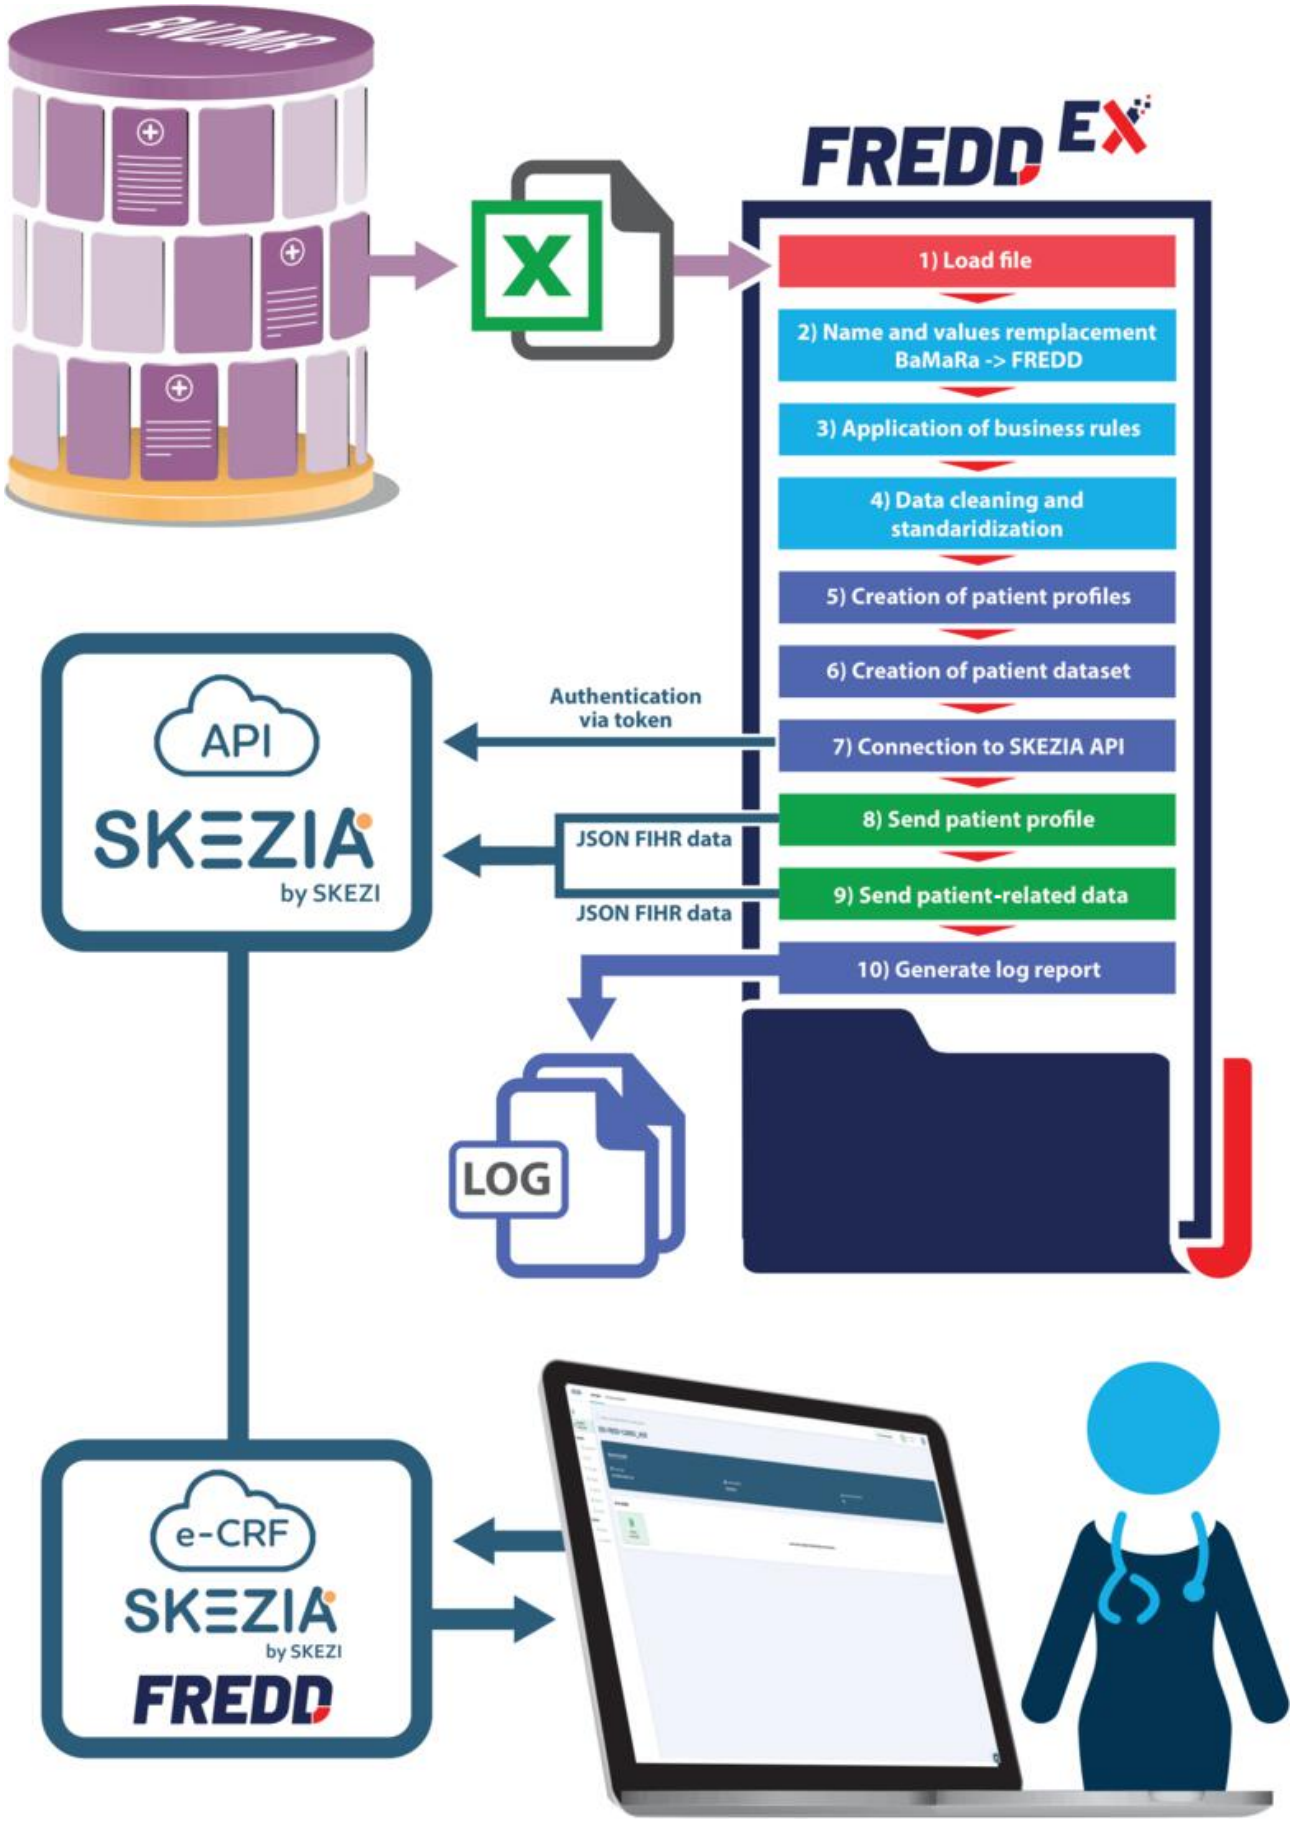
- Error handling and support: FREDDEX generates detailed log files and error reports to facilitate technical support and enable the rapid resolution of integration issues.
- Transparency and auditability: The Python processing engine is extensively documented and generates detailed execution logs, providing dataset-level traceability of all applied transformation rules and facilitating reproducibility and auditability.

These constraints guided the technical design of FREDDEX, ensuring that the tool is functional, deployable, and maintainable in a clinical setting. The application was fully designed and

XSL•FO
RenderX

implemented by the FREDD team, enabling controlled evolution and deployment across participating clinical centers.



FREDDEX follows a classical extract-transform-load architecture, implemented in Python and structured into 3 functional layers as detailed in Figure 3:

1. Extraction layer (in red): FREDDEX takes as input standardized Excel exports generated manually from BaMaRa by the local data manager. These files constitute the raw input layer and preserve the structural organization of BaMaRa clinical domains across multiple worksheets.
2. Transformation layer (in light blue): The transformation process combines deterministic structural mapping and domain-specific logic. It comprises the following:
   - structured ingestion of Excel data
   - deterministic mapping based on a predefined BaMaRa→FREDD correspondence file
   - the application of domain-specific business rules (eg, multiple diagnostic blocks, polydiagnostic cases, and conditional logic for optional variables)
   - data cleaning, normalization, and semantic alignment
   - reformatting into a structure compliant with SKEZIA API specifications and a Fast Health Care Interoperability Resources (FHIR) [30] based on the JSON schema.
3. Loading layer (in green): Once validated, the transformed dataset is serialized into a standardized CSV structure for FREDD import. For API-based ingestion, data are translated into FHIR-compliant resources and transmitted to the SKEZIA platform via authenticated API calls. Patient creation and questionnaire submission are handled sequentially to preserve relational integrity. Authentication relies on short-lived access tokens generated through a secure end point, with credentials encrypted using the Fernet algorithm (AES-128-CBC with HMAC-SHA256 authentication) [31] and decrypted only at runtime. To ensure robustness, the pipeline incorporates controlled submission pacing and retry mechanisms in case of temporary API unavailability.

XSL•FO
RenderX

Figure 3. Diagram illustrating the main functions of FREDDEX. These functions correspond to the “extract” (in red), “transform” (in light blue), and “load” (in green) steps, or (in dark blue) to the application’s technical operations. API: application programming interface; BaMaRa: Base Maladies Rares; e-CRF: electronic case report form; FHIR: Fast Health Care Interoperability Resources; FREDD: French Rare Eye Disease Database.

XSL•FO
RenderX

After each execution, FREDDEX generates a structured report detailing imported patients, applied business rules, selected diagnostic blocks, and rejected or excluded records, thereby ensuring full transparency and auditability.

XSL•FO
RenderX

Having fully designed and implemented FREDDEX's architecture and processing workflow, we next assessed its performance and reliability by validating the software on real-world BaMaRa data.

Validation Dataset, Experimental Design, and Performances

To validate the entire data integration pipeline, a BaMaRa export file containing 1000 real-world patients from the Centre des Affections Rares Génétiques et Ophtalmologiques (CARGO) in Strasbourg was used for validation. The dataset was derived from routine clinical consultations and represented real-world clinical documentation.

The file was processed using FREDDEX and imported into a dedicated test instance of the FREDD e-CRF. After import, all patient records were reexported for comparison with the original BaMaRa dataset to assess mapping consistency and transformation behavior.

A structured validation protocol was applied to evaluate deterministic transformations. Automated checks were performed on directly mapped and inferred variables. Complex relationships between diagnoses, genes, and variants were evaluated on a random sample of 30 patients with genetic data, independently reviewed by a research assistant. Additional validation was performed on 30 patients with multiple diagnoses to assess correct handling of longitudinal clinical information. Duplicate import prevention was assessed by reprocessing a subset of 10 patients after the initial successful import.

