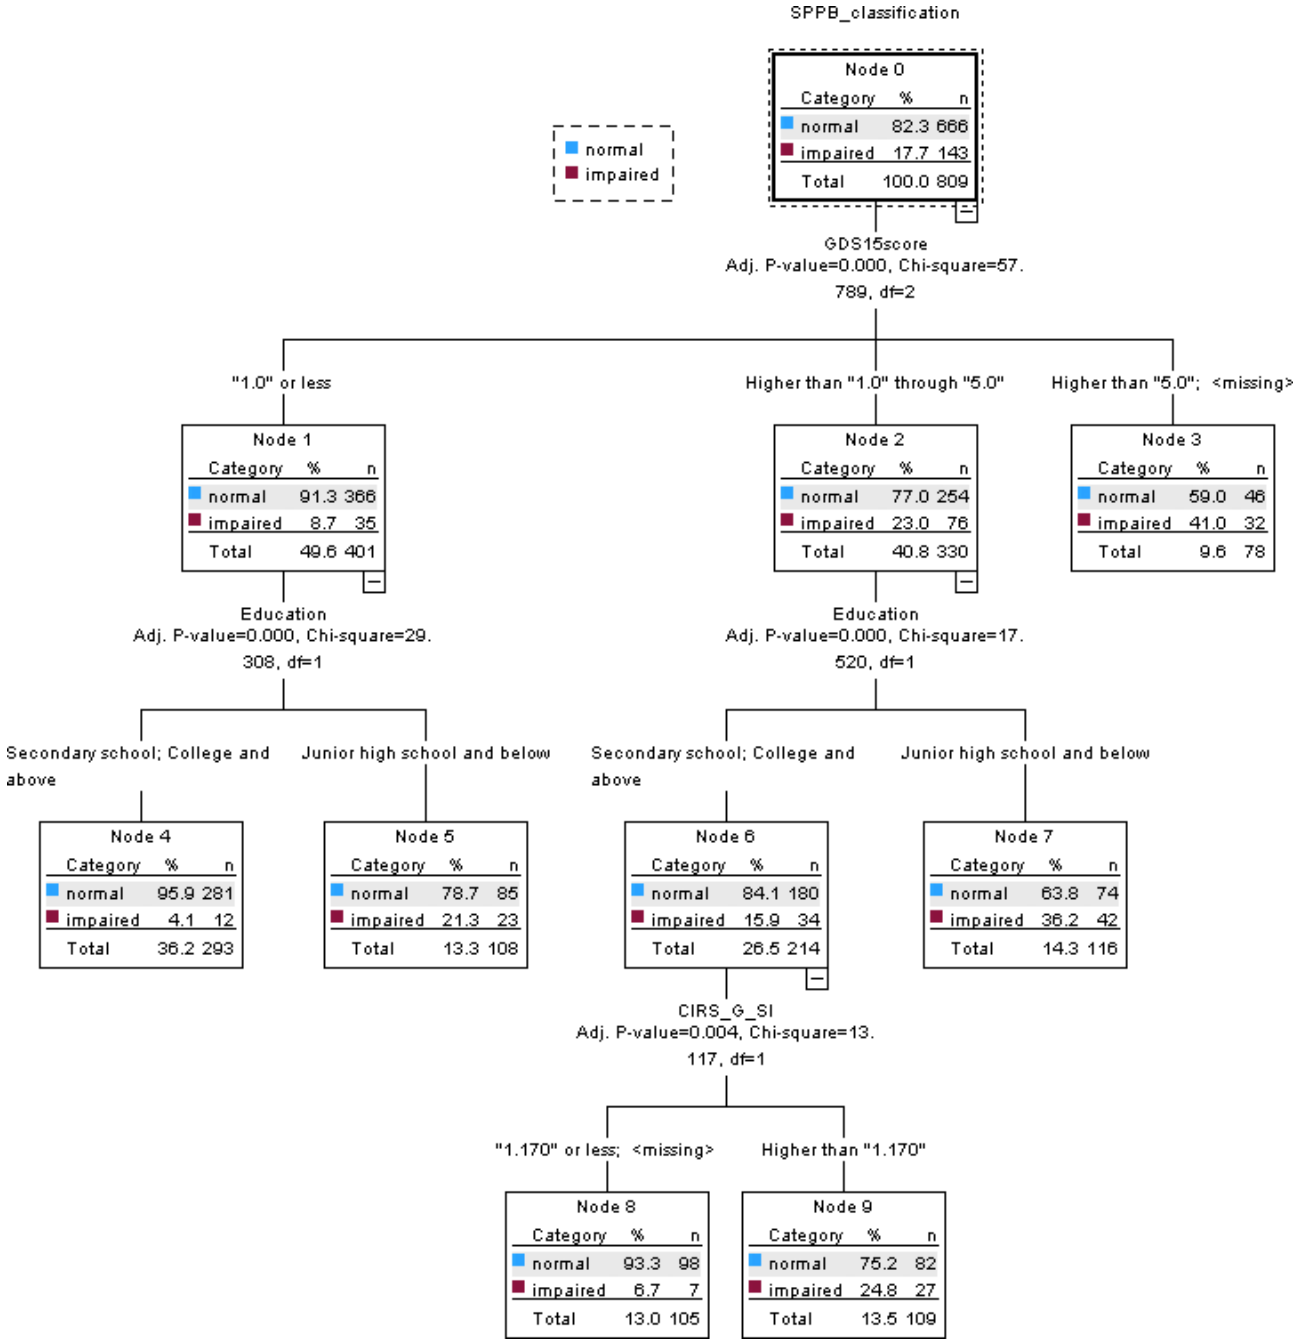
depressive symptom severity alone. Additional hierarchical refinement was provided by calf circumference and age, which identified subgroups with distinct nutritional vulnerability profiles. Smaller calf circumference, a proxy indicator of reduced muscle mass, and older age were associated with a higher prevalence of nutritional risk within specific depressive symptoms and BMI strata.

Figure 1. Chi-square automatic interaction detection (CHAID) decision tree for nutritional status classified using the Mini Nutritional Assessment–Short Form (MNA-SF). Terminal nodes show the number and proportion of participants classified as well-nourished or at risk of malnutrition or malnourished. For improved readability, a higher-resolution version of this figure is reproduced in Multimedia Appendix 1.

Participants with GDS-15 scores ≤1 were predominantly well-nourished, with 91.3% (366/401) classified as having normal nutritional status. However, nutritional risk was higher among individuals with lower BMI and smaller calf circumference, with 27.8% (22/79) classified as at risk of malnutrition or malnourished within this otherwise low depressive symptom group. Nutritional vulnerability was substantially greater among participants with higher depressive symptom severity. In particular, among participants with GDS-15 scores ≥4 and BMI≤23.0 kg/m², 54.1% (45/85) were classified as at risk of malnutrition or malnourished, representing the subgroup with the highest prevalence of nutritional risk identified by the model.

Each terminal node of the decision tree represents a distinct subgroup defined by combinations of depressive symptoms, BMI, calf circumference, and age and displays the corresponding number and proportion of participants classified according to nutritional status. This hierarchical structure illustrates how depressive symptoms together with anthropometric and demographic factors differentiate subgroups with varying prevalences of nutritional risk among community-dwelling adults aged ≥50 years. In addition, the CHAID model had acceptable within-sample classification performance, with accuracies of 84.4% in the training dataset and 85.6% in the test dataset.

CHAID Decision Tree Analysis for Lower Extremity Physical Performance



Short Physical Performance Battery (SPPB)

The CHAID decision tree model for lower-extremity physical performance based on the SPPB is presented in Figure 2. The SPPB ranges from 0 to 12, with higher scores indicating better physical performance and scores ≤9 indicating impaired lower-extremity function. An improvement of approximately 1 point has been suggested as a clinically meaningful change in community-dwelling older adults.

Depressive symptom severity, measured using the GDS-15, was identified as the primary splitting variable in the decision tree (P<.001), dividing participants into 3 groups (≤1, >1 to ≤5, and >5). These findings suggest that depressive symptom burden was an important factor in differentiating patterns of lower-extremity functional impairment.

XSL•FO
RenderX

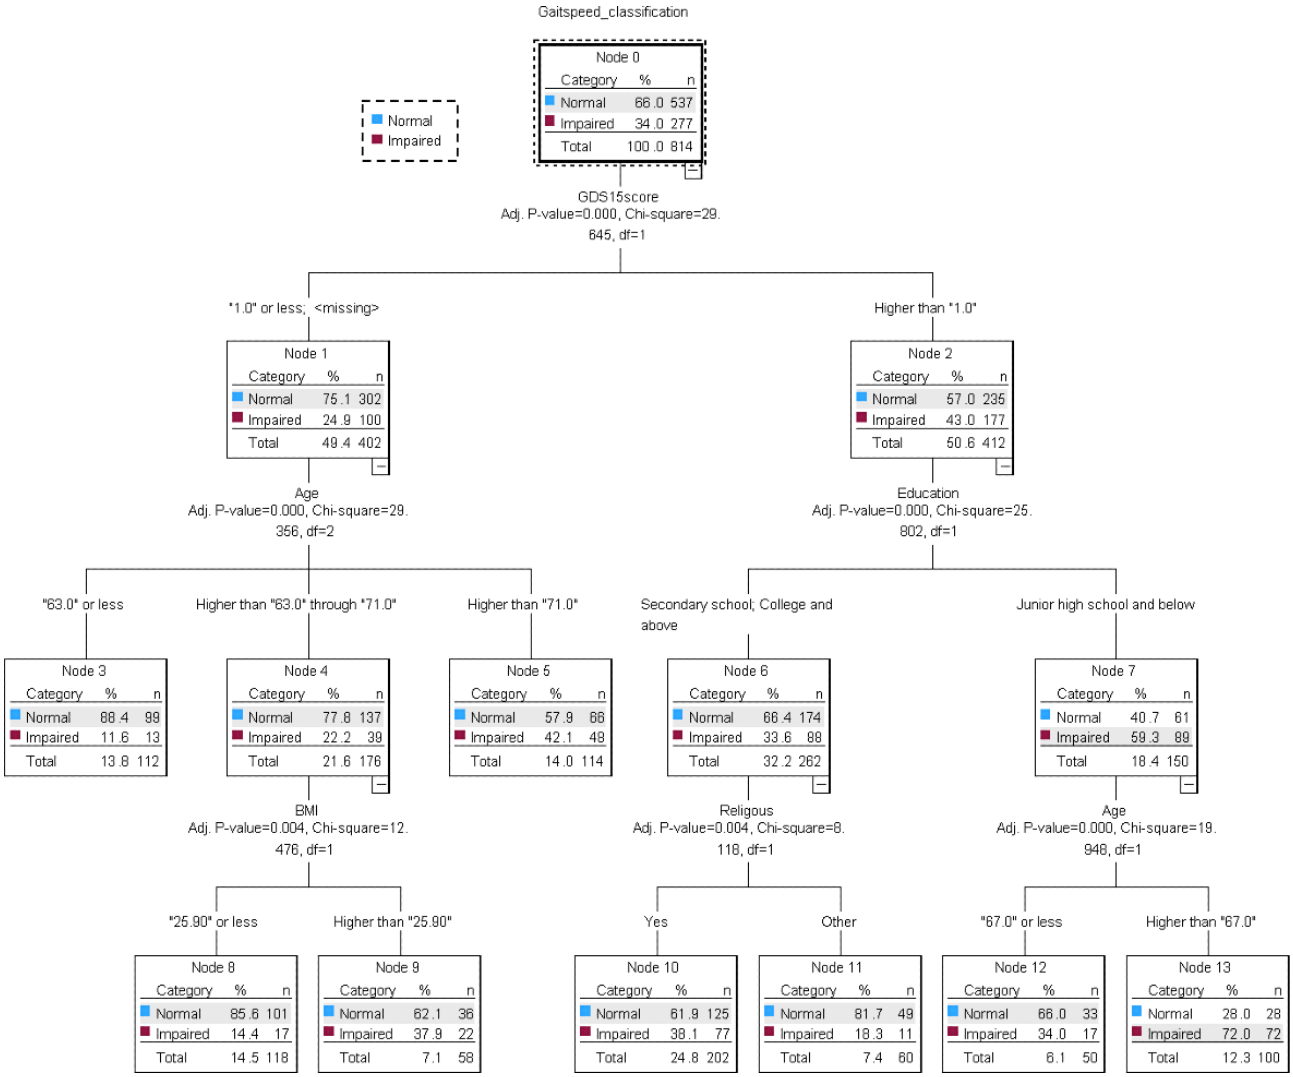
Figure 2. Chi-square automatic interaction detection (CHAID) decision tree for lower-extremity physical performance classified using the Short Physical Performance Battery (SPPB). Terminal nodes show the number and proportion of participants classified as normal or impaired. CIRS-G SI: Cumulative Illness Rating Scale for Geriatrics Severity Index; GDS-15: 15-item Geriatric Depression Scale.

Among participants with lower depressive symptom scores (≤1 and >1 to ≤5), education level emerged as the most influential secondary predictor. Impairment prevalence was substantially higher among individuals with a junior high school education or below than among those with at least secondary education. Specifically, impairment prevalence was 21.3% (23/108) versus 4.1% (12/293) in the ≤1 group and 36.2% (42/116) versus 15.9% (34/214) in the >1 to ≤5 group. These results suggest that lower educational attainment was associated with a higher prevalence of functional impairment, even among individuals with relatively low depressive symptom burden.

Within the intermediate depressive symptom group (>1 to ≤5), comorbidity severity, assessed using the CIRS-G SI, provided further hierarchical refinement. Participants with higher comorbidity severity had a higher impairment prevalence, reaching 24.8% (27/109), suggesting that comorbidity burden may further distinguish impairment patterns beyond depressive symptoms and education level. Participants with GDS-15 scores >5 exhibited consistently elevated impairment prevalence (32/78, 41%), regardless of education level or comorbidity severity. This finding suggests that higher depressive symptom severity was associated with impaired lower-extremity physical performance in this sample.

Each terminal node represents a distinct subgroup defined by combinations of depressive symptom severity, education level, and comorbidity burden and displays the corresponding number and proportion of participants classified according to SPPB impairment status. This hierarchical structure illustrates how

XSL•FO
RenderX



depressive symptoms, together with sociodemographic and clinical factors, differentiate subgroups with varying prevalences of functional impairment among community-dwelling adults aged ≥50 years. In addition, the CHAID model had acceptable within-sample classification performance, with accuracies of 82.3% in the training dataset and 85.1% in the test dataset.

Gait Speed

The CHAID decision tree model for gait speed impairment is presented in Figure 3. Gait speed impairment was defined using a cutoff of ≤1.0 m/s, consistent with established thresholds for identifying mobility limitation in older adults. Habitual gait speed is a clinically meaningful indicator of functional status, and changes of approximately 0.05 m/s to 0.10 m/s have been associated with meaningful functional differences in community-dwelling populations.

Depressive symptom severity, measured using the GDS-15, was identified as the primary splitting variable in the decision tree (P<.001), dividing participants into 2 groups (≤1 and >1). This finding suggests that depressive symptom burden was an important factor in differentiating patterns of gait speed impairment.

Figure 3. Chi-square automatic interaction detection (CHAID) decision tree for lower-extremity physical performance classified using gait speed. Terminal nodes show the number and proportion of participants classified as normal or impaired. GDS-15: 15-item Geriatric Depression Scale.

Among participants with lower depressive symptom scores (GDS-15≤1), gait speed impairment was further differentiated by age and BMI. Impairment prevalence increased substantially with advancing age, ranging from 11.6% (13/112) among participants aged ≤63 years to 42.1% (48/114) among those aged >71 years. Within the intermediate age group (63-71 years), BMI provided additional hierarchical refinement. Impairment prevalence increased from 14.4% (17/118) among participants with BMI≤25.9 kg/m² to 37.9% (22/58) among those with BMI>25.9 kg/m², suggesting that higher BMI was associated with a higher prevalence of gait speed impairment within this age group.

Among participants with higher depressive symptom scores (GDS-15>1), education level emerged as the most influential secondary predictor. Impairment prevalence was substantially higher among individuals with a junior high school education or below (89/150, 59.3%) than among those with higher educational attainment (88/262, 33.6%), suggesting that lower educational attainment was associated with a higher prevalence of gait speed impairment. Religious affiliation and older age (>67 years) provided additional hierarchical refinement,

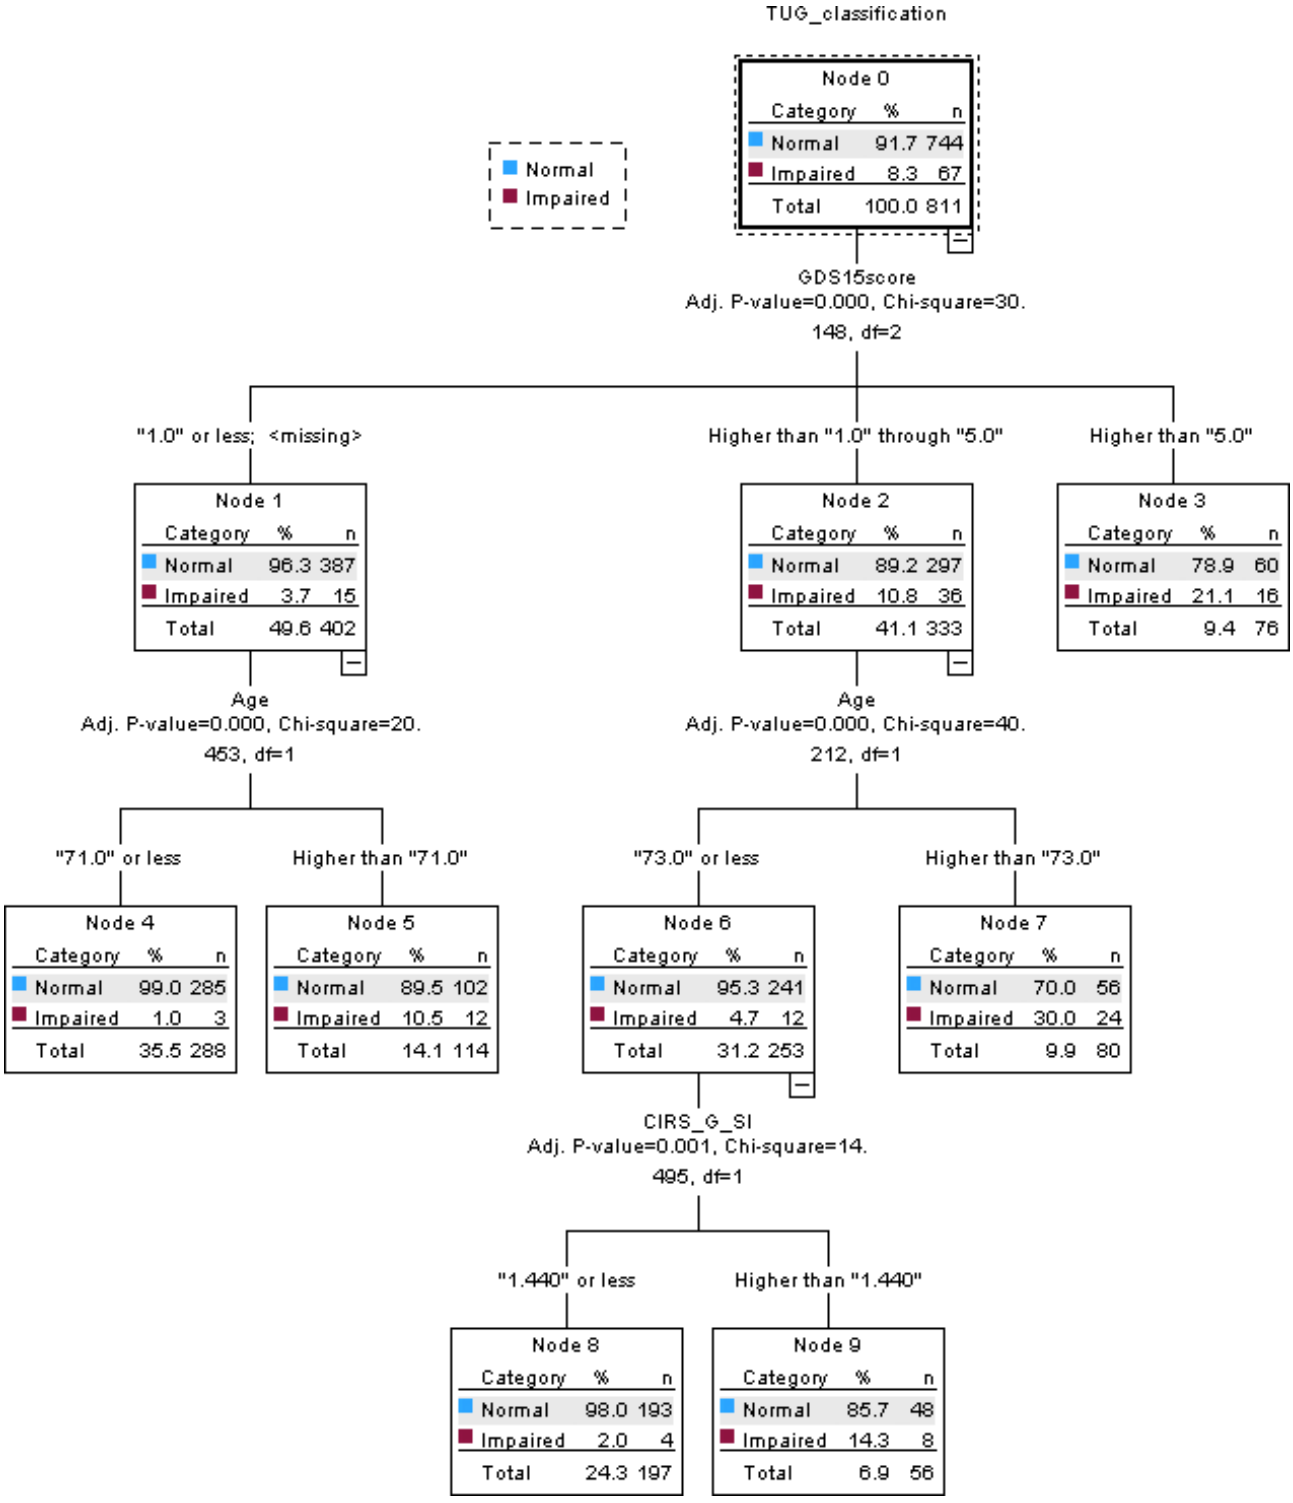
XSL•FO
RenderX

identifying subgroups with further elevated impairment prevalence.

Each terminal node represents a distinct subgroup defined by combinations of depressive symptom severity, age, BMI, education level, and religious affiliation and displays the corresponding number and proportion of participants classified according to gait speed impairment status. This hierarchical structure illustrates how depressive symptoms, together with demographic, anthropometric, and social factors, differentiate subgroups with varying prevalences of gait speed impairment among community-dwelling adults aged ≥50 years. In addition, the CHAID model had acceptable within-sample classification performance, with accuracies of 71.4% in the training dataset and 75.3% in the test dataset.

Timed Up-and-Go (TUG)

The CHAID decision tree model for TUG impairment is presented in Figure 4. TUG performance was assessed using the standard 3-meter test, with longer completion times indicating poorer mobility performance. Impairment was defined as a completion time of ≥12 seconds, consistent with established thresholds for identifying mobility limitation in community-dwelling older adults. Although clinically meaningful change thresholds vary across populations, reported minimal clinically important differences for TUG typically range from approximately 1.2 seconds to 3.4 seconds.



Depressive symptom severity, measured using the GDS-15, was identified as the primary splitting variable in the decision tree (P<.001), dividing participants into 3 groups (≤1, >1 to ≤5, and >5). Participants with GDS-15 scores ≤1 had the lowest prevalence of TUG impairment (15/402, 3.7%). However, impairment prevalence increased with advancing age, reaching 10.5% among participants aged >71 years, suggesting that age further differentiated TUG impairment patterns even among individuals with minimal depressive symptoms.

Within the intermediate depressive symptom group (GDS-15 >1 to ≤5), age served as the most influential secondary predictor. Impairment prevalence increased substantially among participants aged >73 years, reaching 30% (24/80), suggesting that depressive symptom burden together with advanced age was associated with a higher prevalence of TUG impairment. Comorbidity severity, assessed using the CIRS-G SI, provided additional hierarchical refinement. Participants with higher comorbidity severity (CIRS-G SI >1.44) had a higher prevalence of impairment, reaching 14.3% (8/56) among younger individuals, suggesting that comorbidity burden may further distinguish TUG impairment patterns beyond depressive symptoms and age. Participants with GDS-15 scores >5 exhibited consistently an elevated prevalence of impairment (16/76, 21.1%), suggesting that higher depressive symptom severity was strongly associated with impaired functional mobility in this sample.

Each terminal node represents a distinct subgroup defined by combinations of depressive symptom severity, age, and comorbidity burden and displays the corresponding number and proportion of participants classified according to TUG impairment status. This hierarchical structure illustrates how depressive symptoms, together with clinical and demographic factors, differentiate subgroups with varying prevalences of TUG impairment among community-dwelling adults aged ≥50 years. In addition, the CHAID model had acceptable within-sample classification performance, with accuracies of 91.7% in the training dataset and 93.3% in the test dataset.

XSL•FO
RenderX

Figure 4. Chi-square automatic interaction detection (CHAID) decision tree for lower-extremity physical performance classified using the timed up-and-go (TUG) test. Terminal nodes show the number and proportion of participants classified as normal or impaired. CIRS-G SI: Cumulative Illness Rating Scale for Geriatrics Severity Index; GDS-15: 15-item Geriatric Depression Scale.

Summary of CHAID Model Findings

Across all models, the GDS-15 score consistently emerged as the primary splitting variable. Secondary predictors, including BMI, calf circumference, age, comorbidity severity, and education level, provided additional hierarchical refinement and helped differentiate subgroups with varying prevalences of nutritional risk and lower-extremity functional impairment. Overall, these findings suggest that CHAID may serve as a useful exploratory approach for characterizing within-sample patterns, although the performance estimates should be interpreted as preliminary and sample-specific.

Comparison of Interpretable Machine Learning and Regression Models

Table 3 summarizes the classification performance of CHAID, logistic regression, and LASSO logistic regression models for

XSL•FO
RenderX

nutritional status (MNA-SF) and lower-extremity physical performance outcomes, including SPPB, gait speed, and TUG.

Table . Classification performance for nutritional status and lower-extremity physical performance across chi-square automatic interaction detection (CHAID), logistic regression, and least absolute shrinkage and selection operator (LASSO) models.

Outcome and model	AUC[a] (95% CI)	Sensitivity, %	Specificity, %	PPV[b]	NPV[c]	Accuracy, %	F_1 score
MNA-SF[d]							
CHAID model	0.80 (0.72 - 0.88)	57.6	88.8	0.91	0.51	83.5	90
Logistic regression model	0.85 (0.79 - 0.92)	83.9	69.7	1.00	0.00	63.6	77.8
Logistic regression LASSO model	0.96 (0.92 - 0.99)	98.8	78.8	0.96	0.93	95.4	97.2
SPPB[e]							
CHAID model	0.79 (0.71 - 0.87)	0	100	N/A[f]	0.85	0.85	N/A
Logistic regression model	0.87 (0.82 - 0.94)	86.2	82.4	1.00	0.00	3	5.9
Logistic regression LASSO model	0.93 (0.88 - 0.97)	89.7	90.3	0.62	0.98	90.2	73.2
Gait speed							
CHAID model	0.77 (0.70 - 0.83)	56.1	86.7	0.69	0.79	76.3	61.7
Logistic regression model	0.92 (0.87 - 0.96)	83.3	89.1	1.00	0.71	73.2	35
Logistic regression LASSO model	0.95 (0.92 - 0.98)	86.4	94.5	0.89	0.93	91.8	87.7
TUG[g]							
CHAID model	0.74 (0.71 - 0.78)	100	48.9	0.12	1.00	52.3	22
Logistic regression model	1.00 (1-1)	21.2	100	1.00	0.00	4.4	8.5
Logistic regression LASSO model	0.5 (0.5 - 0.5)	0	100	NA	0.93	93.3	N/A

[a]AUC: area under the curve.

[b]PPV: positive predictive value.

[c]NPV: negative predictive value.

[d]MNA-SF: Mini Nutritional Assessment–Short Form.

[e]SPPB: Short Physical Performance Battery.

[f]N/A: not applicable.

[g]TUG: timed up-and-go.

For nutritional status assessed using MNA-SF, the CHAID model had acceptable discrimination, with an AUC of 0.80 (95% CI 0.72 - 0.88), characterized by high specificity but lower sensitivity. Logistic regression analysis had higher overall discrimination, achieving an AUC of 0.85 (95% CI 0.79 - 0.92), with increased sensitivity but reduced specificity compared with CHAID. The LASSO logistic regression model had the highest classification performance, with an AUC of 0.96 (95% CI 0.92 - 0.99), together with the highest overall accuracy and F_1 score.

For lower-extremity physical performance outcomes, model performance varied by outcome measure. For SPPB impairment, all models had acceptable discrimination, with AUC values of 0.79 for the CHAID model, 0.87 for the logistic regression model, and 0.93 for the LASSO logistic regression model. The CHAID model had high specificity but low sensitivity, indicating a lower ability to identify impaired cases. Logistic regression and LASSO logistic regression models had more balanced sensitivity and specificity profiles, with LASSO yielding the highest overall discrimination and classification accuracy. For gait speed impairment, the CHAID model had moderate discrimination, with an AUC of 0.77 (95% CI 0.70 - 0.83), characterized by lower sensitivity and higher specificity. The logistic regression and LASSO logistic regression models had higher discrimination, with AUC values

XSL•FO
RenderX

of 0.92 (95% CI 0.87 - 0.96) and 0.95 (95% CI 0.92 - 0.98), respectively. The LASSO model also achieved the highest overall classification accuracy and F_1 score among the 3 approaches. For TUG impairment, model performance was less consistent. The CHAID model had fair discrimination, with an AUC of 0.74 (95% CI 0.71 - 0.78), characterized by relatively high sensitivity but lower specificity and overall accuracy. The logistic regression model achieved an AUC of 1.00; however, the accompanying classification metrics suggested possible overfitting, as indicated by low sensitivity and overall accuracy despite perfect specificity. The LASSO logistic regression model had poor discrimination, with an AUC of 0.50, indicating limited usefulness for characterizing this outcome in the current sample.

Overall, the LASSO logistic regression model had the strongest and most consistent classification performance for MNA-SF, SPPB, and gait speed outcomes in this sample. In contrast, the CHAID model generally had lower sensitivity but offered transparent hierarchical subgroup characterization. Model performance for TUG was less consistent across approaches, suggesting that this outcome may be more difficult to characterize using the current set of predictors.

Discussion

Principal Findings

In this cross-sectional secondary analysis, depressive symptoms were associated with poorer nutritional status and lower-extremity physical performance among middle- to older-aged adults. Although both the tree-based exploratory approach and regression models identified broadly similar association patterns, the CHAID model offered a more transparent representation of subgroup structure within the study sample. Using data from a large community-based sample, this study examined the cross-sectional associations of depressive symptom severity with nutritional status and lower-extremity physical performance among community-dwelling adults aged 50 years and older. The findings suggest that greater depressive symptom severity was associated with greater nutritional vulnerability and poorer mobility-related performance. These results are consistent with prior studies linking depressive symptoms to frailty-related physiological and functional decline [10,13,17,19].

Using CHAID decision tree analysis, this study identified a hierarchical subgroup structure in which depressive symptom severity was consistently selected as the primary splitting variable across 2 outcome domains: nutritional status and lower-extremity physical performance. Additional predictors, including age, BMI, calf circumference, education level, and comorbidity severity, further refined subgroup patterns across these outcomes. Rather than serving as a definitive risk stratification tool, CHAID in this study provided rule-based subgroup characterization, with potential advantages for visualizing and communicating clinically relevant patterns within the sample. Together, these findings suggest that depressive symptoms may represent an important clinical marker within the multidimensional pathways linking psychological, nutritional, and functional health in aging populations. Importantly, our findings support the view that health status may be conceptualized as a continuous spectrum, such that older adults classified as low risk or as having only mild impairment may still exhibit substantial internal heterogeneity [46,47] and variation in scores below the conventional cutoff may still carry clinical warning value and help distinguish subgroups with different levels of nutritional vulnerability and functional impairment, which is particularly meaningful for prevention-oriented assessment.

In the comparative model analyses, the LASSO logistic regression model had the highest classification performance and the most balanced sensitivity and specificity profiles for the MNA-SF, SPPB, and gait speed outcomes, suggesting that regularized regression analysis may be useful for classification in datasets with multiple correlated clinical variables. In contrast, although the CHAID decision tree model generally had lower sensitivity, it demonstrated acceptable within-sample classification performance and offered a transparent, rule-based approach for subgroup characterization. Rather than serving as a definitive screening or stratification tool, CHAID may provide complementary value by making subgroup patterns, threshold splits, and variable interactions easier to visualize and communicate in clinical contexts. Taken together, these findings suggest complementary roles for the tree-based exploratory approach and regression-based methods: The LASSO regression model had higher classification performance, whereas the CHAID model offered transparent, rule-based subgroup characterization that may facilitate visualization and communication of clinically relevant patterns within the study sample.

Comparison With Previous Work

These findings extend prior research on multifactorial geriatric assessment by showing that routinely collected clinical and functional measures can be examined together using a transparent, interpretable analytic approach to characterize patterns of nutritional vulnerability and mobility impairment. Consistent with previous studies emphasizing the multidimensional nature of frailty and functional decline [1,36,48,49], the CHAID decision tree model identified a hierarchical subgroup structure that differentiated participants with varying levels of nutritional and physical vulnerability. More broadly, these findings illustrate how interpretable analytic approaches may complement conventional geriatric assessment by supporting transparent pattern recognition and subgroup characterization.

Overall, 14.2% of participants in our study screened positive for depressive symptoms, which was lower than the 21.3% prevalence reported in a previous study [5]. This difference may reflect variation in sample characteristics, recruitment settings, and population composition across studies. Compared with those without depressive symptoms, participants with depressive symptoms had poorer nutritional status and lower-extremity physical performance, including higher malnutrition risk, lower SPPB scores, and slower gait speed. These associations are consistent with established physiological and behavioral mechanisms linking depression to frailty progression, as depression has been associated with reduced motivation, appetite, and physical activity, which may contribute to reduced

XSL•FO
RenderX

dietary intake, sarcopenia, and functional decline [8,10-14]. Taken together, these findings support the relevance of depressive symptoms as a clinical marker of multidimensional vulnerability in aging populations. The decision tree analysis further extends previous work by illustrating how depressive symptoms interact with demographic, anthropometric, and clinical factors to differentiate subgroups with varying levels of nutritional and functional vulnerability. Nutritional and functional patterns varied according to depressive symptom severity in combination with body composition, age, education level, and comorbidity burden. These hierarchical subgroup patterns align with prior evidence linking depression, sarcopenia, and functional decline while also offering a transparent way to visualize and describe heterogeneity within the sample.

At the health systems level, these findings are consistent with international recommendations advocating integrated care models that address mental health, nutrition, and physical function as interconnected determinants of healthy aging [48,49]. Incorporating depression screening into routine geriatric assessment may help identify older adults with coexisting nutritional and functional vulnerabilities. Interpretable analytic approaches such as CHAID may support this process by providing transparent, rule-based subgroup characterization. However, external validation and prospective evaluation are still needed before such approaches can be considered for broader clinical use. In addition, this study focused on a selected tree-based exploratory approach and did not compare the full range of interpretable machine learning methods.

Strengths and Limitations

This study has several important strengths. First, it applied both a tree-based exploratory approach and regression-based approaches to examine depression-related patterns using routinely collected geriatric assessment measures. This comparative framework enabled assessment of both classification performance and subgroup interpretability. Second, the use of well-validated clinical instruments, including the GDS-15, MNA-SF, SPPB, gait speed, and TUG, enhances the clinical relevance of the findings. Third, the relatively large community-based sample supported model estimation and subgroup characterization across nutritional and lower-extremity functional outcomes. Finally, the tree-based exploratory approach enabled transparent, rule-based identification of hierarchical subgroup patterns, which may facilitate visualization and communication of clinically relevant heterogeneity within the sample.

Several limitations should also be considered. First, the study focused on a selected tree-based exploratory approach and did not compare the full range of interpretable machine learning methods. Second, model evaluation relied only on an internal training-testing split, without cross-validation, bootstrapping, or external validation. Accordingly, the reported performance metrics should be interpreted as exploratory and sample-specific and should not be taken as evidence of generalizability beyond the current sample. Future studies should incorporate more rigorous internal validation procedures and external validation in independent populations. Third, the cross-sectional study design precludes causal inference and does not establish temporal relationships among depressive symptoms, nutritional status, and physical performance. Fourth, participants were recruited through convenience sampling from a single geographic region, which may limit generalizability to other populations or health care settings. Fifth, depressive symptoms were assessed using a screening instrument rather than a diagnostic interview and therefore may not fully capture clinical depression severity. Finally, model performance varied across outcomes, particularly for TUG impairment, suggesting that additional predictors or alternative analytic approaches may be needed to better characterize this outcome.

Conclusions

In this community-based sample of adults aged 50 years and older, depressive symptom severity was associated with nutritional vulnerability and poorer lower-extremity physical performance. Using a CHAID decision tree approach, this study identified hierarchical subgroup patterns showing that depressive symptoms, including subthreshold levels, together with age, BMI, calf circumference, education level, and comorbidity burden, were related to variation in nutritional and functional vulnerability. Although LASSO logistic regression analysis had higher overall classification performance, the CHAID model offered transparent, rule-based subgroup characterization that may facilitate visualization and communication of clinically relevant patterns within the study sample. These findings suggest that combining depression screening with nutritional and functional assessment may help identify older adults with coexisting vulnerabilities and may support prevention-oriented geriatric assessment. They also support the view that health status may be better understood as a continuum, such that even depressive symptom scores below the conventional cutoff may still carry clinical relevance.

Abstract

Background: Gastrointestinal (GI) cancers are a significant health concern in South Korea. Recently, machine learning (ML) models have emerged as powerful tools to support early screening efforts and identify people at risk before disease onset. However, the low incidence of GI malignancies in prospective cohorts leads to severe class imbalance, often causing ML models to favor the majority “healthy” class at the expense of clinical sensitivity.

Objective: This study aimed to evaluate class imbalance mitigation strategies and develop ML-based GI cancer risk prediction models using noninvasive and minimally invasive predictors linked to modifiable behavioral and metabolic risk factors.

Methods: We analyzed a prospective cohort (n=7652) with 156 incident GI cancer cases (2%) identified over a 14-year follow-up period. The data were randomly split into training (5356/7652, 70%) and testing (2296/7652, 30%) sets. To address class imbalance while preserving observed population structure, we developed a patient-centered undersampling technique (PCUSTe) based on the logic of frequency-matched case-control studies. PCUSTe was compared with commonly used resampling approaches, including synthetic minority oversampling (SMOTE), adaptive synthetic sampling (ADASYN), and SMOTE with edited nearest neighbors (ENN). Six classifiers were implemented, including both batch and incremental training variants. To account for the prior shift introduced by resampling, probability correction was applied. Model performance was evaluated on the independent test set using a classification threshold equal to the observed event proportion (cumulative incidence) in the training data and then across thresholds reflecting incidence values between 1% and 5%. Primary performance metrics included sensitivity, specificity, Matthews correlation coefficient, and area under the receiver operating characteristic curve (AUC).

Results: Models trained using PCUSTe demonstrated improved sensitivity compared with standard resampling techniques, particularly for more complex classifiers. The incrementally trained stochastic gradient descent model achieved the highest overall performance trained on PCUSTe data with a sensitivity of 0.77 (95% CI 0.64 - 0.89), specificity of 0.65 (95% CI 0.63 - 0.67), AUC of 0.77 (95% CI 0.70 - 0.84), and Matthews correlation coefficient of 0.12 (95% CI 0.08 - 0.16). In contrast, logistic regression achieved balanced performance without resampling (sensitivity 0.70, 95% CI 0.57 - 0.83; specificity 0.71, 95% CI 0.69 - 0.72; AUC 0.75, 95% CI 0.68 - 0.82). Our results showed that PCUSTe primarily enhanced sensitivity in more complex models at the expense of specificity.

Conclusions: Integrating epidemiological principles, including covariate frequency matching and threshold selection based on the observed cumulative incidence in the training data, improved minority class detection in GI cancer risk prediction. However, model performance varied by algorithm, and in some cases, decision threshold adjustment alone achieved comparable or superior results to data resampling. These findings highlight the importance of carefully selecting imbalance mitigation strategies based on modeling objectives. The resulting models achieved sensitivity levels that may be suitable for early risk identification in cohort settings and could contribute to personalized risk stratification and targeted prevention or screening strategies.

Introduction

Gastrointestinal (GI) cancers pose a significant global health burden, with nearly 5 million new cases and over 3 million deaths reported in 2022 [1-4]. The impact is particularly severe in Asia, where GI cancers account for nearly 30% of all cancer cases, largely due to lifestyle habits, dietary factors, *Helicobacter pylori* infections, and genetic predispositions [4-8]. These trends underscore the urgent need for region-specific prevention and early detection strategies.

Predictive models play a critical role in identifying high-risk individuals and enabling targeted preventive measures [9-11]. However, accurate risk prediction requires pre-diagnosis patient data, which is best obtained from the prospective cohort studies—longitudinal studies that track healthy individuals over extended periods. Compared with other observational designs, prospective cohorts are less susceptible to selection bias because they minimize reliance on recall and are robust to differential survival. Although they do not guarantee perfect generalizability, they typically provide a closer approximation of the true population. These studies offer high-quality, temporally structured data, but their high cost and resource-intensive nature limit their availability. Moreover, many potential risk factors involved in disease development exhibit complex, nonlinear relationships, posing additional challenges for traditional analytic approaches.

In this context, advances in machine learning (ML) offer a promising solution. With the increasing availability of large-scale health datasets, ML has emerged as a powerful tool for disease risk prediction, offering advantages over conventional statistical methods in modeling complex, multidimensional data [12,13]. ML-driven models can uncover nonlinear interactions among risk factors, improving predictive performance in early cancer detection. Although the application of ML methods has demonstrated promising results in GI cancer risk prediction using biomarkers, anthropometric measures, and socioeconomic data, its application remains limited [14,15].

One of the major challenges in applying ML to GI cancer risk prediction is the severe class imbalance inherent in cohort studies, where cancer cases constitute only a small fraction of the population. This imbalance skews model performance, leading to high accuracy for the majority class (noncancer) but poor sensitivity for cancer cases [16-18]. Additionally, integrating diverse risk factors—such as biomarkers, dietary intake, and lifestyle data—compounds this challenge, as these variables often exhibit high variability and sparse representation. Given the heterogeneous nature of GI cancers, incorporating a wider range of risk factors may support the development of more effective screening and prevention strategies [19-24].

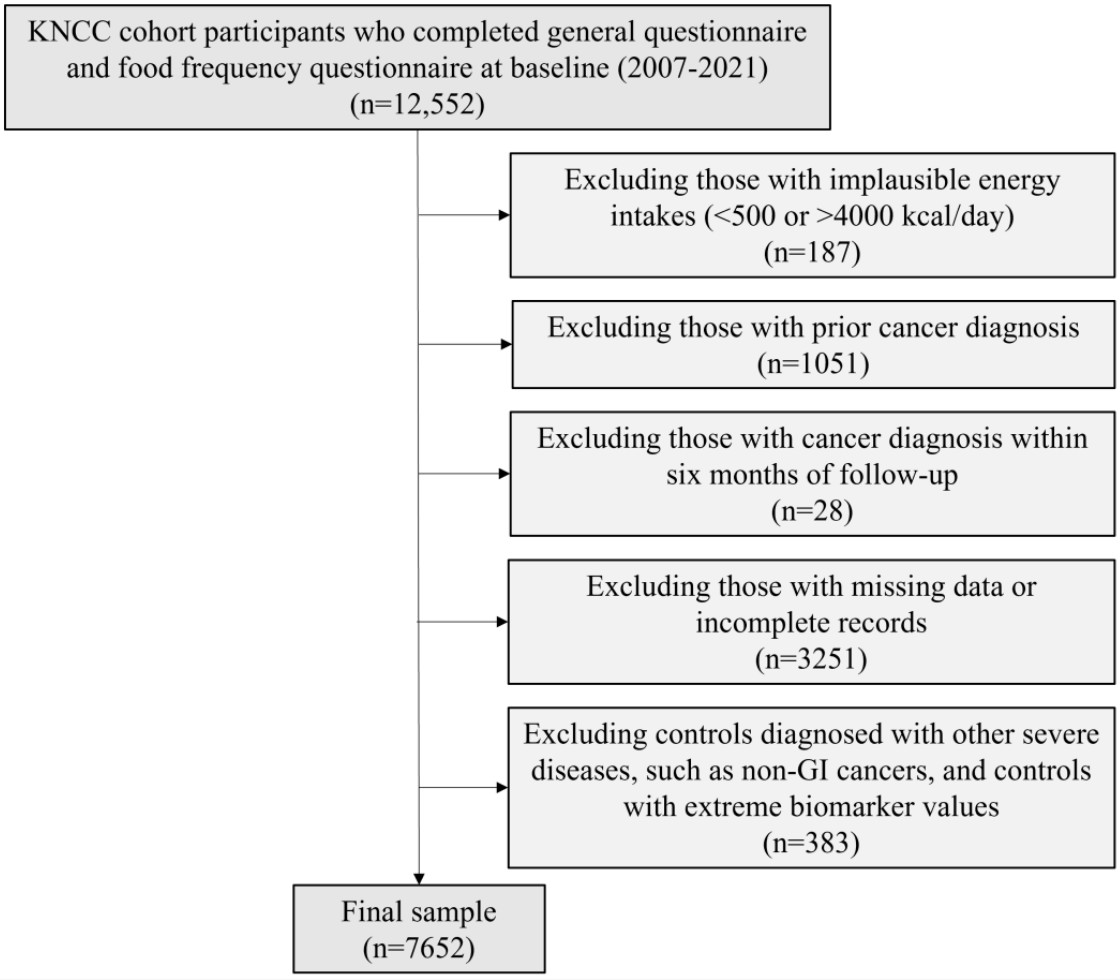
While previous studies have been conducted for GI cancer risk prediction, many have relied on relatively balanced datasets from cross-sectional studies, narrow predictor sets, or traditional statistical models, which may not fully capture the complex, nonlinear interactions among diverse risk factors [12-15,25]. To address these limitations, this study used a diverse set of predictors and focused on risk prediction in highly imbalanced cohort data.

To address class imbalance in ML-based GI cancer risk prediction, we evaluated multiple imbalance mitigation strategies, including a patient-centered undersampling technique (PCUSTe) grounded in epidemiological principles of frequency-based case-control matching. PCUSTe was designed to preserve observed population structure in small, highly imbalanced cohorts and was compared with established resampling approaches, including synthetic minority oversampling (SMOTE), adaptive synthetic sampling (ADASYN), and hybrid resampling methods [26]. In addition to data-level strategies, we incorporated probability correction for models trained on resampled data and decision threshold adjustment based on observed cumulative incidence. Model behavior and performance were systematically compared across imbalance mitigation strategies using multiple ML algorithms and hyperparameter settings to examine their influence on GI cancer risk prediction in highly imbalanced cohort data.

Methods

Study Design and Participants

This study used data from 12,552 South Korean adults enrolled in the Korea National Cancer Center (KNCC) Screenee Cohort, a longitudinal study initiated in 2002 by the National Cancer Center in South Korea [27]. To ensure data quality and minimize potential bias, several exclusion criteria were applied. Participants were excluded if they had a prior cancer diagnosis (n=1051), were diagnosed with GI cancer within 6 months of follow-up (n=28), or reported implausible total energy intake (<500 or >4000 kcal/day), which may indicate dietary misreporting or data entry errors (n=187). Participants with missing or incomplete records were also excluded, and a complete-case analysis was conducted (n=3251). In addition, controls with other severe conditions—including non-GI cancers or extreme biomarker values suggestive of acute metabolic or hepatic abnormalities—were excluded. These abnormalities were defined as triglycerides, aspartate aminotransferase, or gamma-glutamyl transferase levels exceeding 1000, or fasting glucose levels below 55 or above 200 mg/dL (n=383) [28-30]. Participant selection and exclusion steps are illustrated in Figure 1.



Participants were followed for up to 14 years (2007 - 2021). GI cancers were defined according to the *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) as follows: esophageal cancer (C15), gastric cancer (C16), small intestine cancer (C17), colorectal cancer (C18-C20), anal cancer (C21), liver cancer (C22), gallbladder cancer (C23-C24), and pancreatic cancer (C25). Individuals who developed GI cancer during the follow-up period were classified as cases, while those who remained cancer-free served as controls. Based on this labeling, a supervised ML framework was constructed to address a binary classification task—identifying individuals at risk for developing GI cancer.

The final dataset consisted of 7652 participants (61% of the original cohort), including 156 (2.0%) incident GI cancer cases and 7496 (98.0%) controls. Some participants developed malignancies at multiple GI sites, resulting in a total of 162 cancer diagnoses. The most frequently diagnosed cancers were

XSL•FO
RenderX

gastric (62/162, 38.3%), colorectal (43/162, 26.5%), and hepatic (30/162, 18.5%).

Figure 1. Flowchart of the study participant selection. GI: gastrointestinal; KNCC: Korea National Cancer Center.

Data Collection and Preprocessing

All participants in the KNCC Screenee Cohort completed self-administered questionnaires capturing socio-demographic characteristics and lifestyle behaviors. Additionally, data were collected on anthropometric measurements, clinical biomarkers, and dietary intake. Dietary intake was assessed at baseline using a validated 106-item semiquantitative food frequency questionnaire [31,32].

To adjust for total energy intake's influence on nutrient intake, we applied the residual method in Python (version 3.12) [33]. Categorical variables, such as lifestyle habits, gender, and socioeconomic characteristics, were binarized, and low-density lipoproteins were calculated using Friedewald's equation [34].

The dataset was randomly split into a training set (5356/7652, 70%) and a test set (2296/7652, 30%). The training set included 109 cases and 5247 controls, while the test set consisted of 47 cases and 2249 controls. Continuous variables were standardized using an adapted Z-score normalization based on the control population. For each predictor, the mean and standard deviation were calculated using only control individuals in the training set, and these parameters were applied to transform both cases and controls in the training data. The same parameters were then applied to the corresponding test data.

Ethical Considerations

This study was conducted as a secondary analysis of existing cohort data from participants who had previously provided broad informed consent for future research use at enrollment in the KNCC Screenee Cohort. The study was noninterventional and did not affect participant care. Personal identifiers were used solely for pseudonymized linkage with national cancer registry data by an authorized data linkage institution and were removed immediately thereafter. Only deidentified data were accessed by authorized research personnel within a secure analysis environment. Given the use of deidentified data and the absence of participant contact or intervention, the risk to participants was considered minimal, and no additional informed consent, compensation, or participant support was required. This study was reviewed and approved by the Institutional Review Board of the National Cancer Center, Korea (approval number NCC2024-0106).

Statistical Analysis

Descriptive statistics were generated using Python (version 3.12) following the energy adjustment of nutrient intakes. To ensure the representativeness of the study population and identify potential selection or partitioning bias, baseline characteristics were compared across several cohorts: the final analyzed cohort, individuals excluded due to missing data, and

XSL•FO
RenderX

the training and test data splits. Continuous variables were summarized as means and standard deviations and evaluated using Welch *t* test to account for potential unequal variances. Categorical variables were expressed as frequencies and percentages, with differences assessed using Pearson chi-square tests [35]. All statistical tests were 2-sided, and a *P* value <.05 was considered to indicate statistical significance.

Sample Size Considerations

In the absence of a universally accepted criterion for determining sample size adequacy in ML prediction models, we adopted the event-per-variable (EPV) framework from regression modeling as a conservative reference. Although an EPV of ≥10 has traditionally been recommended for logistic regression (LR), recent evidence suggests that lower EPV values may be acceptable when penalization and shrinkage techniques are applied [36]. With 109 GI cancer cases and 20 selected predictors, the EPV for tuned models in our study was 5.45:

$$EPV=\text{Number of Events}\text{Number of Predictors}=10920=5.45$$

In addition to tuned configurations, we evaluated baseline models using all 34 available predictors without hyperparameter tuning or feature selection. This approach was adopted to examine whether systematic tuning materially altered predictive performance, given that default parameter settings may perform comparably to, or occasionally outperform, extensively tuned models. In these baseline configurations, the nominal EPV decreased below the selected threshold.

All evaluated models incorporated model-specific regularization or complexity control mechanisms. To further assess robustness, we examined model stability across a range of EPV values from 9.9 (11 predictors) to 3.2 (34 predictors). These analyses were conducted to evaluate stability across model complexities rather than to infer optimal predictive performance.

Data Resampling Strategies

Algorithm Selection

Resampling methods are commonly used to address class imbalance and can be broadly categorized as oversampling or undersampling. Oversampling enlarges the minority class by generating synthetic observations, which may improve sensitivity but can introduce synthetic noise and overfitting. Undersampling, in contrast, reduces the majority class size to preserve data authenticity but risks discarding informative samples and distorting population structure. To achieve a better balance between data integrity and population representativeness, we developed PCUSTe, a patient-centered undersampling method.

Patient-Centered Undersampling Method

Similar to other undersampling methods, PCUSTe addresses class imbalance without generating synthetic data. However, unlike conventional methods that randomly remove majority-class samples or rely on geometric distances in feature space, PCUSTe uses case distribution guided sampling based on categorical matching covariates. Controls are selected in proportion to the empirical distribution of cases across these strata, ensuring that the resulting training data preserve the covariate composition of the study population. This approach integrates the design logic of frequency-matched case-control studies into ML preprocessing context, thereby minimizing distributional bias introduced by random or distance-based undersampling.

The method is parameterized by the case-to-control ratio (1:1 in this study, though extendable) and the covariates guiding sampling. Random seeds can be specified to ensure reproducibility. Finally, the combined dataset is shuffled to prevent ordering bias. In this study, we tested 2 parameterizations: PCUSTe-1 (PCUSTe with sociodemographic matching [education, employment, income, and marital status]) and PCUSTe-2 (PCUSTe with lifestyle matching [smoking and drinking]). The pseudocode for the PCUSTe method is provided in the Multimedia Appendix 1.

Synthetic Oversampling Methods

To complement the undersampling strategy, we also implemented synthetic oversampling using 3 established methods. SMOTE generates new samples of the minority class by interpolating between existing cases. ADASYN extends this approach by focusing more on generating samples near harder-to-classify instances. Additionally, we used a hybrid technique that combines SMOTE with edited nearest neighbors (ENN), which removes misclassified samples following oversampling to sharpen class boundaries and improve data quality.

We further optimized SMOTE, SMOTE+ ENN, and ADASYN by varying the k-nearest neighbors (k-NN) parameter as a function of the training set size. Specifically, k was defined as a proportion of the number of cases in the training data, and 6 values were evaluated: 2% (2/109), 5% (5/109), 10% (10/109), 30% (32/109), 50% (54/109), and 80% (87/109) of the case count. For reference, setting k to 5% of n resulted in 5 neighbors, which is the default setting for all 3 methods.

ML Modeling

Algorithm Selection

We implemented a range of ML algorithms selected for their relevance to cancer risk prediction. LR served as the baseline model due to its simplicity, high interpretability, and computational efficiency, and was implemented with regularization to improve generalizability [37]. To explore the difference between batch and incremental learning approaches, we also applied stochastic gradient descent (SGD), which represents an incremental version of LR suitable for streaming or large-scale data applications [38]. In addition to linear models, we used random forest (RF), a decision-tree-based ensemble algorithm known for its robustness and ability to model nonlinear relationships [39].

To assess the benefits of more sophisticated models, we implemented extreme gradient boosting (XGBoost), which is widely recognized for its performance in structured data and its ability to handle class imbalance effectively [40]. Both batch and incremental training modes were explored for XGBoost. Support vector machines (SVM) were included as well, given their efficacy in handling high-dimensional datasets and their resilience to overfitting in small, imbalanced datasets [41].

XSL•FO
RenderX

To maximize the utility of the PCUSTe, we implemented an incremental learning variant using the SGD classifier. This approach involved 1000 training iterations, where each iteration generated a unique undersampled training set maintaining the specified covariate matching constraints. The iterative strategy was designed to mitigate the primary drawback of undersampling—the loss of information—by ensuring the model was exposed to more of the control population over time. For reproducibility, the random seed for each PCUSTe generation was updated by incrementing a base seed by the current iteration index. While the case samples remained constant across all iterations, the control subsets varied, allowing for partial overlap and a more robust representation of the original control distribution than a single-pass undersampling would allow. This high number of iterations was selected to ensure that the vast majority of the control population was used in the optimization process.

Predictor Selection

To ensure methodological consistency across resampling strategies, and because SMOTE-based approaches generate synthetic observations via interpolation in continuous feature space, predictor selection was restricted to continuous variables. Recursive feature elimination was applied using each target model's own baseline estimator as the base learner, rather than a shared estimator across models.

Predictor selection was conducted exclusively within the training data to prevent information leakage and was integrated into the cross-validation pipeline together with hyperparameter optimization. To evaluate predictor relevance and stability across configurations, feature importance was further examined using Shapley Additive Explanations (SHAP) analysis [42].

Hyperparameter Optimization

Hyperparameter optimization was performed using RandomizedSearchCV (RS) exclusively on training data. Two performance metrics were used as optimization objectives: area under the receiver operating characteristic curve (AUC) and Matthews correlation coefficient (MCC). This resulted in 3 parameter configurations per model: None (default model settings), RS-AUC, and RS-MCC. The dual-objective optimization strategy allowed us to evaluate both probabilistic discrimination (AUC) and balanced classification performance (MCC), which is particularly relevant in imbalanced settings.

For SGD models, hyperparameter tuning was constrained to preserve incremental training properties: L2 regularization was fixed a priori, tolerance was disabled, and the number of iterations was set to one. Consequently, RS was applied only to selected learning-rate and regularization strength parameters (eta0 and alpha).

Tuned model development was implemented within a unified k-fold cross-validation pipeline. In each iteration, k–1 folds were used for training and hold-out fold for validation. Resampling was applied exclusively to the training folds, followed by recursive feature elimination for feature selection and RS for hyperparameter optimization. Performance was evaluated on the held-out validation fold. The independent test set was not involved in any stage of model development.

Performance Evaluation

To comprehensively assess model performance, evaluation metrics specifically suited for imbalanced data were prioritized [43,44]. Sensitivity, AUC, MCC, and specificity served as primary metrics to capture class-wise discrimination and model separability. Secondary metrics, including positive predictive value, negative predictive value, Brier score, accuracy, and overall weighted F_1-scores, were also estimated to provide a complete view of precision and calibration. Performance metrics were computed with 95% CIs estimated using 1000 bootstrap iterations.

Because resampling alters the class prior and can distort predicted probabilities, models trained on resampled data underwent prior probability correction to restore calibration relative to the original class distribution [45]. Decision-based performance metrics (sensitivity, specificity, and MCC) were then computed using a classification threshold of 0.02, corresponding to the observed disease incidence in the training cohort. This threshold reflects a deployment-aligned operating point, where individuals with predicted risk exceeding the baseline population incidence would be considered high risk. Thresholds were defined to reflect epidemiologically plausible deployment scenarios, where the decision cutoff may be aligned with a priori expected disease incidence rather than determined by maximizing performance metrics within the training data. Sensitivity analyses were conducted across thresholds ranging from 0.01 to 0.05 to assess robustness under plausible real-world incidence scenarios.