To evaluate the software performance and scalability, runtime was measured from the opening of the FREDDEX interface to the display of the "Processing completed" window, while peak memory usage was monitored using the Python *psutil* library. After each major processing function, the resident memory size of the running process was recorded, and the highest observed value during execution was retained as the peak memory usage.

Results

Software Validation

From the BaMaRa export of 1000 real patients from the CARGO cohort in Strasbourg, FREDDEX successfully filtered eligible patients and created 641 patient profiles in the FREDD e-CRF, corresponding to the number of questionnaires imported without errors. Seven questionnaires failed to import due to mapping errors in an HPO field. Among the 641 imported patients, 9 had ORPHA codes not listed in the configuration file. These patients were still imported because they met the alternative inclusion criterion: a diagnostic status of "Undetermined" with at least one HPO code recorded. The transformation from BaMaRa to FREDD was validated by comparing the exported files from both systems. All directly mapped and inferred variables showed 100% concordance.

Among the 641 imported patients, 129 had at least one gene with one associated variant recorded. A random sample of 30 patients was manually reviewed to ensure that the correct genes were assigned to the appropriate diagnoses and that variants were correctly linked to their respective genes. This review confirmed 100% concordance.

Out of the 641 imported patients, 95 had at least 2 diagnostic blocks. Among these, 25 patients had multiple REDs, while the remaining 70 patients had multiple blocks corresponding to a single disease.

- Patients with multiple diagnostic blocks: For the 70 patients with multiple blocks for a single disease, FREDDEX retained the most recent and most complete block. A manual review of 30 patients confirmed 100% concordance.
- Patients with multiple diagnoses in FREDD: Of the 25 patients with multiple rare diseases, only 7 had 2 RED diagnoses recorded. The remaining diagnoses were excluded due to either an unauthorized ORPHA code or a diagnostic status not meeting inclusion criteria. For each retained block, all variables were verified to ensure accurate transfer and representation in FREDD.
- Duplicate import prevention: On all 10 patients deliberately reprocessed after the successful initial import, the second import attempt was correctly blocked. Existing records were identified based on identity criteria (name, surname, and date of birth), and no duplication or unintended overwriting occurred.

These results are summarized in Table 4.

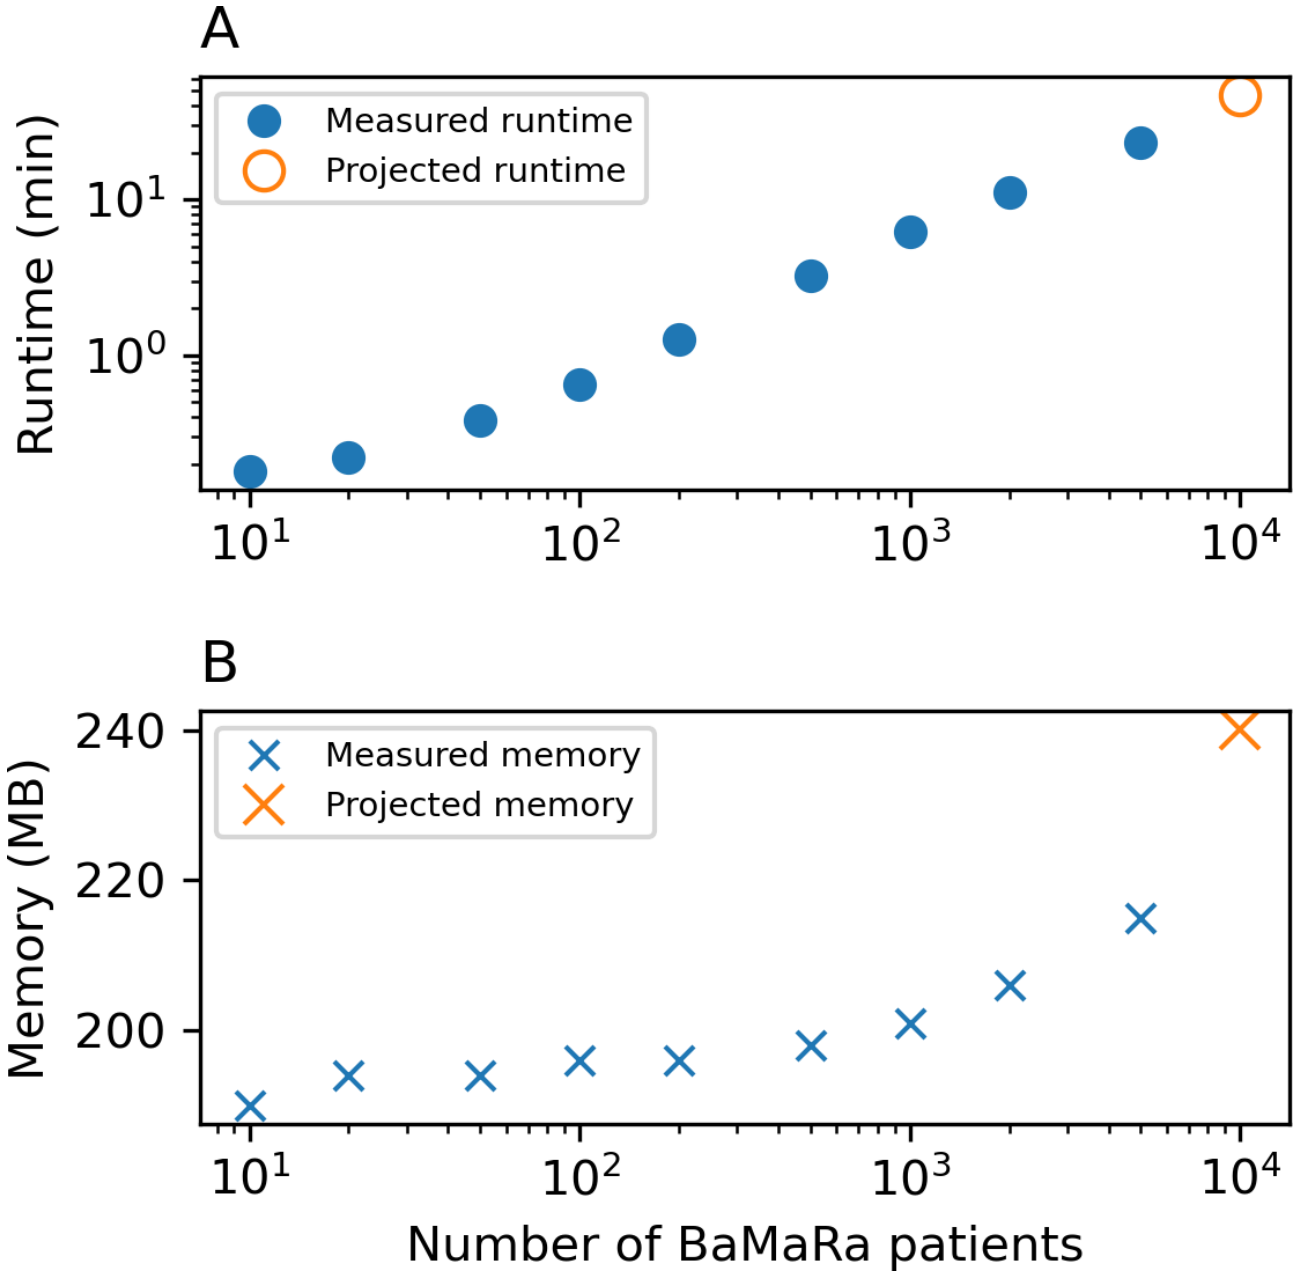
XSL•FO
RenderX

Table . Success rates and error tracking for BaMaRa[a]-to-FREDD[b] data transformation.

Patients concerned	Step	Success	Errors or exclusions	Success rate of eligible patients (%)	Cause
1000	Filtering per ORPHA/diagnostic status	648	0	100	352 patients excluded: only those with valid ORPHA+ probable/confirmed or undetermined+ HPO[c] included
648	Initial import into FREDD	641	7	98.9	7 patients failed due to HPO mapping errors
641	Directly mapped and inferred variables	641	0	100	Concordance checked by code between BaMaRa and FREDD
30 randomly selected patients (out of 129 with ≥1 gene and variant)	Genetic data reconstruction	30 (manual review)	0	100	Random sample of 30 manually checked; correct genes/variants assigned to correct diagnosis
30 randomly selected patients (out of 95 with ≥2 diagnostic blocks)	Multidiagnostic blocks	30 (manual review)	0	100	Manual review of 30 patients confirms the most recent block correctly represented
25	Patients with multiple rare diseases	7 (manual review)	0	100	Remaining 18 excluded due to ORPHA/status rules; all manually verified
10	Duplicate import prevention (reimport test)	10	0	100	Second import attempt correctly rejected; identity matched on name, surname, and date of birth

[a]BaMaRa: Base Maladies Rares.

[b]FREDD: French Rare Eye Disease Database.



[c]HPO: human phenotype ontology.

Performances Validation

Performance measurements were conducted on datasets ranging from 10 to 5000 patients. The results indicate that execution time grows near-linearly with the number of patients (Figure 4A), while peak memory consumption remains stable between 190 and 215 MB (Figure 4B). Based on extrapolation from observed measurements, processing 10,000 patients is estimated to require approximately 46 to 47 minutes of runtime, with memory usage remaining within the observed range.

XSL•FO
RenderX

Figure 4. .Performance evaluation of the pipeline. (A) Runtime as a function of the number of BaMaRa (Base Maladies Rares) patients (log-log scale). (B) Memory consumption during execution. Orange markers indicate projections for 10,000 patients.

Discussion

Performance Evaluation of FREDDEX in Large-Scale Clinical Data Integration

In this study, FREDDEX successfully transformed and integrated the BaMaRa data into the FREDD data warehouse, generating 641 patient profiles from an initial dataset of 1000 patients and achieving a 99% success rate with full concordance for mapped and inferred variables. The tool also accurately reconstructed genetic data and handled complex clinical cases, including multiple diagnostic blocks, while demonstrating near-linear scalability. The development of FREDDEX represents a significant step toward harmonizing clinical data flows between routine care and research infrastructures, supporting the reuse of health data while reducing the burden on clinical centers.

Bridging Clinical and Research Infrastructures

One of the main achievements of this work is its ability to operationalize the concept of interoperability in the rare disease ecosystem. While BaMaRa was not initially designed with research reuse in mind, its widespread adoption across expert centers makes it a key asset in the national rare disease data landscape. FREDD, as a domain-specific data warehouse, provides the necessary structure and enrichment layers to enable high-quality research on a specific field of RED. The integration tool serves as a bridge between these 2 complementary infrastructures, fostering data continuity without duplicative entry.

This approach aligns with broader national and European strategies for rare disease data management, including the REDgistry platform and the upcoming European Health Data Space, both of which emphasize data standardization and reuse.

XSL•FO
RenderX

Beyond the technical alignment, the deployment of this application demonstrates that secure, regulation-compliant data transfers between clinical databases are feasible and can significantly preserve valuable human resources in expert centers. Moreover, the implementation of BaMaRa-specific business rules allows the tool to handle the complex realities of clinical data capture with nuance and flexibility. These rule-based transformations are key to ensuring semantic coherence and avoiding misinterpretation during downstream data use.

However, such integrations would be vastly simplified if a dedicated data entry software for rare diseases existed at the European level, built natively on the SDM-MR and embedding essential reference ontologies, such as ORPHA codes, HPO, and HUGO Gene Nomenclature Committee. In such a scenario, the "transform" step of extract-transform-load processes would become minimal or even obsolete, substantially easing the burden on technical teams managing rare disease data infrastructures.

More broadly, this highlights the need for public policy to support not only semantic and legal harmonization efforts but also concrete operational infrastructures—such as shared data entry tools—capable of ensuring sustainability, technical interoperability, and equity of access across national health systems. Strengthening these foundations is essential to fully realize the promise of federated rare disease data platforms in Europe.

Flexibility, Interoperability, and Versioning

FREDDEX is built on a modular architecture with clearly compartmentalized components responsible for data ingestion, semantic mapping, transformation, and API export. This modular design ensures the independent operation of each stage, facilitating maintenance, debugging, and future enhancements. The BaMaRa → FREDD mapping is maintained externally from the source code, allowing variables to be added, removed, or modified without altering the core application logic. Similarly, the API layer is fully decoupled from upstream processing, enabling flexible integration with different export targets and supporting future alignment with common data models, such as FHIR or Observational Medical Outcomes Partnership.

To ensure reproducibility and traceability, FREDDEX follows a strict versioning strategy. A new version is released whenever bug fixes, user-interface improvements, or adjustments due to updates in BaMaRa or the SKEZIA API are required. Each version is distributed with instructions to discontinue the previous one, and the version number used for each import is recorded in the final report, enabling the full auditability of all data transformations.

Usability Considerations and Field Observations

No formal usability study was conducted in this work, and no standardized evaluation instruments (eg, system usability scale) were applied, as the primary focus was on the methodological and architectural design of the data integration pipeline. Nevertheless, the informal qualitative feedback collected during real-world deployment across several clinical centers provided contextual insights into the system use in operational environments. These observations suggested that the tool was perceived as easy to adopt in routine workflows and that it may reduce the complexity of data extraction–transformation–loading processes compared to manual approaches.

Limitations and Considerations

Despite its advantages, FREDDEX is not without limitations. The system has been developed and evaluated using real-world clinical datasets, which constitute a meaningful stress test for any data integration pipeline. In practice, heterogeneous data entry conditions—particularly in free-text fields—may introduce special characters, encoding inconsistencies, or syntactic irregularities capable of disrupting automated processing. Although BaMaRa increasingly relies on structured fields and controlled vocabularies, residual variability inherent to routine clinical documentation remains an operational constraint.

To mitigate these risks, FREDDEX incorporates multiple safeguards, including error-handling mechanisms. As previously stated, when critical inconsistencies are detected, the import of the corresponding patient record is automatically blocked. Nevertheless, these technical safeguards do not eliminate the need for vigilant downstream data management, including routine quality control procedures, reconciliation checks, and periodic validation of transformation outputs against source data.

Another structural consideration lies in the need to maintain alignment with evolving upstream and downstream systems. FREDDEX operates at the intersection of BaMaRa and SKEZIA and must therefore accommodate changes originating from both environments, including modifications to the BaMaRa's export structure, updates to SKEZIA's API specifications, or the internal evolution of the FREDD e-CRF. Any structural modification affecting variables, formats, or validation constraints must be consistently reflected in the mapping configuration and transformation logic to preserve interoperability and semantic integrity. This requires the rapid identification and implementation of changes as soon as they are known to minimize disruption to ongoing data collection.

From a scalability perspective, FREDDEX has been stress-tested with datasets comprising up to 5000 patients in a single import batch. While such a volume already exceeds typical expected operational loads for RED registries—where routine imports are generally expected to involve 100 to 200 patients—it remains lower than the scale encountered in large university hospital environments managing very large patient cohorts.

Finally, FREDDEX is currently configured specifically for RED within a French national context, embedding business rules aligned with observed RED clinical practice and the variables defined within FREDD. While the externalized mapping configuration facilitates adaptation to alternative target data warehouses or disease domains, the validity and completeness of rule translation would require a strong reassessment if FREDDEX was deployed for other REDs, different RED networks, or in different national settings. The modular architecture lowers the technical barrier to such adaptation; however, domain-specific semantic alignment, workflow

XSL•FO
RenderX

validation, and regulatory compliance checks would remain necessary.

Future Directions

Several future directions emerge from this work, spanning interoperability with European infrastructures, methodological generalization, usability assessment, and support for longitudinal data integration.

- Integration with European infrastructures: REDgistry's data model, developed around the Joint Research Center minimal European dataset, is based on the French SDM-MR but is not yet fully harmonized. FREDDEX's modular mapping and transformation layers could be extended to act as a bridge between SDM-MR and the Joint Research Center model, enabling automated, traceable data conversion, and seamless interoperability across national and European registries, while reducing the need for complex manual transformations.
- Generalization to other domains: The modular structure of FREDDEX could be tested through a concrete use case in a different rare disease registry. Developing and deploying a FREDDEX instance for an alternative data source would allow for the evaluation of its modularity, adaptability of mapping rules, and robustness of the pipeline in a new context, providing practical insights for future scaling to other networks.
- Additional feedback from the field: Although informal field observations suggest that FREDDEX is rapidly appropriated by clinical data technicians with limited training and facilitates the data collection, a structured usability evaluation remains necessary. Conducting a formal assessment—potentially using standardized instruments such as the system usability scale—would provide the quantitative evidence of usability, identify unseen issues, and guide future improvements to enhance adoption and user experience.
- Longitudinal data tracking: As FREDD may eventually support a longitudinal patient follow-up, FREDDEX will need to adapt to enable incremental updates and synchronization of new or updated clinical data. This would require implementing mechanisms to detect previously imported patients, reconcile changes with existing records, and ensure that follow-up information is correctly linked to prior diagnostic blocks while preserving auditability and semantic consistency.

Abstract

Background: Population health management requires tools that transform complex clinical data into actionable insights to guide care coordination, community outreach, and system-level planning.

Objective: The objective of this study is to develop and apply a population health intelligence dashboard that integrates inpatient utilization, process indicators, and health status data for patients with diabetes mellitus, using a clinically meaningful classification system and geospatial visualization.

Methods: We used data from the SingHealth Diabetes Registry (SDR; 2019 - 2024) to build an interactive dashboard using R Shiny (Posit Software). A semiautomated mapping algorithm was developed to map *ICD-10-AM* (*International Classification of Diseases, 10th Revision, Australian Modification*) principal diagnosis codes into CCSR (Clinical Classifications Software Refined) categories. We built an interactive dashboard in R Shiny incorporating 3 analytic domains: inpatient utilization (by admission count, length of stay, and prolonged stays), diabetes care process indicators, and health status indicators (eg, comorbidities, laboratory results, and diabetes-related complications). Geographic information system mapping enabled spatial visualization by patients' residential locations.

Results: Diabetes mellitus with complication (END003) was the leading cause of admission (7.0% - 8.1% annually), followed by pneumonia (RSP002, 3.7% - 5.1%), fluid and electrolyte disorders (END011, 3.4% - 4.1%), and skin infections (SKN001, 2.8% - 3.1%). In 2024, top *ICD-10-AM* diagnoses under END003 included E1122—type 2 diabetes mellitus with established diabetic nephropathy, E1173—type 2 diabetes mellitus with foot ulcer due to multiple causes, and E1172—type 2 diabetes mellitus with features of insulin resistance. For END011, the most frequent diagnosis codes were E877—fluid overload, R18—ascites, E875—hyperkalemia, and hypo-osmolality and hyponatremia. In total, SingHealth Diabetes Registry patients accounted for 687,062 inpatient bed days in 2024. Circulatory conditions (eg, cerebral infarction and heart failure) contributed 124,417 (17.7%) bed days, while injuries (eg, hip fractures and surgical complications) accounted for 86,541 (12.6%) bed days. CCSR-based analyses revealed distinct patterns when comparing conditions driving admission frequency versus prolonged length of stay. GIS mapping identified residential clusters with high inpatient utilization, unmet care processes, and poor cardiometabolic control, supporting region-specific intervention planning.

Conclusions: The dashboard demonstrates a novel, interactive approach to visualizing inpatient utilization, care gaps, and health status, enabling targeted, place-based interventions. It represents a scalable framework for operationalizing population health intelligence across other chronic disease areas and health care systems.

Introduction

Across the globe, many countries are undergoing demographic and epidemiological transitions, marked by a rising burden of chronic conditions such as diabetes, hypertension, and hyperlipidemia, along with their associated complications. These conditions significantly increase health care utilization and place growing strain on health systems and resources. Population health management (PHM) has emerged as a strategic approach to address these challenges by proactively identifying at-risk populations, coordinating care across settings, and implementing targeted interventions to prevent complications, reduce avoidable utilization, and improve long-term health outcomes [1].

PHM emphasizes addressing the broader determinants of health for populations within defined geographic areas, often in collaboration with a range of health and community partners [2]. A critical enabler of PHM is the availability of robust information technology infrastructure that can integrate diverse data sources to support in-depth analyses, inform targeted interventions, and assess the outcomes of these interventions [1,2].

Three key challenges commonly affect PHM: identifying the clinical drivers of health care utilization across a health system, making sense of complex disease and utilization data in a structured, actionable way, and leveraging digital technologies to design programs that reduce preventable utilization. Addressing these challenges requires integrated, multifunctional data dashboards and analytic tools [1].

A recent scoping review found that most dashboards served either clinical purposes (direct care, PHM, and care coordination) or administrative purposes (performance monitoring, utilization tracking, and resource management), and few served both purposes [3]. Furthermore, clinical dashboards often had a narrow disease focus, typically targeting specific conditions or objectives. Notably, the review found no dashboard that integrated PHM, care coordination, and utilization tracking—functions critical to delivering integrated, proactive care.

In this paper, we describe the development of a population health intelligence dashboard designed to uncover both clinical and administrative priorities for patients with diabetes mellitus. The dashboard was engineered to dynamically support varying levels of disease specificity—enabling users to explore health care utilization trends across a broad range of conditions or drill down into specific disease areas as needed. By integrating core functions such as PHM, care coordination, and utilization tracking, the platform facilitates data-driven planning and supports the design of targeted interventions to improve system-level performance and public health outcomes.

Methods

Study Setting and Data Sources

We used data from the SingHealth Diabetes Registry (SDR), a comprehensive, multi-institutional repository of diabetes-related patient data from the Singapore Health Services (SingHealth) Regional Health System. SingHealth is the largest of the 3 public health care clusters in Singapore, comprising 4 acute hospitals, 5 national specialty centers, 3 community hospitals, and a network of 10 primary care polyclinics, and is responsible for the care of almost half of Singapore's population.

The SDR integrates data from electronic medical records and clinical databases and includes all individuals aged 18 years and older diagnosed with diabetes mellitus, excluding those with prediabetes. Cases are identified annually using a combination of diagnostic criteria, including *International Classification of Diseases, 9th and 10th Revisions* (*ICD-9* and *ICD-10*), prescription records, and laboratory test results [4]. We included patients recorded in the SDR during the 5-year study period from January 1, 2019, to December 31, 2024.

The SDR was selected as the data source for this study because it is the most established and quality-assured chronic disease registry in our institution. It offers a high degree of data completeness, standardized variable definitions, and regular validation processes, making it well-suited for longitudinal and system-wide analysis. Its integration across care settings—from primary care to tertiary hospitals—enables a holistic view of population health among individuals living with a chronic condition of public health importance.

Key Dashboard Features

The development of the dashboard was iterative and guided by stakeholder engagement to address both clinical and administrative priorities. Through this process, 3 core analytic domains consistently emerged as critical for population health decision-makers and clinicians managing diabetes care: (1) health status indicators, (2) process indicators, and (3) inpatient utilization—detailed in Textbox 1.

XSL•FO
RenderX

Textbox 1. Variables used for analytical domains.