After model development, all configurations (crude and tuned) were evaluated once on the reserved independent test set without further modification. The test set served as a common hold-out benchmark for comparing predefined algorithm–resampling–tuning configurations. For descriptive comparison, one configuration per ML algorithm was additionally evaluated against a null incidence-based model defined as a classifier that predicts the minority class for all observations. Under this specification, the baseline represents the upper bound for recall and the lower bound for precision given the observed outcome incidence.

To differentiate between generalization, learning, and memorization, model performance was compared across the original imbalanced test set, the original imbalanced training set, and the resampled training datasets. This framework enabled direct assessment of the models' ability to distinguish classes while facilitating detection of potential overfitting to synthetic noise or oversampling artifacts.

Data Distribution Analysis

To assess how resampling techniques influenced data distribution, principal component analysis (PCA) was used for 2D projection and visual inspection of structural shifts. PCA reduces high-dimensional data into orthogonal components that capture the greatest proportion of variance, enabling visual comparison of the structural characteristics of the original and resampled datasets [46].

To quantify overall separation between outcome groups, the mean Euclidean distance between cases and controls was

XSL•FO
RenderX

calculated for each dataset. Pairwise Euclidean distances were computed between all case and control observations in the standardized feature space, and the average of these distances was used as a summary measure of inter-group separation.

In addition, predictor-level associations with the outcome were examined by calculating correlations between each individual predictor and the binary outcome variable. Correlation coefficients were computed independently for each dataset.

Results

Study Participant Characteristics

The study identified significant demographic, clinical, and dietary differences between cases and controls. GI cancer cases were more likely to be male, older, smokers, and to have a lower monthly income (below 2 million Korean won) compared with controls, while no significant differences were observed for alcohol consumption, marital status, employment, or education. Clinically, cases showed significantly higher BMI, systolic blood pressure (SBP), diastolic blood pressure (DBP), fasting blood glucose, aspartate aminotransferase, and gamma-glutamyl transferase, along with lower high-density lipoprotein cholesterol. Dietary intake differed modestly, with cases reporting significantly lower intakes of sugar, dietary fiber, niacin, potassium, and vitamin C, whereas total energy intake and most other nutrients did not differ significantly between groups. Detailed statistics of the whole study population are presented in Table 1.

[i]PUFA: polyunsaturated fatty acids.
[j]SBP: systolic blood pressure.
[k]SFA: saturated fatty acids.

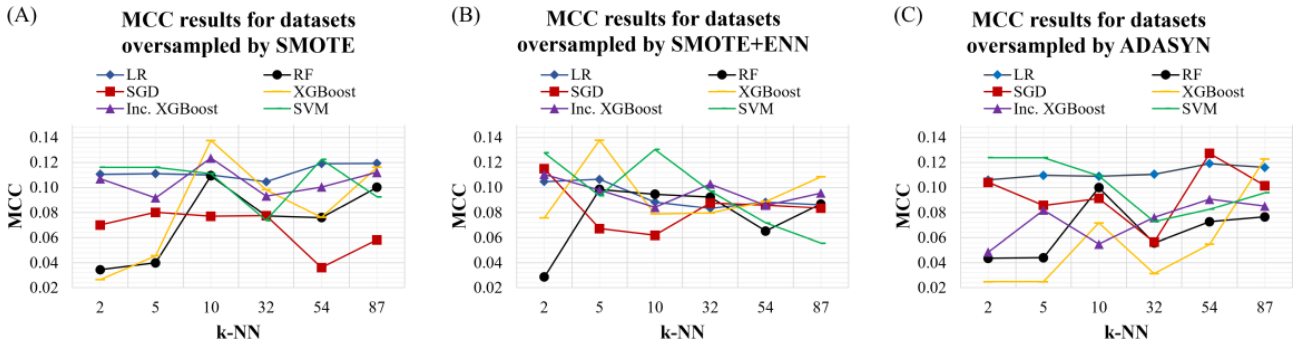
A comparative analysis of baseline characteristics revealed no critical concerns regarding the representativeness of the data splits or the impact of participant exclusion (Tables S1-S4 in Multimedia Appendix 2). Characteristics of the training and test datasets were highly consistent, although minor discrepancies in statistical significance were observed for some nutritional variables, including total fat, zinc, thiamin and vitamin D, and fatty acids. However, these discrepancies were primarily driven by the differences in statistical power between the 2 partitions, as the absolute mean values and standard deviations remained stable across both sets.

Similarly, participants excluded due to missing data exhibited baseline characteristics generally consistent with those of the analyzed cohort. While the magnitude of statistical significance varied between these groups, the underlying clinical trends remained stable across all comparisons. For instance, although the association between drinking status and the outcome only reached statistical significance within the excluded cohort, cases were more likely to report alcohol consumption in both groups. Likewise, mean BMI was consistently higher among cases in both cohorts, though this difference only attained statistical significance in the larger analyzed cohort. Collectively, these findings suggest that no critical systematic differences exist between the analyzed, excluded, and partitioned groups, indicating that neither inclusion bias nor data-splitting artifacts materially affected the study results.

Data Resampling Strategies

Patient-Centered Undersampling Method

PCUSTe enabled stronger performance for nonlinear models. However, resampling approaches were less effective for linear models. Notably, adjusting the threshold for model probabilities was sufficient to stabilize LR performance and achieve a 0.7 score for both sensitivity and specificity on crude, nonresampled data. Similarly, RF performed well while trained on crude training data, although results were improved after model tuning and PCUSTe resampling.



Synthetic Oversampling Methods

Experiments evaluating k-NN parameter tuning for synthetic oversampling methods indicated that the default k-NN setting may not be optimal and that tuning this parameter can substantially influence model performance. In our study, higher k-NN values—corresponding to approximately 10% - 80% of the minority class sample size—often yielded better performance than the default setting. These findings suggest that, when

XSL•FO
RenderX

applying synthetic oversampling to small and extremely imbalanced datasets, tuning the k-NN parameter should be explicitly considered. We present an example of model performance based on MCC metric for each ML algorithm trained on oversampled data with different k-NN in Figure 2 (all models with default parameter settings).

Figure 2. MCC scores of models evaluated on datasets oversampled using 3 different techniques: (A) SMOTE (left); (B) SMOTE+ ENN (middle); (C) ADASYN (right). Each subplot shows performance across varying values of the k parameter (number of nearest neighbors used for resampling): 2% (2/109), 5% (5/109), 10% (10/109), 30% (32/109), 50% (54/109), and 80% (87/109). Lines represent individual models, including logistic regression (LR), random forest (RF), stochastic gradient descent (SGD), support vector machine (SVM), and 2 extreme gradient boosting (XGBoost) variants. ADASYN: adaptive synthetic sampling; ENN: edited nearest neighbors; k-NN: k-nearest neighbors; LR: logistic regression; MCC: Matthews correlation coefficient; RF: random forest; SVM: support vector machine; XGBoost: extreme gradient boosting.

ML Modeling

Tuned model hyperparameters, feature sets, and optimization metric scores for the selected configuration are presented in Tables S5 and S6 in Multimedia Appendix 2.

Predictor Selection

SHAP analyses revealed substantial algorithm-specific differences in dominant predictors, with linear and incrementally trained models emphasizing dietary exposures, whereas tree-based models prioritized clinical and physiological markers (Figure S1, in Multimedia Appendix 2). Across all models, higher age consistently emerged as an important predictor of GI cancer risk; however, in the LR and SGD models, its relative influence was lower than that of dietary factors, including macronutrients, saturated fatty acids, and selected micronutrients. Elevated blood pressure was another consistently influential predictor across modeling approaches.

EPV sensitivity analysis results are presented in Figure S2 in Multimedia Appendix 2. As the number of predictors decreased (resulting in higher EPV ratios), MCC scores generally tended to decline across most models, although the magnitude of change varied by algorithm. In this study, the number of predictors was predefined (34 for crude models and 20 for tuned models). These findings suggest that reducing the predictor set may lead to information loss and that model performance could potentially be improved through more advanced predictor selection approaches.

Hyperparameter Optimization

RS yielded distinct optimal hyperparameter configurations depending on both the resampling strategy and the optimization metric. Based on inner cross-validation results within the training data, the highest AUC scores for LR, RF, and XGBoost models were achieved with PCUSTe-1 resampling, whereas SVM achieved the highest cross-validation AUC with SMOTE resampling. In contrast, MCC values were more consistent across resampling strategies, with most models achieving similar performance regardless of the sampling method used.

SVM models demonstrated metric-dependent kernel selection. Linear kernels were predominantly selected when optimizing for AUC, whereas radial basis function kernels were favored when optimizing for MCC in models trained on oversampled data. Under PCUSTe variants and hybrid resampling strategies, linear kernels were selected across both optimization metrics.

Performance Evaluation

Overall Performance

Despite pronounced class imbalance, some models trained on crude (nonresampled) data achieved moderate discriminatory performance when decision thresholds were set to the empirical disease incidence in training data. Under this setting, linear classifiers exhibited relatively stable behavior. Notably, the LR model trained on the original (nonresampled) data achieved the best performance among all algorithms in the crude evaluation. Importantly, without threshold adjustment, this model predicted all test set samples as controls. This finding suggests that when a strong linear signal is present, resampling may offer limited benefit, particularly when balanced sensitivity-specificity trade-offs are prioritized over aggressive minority class detection.

Undersampling methods consistently improved sensitivity across all model types, aligning better with screening-oriented objectives and the purpose of the classification task of our study. In contrast, oversampling approaches generally increased specificity at the expense of sensitivity, indicating a tendency to favor the majority class. Nonlinear models benefited most from undersampling strategies, whereas the same models trained on crude or oversampled data exhibited performance patterns consistent with majority-class overfitting. Detailed results for crude model evaluations are provided in Table S7 in Multimedia Appendix 2.

Tuned model performance results are reported in Tables S8 and S9 in Multimedia Appendix 2. Performance differences across resampling strategies were marginal for linear models but more pronounced for nonlinear models. Across most comparisons,

XSL•FO
RenderX

PCUSTe-based methods outperformed oversampling approaches.

Table 2 contrasts one model configuration for each ML algorithm with the null (incidence-only) model, which classifies all samples as belonging to the minority class. All results are reported for the unseen nonresampled test set, the nonresampled training set, and the resampled training set. The selected configurations were not modified after the initial evaluation on the test set, ensuring that the results reflect predefined configurations and enabling comparison of model performance across ML algorithms and potential overfitting patterns.

Table . Performance results by machine learning algorithms on the original test and train, and resampled train datasets. Values represent point estimates with 95% CIs calculated by bootstrapping.

Model	Point estimate (95% CI)

[a]AUC: area under the receiver operating characteristic curve.

[b]MCC: Matthews correlation coefficient.

[c]Null: model that always predicts positive class (incidence-only).

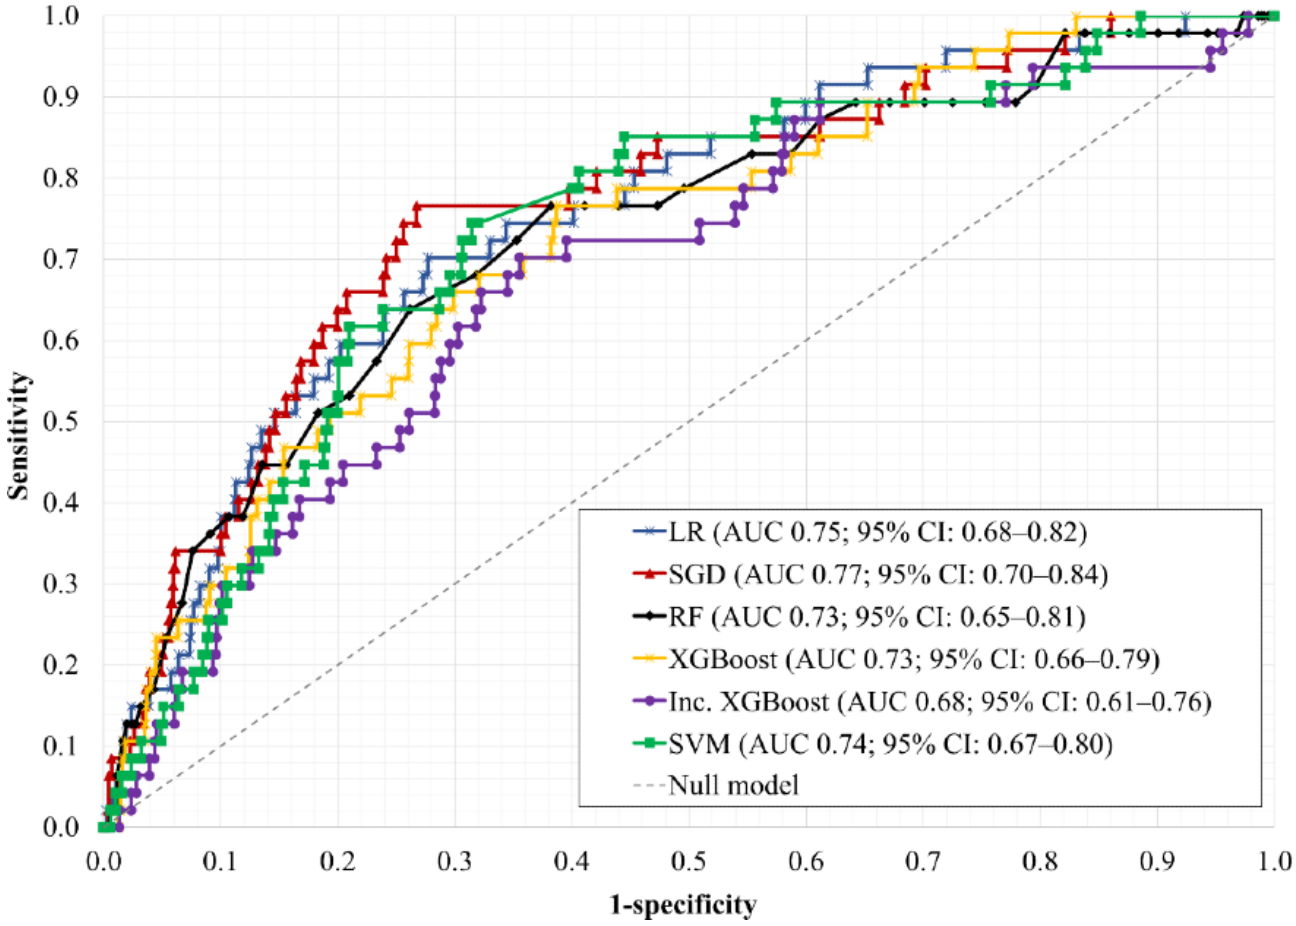
[d]LR: logistic regression trained on nonresampled training split, crude model.

[e]SGD: stochastic gradient descent trained incrementally on varying data resampled by PCUSTe-1 method, crude model.

[f]RF: random forest trained on data resampled by PCUSTe-2 method, crude model.

[g]XGBoost: extreme gradient boosting trained on data resampled by SMOTE+ ENN (k=54) method, tuned via RS-AUC.

[h]Inc. XGBoost: extreme gradient boosting trained on data resampled by PCUSTe-2 method, crude model.



[i]SVM: support vector machine trained on data resampled by PCUSTe-2 method, crude model.

Although MCC values were numerically low (0.09 - 0.18) for the test and original training datasets, this reflects the extreme class imbalance in these sets, where even a small number of false-positive predictions disproportionately reduces MCC.

XSL•FO
RenderX

Because the resampled training set was balanced across classes, MCC values appear substantially higher in that dataset. To better contextualize predictive performance, MCC values can be compared with those of the null model (MCC=0). Based on this comparison, the developed models achieved improvements of up to 0.13 in MCC, which may represent meaningful discrimination given the very low disease incidence in the test set. Overall, all ML algorithms demonstrated reasonable performance under at least one configuration. Receiver operating characteristic–AUC curves for selected model configurations are shown in Figure 3, and secondary performance metrics are provided in Table S10 in Multimedia Appendix 2. Compared with the null model, the developed models improved positive predictive value from 0.02 to up to 0.05 and achieved a high negative predictive value (up to 0.99), while maintaining a similar Brier score (0.02).

Figure 3. ROC curves for the selected configuration of each ML algorithm. AUC values in the legend represent point estimates on the test set with 95% CIs calculated by bootstrapping. AUC: area under the receiver operating characteristic curve; LR: logistic regression; RF: random forest; ROC: receiver operating characteristic; SGD: stochastic gradient descent; SVM: support vector machine; XGBoost: extreme gradient boosting.

LR Model

During model evaluation, the LR model trained on resampled datasets demonstrated a modest increase in sensitivity compared with the model trained on the original nonresampled data, and notably degraded specificity. Thus, for ML algorithm-based comparison, we have retained the crude LR model with all predictors and default hyperparameters. This model demonstrated balanced performance, achieving a test sensitivity of 0.70 (95% CI 0.57 - 0.83), specificity of 0.71 (95% CI 0.69 - 0.72), and an AUC of 0.75 (95% CI 0.68 - 0.82). Importantly, the model showed no evidence of overfitting, with performance metrics remaining consistent across data splits.

SGD Model

SGD, particularly when trained using the incrementally implemented PCUSTe-1 strategy with no tuning, achieved the strongest overall performance among the evaluated models. The highest observed performance was sensitivity of 0.77 (95% CI 0.64 - 0.89), specificity of 0.65 (95% CI 0.63 - 0.67), AUC of 0.77 (95% CI 0.70 - 0.84), and MCC of 0.12 (95% CI 0.08 - 0.16). Performance on training sets was highly consistent, although slightly lower compared with the test set. This model misclassified 11 out of 47 cancer cases as controls. Among the false negatives, diagnoses included colorectal (6/11), gastric (3/11), liver (1/11), and esophageal cancer (1/11), indicating that misclassification was not confined to a single GI cancer subtype.

RF Model

RF showed over-optimization to the resampled training distribution, with a perfect training AUC that decreased significantly on the test set 0.73 (95% CI 0.65 - 0.81). Nevertheless, the model maintained a test sensitivity of 0.77 (95% CI 0.65 - 0.89) and specificity of 0.62 (95% CI 0.60 - 0.64) while trained on PCUSTe-2 dataset, suggesting moderate generalization despite evidence of overfitting. Notably, RF exhibited majority class overfitting when trained on all

XSL•FO
RenderX

oversampling-based datasets. In contrast, no resampling or undersampling via PCUSTe resulted in a more balanced classification.

XGBoost Model

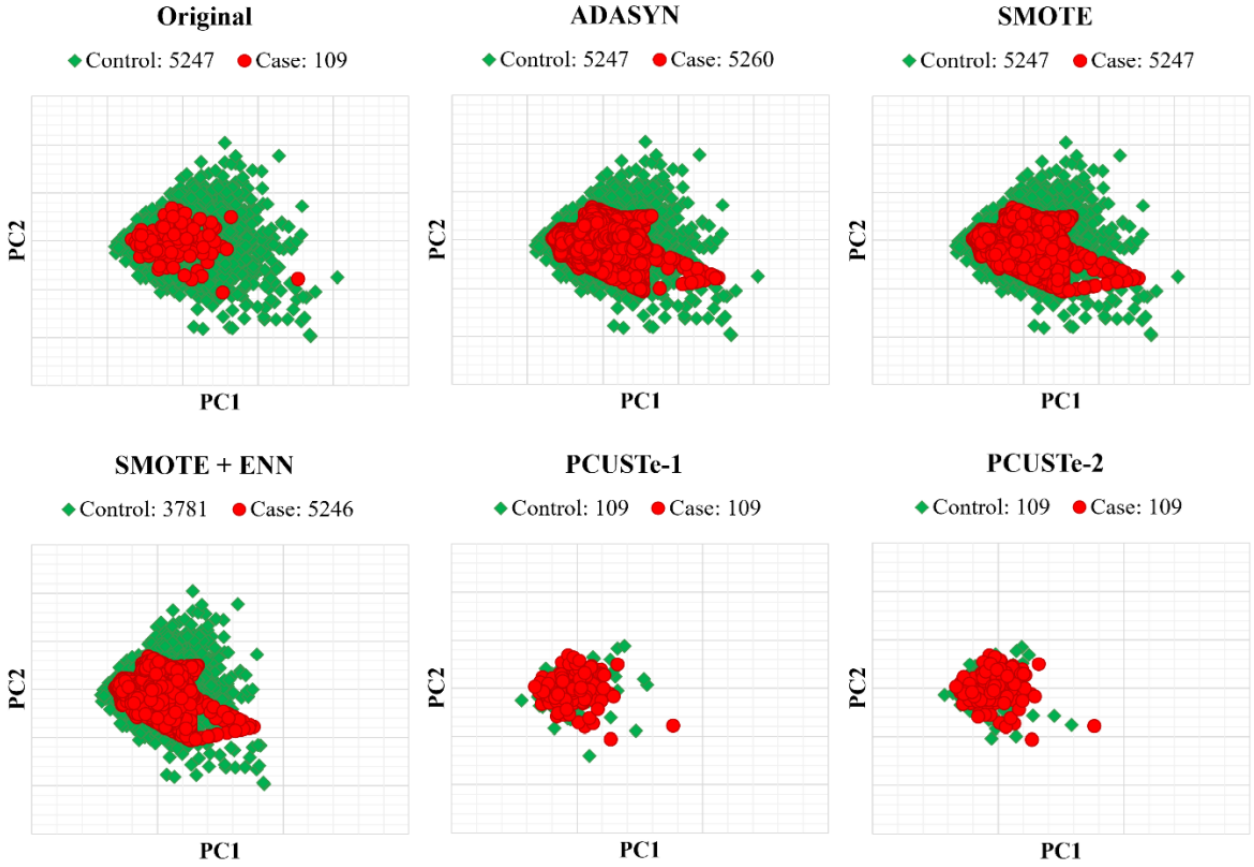
Boosting models exhibited high sensitivity to hyperparameter tuning, especially when trained on oversampled data. The batch-trained XGBoost model demonstrated strong predictive capacity but exhibited substantial performance variability between training and test environments. Although it achieved a test sensitivity of 0.77 (95% CI 0.65 - 0.89), specificity of 0.60 (95% CI 0.58 - 0.62), AUC of 0.73 (95% CI 0.66 - 0.79), and MCC of 0.11 (95% CI 0.07 - 0.14), near-perfect performance on resampled training data (AUC 0.98) indicated pronounced overfitting. This effect was further amplified in the incremental XGBoost implementation, which showed slightly reduced test performance (sensitivity 0.70, specificity 0.62; AUC 0.68; MCC 0.09) alongside increased overfitting.

SVM Model

SVM achieved the highest overall sensitivity of 0.79 (95% CI 0.67 - 0.90). However, compared with the SGD model, this was accompanied by lower specificity (0.60; 95% CI 0.58 - 0.62) and AUC (0.74; 95% CI 0.67 - 0.80). Compared with boosting- and tree-based approaches, SVM exhibited less overfitting, maintaining stable discriminatory performance under the 2% incidence setting. Notably, we observed relatively stable SVM performance across all resampling methods.

Figure S3 in Multimedia Appendix 2 illustrates the performance of models across decision thresholds between 0.01 and 0.05. As expected, increasing the decision threshold resulted in a decrease in sensitivity and a corresponding increase in specificity. LR, SGD, and boosting models exhibited stable and monotonic sensitivity-specificity trade-offs, with SGD demonstrating an optimal balance between 0.02 and 0.03.

Data Distribution Analysis



The PCA projections provide a top-level visual comparison of how each resampling method altered the class proportions within the primary components of variance (Figure 4). In the original dataset, the minority class is concentrated within a specific region already occupied by a high density of controls. The oversampling techniques increased the visibility of the minority class by increasing point density within those existing regions. In contrast, the undersampling methods did not alter the minority class but reduced the majority class instead. Notably, SMOTE+ ENN aggressively reduced the control population—resulting in a dataset that was no longer balanced (with cases becoming the majority). Across all methods, the 2D projections suggest that resampling primarily shifts the relative density of the classes rather than creating clear linear separation in the first 2 principal components.

The distance heatmap evaluates the mean absolute predictor-wise difference between cases and controls (Figure S4 in Multimedia Appendix 2). Both PCUSTe-1 and PCUSTe-2 markedly reduced distances for age and several additional biological variables, despite these factors not being explicitly used for proportional matching. Distances between fatty acids and some micronutrients were increased instead. This suggests that matching based on socioeconomic variables (PCUSTe-1) or lifestyle factors (PCUSTe-2) indirectly aligns unselected physiological characteristics between cases and controls. In contrast, SMOTE+ ENN increased overall distances for age, blood pressure, and multiple other predictors.

The comparative analysis across varying k-NN values demonstrated that SMOTE and ADASYN exhibit highly similar behavior, generally maintaining the lowest mean distances to the original dataset and the narrowest gaps between classes (Figure 5). In contrast, SMOTE+ ENN showed a distinct upward trend in both case-control and control-control distances as the k-NN parameter increases. This suggests that the ENN cleaning process becomes more aggressive at higher neighbor scales, significantly increasing data sparsity and class separability by removing ambiguous majority instances. The PCUSTe-1 undersampling method remained constant as it is k-independent. Notably, PCUSTe-1 maintained significantly larger mean distances for cases compared with oversampling methods—this is expected, as oversampling generates synthetic samples in close proximity to original minority observations—whereas undersampling preserves the sparse, natural distribution of the original cases.

Discussion

Principal Findings

Our analysis highlights that extreme class imbalance materially affects ML performance in cohort-based GI cancer prediction. In our experiments, extensive oversampling—even after k-NN parameter tuning—resulted in overfitting in complex nonlinear classifiers (RF, XGBoost, and SVM), whereas linear classifiers (LR and SGD) were comparatively robust. We developed an undersampling method, PCUSTe, which achieved stable test set performance across multiple classifiers without relying on synthetic data. To mitigate the reduction in training data inherent to undersampling, we combined PCUSTe with an incrementally trained SGD model. Among all evaluated configurations, this approach yielded the greatest improvement in predictive performance. The model with the highest performance achieved an AUC of 0.77 (95% CI 0.70 - 0.84) and sensitivity of 0.77 (95% CI 0.64 - 0.89), while maintaining moderate specificity (0.65, 95% CI 0.63 - 0.67). Importantly, our findings indicate that the application of resampling techniques to address extreme class imbalance should be tailored to specific study objectives. In this study, we prioritized sensitivity over specificity, consistent with the objective of identifying individuals at elevated GI cancer risk who may benefit from modification of dietary and early metabolic risk factors. Conversely, in settings where a high false-positive rate may impose a substantial burden on participants, threshold adjustment alone may be preferable to resampling-based approaches.

Comparison to Previous Work

Cohort studies provide longitudinal insights into individual health trajectories prior to disease onset, offering valuable data for identifying early risk factors and informing preventive strategies. However, for diseases that are uncommon in the general population, class imbalance remains a persistent challenge. A US-based study using blood count data to predict GI cancers achieved moderate discrimination (area under the receiver operating characteristic curve [AUROC]=0.75) but a low F_1-score (0.03) when addressing imbalance solely via class

XSL•FO
RenderX

weights [47]. Similarly, although models such as XGBoost and SVM can outperform linear classifiers when combined with class weighting, they are not inherently robust to extreme imbalance [48,49].

In our study, nonlinear models trained without resampling yielded low to moderate sensitivity, often improving sensitivity at the expense of specificity or vice versa. For example, the XGBoost model trained on nonresampled data achieved only 0.06 sensitivity and 0.98 specificity, whereas the SVM trained on the same data showed 0.64 sensitivity and 0.54 specificity. Performance for both algorithms improved substantially when models were trained on data resampled using the PCUSTe-2 method. For instance, the XGBoost model trained on this dataset achieved a sensitivity of 0.66 with a specificity of 0.61 prior to tuning and sensitivity of 0.73 with specificity of 0.63 after tuning. These findings suggest that, in settings of extreme imbalance, algorithm choice alone may be insufficient to achieve adequate minority-class detection.

Resampling has therefore emerged as one of the most commonly used strategies to mitigate class imbalance. For instance, oversampling is frequently applied in biomedical ML model training, and previous studies have reported improved cancer prediction using methods such as SMOTE and its variants [50,51]. Although oversampling can help address moderate imbalance, the aggressive oversampling required to correct severe imbalance remains challenging, particularly when complex ML algorithms are used. For example, a Korean study using national health insurance data to predict gastric cancer in adults (65,657 cases and 10,450,292 controls) used the Random Oversampling Examples (ROSE) method to address imbalance [52]. The authors reported the best performance with an LR model (AUROC 0.71) compared with decision tree and XGBoost classifiers. This aligns with our findings, where LR models trained on oversampled data consistently outperformed more complex classifiers trained on the same data.

When comparing performance across resampling strategies, complex models showed clear signs of overfitting, particularly on oversampled data. Overfitting in such datasets is well documented and remains an ongoing challenge despite numerous mitigation attempts [53]. During oversampling with the default k-NN setting (k=5), synthetic minority instances are generated in very close proximity to the original samples. As shown in our data distribution analyses, the resulting datasets did not create a clear linear separation in the first 2 principal components but instead shifted the relative density of the classes. Larger k values produced sparser training datasets and reduced overfitting. Although oversampling methods are widely used in biomedical ML, many studies rely on default parameter settings. Our findings extend prior work by demonstrating that k-NN tuning substantially influences model performance, with higher k values potentially yielding more stable and accurate predictions.

In contrast, models trained on undersampled data may be less prone to overfitting but are limited to a reduced training size. By combining undersampling with an incremental SGD model, we attempted to address this limitation and expose models to a larger proportion of the original training dataset. Our results show that this approach improved sensitivity while maintaining moderate specificity. Compared with other evaluated models trained on undersampled data, this combined strategy produced better performance. However, due to the customized implementation, model tuning was difficult, and our tuning strategy did not improve test performance relative to the crude model, suggesting that more sophisticated tuning approaches may be required to further improve baseline performance.

When comparing performance across ML algorithms, our results showed a clear distinction between linear and more complex classifiers in terms of overfitting behavior. Prior studies have shown that RFs and boosted trees are particularly susceptible to overfitting in small or noisy datasets. For instance, a recent simulation study demonstrated that deep trees can form local probability “peaks” around training samples, inflating apparent discrimination while reducing generalizability [54]. Interestingly, that study also found that RF models, despite overfitting the training data, could still achieve strong test performance. Consistent with these findings, although high training accuracy suggested overfitting, RF models trained on undersampled data maintained strong test-set performance in our study. When trained on oversampled data, RF models likely formed localized decision regions around dense clusters of synthetic minority samples, which may have led to much of the remaining feature space being classified as the majority class. Performance improved when a larger k parameter and ENN cleaning were applied, likely because increased inter-sample distances produced a more dispersed minority distribution and reduced this form of overfitting. In contrast, the SGD model exhibited benign underfitting, a form of regularization that limits training accuracy but enhances generalization [55].

Several studies have raised concerns about data resampling approaches due to their potential to distort population structure and adversely affect model calibration [56]. Decision threshold adjustment, therefore, emerges as an alternative strategy for addressing class imbalance. However, selecting an appropriate decision threshold remains challenging, and a variety of automated threshold-search methods have been proposed [57]. Because this study focuses on strategies to mitigate class imbalance in GI cancer binary classification, we adopted the observed disease incidence as the decision threshold. Although the exact incidence in a target population cannot be known with certainty, estimates from epidemiologic studies are widely available and may be more appropriate for risk stratification in biomedical settings than thresholds derived from purely algorithmic optimization.

Despite achieving strong performance with decision threshold adjustment alone for selected models, PCUSTe-based training set resampling improved minority-class detection across most configurations, particularly among more complex learning algorithms. Both evaluated configurations—PCUSTe-1 (matching on marital status, education, employment, and income) and PCUSTe-2 (matching on smoking and alcohol consumption)—supported favorable predictive performance, consistent with established associations between socioeconomic, lifestyle factors, and cancer risk [58,59]. Importantly, PCUSTe’s flexible parameterization—defined by its matching criteria and case-control ratio—allows adaptation to different datasets and

XSL•FO
RenderX

research contexts. We observed that linear models tended to perform better under PCUSTe-1 resampling, whereas more complex classifiers showed improved performance with PCUSTe-2. When considered alongside SHAP analyses, which indicated stronger contributions of dietary factors in linear models and greater influence of physiological signals in nonlinear models, this pattern may suggest that the 2 matching strategies emphasize distinct aspects of GI cancer risk. Collectively, these findings reinforce that no single ML algorithm or imbalance mitigation strategy is universally optimal. Instead, adaptable modeling frameworks capable of efficient retraining across populations may be better suited to support precision prevention in nutrition and cancer research [60].

In ML, large sample sizes are often favored, and some studies address data sparsity by pooling multiple data sources. For example, a recent Danish study combined 3 national registries and full-text medical records to develop a multi-cancer prediction model comprising 6.7 million individuals. Although internal validation showed strong performance for GI cancers (AUCs: pancreatic 0.86, liver 0.90, colorectal 0.85, gastric 0.85, oesophageal 0.89), external validation using the UK Biobank yielded substantially lower AUCs (0.65 - 0.74) [61]. Supported by multiple large-scale grants, this study illustrates the substantial resources required for population-level modeling. In contrast, our study used a smaller, grouped GI cancer dataset and has not yet undergone external validation. While direct comparison is limited due to differences in sample size and feature composition, our models nonetheless demonstrated promising predictive performance. These findings suggest that careful resampling and study design may partially mitigate limitations inherent to small, highly imbalanced datasets, although they cannot substitute for large-scale population data.

Strengths and Limitations

This study has several notable strengths. First, we leveraged longitudinal cohort data, enabling a robust assessment of risk factors preceding disease onset, and implemented a rigorous evaluation framework with strict separation between training and test datasets. Second, we introduced PCUSTe, a patient-centered undersampling framework that flexibly parameterizes matching criteria, offering a customizable, epidemiologically grounded approach to addressing class imbalance in small biomedical datasets. Third, we conducted a comprehensive comparison of resampling strategies across multiple ML algorithms and hyperparameter configurations.

Several limitations should also be acknowledged. First, dietary intake data were self-reported, introducing potential recall bias, and the lack of repeated dietary assessments limited our ability to capture temporal changes in exposure. To partially mitigate this, analyses were restricted to baseline assessments collected prior to diagnosis using standardized instruments. Second, although internal validation was performed, external validation is required to assess generalizability. While this limitation was partially addressed through conservative model evaluation, validation in independent cohorts remains an important next step. Third, the relatively small number of GI cancer cases may have constrained model performance and limited extrapolation to broader populations. We attempted to mitigate this by using multiple resampling strategies and applying class-prior-based decision threshold adjustment; however, larger sample sizes are needed to confirm the stability of the observed results.

In addition, the limited number of positive cases precluded robust modeling of site-specific GI cancer subtypes, necessitating a binarized pooled outcome. Although the final models did not appear to systematically misclassify risk for any specific GI cancer site, the biological and clinical heterogeneity of these malignancies should be acknowledged. Future analyses incorporating multi-site classification will be needed once sufficient sample sizes become available. Finally, while PCUSTe provides a promising solution for smaller cohorts, it further reduces the control population, and models trained on limited samples are inherently less competitive than those developed using large-scale datasets. To mitigate this, we paired PCUSTe with an incrementally trained SGD model, allowing iterative learning from multiple control subsets constrained by case covariate distributions. Nevertheless, caution is warranted when extrapolating model performance to broader clinical settings.

Future Work

While PCUSTe and incidence-based threshold adjustment offer a practical and adaptable framework for improving risk stratification in cohort-based cancer prediction studies, external validation in larger and more diverse cohorts is required to establish the generalizability and scalability of these methods.

Conclusions

This study demonstrates that a class imbalance mitigation strategy is a critical determinant of ML model performance in GI cancer risk prediction. By incorporating epidemiologically grounded matching principles, our patient-centered undersampling framework, PCUSTe, consistently outperformed conventional oversampling and hybrid approaches across multiple model architectures. However, incidence-based decision threshold adjustment alone, paired with a baseline LR model, showed better balance between sensitivity and specificity metrics. These findings underscore the value of aligning ML workflows with real-world population characteristics to enhance minority class detection in small, highly imbalanced datasets typical of rare or low-incidence disease research. Furthermore, the choice of the best class imbalance mitigation strategy may not be uniform across different study objectives.

Abstract

Background: Chronic kidney disease (CKD) is a global health burden characterized by heterogeneous progression trajectories. Without timely and appropriate management, CKD can lead to increased morbidity and mortality and a reduced quality of life. Therefore, early identification of patients at high risk of developing end-stage renal disease (ESRD) or mortality is essential to facilitate timely intervention and improve patient outcomes.

Objective: This study aimed to develop and validate machine learning models to predict ESRD and all-cause mortality in patients with CKD.

Methods: We developed and validated machine learning models using data from patients with CKD and an estimated glomerular filtration rate of <60 mL/min/1.73 m^2, who were treated at Taipei Veterans General Hospital between 2011 and 2021. Predictors included 69 routinely available demographic, clinical, medication, laboratory, and echocardiographic variables. The outcomes were ESRD and all-cause mortality. The cohort was randomly divided into training (n=23,741, 80%) and testing (n=5936, 20%) sets. The evaluated models included extreme gradient boosting, light gradient boosting machine, categorical boosting, random forest, and a stacking classifier. Model performance was assessed using the area under the receiver operating characteristic curve (AUROC), the area under the precision-recall curve, calibration, and decision-curve analysis. Supplementary time-to-event analyses were performed using the kidney failure risk equation and survival-based machine learning models.

Results: A total of 29,677 patients were included in the study. The median age was 79 (IQR 70.0 - 88.0) years, and 16,359 (55.1%) were male. Among these patients, 14,993 (50.5%) had hypertension, 7908 (26.6%) had diabetes mellitus, and 1768 (6%) had cancer. During follow-up, 649 patients (2.2%) developed ESRD and 3631 (12.2%) died. The models demonstrated high predictive performance for ESRD, with AUROCs ranging from 0.839 to 0.894. For all-cause mortality, the predictive performance was more modest, with AUROCs ranging from 0.752 to 0.774. Given the low incidence of ESRD in this cohort, model performance was additionally evaluated using precision-recall curves. The area under the precision-recall curve ranged from 0.172 to 0.216 for ESRD prediction and from 0.330 to 0.356 for all-cause mortality across models. Calibration and decision-curve analyses supported model reliability and clinical utility.

Conclusions: Machine learning algorithms may serve as useful tools for risk stratification of ESRD and all-cause mortality in patients with CKD, with the potential to support more individualized clinical management.

Introduction

Chronic kidney disease (CKD) is recognized as a major global public health challenge, with substantial impacts on morbidity and health care utilization worldwide [1,2]. In Taiwan, CKD affects approximately 10% of the adult population. The consistently high end-stage renal disease (ESRD) incidence imposes a substantial burden on the health care system and is accompanied by steadily increasing financial pressure [3,4]. This local epidemiologic context supports the need to improve risk stratification for kidney failure and mortality using Taiwan-based real-world data. Despite advancements in CKD research and management, accurately predicting progression to ESRD remains challenging. CKD is heterogeneous, with diverse etiologies, clinical presentations, and pathological features, and progression rates can vary substantially even among patients with identical primary kidney diseases [5]. Numerous clinical factors, including baseline estimated glomerular filtration rate (eGFR), proteinuria levels, age, and comorbidities, have been identified as contributors to CKD progression [6,7]. However, these factors and traditional risk equations, such as the kidney failure risk equation (KFRE), may not fully capture the complex, multidimensional nature of CKD, in which clinical, laboratory, and demographic variables can interact nonlinearly.

In recent years, advancements in artificial intelligence have significantly impacted the medical field. The integration of machine learning and deep learning with big data has found extensive applications across various medical disciplines, including image interpretation, disease diagnosis, and risk prediction [8]. Previous research has highlighted the potential of artificial intelligence for predicting the risk of patients with diabetes developing diabetic kidney disease or progressing to ESRD [9,10]. By incorporating a comprehensive range of clinical, demographic, and laboratory variables, these machine learning models have demonstrated considerable promise for achieving more precise risk stratification compared to traditional methods. Despite these advantages, several challenges remain in translating machine learning models into clinical practice. Many models have limited transparency, which can reduce interpretability and clinician trust [11]. In addition, differences in data sources, preprocessing strategies, and modeling pipelines may affect reproducibility across studies [12,13]. Furthermore, a substantial proportion of published machine learning prediction models lack external validation, which raises concerns about their generalizability and real-world clinical usefulness [14]. To bridge this gap between predictive modeling and clinical application, there is a critical need for transparent algorithms that can accurately handle the complex, time-to-event nature of chronic disease progression. Integrating tools such as Shapley additive explanations (SHAP) and survival-based machine learning techniques can demystify these models, providing clinicians with actionable insights into individual risk trajectories over time.

The aim of this study was to develop and validate machine learning–based models to predict the risks of ESRD and all-cause mortality in patients with CKD using a large-scale single-center cohort. We hypothesized that these models would enhance the precision of risk stratification, identify clinically meaningful predictors to inform clinical decision-making, and ultimately facilitate timely interventions to improve patient outcomes.

Methods

Data Sources and Study Population

This retrospective cohort study involved patients with CKD, defined as persistent eGFR <60 mL/min/1.73 m² for at least 3 months. Data were comprehensively obtained from the Taipei Veterans General Hospital Big Data Center, covering the period from January 2011 to December 2021. Patient information included demographic data, comorbidities, medication prescriptions, laboratory results, and echocardiography findings. Exclusion criteria were prior renal replacement therapy (dialysis or kidney transplantation) before study enrollment and individuals younger than 20 years at the time of CKD diagnosis. eGFR calculations used the 2021 Chronic Kidney Disease Epidemiology Collaboration equation [15].

Feature Selection

Our machine learning models incorporated 69 features across multiple clinical domains, comprising a broad set of routinely available electronic health record (EHR) variables to capture multidimensional risk domains relevant to CKD progression and all-cause mortality. Demographic and lifestyle characteristics included age, sex, body weight, BMI, systolic and diastolic blood pressure, alcohol consumption, betel nut chewing, and cigarette smoking. Comorbidity profiles included hypertension, diabetes mellitus, and cancer. Medication history encompassed antidiabetic agents (metformin, sodium-glucose cotransporter 2 inhibitors, glucagon-like peptide-1 receptor agonists, sulfonylureas, α-glucosidase inhibitors, thiazolidinediones, dipeptidyl peptidase-4 inhibitors, insulin), cardiovascular drugs (statins, aspirin, clopidogrel, direct oral anticoagulants, warfarin, angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, beta-blockers, calcium channel blockers, thiazide diuretics, loop diuretics, mineralocorticoid receptor antagonists, nitrates, sacubitril or valsartan), and anti-inflammatory medications (nonsteroidal anti-inflammatory drugs, cyclooxygenase-2 inhibitors). Laboratory parameters included serum creatinine, blood urea nitrogen, sodium, potassium, chloride, bicarbonate, uric acid, calcium, phosphate, serum albumin, total protein, creatine kinase, glucose, hemoglobin A_{1c}, total cholesterol, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, triglycerides, alanine aminotransferase, alkaline phosphatase, gamma-glutamyl transferase, total bilirubin, international normalized ratio, free thyroxine, thyroid-stimulating hormone, white blood cell count, hemoglobin, platelet count, urine protein-to-creatinine ratio (UPCR), and urine albumin-to-creatinine ratio (UACR). Cardiac function was evaluated using left ventricular ejection fraction via echocardiography.

Outcome Definition

The primary clinical outcomes were progression to ESRD and all-cause mortality. Both outcomes were ascertained using electronic health records from the Taipei Veterans General

XSL•FO
RenderX

Hospital. To prevent the misclassification of temporary acute dialysis, ESRD was strictly defined as the presence of dialysis-related procedure codes recorded for at least 3 consecutive months, or the occurrence of kidney transplantation identified by the *International Classification of Diseases, Ninth or Tenth Revision*, Clinical Modification codes. Outcomes were represented as binary variables, with 1 indicating occurrence and 0 indicating nonoccurrence during follow-up.

Data Preprocessing

Categorical variables were summarized as frequencies (percentages) and continuous variables as medians with IQRs. The dataset was randomly divided into training (23,741/29,677, 80%) and testing (5936/29,677, 20%) sets using stratified sampling with a fixed random seed to preserve the outcome distribution. Infinite values were converted to missing values, and only numeric variables were retained for model development. In the primary analysis, missing values were imputed using K-nearest-neighbor imputation (k=5), fitted on the training set, and then applied to the testing set. Continuous variables were standardized using a StandardScaler fitted on the training set. To address significant class imbalance for ESRD, the Synthetic Minority Over-sampling Technique (SMOTE) was applied to the training data only with a sampling strategy of 0.9.

Machine Learning Models

The analysis used five advanced machine learning models: extreme gradient boosting (XGBoost), light gradient boosting machine (LightGBM), categorical boosting (CatBoost), random forest, and a stacking classifier integrating these base models. Each tree-based algorithm applied ensemble learning with distinct optimization strategies. The stacking classifier used logistic regression as a meta-learner to leverage complementary strengths, reduce variance, and enhance overall predictive accuracy.

Hyperparameter Optimization

Hyperparameter optimization was conducted using randomized search combined with 3-fold cross-validation, targeting the maximization of the area under the precision-recall curve (AUPRC), which is more appropriate for imbalanced outcomes. The optimization explored 30 random combinations within predefined parameter ranges, identifying optimal configurations efficiently. Key hyperparameters included learning rates, tree depths, regularization parameters, and specific configurations for each algorithm. The stacking classifier used logistic regression as the final meta-learner.

Model Evaluation and Feature Importance

Model performance was comprehensively evaluated using multiple metrics, with the area under the receiver operating characteristic curve (AUROC) as the primary measure of discrimination. Additional evaluation metrics included the AUPRC, accuracy, precision, recall, F_1 score, specificity, and log loss. Confusion matrices were also generated using the optimal cutoff determined by the Youden index. Calibration and clinical utility were further assessed using calibration curves and decision-curve analysis. Feature importance was evaluated using SHAP, which quantified the contribution of individual variables to model predictions and facilitated interpretation of clinically relevant predictors.

Survival Analyses

As time-to-event analyses for ESRD, we evaluated the KFRE and random survival forest (RSF) at 2-year and 5-year horizons. To ensure a fair comparison, these models were evaluated using a unified horizon-specific test mask requiring landmark eligibility, complete age, sex, eGFR, and UACR inputs and nonmissing model predictions. Time-dependent discrimination was assessed using inverse probability of censoring weighting–based AUROC.

Sensitivity Analyses

Sensitivity analyses were performed to assess the robustness of model performance. First, an age-stratified analysis was conducted using the XGBoost model to evaluate discrimination separately in patients aged ≥60 years and <60 years in the testing set. Second, to examine the influence of missing-data handling, we repeated model evaluation without imputation using complete-case data only. Model discrimination in these sensitivity analyses was assessed using AUROC.

Implementation Details

Analyses were implemented using Python 3.9 with specialized libraries. Scikit-learn provided core machine learning functionality, supplemented by XGBoost, LightGBM, and CatBoost for gradient boosting. The stacking classifier was implemented using sklearn.ensemble.StackingClassifier with logistic regression as the final estimator. Pandas and NumPy facilitated data manipulation, while visualization was achieved using Matplotlib and Seaborn. Missing value imputation used sklearn.impute.KNNImputer, dataset partitioning used sklearn.model_selection.train_test_split, and class balancing used imblearn.over_sampling.SMOTE. Hyperparameter optimization applied sklearn.model_selection.RandomizedSearchCV, and stratified k-fold cross-validation used sklearn.model_selection.StratifiedKFold. Complementary statistical analyses were performed with SAS version 9.4 (SAS Institute, Cary, NC), and statistical significance was defined as P<.05. Complementary survival analyses were implemented using scikit-survival and PyTorch for time-to-event modeling and inverse probability of censoring weighting–based evaluation.

Ethical Considerations

This study protocol was approved by the institutional review board of Taipei Veterans General Hospital (approval number 2023-07-001CC), with informed consent waived due to the use of deidentified data.

Results

Characteristics and Distribution of Patients

A total of 29,677 patients with CKD were enrolled during the 10-year study period. Detailed patient demographic data are presented in Table 1. The median patient age was 79.0 (IQR 70.0 - 88.0) years, and 16,359 (55.1%) patients were male.

XSL•FO
RenderX

Additionally, 14,993 (50.5%) patients had hypertension, 7908 (26.6%) patients had diabetes mellitus, and 1768 (6%) patients had cancer. Within the entire CKD cohort, 649 (2.2%) patients progressed to ESRD, including 519 of 23,741 (2.2%) in the training set and 130 of 5936 (2.2%) in the testing set. All-cause mortality occurred in 3631 of 29,677 patients (12.2%), including 2905 of 23,741 (12.2%) in the training set and 726 of 5936 (12.2%) in the testing set.

Model Performance

Five machine learning algorithms, including XGBoost, LightGBM, CatBoost, random forest, and a stacking classifier, were trained on 80% (n=23,741) of the cohort and evaluated on the remaining 20% (n=5936). Figure 1A displays ROC curves illustrating the predictive performance of each algorithm for ESRD prediction in the testing set. Overall, all models showed good discrimination, with AUROC values ranging from 0.839 to 0.894. XGBoost achieved the highest AUROC of 0.894, followed by the stacking classifier (0.890), random forest (0.885), LightGBM (0.872), and CatBoost (0.839).

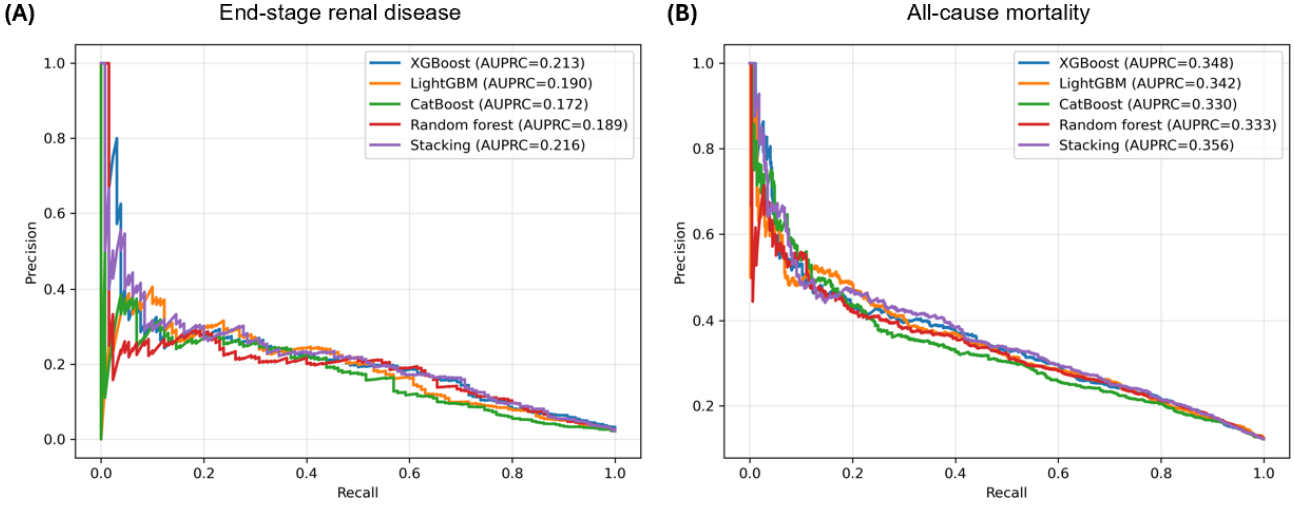

Figure 1. Receiver operating characteristic curves of the machine learning models for prediction of (A) end-stage renal disease and (B) all-cause mortality in the testing set. AUROC: area under the receiver operating characteristic curve; CatBoost: categorical boosting; LightGBM: light gradient boosting machine; XGBoost: extreme gradient boosting.

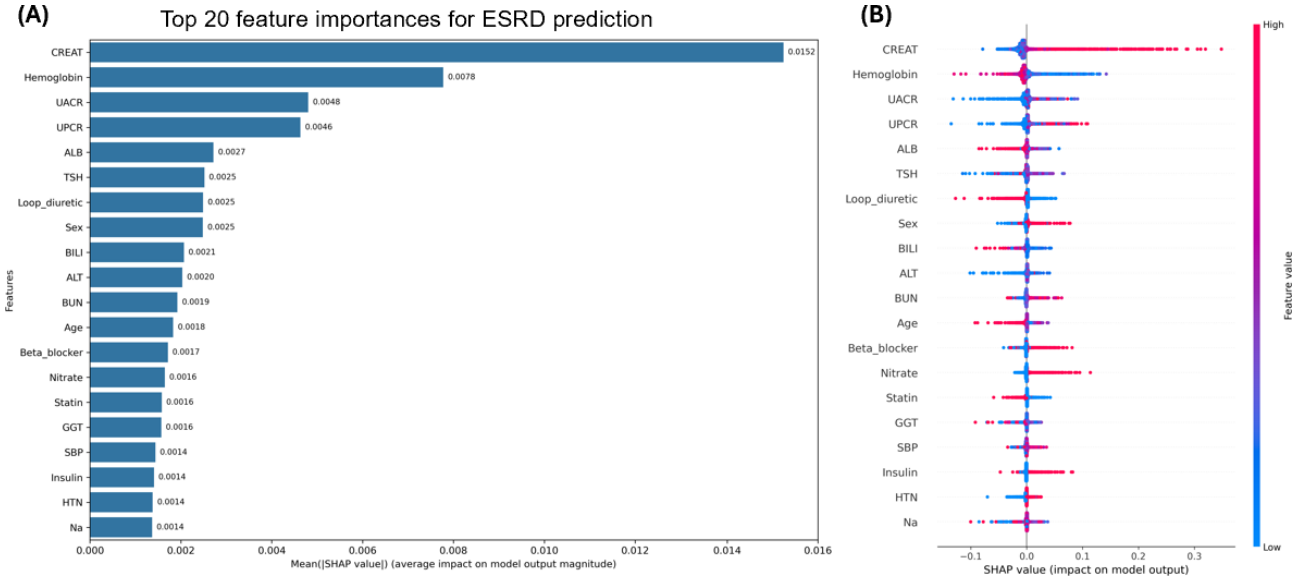
Predictive performance for all-cause mortality was lower than that for ESRD, with AUROC values ranging from 0.752 to 0.774 (Figure 1B). The stacking classifier achieved the highest AUROC of 0.774, followed by XGBoost (0.770), LightGBM (0.768), random forest (0.768), and CatBoost (0.752).

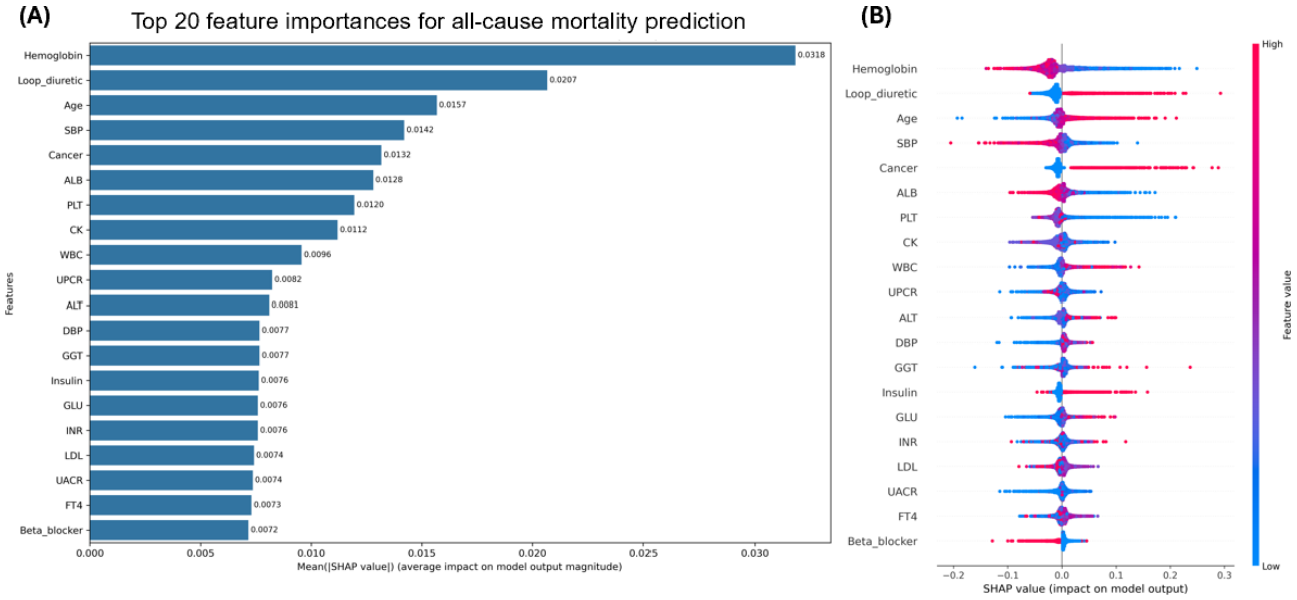
Given the low incidence of ESRD in the study cohort, precision-recall analysis was additionally performed. The AUPRC ranged from 0.172 to 0.216 (Figure 2A). The stacking classifier achieved the highest AUPRC of 0.216, followed by XGBoost (0.213), LightGBM (0.190), random forest (0.189), and CatBoost (0.172). For all-cause mortality, the AUPRC ranged from 0.330 to 0.356 (Figure 2B). The stacking classifier achieved the highest AUPRC of 0.356, followed by XGBoost (0.348), LightGBM (0.342), random forest (0.333), and CatBoost (0.330). Additional performance metrics, including accuracy, precision, recall, F_1 score, specificity, and log loss, are summarized in Tables S1 and S2 in Multimedia Appendix 1. Confusion matrices for ESRD and all-cause mortality prediction using the XGBoost model are shown in Figure S1 in Multimedia Appendix 1.

Figure 2. Precision-recall curves of the machine learning models for prediction of (A) end-stage renal disease and (B) all-cause mortality in the testing set. AUPRC: area under the precision-recall curve; CatBoost: categorical boosting; LightGBM: light gradient boosting machine; XGBoost: extreme gradient boosting.



Ranks of Feature Importance and SHAP Values in the XGBoost Model

Feature attribution analyses using SHAP identified key predictors for ESRD and all-cause mortality. Figure 3A presents feature importance rankings from the XGBoost model for ESRD prediction, arranged in descending order based on impact. The top 5 most influential features were serum creatinine, hemoglobin, UACR, UPCR, and albumin. Figure 3B illustrates the SHAP summary plot, where red points represent higher feature values and blue points indicate lower values. Positive SHAP values suggest increased ESRD risk, while negative values indicate lower risk. Higher values of serum creatinine, UACR, and UPCR, as well as lower hemoglobin and albumin levels, were associated with a higher predicted risk of ESRD.



XSL•FO
RenderX

Figure 3. Shapley additive explanations (SHAP) analysis for the prediction of end-stage renal disease (ESRD). (A) Mean absolute SHAP values showing the top 20 most influential features in the extreme gradient boosting (XGBoost) model. (B) SHAP summary plot showing the direction and magnitude of feature effects on the model output. Red indicates higher feature values, and blue indicates lower feature values. ALB: albumin; ALT: alanine aminotransferase; BILI: total bilirubin; BUN: blood urea nitrogen; CREAT: creatinine; CI: chloride; GGT: gamma-glutamyl transferase; HTN: hypertension; Na: sodium; SBP: systolic blood pressure; TSH: thyroid-stimulating hormone; UACR: urine albumin-to-creatinine ratio; UPCR: urine protein-to-creatinine ratio.