Health status indicators

- Demographic filters
  - Gender
  - Age band (<40 y, 40-59 y, 60-69 y, 70-79 y, >80 y)
- Health and comorbidity filters
  - Ethnicity
  - Asian BMI category
  - Housing type
  - Smoking status
  - Diabetes type
  - Average hemoglobin A_{1c} (HbA_{1c}) (%) in the calendar year
  - Hypertension status
  - Hyperlipidemia status
  - Average low-density lipoprotein cholesterol in calendar year
  - Estimated glomerular filtration rate (eGFR) category based on average eGFR in calendar year
  - Dialysis status
- Diabetes-related complications
  - Ischemic heart disease status
  - Acute myocardial infarction status
  - Peripheral arterial disease status
  - Cerebrovascular accident (ischemic and hemorrhagic) status

Process indicators (in calendar year)

- No low-density lipoprotein cholesterol
- Less than 2 HbA_{1c}
- No diabetic retinal photography
- No diabetic retinal photography or ophthalmology visit
- No eGFR lab result
- No urine albumin creatinine ratio lab result
- No diabetic foot screening

Health status indicators captured markers of disease control, concomitant comorbidities, and prevalent diabetes-related complications. The methodology for identifying diabetes-related complications has been previously described [5]. Process indicators reflect adherence to local evidence-based care protocols [6] and provide insight into the consistency and quality of chronic disease management across the care continuum. Inpatient utilization represents downstream, resource-intensive events that may indicate priority areas for disease control or access to care, offering actionable insight into clinical drivers and the geographic distribution of hospital admissions.

Together, these domains form the conceptual foundation of the dashboard, informing its data architecture, user interface (UI), and decision-support functions. By integrating clinical outcomes, care quality metrics, and utilization data, the dashboard provides a comprehensive and actionable view of diabetes care—bridging community-based and hospital-level programs while informing targeted interventions and policy decisions.

Assessing Inpatient Utilization Using the Clinical Classifications Software Refined

To facilitate interpretation of the highly granular and diverse clinical conditions represented in *ICD-10*, we utilized the CCSR (Clinical Classifications Software Refined), a software tool developed by the US Agency for Healthcare Research and Quality [7]. The CCSR groups *ICD-10-CM* (*International Classification of Diseases, 10th Revision, Clinical Modification*)

XSL•FO
RenderX

codes into approximately 530 clinically meaningful categories, enabling research about disease-specific health care utilization and outcomes [7,8].

As our health care system uses the *ICD-10-AM* (*International Classification of Diseases, 10th Revision, Australian Modification*), we developed a semiautomated algorithm for mapping *ICD-10-AM* codes to corresponding CCSR categories, adapting the methodology described by Malecki et al [8]. The algorithm is based on the official CCSR tool (v2025.1; United States Agency for Healthcare Research and Quality) [7], which assigns a default CCSR code to each principal diagnostic code. The matching algorithm was developed and implemented in R (version 4.4.3; R Core Team), and the code is available in Box 1 in Multimedia Appendix 1.

Unique *ICD-10-AM* principal diagnostic codes were extracted from the SDR and mapped according to the schematic shown in Figure S1 in Multimedia Appendix 1. Codes with exact matches to *ICD-10-CM* entries in the official CCSR file were assigned the default CCSR category (direct mapping). Codes without a direct match underwent an iterative mapping process using the hierarchical structure of *ICD-10*, progressively matching to parent, child, or sibling codes assumed to share similar clinical characteristics.

Mapping proceeded sequentially—beginning with 5-character *ICD-10-CM* codes, followed by 4-character and 3-character codes—allowing for both one-to-one and one-to-many mappings. Unmatched codes were truncated as needed to enable parent or grandparent-level matching. This process was repeated iteratively until all possible matches were exhausted.

Finally, 2 clinicians (authors JKT and HYT) independently reviewed all mapped codes. Those mapped to a single CCSR category were validated directly, while codes mapped to multiple categories or those that remained unmatched were manually reviewed and assigned to the most appropriate category, using the official CCSR documentation as reference. Discrepancies were resolved through consensus discussion, and where needed, a third clinician (the author GGRS) was consulted.

Data Visualization

To visualize the data across the 3 analytic domains, we developed an interactive web-based application (herein referred to as the dashboard) using Shiny (Posit Software), an R package to build interactive UIs. For inpatient utilization, we implemented interactive nested treemaps to display the hierarchical relationships between CCSR categories and *ICD-10-AM* codes. These treemaps allowed users to easily identify high-volume classifications and to apply filters by year, health care institution, clinical specialty, and length of stay (LOS).

Geographic information system (GIS) mapping was used to visualize spatial patterns in inpatient utilization, health status indicators, and process indicators, supporting place-based planning and targeted community interventions. Additional geographic markers for community health care assets (eg, general practitioner [GP] clinics, polyclinics, active aging centers [AACs], and other community partners) were also displayed. Geocoding was performed using the Singapore Land Authority's OneMap application programming interface [9].

The dashboard was developed using a collaborative and iterative approach, incorporating feedback from clinicians and health system stakeholders through cyclical testing and refinement [10,11]. It was designed to be code-free and intuitive, allowing users to customize data views via interactive filters and toggles, with key metrics surfaced rapidly through pop-up windows and dynamic counter boxes, powered by reactive UI elements and real-time data binding to support efficient, insight-driven exploration.

Ethical Considerations

The SingHealth Centralised Institutional Review Board determined that an ethics review was not required for the use of deidentified data obtained during routine clinical care (SingHealth Centralised Institutional Review Board reference number 2022/2133). As all participant data were deidentified, a waiver for participant consent was also obtained.

Results

Inpatient Utilization Within the SDR

Between 2019 and 2024, there were 458,155 inpatient admission events in the SDR across the SingHealth cluster (Table 1). These events involved 5892 unique primary discharge diagnoses coded using *ICD-10-AM*. Using the *ICD-10-CM*–based CCSR framework, these codes were algorithmically mapped to CCSR categories, as illustrated in Figure S2 in Multimedia Appendix 1.

Table . Top 5 most frequent clinical conditions (Clinical Classification Software Refined [CCSR] categories) for inpatient admissions (2019 - 2024).

Year: number of inpatient admissions and top 5 CCSR categories (code)	Values, n (%)
Year 2019: 71,615 admissions	
Diabetes mellitus with complications (END003)	5792 (8.1)
Pneumonia (except that caused by tuberculosis) (RSP002)	2635 (3.7)
Fluid and electrolyte disorders (END011)	2284 (3.2)
Coronary atherosclerosis and other heart diseases (CIR011)	2261 (3.2)
Urinary tract infections (GEN004)	2215 (3.1)
Year 2020: 69,735 admissions	
Diabetes mellitus with complications (END003)	5515 (7.9)
Fluid and electrolyte disorders (END011)	2869 (4.1)
Pneumonia (except that caused by tuberculosis) (RSP002)	2607 (3.7)
Urinary tract infections (GEN004)	2269 (3.3)
Skin and subcutaneous tissue infections (SKN001)	2198 (3.2)
Year 2021: 71,106 admissions	
Diabetes mellitus with complications (END003)	6111 (8.6)
Pneumonia (except that caused by tuberculosis) (RSP002)	2867 (4.0)
Fluid and electrolyte disorders (END011)	2481 (3.5)
Urinary tract infections (GEN004)	2268 (3.2)
Skin and subcutaneous tissue infections (SKN001)	2164 (3.0)
Year 2022: 76,656 admissions	
Diabetes mellitus with complications (END003)	6204 (8.1)
Pneumonia (except that caused by tuberculosis) (RSP002)	3640 (4.7)
Fluid and electrolyte disorders (END011)	2618 (3.4)
Other specified upper respiratory infections (RSP006)	2358 (3.1)
Skin and subcutaneous tissue infections (SKN001)	2182 (2.8)
Year 2023: 82,308 admissions	
Diabetes mellitus with complications (END003)	6139 (7.5)
Pneumonia (except that caused by tuberculosis) (RSP002)	4237 (5.1)
Fluid and electrolyte disorders (END011)	2903 (3.5)
Skin and subcutaneous tissue infections (SKN001)	2466 (3.0)
Urinary tract infections (GEN004)	2322 (2.8)
Year 2024: 86,735 admissions	
Diabetes mellitus with complications (END003)	6078 (7.0)
Pneumonia (except that caused by tuberculosis) (RSP002)	4001 (4.6)
Fluid and electrolyte disorders (END011)	2988 (3.4)
Coronary atherosclerosis and other heart diseases (CIR011)	2984 (3.4)
Skin and subcutaneous tissue infections (SKN001)	2722 (3.1)

Briefly, of the 5892 *ICD-10-AM* codes, 5738 (97.4%) were successfully mapped, while 154 (2.6%) remained unmapped. Among the mapped codes, 4630 (80.7%) corresponded to a single CCSR category, whereas 1108 (19.3%) were linked to multiple categories. A comprehensive manual review referencing the original CCSR documentation was conducted to validate and refine the mappings; 1277 codes were manually modified or reassigned, and all *ICD-10-AM* codes were mapped to one of 422 CCSR categories.

Top Clinical Conditions and Diagnoses Contributing to Admissions

Table 1 presents the 5 most frequent conditions by the CCSR category for inpatient admissions between 2019 and 2024.

XSL•FO
RenderX

Across all years studied, diabetes mellitus with complication (END003) was the leading cause of admission, accounting for 7.0% to 8.1% of total hospitalizations annually. Pneumonia (RSP002) was the second most common condition in most years, contributing 3.7% to 5.1% of admissions. This was followed by fluid and electrolyte disorders (END011) at 3.4% to 4.1%, and skin and subcutaneous tissue infections (SKN001) at 2.8% to 3.1%.

Table 2 presents the 10 most frequent *ICD-10-AM* principal discharge codes under the CCSR categories "diabetes mellitus with complication" (END003) and "fluid and electrolyte disorders" (END011) for inpatient admissions in 2024.

Table . Top 10 most frequent *International Classification of Disease, 10th Revision, Australian Modification* (*ICD-10-AM*) principal discharge codes under the Clinical Classification Software Refined (CCSR) categories "diabetes mellitus with complication" (END003) and "fluid and electrolyte disorders" (END011) for inpatient admissions in 2024.

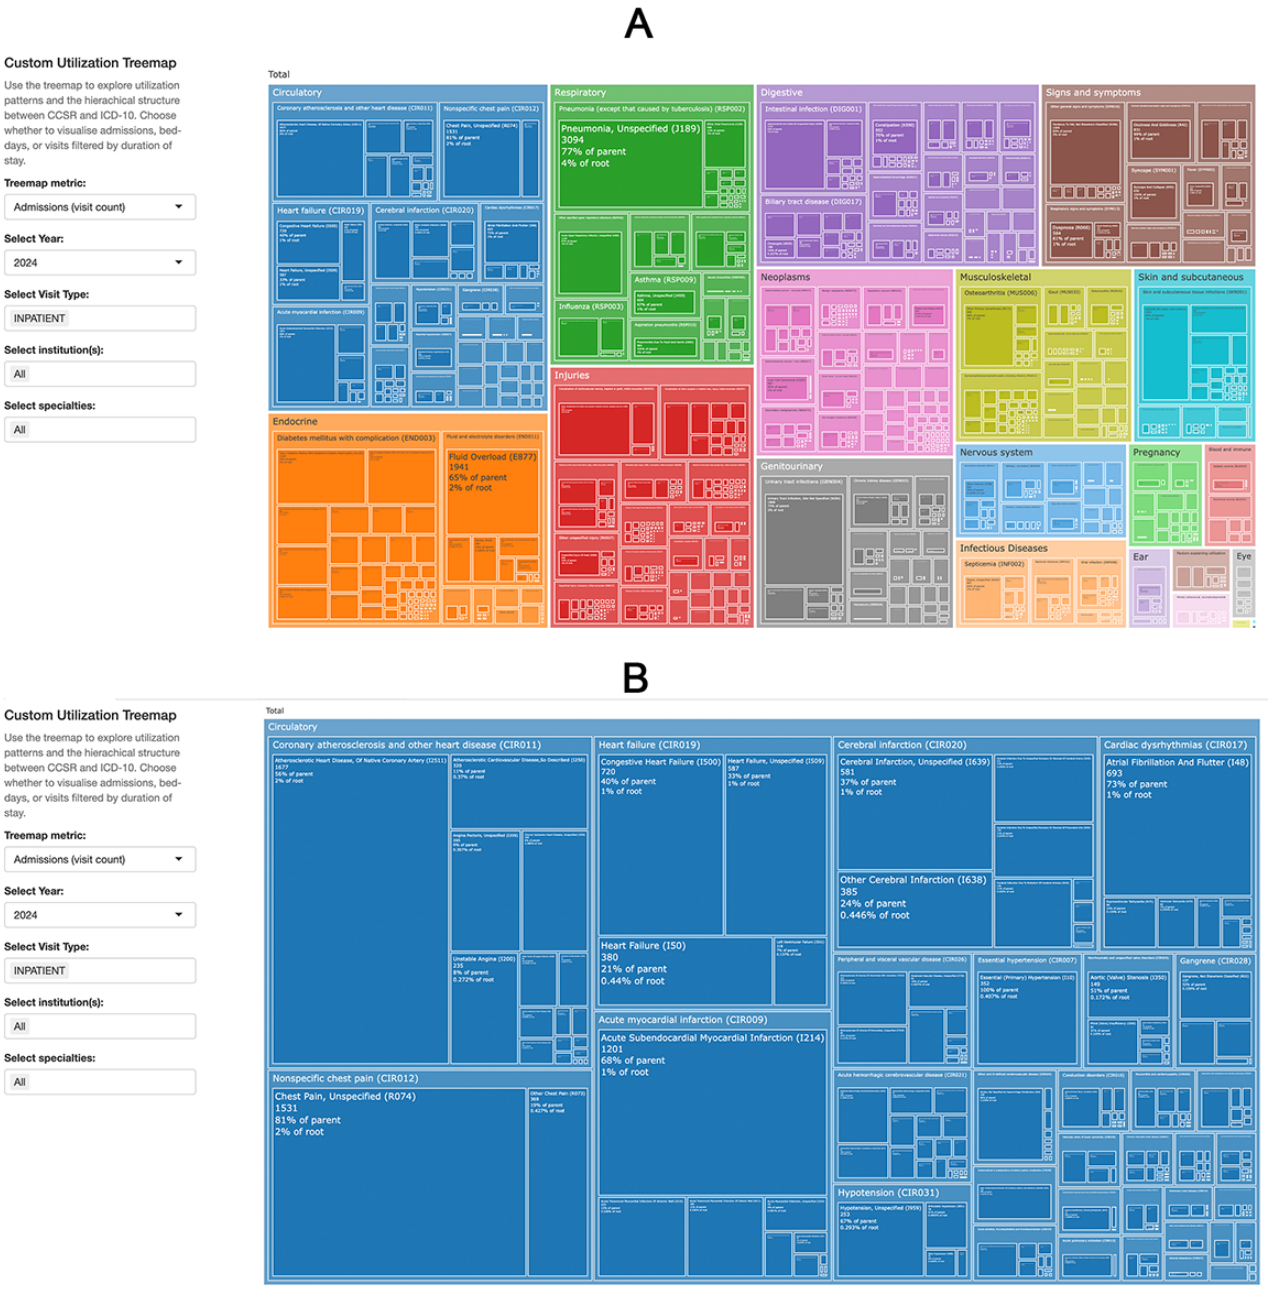
ICD-10-AM primary discharge codes	Values, n (%)
Top 10 codes in diabetes mellitus with complication (END003)	
E1122—type 2 diabetes mellitus with established diabetic nephropathy	1128 (18.6)
E1173—type 2 diabetes mellitus with foot ulcer due to multiple causes	874 (14.4)
E1172—type 2 diabetes mellitus with features of insulin resistance	468 (7.7)
E1129—type 2 diabetes mellitus with other specified kidney complications	467 (7.7)
E1164—type 2 diabetes mellitus with hypoglycemia	402 (6.6)
E1152—type 2 diabetes mellitus with peripheral angiopathy, with gangrene	273 (4.5)
E1422—unspecified diabetes mellitus with established diabetic nephropathy	217 (3.6)
E1464—unspecified diabetes mellitus with hypoglycemia	216 (3.6)
E1169—type 2 diabetes mellitus with other specified complication	206 (3.4)
E1165—type 2 diabetes mellitus with poor control	192 (3.2)
Top 10 codes in fluid and electrolyte disorders (END011)	
E877—fluid overload	1941 (65.0)
R18—ascites	290 (9.7)
E875—hyperkalemia	290 (9.7)
E871—hypo-osmolality and hyponatremia	217 (7.3)
E86—volume depletion	104 (3.5)
E876—hypokalemia	93 (3.1)
E872—acidosis	28 (0.9)
E870—hyperosmolality and hypernatremia	11 (0.4)
E878—other disorders of electrolyte and fluid balance, not elsewhere classified	9 (0.3)
E87—other disorders of fluid, electrolyte and acid-base balance	5 (0.2)

In 2024, within diabetes mellitus with complications (END003), the most common diagnoses were E1122—type 2 diabetes mellitus with established diabetic nephropathy (n=1128, 18.6%), E1173—type 2 diabetes mellitus with foot ulcer due to multiple causes (n=874, 14.4%), and E1172—type 2 diabetes mellitus with features of insulin resistance (n=468, 7.7%). Other frequently recorded conditions included hypoglycemia, peripheral angiopathy with gangrene, and poor glycemic control.

For fluid and electrolyte disorders (END011), the most frequent diagnosis codes were E877—fluid overload (n=1941, 65%), followed by R18—ascites (n=290, 9.7%), E875—hyperkalemia (n=290, 9.7%), and hypo-osmolality and hyponatremia (n=217, 7.3%).

CCSR categories and their corresponding *ICD-10-AM* codes were visualized using interactive nested treemaps, enabling users to explore the hierarchical structure of conditions and examine the data at varying levels of detail. These treemaps illustrated the parent-child relationships between CCSR categories and *ICD-10-AM* codes, allowing users to identify high-volume diagnoses and discern patterns across diagnostic groupings. Inpatient utilization was quantified by both admission counts (Figure 1) and total LOS (Figure S3 in Multimedia Appendix 1). Users could apply filters to refine the data view by the LOS categories (in weeks), health care institution, and clinical specialty within our health care cluster. This functionality supported flexible, user-driven analysis of

XSL•FO
RenderX



hospitalization patterns across clinical and operational dimensions.

Regarding inpatient utilization by total LOS (Figure S3 in Multimedia Appendix 1), patients in the SDR accounted for 687,062 inpatient bed days in 2024. Circulatory-related CCSR conditions contributed 124,417 (17.7%) bed days, while injuries-related conditions accounted for 86,541 (12.6%) bed days. Among circulatory conditions, the top contributors were CIR020—cerebral infarction, CIR019—heart failure, CIR011—coronary atherosclerosis and other heart diseases, and CIR009—acute myocardial infarction. For injuries-related conditions, the leading contributors were INJ006—fracture of the neck of femur, INJ037—complications of other surgical or medical care, and INJ033—complications related to cardiovascular devices, implants, or grafts.

Inpatient utilization filtered by admission count and LOS provided further insights into conditions associated with prolonged hospitalizations. Figure S4 in Multimedia Appendix 1 presents admissions lasting 4 weeks or more in 2024, totaling 4425 encounters. Of these, circulatory-related conditions accounted for 883 (20.0%) admissions, while injuries-related conditions comprised 658 (14.9%) admissions. Leading circulatory conditions associated with extended stays included CIR020—cerebral infarction, CIR021—acute hemorrhagic cerebrovascular disease, and CIR009—acute myocardial infarction. For injuries-related conditions, top contributors were fracture of the INJ006—neck of femur, INJ037—complications of other surgical or medical care, and INJ005—fractures of the lower limb excluding hip fractures.

XSL•FO
RenderX

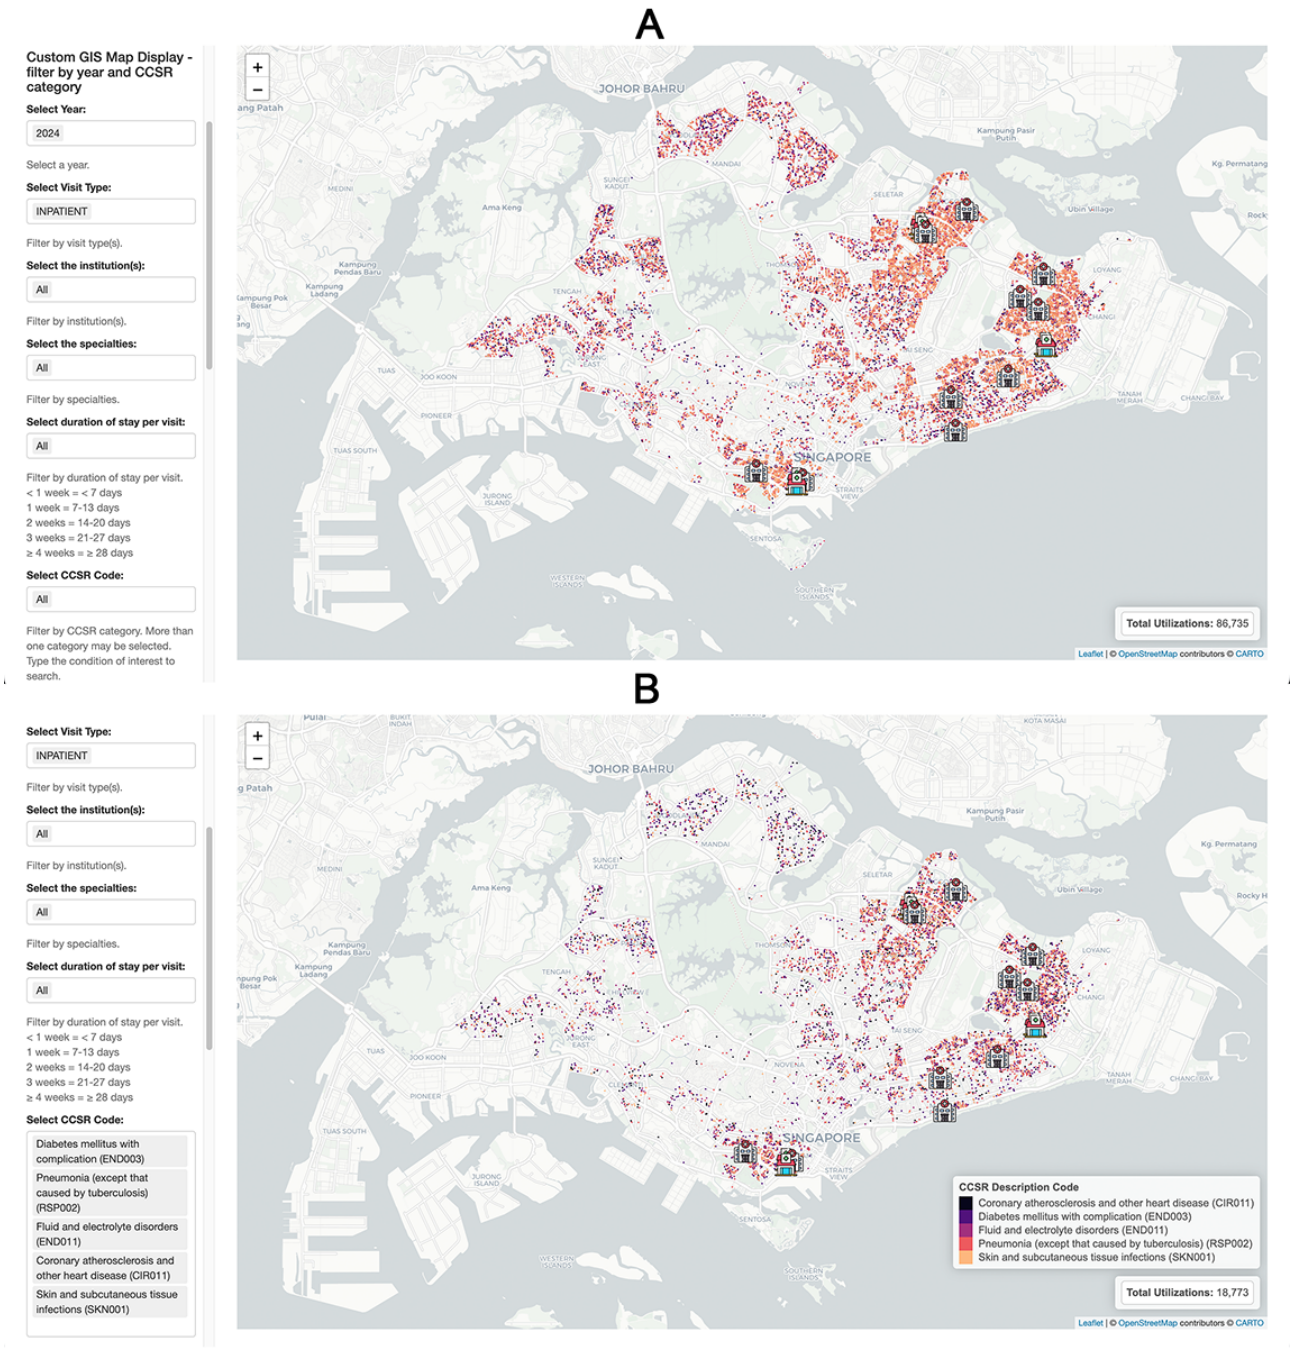
Figure 1. Interactive treemaps depicting inpatient utilization patterns by admission counts in 2024. (A) Overview of all inpatient admissions, visualized by Clinical Classifications Software Refined (CCSR) categories. (B) Expanded view of the circulatory system category, showing corresponding *ICD-10-AM* (*International Classification of Disease, 10th Revision, Australian Modification*) codes nested within each CCSR classification.