For all-cause mortality, Figure 4A displays feature importance rankings from the XGBoost model. Hemoglobin and loop diuretic use were the most impactful features, followed by age, systolic blood pressure, and cancer. Figure 4B shows the SHAP summary plot for all-cause mortality. Lower hemoglobin levels, loop diuretic use, older age, lower systolic blood pressure, and the presence of cancer were generally associated with a higher predicted mortality risk.

Figure 4. Shapley additive explanations (SHAP) analysis for the prediction of all-cause mortality. (A) Mean absolute SHAP values showing the top 20 most influential features in the extreme gradient boosting (XGBoost) model. (B) SHAP summary plot showing the direction and magnitude of feature effects on the model output. Red indicates higher feature values, and blue indicates lower feature values. ALB: albumin; ALT: alanine aminotransferase; CK: creatine kinase; DBP: diastolic blood pressure; FT4: free thyroxine; GGT: gamma-glutamyl transferase; GLU: glucose; INR: international normalized ratio; LDL: low-density lipoprotein cholesterol; PLT: platelet count; SBP: systolic blood pressure; UACR: urine albumin-to-creatinine ratio; UPCR: urine protein-to-creatinine ratio; WBC: white blood cell count.

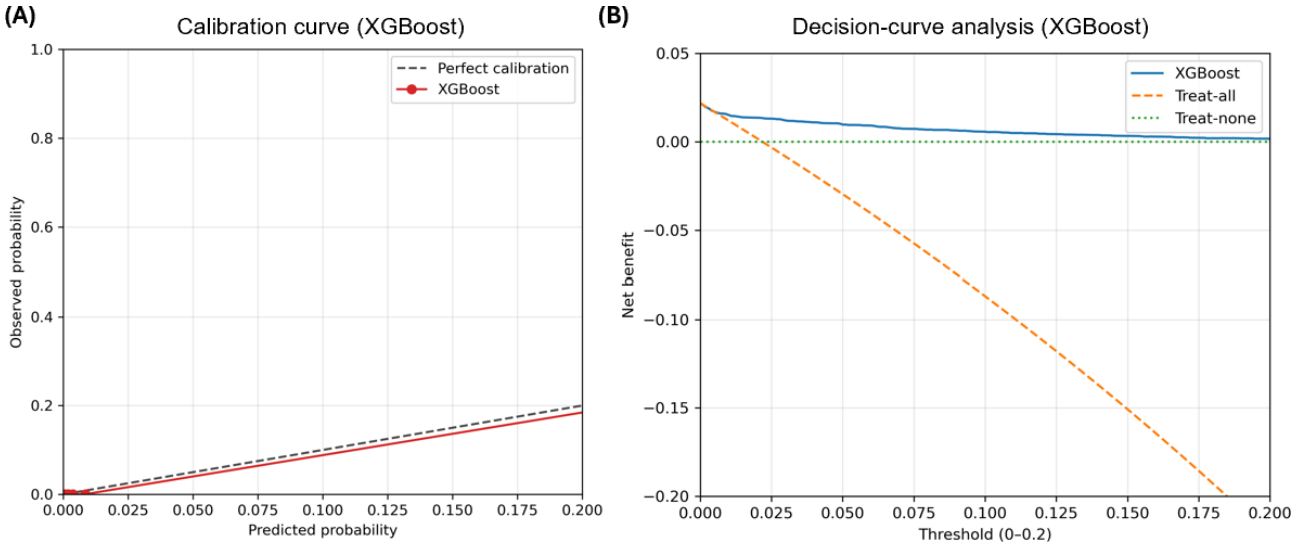
Calibration and Decision-Curve Analysis

To further assess clinical usefulness, calibration and decision-curve analyses of the XGBoost model were performed in the testing set. The calibration curve showed overall agreement between predicted and observed ESRD risks (Figure 5A). In the decision-curve analysis, the XGBoost model showed a higher net benefit than the treat-all and treat-none strategies across threshold probabilities ranging from 0 to 0.20 (Figure 5B). For all-cause mortality, the calibration curve also showed overall agreement between predicted and observed risks (Figure 6A). In the decision-curve analysis, the XGBoost model showed

XSL•FO
RenderX

a positive net benefit across a broad range of threshold probabilities, although the treat-all strategy provided slightly higher net benefit at very low thresholds (Figure 6B).

Figure 5. Calibration and decision-curve analyses of the extreme gradient boosting (XGBoost) model for end-stage renal disease prediction in the testing set. (A) Calibration curve comparing predicted and observed event probabilities. (B) Decision-curve analysis comparing the net benefit of the XGBoost model with the treat-all and treat-none strategies.



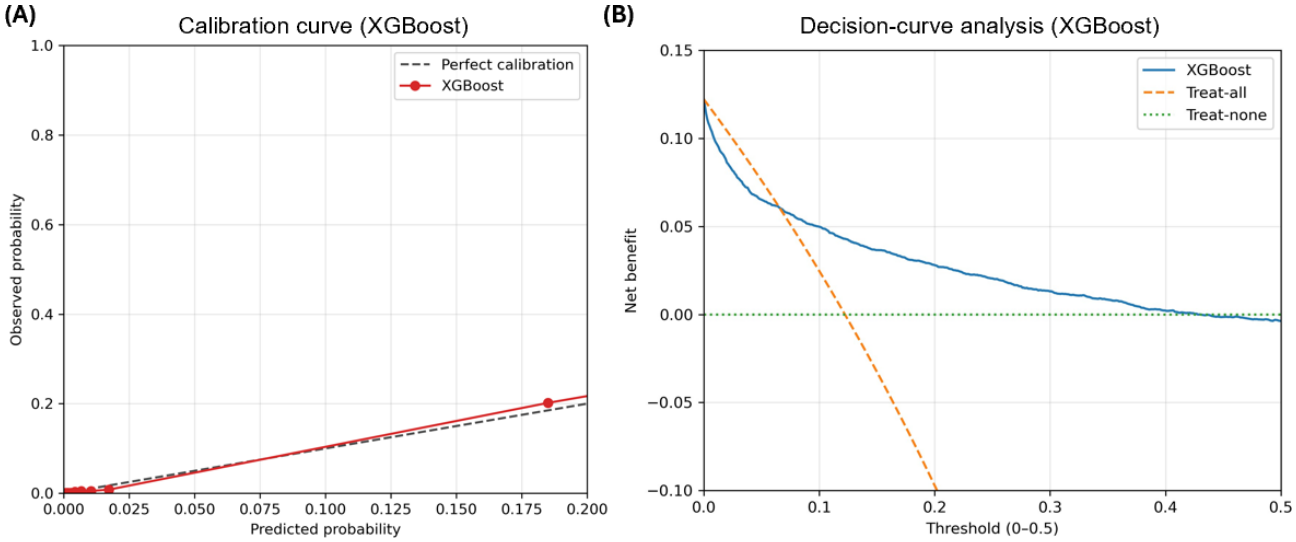


Figure 6. Calibration and decision-curve analyses of the extreme gradient boosting (XGBoost) model for all-cause mortality prediction in the testing set. (A) Calibration curve comparing predicted and observed event probabilities. (B) Decision-curve analysis comparing the net benefit of the XGBoost model with the treat-all and treat-none strategies.

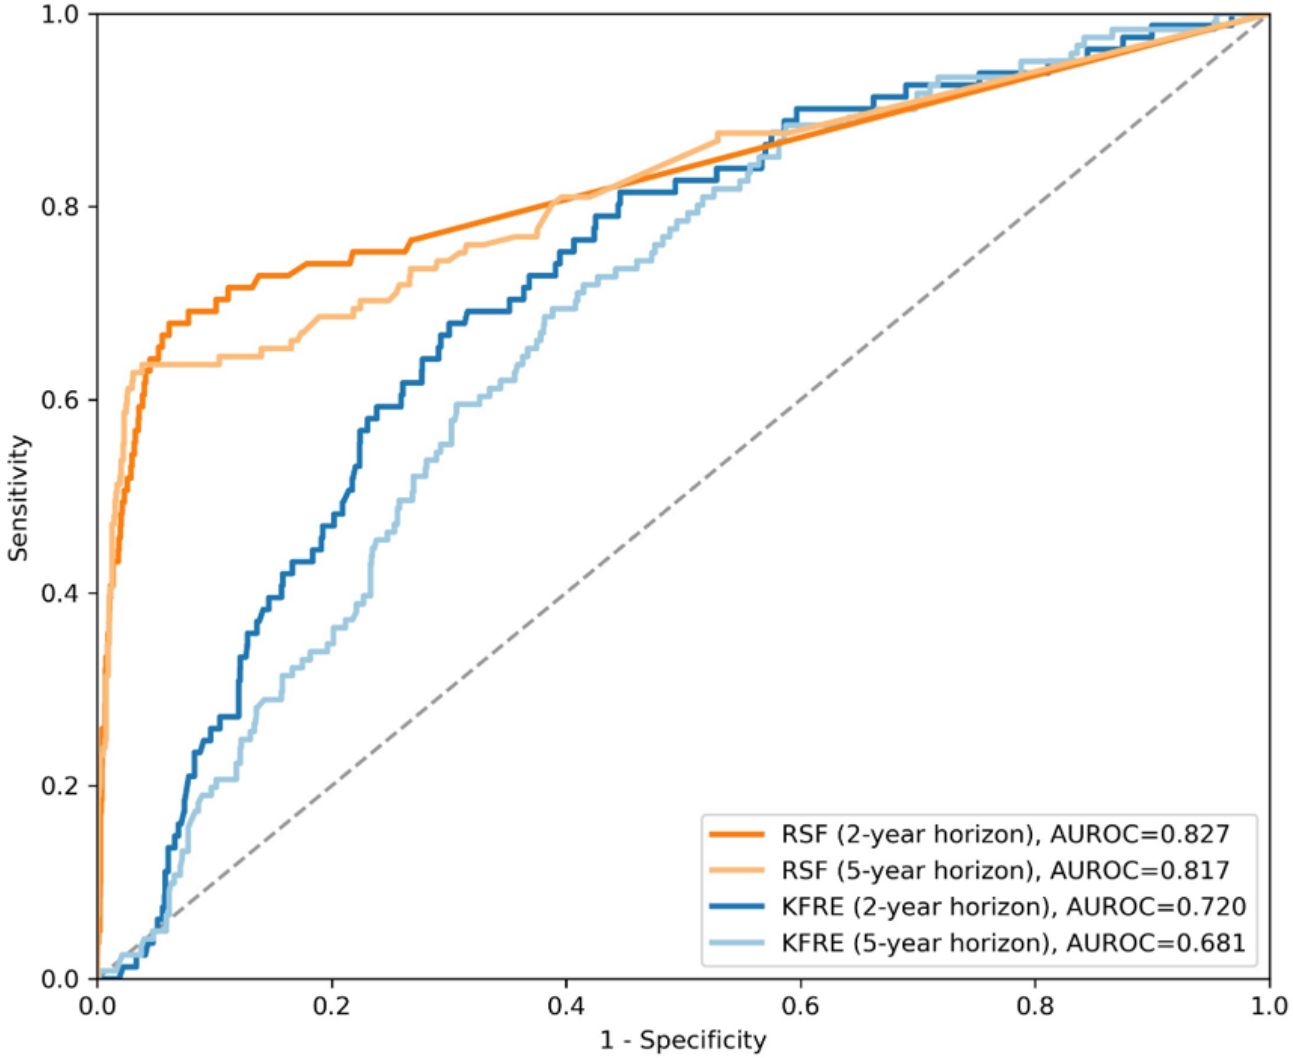

Survival Analysis Using RSF and Comparison With KFRE

To better account for the time-to-event nature of ESRD, we additionally performed survival analysis using RSF. The predictive performance of RSF was then compared with that of the KFRE at the 2- and 5-year horizons (Figure 7). RSF demonstrated better discrimination than KFRE at both time points, with AUROCs of 0.827 versus 0.720 at 2 years and 0.817 versus 0.681 at 5 years.

XSL•FO
RenderX

Figure 7. Receiver operating characteristic curves comparing the random survival forest (RSF) and the kidney failure risk equation (KFRE) for the prediction of end-stage renal disease at the 2- and 5-year horizons. AUROC: area under the receiver operating characteristic curve.

Sensitivity Analyses

In the age-stratified analysis, model discrimination remained similar between patients aged ≥60 years and <60 years, with AUROCs of 0.896 (95% CI 0.867 - 0.921) and 0.866 (95% CI 0.777 - 0.939), respectively (Figure S2 in Multimedia Appendix 1). In analyses without imputation, AUROCs for ESRD ranged from 0.888 to 0.903 and AUROCs for all-cause mortality ranged from 0.797 to 0.808 across models (Figure S3 in Multimedia Appendix 1), showing results comparable to the primary analysis.

Discussion

In this study, we developed and validated machine learning models to predict the risk of ESRD and all-cause mortality in a large cohort of patients with CKD. Our findings showed that the evaluated machine learning algorithms, including XGBoost, LightGBM, CatBoost, random forest, and a stacking classifier, achieved good discrimination for ESRD prediction, with a maximum AUROC of 0.894. Predictive performance for all-cause mortality was more modest, with a maximum AUROC of 0.774. In addition, calibration and decision-curve analyses supported the overall reliability and clinical utility of the model.

A previous study developed predictive models for CKD progression using traditional statistical methods and clinical variables from Canadian cohorts collected between 2001 and 2008 [7]. These models, based on Cox proportional hazards regression, showed reasonable predictive performance by incorporating key demographic and laboratory parameters, such as eGFR and albuminuria. However, their reliance on conventional statistical techniques and a limited number of variables may restrict their ability to fully capture complex relationships among CKD progression risk factors. Furthermore, evolving clinical practices, therapeutic strategies, and diagnostic methods over time might limit their applicability to contemporary patient populations.

Using advanced machine learning techniques allows the integration of a broader range of clinical, demographic, and laboratory features into predictive models, enabling more precise risk assessment for CKD progression [16,17]. Unlike traditional statistical methods, which are often constrained by linear assumptions and limited predictors, machine learning algorithms can capture complex, nonlinear interactions among variables. Additionally, these models manage high-dimensional data, autonomously identify relevant features, and continuously adapt to evolving clinical practices and patient populations. The

XSL•FO
RenderX

incorporation of explainability tools, such as SHAP, further enhances interpretability by clarifying individual risk factor contributions [18]. A recent study by Tangri et al [19] validated the Klinrisk machine learning model using data from the CANVAS (Canagliflozin Cardiovascular Assessment Study) and CREDENCE (Canagliflozin and Renal Events in Diabetes With Established Nephropathy Clinical Evaluation) clinical trials, demonstrating superior performance compared to KDIGO (Kidney Disease: Improving Global Outcomes) risk classification, with an AUROC of 0.88 at 3 years. In addition, our survival-based comparative analysis showed that RSF outperformed the KFRE at both the 2- and 5-year horizons, suggesting that machine learning approaches incorporating time-to-event information may provide improved discrimination over conventional risk equations.

Another study used machine learning models to predict ESRD risk in newly diagnosed patients with type 2 diabetes mellitus (T2DM), illustrating the effectiveness of these approaches in risk stratification [10]. Among the evaluated algorithms, XGBoost achieved the highest predictive performance. This study also used SHAP to interpret predictions, identifying baseline serum creatinine, mean serum creatinine within 1 year before T2DM diagnosis, high-sensitivity C-reactive protein, and UPCR as key predictors. However, its limitation to patients with diabetes restricts generalizability to broader CKD populations. Given CKD's heterogeneity, with significantly varying etiologies and progression rates between patients with diabetes and those without diabetes, models trained exclusively on T2DM populations might not fully capture CKD's complexity. Our study extends the application of machine learning in CKD risk prediction by analyzing CKD cohort with varied etiologies, offering a comprehensive ESRD risk assessment beyond diabetes-related kidney disease. Previous machine learning studies predicting CKD progression often had limited sample sizes and narrow feature sets [20-22]. Our study, in contrast, uses a significantly larger cohort and broader clinical, laboratory, and demographic features, likely enhancing observed model performance. This comprehensive approach improves the applicability of machine learning–based models in clinical settings, aiding early identification and intervention for patients at high risk of ESRD.

We identified baseline serum creatinine, UACR, and UPCR as top predictors of ESRD, consistent with established CKD progression knowledge. These biomarkers have long been recognized as key indicators of kidney function decline, and their prominence reinforces their critical role in risk assessment. Hemoglobin also emerged as a strong predictor, suggesting anemia's potentially significant role in CKD progression. Anemia is common in CKD, primarily due to reduced erythropoietin production, iron deficiency, and chronic inflammation []. It has been linked to increased cardiovascular risk and impaired quality of life, particularly among patients with CKD [23-25]. A study using data from the SOLVD trial, enrolling patients with heart failure with significantly reduced left ventricular ejection fractions of 35% or less, showed anemia significantly associated with accelerated eGFR decline, especially pronounced in patients with baseline CKD [26]. The complex interaction among anemia, cardiovascular disease, and renal function decline underscores the importance of comprehensive clinical management in CKD [27].

The predictive performance for all-cause mortality was lower than that for ESRD, likely reflecting the greater heterogeneity of mortality as an outcome. Unlike ESRD, which is more directly linked to renal function and proteinuria-related measures, all-cause mortality is influenced by a broader range of renal and nonrenal factors. Routinely collected structured EHR variables may not fully capture important dimensions of mortality risk, such as frailty, functional status, nutritional reserve, cognitive impairment, and overall disease severity. Incorporating these variables may improve mortality prediction in future studies. Top predictors identified by SHAP analysis were hemoglobin, loop diuretic use, age, systolic blood pressure, cancer, and albumin. In patients with CKD, lower hemoglobin levels may reflect reduced erythropoietin production, chronic inflammation, malnutrition, and a greater comorbidity burden, all of which can contribute to vulnerability and adverse outcomes [28]. Loop diuretic use may indicate underlying volume overload or more advanced heart or kidney disease. Lower systolic blood pressure also emerged as an important predictor of mortality. This finding is consistent with prior studies in older adults with CKD and may be especially relevant in our cohort, given its advanced age distribution [29]. In this setting, lower systolic blood pressure may reflect frailty, impaired cardiac function, malnutrition, or overall physiologic vulnerability. Serum albumin is a well-established marker of both nutritional status and systemic inflammation [30,31]. Hypoalbuminemia has been consistently linked to increased short- and long-term mortality across diverse patient populations, including those with and without chronic kidney disease [32-34]. Proteinuria, commonly used to assess renal progression, also reflects systemic endothelial dysfunction and microvascular damage, contributing to increased cardiovascular morbidity and mortality. Studies have linked proteinuria with increased risk of coronary artery disease, stroke, heart failure, and arrhythmias [35-39]. Even low-grade albuminuria has been associated with adverse cardiac remodeling and unfavorable cardiovascular outcomes. A recent large-scale cohort study further demonstrated that proteinuria significantly increases the risk of sudden cardiac arrest in young adults, particularly in those with CKD [40]. Despite its well-established prognostic value in cardiovascular disease, proteinuria remains underutilized in routine cardiovascular risk stratification [41]. Our findings reinforce the clinical importance of proteinuria and support its broader integration into multidisciplinary risk evaluation strategies, especially within CKD populations.

From a clinical perspective, the practical value of these machine learning models lies in their potential integration into routine electronic health record workflows. Such risk estimates may help clinicians identify patients at high risk for ESRD or death who may benefit from closer follow-up, earlier nephrology referral, intensified management of modifiable risk factors, and more timely preparation for kidney replacement therapy. In addition, the decision-curve analysis suggests that the model may support risk-based clinical decision-making across a range of threshold probabilities. However, the optimal thresholds for

XSL•FO
RenderX

intervention and the clinical impact of implementing such a model should be established in future prospective studies.

The strengths of our study include a large real-world CKD dataset with comprehensive clinical and laboratory information. Multiple machine learning algorithms, enhanced by advanced techniques such as SMOTE and SHAP, strengthen our findings' robustness and applicability. Consistency in model performance across different frameworks further supports reliability. However, several limitations should be acknowledged. First, this was a retrospective, single-center study, which may introduce selection bias and limit generalizability. In particular, the cohort had a relatively advanced age distribution, likely reflecting the older patient population served by our institution. Nevertheless, age-stratified subgroup analysis showed similar model discrimination in patients aged ≥60 and <60 years, although external validation in younger populations remains necessary. Second, although we included a broad set of routinely available clinical variables, some potentially relevant factors, such as genetic markers and socioeconomic influences, were not included because they were not consistently available in structured form in our EHRs. Future studies incorporating multiomics data and social determinants may enhance predictive accuracy. Third, preprocessing methods may have introduced bias. KNN imputation may smooth extreme laboratory values, and SMOTE may generate synthetic minority samples that do not fully reflect the true clinical distribution, particularly for laboratory-based predictors. However, sensitivity analyses without imputation showed comparable model discrimination, suggesting that the overall results were broadly similar without imputation. Finally, the relative homogeneity of this hospital-based cohort may limit broader generalizability, and external validation in independent and more diverse CKD populations remains necessary.

In conclusion, machine learning models may provide useful tools for risk stratification of ESRD and all-cause mortality in patients with CKD. However, further validation is required before broader clinical application.

Abstract

Background: Non–small-cell lung cancer (NSCLC) is one of the most common cancers and a leading cause of cancer-related mortality, making prognostic prediction clinically essential. Machine learning models are increasingly used to assess prognosis; however, developing systems that combine high discrimination with clear, clinically interpretable reasoning remains challenging.

Objective: This study aimed to develop deep learning models that predict 5-year mortality in NSCLC using data from the Korea Central Cancer Registry and quantify feature importance through permutation testing.

Methods: We identified 3144 patients diagnosed between 2014 and 2017 who had complete clinical data, pulmonary function test results, histological information, genomic data, and staging details. After preprocessing, the cohort was divided into stratified training, validation, and test sets in a 70%-15%-15% ratio. Five models were tuned using Hyperband across 10 predefined feature groups. The primary evaluation metric was the area under the receiver operating characteristic curve (AUC); additional metrics included accuracy, F_1-score, precision, and recall. Groupwise permutation importance was calculated for each model, and the concordance of importance rankings was assessed using the Friedman test.

Results: All 5 models yielded comparable discrimination values on the test set (AUC=0.875 - 0.879). Model A was selected as the primary model and achieved an AUC of 0.879, an accuracy of 0.806, an F_1-score of 0.824, and a Brier score of 0.142. Permuting the stage resulted in the largest decrease in AUC (0.217), followed by the pulmonary function test (0.016). Gene mutation had a modest overall impact but became more influential within the adenocarcinoma subset. The Friedman test showed no statistically significant differences in importance rankings across the models (P=.93).

Conclusions: A grouped-input deep learning framework achieved discrimination comparable to a conventional Cox proportional hazards model using the same routine clinical variables for 5-year mortality prediction in NSCLC. Group-level permutation importance provided stable and reproducible insights into the clinical factors influencing risk, which may guide future model refinement and clinical decision-making.

Introduction

Non–small-cell lung cancer (NSCLC) is one of the most prevalent cancers worldwide and, despite advancements in prognosis, remains a leading cause of cancer-related mortality [1-3]. The prognosis of NSCLC is influenced by various factors, including the stage at diagnosis and molecular biomarkers such as alterations in the epidermal growth factor receptor (EGFR) and anaplastic lymphoma kinase (ALK). Therefore, predicting an individual patient's clinical course is crucial for tailoring treatment strategies [2,4,5].

Machine learning has gained significant traction in oncology due to its ability to capture complex, nonlinear relationships and integrate heterogeneous data modalities [6,7]. Among the various approaches, deep learning stands out for its strong predictive performance and capacity to automatically learn features [8]. However, its limited interpretability and reliance on large, well-curated datasets hinder broad adoption in medical

XSL•FO
RenderX

research [9,10]. Despite these challenges, many researchers continue to explore deep learning solutions, and growing evidence indicates that this approach enhances decision-making and supports tasks ranging from screening and diagnosis to prognostic prediction in lung cancer and other malignancies [11-14]. Nevertheless, many previous studies have relied on small, single-institution cohorts, increasing the risk of overfitting, and often inadequately reported data preprocessing or hyperparameter tuning procedures, thereby limiting reproducibility [5,11]. Assembling a sufficiently large, well-curated dataset and developing a clinically practical model remain significant challenges for clinicians.

The Korea Central Cancer Registry (KCCR) is a national population-based registry that systematically collects data on all patients with cancer diagnosed in South Korea. For lung cancer, the KCCR enhanced the staging survey, which samples 10% of all incident lung cancer cases each year. This survey includes demographic variables and clinical details such as symptoms; tumor, node, metastasis (TNM) stage; histologic subtype; and biomarker profiles [15]. By aggregating deidentified records from over 50 medical centers, the KCCR offers a large, multicenter cohort suitable for robust deep learning analyses. This dataset is particularly suitable for deep learning analyses because it captures complex interactions among heterogeneous clinical variables.

Accordingly, we developed and validated a deep learning model for 5-year mortality prediction in NSCLC using nationwide registry data from the KCCR and routinely collected clinical features. We implemented a grouped-input architecture that mirrors clinically coherent feature domains and incorporated permutation-based, group-level importance to provide a transparent and reproducible assessment of feature contributions across model configurations [16]. Collectively, this design targets clinically applicable use with limited routine variables while maintaining interpretability and clear reporting of preprocessing and hyperparameter tuning.

Methods

Data Selection, Preprocessing, and Stratified Splitting

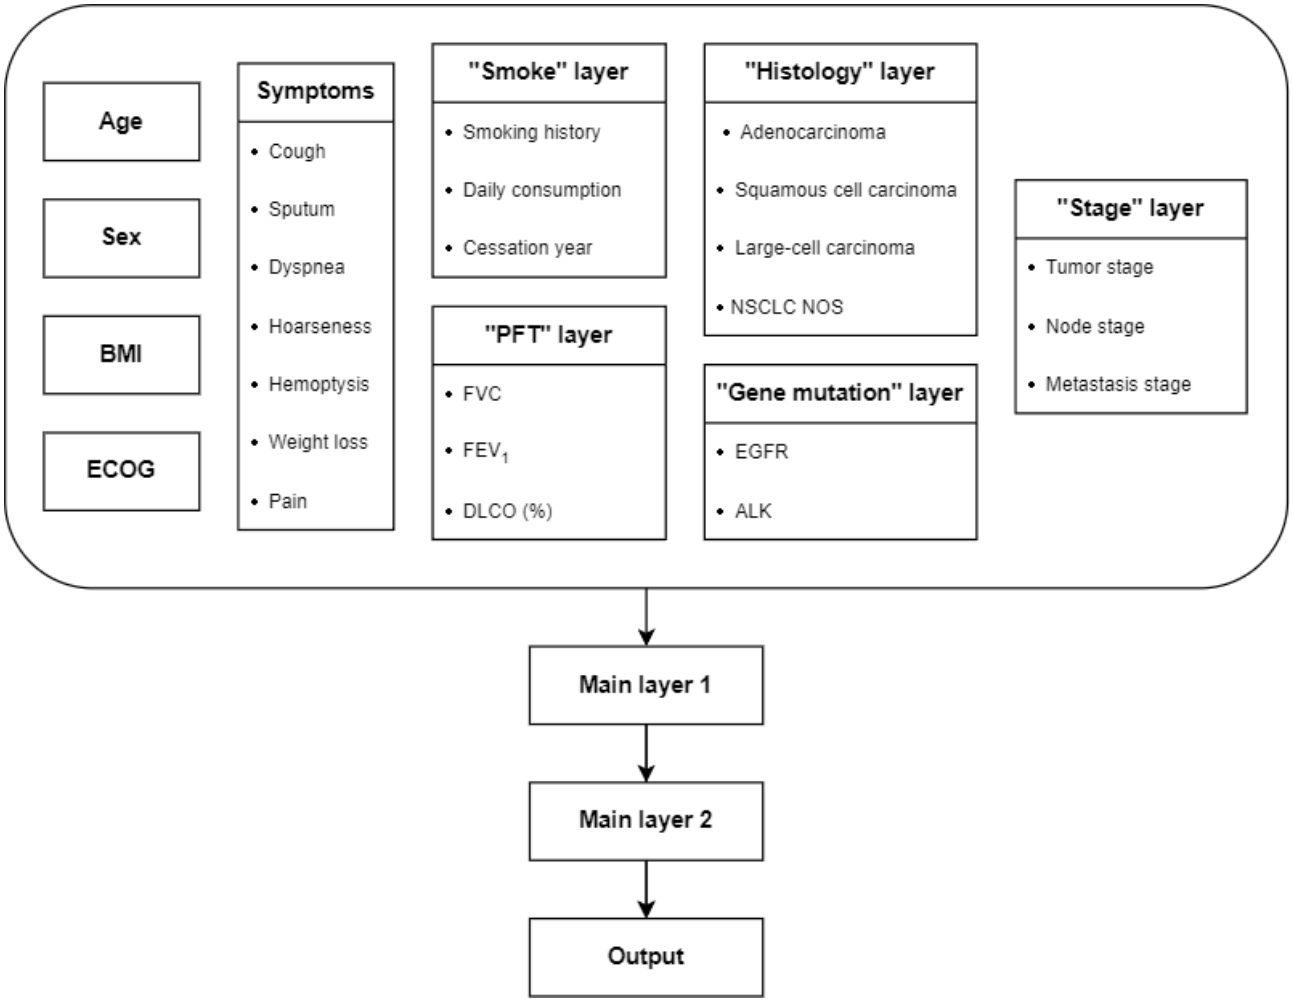
We obtained data from the KCCR nationwide lung cancer staging survey, which includes patients with NSCLC from 52 hospitals across South Korea. Records from patients diagnosed between 2014 and 2017 were used, excluding those with missing or uncertain information regarding TNM stage, gene mutations (EGFR or ALK), or diagnosis date. Patients with logically inconsistent smoking cessation dates (eg, a missing cessation date despite being recorded as a former smoker, a cessation date earlier than the smoking start date, or a cessation date later than the date of death) were also excluded. An Eastern Cooperative Oncology Group (ECOG) performance status recorded as "unknown" was recoded as 0. For records with "unknown" smoking history, the smoking amount and duration fields were also missing; therefore, these cases were recoded as never smokers. We used a complete-case approach for the core variables to avoid unverifiable imputation assumptions and ensure consistency across clinical feature domains. Because this approach may introduce selection bias, we compared baseline characteristics between included and excluded patients using absolute standardized mean differences (SMDs).

A comprehensive set of demographic and clinical variables was extracted from the original records, including age, sex, BMI (calculated from weight and height), smoking history, symptoms, ECOG performance status, pulmonary function test (PFT) results, clinical stage, and pathological features. For PFT variables, we included one-hot availability indicators derived from the PFT status field along with scaled continuous measurements. Unmeasured values (ie, when the test was not performed) were coded using a sentinel value to indicate nonavailability rather than physiologic zero. Smoking status was one-hot encoded, and quit duration was modeled as a continuous variable only for former smokers. We used a sentinel value for never smokers to denote "not applicable," whereas quit duration was set to 0 for current smokers. To assess the potential impact of recoding missing clinical information to the healthiest baseline, we additionally trained an "unknown-aware" version of our primary model in which "unknown" ECOG performance status and smoking history were retained as distinct categories. The same data splits, model architecture, and evaluation procedures were used for direct comparison.

Five-year mortality and survival were defined as an interval of at least 60 months between diagnosis and death or last follow-up. Patients who met this threshold were classified as 5-year survivors, whereas the others were categorized as nonsurvivors. Detailed preprocessing steps are summarized in Table S1 in Multimedia Appendix 1.

The resulting data were stratified by sex, age, smoking history, PFT status (performed or not), gene mutation status, and 5-year mortality. Accordingly, 70% of patients were allocated to the training dataset, 15% were allocated to the validation set, and 15% were allocated to the test set. Immediately before model training, all continuous variables were scaled to the range of 0 to 1 using min-max normalization, with parameters estimated solely from the training subset. The same transformation was then applied unchanged to the validation and test subsets. Categorical variables were one-hot encoded in a similar manner: the encoder was fitted on the training set and reused for the other sets. Symptoms and histology were recorded as binary indicators (0=absent; 1=present). Instead of encoding each variable separately, we combined the symptom and histology indicators into a single composite vector and applied one-hot encoding. EGFR and ALK mutation indicators were handled similarly, being merged into 1 vector prior to one-hot encoding.

Model Construction and Hyperparameter Tuning



A multilayer perceptron (MLP) was developed to predict 5-year mortality (Figure 1). The model consists of 2 primary layers preceding the output layer. Age, sex, BMI, ECOG score, and symptoms were directly input into the first main layer, whereas other features (eg, smoking status, PFT, stage, histology, and gene mutation) were grouped into dedicated sublayers. This grouped-input design mirrors clinically coherent feature domains, improving interpretability and enabling domain-level regularization (eg, group-specific widths and dropout) in the presence of correlated predictors; it also stabilizes training under sparsity and collinearity. The outputs from these sublayers were

XSL•FO
RenderX

then concatenated and fed into the first primary layer. All sublayers and primary layers used rectified linear unit activation functions, whereas the output layer used a sigmoid function for binary classification. Dropout and L2 regularization techniques were applied throughout these layers to reduce the risk of overfitting.

Our model was implemented in Python (version 3.12.5; Python Software Foundation) using TensorFlow (version 2.18; Google Brain Team) and scikit-learn (version 1.6.1; Google Summer of Code project). We used the Adam optimizer and binary cross-entropy loss for training. Hyperparameters were tuned using the Keras Hyperband tuner. We selected Hyperband because it efficiently explores large search spaces by allocating more epochs to promising configurations and aggressively pruning unpromising ones (successive halving with early stopping), thereby reducing computational cost and overfitting risk. The hyperparameters were evaluated across the following ranges: sublayer units (4, 8, or 16 for most features and 8, 16, or 32 for stage), main layer units (32, 64, or 128), dropout rates (0.30 - 0.50 in increments of 0.05), L2 regularization strength (λ in 10^{-6} to 10^{-3}; log scale), and learning rate (10^{-4} to 10^{-2}; log scale).

Figure 1. Grouped-input multilayer perceptron architecture for 5-year mortality prediction in non–small-cell lung cancer (NSCLC). Input variables were organized into clinically defined feature domains (demographics; symptoms; smoking variables; pulmonary function test [PFT] measurements; histology; gene mutation; and tumor, node, metastasis stage), processed through domain-specific input layers, and merged into shared hidden layers to generate the final prediction. ALK: anaplastic lymphoma kinase; DLCO: diffusion capacity of the lungs for carbon monoxide; ECOG: Eastern Cooperative Oncology Group performance status; EGFR: epidermal growth factor receptor; FEV_1: forced expiratory volume in 1 second; FVC: forced vital capacity; NOS: not otherwise specified.

Each candidate architecture was trained for up to 100 epochs, with successive Hyperband rounds retaining approximately the top one-third of models and granting them progressively larger training budgets. The optimization target was the area under the receiver operating characteristic curve (AUC), evaluated on the held-out validation cohort. During each trial, an early-stopping callback monitored the same metric and restored the best weights after 5 epochs without improvement. This approach helped prevent overfitting and reduced runtime. The batch size was fixed at 32. This configuration facilitated efficient evaluation of numerous hyperparameter combinations, allowing for the identification of a set that delivered robust performance with minimal overfitting.

Performance Evaluation

AUC was prespecified as the primary metric given outcome imbalance and its threshold-free nature; accuracy, precision, recall, F_1-score, and the area under the precision-recall curve (AUPRC) were reported for completeness. Each metric was calculated for the training, validation, and test datasets. We

XSL•FO
RenderX

estimated the 95% CIs through bootstrapping with 1000 resamples. Because our primary objective was to determine whether a patient survived for 5 years, AUC was regarded as the main criterion for performance evaluation and for detecting overfitting. The target for the test set was an AUC exceeding 0.800, with the difference in AUC between the training and test sets remaining below 0.05.

Cox proportional hazards (CPH) models were established as baselines for comparison using the same predictors. First, a full CPH model was fitted using the same set of predictors as the MLP models. In addition, a TNM-only CPH benchmark model was constructed using only the tumor, node, and metastasis variables to quantify the incremental predictive value of nonstaging clinical features beyond TNM staging. Predicted 5-year mortality probabilities were evaluated using the same set of discrimination and classification metrics across models, enabling direct performance comparisons between the CPH and MLP models.

Permutation-Based Feature Importance

A permutation-based approach was used to assess the importance of each feature (Figure 2). First, a baseline model was trained using the original test dataset to establish a reference AUC. Then, for each individual feature or feature group, we randomly permuted its variables 100 times while keeping the other features intact and retrained the model on each permuted dataset. The resulting AUC values were compared with the baseline AUC, and the average reductions across permutations were calculated to obtain a mean reduction. A greater reduction indicates a higher contribution of that feature group to the predictive performance of the model.

XSL•FO
RenderX

Figure 2. Schematic overview of the grouped-feature permutation importance procedure. For each clinically defined feature group, values were permuted, whereas the features in all other groups were held fixed, generating 100 permuted datasets. The trained model was evaluated on each dataset, and feature group importance was quantified as the decrease in area under the receiver operating characteristic curve (AUC) relative to the baseline (mean AUC drop across iterations).

The Friedman test using R (version 4.4.0; R Foundation for Statistical Computing) was conducted on the mean AUC reductions to assess consistency across multiple model configurations. This statistical test evaluates the rank order of feature group importance among models to determine whether significant differences in feature rankings exist. A *P* value below .05 was considered statistically significant.

Ethical Considerations

The institutional review board of Asan Medical Center approved this retrospective study (2025-0572; approval date: May 13, 2025). The requirement for written informed consent was waived by the institutional review board because this study involved secondary analysis of routinely collected registry data and posed minimal risk to participants. The investigators received a deidentified dataset from the KCCR and had no access to directly identifiable personal information. Data were analyzed in accordance with institutional policies on data security and confidentiality. No compensation was provided, as participants were not prospectively recruited and there was no direct contact with patients. The manuscript and supplementary materials do not include any images or information that could identify individual participants.

Results

Baseline Demographics of the Patients

A total of 8664 patients diagnosed with NSCLC from 2014 to 2017 were identified in the KCCR. Of these 8664 patients, 3144 (36.3%) had complete data suitable for analysis. Stratified sampling was conducted to assign patients to the training (2215/3144, 70.5%), validation (464/3144, 14.8%), or test (465/3144, 14.8%; Figure 3) groups. Additionally, 50 patients who lacked matching counterparts during stratification were included in the training set.

Figure 3. Flowchart of cohort selection and dataset splitting for a retrospective registry-based study of non–small-cell lung cancer (NSCLC) in South Korea using the Korea Central Cancer Registry (2014 - 2017). Of 8664 registered patients, 5520 (63.7%) were excluded due to missing tumor, node, metastasis (TNM) stage information; missing gene mutation data; uncertain smoking cessation year; or missing diagnosis date. The final analytic cohort included 3144 patients and was split using stratified sampling into training, validation, and test sets.

Patients' baseline characteristics are summarized in Table 1. Among the total cohort, 60.7% (1908/3144) of the participants were male. The median age at diagnosis was 66 (IQR 58 - 74) years. Most patients had an ECOG performance status of 0 (1902/3144, 60.5%), followed by a score of 1 (1023/3144, 32.5%). Table 2 presents details of the cancer-related characteristics. Most patients (2490/3144, 79.2%) were diagnosed with adenocarcinoma. Regarding stage, 35.4% (1113/3144) of the patients were diagnosed at stage 1, whereas the largest subgroup was those diagnosed at stage 4 (1282/3144, 40.8%). EGFR mutations were detected in 36.0% (1131/3144) of the patients, whereas ALK mutations were less common, occurring in 6.6% (209/3144) of the patients. A total of 42.9% (1350/3144) of the patients survived at least 5 years after diagnosis. There were no statistically significant differences in baseline characteristics among the training, validation, and test cohorts.

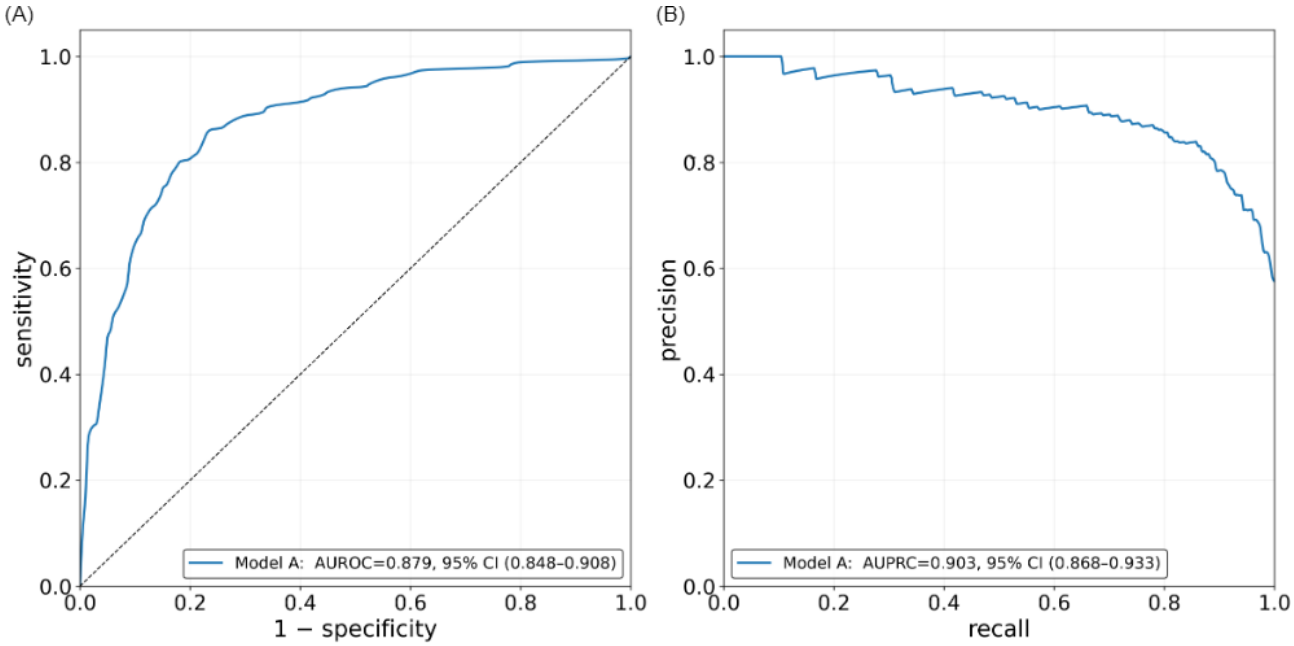
[b]Stage was classified according to the eighth edition of the American Joint Committee on Cancer staging system.

[c]EGFR: epidermal growth factor receptor.

[d]ALK: anaplastic lymphoma kinase.

Absolute SMD values for baseline characteristics between included and excluded patients are shown in Table S2 in Multimedia Appendix 1. Excluded patients had higher 5-year mortality than included patients (3793/5520, 68.7% vs 1794/3144, 57.1%; SMD 0.241) and were older (mean 68.4, SD 10.7 vs 65.5, SD 10.7 years; SMD 0.278).



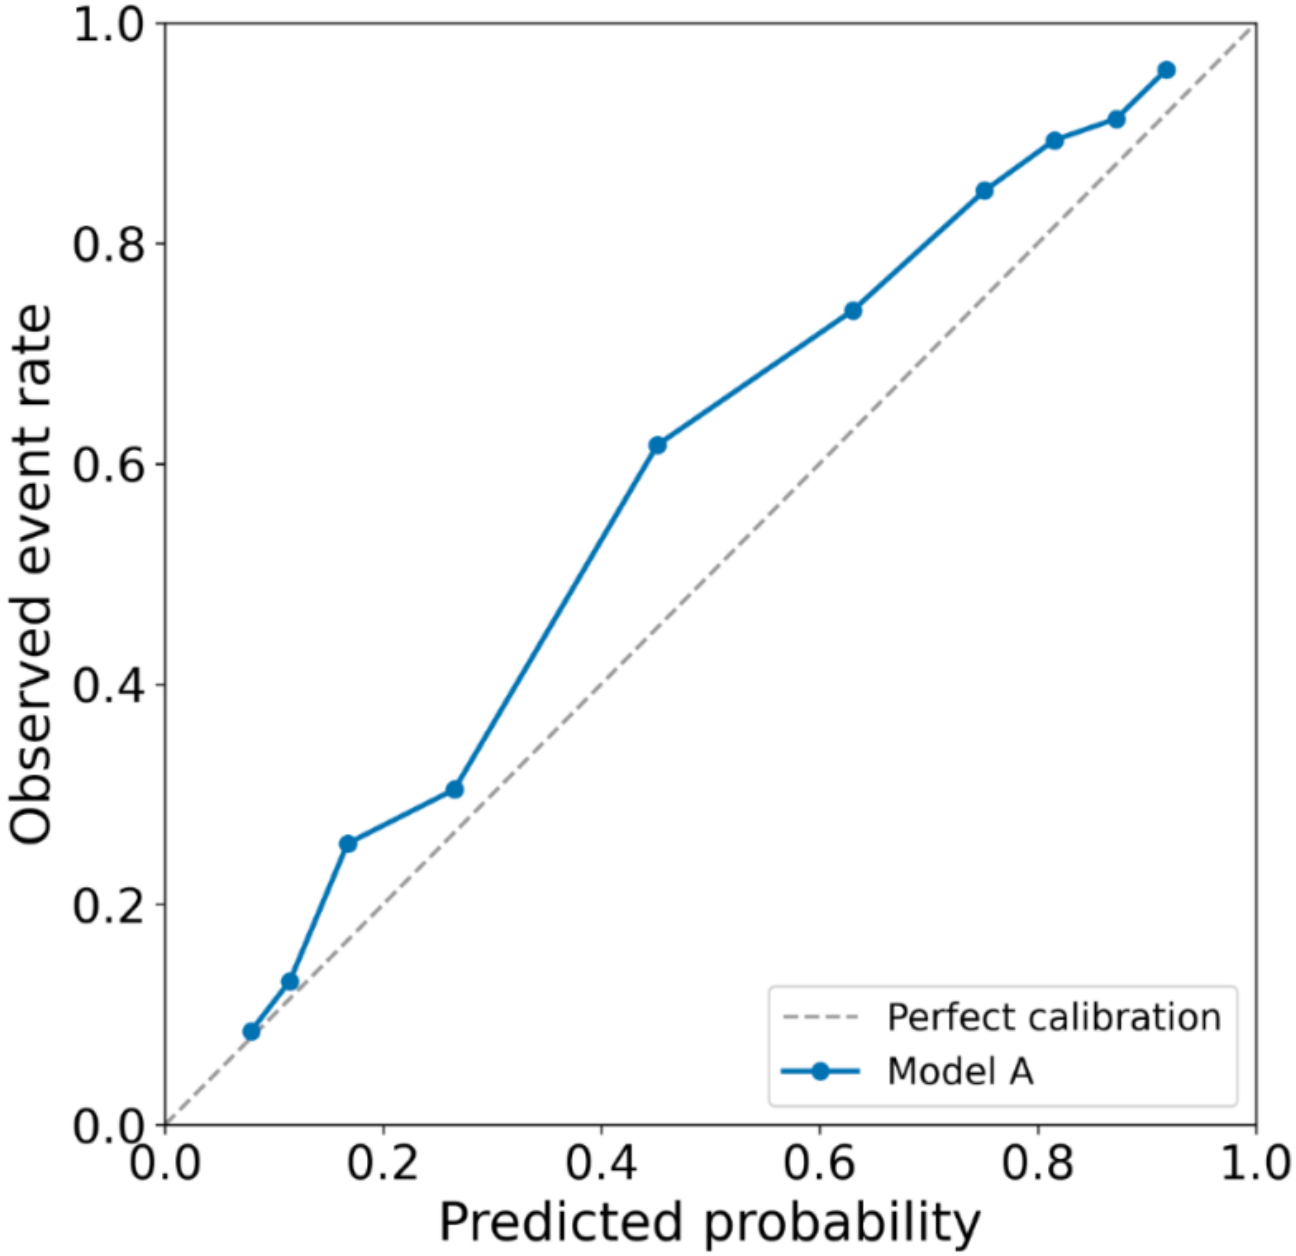
Training Models and Performance Evaluation

We selected 5 distinct hyperparameter configurations from the Hyperband optimization (Table S3 in Multimedia Appendix 1). For each configuration, we rebuilt the network using the corresponding tuned settings, retrained it on the training cohort, and evaluated its performance on both the training and test sets. During this process, we recorded a comprehensive set of performance metrics to facilitate direct comparisons across models. Each final model was serialized into a Keras file to ensure reproducibility and enable downstream inference. Each file contained the complete network architecture, learned weights, and optimizer state, allowing the model to be reloaded and applied with a single command in any compatible Python environment.

Of the 5 models, we designated model A as the primary model for reporting. On the held-out test set, model A achieved an AUC of 0.879 (95% CI 0.848 - 0.908), with an accuracy of 0.806 (95% CI 0.774 - 0.841) and an F_1-score of 0.824 (95% CI 0.788 - 0.858). The AUC and AUPRC of model A are shown in Figure 4. Model A also demonstrated reasonable calibration on the test set (Figure 5), with a Brier score of 0.142. Model U (unknown-aware encoding) achieved a test AUC of 0.865 (95% CI 0.830 - 0.897), corresponding to a small decrease compared with model A (ΔAUC=−0.014, 95% CI −0.025 to −0.003). Other discrimination and classification metrics showed similarly small differences (Table S4 in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 4. Discrimination performance of model A on the test set: (A) receiver operating characteristic curve and (B) precision-recall curve. AUPRC: area under the precision-recall curve; AUROC: area under the receiver operating characteristic curve.

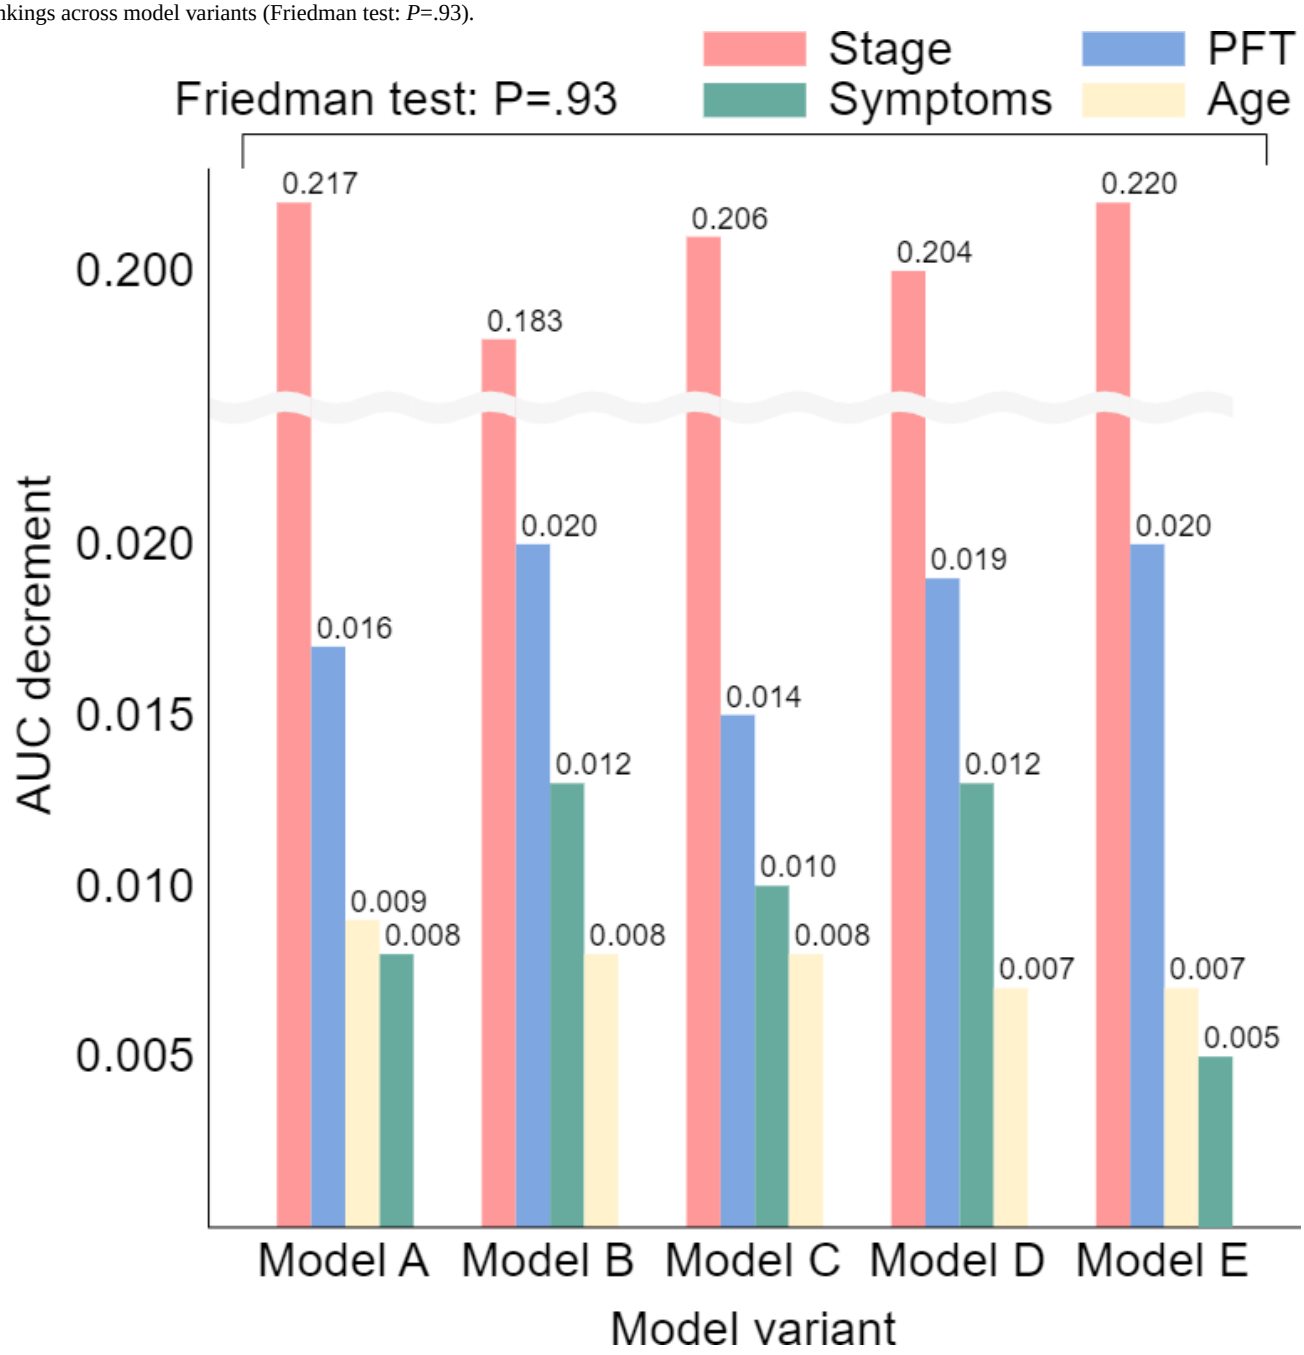


Figures S1 and S2 in Multimedia Appendix 1 show the discrimination performance and calibration curves of the 5 models on the test set. Across models A to E, performance was highly consistent, with AUC ranging from 0.875 to 0.879 and AUPRC ranging from 0.894 to 0.903. The CPH model exhibited similar performance, with an AUC of 0.878 (95% CI 0.844 - 0.908). The TNM-only CPH benchmark model yielded a lower test AUC of 0.845 (95% CI 0.806 - 0.880). Table S5 in Multimedia Appendix 1 provides the complete set of discrimination and classification metrics for all models, including both CPH baselines (full and TNM only). Brier scores for models A to E were also similar (approximately 0.140; Table S6 in Multimedia Appendix 1), indicating comparable calibration across model variants.

We evaluated within-stage discrimination for the primary model (model A). Within-stage performance was generally clinically meaningful in stages 1, 3, and 4 (AUC of 0.753, 95% CI 0.653 - 0.844 in stage 1; 0.722, 95% CI 0.569 - 0.855 in stage 3; and 0.725, 95% CI 0.625 - 0.825 in stage 4). Stage 2 exhibited the lowest AUC and a wide 95% CI (0.642, 95% CI 0.471 - 0.796). Detailed within-stage performance metrics for models A to E are summarized in Table S7 in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 5. Calibration plot of model A on the test set. The dashed diagonal line indicates perfect calibration.



Feature Permutation and Changes in AUC

We conducted grouped-feature permutation analyses to assess feature importance. Stage yielded the largest decrease in AUC (0.217, 95% CI 0.212 - 0.221), indicating this feature's predominant contribution. PFT ranked second (0.016, 95% CI 0.015 - 0.017), followed by age (0.009, 95% CI 0.009 - 0.010) and symptoms (0.008, 95% CI 0.007 - 0.008). The permutation-based importance hierarchy was highly consistent across the 5 model variants (Figure 6 and Table S8 in Multimedia Appendix 1). A Friedman test showed no statistically significant differences in importance rankings across models (P=.93).

Feature importance was analyzed separately by histologic subtype (Table S9 in Multimedia Appendix 1). Discrimination was higher in the adenocarcinoma cohort than in the squamous cell carcinoma cohort. Within adenocarcinoma, gene mutation showed a larger decrease in AUC than in the overall analysis (0.003, 95% CI 0.003 - 0.003), a pattern that was consistent across all 5 model variants. This pattern was not observed in the squamous cell carcinoma cohort.

XSL•FO
RenderX

Figure 6. Mean decrease in test set area under the receiver operating characteristic curve (AUC) after grouped feature permutation across the 5 model variants (models A-E). Stage produced the largest decrease in AUC, followed by pulmonary function test (PFT), symptoms, and age, with consistent rankings across model variants (Friedman test: *P*=.93).

Discussion

Overall Findings

Using the nationwide KCCR lung cancer cohort, we developed and validated a grouped-input deep learning model to predict 5-year mortality in NSCLC. We ensured reproducibility and minimized data leakage by implementing stratified training, validation, and test splits, with all preprocessing confined to the training set. On the test set, model A demonstrated strong discrimination and reasonable calibration. Across the 5 Hyperband-tuned model variants, test set performance (AUC=0.875 - 0.879) and grouped-feature permutation profiles were highly consistent, supporting the robustness of the proposed framework.

Model Performance

The grouped-input deep learning model demonstrated statistically comparable discrimination to that of a conventional CPH model built on the same routine clinical variables. This finding suggests that, for low-dimensional tabular clinical data without multimodal integration, complex neural network architectures may offer limited incremental benefit over interpretable regression-based approaches [17,18]. Taken together, these results reinforce that model complexity should be guided by data structure rather than architectural novelty. In this context, our findings are best interpreted as a methodological comparison rather than evidence that deep learning is inherently superior for 5-year mortality prediction using registry-based clinical features alone. Nevertheless, deep

XSL•FO
RenderX

learning architectures can model nonlinear interactions and readily integrate radiological or molecular data. Consistency across the 5 Hyperband-tuned model variants supports the robustness of the preprocessing pipeline, suggesting that the proposed framework provides a stable foundation for future multimodal extensions.