Visualizing Inpatient Utilization, Process Indicators, and Health Status Indicators

The CCSR framework enabled the geospatial visualization of inpatient utilization patterns by residential location (Figure 2). Figure 2A displays utilization in 2024 for all patients in the SDR across all CCSR categories, highlighting that while the density of inpatient utilization was higher in areas within the SingHealth catchment, patients also originated from residential precincts across the island, including those served by other health care clusters. Figure 2B illustrates utilization among patients with the top 5 CCSR categories.

The dashboard enabled the geospatial visualization of patients with unmet diabetes-related process indicators. Figure 3 illustrates this for 2024, highlighting patients without documentation for diabetic retinal photography, urine albumin-to-creatinine ratio, and diabetic foot screening. Each black bubble represents a cluster of patients residing in the same area with all 3 indicators unmet. Panel A displays the nationwide distribution, whereas panel B zooms into the southeastern region.

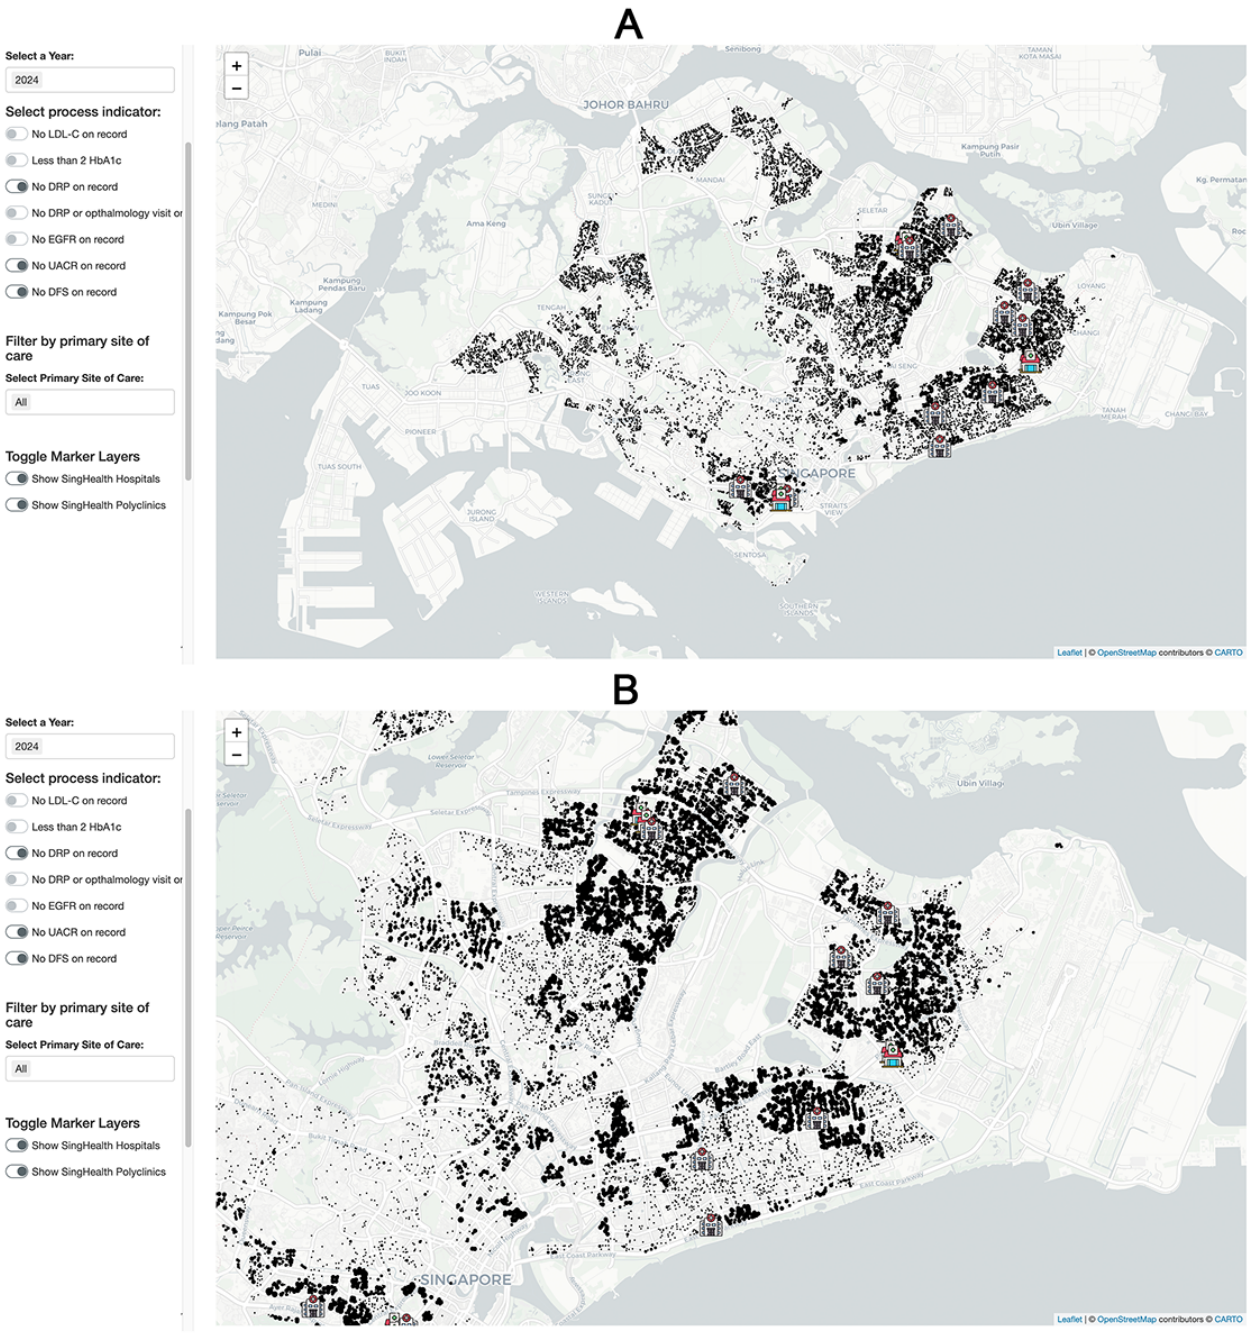
Prominent clusters were observed in high-density residential zones in the east and northeast, suggesting care delivery gaps and opportunities for targeted community outreach, screening initiatives, and enhanced primary care engagement.



The dashboard also mapped individuals with poor health status and diabetes-related complications. In Figure 4, panel A displays