Importantly, our model is a baseline prognostic model and does not explicitly incorporate treatment exposures, which can substantially modify survival. Thus, predicted risk represents an average prognosis across heterogeneous treatment pathways in the cohort and should not be interpreted as a treatment-conditional estimate.

Although the TNM-only benchmark yielded lower overall discrimination (AUC=0.845, 95% CI 0.806 - 0.880), we further assessed model performance within each stage to evaluate whether nonstaging variables retained discriminatory value when staging information was held constant. Our within-stage analysis indicates that the model provides prognostic discrimination beyond TNM staging alone. Within-stage performance was favorable in stages 1, 3, and 4 (AUCs generally of >0.700). In contrast, discrimination in stage 2 was lower and imprecise, with wide CIs that in some cases crossed 0.50, likely reflecting the small sample size in this subgroup. This may also partly reflect unmeasured heterogeneity in treatment pathways within stage 2, which could not be explicitly modeled due to incomplete treatment data. Prior validations of the TNM system have shown that revisions from the seventh to the eighth and ninth editions of the American Joint Committee on Cancer staging system yielded only modest gains in discriminatory ability and overall prognostic separation remained limited [19,20]. Although the model demonstrated incremental prognostic value beyond stage in the overall cohort, discrimination within stage 2 was modest (AUC=0.642). The relatively small sample size of stage 2 patients may have contributed to wider CIs and statistical instability; however, even accounting for this uncertainty, the current performance suggests that the model is not sufficiently robust for clinical risk stratification in stage 2 NSCLC. Additional prognostic variables and external validation would likely be required to improve reliability in this subgroup.

Recent studies have used diverse machine learning techniques to predict lung cancer survival, with reported AUCs ranging from approximately 0.650 to 0.800 [11,21]. In many of these investigations, tree-based ensembles such as random forests and Extreme Gradient Boosting reported stronger discrimination than simple deep learning methods [22-24]. Nevertheless, because of their ability to integrate heterogeneous inputs, researchers continue to explore deep learning models in NSCLC. For example, Lai et al [25] combined biomarker and clinical data, achieving an AUC of 0.816 with an accuracy of 0.754. Wang et al [26] reported an AUC of 0.715 using a similar multimodal design. In contrast, Hindocha et al [23] developed an ensemble model based solely on clinical variables, which reached an AUC of 0.717. By comparison, our models—despite relying exclusively on routine clinical features—produced AUCs exceeding 0.875 and accuracies of approximately 0.800. These differences may reflect a combination of factors, including the grouped-input design (which mitigates sparsity, shares weights within clinically coherent groups, and captures nonlinear relationships) [27,28], rigorous leakage control, and large multicenter settings. Deep learning models trained on substantially smaller cohorts frequently show weaker discrimination and greater overfitting tendencies [11]. However, cross-study comparisons should be interpreted cautiously due to heterogeneity in cohorts, end points, and validation protocols.

Permutation-Based Feature Importance

Permutation-based importance analysis showed that stage was the dominant predictor of mortality, followed by PFT, symptoms, and age, consistent with earlier studies [29-33]. Because permutation importance can undervalue variables that are correlated with a single dominant predictor, this dominance may have led to a relative underestimation of other clinically relevant features [21,34,35]. To minimize such bias, variables were permuted at the group level rather than individually [36]. However, interpretation requires caution. For example, PFT included not only spirometric measurements (forced vital capacity, forced expiratory volume in 1 second, and diffusion capacity of the lungs for carbon monoxide) but also indicators of test availability. Given our sentinel-based encoding for unmeasured PFTs, the apparent importance of PFT may partly capture care process information (eg, workup completeness or surgical candidacy) rather than the prognostic effect of lung function values themselves. This likely reflects a characteristic of real-world registry data, in which diagnostic testing patterns may be correlated with clinical severity and treatment eligibility. Accordingly, feature importance in this context should not be interpreted as reflecting the independent prognostic effect of spirometry alone but rather as a combination of lung function measurements and care-related factors.

Smoking-related variables and histology exhibited only modest marginal importance, which is consistent with the feature distribution imbalance of the cohort (a high prevalence of never smokers and adenocarcinoma), reducing variability in smoking metrics and limiting representation of squamous or large-cell carcinoma [37,38]. The relatively low importance of BMI is compatible with the reported “obesity paradox,” in which risk appears nonlinear and a single baseline measurement may dilute the marginal effect [39,40]. We also evaluated whether model-level factors could bias these rankings. The 5 models were trained using distinct hyperparameter settings, including different dropout rates and different numbers of hidden units in the feature group–specific layers. Although such differences can influence importance estimates [41], the rankings were highly concordant across models, suggesting that any bias from hyperparameter choices was negligible.

This study examined the importance of gene mutations within histological subgroups. In adenocarcinoma, gene mutation became modestly more influential than in the overall analysis, with EGFR consistently surpassing ALK across all 5 models. In contrast, neither mutation provided meaningful predictive value in squamous cell carcinoma. Although both EGFR and ALK have clear therapeutic relevance in NSCLC as targets of tyrosine kinase inhibitors, their apparent prognostic contributions can vary by histology and prevalence [2,42]. Our findings align with those of previous reports in which EGFR was associated

XSL•FO
RenderX

with more favorable outcomes in adenocarcinoma, whereas ALK mutations were less frequent and exhibited weaker associations with survival [42-44]. Because squamous cell carcinoma rarely harbors either mutation and is associated with intrinsically poorer outcomes [44], effect estimates in this subgroup are inherently uncertain. Moreover, residual confounding by therapy exposure cannot be excluded in the absence of treatment-level data. Different patterns may emerge in cohorts with larger proportions of squamous cell carcinoma or higher ALK mutation frequencies.

Limitations

This study has several limitations. First, it was a retrospective analysis limited to a Korean cohort; interethnic differences in EGFR mutation prevalence, histology, and smoking patterns may affect generalizability [45,46]. Second, registry-based data have inherent constraints. Because our cohort was diagnosed between 2014 and 2017, key biomarkers (eg, KRAS mutation, programmed death-ligand 1, and tumor mutational burden) and detailed treatment variables were not routinely available or consistently recorded. As a result, the absolute mortality estimates generated by our model may be higher than those observed under contemporary treatment standards, and model calibration may shift in more recent patient populations. Therefore, external validation and potential recalibration in temporally distinct cohorts will be necessary before clinical implementation. Third, "unknown" values for ECOG status and smoking history were recoded to default categories to enable complete input vectors. If these values were not missing at random, this preprocessing step might have introduced optimistic bias in survival prediction. Fourth, although the overall sample size was large, some subgroup analyses were underpowered. Notably, the stage 2 subgroup in the test set was small (46/465, 9.9%) with wide CIs, some of which crossed 0.50. This is particularly important because stage 2 represents a key clinical decision point for adjuvant therapy. Fifth, although we compared our model with a conventional CPH model, we did not conduct extensive benchmarking against multiple strong tabular learners; therefore, comparative performance across alternative tabular modeling approaches should be interpreted cautiously. Because TNM stage dominated permutation-based importance, residual correlation-related bias cannot be excluded and may attenuate the apparent importance of correlated predictors. Finally, our evaluation relied on internal validation within a single registry split. As a result, the transportability of the model across different health care systems, patient populations, and treatment eras remains uncertain. Given these constraints, external validation in an independent cohort is required to assess both discrimination and calibration stability before clinical deployment or widespread adoption.

Conclusions

In this study, a deep learning model based on the nationwide lung cancer staging dataset from the KCCR demonstrated performance comparable to that of a conventional CPH model and previously reported machine learning methods. By aligning inputs with clinically coherent groups and quantifying contributions through permutation-based, group-level importance, the framework provides transparent and reproducible explanations using routine clinical variables. These features position the model as a practical foundation for future clinical evaluation and integration of additional modalities such as imaging or molecular data in more complex predictive settings. Future work should include external validation in independent and temporally distinct cohorts as well as prospective evaluation of clinical utility before routine clinical implementation.

Acknowledgments

The data used in this study were obtained from the Korea Central Cancer Registry supported by the Korean Association for Lung Cancer. During preparation of this manuscript, the authors used generative artificial intelligence tools ChatGPT (OpenAI; models GPT-4o, o3, and GPT-5.2) to assist with code revision and organize ideas. No artificial intelligence–generated text was used verbatim in the manuscript. The authors take full responsibility for the content, analyses, interpretation, and conclusions. Abstract

Background: Parkinson disease frequently manifests early vocal impairment, motivating the development of noninvasive and scalable digital screening tools.

Objective: This study proposes a multiview spectrogram-based deep learning framework integrating recognition-aware context for Parkinson disease detection from voice recordings.

Methods: Voice recordings from 203 participants (121 with Parkinson disease and 82 healthy controls) were collected prospectively. Three spectrogram representations (Mel, short-time Fourier transform, and constant-Q transform) were extracted and processed through parallel convolutional neural network branches. A recognition ratio (RR) feature vector derived from automatic speech recognition transcript agreement was optionally fused with spectrogram embeddings. Models were evaluated using strict subject-wise 5-fold cross-validation.

Results: Multiview spectrogram recognition-aware Parkinson detection network achieved a mean test accuracy of 86.9% (SD 25.2%) using 3-view spectrogram fusion, improving to 97.4% (SD 5.7%) when incorporating the RR feature. RR integration reduced the false negative rate by approximately 84.5%, substantially improving sensitivity in screening-oriented settings.

Conclusions: Combining multiview spectrogram learning with recognition-aware context significantly enhances voice-based Parkinson disease classification under leakage-free evaluation. These findings support the potential of this approach for noninvasive screening in structured recording settings, while further validation in diverse real-world environments is needed.

KEYWORDS

Parkinson disease; voice-based screening; multiview spectrogram; deep learning; multiview learning; automatic speech recognition

Introduction

Parkinson disease is a neurological condition that progresses over time and manifests with various motor and nonmotor symptoms [1]. There is an increasing need for accurate health informatics systems to support its identification because early detection can improve clinical outcomes and enable timely intervention. Automated screening tools can also reduce the workload for clinicians and support large-scale monitoring [2,3]. Among accessible sensing modalities, vocal impairment is one of the most prevalent early symptoms, and voice-based assessment has become an important direction for Parkinson disease identification research [4-6].

Speech impairments are highly prevalent in Parkinson disease and may involve both speech production and language-related difficulties [7]. Clinically, these impairments encompass reduced vocal loudness (hypophonia), imprecise articulation, a monotone or breathy voice quality, and festinating speech, all of which reflect the combined effects of motor rigidity, bradykinesia, and reduced respiratory drive on the phonatory system [8]. Increasing evidence suggests that speech and language abnormalities can emerge prior to prominent motor signs and

XSL•FO
RenderX

formal diagnosis [9]. Consequently, speech and language pathology has been recognized in clinical guidelines as a crucial component of Parkinson disease care from the early stage of diagnosis [8]. Recent research highlights the potential of objective acoustic markers to identify Parkinson disease in early or prodromal stages, creating a therapeutic window for early intervention [10,11]. Speech and language characteristics can also serve as surrogate markers for tracking disease progression [12], and distinct patterns of impairment have been linked to Parkinson disease subtypes and related movement disorders, supporting differential diagnosis using voice biomarkers [13-15].

Earlier studies in Parkinson disease voice analysis primarily relied on handcrafted acoustic features such as jitter, shimmer, harmonics-to-noise ratio, and Mel-frequency cepstral coefficients, combined with supervised classifiers such as support vector machines, random forests, or gradient-boosted trees [16,17]. More recent studies extend this paradigm through improved feature selection, interpretable machine learning, and cross-corpus evaluation [17-19]. Despite these advances, many approaches still depend on manually engineered descriptors and may underuse the richer structure present in the speech signal. To better capture Parkinson disease–related phonatory and articulatory cues, many groups transform audio into time-frequency representations and apply convolutional neural networks (CNNs) or transformer models directly to spectrograms [20,21]. Spectrogram features combined with artificial intelligence models have achieved strong performance for early diagnosis, supporting the clinical viability of spectrogram-driven approaches [22].

Despite these advances, most models still operate on a single spectrogram view. This is a limitation because different time-frequency representations emphasize complementary aspects of the signal: the short-time Fourier transform (STFT) provides a linear frequency axis with uniform resolution, Mel spectrograms approximate human auditory spacing and emphasize low-to-mid frequencies, and the constant-Q transform (CQT) yields a logarithmic frequency grid that can better represent harmonic and pitch-related patterns relevant to the vocal tremor and dysphonia observed in Parkinson disease. Prior research works in audio and biomedical sound classification show that fusing multiple spectrogram representations can yield more discriminative embeddings than any single representation alone [23-25]. For Parkinson disease speech, however, multispectrogram fusion remains underexplored [26,27].

A second challenge is data scarcity and overfitting. Even recent cohorts often include only a few dozen to a few hundred participants, and many studies rely on highly reused benchmark datasets. Previous studies have emphasized concerns, such as participant overlap between training and evaluation sets and optimistic performance estimates, that hinder clinical translation [16,28]. To address these issues, our study emphasizes strict participant-wise separation, controlled preprocessing, consistent model comparisons, and ablation-based analysis.

Finally, global context–based and recognition-based voice features are rarely integrated into voice-based Parkinson disease classification models. Digital biomarker research increasingly highlights the value of multimodal and metadata-informed fusion for stabilizing predictions [29-31]. For voice, a compact recognition-based feature vector can be derived from the same speech recording, referred to here as the recognition ratio (RR). Intuitively, the RR measures how accurately an automatic speech recognition system can transcribe what a participant said: a high RR indicates clear, intelligible speech, whereas a low value reflects speech that is difficult for the system to parse—consistent with the articulatory and phonation difficulties clinically observed in Parkinson disease [7]. People with Parkinson disease may experience difficulty in clearly pronouncing sentences, which can reduce speech intelligibility and articulation clarity. As a result, the RR can serve as a global, recording-level indicator of intelligibility, providing complementary context to the local spectro-temporal patterns learned from spectrograms. Such recognition-aware integration strategies remain uncommon in voice-based Parkinson disease classification models. From a clinical perspective, these speech abnormalities are directly reflected in acoustic representations of voice. Time-frequency spectrograms can capture changes in vocal intensity, pitch stability, and articulation patterns associated with Parkinson disease speech impairment, while the RR provides a complementary measure of speech intelligibility at the utterance level [7,8,22]. Therefore, combining multiview spectrogram features with recognition-aware information allows the model to capture both local acoustic patterns and global intelligibility deficits that are clinically relevant in Parkinson disease.

In this study, we propose a multiview spectrogram-based deep architecture for noninvasive Parkinson disease screening from voice. From each recording, we derive 3 normalized spectrogram types (Mel, STFT, and CQT) and feed them into parallel CNN branches whose outputs are concatenated. We further introduce a low-dimensional RR vector computed from the same audio but outside the image domain and concatenate it with the spectrogram-based representation to provide global context. Model evaluation is performed under participant-wise cross-validation with strict separation of speakers between folds.

The contributions of this study are 3-fold:

1. A multibranch CNN architecture is introduced that exploits Mel, STFT, and CQT spectrograms through parallel branches, and multiview feature concatenation is shown to improve performance compared with single-view models and recent spectrogram-based baselines.
2. The effect of recognition-based features is evaluated by integrating a low-dimensional RR vector as lightweight global context. Performance gains are quantified using accuracy, precision, recall, F_1-score, and area under the receiver operating characteristic curve, demonstrating that contextual information can stabilize Parkinson disease voice classification.
3. A unified benchmark comparison is presented between classical acoustic feature machine learning baselines and spectrogram-based CNNs using a consistent participant-wise protocol. Comparison with recent state-of-the-art deep learning methods is also provided to contextualize the approach within the broader literature.

Methods

Dataset

A total of 203 participants were enrolled, including 121 individuals diagnosed with Parkinson disease and 82 healthy controls. The Parkinson disease group comprised 53 female participants and 68 male participants, while the healthy control group comprised 50 female participants and 32 male participants. The mean age was 68.7 (SD 8.9) years in the Parkinson disease group and 65.3 (SD 9.8) years in the healthy control group. Disease severity was assessed using the MDS-UPDRS-III (Movement Disorder Society–Sponsored Revision of the Unified Parkinson Disease Rating Scale) score (range 3 - 55; mean 26.7, SD 10.6, and median 25.5, IQR 19.0-34.0). Of these, 192 participants (112 with Parkinson disease and 80 healthy controls) had complete and usable audio recordings across all required speech tasks and were included in model training and evaluation. Eleven participants (9 with Parkinson disease and 2 healthy controls) were excluded due to missing recordings or data quality issues identified in the source dataset. Table 1 summarizes participant characteristics.

Recordings were collected in a hospital inspection room using a Samsung Galaxy Tab S7 FE positioned approximately 30 cm from the participant's mouth. Audio was recorded in MP3 format at 48 kHz (32-bit) and converted to WAV format prior to preprocessing. The speech protocol included 2 tasks: sustained vowel phonation of /a/ (Task 1) and reading 20 sentences comprising 10 nonmeaningful and 10 meaningful sentences (Task 2). The 20 sentence-reading items are indexed as test cases 1 - 20; test cases 1 - 10 correspond to nonmeaningful utterances, and test cases 11 - 20 correspond to meaningful sentences.

Table . Summary of study population characteristics.

Characteristic	PD[a] group (n=121)	HC[b] group (n=82)
Sex

[a]PD: Parkinson disease.

[b]HC: healthy control.

[c]MDS-UPDRS-III: Movement Disorder Society–Sponsored Revision of the Unified Parkinson Disease Rating Scale.

[d]Not applicable.

Audio Preprocessing

Preprocessing was performed for 2 components: (1) time-frequency spectrogram representations used as CNN inputs, and (2) RR features used as the recognition-aware component. Each recording was standardized in the time domain (resampling to a fixed sampling rate, mono conversion, and conservative trimming), converted into 3 time-frequency views (Mel, CQT, and STFT), log-compressed, normalized using training-fold statistics, and resized to 128×128 grayscale images for network input. Detailed spectrogram normalization equations are provided in Multimedia Appendix 1. All normalization parameters were estimated using only the training subset within each fold and applied unchanged to the validation and test subsets to prevent data leakage.

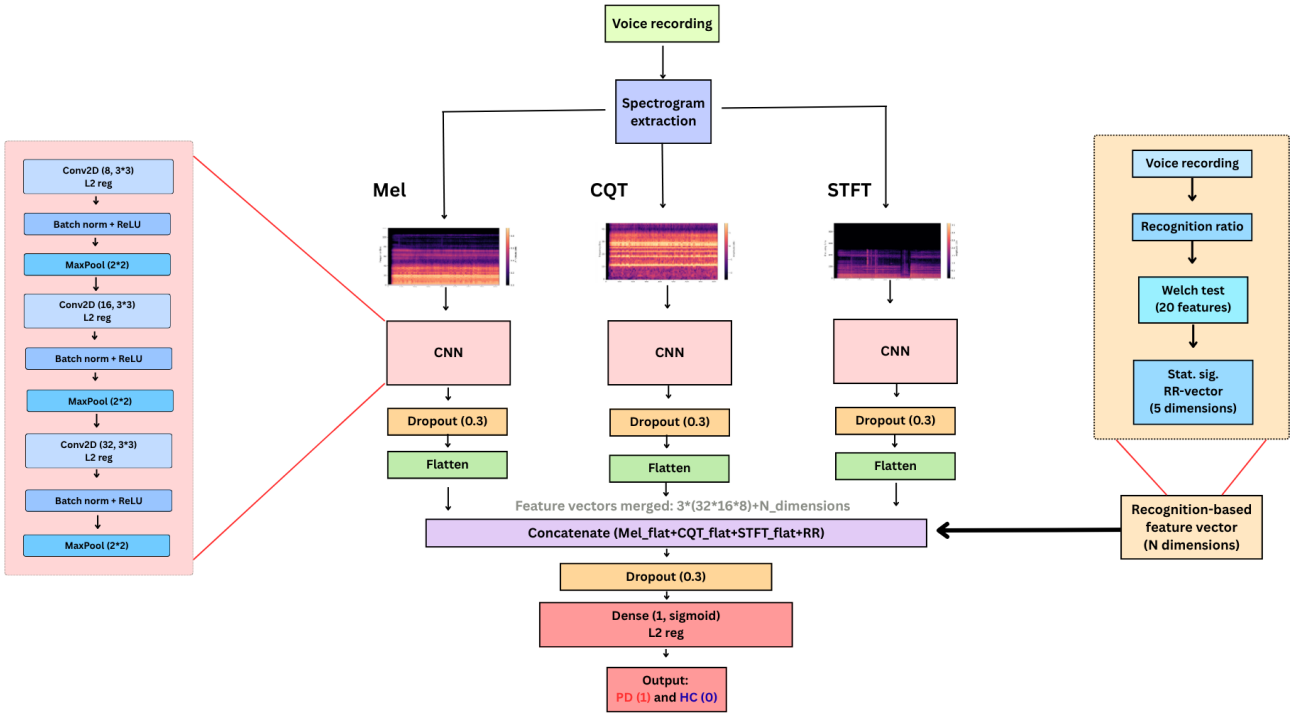
Audio files were loaded from WAV format and processed using librosa [32]. The Mel representation used 128 Mel bands, a fast Fourier transform size of 2048, Hann window length of 2048, and a hop length of 512. The CQT used a hop length of 512, a minimum frequency of approximately 32.7 Hz, 12 bins per octave, and 84 frequency bins. The STFT used a fast Fourier transform size of 2048, Hann window length of 2048, and a hop length of 512. Modality-specific normalization (min-max for Mel, *z*-score for CQT, and robust scaling for STFT) was applied fold-wise using training statistics only (Multimedia Appendix 1).

To obtain the recognition-aware feature, we used RR, which provides an intuitive measure of how well an automatic speech recognition system understands the participant's speech. Higher RR values indicate clearer and more intelligible speech, whereas lower values reflect reduced speech clarity.

Speech intelligibility is frequently compromised in individuals with Parkinson disease due to the progressive deterioration of motor control underlying speech production [33,34]. This deterioration often results in decreased articulatory precision, particularly evident when producing phonetically complex utterances that demand fine-grained neuromuscular coordination [35,36]. To capture this clinically relevant dimension of speech, we incorporate RR as a complementary feature. The sentence-reading task used in this study was designed to encompass both contextually meaningful sentences and phonetically demanding word sequences, providing a suitable basis for RR to reflect the degree of articulatory impairment.

XSL•FO
RenderX

The RR was computed from the sentence-reading task by comparing the target transcript with the automatic speech recognition output using a normalized edit distance:



$$(1) RR(\%) = 100(1 - d_{edit}(y_{target}, y_{rec})|y_{target}|), RR(\%) \in [0,100]$$

where $d_{edit}(\cdot,\cdot)$ is the Levenshtein distance and $|y_{target}|$ is the number of characters in the target string. The RR is computed independently for each recording using only its corresponding speech input and target transcript, without using any information from other participants. Therefore, RR extraction does not introduce any data leakage between training and test sets. All normalization parameters for RR features are estimated using only the training subset within each fold and applied unchanged to validation and test subsets, consistent with the approach used for spectrogram normalization. RR was computed for each of the 20 test cases, and the resulting 20 values were concatenated to form a fixed-length feature vector per subject.

Model Architecture

To accurately classify Parkinson disease through recorded voice, we propose the multiview spectrogram recognition-aware Parkinson detection network (MSR-PDNet), which combines a multibranch CNN with a recognition-aware component derived from the RR. As illustrated in Figure 1, MSR-PDNet receives 3 normalized spectrogram images (Mel, CQT, and STFT) as parallel inputs. Each branch applies stacked 2-dimensional convolutional blocks (convolution, batch normalization, nonlinear activation, and pooling), followed by global pooling to produce a fixed-length embedding vector. The 3 embedding vectors are concatenated into a fused multispectrogram representation, followed by batch normalization and a compact classification head. The output uses a single sigmoid activation to produce the Parkinson disease probability $P(\text{PD} \mid x) \in [0, 1]$. In the full MSR-PDNet model, the RR feature vector is concatenated with the fused spectrogram representation before the classification head, providing lightweight recording-level intelligibility context that complements local spectro-temporal patterns. An ablated variant without RR was also trained under the same protocol.

Figure 1. Complete architecture of the proposed multiview spectrogram recognition-aware Parkinson detection network. CNN: convolutional neural network; CQT: constant-Q transform; HC: healthy control; L2 reg: L2 regularization; MaxPool: max pooling; PD: Parkinson disease; ReLU: rectified linear unit; RR: recognition ratio; Stat. Sig.: statistically significant; STFT: short-time Fourier transform.

Models were implemented using TensorFlow and Keras (v2.19.0) and trained with the Adam optimizer at a learning rate of $\eta=1\times10^{-4}$, binary cross-entropy loss, batch size of 16, and dropout of 0.3, for up to 40 epochs. Early stopping required a minimum of 20 epochs and stopped if the validation loss did not improve for 5 consecutive epochs.

Ethical Considerations

Voice recordings were obtained as part of a prospective clinical study conducted at the Department of Neurology, Inha University Hospital (Incheon, South Korea). The study protocol was approved by the Institutional Review Board of Inha University Hospital (IRB 2022-09-037). All experiments involving human participants were performed in accordance with relevant guidelines and regulations, and written informed consent was obtained from all participants and their legal guardians prior to participation. All collected data were deidentified before analysis. Participants were assigned unique study identification numbers, and only initials and study identification numbers were used during data collection and management. No compensation was provided to participants for their participation in this study.

XSL•FO
RenderX

Results

This section reports comparative results for MSR-PDNet against traditional machine learning and single-view CNN baselines, together with ablations over spectrogram views and the RR feature.

Experimental Setup

All models were evaluated using the same 5-fold participant-wise cross-validation protocol. In each fold, all spectrograms and RR feature vectors derived from a given participant were assigned exclusively to either the training or the held-out test set (no participant contributed data to both). For each fold, 80% of participants were used for training and 20% were held out for testing. Within each fold, class imbalance was addressed by bootstrap oversampling of the minority class in the training split only; the held-out test split remained unchanged. All experiments were executed on an Apple Silicon workstation (Apple M4).

Performance Metrics

Performance was evaluated on the held-out 20% test split using accuracy, precision, recall (sensitivity), F_1-score, and the area under the receiver operating characteristic curve. Parkinson disease was treated as the positive class with a decision threshold of 0.5. Standard confusion matrix counts (true positive [TP], true negative [TN], false positive [FP], false negative [FN]) were used to compute accuracy, precision, recall, and F_1-score:

(2)Accuracy=TP+TNTP+TN+FP+FN

(3)Precision=TPTP+FP

(4)Recall=TPTP+FN

(5)F1=2 (Precision×Recall)Precision+Recall

The false negative rate (FNR) was defined as FNR=1−Recall. Receiver operating characteristic curves were computed by sweeping the decision threshold, and the area under the curve was averaged across folds. All performance metrics are reported as mean (SD) across the 5-fold participant-wise cross-validation to reflect variability across folds.

Comparison With Traditional Acoustic Feature–Based Models

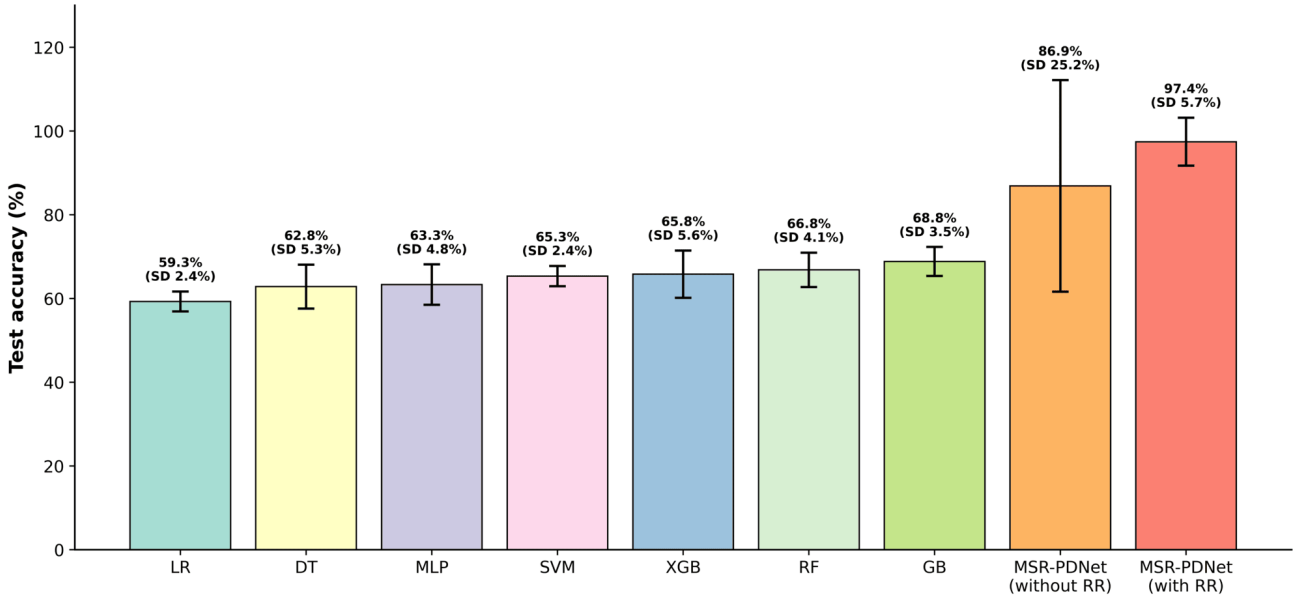
A reference baseline was established using traditional acoustic feature–based machine learning models trained on acoustic descriptors (pitch and loudness statistics, jitter, shimmer, Mel-frequency cepstral coefficient bands 1 - 4, and duration) under the same 5-fold participant-wise cross-validation protocol. Mean test accuracy ranged from 59.28% (SD 2.39% for logistic regression) to 68.83% (SD 3.47% for gradient boosting; Table 2; Figure 2).

Table . Traditional machine learning baselines trained on acoustic features: mean (SD) test accuracy under 5-fold cross-validation.

Model[a]	Test accuracy (%), mean (SD)
Logistic regression	59.28 (2.39)
Decision tree	62.83 (5.26)
MLP[b]	63.32 (4.82)
SVM[c] (RBF[d] kernel)	65.35 (2.43)
XGBoost[e]	65.81 (5.64)
Random forest	66.83 (4.10)
Gradient boosting	68.83 (3.47)

[a]Models are sorted in ascending order of mean test accuracy.

[b]MLP: multilayer perceptron.



[c]SVM: support vector machine.

[d]RBF: radial basis function.

[e]XGBoost: Extreme Gradient Boosting.

XSL•FO
RenderX

Figure 2. Mean test accuracy comparison between traditional machine learning baselines (acoustic features) and multiview spectrogram recognition-aware Parkinson detection network (with and without RR) under 5-fold cross-validation. DT: decision tree; GB: gradient boosting; LR: logistic regression; MLP: multilayer perceptron; MSR-PDNet: multiview spectrogram recognition-aware Parkinson detection network; RF: random forest; RR: recognition ratio; SVM: support vector machine; XGB: Extreme Gradient BoostIng.

The multilayer perceptron achieved 63.32% (SD 4.82%) mean test accuracy, representing the best-performing configuration under the experimental setup. Key hyperparameters, including the number of hidden layers, neurons per layer, learning rate, activation function, and dropout rate, were systematically tuned using validation performance within each fold. Despite this optimization, the performance of the multilayer perceptron remained lower than that of convolutional models, which may reflect differences in inductive bias. Convolutional architectures are better suited to exploit spatial structure in spectrogram representations, whereas the multilayer perceptron operates on flattened feature vectors.

MSR-PDNet achieved mean test accuracy of 86.9% (SD 25.2%) without RR and 97.4% (SD 5.7%) with RR (Figure 2). The 97.4% result is 38.12 percentage points higher than logistic regression (mean 59.28%, SD 2.39%) and 28.57 percentage points higher than gradient boosting (mean 68.83%, SD 3.47%).

Ablation Study on Spectrogram Representations

Ablation results quantify the impact of individual spectrogram views, 2-view fusion, and the RR on classification performance. Single-branch CNN baselines achieved mean test accuracies of 82.3% (SD 13.7% for STFT-only), 80% (SD 16.6% for Mel-only), and 76.9% (SD 11.6% for CQT-only; Table 3; Figure 3). The 3-branch fusion model achieved 86.9% (SD 25.2%) mean test accuracy using spectrograms alone, which is 4.6 percentage points higher than the best single-branch baseline. Incorporating the RR increased accuracy to 97.4% (SD 5.7%; +10.5 percentage points).

Two-branch ablations yielded 65.6% (SD 5.6%, without CQT; Mel and STFT), 61.0% (SD, 8.9%, without STFT; Mel and CQT), and 60.9% (SD 14.5%, without Mel; CQT and STFT; Table 4; Figure 4).

Table . Single-branch convolutional neural network baselines and MSR-PDNet variants under 5-fold cross-validation. Results are reported as mean (SD).

Model	Accuracy (%), mean (SD)	Precision (%), mean (SD)	Recall (%), mean (SD)	F_1-score (%), mean (SD)	ROC-AUC[a] (%), mean (SD)
CQT[b]-only	76.9 (11.6)	85.7 (10)	74.6 (22.2)	77.7 (13.6)	83.2 (8.2)
Mel-only	80 (16.6)	88.1 (7.2)	74.4 (25.1)	79.5 (18.1)	81.9 (12)
STFT[c]-only	82.3 (13.7)	86.9 (8.8)	81 (20.7)	83.1 (14.3)	83.7 (11.8)

Figure 4. Ablation: mean test accuracy of 2-branch fusion variants and MSR-PDNet (with or without RR) under 5-fold cross-validation. CQT: constant-Q transform; MSR-PDNet: multiview spectrogram recognition-aware Parkinson detection network; RR: recognition ratio; STFT: short-time Fourier transform.

Notably, the spectrogram-only MSR-PDNet configuration showed substantially higher variability across folds (mean 86.9%, SD 25.2%) than the RR-augmented model (mean 97.4%, SD 5.7%), indicating that the recognition-aware feature improves not only accuracy but also stability under participant-wise cross-validation.

Effect of Recognition-Aware Information on Parkinson Disease Classification

To examine whether RR differs between groups, the Parkinson disease and healthy control groups were compared using Welch 2-tailed *t* test independently for each of the 20 test cases. Five test cases showed statistically significant differences at $P<.05$: test cases 2, 10, and 18 - 20 (Table 5). Two test cases (10 and 19) remained significant after Bonferroni correction. Concentrating on significant test cases increased the Dunn index from 0.0570 (all test cases) to 0.1640 (significant test cases only), corresponding to a 2.88× increase in cluster separability (Figure 5; Figure 6).

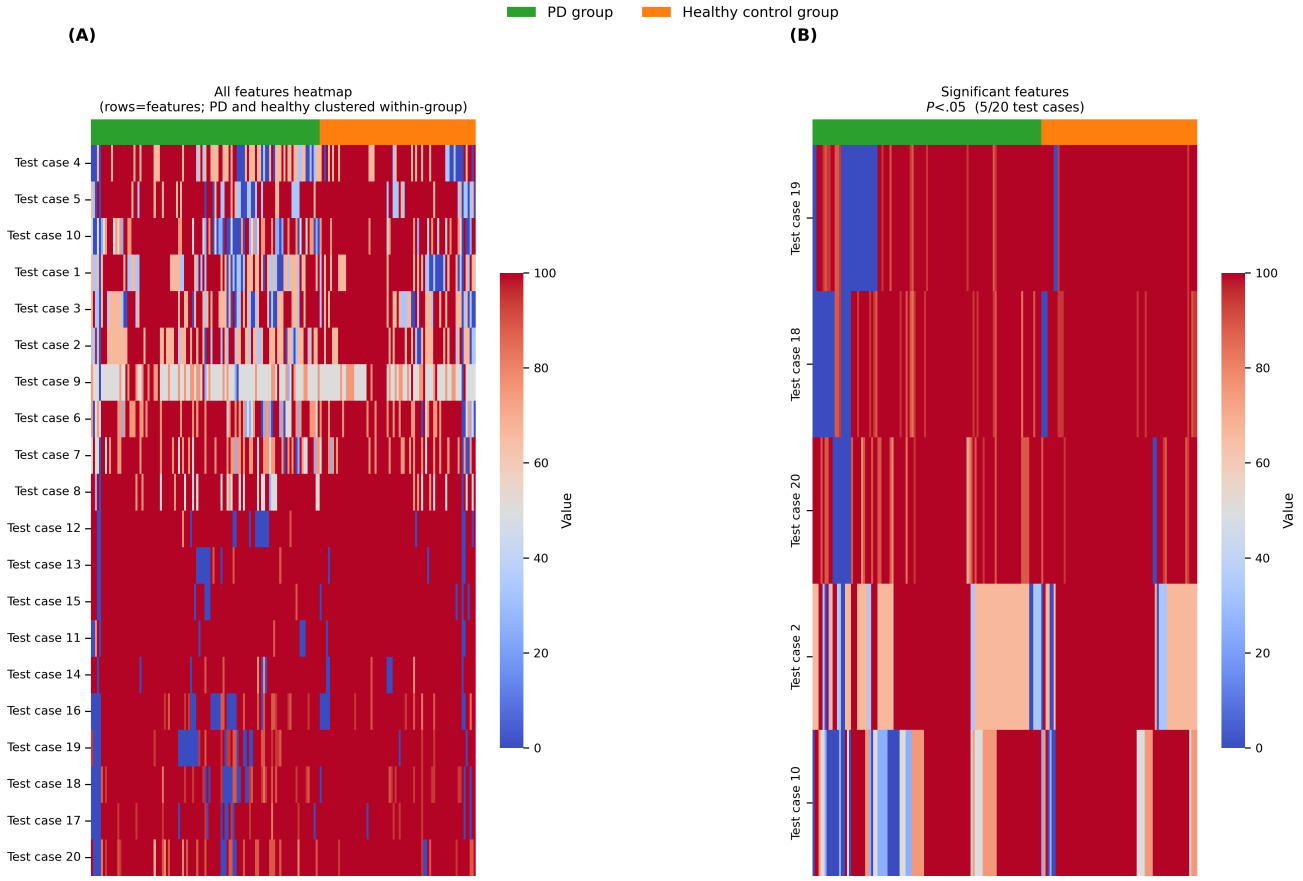
Table . Recognition ratio test cases showing statistically significant differences between Parkinson disease and healthy control groups.

Test case	*t* test (*df*)[a]	*P* value
Test case 2	−2.103 (162.7)	.04
Test case 10	−4.411 (187.9)	<.001
Test case 18	−2.798 (182.2)	.006
Test case 19	−3.988 (161.9)	<.001
Test case 20	−2.366 (185.0)	.02

[a]A 2-tailed Welch *t* test was used. A negative *t* indicates a lower mean recognition ratio in the Parkinson disease group. Nominal significance: $P<.05$.

XSL•FO
RenderX

Figure 5. Recognition ratio heatmaps. (A) All test cases and (B) statistically significant test cases (P<.05; 5/20). Top annotation indicates Parkinson disease (green) and healthy controls (orange). PD: Parkinson disease.



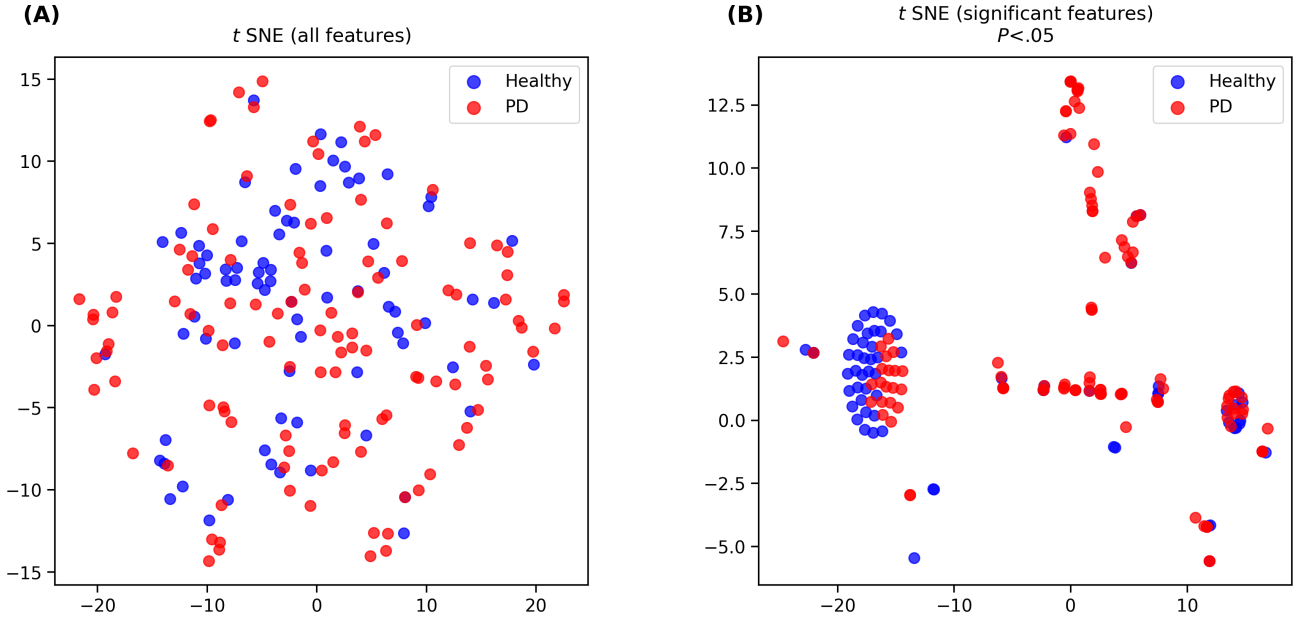


Figure 6. *t* SNE visualizations of the recognition ratio feature space. (A) All test cases and (B) statistically significant test cases. *t* SNE: *t*-distributed stochastic neighbor embedding. PD: Parkinson disease.

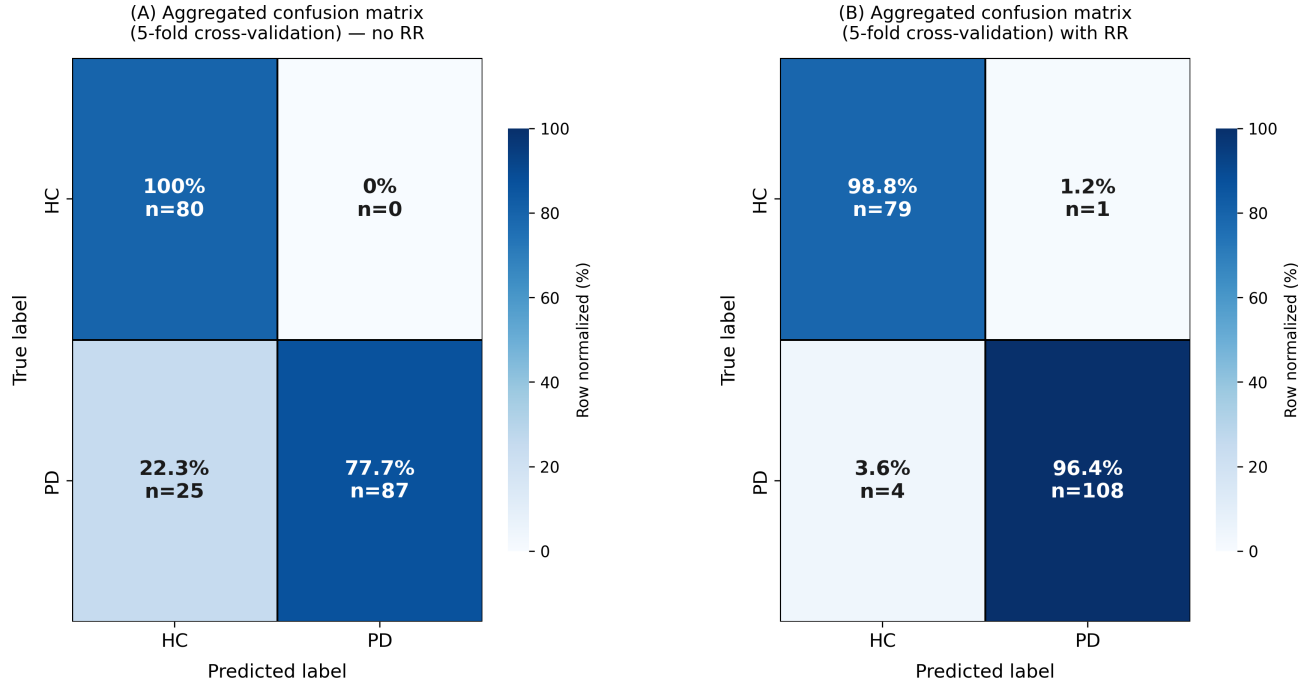

Incorporating RR increased the mean test accuracy from 86.9% (SD 25.2%) to 97.4% (SD 5.7%; Table 3). The mean FNR decreased from 0.226 to 0.035, yielding an approximate type II error reduction:

$$\Delta\text{type II}(\%) = \text{FNR}_{\text{no RR}} - \text{FNR}_{\text{RR}} \text{FNR}_{\text{no RR}} \times 100 \approx 84.5\% \quad (6)$$

Aggregated confusion matrices are shown in Figure 7.

XSL•FO
RenderX

Figure 7. Aggregated 5-fold test confusion matrices for multiview spectrogram recognition-aware Parkinson detection network without RR (A) and with RR (B). Matrices reflect 192 of 203 enrolled participants evaluated at test time (112 with PD and 80 HCs). Eleven participants with missing or unusable recordings were excluded prior to training. Row percentages are computed from pooled counts across all 5 folds. HC: healthy control; PD: Parkinson disease; RR: recognition ratio.

Discussion

Principal Findings

MSR-PDNet integrates 3 complementary spectrogram representations (Mel, STFT, and CQT) with an RR feature vector derived from the same voice recording to support noninvasive Parkinson disease screening. Under strict participant-wise 5-fold cross-validation, 3 main outcomes were observed: spectrogram-based CNN models outperformed traditional acoustic feature machine learning baselines; 3-view spectrogram fusion improved spectrogram-only performance beyond single-view baselines; and integrating the RR produced the largest gain. Mean accuracy increased from 86.9% (SD 25.2%) to 97.4% (SD 5.7%) with RR (+10.5 percentage points), and mean recall increased from 77.4% (SD 43.3%) to 96.5% (SD 7.8%; +19.1 percentage points), reducing the mean FNR from 0.226 to 0.035.

Spectrogram-based CNN models achieved higher held-out accuracy than acoustic feature machine learning baselines under the same protocol. The best single-view baseline (STFT only) reached 82.31% (SD 13.69%), whereas the strongest acoustic feature baseline (gradient boosting) reached 68.83% (SD 3.47%), a 13.47 percentage-point difference. This gap is consistent with time-frequency representations preserving local spectro-temporal patterns that are attenuated when recordings are compressed into summary acoustic statistics.

Three-view spectrogram fusion provided the strongest spectrogram-only performance (mean 86.9%, SD 25.2%), exceeding the best single-view baseline by 4.6 percentage points. Two-view configurations achieved only 60.9% (SD 14.5%) to 65.6% (SD 5.6%), indicating that fusion benefits depend on the specific view combination. Among 2-view configurations, removing Mel features yielded the lowest accuracy, indicating that Mel representations contribute important complementary information consistent with prior Parkinson disease voice classification studies [37-39].

The strong performance of MSR-PDNet (97.4% [SD 5.7%] with RR) likely reflects the complementarity of the proposed feature representation. The 3 spectrogram views (Mel, STFT, and CQT) capture different acoustic aspects of the same voice signal, while the RR provides recording-level information that is not explicitly encoded in local spectrogram patterns. This interpretation is supported by the ablation results: single-view baselines achieved 76.9% (SD 11.6%) to 82.3% (13.7%), 3-view fusion reached 86.9% (SD 25.2%), and adding RR further increased accuracy to 97.4% (SD 5.7%). At the same time, the controlled recording environment, fixed device, and structured reading task may also have contributed to the observed performance.

From a clinical perspective, the proposed model likely captures speech abnormalities associated with hypokinetic dysarthria, a motor speech disorder affecting up to 90% of individuals with Parkinson disease and characterized by reduced vocal loudness, monotonic pitch, imprecise consonant articulation, and diminished speech intelligibility [7,40]. These impairments arise from the progressive degeneration of dopaminergic pathways that govern laryngeal, respiratory, and articulatory musculature, and they constitute some of the earliest detectable nonmotor biomarkers of the disease [8,41]. The 3 spectrogram branches of MSR-PDNet are architecturally aligned with distinct acoustic manifestations of these clinical symptoms. The STFT branch operates on short-time Fourier representations and is particularly sensitive to rapid spectral fluctuations, including vocal tremor, fundamental frequency (F0) instability, and aperiodic noise components that characterize impaired phonation in Parkinson

XSL•FO
RenderX

disease [7,42]. The Mel-scale branch maps frequency content onto a perceptually weighted scale that emphasizes the low-to-mid frequency range, making it well-suited to detecting reduced vocal loudness, disrupted harmonic structure, and the breathy voice quality associated with hypophonia in Parkinson disease [22,41]. The CQT branch provides logarithmic frequency resolution with high spectral precision at lower frequencies, enabling the model to identify monopitch patterns, harmonic distortion, and reduced vowel space that correspond to the monotone speech and imprecise articulation characteristic of hypokinetic dysarthria [40,43]. By fusing these 3 complementary representations, MSR-PDNet captures a broader and more clinically complete acoustic profile of Parkinson disease–related vocal impairment than any single-branch spectrogram could encode independently, which is directly consistent with the ablation results, showing that removing any single view substantially reduces performance.

Beyond vocal spectrograms, the RR feature incorporated in the full MSR-PDNet model reflects a clinically distinct dimension of Parkinson disease pathophysiology: respiratory motor dysfunction. A recent meta-analysis confirmed significantly elevated resting respiratory rates in Parkinson disease patients compared with healthy controls [44], and a large-scale clinical study reported a 44% prevalence of respiratory dysfunction in Parkinson disease, attributing it to impaired thoracic musculature control and reduced respiratory drive [45]. The RR, derived from sentence-reading performance, encodes both articulatory precision and respiratory support for speech, thereby providing physiological information that is qualitatively complementary to the spectral features captured by the 3 spectrogram branches. This clinical complementarity explains the substantial accuracy gain observed when the RR is added to the spectrogram-only model (mean 86.9%, SD 25.2% to mean 97.4%, SD 5.7%): the 2-feature modalities jointly reflect the vocal tract impairment and the respiratory motor impairment that together define hypokinetic dysarthria in Parkinson disease. Therefore, the model's behavior can be interpreted in terms of clinically meaningful manifestations of Parkinson disease–related speech impairment rather than purely abstract signal patterns.

RR integration produced the largest improvement in accuracy and sensitivity. The corresponding FNR decreased from 0.226 to 0.035 (approximately 84.5% reduction), which is relevant for screening-oriented settings where missed cases are clinically undesirable.

Although the RR may be affected by factors such as accent, language proficiency, and recording quality, several findings support its relevance to Parkinson disease–related speech changes. RR differences were observed between relatively age-matched Parkinson disease and healthy control groups (mean age 68.7 [SD 8.9] y vs 65.3 [SD 9.8] y), significant differences were identified across specific sentence-reading tasks (Table 5), and controlled acquisition conditions reduced recording-related variability. Therefore, although RR should not be regarded as a fully disease-specific biomarker in isolation, it appears to provide a meaningful recognition-aware feature reflecting Parkinson disease speech characteristics.

Recent state-of-the-art voice-based Parkinson disease classification studies were reviewed alongside MSR-PDNet, as summarized in Table 6. Given that each study adopts its own dataset, feature extraction approach, and evaluation protocol, the figures presented here serve as a broad reference point rather than a strict performance benchmark.

XSL•FO
RenderX

Table . Comparison with recent state-of-the-art voice-based Parkinson disease classification methods, including MSR-PDNet (spectrogram only) and MSR-PDNet (spectrogram+RR).

Method	Type	Accuracy (%)	Reference
Vision transformer (ViT+AST[a])	Single	73	Perrone et al [46]
ResNet CNN[b]	Single	84	Escobar-Grisales et al [47]
EfficientNet-B2	Multi	84.39	Malekroodi et al [48]
MSR-PDNet[c] (spectrogram only)	Multi	86.9	Ours
DenseNet-161 (TL[d])	Single	89.75	Karaman et al [49]
VGG-16[e]	Single	91.8	Malekroodi et al [50]
VGG-16	Single	92	Bhatt et al [51]
DenseNet+MobileNet+ShuffleNet	Multi	95.56	Chen et al [26]
CNN-LSTM[f]	Single	95.67	Shibina and Thasleema [52]
MSR-PDNet (spectrogram+RR[g])	Multi	97.4	Ours

[a]AST: audio spectrogram transformer.

[b]CNN: convolutional neural network.

[c]MSR-PDNet: multiview spectrogram recognition-aware Parkinson detection network.

[d]TL: transfer learning.

[e]VGG-16: visual geometry group 16.

[f]LSTM: long short-term memory.

[g]RR: recognition ratio.

Among single-spectrogram approaches, reported accuracies ranged from 73% to 84%, with several architectures, including DenseNet-161 (89.75% [49]), visual geometry group 16 (VGG-16: 91.8% [50]), Superlet-based VGG-16 (92% [51]), and CNN and long short-term memory (95.67% [52]), yielding higher values under their own experimental conditions. MSR-PDNet with RR achieved 97.4%, representing a strong result within this broader landscape, although cross-study variability in datasets and evaluation protocols limits direct interpretability.

Similarly, multibranch and multimodel configurations such as EfficientNet-B2 fusion (84.39% [48]) and ensemble models (95.56% [26]) reflect the growing interest in combining multiple representations, which aligns with the motivation behind integrating multiview spectrograms with RR features in the proposed approach.

Despite these promising results, several limitations should be noted. First, evaluation was performed on a single-center dataset collected under controlled conditions using the same recording device and protocol. Accordingly, performance is expected to generalize best to similar clinical settings, whereas different cohorts, devices, and real-world environments may introduce distribution shifts that affect both spectrogram features and RR computation. Future work should therefore include multicenter validation, noise-aware data augmentation, and domain adaptation to improve robustness.

Second, bootstrap oversampling was applied in the training split to address class imbalance; further evaluation of probability calibration would be beneficial for clinically meaningful sensitivity-specificity tradeoffs.

Third, RR depends on the speech task design and the automatic speech recognition pipeline, and it may vary across languages, prompts, and recognition systems.

Fourth, the current system requires a standardized sentence-reading task with predefined prompts to compute the RR, making it most suitable for supervised clinical or at-home screening. Performance may be affected by background noise, device variability, and shorter recordings, and adaptation would be needed for spontaneous-speech settings. Furthermore, the effectiveness of the RR is likely sensitive to the phonetic and articulatory characteristics of the selected prompts. While the current 20-sentence protocol contributed to improved classification performance, systematically optimized sentence designs may further enhance the ability to capture Parkinson disease–related speech impairments. Future work should therefore evaluate robustness under diverse recording conditions, explore more flexible speech protocols, and investigate prompt optimization strategies to maximize the diagnostic sensitivity of the RR feature.

Finally, the low accuracy of 2-view configurations indicates that fusion benefits depend strongly on view pairing and training stability, and broader testing across datasets and alternative fusion strategies is warranted.

Conclusions

This study presents MSR-PDNet, a multiview spectrogram-based framework for noninvasive Parkinson disease screening from voice recordings. Across participant-wise 5-fold cross-validation, the method achieved 86.9% (SD 25.2%) mean test accuracy using spectrogram fusion, improving to 97.4% (SD 5.7%) when the RR vector was added. The RR-augmented

XSL•FO
RenderX

model showed higher sensitivity (recall: mean 96.5%, SD 7.8%) compared with the spectrogram-only configuration (mean 77.4%, SD 43.3%), with a substantially reduced FNR relevant for screening. Comparison with recent state-of-the-art methods suggested that MSR-PDNet is competitive within the current literature. Future work will focus on external validation, robustness testing across multidevice and multicenter cohorts, and adaptation to more flexible recording conditions to support clinical translation.

Abstract

Background: Lymph node metastasis (LNM) is a critical clinical indicator for determining the initial treatment strategy for patients with lung cancer. However, accurately diagnosing LNM preoperatively remains a significant challenge. Data-driven predictive modeling has become a mainstream approach to address this issue, yet it often overlooks existing clinical knowledge. Large language models (LLMs) have demonstrated the potential to predict clinical risks in a zero-shot manner based on the extensive clinical knowledge learned from large-scale corpora.

Objective: LLMs have demonstrated the potential to predict clinical risks in a zero-shot manner based on the extensive clinical knowledge learned from large-scale corpora. This study aims to investigate the integration of LLM-derived knowledge with data-driven patterns to enhance the accuracy of LNM prediction.

Methods: We propose a novel ensemble framework that combines the strengths of LLMs and machine learning (ML) models for LNM prediction in lung cancer. Specifically, 3 ML models were trained using clinical data, and their predicted probabilities, along with the original clinical features, were incorporated into prompts for LLMs. Three LLMs—GPT-5.4, GPT-5.4-nano, and DeepSeek-V3.2—were used to independently predict LNM risk 5 times, and 4 ensemble strategies were applied to aggregate their predictions into a final outcome.

Results: The proposed approach was evaluated on clinical data from 767 patients with lung cancer at Peking University Cancer Hospital. Experimental results show that our proposed framework significantly outperforms base ML models, achieving an area under the curve of 0.781 and an average precision of 0.420. Compared with the no reasoning English setting, both the reasoning English setting and nonreasoning Chinese setting showed a lower area under the curve but higher average precision.

Conclusions: This study presents a novel knowledge-augmented strategy for integrating the clinical knowledge embedded in LLMs with the statistical patterns captured by ML models to improve the LNM prediction of lung cancer, offering a new paradigm for integrating medical knowledge and patient data in clinical predictions.

KEYWORDS

large language models; machine learning models; lymph node metastasis; lung cancer; clinical risk prediction

Introduction

Lung cancer remains the leading cause of cancer-related mortality worldwide [1]. For patients with early-stage lung cancer, surgical resection represents the only potentially curative treatment [2]. The determination of lymph node metastasis (LNM) is critical in assessing surgical eligibility and the need for additional neoadjuvant therapy. However, accurately diagnosing LNM preoperatively through noninvasive examinations and tests poses significant challenges in clinical

XSL•FO
RenderX

practice, often leading to suboptimal treatment decisions and adversely affecting patient outcomes [3].

To achieve an accurate preoperative diagnosis of LNM, data-driven approaches have become the most commonly used methods for developing LNM prediction models. Initially, researchers used patient clinical characteristics in combination with statistical methods to construct predictive models [4,5]. To leverage imaging data, the radiomics approach was introduced, allowing the extraction of first-order, second-order, texture, and other features from the image data, which were then integrated with clinical characteristics to enhance predictive precision [6-8]. To further explore the nonlinear relationships among these features, machine learning (ML) methods such as random forest (RF), support vector machine (SVM), and multilayer perceptron were used, resulting in improved model performance [9-12]. With the rapid advancement of deep learning, researchers began to use deep learning techniques to automatically extract deep features from images for LNM prediction [13-17]. Unlike radiomics methods, deep learning approaches do not require manual delineation of regions of interest in the images. Instead, they can directly extract deep image features related to the prediction target through error backpropagation, making deep learning the most popular and effective approach for LNM prediction.

Recently, large language models (LLMs), such as ChatGPT [18] and GPT-4 [19], have captured global attention due to their impressive text generation capabilities. These models, pretrained on vast corpora, demonstrate remarkable performance on previously unseen tasks using zero-shot, one-shot, or few-shot prompts without parameter updates [20]. By incorporating reinforcement learning from human feedback [21], LLMs are further refined to produce content that is safe and aligns with human expectations. This success has led to a paradigm shift in natural language processing research and is gradually influencing clinical prediction research [22-26].

Leveraging the medical knowledge learned from extensive corpora, LLMs show potential in diagnosing and evaluating patient prognoses. Many studies have investigated the capabilities of LLMs in predicting clinical outcomes such as readmission, length of stay, and hospital mortality [27-30]. These studies typically develop prompts using patient data and instruct LLMs to provide answers for specific tasks. Although LLMs can generate predictive results based on patient information and instructions prompted, their predictive performance rarely surpasses that of traditional data-driven ML models when they only use the medical knowledge they learned from the corpora [27,28].

In this study, we propose a novel knowledge-augmented method that integrates the medical knowledge of LLMs with the statistical patterns identified by data-driven models to predict LNM in lung cancer. This method first combines the clinical characteristics of patients with the risk probabilities predicted by ML models using prompt engineering, then ensembles the multiple responses of LLMs as the final predictions. When evaluated on real clinical data, our approach demonstrates that by combining the strengths of both knowledge-based and data-driven models, we can achieve superior predictive performance compared to using either model alone.

Methods

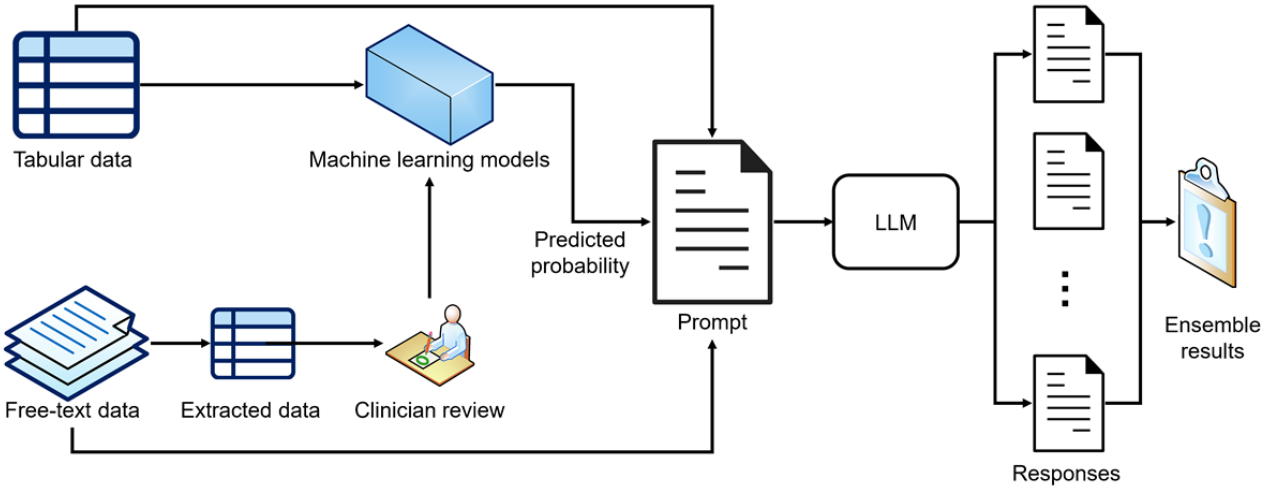
Patients

We collected data from 767 patients with lung cancer treated at Peking University Cancer Hospital. All patients underwent pulmonary resection with systematic mediastinal lymphadenectomy between 2010 and 2018 and received contrast-enhanced computed tomography (CT) scans and tumor biomarker tests within 2 months before surgery. Patients who received preoperative chemotherapy or radiotherapy were excluded to avoid potential confounding due to complete responses to these treatments.

The data collected included structured clinical information such as demographics and tumor biomarkers, as well as unstructured data such as disease history, CT scan, and pathological reports. A clinician annotated LNM statuses based on postoperative pathological reports, which were processed using our previously developed information extraction models [26,31], followed by a manual review by a clinician to ensure accuracy, which served as the gold standard labels. Data quality was further ensured through consistency checks and verification of missing values before model training.

Ethical Considerations

Ethical approval for this study was granted by the ethics committee of Peking University Cancer Hospital (2022KT128) prior to its commencement. Informed consent was waived due to the retrospective design of this study. All data were stored securely. Identifiable information was removed prior to analysis, and no personally identifiable information was included in the study or its supplementary materials.



Study Design

This study aims to integrate the advantages of LLMs and ML models to accurately predict LNM in patients with lung cancer. The overall study design is depicted in Figure 1.

First, unstructured clinical data were collected, and key features were extracted using information extraction models previously developed by our team [26,31]. The extracted features were then reviewed by the clinicians. Next, we combined the extracted features with the tabular clinical data to develop ML models to predict the risk of LNM in patients. We then constructed prompts for LLMs using the predicted probabilities and patient clinical features and gathered several responses from LLMs using the same prompt. Finally, we integrated the various predicted results of the LLMs to generate the final ensemble results.

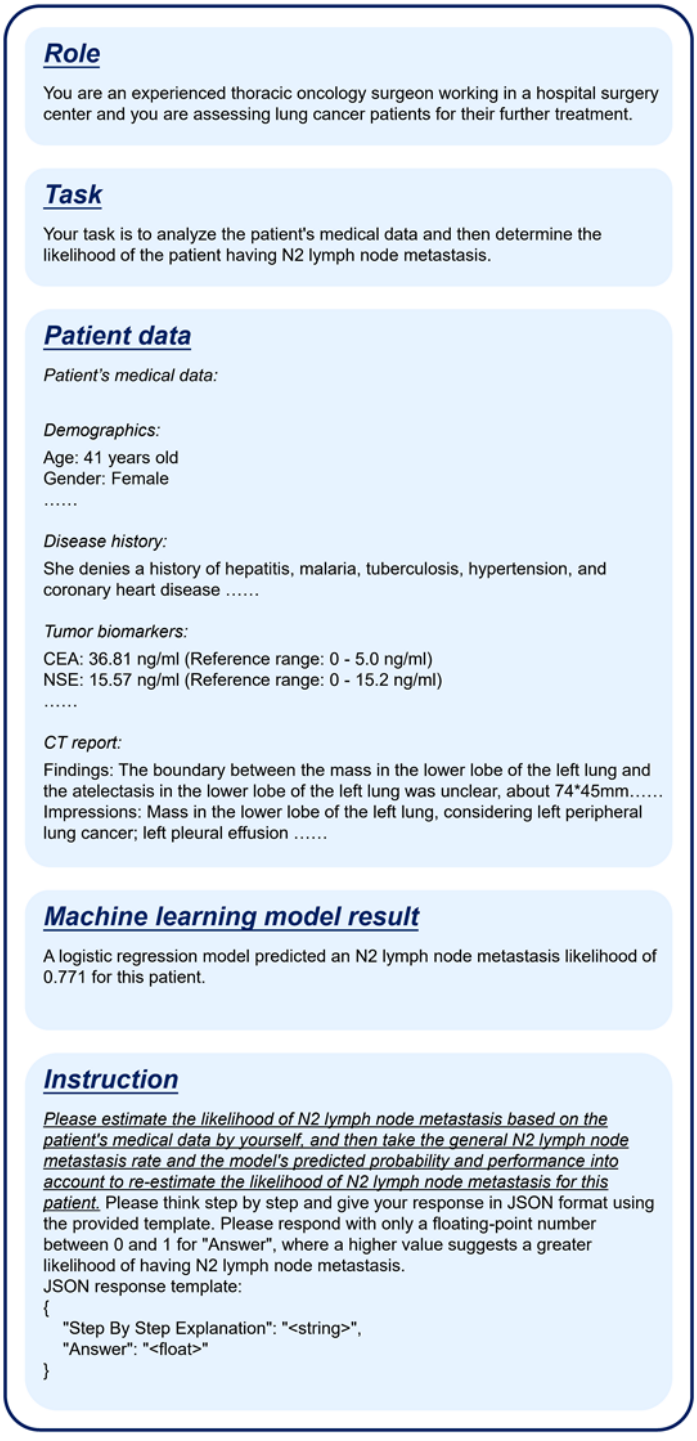
XSL•FO
RenderX

Figure 1. Overall study design. LLM: large language model.

ML Models

In this study, we selected 3 classical ML methods, that is, logistic regression (LR), RF, and SVM, as well as a transformer-based deep learning model, to identify latent patterns between patient clinical data and LNM status. We trained and tested these ML models on our clinical data. We used the test results and predicted probabilities to construct the prompt, aiming to achieve the integration of data and knowledge.

Prompt Design



The prompt template used in this study is shown in Figure 2.

The proposed prompt template consists of the following 5 elements:

- Role: this element defines the role that LLMs should assume to generate responses for specific tasks. In this study, we instructed the LLMs to act as thoracic surgeons, who generally assess a patient's LNM and determine whether the patient can directly receive surgical resection.
- Task: This element specifies the clinical prediction task assigned to LLMs. We instructed the LLMs to predict the likelihood that a patient would have N2 LNM.
- Patient data: this element outlines the patient's clinical data used for the evaluation by LLMs. We provided patient demographics, disease history, tumor biomarkers, and CT reports. It is important to note that the original disease history and CT reports were in Chinese free-text format; therefore, we used the Google Translate Application Programming Interface (API) via googletrans to translate them into English. Additionally, for tumor biomarkers, we supplied the reference ranges as external knowledge.
- Machine learning model result: this element is used to integrate the predicted result from the data-driven model as a reference for the LLMs. We only provide the predicted probability and the model type to prevent any potential data leakage issues.
- Instruction: in this element, we instructed the LLMs to initially estimate the likelihood of N2 LNM based solely on the patient data. Subsequently, they were instructed to reestimate the likelihood by considering the N2 LNM rate and the predicted probability provided by the ML model. We also used the chain-of-thought strategy to require the LLMs to reason step by step. Additionally, the LLMs were instructed to provide their responses in JSON format with key-value pairs, such as "Step by Step Explanation":"<string>" and "Answer":"<float>."

XSL•FO
RenderX

Figure 2. Proposed prompt template. CEA: carcinoembryonic antigen; NSE: neuron-specific enolase.

Ensemble Models

Using the designed prompt template, we developed individualized prompts for each patient sample. We selected 3 LLMs—GPT-5.4, GPT-5.4-nano, and Deepseek-v3.2—to generate these responses through the official APIs.

Considering that LLMs can produce varying outputs even with identical prompts, we input the same prompt 5 times for each patient to obtain 3 distinct responses. We then applied 4 strategies—maximum value, minimum value, median value, and mean value—to process these 5 responses and derive the ensemble results. The complete prompt template is shown in Figure 2.

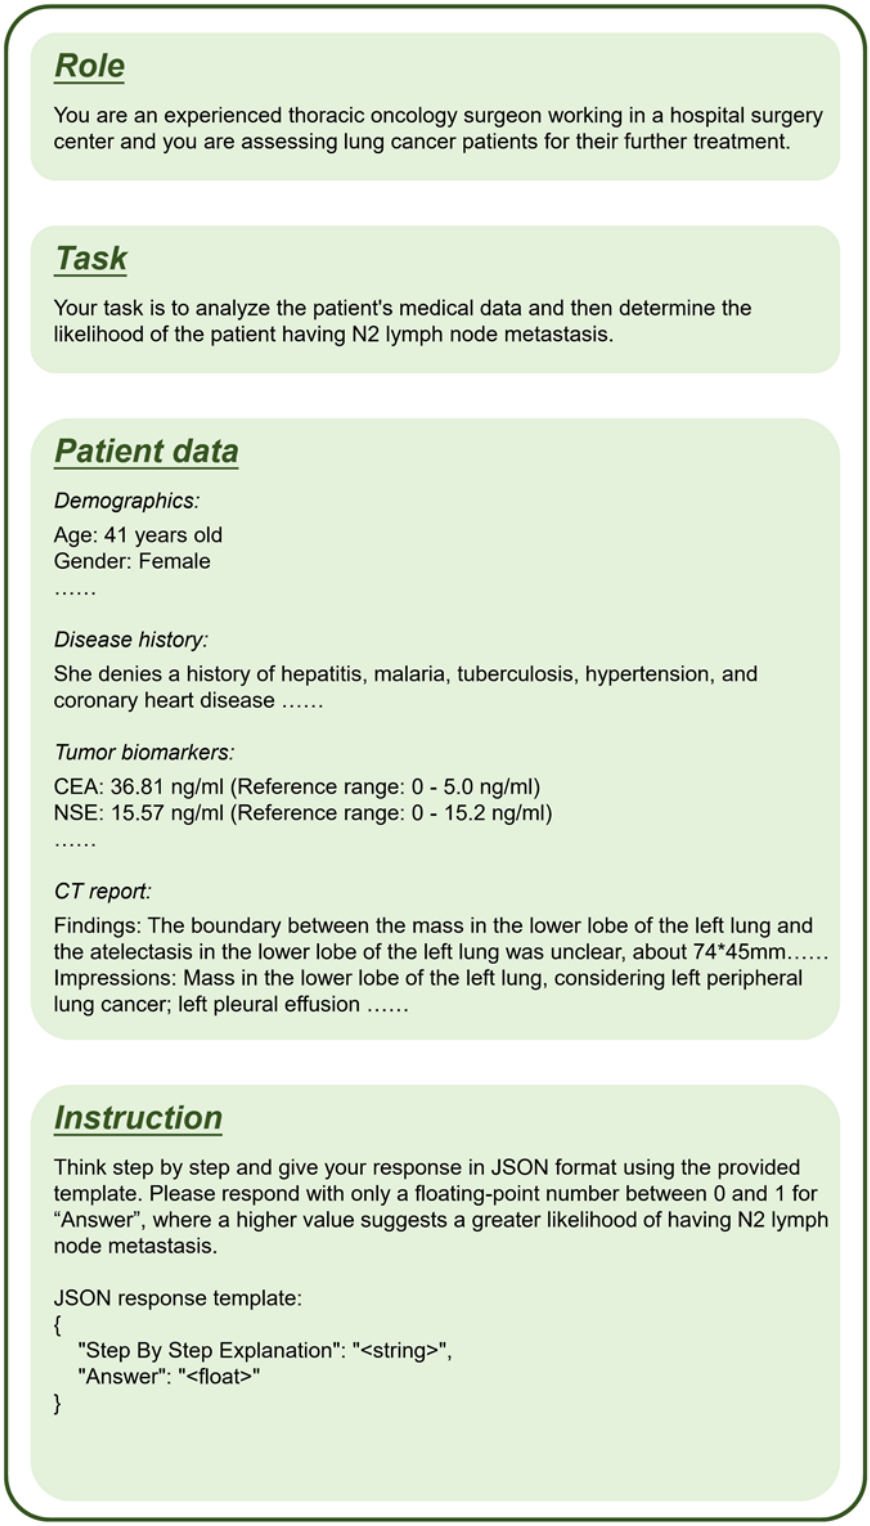
Experimental Setup

Before model training, missing values in the dataset were imputed. For categorical features (eg, smoking history, drinking history, family tumor history, gender, and comorbidities), the

XSL•FO
RenderX

mode was used for imputation. For continuous features (eg, age, height, weight, tumor size, carcinoembryonic antigen [CEA], carbohydrate antigen 19-9 [CA19-9], carbohydrate antigen 125 [CA125], neuron-specific enolase [NSE], cytokeratin 19-fragments [Cyfra21-1], and squamous cell carcinoma antigen [SCCAG]), the median was used.

When developing ML models, a 10-fold cross-validation strategy was used to train and test the models. During each fold iteration, we used an additional 5-fold cross-validation to optimize hyperparameters, subsequently retraining the model on the entire training set using the best hyperparameters. The trained model was then tested on the test set to obtain the final test results. After the completion of all 10-fold iterations, we obtained 10 test results for each fold and the predicted probability of LNM for each patient. To ensure reproducibility, we set 30 as the random seed for the 10-fold stratified cross-validation and model training. Hyperparameters were optimized via grid search combined with 5-fold cross-validation. We set the class weight as "balanced" to address class imbalance for LR, RF, and SVM models.



All LLMs were accessed through the official APIs, and we used the default hyperparameters for response generation. Specifically, the default temperature value is 1 for DeepSeek-V3.2, GPT-5.4 (version: gpt-5.4-2026-03-05), and GPT-5.4-nano (version: gpt-5.4-nano-2026-03-17). No reasoning effort was enabled. We extracted the float values of the key "Answer" from the JSON format responses as the predicted probabilities of the LLMs. Then, we calculated the ensemble results based on the 5-time predictions as the final results.

In addition to the proposed approach that uses the predictions of ML models, we also evaluate the performance of LLMs alone in predicting N2 LNM. The corresponding prompt template is provided in Figure 3.

The performance of the models was evaluated using 2 metrics: the area under the receiver operating characteristic curve (AUC) and the average precision value (AP). To test the differences in performance between models, we used the paired 2-tailed *t* test. A *P* value of less than .05 was considered statistically significant.

Results

Clinical Data

Among the 767 patients, 104 (13.6%) were confirmed to have N2 LNM according to their postoperative pathology reports. In this study, a total of 26 types of clinical features were included. Features such as spiculation, lobulation, mediastinal lymph node short axis, hilar lymph node short axis, tumor location, and tumor density were extracted from CT reports and reviewed by a clinician. Table 1 presents the statistics of the clinical data.

[a]LR: logistic regression.

[b]Not applicable.

[c]RF: random forest.

[d]SVM: support vector machine.

When leveraging predictions from the LR model, the proposed approach achieved statistically significant improvements in AUC across multiple ensemble strategies. For example, GPT-5.4 nano combined with LR achieved higher AUC values under the max, min, median, and mean strategies (all $P<.05$), with the mean-ensemble also showing a significant improvement in AP ($P=.02$). Similar trends were observed for GPT-5.4 and Deepseek-v3.2, where consistent improvements in AUC and AP were achieved, although not all reached statistical significance. Using predictions from the RF model, GPT-5.4 nano demonstrated the most notable improvements, with significant gains in AUC under max, min, median, and mean ensemble strategies (all $P<.05$), achieving the highest AUC of 0.782. However, improvements in AP were generally limited and not statistically significant. For the SVM model, the proposed framework again improved AUC, particularly for GPT-5.4 nano under the min, median, and mean ensemble strategies ($P<.05$). In contrast, improvements in AP were modest and did not reach statistical significance. When using the transformer model as the base learner, the LLM-based approach also led to consistent improvements in both AUC and AP. Notably, GPT-5.4 achieved statistically significant gains in AP across multiple ensemble strategies (eg, min, median, and mean), and GPT-5.4 nano with the mean ensemble also showed a significant improvement in AP ($P=.01$). The AUC and AP values of each iteration of the baseline ML models and proposed

XSL•FO
RenderX

models are listed in Table S1 in Multimedia Appendix 1. The sensitivity, specificity, positive predictive value, and negative predictive value of the base ML models and the proposed models are listed in Table S2 in Multimedia Appendix 1.

To further evaluate the effectiveness of the ensemble strategy, we compared the proposed models with the stand-alone LLMs, ML models, and the conventional stacking model. As shown in Table 3, stand-alone LLMs exhibited relatively unstable performance, with noticeable variability between the worst and best responses (eg, GPT-5.4 nano AUC: 0.737 - 0.750; AP: 0.296 - 0.321), and overall inferior performance compared to ML models.

Table . The area under the curve (AUC) and average precision (AP) values of the baseline machine learning (ML) models, stand-alone large language models (LLMs), stacking model, and the proposed models.

[a]LR: logistic regression.

[b]RF: random forest.

[c]SVM: support vector machine.

Applying simple aggregation strategies (eg, max, min, median, and mean) slightly improved the stability of LLM predictions, but their performance remained below that of traditional ML baselines. In contrast, the conventional stacking approach combining LR, RF, SVM, and transformer achieved moderate

XSL•FO
RenderX

improvement (AUC: 0.767) but did not consistently outperform the best individual models in terms of AP.

Notably, when integrating LLMs with ML predictions, the proposed framework achieved further performance gains. We selected the models with the best AUC and AP values to compare with the baselines. GPT-5.4 nano combined with RF (mean ensemble) achieved the highest AUC (0.781) and improved AP (0.415), while GPT-5.4 nano+LR (mean) also showed substantial gains (AUC: 0.772, AP: 0.420). Similar improvements were observed for GPT-5.4+SVM and transformer-based combinations. Additionally, we presented the calibration curves and decision curve analysis of the selected models in Figure S2 in Multimedia Appendix 1.

These results indicate that, while stand-alone LLM predictions are unstable and conventional stacking provides limited gains, the proposed LLM-based integration framework can more effectively leverage complementary information from both data-driven models and LLM reasoning, resulting in more robust and improved predictive performance. We also provide the sensitivity, specificity, positive predictive value, and negative predictive value of these models in Table S2 in Multimedia Appendix 1.

To further investigate the impact of reasoning and language settings, we compared GPT-5.4 nano under 3 configurations: nonreasoning (English), reasoning (English), and nonreasoning (Chinese) across different base models and ensemble strategies. Since the original clinical data were in Chinese, the use of English prompts required translation, which may have introduced potential errors. To rigorously assess this risk, we conducted a human evaluation in which a clinician reviewed 100 translated prompts using a 5-point Likert scale (1="incorrect or unusable" to 5="fully accurate and clinically appropriate"). The results showed that 67% (67/100) of the samples were rated as 5, 30% (30/100) as 4, and only 3% (3/100) as 3, with no samples rated below 3, yielding an average score of 4.64. This indicates that the translated prompts generally preserved the original clinical meaning with high fidelity. The experimental results are summarized in Table 4.

[a]LLM: large language model.

[b]LR: logistic regression.

[c]RF: random forest.

[d]SVM: support vector machine.

To provide a clearer comparison, we identified the best-performing models under each setting based on both AUC and AP. Specifically, the optimal model in the nonreasoning (English) setting was LLM+RF with mean ensemble (AUC=0.781; AP=0.415), in the reasoning (English) setting was LLM+LR with median ensemble (AUC=0.777; AP=0.433), and in the nonreasoning (Chinese) setting was LLM+LR with min ensemble (AUC=0.779; AP: 0.431). Overall, these best results are highly comparable across the three settings. The highest AUC was achieved by the nonreasoning English configuration (0.781), while the highest AP was observed in the reasoning setting (0.433), with the Chinese setting yielding a very similar AP (0.431).

Discussion

Principal Results

In this study, we propose a knowledge-augmented prediction framework that integrates ML model outputs with LLM-derived clinical knowledge for preoperative prediction of N2 LNM in patients with lung cancer. Consistent with our study objective, the results demonstrate that incorporating LLM-based refinement into data-driven predictions leads to consistent improvements in predictive performance across multiple base models and ensemble strategies. Specifically, the proposed framework achieved the best performance with an AUC of 0.781 and an AP of 0.420, outperforming stand-alone ML models as well as a conventional stacking approach.

XSL•FO
RenderX

LLMs as Knowledge-Informed Calibrators

In contrast to stand-alone LLM predictions, which were relatively unstable and generally inferior to ML models, the integrated framework consistently improved performance. These findings suggest that the primary value of LLMs in this setting lies not in independent prediction, but in post hoc refinement of model outputs through the incorporation of clinical context. Unlike zero-shot or few-shot prediction paradigms used in prior studies, our framework positions LLMs as knowledge-informed calibrators, refining ML predictions based on their own evaluation of patient-specific information.

The cases presented in Multimedia Appendix 1 further support this interpretation. We observed that the LLM can adjust predictions in both directions depending on the clinical context—for example, down-weighting overestimated risks when key radiological signs are absent and up-weighting underestimated risks when clinically significant features are present. From a methodological perspective, this behavior can be interpreted as introducing clinical prior knowledge into the prediction process, complementing the cohort-specific statistical patterns learned by ML models.

To further assess whether the LLM-generated reasoning is clinically meaningful rather than spurious, we conducted a clinician-based evaluation of the step-by-step reasoning traces. Specifically, a clinician reviewed 100 cases and rated the reasoning quality using a 5-point Likert scale, considering logical coherence, factual correctness, and potential hallucinations. The results showed that 91% of the reasoning traces were rated as 5, and the remaining 9% as 4, with no cases rated as moderate or poor quality. These findings suggest that the reasoning processes elicited by the "step-by-step" prompting strategy are generally clinically coherent and medically sound, rather than arbitrary explanations fitted to the final prediction. This supports the interpretation that the LLM contributes meaningful clinical context when refining model outputs, although it does not fully eliminate the possibility of subtle reasoning errors.

Effect of Ensemble Strategies, Reasoning Modes, and Language

In this study, we explored multiple ensemble strategies to identify a robust aggregation approach. Overall, the results demonstrate that the proposed framework can effectively enhance predictive performance across different base models. While statistically significant improvements were more consistently observed with GPT-5.4 nano, GPT-5.4, and Deepseek-v3.2 achieved comparable AUC and AP values but did not consistently reach statistical significance, likely due to greater variability across cross-validation folds. Importantly, across models and settings, the mean ensemble consistently performed among the best or near-best strategies. This suggests that mean aggregation represents a practical and robust candidate for a universal ensemble strategy, as it provides a favorable balance between performance, stability, and simplicity.

We also investigated the effects of reasoning mode and input language on predictive performance. The results indicate that enabling reasoning mode and using Chinese prompts tend to slightly improve AP, potentially by better capturing positive cases. From a practical perspective, the reasoning mode introduces additional token consumption and computational cost, which should be carefully considered in real-world deployment. Therefore, selecting between reasoning and nonreasoning configurations involves a trade-off between predictive performance (especially AP) and computational efficiency. Meanwhile, the comparable performance between English and Chinese prompts indicates that the model is robust to language variations, offering flexibility for practical clinical applications.

Limitations

This study has several limitations that should be acknowledged.

First, this is a single-center retrospective study for 1 clinical task based on 767 patients from one institution, without external validation. Although we used nested cross-validation to improve internal robustness, the generalizability of the findings remains uncertain. Future work should include multicenter and prospective validation and expand to other clinical tasks. Second, given the multiple comparisons conducted between the baseline and the proposed models, the reported *P* values should be interpreted with caution, and emphasis should be placed on consistent performance trends across models. Third, although clinician evaluation suggests that the generated reasoning and English translation are generally of high quality, this assessment was conducted on a limited sample and may not fully capture all potential failure modes. These evaluations, while providing preliminary evidence for feasibility and acceptability, should be interpreted with caution. Further large-scale and multiexpert evaluation would be needed to more rigorously assess the reliability of LLM-generated clinical reasoning and translation. Fourth, this study did not incorporate image data to create a multimodal prediction task. Some studies have explored the use of LLMs like GPT-4 to diagnose diseases using image data; however, they did not show competitive performance in interpreting real-world medical images [32-35]. Future research should investigate how to integrate image data to further improve the predictive performance of LLMs. Finally, fine-tuning LLMs may be a possible way to further improve their predictive ability for clinical risk prediction. However, designing the ground truth label for fine-tuning is challenging when predicting the probability of a clinical problem, as the real label is binary. We will try to explore this question in the future.

Conclusions

In this study, we propose a knowledge-augmented framework that integrates LLM-derived clinical knowledge with data-driven model predictions for LNM risk estimation. The results suggest that LLMs can act as knowledge-informed calibrators, combining statistical patterns with clinically relevant prior knowledge to improve prediction performance. These findings suggest that LLMs can excel in clinical risk prediction tasks, offering a new paradigm for integrating medical knowledge and patient data in clinical predictions.

Abstract

Background: Smart bioelectronics are electronic medical devices that combine hardware and artificial intelligence (AI)–based software. These convergent medical devices analyze bio-signals measured through hardware using AI algorithms and deliver physical stimulation to enhance therapeutic effects.

Objective: This study aimed to systematically analyze recent research trends in smart bioelectronics to understand their evolving role in digital health care and to provide evidence-based insights for shaping future research and development strategies.

Methods: A total of 92 publications indexed in PubMed between 2020 and 2024 were analyzed. Latent Dirichlet allocation–based topic modeling, optimized using coherence scores, was applied to identify latent research themes.

Results: The results indicate a steady increase in related research over the past 5 years, along with a clear shift in research focus from bio-signal sensing and bioelectronic device materials toward AI-driven analysis and disease-oriented applications, ultimately evolving into intelligent and adaptive bioelectronic therapeutic systems. Three major research topics were identified: bio-signal–based neuromodulation (n=23, 25%), AI-driven neurological disease analysis (n=32, 34.7%), and implantable bioelectronics and biomaterials (n=37, 40.2%).

Conclusions: By mapping the evolving landscape of smart bioelectronics, this study provides valuable insights into their multidisciplinary development and highlights their potential applications in clinical decision support, personalized rehabilitation, and next-generation medical device innovation.

smart bioelectronics; keyword analysis; topic modeling; research trends; PubMed

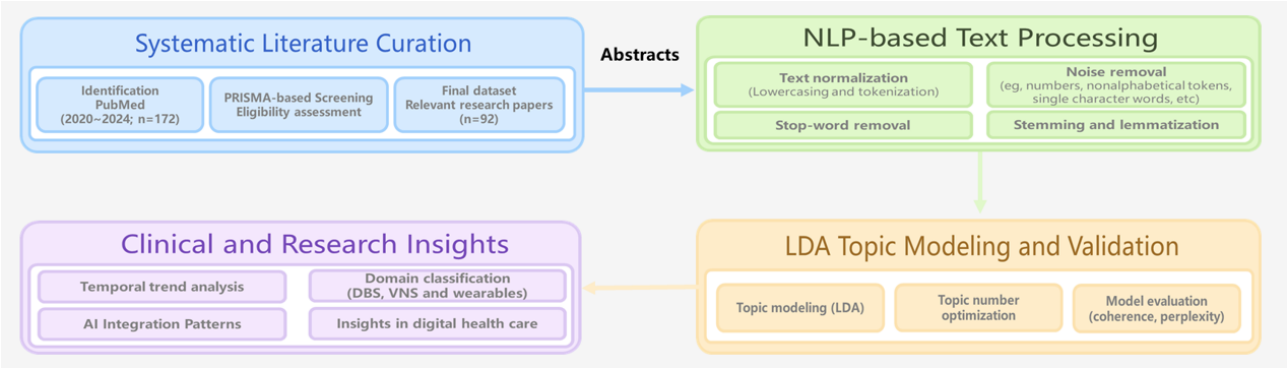
Introduction

Background

Bioelectronics are medical devices that provide therapeutic effects through physical stimulation without using drugs and are receiving attention in the medical community because they can solve the side effects and misuse problems associated with existing drug treatments [1]. Although existing drug treatments use chemical components to cause biochemical reactions in the body to relieve symptoms, bioelectronics directly stimulate nerves to induce therapeutic effects; therefore, their mechanism of action is clear, and side effects are relatively low. In addition, real-time treatment monitoring and immediate feedback are possible, allowing for more precise treatment.

In the past, bioelectronics were used in a limited manner by inserting them into the body, such as pacemakers, but recently, as they have evolved into noninvasive methods, an environment is being created where patients can receive treatment at home [2]. In addition, the market is rapidly expanding as clinical efficacy has been proven for various diseases such as depression, insomnia, headache, dementia, and epilepsy. In the global market, commercialization of bioelectronics is actively progressing, centered around the United States and Europe, and the number of related products is gradually increasing. In contrast, the domestic bioelectronics market is still in its initial stages, and product development and clinical application are not active, so competitiveness is low. Accordingly, research and new technology development for effective clinical application of bioelectronics are essential in Korea as well, and it is necessary to increase treatment precision and strengthen

XSL•FO
RenderX



the competitiveness of the medical device industry through the combination with artificial intelligence (AI), big data, and wearable technology.

In the health care field, the amount of data, such as research papers, patents, and clinical data, is increasing exponentially. These data provide important research insights, but the volume is so large that manual analysis is limited. However, data analysis is essential for suggesting research directions and exploring innovative treatments. Accordingly, research trend analysis using text mining and topic modeling is actively being conducted.

Text mining is a technology that extracts meaningful information by formalizing unstructured data and is used to quantitatively understand research trends by analyzing research papers and patent documents. Topic modeling is a technique that automatically derives key topics from large numbers of documents and is useful for classifying topics in research papers and analyzing research trends [3]. Through these approaches, it is possible to analyze which topics are currently being studied most actively and how the proportion of specific studies has changed over time. A study that analyzed the main topics of health literacy–related research identified research trends over the past 10 years and suggested future research directions [4]. In another study, the topic modeling techniques were applied to derive key technologies and major issues in the analysis of domestic research trends related to the Fourth Industrial Revolution [5]. Using these techniques can contribute to a more systematic understanding of the latest trends in electronic pharmaceutical research and help establish future research directions.

This study aims to analyze the trends in smart electronic drug research over the past 5 years, to analyze how research on the topic of "smart electronic drugs" is progressing, and to suggest future research directions. Relevant studies were identified from the PubMed database using bioelectronics-related keywords combined with AI-related terms in the titles or abstracts. Frequency analysis and latent Dirichlet allocation (LDA)–based topic modeling were applied. First, we analyzed the quantitative research flow and meaning by identifying the trends and changes in the core keywords of smart electronic drugs research over time through frequency analysis. Next, we analyzed the main topics and distribution of the research content using LDA-based topic modeling to explore overall research trends and their implications (Figure 1).

Figure 1. Analytical framework for smart bioelectronics research trend analysis: the workflow began with systematic literature curation using a PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses)–based screening process, followed by natural language processing (NLP)–based text preprocessing, including normalization, tokenization, and stop-word removal. Latent Dirichlet allocation (LDA) was applied for topic modeling, with model evaluation and topic number optimization performed using coherence metrics. The resulting topics were further analyzed to identify temporal research trends, domain-specific classifications, and emerging artificial intelligence (AI) integration patterns, providing clinically relevant and translational insights in digital health care. DBS: deep brain stimulation: VNS: vagus nerve stimulation.

In addition, this study set 3 research topics to identify trends in smart bioelectronics research and suggest future directions, and the following implications were derived from the analysis results of each topic:

- Research topic 1: how have research trends in smart bioelectronics changed over the past 5 years, and what do they mean?
- Research topic 2: what are the core keywords and main topics of smart bioelectronics research trends, and what do they mean?
- Research topic 3: what are the characteristics of the main topics derived from the topic analysis, and what strategic directions can be derived from each topic?

Smart Bioelectronics

Smart bioelectronics are advanced technologies that combine AI-based software with hardware-based bio-stimulation devices to measure bio-signals in real time, analyze them with AI algorithms, and provide physical stimulation optimized for an individual's condition, thereby maximizing therapeutic effects [6]. Unlike conventional chemical drug treatments, smart bioelectronics directly stimulate nerves and tissues to induce physiological responses, enabling precise and personalized treatment. Consequently, they are attracting attention as a new alternative for chronic diseases, neurological diseases, and rehabilitation treatment.

Meanwhile, the term referring to electronic drugs first appeared in earnest in 2013 when GlaxoSmithKline introduced a therapeutic device that controls neural circuits through electrical stimulation and used the expression "electroceutical." However, the terminology in this field has not been unified to date, and the terms "electroceutical" and "bioelectronic medicine" are used interchangeably, and "bioelectronics" and "electronic drugs" are also used in various ways depending on the literature. As this confusion of terms can obscure technical and academic identities, it is necessary to establish clear concepts and a

XSL•FO
RenderX

classification system in future research and industrialization stages.

Topic Modeling

Topic modeling is a technique that uses machine learning and natural language processing technology to analyze large amounts of text data and automatically extract major topics from documents [3]. It is used to understand the content of documents, group related topics, and explore hidden patterns within data. Topic modeling is particularly useful for extracting meaningful information from massive document datasets, such as research papers, news articles, and electronic medical records, and is widely applied across various fields, including medicine and biology.

Recently, topic modeling has been increasingly applied in the medical field to analyze large-scale biomedical data and uncover hidden patterns that provide new insights. For example, previous studies have applied topic modeling techniques to analyze public responses to the COVID-19 vaccine using social media data and identified key discussion themes such as vaccine side effects, vaccine hesitancy, and infectious disease management policies [7]. In addition, advanced topic modeling approaches such as the graph attention-embedded topic model have been applied to electronic health record data to identify potential disease-related topics and improve the interpretability of large-scale clinical datasets [8].

Topic modeling is also widely used to identify research trends in scientific literature. For example, previous studies have applied LDA-based topic modeling to analyze research trends in precision medicine and medical device usability by examining large collections of journal papers and media data, enabling the discovery of emerging research themes and key industry elements [9,10]. In addition, studies by Özyurt et al [11-14] demonstrated effective approaches for reporting LDA parameters, selecting optimal topic numbers based on coherence scores, and interpreting temporal research trends. These studies provide important methodological benchmarks for conducting bibliometric topic modeling analysis.

Following these approaches, this study applies LDA-based topic modeling to analyze research trends in smart bioelectronics literature.

Methods

Data Collection

This study used the PubMed database to collect publications related to smart bioelectronics. PubMed is a widely used biomedical database that provides access to references and abstracts in the life sciences and biomedical fields, primarily including MEDLINE-indexed literature.

The literature search targeted studies related to bioelectronics and electroceutical research combined with AI. Because there is currently no dedicated Medical Subject Headings term for electroceutical or bioelectronic medicine, the search was conducted using keywords appearing in the titles and abstracts of papers.

To capture the heterogeneous terminology used in this emerging research area, 2 complementary PubMed database search strategies were used. The first query focused on electroceutical and neuromodulation-related terminology combined with AI-related keywords, while the second query targeted bioelectronics together with AI, sensor, wearable, and closed-loop control concepts.

The criteria for paper selection were as follows:

- Studies containing bioelectronics-related keywords (eg, “bioelectronics,” “electroceutical,” or “neuromodulation”) and AI-related terms (eg, “artificial intelligence,” “machine learning,” “deep learning,” or “reinforcement learning”) in the title or abstract
- Papers published between January 1, 2020, and December 31, 2024
- Studies involving human subjects
- Papers providing free full text and abstracts
- Exclusion of review papers

The PubMed search was conducted using the following queries:

- Query 1: (electroceutical*[Tiab] OR neuromodulation[Tiab] OR “bioelectronic medicine”[Tiab] OR “vagus nerve stimulation”[Tiab] OR “nerve stimulation”[Tiab] OR “deep brain stimulation”[Tiab]) AND (“artificial intelligence”[Tiab] OR “machine learning”[Tiab] OR “deep learning”[Tiab] OR “reinforcement learning”[Tiab]) AND (“2020/01/01”[pdat] : “2024/12/31”[pdat]) AND humans[MeSH Terms] AND fha[Filter] NOT review[pt]
- Query 2: (bioelectronic*[Tiab] OR electroceutical*[Tiab] OR “bioelectronic medicine”[Tiab]) AND (“Artificial Intelligence”[Tiab] OR AI[Tiab] OR “Machine Learning”[Tiab] OR “Deep Learning”[Tiab] OR sensor*[Tiab] OR wearable*[Tiab] OR “closed-loop”[Tiab] OR “closed loop”[Tiab]) AND (“2020/01/01”[pdat] : “2024/12/31”[pdat]) AND humans[MeSH Terms] AND fha[Filter] NOT review[pt]

After applying the inclusion criteria and conducting manual screening based on titles and abstracts, 49 studies from query 1 and 43 studies from query 2 were retained. Duplicate records were checked using title and DOI matching; however, no duplicate studies were identified between the 2 query results. Consequently, a total of 92 studies were included in the final dataset for the subsequent text mining and LDA-based topic modeling analysis, as listed in Multimedia Appendix 1 [15-106].

Ethical Considerations

This study used publicly available bibliographic data retrieved from PubMed. No individual participant data or identifiable personal information was included. Therefore, institutional review board approval and informed consent were not required for this study.

Data Preprocessing

Preprocessing was performed to ensure the quality of the bibliographic data from the 92 selected papers. The preprocessing steps are as follows. First, the entire text was converted to lowercase to ensure consistency in word notation. To select only the words essential for semantic analysis, 7571

XSL•FO
RenderX

nouns were selected through headword extraction and part-of-speech tagging. Subsequently, special characters and stop words were removed, as they were unnecessary for analysis. Stop-word removal was performed using the Natural Language Toolkit (NLTK) default stop-word dictionary [12] to remove common stop words. Additionally, 2886 stop words were removed, including custom stop words such as “system,” “study,” and “patient,” which frequently appeared in papers but did not contribute to semantic differentiation. Finally, 49 single-letter words were filtered out, resulting in 4452 text data items suitable for analysis (Table 1).

Table . Data preprocessing steps and main tasks.

Preprocessing stage	Main tasks
Convert to lowercase	Ensuring text consistency
Noun and headword extraction	Perform lemmatization and extract nouns
Remove special characters	Remove unnecessary symbols such as !, ", #, $, %, &, ’, (), and *
Remove stop words	Natural Language Toolkit stop words and custom stop words (eg, “system” and “study”)
Word filtering	Remove 1-letter words

The list of custom stop words was categorized as follows. A total of 122 words with low contribution to semantic distinction were selected and classified into types as follows: (1) research and analysis, (2) technology or system, (3) AI and data, (4) medical or health, (5) sensors and devices, and (6) other terms (Table 2).

Table . Custom stop-word list.

Category	Stop words
Research and analysis	study, analysis, method, approach, result, performance, accuracy, effect, outcome, score, rate, parameter, process, objective, finding, design, test, validation, conclusion, research, optimization, correlation, scale, mapping, precision, AUC (Area Under the Curve), classifier, classification, regression, crossvalidation, solution, response, beta, reference, application
Technology and systems	system, technology, technique, development, network, tool, array, setting, delivery, management
Artificial intelligence and data	data, model, machine, artificial intelligence, AI (Artificial Intelligence), ML (Machine Learning), SVM (Support Vector Machine), GPT (Generative Pre-trained Transformer), RL (Reinforcement Learning), layer, input, decision, baseline, ratio, difference, set, information, feature, support, forest
Medical and health	patient, participant, subject, cohort, treatment, trial, intervention, condition, risk, brain, motor, activity, efficacy, medication, healthcare, drug, sensation
Sensors and devices	sensor, device, biosensor, bioelectronics, stimulation, DBS (deep brain stimulation), VNS (vagus nerve stimulation), tcVNS (Transcutaneous cervical vagus nerve stimulation), tVNS (Transcutaneous Vagus Nerve Stimulation), STN (Subthalamic Nucleus), neuromodulation
Other	potential, group, area, case, ability, side, number, quality, level, state, time, change, addition, challenge, task, target, background, individual, rating, selection, use, value, field, function, Hz (Hertz), paper, region

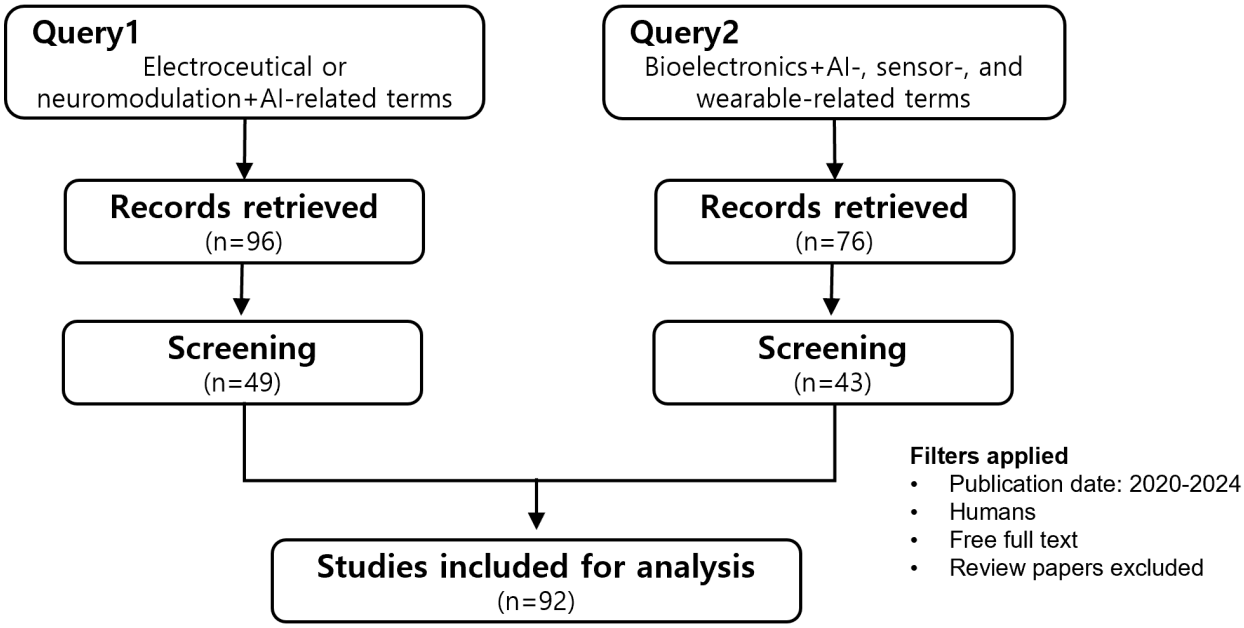
Word Clouds

Word cloud analysis is a representative technique for visualizing text-based unstructured data. It allows intuitive identification of key keywords by varying the font size based on word frequency. In this study, frequency analysis was performed on the collected text data to identify the frequency of key keywords. The preprocessed text was tokenized into words, and keywords were extracted based on their frequency of appearance. Word frequency was calculated using the “explode()” and “value_counts()” functions in the pandas library. To ensure inclusion of all words, the minimum frequency (min_word_count) was set to 5 for extraction. On the basis of these results, visualization was performed using Python’s WordCloud library, allowing an at-a-glance identification of key keywords related to smart bioelectronics.

LDA Algorithm

LDA was used for topic modeling analysis. It is an unsupervised probabilistic model that represents each document as a mixture of topics and each topic as a distribution over words. The analysis was performed using the LDA algorithm implemented in the Gensim library. The model parameters were set to “iterations=100” and “random_state=4190,” and the number of topics was explored in the range of 3 to 10 with an interval of 1.

XSL•FO
RenderX



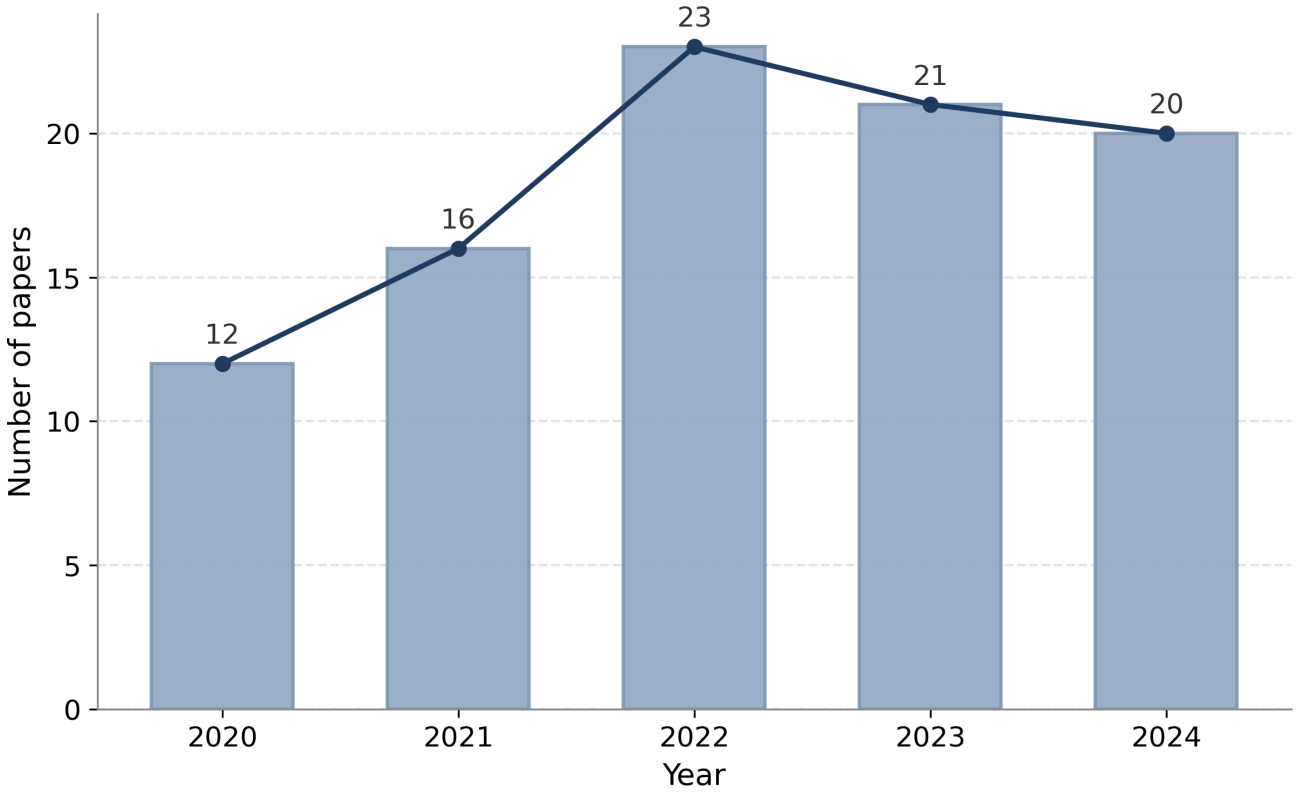
The optimal number of topics was determined based on coherence scores, which measure the semantic consistency of keywords within each topic. Perplexity was also examined as a supplementary metric for model evaluation; however, coherence was used as the primary criterion for selecting the optimal number of topics. Furthermore, the results of the LDA models were visualized using pyLDAvis, and the main keywords for each topic were identified based on the top 10 keywords generated by the model.

Results

Frequency Analysis Results by Research Period

The literature search and dataset construction process is illustrated in Figure 2. Because terminology in electroceutical and bioelectronic medicine research remains heterogeneous, some relevant studies may not have been captured by the predefined queries. Nevertheless, the 2 complementary search strategies were designed to improve coverage of this rapidly evolving research field. The annual publication trend for smart bioelectronics-related studies from 2020 to 2024 is shown in Figure 3. The number of publications increased steadily from 12 in 2020 to a peak of 23 in 2022, reflecting the growing research interest in smart bioelectronics (Figure 3).

Figure 2. Literature search and dataset construction process. AI: artificial intelligence.



Using the term frequency–inverse document frequency (TF-IDF) technique, we visualized the most representative keywords for each year from 2020 to 2024 using word clouds. The results reveal a gradual evolution in research focus within the smart bioelectronics field.

In the early stage (2020), keywords such as “biomarkers,” “electrode,” “subcallosal cingulate,” “hydrogel,” “skin,” and “ECG (Electrocardiography)” were dominant, indicating that early research primarily focused on bio-signal sensing technologies and bioelectronic device materials. These keywords reflect the importance of physiological monitoring and electrode-based interfaces in early smart bioelectronics studies. In 2021, disease-oriented terms such as “parkinson disease,” “pain,” and “disease” became more prominent, together with signal acquisition and processing technologies, including “EEG,” “algorithm,” and “control.” This pattern suggests an increasing focus on neurological disorders and the application of computational methods in bioelectronic systems. In 2022, keywords such as “prediction,” “control,” “monitoring,” “therapy,” and “signal” appeared more frequently. These terms indicate the growing integration of computational analysis, signal processing, and control mechanisms in smart bioelectronic systems, reflecting a transition toward data-driven medical device technologies. In 2023, keywords including “algorithm,” “biomarkers,” “sleep,” “tremor,” and “disease” emerged, suggesting increased interest in AI-assisted clinical monitoring and biomarker analysis for neurological and physiological conditions. Finally, in 2024, AI-related keywords such as “learning” and “prediction” became more prominent alongside clinical and device-related terms such as “surgery,” “monitoring,” “tissue,” and “electrode.” These findings indicate a growing integration of AI and predictive analytics in smart bioelectronics research, suggesting a shift toward more intelligent and adaptive bioelectronic therapeutic systems.

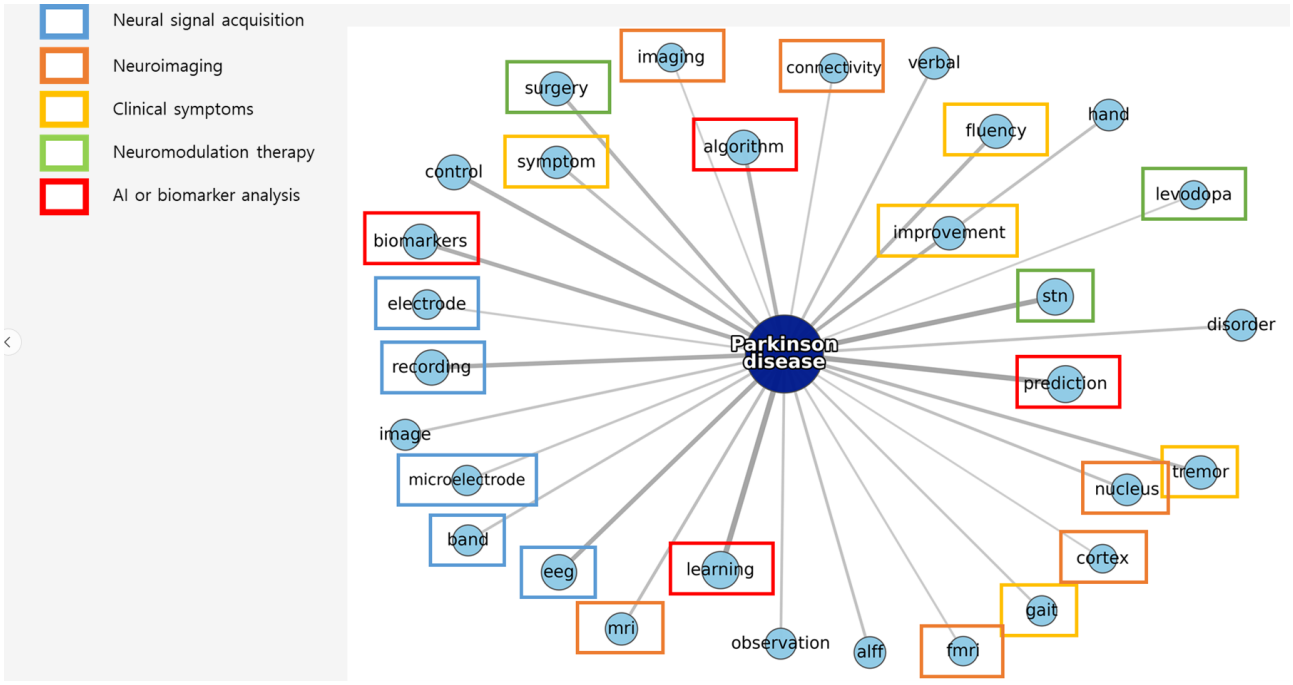
Figure 3. Number of papers by years during the study period (2020-2024). Among the study years, 2022 recorded the highest number of publications, with a total of 23 papers.

Word Cloud Analysis Results

Word clouds were generated from the top 10 keywords based on the bag-of-words (BoW) and TF-IDF methods. The BoW-based word cloud highlights keywords such as “Parkinson disease,” “biomarkers,” “disease,” “electrode,” “learning,” “prediction,” “algorithm,” “therapy,” “control,” and “EEG.” In contrast, the TF-IDF-based word cloud includes “Parkinson disease,” “biomarkers,” “control,” “prediction,” “electrode,” “EEG,” “disease,” “learning,” “therapy,” and “tissue.”

These keywords can be categorized as follows based on a semantic approach. First, “Sensor/Hardware” refers to terms associated with neural interfaces and bioelectronic sensing components that enable signal acquisition from biological systems, including keywords such as “electrode” and “tissue.” Second, “Application” relates to clinical and therapeutic contexts where bioelectronic technologies are applied for disease management, including terms such as “parkinson disease” and “therapy.” Third, “Analysis/Processing” refers to computational approaches used to analyze and interpret bio-signals, including keywords such as “prediction,” “learning,” “algorithm,” and “control.” Finally, “Signal Monitoring and Biomarkers” refers to the measurement and identification of physiological indicators used to monitor neural activity and disease states, including terms such as “EEG” and “biomarkers.”



“Parkinson disease” emerged as the most prominent keyword in both BoW and TF-IDF analyses. Accordingly, co-occurrence analysis was conducted to examine the relationships between keywords appearing alongside “Parkinson disease.” Network visualization was performed using the top 30 co-occurring keywords.

The results revealed that the research landscape can be broadly categorized into 5 major domains: neural signal acquisition, neuroimaging, clinical symptoms, neuromodulation therapy, and AI-based biomarker analysis. These findings suggest that Parkinson disease research extends beyond clinical observation, encompassing neural signal processing, advanced imaging techniques, therapeutic interventions, and data-driven analytical approaches.

Specifically, neural signal acquisition includes electrocardiogram, electrode, microelectrode, band, and recording; neuroimaging includes magnetic resonance imaging, functional magnetic resonance imaging, imaging, cortex, nucleus, and connectivity; clinical symptoms include tremor, gait, symptom, fluency, and impairment; neuromodulation therapy includes subthalamic nucleus, surgery, and levodopa; and AI-based biomarker analysis includes prediction, algorithm, learning, and biomarkers (Figure 4)

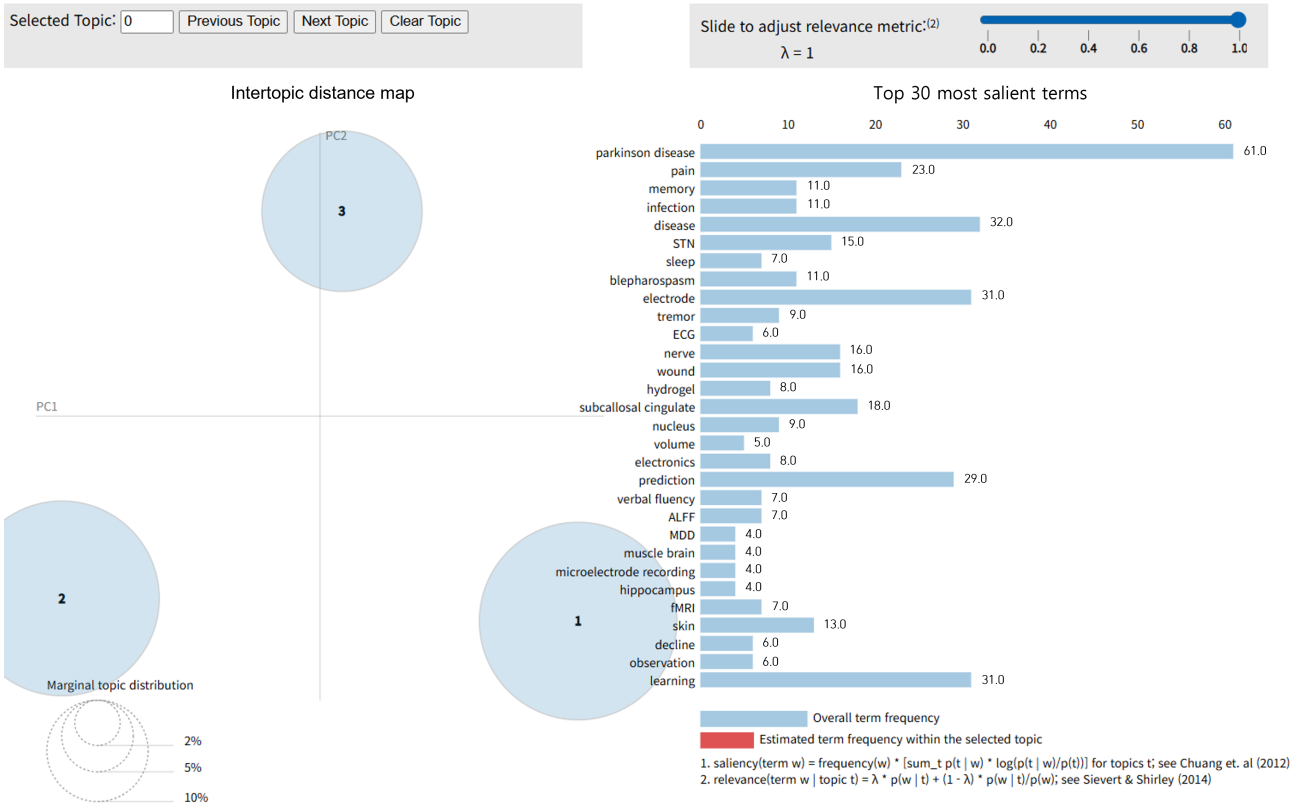
Topic Modeling Analysis Results

The coherence score was used to evaluate the LDA model across different numbers of topics, and the optimal number of topics was determined based on the highest coherence value (Figure 5). Accordingly, 3 topics were selected for the final model, and the intertopic distance map is presented in Figure 6.