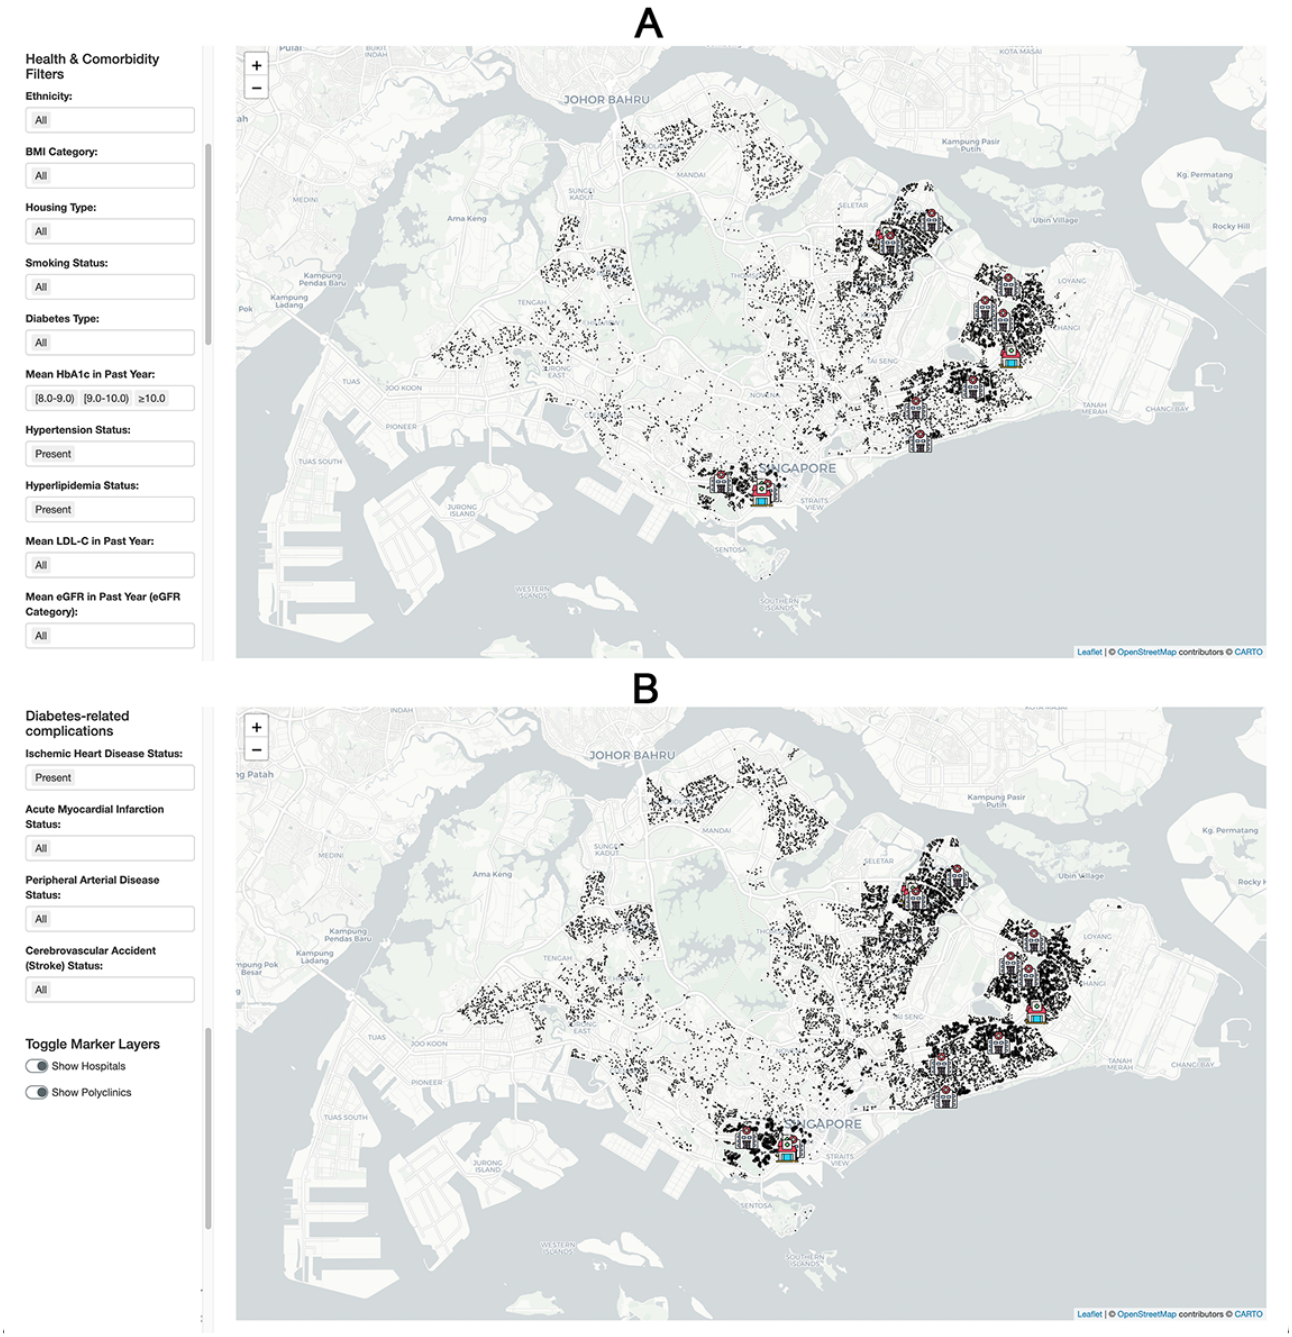
XSL•FO
RenderX

individuals with suboptimal cardiometabolic control ($HbA_{1c} \geq 8.0\%$) and coexisting hypertension and hyperlipidemia. Panel B depicts the spatial distribution of patients with prevalent ischemic heart disease, illustrating geographic variation in chronic disease burden.



These interactive maps allow users to zoom to the postal code level, apply filters by health indicators and comorbidities, and overlay health care and community resources—facilitating data-driven, localized planning and intervention design.

Figure 2. Geospatial bubble maps illustrating inpatient utilization based on the residential addresses of patients in 2024. SingHealth's acute hospitals, community hospitals, and polyclinics are represented as icons. (A) All Clinical Classification Software Refined (CCSR) categories included. (B) Geospatial map with top 5 CCSR categories for 2024.



XSL•FO
RenderX

Figure 3. Geospatial bubble maps depicting the residential distribution of patients who did not meet selected diabetes-related process indicators in 2024. Each black bubble represents a geographic cluster of patients missing documentation for all of the following: diabetic retinal photography (DRP), urine albumin-to-creatinine ratio (uACR), and diabetic foot screening (DFS). The size of the bubble reflects the number of affected patients at that location. (A) Full view of Singapore. (B) Zoomed-in view of the southeastern region.

(B) Map selected for patients with documented ischemic heart disease.

Discussion

Principal Results

Health care data are inherently complex, often exhibiting hierarchical, relational, and temporal dimensions. While modern health information systems capture large volumes of data, transforming them into actionable insights that support impactful interventions remains a persistent challenge. In this study, we applied the CCSR framework to organize *ICD-10-AM* primary discharge codes into clinically meaningful categories, then leveraged interactive treemaps to facilitate exploration of inpatient utilization patterns, particularly for high-burden conditions while retaining the hierarchical relationships between CCSR categories and *ICD-10-AM* codes. In parallel, we employed GIS mapping to display spatial patterns in inpatient utilization, care process adherence, and health status indicators, enabling interactive, user-driven exploration and regional customization.

Comparison With Prior Work and Contribution to the Field

While health care dashboards are widely used [10], the literature on dashboards specifically designed for PHM remains limited. In Queensland, Australia, a proof-of-concept dashboard was developed using synthetic data to demonstrate the potential of routinely collected electronic health records for geospatial,

XSL•FO
RenderX

descriptive, and longitudinal analytics on obesity surveillance [12]. In the United States, the Veterans Affairs system implemented a national heart failure dashboard focused on administrative tracking and quality monitoring across its patient population [13]. Although both examples highlight the promise of dashboards for informing public health action, they remain limited in scope—either focusing on a single condition or lacking integration across multiple domains of care.

Building on this, our dashboard represents a novel application that unifies inpatient utilization data, health status indicators, and care processes into a single platform. It supports multidimensional, area-level analyses through the combined use of the CCSR framework and geospatial mapping. To the best of our knowledge, this is among the first applications of CCSR categories within an interactive GIS dashboard to enable regional assessment of health care utilization and to identify potential priorities for population health planning at both clinical and administrative levels.

Beyond the technical implementation, our experience highlighted several practical considerations relevant to the development of population health dashboards. First, iterative development through sustained stakeholder engagement was highly valuable. Close collaboration among clinicians, technical developers, population health planners, and community partners was important to identify the core analytic features and ensure that these were technically feasible, operationally relevant, and aligned with real-world population health workflows. Importantly, dashboard development remained an ongoing and adaptive process, with continued refinement of analytic features and outputs through iterative engagement with stakeholders beyond the period described in this paper.

Second, dashboard outputs needed to align closely with clinical and operational processes to ensure that the information presented was both clinically interpretable and practically actionable. In this regard, engagement with domain experts and operational stakeholders was essential for contextualizing findings and guiding appropriate interpretation of the data. Finally, user experience and interface design were critical in balancing analytical complexity with usability for nontechnical users, particularly for stakeholders involved in operational planning and community-based care delivery.

Insights Into Inpatient Utilization

The application of the CCSR framework proved valuable in addressing the granularity of *ICD-10-AM* diagnostic codes by grouping them into clinically meaningful categories. Interactive nested treemaps enabled users to explore the hierarchical relationships between CCSR categories and individual *ICD-10-AM* codes. Categorizing inpatient utilization using 3 complementary metrics—admission counts, total LOS, and admission counts stratified by LOS—allowed health care utilization to be examined through different analytical lenses.

Admission counts provide a broad estimate of disease burden based on the frequency of visits, although they may include repeat visits by the same individual. In contrast, total LOS provides insights into the intensity of resource use, reflecting the cumulative demand placed on finite bed capacity. Stratifying admission counts by LOS further enables the identification of conditions associated with prolonged hospitalizations. Together, these complementary perspectives support a multidimensional understanding of health care utilization, with relevance for population health planning, service delivery optimization, and operational decision-making.

From the perspective of admission frequency, our analysis identified several high-burden conditions, including diabetes-related renal complications, foot ulcers, pneumonia, fluid overload, electrolyte disorders, and skin and subcutaneous tissue infections. In contrast, when examining inpatient utilization based on total bed days and prolonged admissions (≥4 wk), conditions related to circulatory disease and injuries emerged as major contributors. These findings suggest that conditions driving high admission volumes may differ from those associated with the greatest resource intensity, underscoring the importance of considering different utilization metrics when informing health care planning and prioritization.

While this discussion focuses on the most prevalent CCSR categories, less common conditions may also contribute meaningfully to health care resource use and present opportunities for intervention. Continued engagement with stakeholders remains important for identifying underrecognized patterns of utilization and informing future population health planning priorities.

Geospatial Mapping for Community Targeting and Strategic Planning

GIS mapping enabled the visualization of inpatient utilization patterns, gaps in adherence to recommended process indicators, and areas with poor health status based on the residential locations of patients. These spatial insights supported community-based situational analysis and population health planning. For instance, among the top 5 CCSR conditions in 2024, distinct geographic variation in distribution was observed, suggesting that different regions may have different population health needs and service demands. For example, areas with high rates of diabetes-related complications may benefit from enhanced postdischarge support and community nursing services, while regions with a high burden of pneumonia-related admissions may warrant strengthened partnerships with local private GPs to facilitate follow-up care and delivery of preventive services, including influenza and pneumococcal vaccinations, aligned with national vaccination guidelines [14].

GIS mapping of process indicators also proved valuable for population health operations. By overlaying community-based assets such as partner GP clinics and AACs onto residential areas where patients had not received annual diabetic retinal photography and diabetic foot screening, health care planners were able to identify priority locations for the strategic deployment of screening services. Importantly, prioritization was influenced not only by the concentration of unmet needs but also by the availability and readiness of community assets to support screening and follow-up activities. This alignment of need and capacity was important to ensure that proposed initiatives were feasible within the existing community infrastructure.

XSL•FO
RenderX

Similarly, GIS mapping of health status indicators enabled planners to identify geographic areas with suboptimal diabetes control, abnormal biomarker profiles, or a high burden of diabetes-related complications. These insights informed engagement between community teams and stakeholders, including community nurses, partner GPs, AACs, and grassroots leaders, to support planning discussions. Furthermore, these data have informed infrastructure planning. For example, as SingHealth prepares to establish a new acute hospital in the eastern region of Singapore, spatial analyses of inpatient utilization and population health metrics are being used to support service planning and resource allocation considerations for the new facility.

These experiences highlight the dashboard's utility for situational analysis and operations planning. Future development could extend its use toward longitudinal monitoring of health status, process adherence, and utilization patterns across geographic regions over time. Such analyses may help health care planners evaluate the effects of targeted interventions on specific health outcomes and support data-informed decision-making.

Limitations

This study has several limitations. First, our analysis focused on primary *ICD-10-AM* diagnosis codes and did not incorporate secondary diagnoses. While secondary diagnosis codes may provide additional clinical context—particularly regarding comorbidities and contributing conditions—their inclusion would substantially increase analytical complexity due to their volume and variability in coding practices. In addition, the completeness and consistency of secondary diagnosis coding may differ across encounters and institutions, potentially introducing bias. Further methodological work is needed to determine how secondary diagnosis data can be systematically incorporated to generate reliable and actionable insights for population health analysis.