Three main thematic areas were identified in smart bioelectronics (Table 3).

Table . Topic modeling results with representative keywords for each topic.

Topic	Representative keywords
Topic 1: bio-signal–based neuromodulation (publications: 23/92, 25.0%)	1. pain 2. biomarkers 3. nerve 4. therapy 5. signal 6. tissue 7. monitoring 8. control 9. skin
Topic 2: artificial intelligence–driven neurological disease analysis (publications: 32/92, 34.7%)	1. parkinson disease 2. disease 3. learning 4. EEG[a] 5. algorithm 6. control 7. STN[b] 8. subcallosal cingulate 9. image
Topic 3: implantable bioelectronics and biomaterials (publications: 37/92, 40.2%)	1. electrode 2. prediction 3. memory 4. infection 5. learning 6. parkinson disease 7. sleep 8. tissue 9. Hydrogel

[a]EEG: electrocardiogram.

[b]STN: subthalamic nucleus.

Topic 1 represents bio-signal–based neuromodulation, characterized by keywords such as “pain,” “biomarkers,” “nerve,” and “signal,” indicating a focus on physiological signal acquisition and biomarker-driven therapeutic approaches. From a technical perspective, this topic primarily relies on signal sensing and feature extraction techniques, which form the foundation for subsequent data-driven analysis. Clinically, these approaches enable continuous physiological monitoring and provide objective biomarkers for disease assessment and treatment evaluation.

Topic 2 corresponds to AI-driven neurological disease analysis, including “Parkinson disease,” “EEG,” “learning,” and “algorithm,” suggesting the increasing use of machine learning techniques for the analysis and interpretation of neurological disorders. These approaches are commonly associated with advanced AI methodologies, such as deep learning architectures for bio-signal processing and pattern recognition. From a clinical perspective, these developments contribute to improved diagnostic accuracy, early detection of neurological conditions, and more personalized treatment strategies.

Topic 3 reflects implantable bioelectronics and biomaterials, with representative keywords such as “electrode,” “hydrogel,” “tissue,” and “wound,” highlighting advancements in implantable devices and their interaction with biological systems. The inclusion of terms such as “prediction” and “learning” further indicates the integration of data-driven approaches with implantable systems, enabling intelligent and adaptive therapeutic functions. Clinically, these technologies support real-time monitoring, closed-loop stimulation, and improved treatment efficiency through dynamic adjustment of therapeutic parameters.

Overall, these topics illustrate the evolving research landscape of smart bioelectronics, progressing from bio-signal–based monitoring to AI-driven analysis and, more recently, to intelligent, adaptive, and clinically applicable bioelectronic systems. This progression reflects a paradigm shift toward precision medicine, in which data-driven insights and responsive therapeutic devices are increasingly integrated to address key clinical challenges.

The temporal distribution of topics reveals a clear evolution in smart bioelectronics research (Figure 7). Early studies were dominated by topic 3, reflecting a strong focus on bioelectronic devices and materials. Between 2021 and 2022, topic 2 became predominant, indicating a rapid expansion of AI-driven analysis and disease-oriented research. In 2023, the distribution became more balanced across topics, suggesting an integration phase [105]. By 2024, topic 3 regained prominence, highlighting a shift toward the practical application and clinical translation of intelligent bioelectronic systems.

Table S1 in Multimedia Appendix 1 summarizes the results of a preliminary review of 92 key papers related to smart bioelectronics [15-106]. These papers were published in leading journals such as *Nat Commun*, *Adv Sci* (*Weinh*), *Sensors* (*Basel*), and *Brain Stimul*. The most frequently appearing keywords were "machine learning," "bioelectronics," "deep brain stimulation (DBS)," and "Parkinson's disease," indicating that smart bioelectronics research is evolving beyond general AI-based analysis toward clinically oriented applications, particularly in neuromodulation and neurological disorder management. Although traditional machine learning models, such as support vector machines and random forests, remain the most frequently used approaches, deep learning models, including convolutional neural networks, are increasingly being adopted, indicating a gradual shift toward more advanced analytical techniques.

Discussion

Principal Findings

This study conducted keyword analysis and topic modeling based on academic papers on smart bioelectronics published over the past 5 years. The analysis identified three major thematic areas: (1) bio-signal–based neuromodulation, (2) AI-driven neurological disease analysis, and (3) implantable bioelectronics and biomaterials. These findings demonstrate that smart bioelectronics are expanding across diverse domains, both technologically and clinically. In particular, they are emerging as a convergent technology that enables integrated disease management, spanning early detection, diagnosis, treatment, and continuous monitoring.

Furthermore, the coexistence and intermingling of terms such as "bioelectronic medicine" and "electronic drug" highlight the need for clearer conceptual definitions and a standardized classification system in this field. Establishing consistent terminology and conceptual frameworks will be essential to improve the efficiency, interoperability, and advancement of interdisciplinary research and technological applications.

From a technological perspective, conventional bioelectronic devices have traditionally relied on hardware-based electrical stimulation to induce therapeutic effects. In contrast, smart bioelectronics are increasingly developing into integrated systems that combine bio-signal sensing, wireless communication, and data-driven analytical capabilities. Consistent with these findings, the identified topics indicate a transition toward systems that combine continuous bio-signal monitoring, machine learning-based data analysis, and adaptive therapeutic functions.

These technological advancements are closely linked to their clinical relevance. Bio-signal–based approaches enable continuous and objective physiological monitoring, while AI-driven analytical methods support more accurate diagnosis and interpretation of complex neurological conditions. In addition, implantable bioelectronic systems facilitate real-time monitoring and closed-loop therapeutic interventions, allowing treatments to be dynamically adjusted based on patient-specific conditions. Collectively, these developments highlight the potential of smart bioelectronics to improve diagnostic accuracy, enhance treatment personalization, and support more efficient long-term disease management.

Despite these contributions, this study has several limitations. The dataset consisted of 92 papers, representing a moderate

XSL•FO
RenderX

sample size for exploratory topic modeling. However, the relatively limited number of documents may affect the stability of probabilistic models such as LDA; therefore, the identified topics should be interpreted as indicative trends rather than definitive thematic structures. In addition, data collection was limited to the PubMed database, which may restrict the comprehensive coverage of the research landscape. Future research should expand the scope of literature collection to include multiple academic databases, such as IEEE Xplore and Embase, to improve coverage and robustness. The application of advanced natural language processing techniques, such as BERTopic, may further enhance analytical precision and enable more fine-grained topic extraction. These efforts will contribute to a more comprehensive understanding of the technological evolution and core research directions in smart bioelectronics. Smart bioelectronics represent a multidisciplinary research field encompassing medical technology, information technology, and life sciences. Continued integration of clinical research and technological innovation, along with collaboration among academia, industry, and health care systems, will be essential to accelerate the development of AI-driven medical data analysis systems and expand clinical applications, ultimately advancing next-generation precision health care.

Conclusions

This study analyzed recent research trends in the field of smart bioelectronics by conducting keyword analysis and LDA-based topic modeling on 92 papers collected from PubMed. The findings reveal an increasing trend in research activity over the past 5 years, with topics evolving from bio-signal sensing and device-level technologies to AI-driven analysis, predictive modeling, and clinically oriented, adaptive bioelectronic systems for precision medicine. These results provide a foundation for shaping domestic research and development strategies in smart bioelectronics and offer insights for applications in digital health care, AI-driven therapeutics, and next-generation wearable medical devices. Despite these contributions, this study is limited by the relatively small number of papers analyzed and its reliance on a single database. Future research should integrate data from multiple international databases and adopt more advanced computational approaches, such as transformer-based topic modeling and network analysis, to better capture diverse research trends and uncover emerging subfields in bioelectronics.

Funding

This research was supported by a grant from the Korea Health Technology R&D Project through the Korea Health Industry Development Institute, funded by the Ministry of Health and Welfare, Republic of Korea (grant RS-2024-00439193).

Abstract

Background: Predicting mortality among people living with HIV enables clinicians to implement timely, targeted, and preventive interventions at the start of antiretroviral therapy (ART). However, prognostic models must rely strictly on baseline predictors to avoid look-ahead bias and ensure scientific validity. This study evaluates machine-learning (ML) algorithms for baseline mortality prediction using routine electronic medical record data.

Objective: This study aims to predict mortality among people living with HIV receiving ART using baseline clinical and sociodemographic characteristics through ML models in public health facilities of Gondar City Administration, Northwest Ethiopia.

Methods: The retrospective cohort study was conducted using electronic medical record data from 12,871 people living with HIV on ART (2005 - 2024). Seven base classifiers were evaluated using stratified 10-fold cross-validation. Synthetic minority oversampling technique (SMOTE)–balanced variants were used only for sensitivity analysis. SMOTE oversampling was applied only to training folds; the final evaluation used the original imbalanced test data. Shapley Additive Explanations (SHAP) analysis identified key baseline predictors.

Results: Gradient boosting on the original data achieved superior performance (accuracy 87.0%, F_1-score 0.619, area under the receiver operating characteristic curve 0.859), outperforming extreme gradient boosting (F_1-score 0.609, area under the receiver operating characteristic curve 0.835) and SMOTE variants. The SHAP analysis identified education level, lack of formal education (+0.84), and a low baseline cluster of differentiation 4 (CD4; a type of immune cell count) count of 140 cells/mm³ (+0.54) as substantially increasing predicted mortality risk. Urban residence (−0.35) and working functional status (−0.12) showed protective effects, whereas age (45 y; −0.02) had minimal influence in the illustrated case. Globally, lower CD4 counts and the absence of formal education were consistently associated with increased mortality risk.

Conclusions: Ensemble ML models demonstrated moderate-to-strong discrimination for predicting mortality among people living with HIV using strictly baseline routine electronic medical record data. SHAP-based interpretability confirmed that educational attainment and baseline CD4 count were the dominant determinants of predicted mortality risk, underscoring the combined influence of socioeconomic vulnerability and immunological status at ART initiation. These findings support the potential utility of interpretable ML models for early risk stratification and targeted clinical decision-making in resource-limited settings; however, external validation is required before routine clinical implementation.

Introduction

Recent advances in machine learning (ML) have enabled the development of predictive models using routinely collected electronic medical record (EMR) data to support clinical decision-making and risk stratification. Several studies demonstrated the feasibility of applying ML algorithms, such as logistic regression, random forest, gradient boosting, and extreme gradient boosting (XGBoost), to predict mortality and other adverse outcomes across diverse clinical settings using EMR or electronic health record data. Systematic reviews highlighted that ML-based mortality prediction models often outperform traditional statistical approaches, while also emphasizing the importance of appropriate validation strategies and the prevention of data leakage through baseline-only predictors [1-3]. EMR-based ML models have been successfully applied to predict short-term and in-hospital mortality among patients with conditions, such as cancer, heart failure, and COVID-19, using structured clinical and laboratory variables [4-6]. These studies underscore the growing role of explainable artificial intelligence (XAI) methods, such as SHAP (Shapley Additive Explanations), in improving the interpretability and clinical relevance of complex ML models, which is a key consideration for adoption in real-world health care settings [5,7].

HIV remains a major public health concern globally and in sub-Saharan Africa, where mortality among people living with HIV persists despite widespread ART coverage. Since the early 2000s, when the global HIV epidemic peaked, new infections and HIV-related deaths have declined. Expanded antiretroviral therapy (ART) coverage has reduced HIV-related mortality by almost 47%, from 2.1 million in 2004 to 630,000 in 2023 [8]. However, the epidemic remains a significant global health issue, especially in regions with limited access to preventive, diagnostic, and treatment services. Currently, an estimated 39.9 million individuals are living with HIV, according to the UNAIDS (Joint United Nations Program on HIV/AIDS) 2024 Global HIV and AIDS Statistics Report.

Sub-Saharan Africa bears the highest global HIV burden, accounting for approximately 67% of HIV cases and over 60% of HIV-related deaths [8]. Southern and Eastern African nations have made progress in reducing mortality and increasing access to ART. However, challenges, such as poverty, stigma, violence, and health care inequality, hinder efforts to decrease HIV-related fatalities. In 2023, approximately 390,000 Africans died from HIV-related causes. While ART rollouts have significantly reduced these numbers, the disease remains a serious public health concern.

Ethiopia has one of the largest HIV epidemics in East Africa, with approximately 610,000 people living with HIV in 2023 [2]. Despite improvements in health care infrastructure and ART coverage, significant challenges persist, especially for individuals with advanced HIV or treatment failure. In 2023, Ethiopia recorded approximately 10,000 HIV-related deaths, with rural areas facing higher mortality due to limited health care access [9]. HIV-related mortality remains high in sub-Saharan Africa, including Ethiopia, even though ART has transformed HIV into a chronic, manageable condition. Key contributors include late ART initiation, poor adherence, medication resistance, and virological failure, which prevent effective viral suppression [10-12]. Virological failure accelerates disease progression and increases the risk of AIDS-related death. Reducing mortality among people living with HIV requires early diagnosis, improved ART regimens, and better patient monitoring.

A 2022 study at the University of Gondar Comprehensive and Specialized Hospital reported a virological failure rate of 14% among people living with HIV on ART [12]. This highlights the urgent need for predictive tools to identify high-risk patients early and improve clinical outcomes. Mortality prediction plays a crucial role in health care, epidemiology, insurance, and policymaking. It helps health care providers identify high-risk individuals, enabling early interventions and personalized treatments that improve patient outcomes [13]. It also supports epidemiological research by analyzing disease patterns and assessing intervention effectiveness [8. Advanced methodologies, such as statistical models, ML, and deep learning, have significantly improved the accuracy and applicability of mortality predictions [14,15].

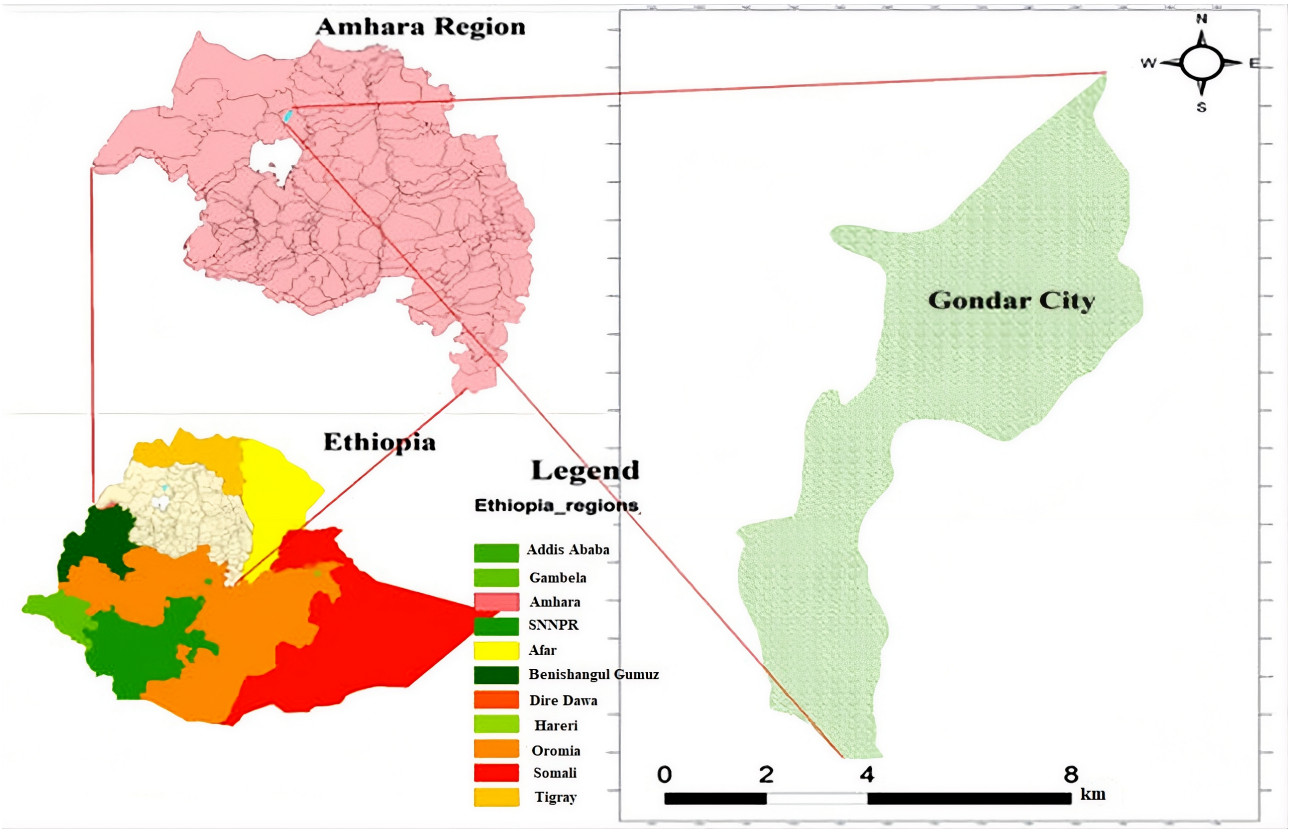
ML offers a data-driven solution for predicting mortality risk in people living with HIV on ART. ML algorithms analyze large datasets to detect complex patterns, risk factors, and interactions that traditional statistical methods may overlook [16]. This study develops interpretable ML models using strictly baseline predictors (recorded at ART initiation) from 12,871 people living with HIV EMRs to enable prospective mortality risk stratification. There is a pressing need to implement advanced predictive tools, such as ML models, to identify individuals at greater risk of treatment failure or death [17]. These tools can enable health care providers to take proactive measures, improve treatment outcomes, and reduce HIV-related mortality in Ethiopia.

This study aimed to develop and validate ensemble ML models predicting mortality among people living with HIV on ART in Gondar, Ethiopia, using baseline-only EMR data, with the SHAP analysis to identify clinically actionable risk factors. Several studies in Africa and Asia have applied ML for HIV-related outcomes, including mortality and treatment interruption. A meta-analysis across 24 studies found that ML models achieved a C-index of ~0.83 for HIV mortality prediction [18]. In China, an XGBoost and random forest ensemble achieved an area under the receiver operating characteristic (ROC) curve (AUC) of ~0.98 for in-hospital mortality among patients with HIV/AIDS with cryptococcal infection [19]. In Nigeria, a large EMR-based ML study of 41,394 people living with HIV reported an AUC of ~0.8 for treatment interruption [20]. However, these studies often used hospital-based cohorts or follow-up predictors, focused on treatment interruption or virological failure rather than long-term mortality, and lacked comprehensive interpretability analyses. Our study addresses these gaps through large-scale public health facility EMR data (n=12,871), strict baseline-only prediction, rigorous temporal validation, and SHAP-based clinical interpretability.

XSL•FO
RenderX

Traditional methods of monitoring and predicting patient outcomes rely on periodic clinical assessments, laboratory tests, and physician judgment. These approaches often detect complications only after symptoms have worsened, leading to delayed interventions that may not prevent adverse outcomes. Additionally, reliance on manual record keeping and retrospective data analysis limits the ability to identify high-risk patients early, reducing the effectiveness of timely medical interventions. In resource-constrained settings, such as the Gondar City Administration, integrating ML models could improve health care delivery, optimize resource distribution, and enhance proactive patient management [21]. This approach aligns with Ethiopia's national HIV/AIDS control strategy and global health goals aimed at reducing HIV-related mortality.

Methods



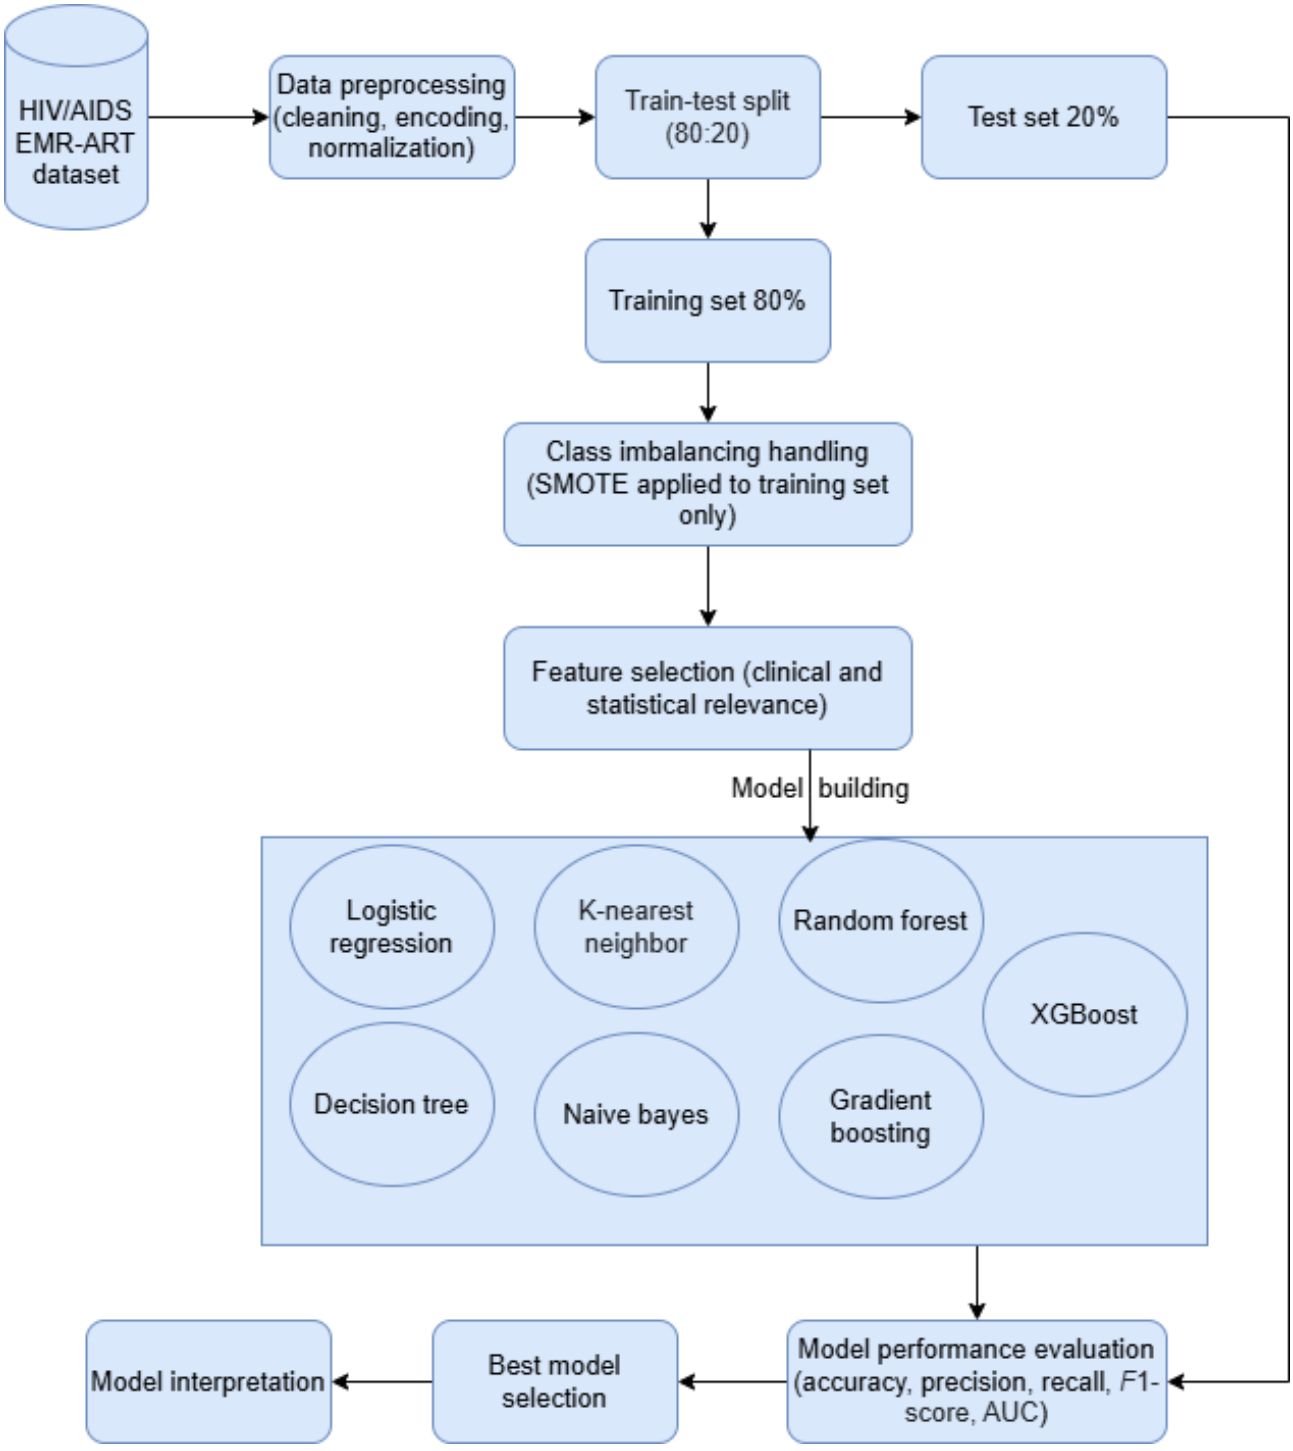
Study Area and Period

Data were extracted from the ART EMRs covering the period from 2005 to 2024. Only patients on ART for ≥6 months before analysis were included to ensure baseline predictor availability.

This study was conducted at public health facilities in Gondar City Administration (Amhara Region, Ethiopia) from October 10 to December 10, 2024. Gondar City (population 457,938) is located 748 km northwest of Addis Ababa. In the Gondar City Administration, several health care facilities provide ART services to people living with HIV. Among them, the University of Gondar Specialized and Comprehensive Hospital serves as a key provider of ART services, offering specialized care to patients. Additionally, multiple health centers, including Azezo Health Center, Gondar Health Center, Maraki Health Center, Mintwab Health Center, St. Gebriel Health Center, Teda Health Center, and Woleka Health Center, also provide ART services, ensuring accessibility to treatment at various levels of health care.

Health facility mapping was conducted to provide context to the data source; however, facility service gaps were not the focus of this predictive modeling study (see Figure 1).

Figure 1. Geographic location of the study area showing the Gondar City Administration, Amhara National Regional State, Northwest Ethiopia, where a retrospective cohort study of adults living with HIV receiving antiretroviral therapy (ART) was conducted using electronic medical records from public health facilities, 2005 - 2024. The map of the study area was adopted from Tamiru AT, Rade BK et al. (2020) [22].



Study Design

The retrospective cohort study analyzed baseline-only EMR data (ART initiation records) to predict prospective mortality (see Figure 2).

XSL•FO
RenderX

Figure 2. Workflow diagram of the machine-learning pipeline used to predict mortality among adults living with HIV on antiretroviral therapy (ART) in public health facilities of Gondar City Administration, Northwest Ethiopia, 2024. AUC: area under the receiver operating characteristic curve; EMR: electronic medical record; SMOTE: synthetic minority oversampling technique; XGBoost: extreme gradient boosting.

Data Source

Data are sourced from EMR-ART databases across Gondar City Administration public health facilities, containing baseline sociodemographic, clinical, laboratory, and treatment initiation data.

Description of the Dataset

The dataset used in this study focused on people living with HIV undergoing ART in public health facilities within the Gondar City Administration, Ethiopia. Data collection covered the entire period since the start of ART services at the facilities.

Inclusion and Exclusion Criteria

Eligible participants were adults aged ≥18 years of age with ≥6 months of ART exposure. Participants were included if baseline variables were recorded at ART initiation; limited missing baseline values (<10%) were addressed using imputation. We excluded patients with incomplete ART start dates, those transferred to other facilities without outcome documentation,

XSL•FO
RenderX

and non-HIV–related deaths (eg, accidents and trauma) to ensure outcome validity.

Predictor Variables

The binary outcome was mortality (follow-up status: alive=0, dead=1). Baseline predictors (all recorded at ART initiation) included 10 variables across 3 domains: sociodemographic (age, sex, marital status, educational level, residence, and religion), clinical (tuberculosis [TB] screening result and functional status), and immunological (baseline cluster of differentiation 4 [CD4] count). The baseline CD4 count was modeled as a continuous numerical feature in all ML algorithms. Descriptive statistics are therefore presented as median and IQR. Variable selection used recursive feature elimination with cross-validation applied exclusively to training data. The subsequent SHAP analysis confirmed the clinical plausibility of retained predictors.

Operational Definitions

Mortality, the outcome variable of interest in the study, is defined as the death of people living with HIV receiving ART. This is directly or indirectly related to the progression of HIV, opportunistic infections, or complications arising from the virus or treatment.

A low CD4 count of less than 200 cells/mm³ indicates a severely weakened immune system, placing the individual at high risk for opportunistic infections and HIV-related complications. A normal CD4 count between 200 and 500 cells/mm³ suggests a moderately functioning immune system. A high CD4 count greater than 500 cells/mm³ is considered within the normal range and reflects a healthier immune system.

Comorbidities are the presence of other chronic health conditions in people living with HIV alongside HIV infection.

Data Collection Tool and Procedures

The data collection tool used in this study was an electronic data extraction form specifically designed to retrieve relevant patient information from the EMR-ART database. The form was developed via a standardized template based on key study variables to ensure data consistency, completeness, and accuracy. The data collection process began with obtaining ethical approval and permission from relevant health authorities. Data collectors were trained in using the extraction tool and procedures to ensure uniformity in data retrieval. Data were extracted by reviewing patient records from the EMR-ART database using selected features and exported into Excel. Each record was thoroughly reviewed for accuracy, and a second data collector cross-verified entries to maintain data consistency.

Ethical Considerations

Ethical approval for this study was obtained from the College of Medicine and Health Sciences Institutional Research Ethics Review Committee (CMHS IRERC) at Debre Markos University (reference number RCSTTD/403/01/17). Due to the retrospective design, the requirement for informed consent was waived by the committee in accordance with national research ethics guidelines.

All data used were deidentified before analysis to ensure participant privacy and confidentiality. No personally identifiable information (eg, names or medical record numbers) was extracted. Data were stored on password-protected computers accessible only to authorized researchers.

There was no financial compensation to participants, as this study relied on existing EMRs. No images or identifiable information about individual participants are presented in this paper. Ethical approval was obtained from the institutional review board of the Amhara Public Health Institute (APHI) (approval number: APHI/322/007). The study was conducted in accordance with the ethical principles of the Declaration of Helsinki and complied with the Ethiopian National Research Ethics Review Guideline [23].

Data Quality Control

Data quality control procedures were applied throughout the study to ensure reliability and validity. These procedures involved consistency checks and the correction of missing entries. Data entry was supervised by experienced clerks, and predefined validation rules flagged inconsistencies.

Data Management and Analysis

Association Rule Mining

Association rule mining was conducted to identify frequent co-occurrence patterns among clinical and treatment-related factors associated with mortality. The Apriori algorithm implemented in the mlxtend Python library was used. The mlxtend Python library was developed by Sebastian Raschka and provides useful extensions for machine learning and data science tasks. Key metrics included support (frequency of rule occurrence), confidence (conditional probability of the consequent given the antecedent), and lift (degree of dependence between antecedent and consequent). Rules with support ≥0.065, confidence ≥0.64, and lift >4.6 were retained for interpretation. These analyses were used to explore unadjusted co-occurrence patterns and were not intended to estimate causal or adjusted effects.

Data Cleaning

This phase involved handling missing values, detecting and removing outliers via Excel filters, and addressing class imbalance. The dataset contained less than 10% missing values for most variables. Median imputation was applied to numerical variables, such as CD4 count, while mode imputation was used for categorical baseline variables, such as marital status, residence, and religion. These simple imputation methods were chosen due to the relatively small proportion of missingness and to maintain data interpretability whereas mode imputation was applied to categorical data. One-hot encoding transforms categorical variables, creating separate columns for each category. To handle class imbalance, various techniques have been tested, with SMOTE (synthetic minority oversampling technique) providing the best accuracy. Other balancing techniques, such as random undersampling and cost-sensitive learning, were initially tested. However, they resulted in reduced sensitivity for the minority class (deceased patients). SMOTE provided the best balance between precision and recall, ensuring robust generalization across folds.

XSL•FO
RenderX

Feature Engineering

By converting raw data into meaningful features, feature engineering enhances model performance. One-hot encoding was used for categorical variables, and normalization ensured comparable feature scales [24].

Feature Selection and Dimensionality Reduction

Feature selection was performed exclusively using recursive feature elimination with cross-validation on the training data to identify the most informative subset of predictors while minimizing redundancy and overfitting.

Data Splitting

A training-test split and K-fold cross-validation ensured robust evaluation. The dataset was divided into training and testing sets, with K-fold validation reducing overfitting and improving generalizability.

Model Training and Evaluation

To prevent data leakage, the dataset was first split into training and hold-out test sets. All preprocessing steps, including imputation, feature scaling, encoding, and feature selection, were conducted exclusively within the training data using a cross-validation framework. Model performance was assessed using stratified 10-fold cross-validation on the training set and subsequently evaluated on the original, imbalanced hold-out test set. Sensitivity analyses were conducted by applying SMOTE to the training data only to assess the robustness of model performance under class imbalance.

Data Leakage Assessment and Stress-Test Validation

To ensure the robustness and validity of the predictive modeling framework, a series of predefined stress tests were conducted to assess potential data leakage, proxy outcome variables, and look-ahead bias.

Stress Test: Broken Split Check (Demographic-Only Model)

To verify independence between training and testing datasets, an XGBoost model was trained using only demographic variables (age and sex). The resulting model achieved an AUC of 0.631 on the hold-out test dataset, consistent with expected performance for demographic-only mortality prediction models. This finding confirmed that the data split procedure did not introduce artificial performance inflation due to overlapping observations or improper sampling procedures.

Model Selection

After the model was trained, several classifiers were evaluated to identify the most suitable model for predicting mortality among people living with HIV users. Given that the outcome variable is categorical and falls into 2 mutually exclusive groups, the problem was framed as a binary classification task. To select the best model, we compared the performance of these classifiers via evaluation metrics, such as accuracy, precision, recall, F_1-score, and AUC [25]. During cross-validation, we examined the consistency of each model's performance across different subsets of the data. The model with the best trade-off between predictive power and generalization to unseen data was chosen for final model selection. This approach ensured that the selected model was the right model for accurately predicting mortality among people living with HIV.

Evaluation Criteria

In this study, the performance of the predictive models was evaluated by testing a dataset within a training-test split and cross-validation. The performance of the trained models was subsequently evaluated on the test set based on the criteria of accuracy score, ROC curve, precision, recall, and *F*-measure. The confusion matrix, which is a matrix of N×N, where N is the number of predicted classes, displaying the number of correct and incorrect predictions made by the classification model, was used in this study. Because mortality prevalence was 20%, F_1-score and AUC were prioritized over accuracy for model comparison.

Results

Description of Sociodemographic Characteristics

A total of 12,871 study participants were included in this study; the majority were between the ages of 38 and 47 years (n=4468, 34.7%), suggesting a largely middle-aged population; 7688 (59.7%) of the sample were female, indicating a gender imbalance; the majority were married (n= 4921, 51.2%) and had completed secondary school education (n=2953, 31.3%), indicating a moderate level of education; a sizable portion lived in urban areas (n=8878, 77.1%), suggesting greater representation of urban areas; and the vast majority were Orthodox Christians (n=8714, 91.5%), representing a highly homogeneous religious composition (see Table 1).

Baseline Clinical and Immunological Characteristics

Among 12,871 people living with HIV at ART initiation, most exhibited preserved functional status (working: n=11,970, 93.1%) with low TB prevalence (n=219, 1.7% positive), consistent with late ART presentation in Ethiopian cohorts (see Table 2). The median baseline CD4 count was 225 (IQR 131 - 367) cells/mm³.

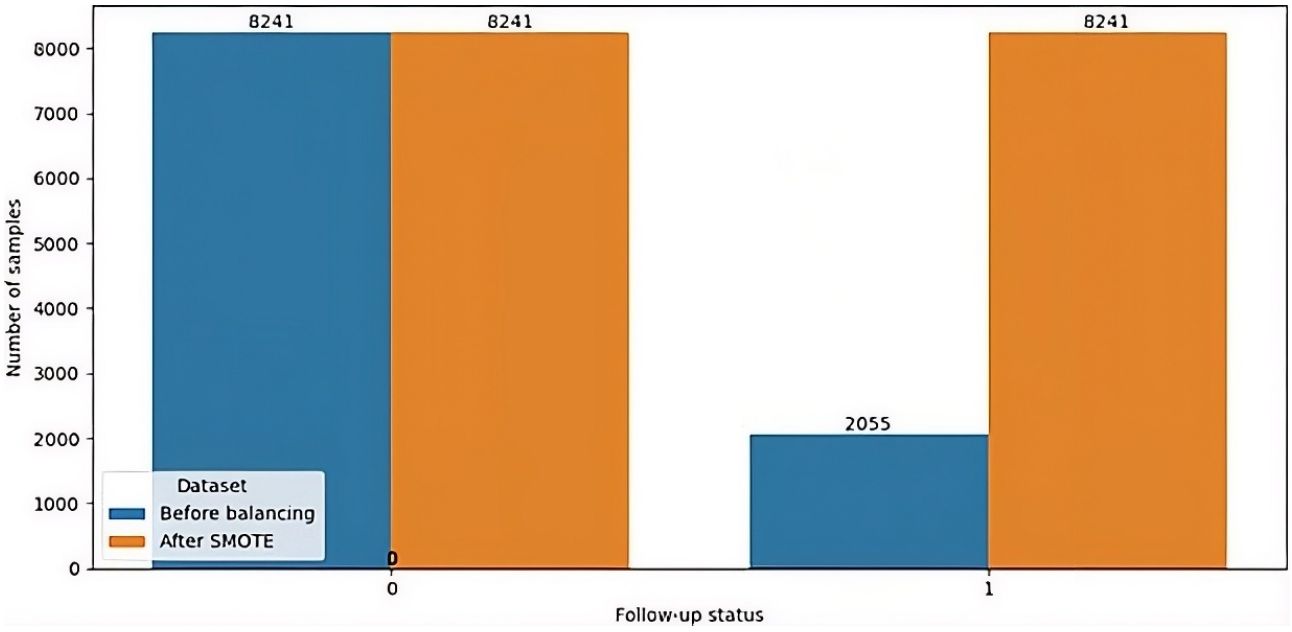
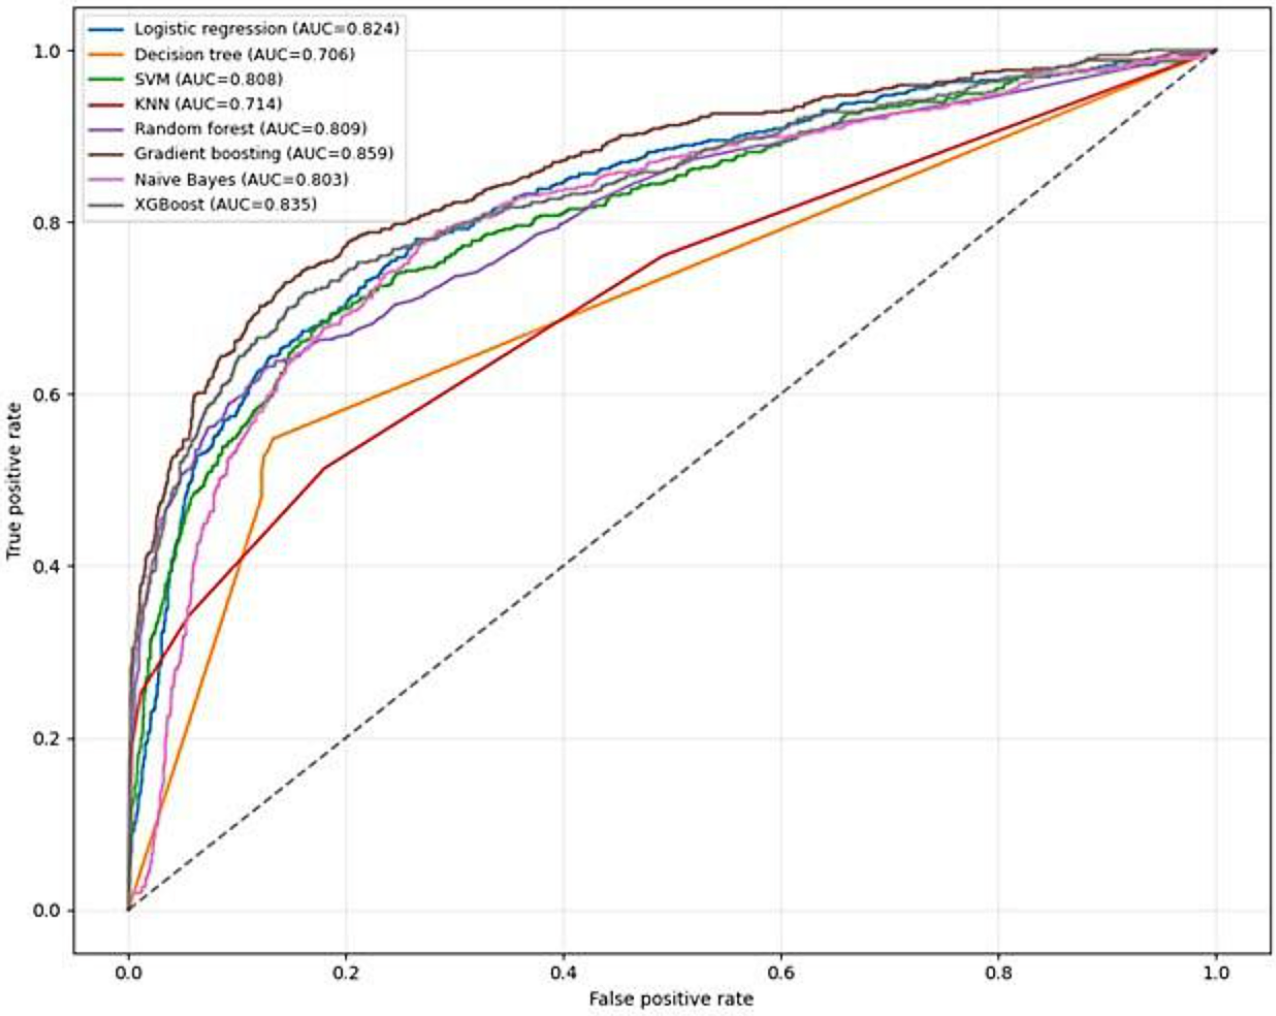
Baseline CD4[a] count (cells/mm³), median (IQR)	225 (131-367)



[a]CD4: cluster of differentiation 4 (a type of immune cell count).

Balancing Dataset

As seen in the descriptive statistics, the prevalence of mortality prediction among people living with HIV was 20%. This shows that the dataset was imbalanced; most observations (80%) were concentrated in the majority class (ie, alive). The SMOTE oversampling strategy added 6186 synthetic observations from the minority group (ie, dead) to balance the unbalanced distribution of the outcome variable. Therefore, the class distribution for mortality prediction among people living with HIV was balanced using SMOTE, resulting in a symmetric training dataset with 8241 observations in each class (alive and dead) to support the development of reliable and robust predictive models (see Figure 3). To avoid data leakage, the dataset was first split into training (80%) and testing (20%) subsets. SMOTE oversampling was then applied only to the training data, while the test set remained in its original, imbalanced form. This ensured unbiased performance evaluation on unseen data.

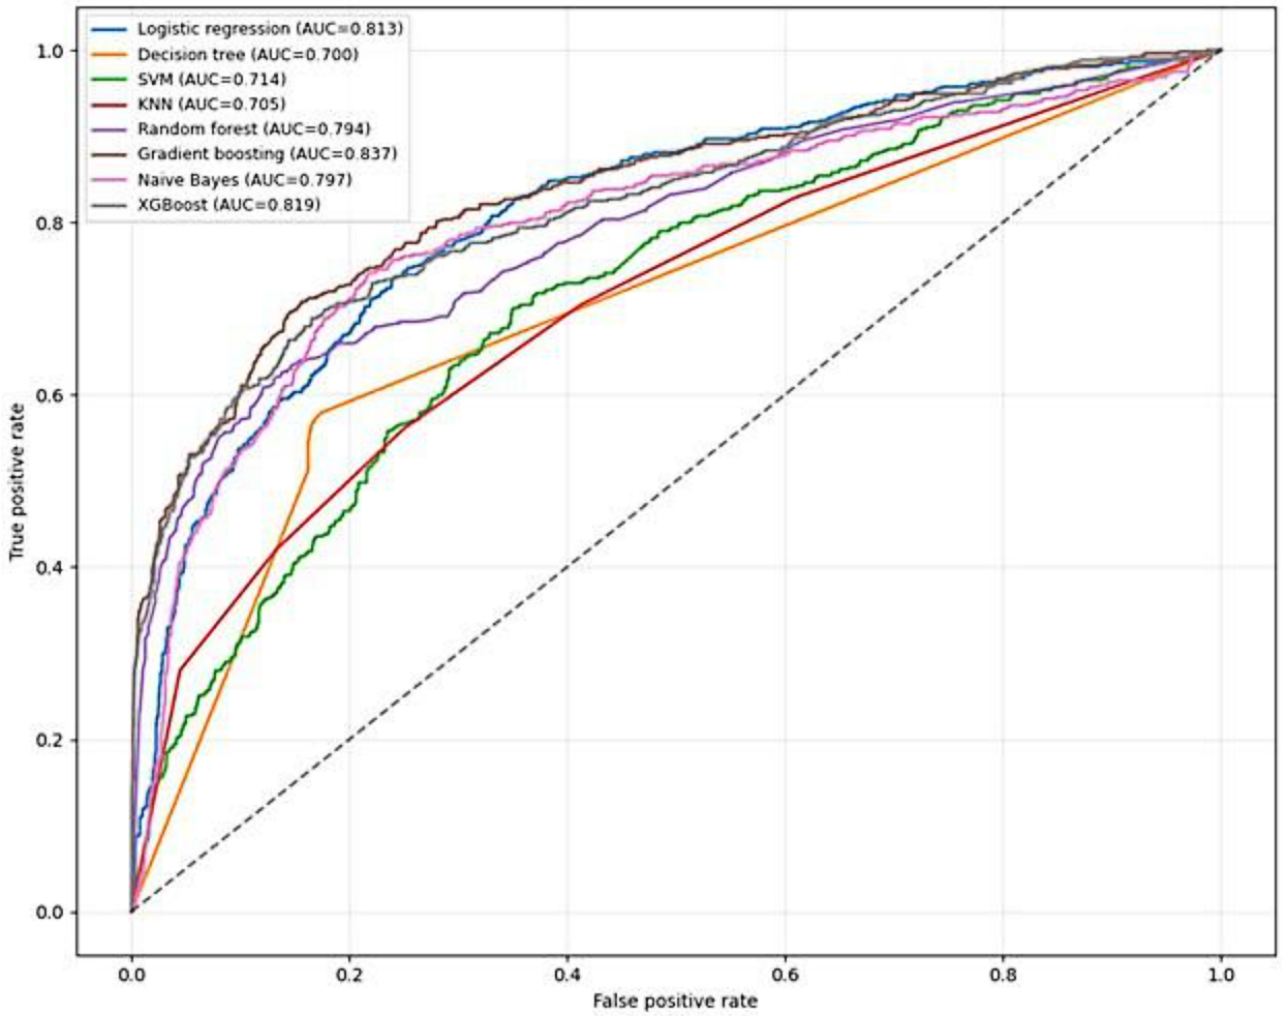


ROC curves for 7 ML models trained on the original imbalanced dataset (20% mortality prevalence) demonstrated clinically realistic discrimination (AUC range: 0.70 - 0.86). Gradient boosting achieved superior performance (AUC=0.859), followed by XGBoost (AUC=0.835) and logistic regression (AUC=0.824). Random forest (AUC=0.809) and Naive Bayes (AUC=0.803) showed moderate discrimination, while k-nearest neighbor (KNN) and decision tree showed lower discrimination compared to ensemble models (see Figure 4).

Figure 3. Class distribution of mortality outcomes (alive vs deceased) among adults living with HIV receiving antiretroviral therapy (ART) in Gondar City Administration, Northwest Ethiopia, showing the original imbalanced dataset and the training set after SMOTE (synthetic minority oversampling technique) was applied to address class imbalance for model development, 2005 - 2024.

XSL•FO
RenderX

Figure 4. Receiver operating characteristic (ROC) curves for 7 machine-learning classifiers evaluated on the original imbalanced test dataset for mortality prediction among adults living with HIV on antiretroviral therapy (ART) in public health facilities of Gondar City Administration, Northwest Ethiopia, reporting discrimination performance before class balancing, 2005 - 2024. AUC: area under the receiver operating characteristic curve; KNN: k-nearest neighbor; SVM: support vector machine; XGBoost: extreme gradient boosting.



SMOTE-balanced models (training only, evaluated on the original imbalanced test set) demonstrated stable discrimination with modest recall improvements but precision trade-offs typical of oversampling. Logistic regression achieved AUC=0.813 (gain +0.0 from original), decision tree AUC=0.700 (−0.006), and KNN AUC=0.705 (−0.009). Tree-based ensembles maintained robustness: andom forest AUC=0.794 (−0.015), gradient boosting AUC=0.837 (−0.022), XGBoost AUC=0.819 (−0.016), and Naive Bayes AUC=0.797 (−0.006). Original configurations outperformed SMOTE variants (median ΔAUC=−0.013 [IQR -0.019 to 0.008]), favoring models trained on unaltered data for potential future clinical implementation, pending external validation (see Figure 5).

Model performance comparison across original and SMOTE-balanced configurations demonstrates gradient boosting original's superiority (F_1-score=0.619, AUC=0.859), outperforming XGBoost original (F_1-score=0.609, AUC=0.835). SMOTE-trained models showed recall gains but precision losses: XGBoost SMOTE (F_1-score=0.592, AUC=0.819; ΔF_1-score=−0.017), random forest SMOTE (F_1-score=0.576, AUC =0.794; ΔF_1-score=−0.021), and gradient boosting SMOTE (F_1-score=0.608, AUC=0.837; ΔF_1-score=−0.011). Ensemble methods maintained robust discrimination after balancing (AUC>0.79), whereas simpler models showed greater variability. KNN and decision tree exhibited the lowest performance across configurations, reaffirming ensemble learning's advantage for high-dimensional, imbalanced HIV mortality prediction.

Original data configurations consistently outperformed SMOTE variants (median ΔF_1-score=−0.011, median ΔAUC=−0.013), supporting potential future clinical implementation pending external validation without synthetic oversampling. This finding aligns with real-world prevalence modeling priorities where precision preservation exceeds recall optimization for resource allocation in ART programs (see Figure 6).

Figure 6. Comparative performance of machine-learning models (accuracy, precision, recall, F_1-score, and area under the receiver operating characteristic curve [AUC]) for mortality prediction among adults living with HIV receiving antiretroviral therapy (ART) in public health facilities of Gondar City Administration, Northwest Ethiopia, 2024. KNN: k-nearest neighbor; SMOTE: synthetic minority oversampling technique; SVM: support vector machine; XGBoost: extreme gradient boosting.

Model Building and Selection

The predictive performance of 7 ML models was comprehensively evaluated using accuracy, precision, recall, F_1-score (primary), and AUC on an 80:20 stratified train-test split. A critical distinction is that all preprocessing procedures, including SMOTE, were applied to training data only; the final evaluation used the original imbalanced test set (20% mortality prevalence) to reflect real-world deployment conditions.

On the original imbalanced test data, gradient boosting demonstrated superior balanced performance (accuracy=87.0%, precision=74.5%, recall=52.9%, F_1-score=0.619, AUC=0.859), outperforming XGBoost (F_1-score=0.609, AUC=0.835) and random forest (F_1-score=0.597, AUC=0.809). Ensemble methods consistently exceeded single classifiers, followed by Naive Bayes (F_1-score=0.562) and logistic regression (F_1-score=0.553).

SMOTE sensitivity analysis (training only) yielded recall gains but precision losses: XGBoost recall improved by +8.2% (F_1-score=0.592, ΔF_1-score=−0.017) and gradient boosting by +14.2% (F_1-score=0.608, ΔF_1-score=−0.011). Original configurations outperformed SMOTE variants across top models (median ΔF_1-score=−0.011 [IQR 0.006-0.019], ΔAUC=−0.013 [IQR 0.008-0.019]), confirming unaltered EMR data superiority for clinical precision.

Gradient boosting (original) was selected as optimal due to the highest F_1-score, cross-validation stability, and SHAP interpretability, establishing moderate-to-strong discrimination performance for 20% prevalence mortality prediction in resource-limited settings (see Table 3).

Association Rule Mining

Association rule mining using the Apriori algorithm (mlxtend; rules with support ≥0.065, confidence ≥0.64, and lift >4.6 were retained for interpretation) identified high-risk sociodemographic profiles among baseline characteristics. The dominant pattern—"rural residence + age 38‐47 years + no formal education + low baseline CD4 → mortality"—exhibited support=0.0686 (6.9% prevalence), confidence=68.3%, and lift=4.76, indicating that this subgroup showed a 4.76-fold higher co-occurrence with mortality compared with the baseline mortality prevalence (20% baseline prevalence).

In addition, demographic context (Christian religion, TB-negative status) maintained high lift values (4.62‐4.74), indicating that this subgroup exhibited the strongest co-occurrence pattern with mortality in the unadjusted association analysis (see Table 4). These association rules reflect co-occurrence patterns and should not be interpreted as causal risk factors.

The gradient boosting model demonstrates strong and clinically plausible classification performance (see Figure 7), which presents the confusion matrix of the optimized gradient boosting classifier.

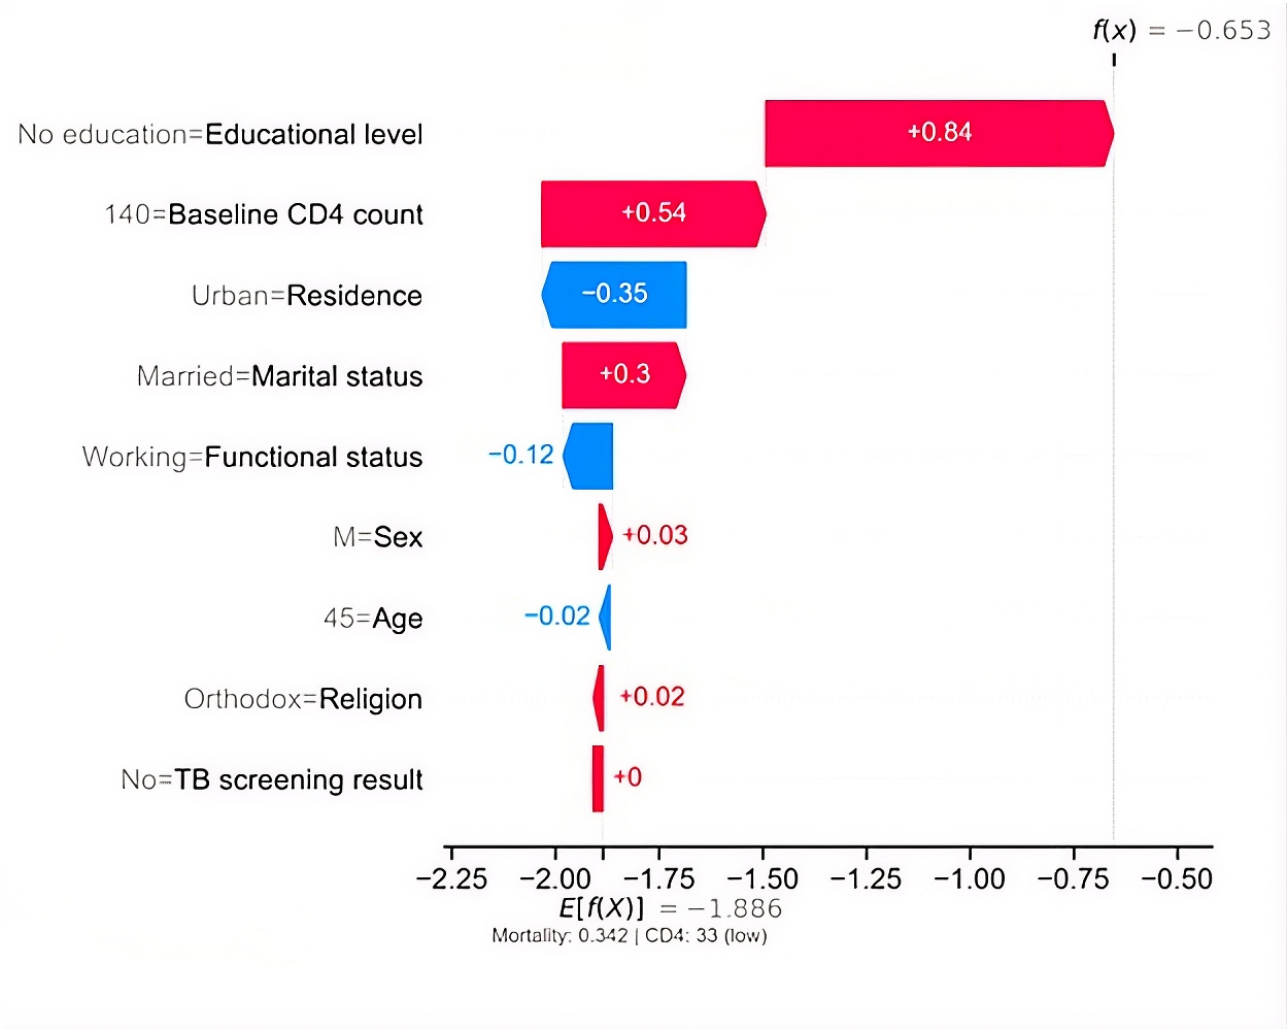
Feature Ranking

Gradient boosting trained on the original dataset was selected as the optimal model, and the SHAP summary analysis was identified as the most influential baseline predictors of mortality among 12,871 people living with HIV at ART initiation. The educational level was ranked as the strongest predictor, with lower education associated with positive SHAP values (increased mortality risk) and higher education demonstrating consistent protective effects. Residence was the second most important factor, with rural residence contributing to higher predicted mortality and urban residence showing protective effects. The baseline CD4 count exhibited a clear biological gradient: lower CD4 values clustered on the positive SHAP side, indicating increased mortality risk, whereas higher CD4 counts were associated with negative SHAP values, reflecting protection. Marital status and age showed moderate influence, with older age generally increasing predicted risk. Functional status also contributed meaningfully, as ambulatory or bedridden states increased mortality risk compared to working status. In contrast, sex, religion, and TB screening results demonstrated relatively small SHAP magnitudes, indicating limited impact on overall prediction. Overall, the SHAP ranking confirms that socioeconomic vulnerability and immunological status at ART initiation are the dominant determinants of predicted mortality risk (see Figure 8).

Figure 8. Global feature importance ranking based on mean absolute Shapley Additive Explanations (SHAP) values from the gradient boosting model, identifying the top predictors of mortality among adults living with HIV on antiretroviral therapy (ART) in Gondar City Administration, Northwest Ethiopia, 2024. CD4: cluster of differentiation 4 (a type of immune cell count); TB: tuberculosis.



Waterfall Plot

The SHAP waterfall plot illustrates the individual prediction for a 45-year-old patient. The model output is expressed on the log-odds scale for the mortality class (dead=1), with the cohort baseline expected value of $E[f(X)]=-1.886$, representing the average predicted mortality risk. For this patient, the cumulative contribution of key baseline features shifts the model output to $f(x)=-0.653$. Because this value is substantially higher than the cohort baseline, it indicates an elevated predicted mortality risk relative to the average patient, although the absolute probability remains below 0.5.

Positive SHAP values (red bars) indicate features that increase predicted mortality risk, whereas negative SHAP values (blue bars) indicate protective effects. The strongest contributor to increased mortality risk was a lack of formal education (+0.84), followed by a low baseline CD4 count of 140 cells/mm³ (+0.54). Married as marital status (+0.30) and male as sex (+0.03) provided additional, smaller risk contributions. In contrast, urban residence (−0.35) and working functional status (−0.12) exerted protective effects by reducing the predicted mortality risk. Age (45 y; −0.02), religion (+0.02), and TB screening results (~0) had minimal influence on the individual prediction (see Figure 9).

Discussion

Principal Findings

To our knowledge, this represents one of the first Ethiopia-based applications of interpretable ensemble ML (gradient boosting combined with SHAP) using baseline EMR data to predict mortality among 12,871 people living with HIV, achieving moderate but clinically realistic performance (F_1-score=0.619, AUC=0.859). Unlike earlier exploratory analyses, the final model was developed strictly using predictors recorded at ART initiation, eliminating postbaseline variables to avoid look-ahead bias and ensure valid prognostic modeling. This study contributes new evidence by demonstrating the feasibility of applying XAI models to routine EMR data to support proactive risk stratification and clinical decision-making in resource-limited settings. However, the model should be interpreted as a decision-support tool rather than a standalone clinical triage system, given its moderate sensitivity. Consistent with findings from studies published in JMIR journals, our results demonstrate the feasibility of integrating XAI models into routine clinical care to support proactive risk stratification and decision-making, particularly in low-resource settings where the efficient use of existing EMR data is critical [1-3].

Gradient boosting trained on verified baseline-only predictors achieved the best overall balance between discrimination and generalization performance (F_1-score=0.619, AUC=0.859), outperforming logistic regression, Naive Bayes, KNN, and decision tree models. While XGBoost and random forest also demonstrated competitive performance, the corrected baseline-only gradient boosting model provided the most stable and clinically interpretable results for the 20% mortality prevalence setting.

SHAP values were calculated with respect to the mortality class (dead=1). Accordingly, positive SHAP values indicate an increase in predicted mortality risk, whereas negative SHAP values represent a reduction in predicted mortality risk (protective effect).

The most influential baseline predictors included educational level, baseline CD4 count, residence, marital status, and functional status. In the illustrated case, lack of formal education and a low baseline CD4 count (140 cells/mm^3) exerted strong positive contributions, substantially increasing the predicted mortality risk. Urban residence and working functional status demonstrated protective contributions.

XSL•FO
RenderX

Importantly, the baseline CD4 count was modeled as a continuous predictor in the ML algorithms, and descriptive statistics have been revised to report a median of 225 (IQR 131-367) cells/mm³ to ensure methodological consistency. Unlike preliminary analyses that yielded inflated performance estimates, the corrected baseline-only model produced moderate but clinically realistic discrimination (AUC=0.859), consistent with previously published EMR-based mortality prediction studies [4-7].

Comparison to Prior Work

These results are consistent in accuracy with studies conducted in Nigeria and Thailand, where ensemble models achieved high predictive accuracy in the clinical context [20,26]. Several studies have explored the use of ML algorithms for mortality prediction among people living with HIV. Similarly, a study from China utilizing a support vector machine reported an accuracy of 86%, which aligns with this study's pre-SMOTE support vector machine performance [16].

The SHAP analysis provided valuable insights into the factors influencing mortality prediction.

The SHAP global importance analysis identified the educational level as the most influential baseline predictor of mortality, followed by residence, baseline CD4 count, marital status, age, and functional status. Specifically, a lack of formal education and lower baseline CD4 values were associated with an increased predicted mortality risk, whereas urban residence and working functional status were protective.

This hierarchy reflects the combined influence of socioeconomic vulnerability and biological immunosuppression at ART initiation, underscoring that both structural and clinical determinants contribute substantially to mortality risk prediction. For instance, a study conducted in Kenya found that patients on ART for extended periods had significantly lower mortality rates, reinforcing the critical role of early and consistent treatment adherence in improving survival [27].

Ensemble methods, such as XGBoost, random forest, and gradient boosting, consistently outperformed simpler models, such as logistic regression and Naive Bayes. Similar findings were reported in studies from Northern Thailand, East Africa, and Nigeria, where ensemble models achieved superior performance in health prediction tasks [28,29].

The model comparison plot demonstrated that gradient boosting achieved an accuracy of 87.0%, precision of 74.5%, recall of 52.9%, F_1-score of 0.619, and AUC of 0.859. Although discrimination was strong, the recall of 52.9% indicates that nearly half of the mortality cases were not identified at the default classification threshold. Therefore, while the model demonstrates predictive capability, its sensitivity limits immediate deployment as a high-stakes early-warning system without threshold optimization.

Limitations

This study used retrospective secondary EMR data, which may contain incomplete or inaccurately recorded variables, introducing potential information bias. Only 1 baseline record per patient was retained to avoid correlated observations, limiting longitudinal analysis. Patients who transferred to other facilities were excluded, potentially introducing selection bias.

Although the cohort required documented baseline ART initiation records, limited variable-level missingness (<10%) was addressed using median (continuous variables) and mode (categorical variables) imputation. Therefore, this was not a strict complete-case analysis. Excluding individuals on ART for less than 6 months may have introduced survivorship bias, potentially inflating performance metrics and limiting generalizability to newly initiated ART populations.

SMOTE-based oversampling may not fully replicate real-world population distributions. External validation using independent datasets was not performed, and model performance may vary in other geographic or clinical contexts. Data were drawn from a single city administration, limiting external validity.

Finally, given the moderate sensitivity (52.9%, 272/514), the model may miss a substantial proportion of high-risk patients at the default threshold. Future implementations should consider threshold calibration based on clinical priorities, particularly if minimizing false negatives is paramount.

Future Directions

Future studies should use multicenter or national-level data to enhance generalizability and external validity. Prospective validation studies are needed to evaluate real-world performance. Threshold optimization strategies should be explored to improve sensitivity where early mortality detection is prioritized. Integrating temporal modeling approaches may capture longitudinal treatment dynamics. Additionally, embedding explainable models within clinical workflows could support structured risk assessment, provided that implementation is accompanied by clinician oversight and contextual calibration.

Conclusion

This study demonstrates that interpretable ensemble ML models trained exclusively on baseline EMR data achieved moderate yet clinically meaningful discrimination in predicting mortality risk among people living with HIV initiating ART. SHAP-based interpretation confirmed that educational attainment and baseline CD4 count were the most influential predictors, followed by residence, age, and functional status, highlighting the combined impact of socioeconomic vulnerability and immunological status at treatment initiation. These findings suggest that transparent and explainable ML approaches may support early risk stratification and targeted intervention planning within HIV care programs. Nevertheless, external validation and prospective evaluation are required before integration into routine clinical decision-making.

Abstract

Background: Brain tumor is one of the most malignant diseases of the central nervous system, and early accurate detection is of great significance for improving patient survival rate. However, the heterogeneity of brain tumors in terms of morphology, size, and location on magnetic resonance imaging (MRI) image, as well as their similarity to surrounding normal brain tissue, poses significant challenges for tumor detection.

Objective: This study aims to develop a high-performance brain tumor detection framework that integrates feature enhancement, channel attention, and progressive pruning, achieving an optimal balance between detection accuracy, model efficiency, and interpretability for slice-level MRI tumor localization tasks.

Methods: This paper proposes a convolution Prewitt-and-pooling–based preprocessing (CSPP) approach, based on the "you only look once" version 11 (YOLOv11) framework, which highlights important structural detail more effectively than traditional statistics. A dynamic convolution–based C3k2 (DCC) module was integrated to more efficiently capture both local and global features. A channel prior convolutional attention (CPCA) module was introduced before the detection head, enabling the network to specifically focus on information-rich channels and key spatial regions. Through a progressive hybrid pruning strategy (PHPS), the model was optimized for efficient inference. Furthermore, Eigen-class activation mapping (Eigen-CAM) was used to interpret the prediction result, making them more transparent.

Results: Extensive experiments on 3 brain tumor MRI datasets demonstrated the superior performance of CDCP-YOLO (CSPP-DCC-CPCA-PHPS–YOLO). On Br35H, the mean average precision (mAP) at an intersection-over-union (IoU) threshold of 0.5 ($mAP_{0.5}$) increased by 2.6%, average mAP over several IoU thresholds (0.50-0.95; $mAP_{0.5:0.95}$) increased by 5.9%, and number of floating-point operations (×10 ; GFLOPs) decreased by 47.7%. On Roboflow, $mAP_{0.5}$ increased by 19.5%, $mAP_{0.5:0.95}$ increased by 7.7%, and GFLOPs decreased by 47.7%. On Capstone, $mAP_{0.5}$ increased by 6.9%, $mAP_{0.5:0.95}$ increased by 5.8%, and GFLOPs decreased by 47.7%.

Conclusions: The proposed CDCP-YOLO framework achieves an optimal balance between accuracy, efficiency, and interpretability, providing a lightweight and reliable solution for slice-level brain tumor detection in MRI images.

Introduction

Background

Brain tumors are a type of highly complex and rapidly progressing major disease within the central nervous system. Their malignancy is often characterized by extreme invasiveness and recurrence, posing a serious threat to patients' lives and health. Medical research indicates that accurate identification and timely diagnosis of tumor types in the early stages can significantly extend patient survival and improve quality of life. Magnetic resonance imaging (MRI) has become the gold standard for preoperative imaging diagnosis of most brain tumors due to its noninvasive, high-resolution, and multimodal imaging advantages, playing a key role in the auxiliary diagnosis and efficacy evaluation of brain tumors [1-3]. Although MRI

XSL•FO
RenderX

provides rich information at the image level, brain tumor detection still faces several challenges:

1. The tumor shape is complex and diverse, with blurred boundaries, and its grayscale distribution often overlaps with normal brain tissue, making it difficult to distinguish and locate accurately.
2. The anatomical structure of the brain is complex and varies significantly between individuals, making it difficult for traditional methods to establish a universally applicable and robust expression model.
3. Manual image segmentation is not only time-consuming and labor-intensive but also susceptible to subjective factors, necessitating efficient and intelligent auxiliary diagnostic tools.

In recent years, an increasing number of researchers have begun to focus on intelligent methods for brain tumor detection. The main research is based on digital image processing and machine learning to assist in identifying brain tumor regions [4]. This type of method usually first uses MRI image acquisition to obtain brain image data; then uses image processing to extract key visual features, such as gray scale, shape contours, and texture patterns; and finally inputs these features into support vector machines, random forests, or k-nearest neighbors for judging the tumor site and type. This type of method, which relies on handcrafted features, is effective for the detection of target lesions, but when faced with complex organizational structures and highly heterogeneous tumor morphologies, it often exhibits poor robustness, sensitivity to image noise, and difficulty in generalization, which limits its widespread application in clinical practice. With the rapid development of the convolutional neural network (CNN), target detection has entered a new stage with end-to-end learning as its core. Girshick et al [5] proposed region-based CNN (R-CNN), which first extracts candidate target regions and then uses support vector machines for classification, significantly improving detection performance. Subsequently, Fast R-CNN and Faster R-CNN [6,7] further accelerated detection speed and improved accuracy by sharing features and a region proposal network. To achieve real-time detection, Redmon et al [8] proposed the "you only look once" (YOLO) series of algorithms, which transformed target detection into a regression problem, simultaneously predicting multiple bounding boxes and categories in a single forward pass, greatly increasing the detection speed. Subsequent versions of YOLO have continuously improved the detection accuracy and network structure and are widely used in scenarios such as autonomous driving and medical image analysis. In addition, single shot multibox detector (SSD) [9] also achieves a balance between speed and accuracy by detecting at multiple feature scales. These deep learning–based algorithms not only overcome the limitations of traditional manual feature engineering but also greatly improve the modeling accuracy and practical application value, becoming the mainstream direction of current image target detection, including brain tumor detection.

Related Works

YOLO-Based Detection on MRI

In recent years, target detection models based on YOLO have been widely applied and continuously optimized in medical imaging. In the area of noninvasive disease detection, researchers have primarily focused on introducing attention mechanism, multitask learning, and lightweight model optimization. Chen et al [10] proposed the MSA-YOLOv5, which combines multiple attention mechanisms to focus on the automatic detection of lesions in acute ischemic stroke. In a multimodal MRI model, the detection of small lesions and embolic signals is enhanced, improving detection accuracy while reducing the number of parameters. Tang et al [11] developed a YOLOv5 model based on the squeeze-and-excitation attention mechanism, which improved the detection of Parkinson disease. The model enhances detection accuracy by adaptively focusing on key features, especially in distinguishing substantia nigra and red nucleus lesions in T2-weighted MRI. Wang et al [12] introduced an improved YOLOv5 architecture for the diagnosis and grading of lumbar disc herniation. This method adds an attention module to the Cross Stage Partial part and enhances the Spatial Pyramid Pooling-Fast part, achieving multitask learning for both classification and grading of Pfirrmann grades, highlighting prominent features in the intervertebral space and high-intensity zones.

In the context of brain tumor MRI detection, the research on improving YOLO has also advanced rapidly. Kang et al [13] proposed a new YOLO architecture named RCS-YOLO, which is optimized for brain tumor detection in medical imaging. RCS-YOLO uses reparameterized convolution combined with channel shuffle (RCS) to enhance the model's computational efficiency and detection accuracy. Kang et al [14] developed BGF-YOLO, an improved YOLOv8 that enhances brain tumor MRI detection performance by introducing multilevel feature fusion, a dynamic attention mechanism, and an additional detection head. Kang et al [15] proposed a new YOLO architecture, pretrained knowledge-guided YOLO (PK-YOLO), optimized for brain tumor detection in multiplanar MRI slices. PK-YOLO uses a pretrained RepViT backbone network combined with sparse mask modeling technology and Focaler-intersection-over-union (IoU) regression loss to improve the detection performance of small targets, making it the first YOLO object detector to introduce pretrained knowledge guidance. Dixit et al [16] proposed a brain tumor detection method based on YOLOv4-tiny, which uses transfer learning and a fine-tuning technique optimized for MRI images. This method leverages features from the pretrained Common Objects in Context (COCO) dataset with the 29-layer YOLOv4-tiny architecture, improving the model's computational efficiency and detection accuracy through precise hyperparameter tuning. Abdusalomov et al [17] proposed an improved YOLOv7 architecture optimized for brain tumor detection in MRI images. This method integrates a Convolutional Block Attention Module, a Spatial Pyramid Pooling Fast+ layer, and a Bidirectional Feature Pyramid Network to improve the detection accuracy for glioma, meningioma, and pituitary tumors.

Pruning Method

As the complexity of the deep neural network continues to increase, how to reduce computational and storage requirements while maintaining high performance has become a key challenge in medical imaging processing. Pruning techniques offer an effective solution to this problem and have demonstrated considerable potential in various medical image analysis applications. Fernandes et al [18] proposed a generative adversarial pruning method based on an evolutionary strategy, specifically optimizing medical image diagnosis. This method selects options through minimal Wasserstein distance. Wu et al [19] developed the FairPrune method, a new technique that achieves fairness by pruning, specifically applied to the diagnosis of skin diseases. This method prunes based on differences in parameter importance, significantly improving the fairness of the model across different demographic groups. Adnan et al [20] proposed a structured pruning method specifically for optimizing the U-Net architecture. This method addresses the pruning complexity between the encoder and decoder in U-Net, compressing the model by assessing the importance of individual channels and tasks. Fernandes et al [21] further developed a structured pruning framework that integrates multitask learning and pruning. This method uses iterative pruning and block-based network deepening, optimizing the model with a policy-based and multiobjective decision-making process. Cocosco et al [22] proposed a fully automated and nonparametric brain tissue classification method. This method uses a nonparametric implementation, training sample selection through the minimum spanning tree method and stereotaxic space priors, showing significant performance improvement in subjects with large morphological variations. Xuan et al [23] introduced a pruning method for k-space subsampling and reconstruction based on a generative model. This method is inspired by network pruning, starting with a fully sampled k-space model and iteratively removing less important k-space phase encoding, demonstrating good performance in single-coil and multicoil MRI reconstruction. Graziani et al [24] developed an interpretable pruning strategy on CNN specifically for scale-variant features in medical images. This method uses deep learning interpretability techniques to analyze the hierarchical scale coding of the InceptionV3 and ResNet50 architectures, finding that scale information peaks in the middle layers and decreases near the softmax layer. This discovery leads to a pruning strategy that significantly improves the performance of nucleus regression and mitosis classification in histopathological images. Holste et al [25] systematically analyzed the impact of the pruning on medical image classification across various long-tailed multilabel disease datasets for the first time. This study in the chest X-ray image diagnosis experimentally demonstrated that the pruning has differential effects on different diseases, with rare diseases being more susceptible to being “forgotten” than common diseases. The study also introduces the concept of pruning-identified exemplars, revealing through human reader studies that pruning-identified exemplars often have more label noise, lower image quality, and higher diagnostic uncertainty. Saleh et al [26] investigated the effectiveness of different network architectures (GoogLeNet, ResNet, and EfficientNet) combined with transfer learning and the network pruning algorithm for medical image classification. They validated the effectiveness of these techniques in both brain tumor classification and chest X-ray inflammation detection. Jaiswal et al [27] proposed a pruning-assisted, self-supervised image localization method. This method uses a “learning by forgetting” training scheme, which significantly improves skin disease localization performance under unsupervised, weakly supervised, and sparsely supervised settings.

Visualization Based on Class Activation Mapping

In recent years, visualization methods based on class activation mapping (CAM) have been widely applied in interpretability research on deep neural networks. The classic gradient-weighted CAM (Grad-CAM) [28] calculated specific category information relative to the feature maps of each layer by determining the weights of each channel, thereby generating a heat map that is closely related to the target category. However, when dealing with multitarget and complex background scenes, Grad-CAM sometimes struggles to capture fine-grained details and local features. To address this limitation, Grad-CAM++ [29] further improved the high-order information, significantly enhancing sensitivity to small targets and overlapping regions. On the other hand, Eigen-CAM [30], which got rid of the reliance on gradient calculation, was based on principal component analysis to extract convolution features, generating class-independent visual interpretations in an unsupervised manner. Furthermore, to further enhance the detail and perceptual awareness of heat maps, LayerCAM [31] was proposed to fuse the activation maps from the deep and shallow convolution layers, resulting in a more pixel-level local correspondence and generating finer-grained heat maps that better express boundary and structural information. To validate the CAM method in medical diagnosis, many recent studies have explored its use. Windisch et al [32] proposed a ResNet50-based brain tumor detection model and used Grad-CAM for model interpretability analysis, used for the identification of meningiomas and gliomas in MRI slices. Shawon et al [33] proposed a cost-sensitive deep neural network that integrated multiple interpretable techniques (including Grad-CAM, LIME, and Score-CAM) for model interpretation, used for brain tumor detection under imbalanced data conditions. Dasanayaka et al [34] proposed a deep learning model based on U-Net and DenseNet, which used Grad-CAM to generate heat maps for brain tumor segmentation and classification. This combined strategy not only achieves effective segmentation and classification but also provides effective visualization. Zeineldin et al [35] proposed an enhanced EfficientNetv2 that integrates a global attention mechanism and efficient channel attention and uses Grad-CAM visualization for model interpretation, applied to MRI-based brain tumor classification. Guluwadi et al [36] proposed a brain MRI detection method that combines ResNet50 with Grad-CAM.

Objectives

In recent years, the rapid advancement of deep learning has significantly propelled the development of brain tumor detection, achieving remarkable results. However, current brain tumor detection models still face several challenges:

XSL•FO
RenderX

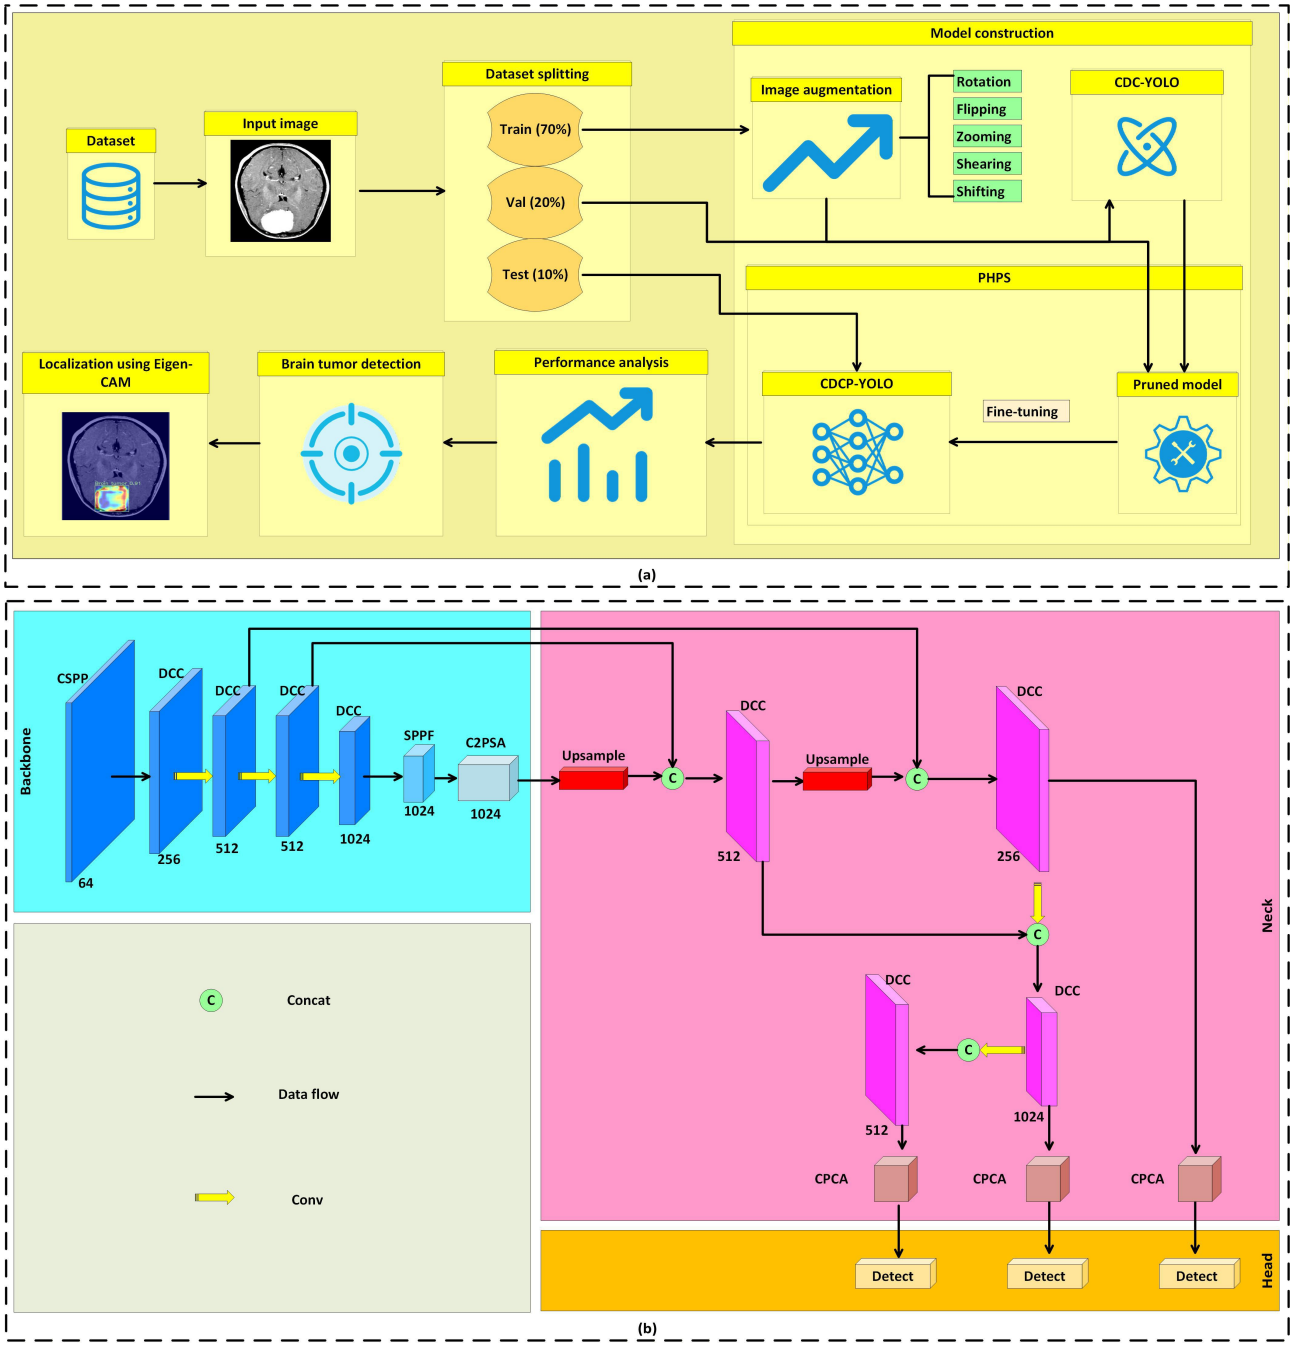
1. The boundaries of brain tumors are often blurry and the structures are irregular. The shallow features extracted by traditional convolutions are insufficient to effectively capture the key regions, leading to high rates of missed detection and false positives.
2. The parameter size of the target detection model is massive, and the computational overhead is high, which is not conducive to deployment on clinical edge devices, thus limiting their practicality. Traditional pruning methods, typically based on a single-weight threshold for coarse-grained pruning, can easily damage key model structures. At the same time, the sparse fine-tuning process, due to its inefficiency, struggles to meet the demands of high efficiency and deployability in medical scenarios.
3. Most target detection methods lack interpretability, making it difficult to clearly present the decision-making basis of the model to doctors, which limits its credibility in auxiliary clinical decision-making.

This paper proposes an interpretable, fine-grained brain tumor MRI detection method based on progressive pruning to address these challenges in an integrated manner. Importantly, CDCP-YOLO (CDC-YOLO with PHPS) is not a simple stacking of existing techniques but a task-driven co-design framework specifically tailored to the structural complexity, computational constraints, and interpretability requirements of brain tumor MRI detection. Its methodological distinctions are summarized as follows. First, unlike RCS-YOLO, which primarily accelerates inference through convolution reparameterization and channel shuffling, CDCP-YOLO introduces structure-aware input-level modeling (convolution Prewitt-and-pooling–based preprocessing [CSPP]) that explicitly embeds classical edge priors into the network. This design targets blurred and ambiguous tumor boundaries at the earliest stage of feature extraction—an issue that reparameterization alone cannot effectively address. Second, whereas BGF-YOLO improves detection performance mainly through multilevel feature fusion and additional detection heads, CDCP-YOLO adopts dynamic convolution–based C3k2 (DCC) feature adaptation, enabling input-dependent kernel generation. This strategy allows the network to flexibly adapt to heterogeneous tumor morphologies and scales without introducing detection head redundancy. Third, while PK-YOLO relies on external pretrained knowledge and sparse mask modeling to enhance small-target detection, CDCP-YOLO does not depend on any external pretraining paradigm. Instead, it improves representation capacity through internal, data-adaptive mechanisms, ensuring robustness and generalizability under limited or domain-specific medical datasets. Fourth, existing pruning-based detectors typically use single-criterion or one-shot pruning strategies that may disrupt critical feature pathways. In contrast, the proposed progressive hybrid pruning strategy (PHPS) jointly considers global channel sparsity and local structural dependency in a staged manner, enabling aggressive model compression while preserving detection-critical structures. Finally, unlike prior works that treat Grad-CAM–style visualization as a post hoc analysis tool, CDCP-YOLO tightly integrates Eigen-CAM into the detection head, treating interpretability as a core design objective rather than an auxiliary component. This integration ensures semantic consistency between detection results and visual explanations, which is essential for clinical decision support.

The main contributions of this work are summarized as follows:

1. Multiscale feature enhancement mechanism: a CSPP module was introduced at the model's input stage, integrating Prewitt edge detection with pooling operations to strengthen the construction of tumor edges and structures. A DCC module was introduced into the backbone and neck networks to achieve adaptive expression for different tumor forms and sizes. A channel prior convolutional attention (CPCA) module was introduced before the detection head to guide the network to focus on the key region of the most discriminative brain tumor.
2. Lightweight pruning strategy: a progressive hybrid pruning strategy was proposed, combining L1-norm and GroupNorm feature statistics. The pruning process is carried out in stages, prioritizing the pruning of redundant channels while maximally preserving key information flow. This method significantly reduces parameter size and computational overhead while effectively mitigating the performance degradation caused by large-scale pruning.
3. Interpretable confidence enhancement: a gradient-free principal component analysis method was adopted, which can generate clear saliency heat maps, visually demonstrating the most important basis for the brain tumor MRI model's decision-making. This significantly improves the transparency, credibility, and practicality of the model in clinical applications.

Methods



Overall Framework

This paper proposes an interpretable and fine-grained brain tumor detection model based on progressive pruning. As shown in Figure 1A, the overall framework was as follows: MRI images were trained on the improved CDC-YOLO network, and an efficient CDCP-YOLO model was obtained through a progressive hybrid pruning strategy and fine-tuning. As shown in Figure 1B, CDC-YOLO is composed of three main structures:

1. Backbone stage: the CSPP module is used to replace the first 2 convolutional layers. CSPP combines Prewitt edge detection with pooling operations to enhance the model's initial feature extraction capability for edges and textures. Subsequently, the main network uses multiple DCC modules, using dynamic convolution to enhance the perceptual ability for multiscale tumor regions.
2. Neck stage: multiscale feature maps are fused through upsampling and concatenation. The C3k2 module introduces dynamic convolution and key location fusion, and the CPCA module is introduced, combining channel and spatial attention mechanisms to guide the model to focus on key diagnostic areas and improve detection accuracy.
3. Head stage: multiple detection heads of different sizes are used to detect targets of different sizes.

Convolution Prewitt-and-Pooling–Based Preprocessing

The head of YOLOv11 includes 2 initial convolution layers, primarily used to extract initial features from the input image. By extracting deeper features layer by layer, the network can construct sufficient information for effective target detection. To enhance the model's perceptual ability for edge structures, the first 2 standard convolutional layers in YOLOv11 are replaced with a self-designed CSPP (Figure 2), which more effectively extracts contour information and local texture features from the image. As the input feature processing unit of the entire CDCP-YOLO, CSPP integrates standard convolution, Prewitt edge detection, and multiscale pooling operations, aiming to enhance the model's perceptual ability for brain tumor edge features and its adaptability to different shapes.

XSL•FO
RenderX

Figure 2. Structural illustration of the convolution Prewitt-and-pooling–based preprocessing (CSPP) module. The module integrates standard convolution, Prewitt edge detection (horizontal and vertical), and max pooling to enhance tumor boundary and texture representation at the input stage. Maxpool, maximum pool.

First, the input image X undergoes a 3×3 convolution operation to obtain the initial feature map X1; this operation completes spatial compression and channel expansion.

(1)X1=Conv(X)

Next, the Prewitt edge detection operator is applied to X1, filtering in the horizontal direction Gx and the vertical direction Gy to extract the edge response in the image.

(2)XPrewitt=PrewittConv(X1)

The output of the Prewitt operator is obtained by calculating the Euclidean distance to combine the responses from both directions, resulting in the complete edge information XPrewitt.

(3)XPrewitt=(X1×Gx)2+(X1×Gy)2

Simultaneously, another branch inputs X1 into a max-pooling layer, and the spatial dimensions are kept unchanged through zero-padding, generating the pooled feature Xpool. The 2 output features, XPrewitt and Xpool, are concatenated along the channel dimension to generate the feature X2. This fusion retains both structural edges and spatial context information.

(4)X2=Concat(XPrewitt,Xpool)

The fused feature map X2 is then passed through a 3×3 convolution to further extract high-level features.

(5)X3=Conv3×3(X2)

Finally, the number of channels is compressed, and the dimensions are adjusted using a 1×1 convolution to generate the final feature Y, which serves as the input to the backbone structure.

(6)Y=Conv1×1(X3)

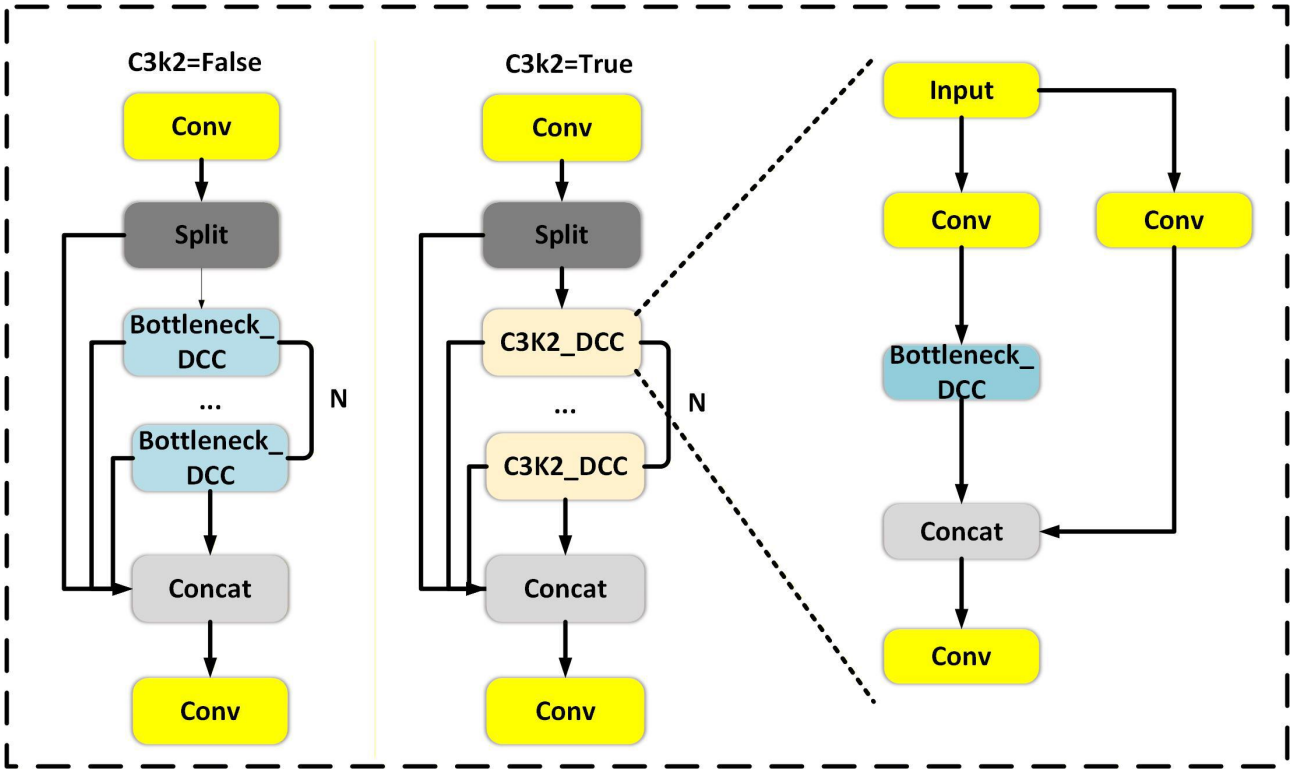
CSPP uses the Prewitt operator in both horizontal and vertical directions to automatically extract prominent edge contours in the image, significantly enhancing the detection capability for blurry contours and unclear tumor regions. At the same time, the output of Prewitt is fused with the original feature map, which not only preserves the local details but also strengthens the expression of structural information. In addition, the pooling operation compresses the spatial dimensions while keeping the feature map size unchanged, providing the network more robustness to variations in tumor size and location.

The CSPP module is designed to introduce deterministic structural priors into the early stages of feature extraction. While standard convolutional layers learn kernels stochastically, the inclusion of a fixed Prewitt operator provides explicit edge-sensitive cues that are critical for delineating tumor boundaries. We acknowledge that in medical imaging physics, difference operators are typically sensitive to high-frequency noise. Therefore, rather than using the Prewitt output directly, the CSPP module integrates it through a multistage fusion strategy. Specifically, the gradient maps are processed via max pooling to perform local maximum selection, which emphasizes strong structural edges while suppressing isolated noise spikes. These features are then fused with learnable convolutional features using a 1×1 convolution layer and batch normalization. This design allows the network to adaptively weight the explicit structural priors against learnable representations, ensuring that the model captures fine-grained morphological details without amplifying imaging artifacts.

Dynamic Convolution-Based C3k2

The C3k2 module is a core feature extraction unit in YOLOv11, and its design goal is to achieve the best balance between feature representation capability and computational efficiency. This module uses a multibranch structure and residual connections to enhance the multiscale feature extraction capability while maintaining training stability. C3k2 supports two configuration modes:

1. In the C3k=True mode, a lightweight C3k branch is used. The input features are divided into multiple groups for separate processing and then fused through concatenation. This group-wise convolution strategy significantly reduces



XSL•FO
RenderX

computational complexity, making it particularly suitable for applications with high real-time requirements.

2. In the C3k=False mode, a more complex bottleneck structure is introduced, combined with additional convolution and activation layers to extract deeper and more discriminative features, thus showing superiority in more accuracy-sensitive tasks.

To enhance the network's modeling capability for complex tumor regions, in this study, we built a DCC module (Figure 3) based on the original C3k2 module by introducing a dynamic convolution [37]. The DCC module enhances the model's capabilities in multiscale structure modeling, detail preservation, and contextual awareness by replacing the fixed convolution with the input-adaptive dynamic convolution.

Figure 3. Architecture of the dynamic convolution–based C3k2 (DCC) module. The convolution kernel is dynamically generated according to the global context of the input feature map, enabling adaptive modeling of tumors with diverse sizes and shapes. Concat, concatenation; Conv, convolution.

Given an input feature X∈RCin×H×W, the DCC module uses a dynamic kernel *W(X)* to perform the convolution operation:

(7)Y=W(X)×X

The generation process of the convolution kernel WX depends on the global context information of the input image. To achieve this weight regeneration, a global average pooling layer is first used to compute the channel-wise global vector:

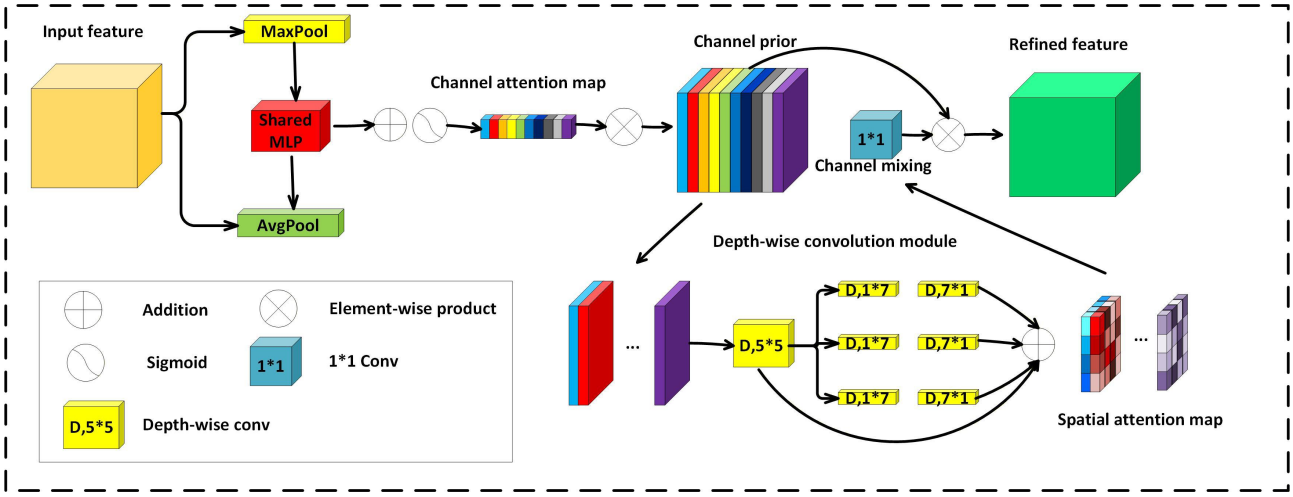
(8)g=1H×W∑i=1H∑j=1WX[:,i,j]

Then, 2 fully connected layers and a nonlinear activation function are used to generate the dynamic attention weights:

(9)θ=FC2(σ(FC1(g)))

Here σ() is the ReLU activation function, and FC1 and FC2 are the first and second fully connected layers, respectively. The final parameter θ determines the weighting of the dynamic convolution kernel WX, thereby adapting to the feature distribution of the current input image for optimal perception.

The C3k2 module mainly extracts higher-level features through multiple bottleneck and convolution layers. This module stacks multiple bottleneck units, replacing standard static convolution operations, enabling the network to adaptively select more suitable feature representations at different spatial scales, and thereby improving the modeling capability for diverse tumor features. Unlike fixed convolution kernels, the dynamic convolution mechanism automatically adjusts the kernel weights based on the input features, making it adaptable to different image contexts. Especially when dealing with tumor regions with blurry boundaries and irregular shapes, dynamic convolution can more finely capture local structures and texture changes. In addition, dynamic convolution also enhances the model's ability to resist interference from complex backgrounds and low signal-to-noise ratios, reducing the occurrence of missed and false detections. At the same time, the DCC module introduces an input-dependent kernel selection strategy, which endows the C3k2 module with stronger language modeling and morphological adaptation capabilities, providing richer and more discriminative feature representations for subsequent detection heads.



Channel Prior Convolutional Attention

The detection head is the key part for the final bounding box regression. However, the detection head relies on the feature maps from the previous layer, and these feature maps may contain a large amount of information, where many channels may be redundant or irrelevant to the target detection. The attention mechanism is proposed to focus on important information. The CPCA module (Figure 4) [38] uses multiscale depth-wise separable convolutions to maintain the channel prior

XSL•FO
RenderX

while extracting spatial relationships, enabling the network to focus on information-rich channels and key spatial regions. The CPCA module includes the sequential placement of channel attention and spatial attention. The spatial information of the feature maps is aggregated by channel attention through operations such as average pooling and max pooling. The spatial attention is then processed through a shared multilayer perceptron and added to generate a channel attention map. The channel prior is obtained by element-wise multiplication of the input feature and the channel attention map. Subsequently, the channel prior is input into a depth-wise convolution block to generate a spatial attention map. The convolution block receives the spatial attention map to perform channel mixing. Finally, the channel mixing result is element-wise multiplied with the channel prior to obtain the optimized feature as output. The channel mixing process helps to enhance the feature representation.

Figure 4. Structure of the channel prior convolutional attention (CPCA) module, which sequentially applies channel attention and spatial attention to emphasize tumor-relevant channels and spatial regions before the detection head. Conv, convolution; MaxPool, maximum pool; AvgPool, average pool.

Given an intermediate feature map F∈ RC×H×W, a 1D channel attention map Mc∈ RC×1×1 is first inferred through the channel attention module. Then, Mc is element-wise multiplied with the input feature F to obtain the channel attention–optimized feature map Fc∈ RC×H×W. Subsequently, the spatial attention (SA) processes Fc to generate a 3D spatial attention map Ms∈ RC×H×W. The final output feature map F^ is obtained by element-wise multiplication of Msand Fc:

(10)Fc=CA(F)⊗F

(11)F^=SA(Fc)⊗Fc

, where ⊗ represents element-wise multiplication. Channel attention (CA) is obtained as follows:

(12)CA(F)=σ(MLP(AvgPool(F))+MLP(MaxPool(F)))

, where σ represents the sigmoid function. Spatial attention (SA) is obtained as follows:

(13)SA(F)=Conv1×1(∑i=03Branchi(DwConv(F)))

, where DwConv represents depth-wise convolution, Branchi represents the *i*th branch, and Branch0 is an identity connection.

Applying CPCA to the predetection layer optimizes the semantic aggregation capability of the predetection feature layer. The detection head, as the key component for classification and bounding box regression, heavily relies on the quality of the preceding feature layers. However, the original feature maps often contain a large amount of redundant channels or low-response regions, which interfere with the model's discrimination process, especially in medical images with blurry tumor boundaries and complex backgrounds. CPCA performs adaptive channel modeling, enabling it to automatically identify and enhance significant channels related to tumors, thereby effectively improving the discriminability of features. Furthermore, this mechanism, combined with a spatial attention strategy, guides the network to focus on key areas of the image, enhancing the perceptual ability for fine-grained features such as lesion edges and structural changes. By introducing CPCA before the detection head, the model can perform inference based on more refined, robust, and contextually sensitive features.

Progressive Hybrid Pruning Strategy

To address the dual requirements of high-precision modeling for complex brain tumor structures and efficient inference, we propose the PHPS, as summarized in Textbox 1. The PHPS first uses an L1-norm–based channel importance evaluation to perform coarse-grained pruning, enabling the rapid removal of globally redundant feature channels. Subsequently, GroupNorm-based grouping information is incorporated to conduct fine-grained structural pruning, which corrects channel importance by considering local structural dependencies and avoids distortions caused by sole reliance on weight magnitude.

XSL•FO
RenderX

Textbox 1. Pruning processing

- Input: pretrained model parameters W, overall pruning ratio s, pruning threshold SC, step pruning ratio M.
- Output: pruned and fine-tuned model W1

1. Initialize CPC-YOLO model.
2. Set target sparsity s; define thresholds SC.
3. Initialize current global sparsity S←0.
4. While S<s, do:
5. For each prunable layer l in the model, do:
6. If the current layer's sparsity SL < SC, then:
7. Compute importance score: ILI(wi).
8. Sort channels in ascending order.
9. Prune the lowest-ranked channels with ratio M.
10. Else:
11. Compute importance score:IGN(Gj)=∑wi∈Gjwi2.
12. Sort groups by IGN(Gj) in ascending order.
13. Prune the lowest-ranked groups with ratio M.
14. End if
15. End for
16. Update the global sparsity S.
17. End while
18. Fine-tune the pruned model on the training dataset.
19. Return the final pruned model W1.

Through this dual evaluation mechanism of global coarse-grained pruning combined with local fine-grained structural correction, the PHPS can more accurately preserve discriminative feature channels under challenging conditions such as blurred tumor boundaries and high intertumor heterogeneity. Importantly, the PHPS adopts a progressive pruning process, in which sparsity is gradually increased toward a predefined global target. Model fine-tuning is performed only once after the entire pruning process is completed, allowing effective recovery of detection performance while avoiding excessive training overhead. This design achieves a balanced optimization between model compression and precision retention.

Interpretability

In the detection head output stage, the feature map is directly sent to the Eigen-CAM branch while being used for bounding box regression. The most representative convolution activation regions are extracted through principal component analysis. This design not only ensures the semantic consistency between interpretation and detection but also allows for reverse influence on model optimization during training. The extraction of saliency regions enables the network to focus more on real lesion boundaries and key structures, enhancing the model's adaptability to blurry edges and complex backgrounds. Unlike traditional Grad-CAM, which relies on backpropagation, Eigen-CAM is based on forward features, is class agnostic, lightweight, and efficient, making it more suitable for brain tumor MRI detection.

In this work, Eigen-CAM was applied to the high-level convolutional feature maps before the detection head, rather than to class-specific logits. Although Eigen-CAM is a class-agnostic visualization method that does not rely on gradients with respect to a specific category, the visualized activations are still strongly task driven. Since the detector is trained to localize tumor regions using bounding box regression and objective supervision, the learned high-level features inherently emphasize spatial regions that are most relevant to tumor detection. As a result, the generated heat maps naturally concentrate on tumor areas instead of irrelevant anatomical structures such as the skull or eyes.

For a certain convolution feature layer $F \in RC \times H \times W$, it is first reshaped into a 2D matrix:

$$F' \in RC \times (H \times W) \quad (14)$$

Then the covariance matrix is calculated:

$$\Sigma = F'F'T \quad (15)$$

Next, eigenvalue decomposition is performed on it, and taking the eigenvector u1 corresponding to the largest eigenvalue, a heat map is finally generated by weighting the principal components:

$$M = \sum c=1Cu1[c] \cdot Fc \quad (16)$$

XSL•FO
RenderX

Ethical Considerations

This study is based entirely on publicly available brain tumor MRI datasets, including Br35H [39], Roboflow dataset [40], and Capstone Brain Tumor dataset [41]. All datasets were obtained from open-access platforms (Kaggle and Roboflow) under their respective terms of use. Each dataset contains anonymized medical images that do not include any personally identifiable information, patient metadata, or clinical identifiers. Therefore, no additional ethical approval or informed consent was required for the use of these datasets.

The datasets were used solely for academic and noncommercial research purposes, strictly following ethical research guidelines and data-sharing policies. All experimental procedures comply with the principles of the Declaration of Helsinki and institutional data protection standards.

Results

Experimental Setup

Br35H [39] was used as the main dataset. This dataset is one of the most representative and widely used public benchmarks in brain tumor MRI detection, covering multiple tumor types and MRI modalities. However, it should be noted that the specific clinical metadata regarding the exact MRI sequences (eg, T1-weighted, T2-weighted, or fluid-attenuated inversion recovery) and the specific tumor subtypes are not provided in the original dataset repository. Despite the absence of these specific labels, its high-quality annotations, imaging diversity, and clinical coverage make it a standard for performance evaluation and comparison in automatic brain tumor detection research. To verify the robustness of CDCP-YOLO, the experiments were also conducted on 2 other datasets, Roboflow [40] and Capstone [41]. We strictly adhered to the original dataset split, as detailed in Table 1.

Table . Dataset splits used for experiments on the Br35H, Roboflow, and Capstone brain tumor magnetic resonance imaging (MRI) datasets.[a]

Dataset	Total number of images, n	Training set, n	Validation set, n	Test set, n
Br35H	801	500	201	100
Roboflow	300	210	60	30
Capstone	911	638	182	91

[a]The table reports the total number of images and the corresponding training, validation, and test splits for each dataset. These official splits were strictly followed in all experiments to ensure fair evaluation and reproducibility of the reported results.

To enhance the robustness and generalizability of the model, data augmentation was performed during the training phase, including geometric transformations such as rotation, flipping, scaling, and shearing of MRI images, as well as random adjustments to the brightness and contrast. This strategy effectively expands the diversity of the training samples, thereby reducing the risk of model overfitting. This enhancement operation was generated in real time during each training epoch, ensuring that the model obtained “new” samples for training in different epochs, improving its adaptability to complex scenes and diverse tumor morphology. The specific data augmentation hyperparameters used during training included mosaic image composition (mosaic=1.0), geometric transformations (random rotation [degress=10], scaling [scale=0.5], and horizontal flipping [fliplr=0.5]), and color-space perturbations in the hue-saturation-value (HSV) domain (hsv_h=0.015, hsv_s=0.7, and hsv_v=0.4). These augmentation strategies are widely adopted in YOLO-based detection frameworks to enhance data diversity and improve model robustness against variations in object scale, orientation, and imaging conditions.

The experiment was conducted using an Intel Xeon Gold 5320 CPU @ 2.20GHz and an NVIDIA A40 48GB GPU. The training was conducted for 300 epochs, with a batch size of 16, using a stochastic gradient descent (SGD) optimizer, and a patience parameter of 50. The learning rate was set to 0.01. The software environment consisted of Ubuntu 20.04 (Canonical), CUDA 11.8 (NVIDIA), and PyTorch 2.1.0 (Meta AI Research).

After the completion of the initial full training stage, the PHPS was applied to the converged model. Specifically, the base model was first trained for 300 epochs using the standard training configuration described above. Once convergence was achieved, structured pruning was performed according to the PHPS criteria to remove redundant channels and blocks.

Following pruning, the resulting compact model was subjected to a dedicated fine-tuning stage, which was treated as an independent optimization phase and clearly distinguished from the initial training process. During this postpruning fine-tuning, the model was trained for 300 epochs under the same hardware and software environment as the initial training stage, using the SGD optimizer. The batch size was set to 8, the learning rate was fixed at 0.01, and a patience parameter of 50 was applied for early stopping.

Evaluation Metrics

Precision is the ratio of the number of correctly predicted positive samples to the total number of the detected samples, as shown below:

(17)Precision=TPTP+FP×100%

Recall is the ratio of the number of correctly predicted positive samples to the number of the actual positive samples, as shown below:

(18)Recall=TPTP+FN×100%

Mean average precision (mAP) is the result obtained by averaging the average precision of all categories, used to measure the detection performance of the model across all categories.

(19)mAP=∑APNC×100%

XSL•FO
RenderX

, where $mAP_{0.5}$ represents the mAP at an IoU threshold of 0.5 and $mAP_{0.5:0.95}$ represents the average mAP over several IoU thresholds (0.50-0.95). Params represents parameter size in the model, the number of floating-point operations (×10 ; GFLOPs) signify computational complexity, and frames per second (FPS) were used to measure inference complexity.

SD was used to measure the variability of a given evaluation metric for the same method across multiple repeated experiments. It was computed as follows:

$$SD=\frac{1}{N-1}\sum_{i=1}^{N}(M_i-\bar{M})^2 \quad (20)$$

, where Mi denotes the value of the evaluation metric obtained in the ith experiment, and $\bar{M}$ represents the mean value of the corresponding metric over N experiments.

Comparative Experiments

This paper compares between a variety of mainstream detection models on Br35H, including the classic YOLO series models (such as YOLOv3, YOLOv5n, YOLOv10n, and YOLOv11n); 2-stage detectors (such as Faster R-CNN and Cascade R-CNN); and a 1-stage detection method, TOOD (Table 2). To ensure a fair and unbiased comparison, all baseline models reported in Table 2 were trained from scratch under a unified experimental protocol.

Table . Performance comparison of different object detection models on the Br35H brain tumor magnetic resonance imaging dataset.[a]

Model	Precision[b]	Recall	$mAP_{0.5}$[c]	$mAP_{0.5:0.95}$[d]	Params (M)[e]	GFLOPs[f]	FPS[g]

TOOD	0.888	0.895	0.925	0.630	32.02	144	13.1
YOLOv10n	0.919	0.84	0.914	0.608	2.27	6.5	131
YOLOv11n	0.904	0.853	0.918	0.585	2.58	6.3	142.2
Faster R-CNN	0.854	0.836	0.896	0.578	41.35	155	15.2
Cascade R-CNN	0.86	0.895	0.874	0.584	69.15	183	14
DINO	0.939	0.75	0.84	0.563	47.54	205	10.5
RCS-YOLO	0.953	0.828	0.824	0.548	45.70	94.5	215.2
BGF-YOLO	0.964	0.885	0.959	0.648	84.30	568.9	32.5
CDC-YOLO	0.881	0.906	0.946	0.660	3.64	7	130
CDCP-YOLO	0.918	0.904	0.944	0.644	2.07	3.3	152

[a]All models were trained and evaluated under the same experimental protocol to ensure a fair comparison. Higher values indicate better performance for accuracy and speed metrics, whereas lower values indicate better efficiency for model complexity metrics.

[b]Precision, recall, $mAP_{0.5}$, and $mAP_{0.5:0.95}$ were used to evaluate detection accuracy.

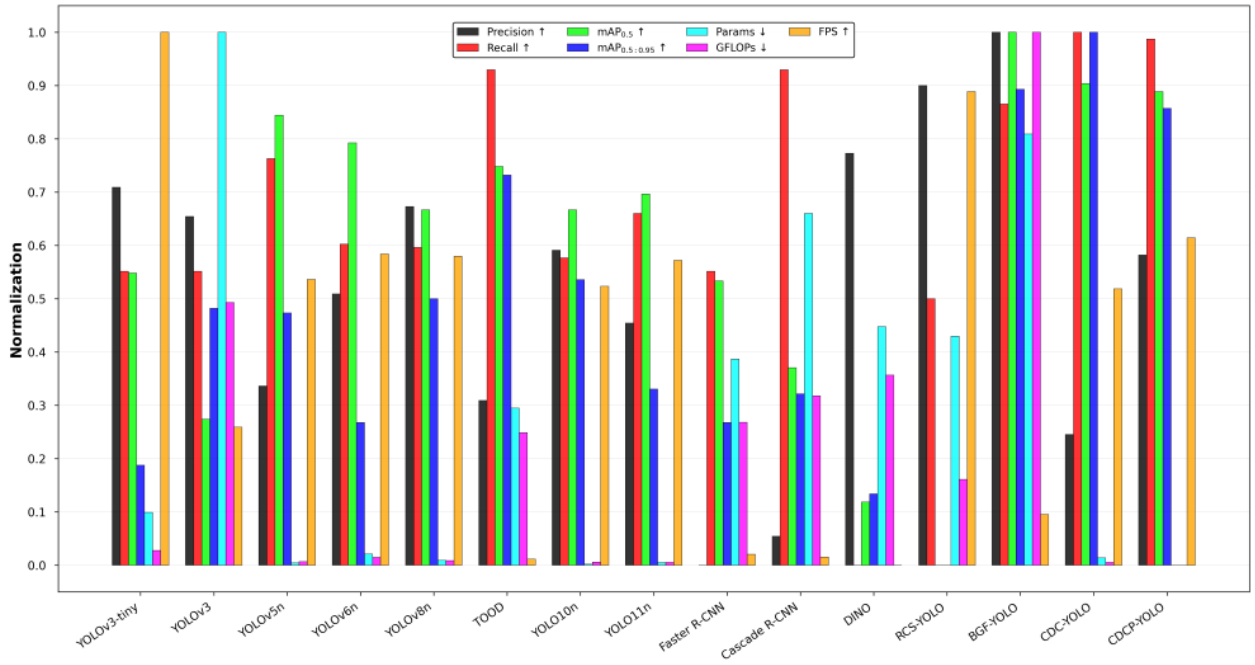
[c]$mAP_{0.5}$: mean average precision at an intersection-over-union threshold of 0.5.

[d]$mAP_{0.5:0.95}$: average mean average precision over several intersection-over-union thresholds (0.50-0.95).

[e]Params (M) was used to measure model size.

[f]GFLOPs: number of floating-point operations (×10); used to measure computational complexity.

[g]FPS: frames per second; used to measure inference efficiency.



CDCP-YOLO reached 0.946 in $mAP_{0.5}$, approaching CDC-YOLO's 0.944, significantly outperforming traditional models such as YOLOv3-tiny (0.898) and YOLOv3 (0.861). At the same time, it achieved a high score of 0.644 on the more challenging $mAP_{0.5:0.95}$ metric, second only to CDC-YOLO (0.660). In addition, CDCP-YOLO's recall (0.904) and precision (0.918) were both at a leading level, indicating its excellent detection capabilities. In terms of model complexity, the parameter count of CDCP-YOLO was only 2.07M, which is about 1/33 of that of Cascade R-CNN (69.15M) and 1/20 of that of Faster R-CNN (41.35M), and was also smaller than that of YOLOv3 (103.67M), achieving the goal of lightweight design. Its computational complexity was 3.3 GFLOPs, which was also significantly lower than that of YOLOv5n (7.1 GFLOPs) and YOLOv6n (11.8 GFLOPs), demonstrating good computational efficiency. In terms of inference speed, CDCP-YOLO reached 152 FPS, which is significantly faster than Cascade R-CNN (14 FPS), Faster R-CNN (15.2 FPS), and even some lightweight YOLO models such as YOLOv5n (134 FPS) and YOLOv10n (131 FPS), showing significant advantages in practical deployment.

As seen in Figure 5, CDCP-YOLO was in the optimal or near-optimal state in terms of accuracy, model size, computational complexity, and inference speed, demonstrating

XSL•FO
RenderX

the advantage of balancing accuracy and efficiency. It is particularly noteworthy that CDCP-YOLO significantly surpassed YOLOv5n (0.644 vs 0.601) and was superior to TOOD (0.644 vs 0.630) on $mAP_{0.5:0.95}$, while it had a much lower parameter count and computational load than these models. This indicates that the model still has stable performance at high IoU thresholds, possessing good robustness and generalizability. CDCP-YOLO achieved high detection accuracy and inference speed under the premise of maintaining a small model size and low computational overhead.

Figure 5. Multimetric normalization comparison of different object detection models on the Br35H brain tumor magnetic resonance imaging dataset. All evaluation metrics are normalized to the range [0, 1] to enable fair comparison across models with different scales. The compared models included YOLOv3-tiny, YOLOv3, YOLOv5n, YOLOv6n, YOLOv8n, YOLOv10n, YOLOv11n, Faster R-CNN, Cascade R-CNN, DINO, RCS-YOLO, BGF-YOLO, CDC-YOLO, and the proposed CDCP-YOLO model. The metrics include precision, recall, $mAP_{0.5}$, $mAP_{0.5:0.95}$, number of parameters (Params), computational complexity (GFLOPs), and inference speed (FPS). Arrows indicate optimization direction: ↑ denotes that higher values are better (precision, recall, $mAP_{0.5}$, $mAP_{0.5:0.95}$, and FPS), while ↓ denotes that lower values are better (Params and GFLOPs). FPS, frames per second; GFLOPs, number of floating-point operations (×10); mAP, mean average precision; $mAP_{0.5}$, mAP at an intersection-over-union threshold of 0.5; $mAP_{0.5:0.95}$, average mAP over several intersection-over-union thresholds (0.50-0.95); R-CNN, region-based convolutional neural network; YOLO, “you only look once” framework.

Ablation Experiment

Using YOLOv11n as a baseline, the effectiveness of each module is compared (Table 3).

XSL•FO
RenderX

Table . Ablation study results of individual modules on the Br35H brain tumor magnetic resonance imaging dataset, showing the incremental impact of the CSPP[a], DCC[b], CPCA[c], and PHPS[d] modules on detection performance and model efficiency.

Model	CSPP	DCC	CPCA	PHPS	Precision[e]	Recall	$mAP_{0.5}$[f]	$mAP_{0.5:0.95}$[g]	Params (M)[h]	GFLOPs[i]	FPS[j]
YOLOv11n	—[k]	—	—	—	0.904	0.853	0.918	0.585	2.58	6.3	142.2
C-YOLO	✓[l]	—	—	—	0.904	0.852	0.921	0.639	2.58	6.5	140
CD-YOLO	✓	✓	—	—	0.900	0.893	0.941	0.660	3.46	6.3	133
CDC-YOLO	✓	✓	✓	—	0.881	0.906	0.946	0.660	3.64	7.0	130
CDCP-YOLO	✓	✓	✓	✓	0.918	0.904	0.944	0.644	2.07	3.3	152

[a]CSPP: convolution Prewitt-and-pooling–based preprocessing.

[b]DCC: dynamic convolution–based C3k2.

[c]CPCA: channel prior convolutional attention.

[d]PHPS: progressive hybrid pruning strategy.

[e]Precision, recall, $mAP_{0.5}$, and $mAP_{0.5:0.95}$ were used to evaluate detection accuracy.

[f]$mAP_{0.5}$: mean average precision at an intersection-over-union threshold of 0.5.

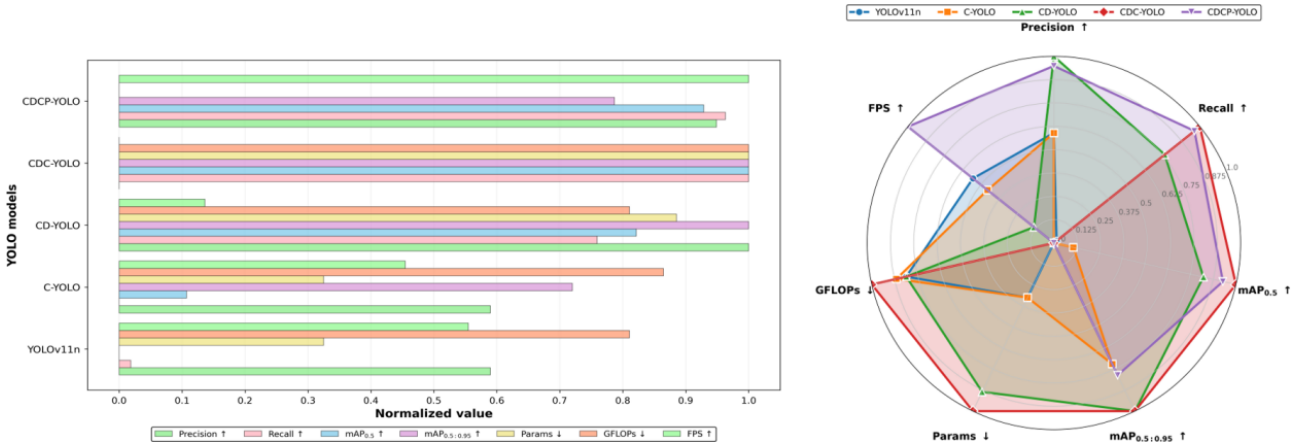
[g]$mAP_{0.5:0.95}$: average mean average precision over several intersection-over-union thresholds (0.50-0.95).

[h]Params (M) was used to measure model size.

[i]GFLOPs: number of floating-point operations (×10); used to measure computational complexity.

[j]FPS: frames per second; used to measure inference efficiency.

[k]Indicates that the corresponding module is absent in the model.



[l]A check mark (✓) indicates that the corresponding module is included in the model.

The $mAP_{0.5}$ of the original YOLOv11n was 0.918, $mAP_{0.5:0.95}$ was 0.585, parameter size was 2.58M, computational complexity was 6.3 GFLOPs, and inference speed was 142.2 FPS. After adding the CSPP module, the $mAP_{0.5}$ of C-YOLO slightly increased to 0.921 and its $mAP_{0.5:0.95}$ significantly increased to 0.639, while the number of parameters and computational complexity remained unchanged, indicating that the CSPP structure has a good effect on improving the model's ability to capture fine-grained features. After introducing the DCC module, the detection accuracy was further improved: the $mAP_{0.5}$ of CD-YOLO increased to 0.941, and the $mAP_{0.5:0.95}$ increased to 0.660. Although the parameter size slightly increased to 3.46M, computational complexity remained at 6.3 GFLOPs, and inference speed dropped to 133 FPS, the model's improvement in accuracy effectively enhanced its contextual modeling capability. Subsequently, with the addition of the CPCA module to obtain CDC-YOLO, the $mAP_{0.5}$ reached 0.946 (the highest value), and the $mAP_{0.5:0.95}$ remained unchanged at 0.660. Although parameter size slightly increased to 3.64M and inference speed dropped to 130 FPS, CDC-YOLO still performed outstandingly in terms of detection accuracy, further verifying the performance improvement effect of CPCA. On the basis of CDC-YOLO, PHPS was introduced to obtain CDCP-YOLO, which achieved a rebalance of model lightweighting and performance. This model reached 0.944 in $mAP_{0.5}$ and 0.644 in $mAP_{0.5:0.95}$, with only 2.07M parameters and computation complexity of 3.3 GFLOPs. The inference speed significantly increased to 152 FPS. This result shows that the PHPS basically retains high performance while compressing the model size.

As Figure 6 shows, CDCP-YOLO achieved a good balance in terms of accuracy, model size, computational load, and speed, showing a high degree of practicality and deployment advantages. Compared with other improved models, CDCP-YOLO had an absolute advantage in the 2 dimensions "fewest parameters" and "fastest inference," while also maintaining excellent performance in detection accuracy.

RenderX

Figure 6. Ablation study results of the proposed CDCP-YOLO on the Br35H brain tumor magnetic resonance imaging dataset. The figure on the left shows the multimetric normalization bar chart, where all evaluation metrics are normalized to the range [0, 1] for fair comparison across models. The metrics include precision, recall, $mAP_{0.5}$, $mAP_{0.5:0.95}$, number of parameters (Params), computational complexity (GFLOPs), and inference speed (FPS). The figure on the right presents a radar-based performance analysis plot summarizing the overall accuracy-efficiency trade-off of different ablation variants (YOLOv11n, C-YOLO, CD-YOLO, CDC-YOLO, and CDCP-YOLO). Arrows indicate metric preference: ↑ denotes that higher values are better (precision, recall, $mAP_{0.5}$, $mAP_{0.5:0.95}$, and FPS), while ↓ denotes that lower values are better (Params and GFLOPs). This figure demonstrates how each module (convolution Prewitt-and-pooling–based preprocessing [CSPP], dynamic convolution–based C3k2 [DCC], channel prior convolutional attention [CPCA], and progressive hybrid pruning strategy [PHPS]) progressively improves detection accuracy while reducing model complexity. FPS, frames per second; GFLOPs, number of floating-point operations (×10); mAP, mean average precision; $mAP_{0.5}$, mAP at an intersection-over-union threshold of 0.5; $mAP_{0.5:0.95}$, average mAP over several intersection-over-union thresholds (0.50-0.95); YOLO, "you only look once" framework.

Performance on Different Datasets

To comprehensively evaluate the performance of CDCP-YOLO, the performance of YOLOv11, CDC-YOLO, and CDCP-YOLO was compared on different datasets (Table 4).

Table . Performance comparison of YOLOv11, CDC-YOLO, and CDCP-YOLO on 3 brain tumor magnetic resonance imaging datasets: Br35H, Roboflow, and Capstone.[a]

Dataset and model	Precision	Recall	$mAP_{0.5}$[b]	$mAP_{0.5:0.95}$[c]	Params (M)[d]	GFLOPs[e]	FPS[f]
Br35H							
YOLOv11	0.904	0.853	0.918	0.585	2.58	6.3	142.2
CDC-YOLO	0.881	0.906	0.946	0.660	3.64	7.0	130
CDCP-YOLO	0.918	0.904	0.944	0.644	2.07	3.3	152
Roboflow							
YOLOv11	0.615	0.467	0.561	0.276	2.58	6.3	117.6

CDCP-YOLO	0.897	0.845	0.909	0.625	2.07	3.3	150

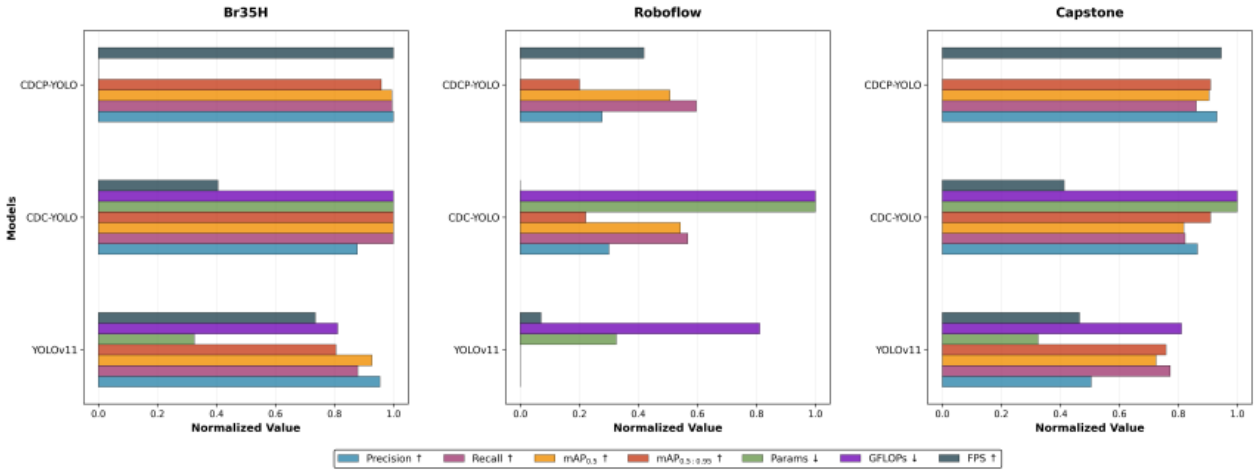
[a]The table reports detection accuracy metrics (precision, recall, $mAP_{0.5}$, and $mAP_{0.5:0.95}$) and efficiency metrics (Params, GFLOPs, and FPS) to evaluate both effectiveness and deployability across different datasets.

[b]$mAP_{0.5}$: mean average precision at an intersection-over-union threshold of 0.5.

[c]$mAP_{0.5:0.95}$: average mean average precision over several intersection-over-union thresholds (0.50-0.95).

[d]Params (M) was used to measure model size.

[e]GFLOPs: number of floating-point operations (×10).



[f]FPS: frames per second.

XSL•FO
RenderX

On Br35H, CDCP-YOLO was superior to other models in terms of precision (0.918) and inference speed (152 FPS). Although its $mAP_{0.5}$ was slightly lower than that of CDC-YOLO (0.944 vs 0.946), the outstanding performance of CDCP-YOLO in terms of parameter size (2.07M) and computational complexity (3.3 GFLOPs) makes it more suitable for practical application scenarios with limited resources. In addition, the $mAP_{0.5:0.95}$ metric showed that it achieved a good trade-off between performance and computational efficiency. The Roboflow dataset represented a more challenging general-purpose detection scenario, resulting in lower overall detection accuracy than that achieved on the Br35H dataset. CDC-YOLO achieved the highest $mAP_{0.5}$ (0.770) and $mAP_{0.5:0.95}$ (0.361), while CDCP-YOLO performed best in recall (0.729), and it had a higher inference speed (130.5 FPS) than CDC-YOLO (115 FPS). The overall performance of YOLOv11 was the weakest, especially with obvious shortcomings in recall (0.467) and $mAP_{0.5:0.95}$ (0.276), indicating that the original model lacked sufficient generalizability on this dataset. On Capstone, CDCP-YOLO once again demonstrated the best overall performance. It also showed the highest precision (0.897), $mAP_{0.5}$ (0.909), and FPS (150), indicating that the model has stronger stability and efficiency in actual inference tasks. Although CDC-YOLO and CDCP-YOLO were comparable in $mAP_{0.5:0.95}$ (both 0.625), CDCP-YOLO demonstrated higher comprehensive advantages by virtue of its smaller model size and faster speed.

As seen in Figure 7, CDCP-YOLO performed outstandingly in terms of "fewest parameters," "lowest computational load," and "fastest FPS," while also maintaining a leading position in detection accuracy metrics, demonstrating an extremely high balance and deployment advantage. YOLOv11, although fast in some scenarios, has lower precision and recall. CDC-YOLO had a slight advantage in precision, but its computational complexity and parameter size were higher.

Figure 7. Multimetric normalization analysis of CDCP-YOLO and baseline models on 3 brain tumor magnetic resonance imaging datasets: Br35H, Roboflow and Capstone. Each graph corresponds to 1 dataset, showing the normalized performance of YOLOv11, CDC-YOLO, and CDCP-YOLO across multiple evaluation metrics. All metrics are normalized to the range [0, 1] to enable fair comparison across datasets with different scales. The evaluated metrics include precision, recall, $mAP_{0.5}$, $mAP_{0.5:0.95}$, number of parameters (Params), computational complexity (GFLOPs), and inference speed (FPS). Arrows indicate the optimization direction: ↑ denotes that higher values are better (precision, recall, $mAP_{0.5}$, $mAP_{0.5:0.95}$, and FPS), while ↓ denotes that lower values are better (Params and GFLOPs). FPS, frames per second; GFLOPs, number of floating-point operations (×10); mAP, mean average precision; $mAP_{0.5}$, mAP at an intersection-over-union threshold of 0.5; $mAP_{0.5:0.95}$, average mAP over several intersection-over-union thresholds (0.50-0.95); YOLO, "you only look once" framework.

Impact of Different Attention Mechanisms

This paper introduces these modules including MixStructureBlock [42], MSCAttention [43], MSPABlock [44], and CPCA for comparing different attention mechanisms (Table 5).

XSL•FO
RenderX

Table . Comparative analysis of different attention mechanisms on the Br35H brain tumor magnetic resonance imaging dataset.[a]

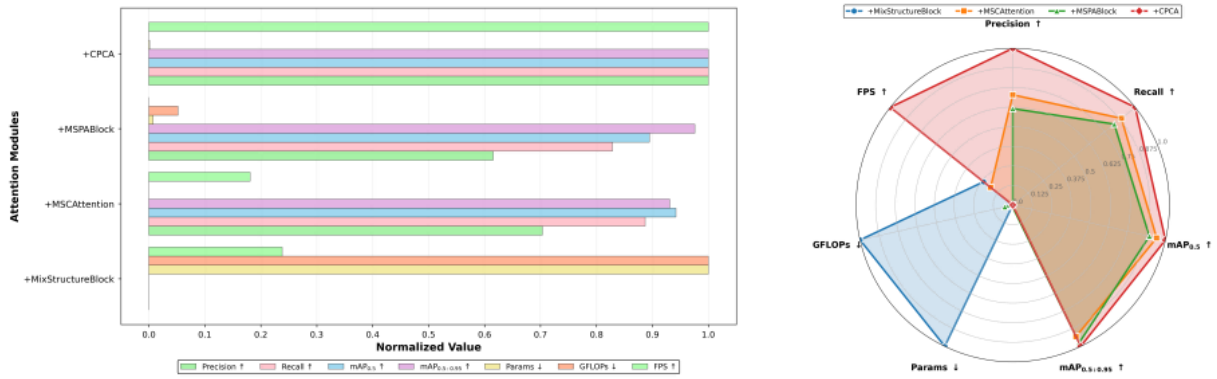
Attention mechanism	Precision	Recall	$mAP_{0.5}$[b]	$mAP_{0.5:0.95}$[c]	Params (M)[e]	GFLOPs[d]	FPS[f]
+MixStructureBlock	0.827	0.665	0.754	0.354	67.90	11	120
+MSCAttention	0.891	0.877	0.933	0.624	2.00	3.3	117.6
+MSPABlock	0.883	0.863	0.924	0.637	2.50	3.7	110
+CPCA[g]	0.918	0.904	0.944	0.644	2.07	3.3	152

[a]The table reports detection accuracy metrics (precision, recall, $mAP_{0.5}$, and $mAP_{0.5:0.95}$) and efficiency metrics (Params, GFLOPs, and FPS) to evaluate the effectiveness and computational cost of different attention modules.

[b]$mAP_{0.5}$: mean average precision at an intersection-over-union threshold of 0.5.

[c]$mAP_{0.5:0.95}$: average mean average precision over several intersection-over-union thresholds (0.50-0.95).

[d]GFLOPs: number of floating-point operations (×10).



[e]Params (M) was used to measure model size.

[f]FPS: frames per second.

[g]CPCA: channel prior convolutional attention.

As Figure 8 shows, CPCA performed excellently in terms of accuracy, efficiency, and resource consumption, making it the most cost-effective attention choice. In contrast, although MixStructureBlock has a complex structure, it was in a disadvantageous position in all performance indicators, indicating that the redundancy in its design was not converted into performance gains.

Figure 8. Comparative analysis of different attention mechanisms on the Br35H brain tumor magnetic resonance imaging dataset. The subfigure on the right shows the multimetric normalization bar chart, where all evaluation metrics are normalized to the range [0,1] for fair comparison among different attention modules. The compared attention mechanisms include MixStructureBlock, MSCAttention, MSPABlock, and the proposed channel prior convolutional attention (CPCA) module. The evaluated metrics include precision, recall, $mAP_{0.5}$, $mAP_{0.5:0.95}$, number of parameters (Params), computational complexity (GFLOPs), and inference speed (FPS). The subfigure on the right presents a radar-based performance analysis plot, summarizing the overall accuracy-efficiency trade-offs of different attention mechanisms. Arrows indicate metric preference: ↑ denotes that higher values are better (precision, recall, $mAP_{0.5}$, $mAP_{0.5:0.95}$, and FPS), while ↓ denotes that lower values are better (Params and GFLOPs). FPS, frames per second; GFLOPs, number of floating-point operations (×10); $mAP_{0.5}$, mean average precision at an intersection-over-union threshold of 0.5; $mAP_{0.5:0.95}$, average mean average precision over several intersection-over-union thresholds (0.50-0.95).

Impact of Different Loss Functions

Comparative experiments were conducted by introducing loss functions such as GIoU [45], DIoU [46], EIoU [47], SIoU, ShapeIoU, PIoU, WIoU, and CIoU (Table 6).

XSL•FO
RenderX

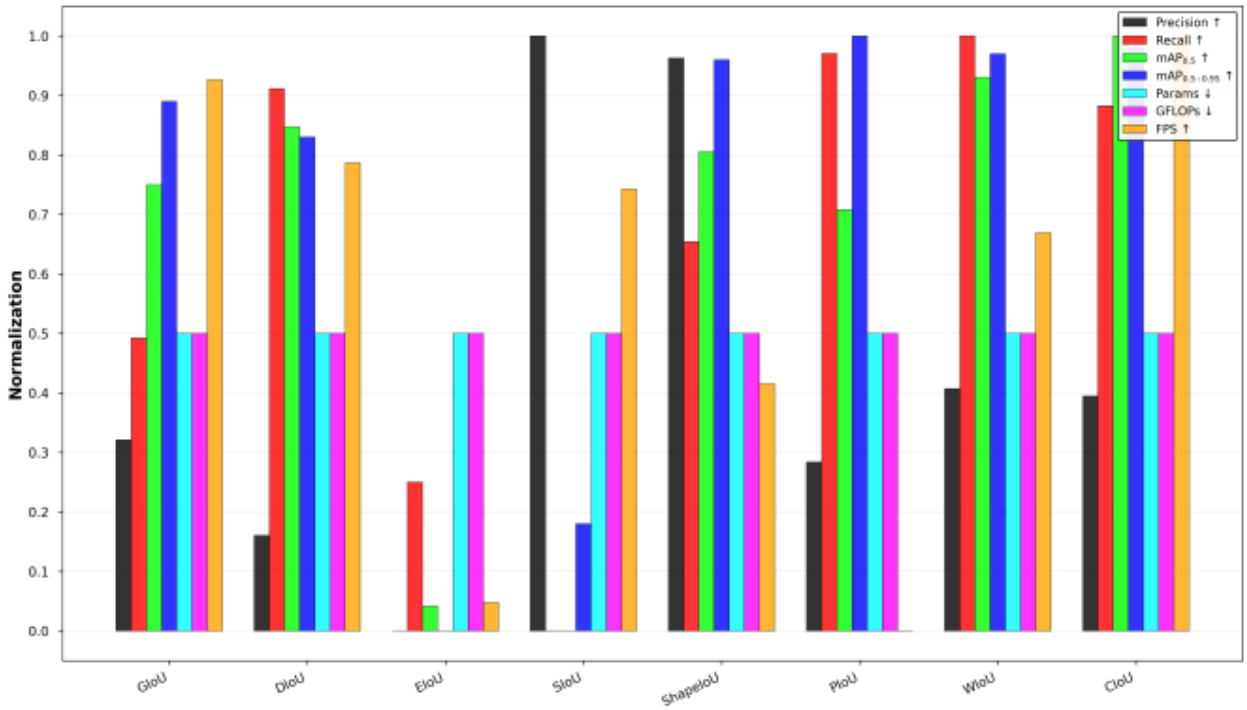
Table . Performance comparison of different bounding box regression loss functions on the Br35H brain tumor magnetic resonance imaging dataset.[a]

Loss function	Precision	Recall	$mAP_{0.5}$[b]	$mAP_{0.5:0.95}$[c]	Params (M)[d]	GFLOPs[e]	FPS[f]
GIoU	0.893	0.820	0.926	0.635	2.07	3.3	150
DIoU	0.880	0.877	0.933	0.629	2.07	3.3	146.2
EIoU	0.867	0.787	0.875	0.546	2.07	3.3	126.1
SIoU	0.948	0.753	0.872	0.564	2.07	3.3	145
ShapeIoU	0.945	0.842	0.930	0.642	2.07	3.3	136.1
PIoU	0.890	0.885	0.923	0.646	2.07	3.3	124.8
WIoU	0.900	0.889	0.939	0.643	2.07	3.3	143
CIoU	0.899	0.873	0.944	0.644	2.07	3.3	152

[a]The table reports detection accuracy metrics (precision, recall, $mAP_{0.5}$, and $mAP_{0.5:0.95}$) and efficiency metrics (Params, GFLOPs, and FPS) to evaluate the impact of different loss functions on detection performance and computational efficiency.

[b]$mAP_{0.5}$: mean average precision at an intersection-over-union threshold of 0.5.

[c]$mAP_{0.5:0.95}$: average mean average precision over several intersection-over-union thresholds (0.50-0.95).



[d]Params (M) was used to measure model size.

[e]GFLOPs: number of floating-point operations (×10).

[f]FPS: frames per second.

As Figure 9 shows, CIoU, as a new generation of bounding box regression loss function, significantly improved the accuracy and stability of target detection under the premise of ensuring model lightweighting, making it the most practical and valuable choice at present. At the same time, ShapeIoU and PIoU also had advantages in scenarios with high precision requirements, while WIoU provided good recall and generalization performance.

Figure 9. Multimetric normalization comparison of different bounding box regression loss functions on the Br35H brain tumor magnetic resonance imaging dataset. All evaluation metrics are normalized to the range [0,1] to enable fair comparison among different loss functions. The compared loss functions include GIoU, DIoU, EIoU, SIoU, ShapeIoU, PIoU, WIoU, and CIoU. The evaluated metrics include precision, recall, $mAP_{0.5}$, $mAP_{0.5:0.95}$, number of parameters (Params), computational complexity (GFLOPs), and inference speed (FPS). Arrows indicate optimization direction: ↑ denotes that higher values are better (precision, recall, $mAP_{0.5}$, $mAP_{0.5:0.95}$, and FPS), while ↓ denotes that lower values are better (Params and GFLOPs). FPS, frames per second; GFLOPs, number of floating-point operations (×10); mAP, mean average precision; $mAP_{0.5}$, mAP at an intersection-over-union threshold of 0.5; $mAP_{0.5:0.95}$, average mAP over several intersection-over-union thresholds (0.50-0.95).

Pruning Experiment

Five common pruning methods were systematically evaluated, including LAMP, L1, Random, GroupNorm, and PHPS (Table 7). All methods were kept consistent in terms of the number of parameters (2.07M) and computational complexity (3.3 GFLOPs) to facilitate a fair comparison of their performance differences.

Table . Performance comparison of different pruning strategies on the Br35H brain tumor magnetic resonance imaging dataset under the same parameter budget.[a]

Pruning method	Precision	Recall	$mAP_{0.5}$[b]	$mAP_{0.5:0.95}$[c]	Params[d]	GFLOPs[e]	FPS[f]
Lamp	0.858	0.891	0.941	0.640	2.07	3.3	137.1
L1	0.893	0.902	0.934	0.640	2.07	3.3	147
Random	0.866	0.902	0.940	0.637	2.07	3.3	150
GroupNorm	0.909	0.861	0.944	0.632	2.07	3.3	146.5
PHPS[g]	0.899	0.873	0.944	0.644	2.07	3.3	152

[a]The table reports detection accuracy metrics (precision, recall, $mAP_{0.5}$, and $mAP_{0.5:0.95}$) and efficiency metrics (Params, GFLOPs, and FPS) to evaluate the impact of different pruning methods on detection performance and inference efficiency.

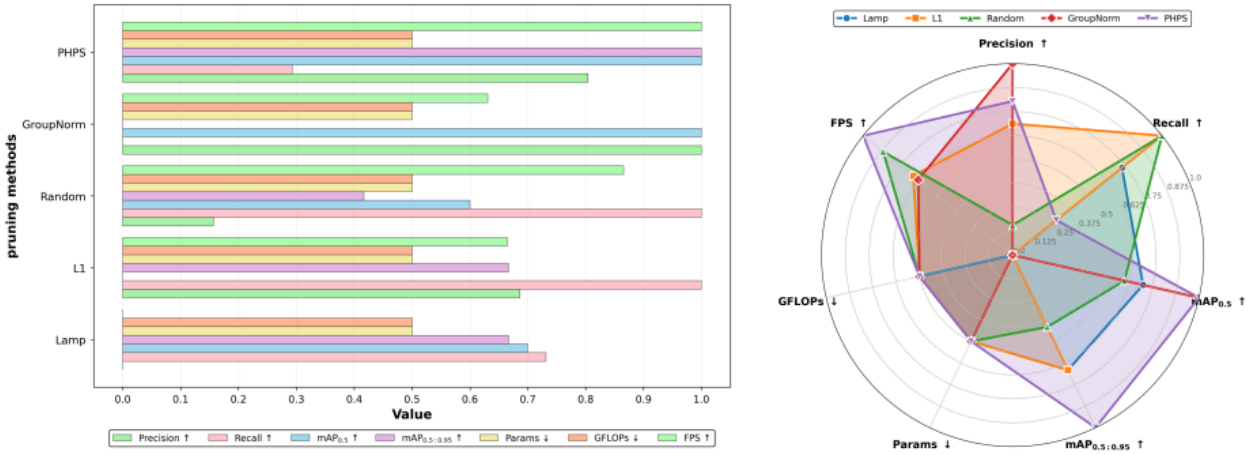
[b]$mAP_{0.5}$: mean average precision at an intersection-over-union threshold of 0.5.

[c]$mAP_{0.5:0.95}$: average mean average precision over several intersection-over-union thresholds (0.50-0.95).

[d]Params (M) was used to measure model size.

[e]GFLOPs: number of floating-point operations (×10).

[f]FPS: frames per second.



[g]PHPS: progressive hybrid pruning strategy.

The performance of PHPS was balanced and optimal across all performance indicators. The $mAP_{0.5}$ was the same as the GroupNorm method at 0.944, but PHPS reached the highest value of 0.644 on $mAP_{0.5:0.95}$ and also had the fastest inference speed (152 FPS), showing the best balance of precision and speed. GroupNorm had an advantage in precision (0.909), but recall rate was low (0.861), and $mAP_{0.5:0.95}$ was not as good as that of PHPS, indicating that its strength in boundary fitting may affect the completeness of target detection. Among the other methods, L1 had a slight advantage in recall (0.902), and the overall precision was stable. Random pruning is simple and has not undergone structural optimization, but it performed well in terms of inference speed (150 FPS). LAMP was inferior in all indicators, especially precision (0.858) and $mAP_{0.5:0.95}$ (0.640), indicating that its pruning method failed to effectively retain key features, weakening the model's detection ability.

Figure 10 shows that PHPS was in the outermost layer in dimensions such as "precision," "recall," "mAP" and "inference speed," representing that it scored the highest on each metric and had extremely strong practicality and deployment advantages. In contrast, the normalized evaluation of LAMP and GroupNorm showed obvious shortcomings, with deficiencies in detection accuracy and speed, respectively, making it difficult to meet the requirements of high-performance real-time tasks.

XSL•FO
RenderX

Figure 10. Comparative analysis of different pruning strategies on the Br35H brain tumor magnetic resonance imaging dataset under the same parameter budget. The left subfigure shows the multimetric normalization bar chart, where all evaluation metrics are normalized to the range [0,1] for fair comparison. The compared pruning methods include LAMP, L1-norm pruning, random pruning, GroupNorm-based pruning, and the proposed progressive hybrid pruning strategy (PHPS). The evaluated metrics include precision, recall, $mAP_{0.5}$, $mAP_{0.5:0.95}$, number of parameters (Params), computational complexity (GFLOPs), and inference speed (FPS). The right subfigure presents a radar-based performance analysis plot summarizing the overall accuracy-efficiency trade-offs of different pruning strategies. Arrows indicate optimization direction: ↑ denotes that higher values are better (precision, recall, $mAP_{0.5}$, $mAP_{0.5:0.95}$, and FPS), while ↓ denotes that lower values are better (Params and GFLOPs). FPS, frames per second; GFLOPs, number of floating-point operations (×10); mAP, mean average precision; $mAP_{0.5}$, mAP at an intersection-over-union threshold of 0.5; $mAP_{0.5:0.95}$, average mAP over several intersection-over-union thresholds (0.50-0.95).

To assess robustness, we fixed the same fully trained baseline checkpoint and repeated the pruning procedure 5 times with different random seeds. For each run, we pruned the model to the same parameter budget as that reported in Table 7 and performed a single final fine-tuning stage. These results demonstrated that, although the mean mAP gap between PHPS and random pruning was limited, PHPS provided significantly improved robustness and stability, which is particularly important for reliable deployment in medical imaging applications (Table 8).

Table . Stability comparison of different pruning strategies under the same parameter budget on the Br35H brain tumor magnetic resonance imaging dataset.[a]

Pruning method	SD ($mAP_{0.5}$[b]) $\times10^{-3}$	SD ($mAP_{0.5:0.95}$[c]) $\times10^{-3}$
Lamp	3.35	5.66
L1	1.41	3.54
Random	7.07	2.12
GroupNorm	2.83	1.42
PHPS[d]	0.71	0.71

[a]The table reports the SD of $mAP_{0.5}$ and $mAP_{0.5:0.95}$ (scaled by 10^{3}) across multiple training runs, which reflects the robustness and training stability of each pruning method.

[b]$mAP_{0.5}$: mean average precision at an intersection-over-union threshold of 0.5.

[c]$mAP_{0.5:0.95}$: average mean average precision over several intersection-over-union thresholds (0.50-0.95).

[d]PHPS: progressive hybrid pruning strategy.

Although different pruning strategies vary in their effectiveness, they also differ in practical implementation costs. Unstructured pruning often introduces limited pruning time overhead but requires sparse inference support, whereas structured pruning incurs additional pruning and fine-tuning costs during training while enabling direct acceleration at inference. The proposed PHPS performs pruning offline during training and does not introduce extra computational overhead at inference, making it suitable for deployment without modifying existing inference pipelines.

Five-Fold Cross-Validation

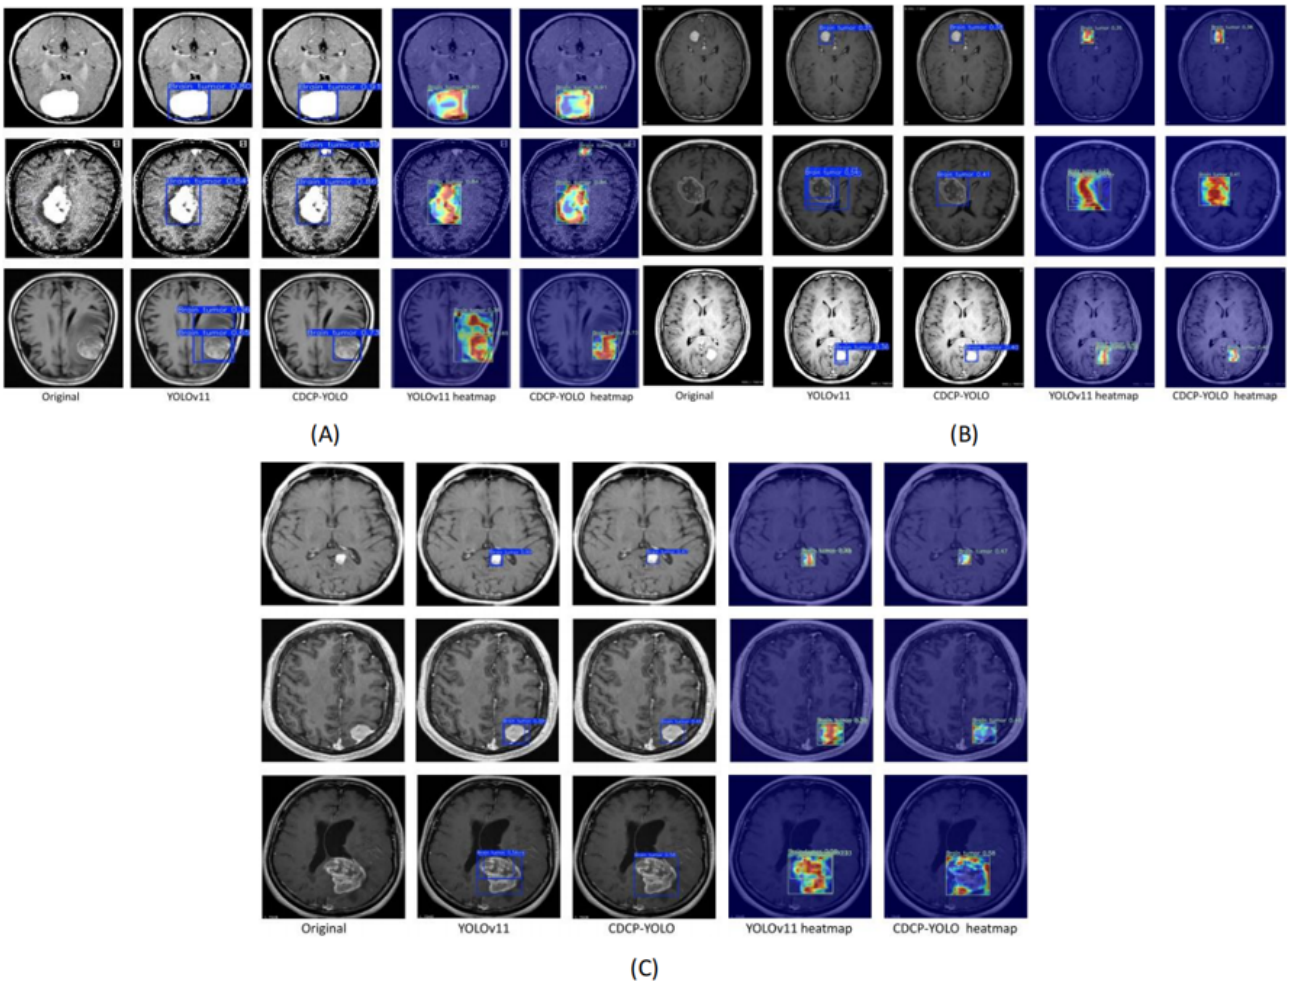
To further evaluate the statistical reliability of the performance gain between CDCP-YOLO and YOLOv11, we conducted a 5-fold cross-validation. The dataset was partitioned into 5 mutually exclusive folds. In each fold, 4 folds were used for training and the remaining one for testing, ensuring that each sample was evaluated exactly once.

All models were trained from scratch under identical training settings for each fold. The final performance was reported as the mean (SD) across the 5 folds.

XSL•FO
RenderX

The mean (SD) values of precision, recall, $mAP_{0.5}$, and $mAP_{0.5:0.95}$ across the 5 folds are reported in Table 9. The results showed that CDCP-YOLO consistently outperformed YOLOv11 across different folds, with lower variance and more stable performance, confirming that the observed improvement was statistically reliable and reproducible, rather than an artifact of random initialization.

Table . Five-fold cross-validation results of YOLOv11 and CDCP-YOLO on the Br35H brain tumor magnetic resonance imaging dataset.[a]



Model	Precision, mean (SD $\times10^{-3}$)	Recall, mean (SD $\times10^{-3}$)	$mAP_{0.5}$, mean (SD $\times10^{-3}$)	$mAP_{0.5:0.95}$, mean (SD $\times10^{-3}$)
YOLOv11	0.907 (17.880)	0.854 (2.492)	0.920 (3.030)	0.588 (11.500)
CDCP-YOLO	0.918 (1.410)	0.906 (2.610)	0.943 (2.590)	0.644 (1.410)

[a]The table reports the mean values of precision, recall, $mAP_{0.5}$, and $mAP_{0.5:0.95}$ across 5 folds, together with the corresponding SD ($\times10^{3}$) values, which reflect the training stability and robustness of each model.

Interpretability

In Figure 11, for each dataset, the first column shows the original MRI image, and the remaining columns show the detection boxes generated by the YOLOv11 and CDCP-YOLO frameworks and the corresponding Eigen-CAM heat maps, respectively. The overall comparison results showed that CDCP-YOLO performed with higher detection confidence, more compact detection boxes, and more focused responses on different datasets, significantly outperforming the YOLOv11 baseline.

Figure 11. Qualitative visual comparison of detection and interpretability results between YOLOv11 and the proposed CDCP-YOLO model on 3 brain tumor magnetic resonance imaging (MRI) datasets. (A) Br35H dataset, (B) Roboflow dataset, and (C) Capstone dataset. For each dataset, the columns (from left to right) show the original MRI slice, detection results of YOLOv11, detection results of CDCP-YOLO, Eigen-CAM heat map of YOLOv11, and Eigen-CAM heat map of CDCP-YOLO. The heat map color gradient ranges from blue to red, indicating low to high activation intensity, respectively, where warmer colors correspond to regions that contribute most to the detection decision. Compared with YOLOv11, CDCP-YOLO produces more compact and accurate bounding boxes and generates more focused and lesion-aligned activation maps, especially for small, blurry, or irregular tumor regions. These results demonstrate the improved detection reliability and interpretability of the proposed framework. Eigen-CAM, Eigen-class activation mapping; YOLO, “you only look once” framework.

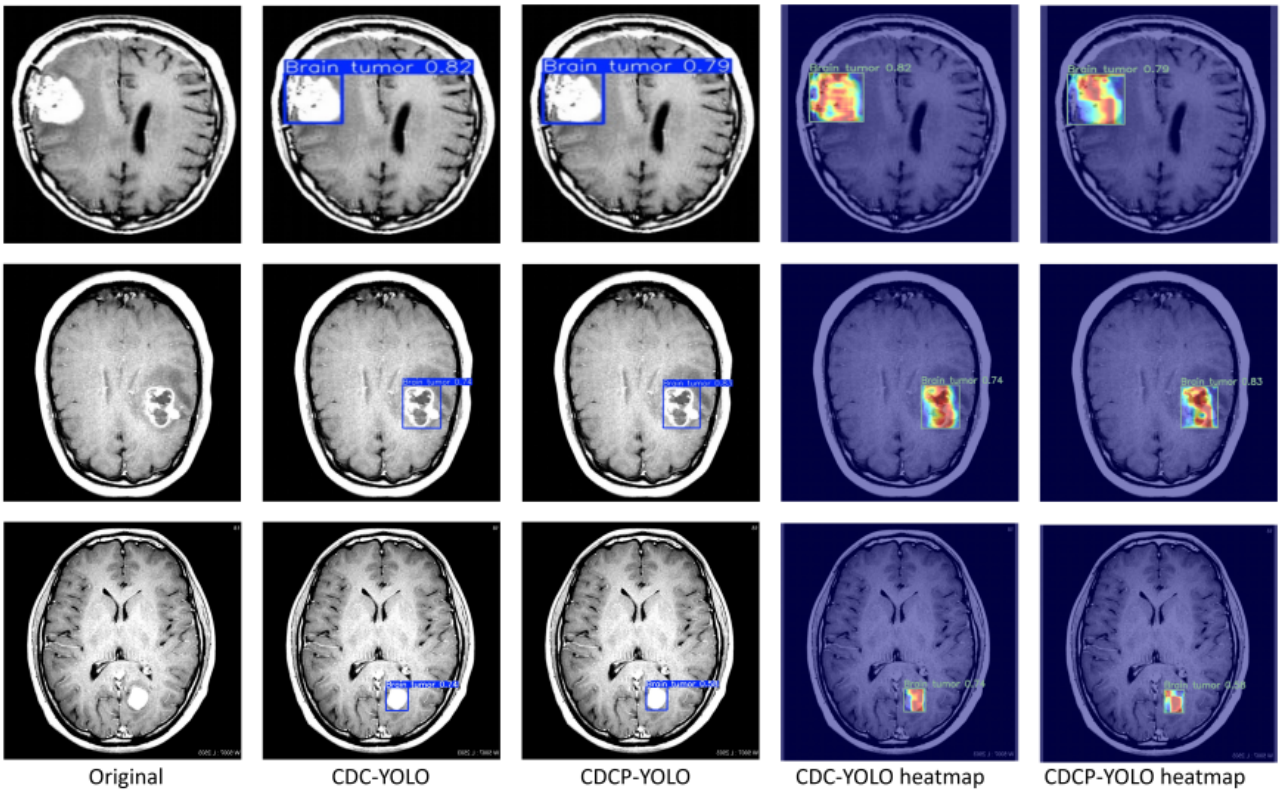
RenderX



From both quantitative and qualitative perspectives: on Br35H, the detection confidence of CDCP-YOLO in the first image was much higher than YOLOv11; in the second image, YOLOv11 failed to detect the tumor on the left, while CDCP-YOLO successfully identified it; in the third image, YOLOv11 produced 2 bounding boxes with inaccurate positioning, while the detection box of CDCP-YOLO was closer to the lesion outline; the Eigen-CAM heat map also mainly covered the high-signal core and extended to the indistinct boundary. On Roboflow, the confidence level of CDCP-YOLO was also significantly higher than that of YOLOv11, and it was more accurate in terms of boundary fit and shape depiction. On Capstone, the 3 sets of images consistently showed that CDCP-YOLO not only has higher detection confidence but its bounding boxes were also more consistent with the actual lesion, and the thermal response was tighter and more focused. In MRI with complex backgrounds, YOLOv11 is often interfered with by shadows and anatomical structures (such as blood vessels and choroid plexus), leading to boundary offsets or missed detections. The heat map of CDCP-YOLO can stably focus on the tumor lesion area, effectively suppressing the interference of shadows and structural noise. This advantage stems from the deep integration of multiscale feature enhancement modules (CSPP and DCC) and CPCA, which significantly enhances the sensitivity and discrimination of tumor regions during feature extraction and judgment.

Clinical Sensitivity and False Negative Analysis

In medical diagnosis, false negatives—particularly missed detections of small or visually ambiguous lesions—pose a critical risk. To evaluate the potential impact of pruning on clinical sensitivity, we further analyzed the behavior of the proposed PHPS from both quantitative and qualitative perspectives.

Quantitatively, the recall remained stable across different pruning configurations, indicating that the progressive pruning process did not significantly impair the model's ability to detect tumor regions. This suggests that the proposed strategy effectively preserved detection-critical channels during compression. Qualitatively, visualization results on representative cases involving small-scale or blurred tumor boundaries showed that the pruned model maintained consistent activation patterns compared with the unpruned baseline. These findings indicate that PHPS mitigates the risk of increased false negatives while achieving substantial model compression, thereby enhancing its suitability for clinical deployment. Despite significant model compression, the pruned CDCP-YOLO preserves consistent tumor localization and activation patterns compared with the unpruned baseline, especially for small-scale or low-contrast lesions. These results indicate that the proposed PHPS did not increase false negative rates and maintained clinical sensitivity under challenging conditions (Figure 12).

Figure 12. Qualitative comparison of detection sensitivity on small or ambiguous brain tumor regions before and after pruning on the Br35H brain tumor magnetic resonance imaging (MRI) dataset. From left to right, each column shows the original MRI slice, detection result of the unpruned CDC-YOLO, detection result of the pruned CDCP-YOLO, Eigen-CAM heat map of CDC-YOLO, and Eigen-CAM heat map of CDCP-YOLO. The heat map color gradient ranges from blue to red, indicating low to high activation intensity, respectively, where warmer colors correspond to regions that contribute most to the detection decision. Eigen-CAM, Eigen-class activation mapping; YOLO, "you only look once" framework.

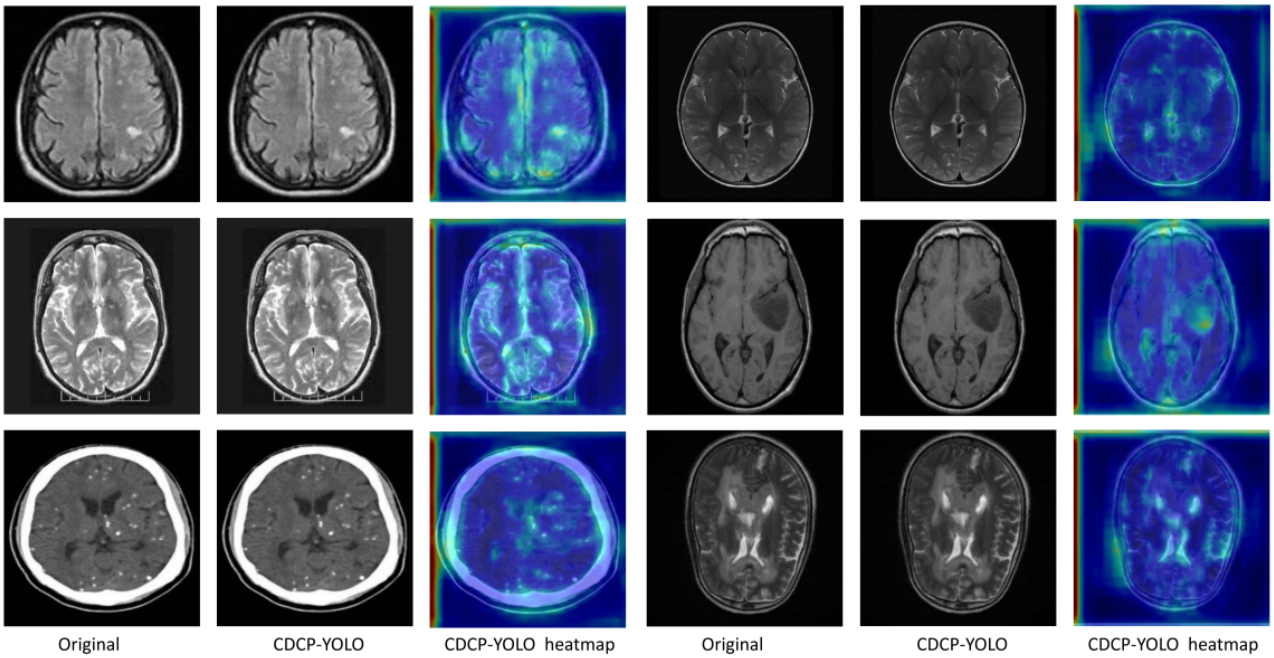
To statistically substantiate the "fine-grained" detection capability and robustness to small-scale tumors, we further evaluated the models using the AP_{small} metric, following the standard COCO evaluation protocol. As summarized in Table

XSL•FO
RenderX

10, CDCP-YOLO exhibited a superior sensitivity to small lesions compared to all baseline models. Specifically, CDCP-YOLO achieved an AP_{small} of 0.487, outperforming the YOLOv11n baseline (0.412) by a substantial margin of 18.2%. This quantitative improvement indicates that the integration of the CSPP and DCC modules for edge and feature enhancement, alongside the CPCA mechanism for precise spatial attention, effectively preserves the subtle morphological features of early-stage or small-scale tumors—details that are frequently overlooked by standard architectures. These results provide rigorous evidence that the proposed framework is not only efficient but also highly reliable for detecting clinically significant small lesions.

Table . Quantitative evaluation of small-lesion detection performance, AP_{small} (the baseline YOLOv11n and the proposed CDCP-YOLO model), on the Br35H brain tumor magnetic resonance imaging dataset using the standard Common Objects in Context (COCO)–style detection metrics.

Model	$mAP_{0.5}$[a]	AP_{small}[b]	Relative gain
YOLOv11n	0.918	0.412	—[c]
CDCP-YOLO	0.944	0.487	+18.2%



[a]$mAP_{0.5}$ denotes the mean average precision at an intersection-over-union threshold of 0.5.

[b]AP_{small} denotes the average precision computed only for small objects, following the COCO definition (ie, objects whose bounding-box area falls within the "small" size range specified by the COCO evaluation protocol).

[c]Not applicable.

To further assess the reliability and specificity of CDCP-YOLO, we conducted an inference-only validation on a negative control cohort of 50 healthy brain MRI slices obtained from the brain tumor dataset [48]. This test aimed to verify that the model does not produce "hallucinated" detections on normal anatomical structures. As shown in Figure 13, the model successfully classified all healthy slices as negative, producing no false positive detection boxes. Moreover, the Eigen-CAM visualizations showed only very weak background-level activations (cool colors) within healthy brain regions, without the high-intensity highlighted responses typically observed in tumor areas. This negative control experiment provided empirical evidence for the model's robust safety profile, ensuring that its high tumor sensitivity is not achieved at the expense of misdiagnosing healthy anatomy.

Figure 13. Representative examples of negative-control validation on healthy brain magnetic resonance imaging (MRI) slices using inference-only CDCP-YOLO and Eigen-CAM visualization. This figure presents an inference-only negative control experiment conducted on healthy brain MRI slices without tumor lesions, used to evaluate the specificity and safety of the proposed CDCP-YOLO model. The healthy slices were obtained from a publicly available brain MRI dataset and were not included in the training process. For each example, the first column shows the original MRI slice, the second column shows the detection result produced by CDCP-YOLO, and the third column presents the corresponding Eigen-CAM heat map overlaid on the original image. The color scale of the heat map represents the relative contribution of image regions to the model's prediction, where warm colors (red/yellow) indicate higher activation intensity, and cool colors (blue) indicate low or background-level responses. Eigen-CAM, Eigen-class activation mapping; YOLO, "you only look once" framework.

Hyperparameter Sensitivity Analysis of PHPS

To further assess the robustness of the proposed method, we conducted a sensitivity analysis on key training and pruning hyperparameters involved in PHPS. Specifically, we analyzed the sparsity coefficient (SC) and the learning rate (LR) schedule, as these parameters directly influence pruning behavior and convergence stability.

In this analysis, only one hyperparameter was varied at a time while all other settings were kept fixed, allowing us to isolate the effect of each parameter. The results are summarized in Table 11. As shown, the proposed method exhibited stable detection performance across a reasonable range of SC values, indicating that PHPS is not overly sensitive to the pruning threshold. In addition, different learning rate schedules led to comparable performance, suggesting that the training process remained robust under different optimization dynamics.

Table . Sensitivity analysis of key hyperparameters in the progressive hybrid pruning strategy (PHPS) on the Br35H brain tumor magnetic resonance imaging dataset.[a]

Hyperparameter	Setting	Precision	Recall	$mAP_{0.5}$[b]	$mAP_{0.5:0.95}$[c]
SC[d]	0.2	0.912	0.898	0.939	0.637
	0.3	0.918	0.904	0.944	0.644
	0.4	0.910	0.895	0.936	0.631
LR[e] schedule	StepLR	0.914	0.899	0.941	0.639
	CosineAnnealingLR	0.918	0.904	0.944	0.644
	CosineAnnealingWarm-Restarts	0.916	0.902	0.940	0.635

[a]The table reports the detection performance under different settings of the sparsity coefficient (SC) and learning rate (LR) scheduling strategies, including StepLR, CosineAnnealingLR, and CosineAnnealingWarmRestarts. Detection accuracy was evaluated using precision, recall, $mAP_{0.5}$ and $mAP_{0.5:0.95}$.

[b]$mAP_{0.5}$: mean average precision at an intersection-over-union threshold of 0.5.

[c]$mAP_{0.5:0.95}$: average mean average precision over several intersection-over-union thresholds (0.50-0.95).

[d]SC: sparsity coefficient.

[e]LR: learning rate.

Ablation Experiments for Architectural and Pruning Analysis

To rigorously isolate the architectural contributions of the proposed CSPP, DCC, and CPCA modules and analyze the impact of pruning, a pruned baseline model (YOLOv11n-1) was included in the ablation study, as summarized in Table 12. Specifically, the standard YOLOv11n backbone was pruned to the same parameter budget (2.07M) using the same PHPS and fine-tuning protocol but without introducing any of the proposed architectural modules. This design allows us to decouple the effect of pruning from that of architectural enhancement. As shown in Table 12, applying PHPS to the standard YOLOv11n resulted in performance degradation, with $mAP_{0.5}$ dropping from 0.918 to 0.902. This outcome demonstrates that aggressive pruning on a baseline backbone without specialized modules inevitably disrupts critical feature pathways, challenging the notion that pruning alone can enhance model capability. In contrast, the proposed CDCP-YOLO model achieved a significantly higher $mAP_{0.5}$ of 0.944 under the same 2.07M parameter budget. These results clarify that the observed performance gains originated from the architectural enhancements—CSPP, DCC, and CPCA—which provided robust feature representation that successfully compensated for the pruning-induced losses. This confirms that jointly designing architectural enhancements and progressive pruning is essential for achieving a superior accuracy-efficiency trade-off in resource-constrained environments.

Table . Ablation study isolating the contributions of architectural modules and pruning, through comparison of (1) the unpruned baseline YOLOv11n; (2) a pruned baseline (YOLOv11n-1) obtained by applying the progressive hybrid pruning strategy (PHPS) to the standard YOLOv11n (without CSPP[a], DCC[b], or CPCA[c]) to match the parameter budget of 2.07M; and (3) the proposed CDCP-YOLO model, which integrated the proposed architectural modules (CSPP, DCC, and CPCA) and was pruned and fine-tuned under the same PHPS setting.

Model	Precision	Recall	$mAP_{0.5}$[d]	$mAP_{0.5:0.95}$[e]	Params (M)[f]	GFLOPs[g]	FPS[h]
YOLOv11n	0.904	0.853	0.918	0.585	2.58	6.3	142.2
YOLOv11n-1	0.905	0.855	0.902	0.580	2.07	2.8	145.3
CDCP-YOLO	0.918	0.904	0.944	0.644	2.07	3.3	152

[a]CSPP: convolution Prewitt-and-pooling–based preprocessing.

[b]DCC: dynamic convolution–based C3k2.

[c]CPCA: channel prior convolutional attention.

[d]$mAP_{0.5}$: mean average precision at an intersection-over-union threshold of 0.5.

[e]$mAP_{0.5:0.95}$: average mean average precision over several intersection-over-union thresholds (0.50-0.95).

[f]Params (M) was used to measure model size.

[g]GFLOPs: number of floating-point operations (×10).

[h]FPS: frames per second.

Impact of Training Budget on Performance Gain