The *ICD-10-AM* to CCSR mapping process also has inherent limitations. Although we used a semiautomated approach informed by the *ICD-10* hierarchical structure and the published CCSR framework, a proportion of codes mapped to multiple potential CCSR categories and required manual clinical review. While these mappings were independently reviewed by clinicians and resolved through consensus using official CCSR guidance documentation, we did not formally assess interrater reliability, conduct external validation, or perform quantitative accuracy testing of the final mappings. As such, some degree of misclassification may remain. Nevertheless, we believe that the mapping approach provided a pragmatic and clinically meaningful framework for exploratory population health analysis in a non-US *ICD-10-AM* setting. Future work should explore more formal validation approaches and reproducibility assessments to strengthen generalizability and methodological robustness.

A key limitation of this study is data latency, as the dashboard currently reflects data that lag behind real time by approximately 1 year. Because health care utilization patterns evolve, patients requiring inpatient care in 1 year may not do so in subsequent years [15]. Ongoing enhancements to our data pipeline may help reduce data latency, and the future incorporation of predictive analytics could further enable more timely and anticipatory interventions [16].

Nevertheless, data latency does not negate the utility of the dashboard. Our analyses of health status and process indicators from 2019 to 2024 demonstrate that geographic areas with persistent gaps in adherence to recommended care processes and consistently poorer health status recur over time. These stable spatial patterns provide a strong empirical basis for prioritizing targeted, place-based interventions and underscore the opportunity for health systems to act decisively on longitudinal insights while continuing to evolve toward more real-time, proactive population health intelligence.

Our study faced practical data-related limitations, as it relied on the SDR—a mature and comprehensively maintained chronic disease data source within our institution. As a result, the dashboard was developed within a single health care cluster in Singapore and focused exclusively on patients with diabetes mellitus. This may limit generalizability to other populations, disease areas, or international contexts. Adapting the dashboard for other settings would require alignment with local coding systems, availability of structured registry or electronic medical record data, and inclusion of contextually relevant indicators. As more quality-assured data repositories become available, the dashboard's modular architecture and use of open-source tools will support broader adoption through appropriate customization.

Another important limitation is that the dashboard does not currently incorporate data from the private primary care sector, restricting its ability to reflect care delivered outside the public health care system. Under Healthier SG [17]—Singapore's national population health initiative—participating GPs are required to use electronic clinic management systems that automatically share selected clinical information with the National Electronic Health Record [18]. These data are subsequently made available by the Ministry of Health to health care clusters and community partners to support outreach and care coordination.

However, Healthier SG primary care data are not yet linked to the SDR or integrated into the dashboard. Ongoing efforts aim to enable this connection, which would significantly enhance the dashboard's ability to support whole-of-system PHM by providing a more complete view of care across settings. Achieving this will require sustained collaboration and policy support to bridge data silos, enable secure cross-sector information sharing, and align data governance and use frameworks. These system-level enablers are essential for unlocking the full potential of digital tools for coordinated, data-driven population health planning.

Additionally, in accordance with current ethical and data governance requirements, the dashboard is built using deidentified patient-level data that cannot be traced back to individuals. Access to the dashboard is restricted to authorized users, and full addresses and postal codes for single-unit housing (ie, nonapartment residences) are masked across all user views. At the same time, these protections introduce practical limitations to the precision of PHM strategies. While

XSL•FO
RenderX

deidentified data are highly valuable for situational analysis, regional planning, and identification of broad population-level patterns, the implementation of targeted interventions—especially those requiring follow-up at the individual level—may require carefully governed access to identifiable data under appropriate ethical, legal, and operational frameworks.

We are mindful of the ethical and governance complexities this entails. Issues of privacy, consent, autonomy, and the risk of overly paternalistic approaches must be carefully considered. Striking the right balance between respecting individuals' rights and enabling timely, data-informed health interventions is an ongoing ethical and conceptual challenge. Addressing this tension will require the development of robust frameworks that extend beyond technical solutions, encompassing ethical deliberation, stakeholder engagement, and policy dialogue.

Finally, while the dashboard was developed through iterative feedback from stakeholders, no structured usability testing, user surveys, or outcome-based assessments were conducted. Future work should incorporate systematic evaluation frameworks to assess how the dashboard influences user behavior, supports care planning, and drives improvements in population health outcomes.

Conclusion

The dashboard developed in this study provides meaningful insights into the health status, care processes, and health care utilization patterns of patients with diabetes within our health system. By integrating these indicators with geospatial visualization, the platform enables rich clinical and operational analyses to support data-informed PHM. Ongoing collaboration with stakeholders—and the planned incorporation of predictive and prescriptive analytics—will further extend its utility by supporting more proactive, targeted, and equitable interventions.

Abstract

Background: Distinguishing vitiligo from postinflammatory hypopigmentation (PIH) is clinically challenging because both conditions may present with similar depigmented lesions. Although deep learning has shown strong potential for dermatologic image classification, limited interpretability remains a barrier to clinical adoption.

Objective: This study aimed to develop an interpretable deep learning framework for accurate differentiation between vitiligo and PIH using a lightweight convolutional neural network and an ensemble of explainability methods.

Methods: A total of 332 clinical images (176 vitiligo and 156 PIH) were collected from King Abdullah University Hospital and publicly available online sources. Images were preprocessed and evaluated using patient-wise 5-fold cross-validation to eliminate patient-level data leakage. A pretrained MobileNetV2 model was fine-tuned by unfreezing the final 30 layers. To enhance interpretability, gradient-weighted class activation mapping (Grad-CAM), integrated gradients, and smooth gradients (SmoothGrad) were combined into an equal-weight ensemble explanation framework. Performance was assessed using accuracy, precision, recall, F_1-score, and the area under the receiver operating characteristic curve (AUC).

Results: The proposed model achieved an overall accuracy of 94.88%, macroaveraged precision of 94.88%, recall of 94.84%, F_1-score of 94.86%, and an AUC of 0.9885 across the 5 validation folds. The ensemble framework produced clinically meaningful explanations in 98.48% of a representative 66-image validation subset used for interpretability analysis.

Conclusions: The proposed framework combines high diagnostic performance with robust interpretability for distinguishing vitiligo from PIH. By integrating multiple complementary explanation methods, the approach enhances clinical transparency and may support dermatologists in the differential diagnosis of pigmentary disorders.

Introduction

Background

Skin disorders are a leading global health issue, affecting approximately 1.9 billion people and representing the fourth leading cause of nonfatal disease burden [1]. They encompass a wide range of conditions that often exhibit similar visual patterns, making timely and accurate diagnosis difficult [2,3]. Two such conditions, vitiligo and postinflammatory hypopigmentation (PIH), frequently present with overlapping features, namely localized depigmented patches [4]. However, their etiologies differ significantly. PIH develops as a secondary reaction to skin inflammation, damage, or healing [4], whereas vitiligo is an autoimmune disorder characterized by the loss of melanocytes [5]. Accurately distinguishing between these

XSL•FO
RenderX

disorders remains a clinical challenge, particularly in the early stages. Misdiagnosis can lead to inappropriate treatment and unnecessary psychological stress for patients.

Visual examination and clinical history play a major role in the traditional clinical diagnosis of these hypopigmented disorders [4]. However, this approach is inherently subjective and may result in misguided diagnoses, particularly in resource-limited settings [4]. Recent dermatological research has highlighted the diagnostic complexity of pigmentary disorders, particularly when different conditions present with similar patterns of hypopigmentation or depigmentation. Variability in lesion morphology, anatomical location, skin phototype, and disease stage can substantially affect visual appearance and complicate clinical differentiation [6]. In particular, distinguishing vitiligo from PIH may be challenging because both conditions can exhibit well-demarcated pale patches with overlapping textural and pigmentary characteristics. These challenges underscore the need for objective and interpretable AI tools to support clinical decision-making and improve diagnostic consistency [7]. AI-based diagnostic tools offer promising support for addressing these challenges, particularly as digital imaging and necessary computational resources for digital image processing become more widely accessible [8].

Deep learning has emerged as a powerful tool in medical image analysis, particularly in dermatology, where it enables automated classification, segmentation, and anomaly detection with performance approaching that of human specialists [9,10]. In particular, convolutional neural networks (CNNs) have demonstrated remarkable effectiveness in skin lesion analysis, achieving dermatologist-level accuracy in various diagnostic tasks [9,11]. Furthermore, advanced deep learning systems have shown strong capability in the differential diagnosis of skin diseases, highlighting their potential in supporting clinical decision-making [12]. Despite these advancements, the opaque nature of deep learning models, often referred to as “black-box” behavior, remains a significant barrier to their widespread clinical adoption, especially in sensitive conditions such as vitiligo diagnosis [13].

The opaque decision-making process of CNNs raises concerns, particularly in domains such as dermatology, where interpretability is essential rather than optional [14]. To address this limitation, recent studies have integrated explainable AI (XAI) methods with deep learning models [14]. XAI techniques aim to improve model trustworthiness and clinical applicability by visualizing and interpreting the internal operations of neural networks [15]. Gradient-weighted class activation mapping (Grad-CAM) [16], integrated gradients [17], and smooth gradients (SmoothGrad) [18] are among the most widely used methods in this field, each providing a different perspective on model decision-making by highlighting relevant regions of input images [16].

Objective

Despite advances in XAI, individual saliency-based methods often exhibit noise, instability, and sensitivity to model architecture and parameter settings [16]. To address these limitations and generate more consistent and clinically meaningful explanation maps, we propose an ensemble interpretability framework that combines Grad-CAM, integrated gradients, and SmoothGrad.

In this study, we present an interpretable deep learning framework for differentiating vitiligo and PIH using a fine-tuned MobileNetV2 architecture [19]. The model was trained on dermatological images collected from both hospital and publicly available sources and evaluated using a patient-wise 5-fold cross-validation strategy. By integrating 3 complementary explainability methods, the proposed framework aims to improve the robustness of visual explanations and enhance the model’s trustworthiness for potential use in clinical decision support systems.

Literature Review

Deep learning has shown considerable promise in automating dermatological diagnoses, particularly for conditions such as vitiligo [4,13,20-22]. However, the clinical reliability of these models depends not only on their classification accuracy but also on their interpretability and generalizability across diverse populations and dermatological conditions.

Several studies have addressed the classification of vitiligo using deep learning, tackling challenges such as data heterogeneity, image acquisition inconsistencies, and computational efficiency. For instance, Kantoria et al [23] used a dataset of 696 images and applied transfer learning with models such as Inception-V3 [24], Visual Geometry Group (VGG)-16, VGG-19 [25], and SqueezeNet [26], followed by classifiers such as k-nearest neighbors, support vector machine, and logistic regression. Although Inception-V3 with logistic regression achieved the highest accuracy (98.0%), the method was computationally intensive, limiting its applicability in real-time settings. Similarly, Guo et al [21] adopted a You Only Look Once (YOLO) v3–based hybrid model using 2720 images for lesion classification, yet reported performance issues in detecting lesions near anatomical boundaries and challenges stemming from label noise.

To enhance image clarity, Luo et al [27] proposed a Cycle-Consistent Adversarial Network (CycleGAN)–based model incorporating super-resolution techniques, achieving a classification accuracy improvement from 76.37% to 85.69%. Despite this gain, the method’s high computational demand posed a practical limitation for resource-limited settings. Zhang et al [28] investigated multiple CNN architectures, including VGG-13, residual network (ResNet)-18, and Densely Connected Convolutional Networks (DenseNet)-121 [29], across in-house and public datasets. Their models outperformed dermatologists in certain tasks; however, the datasets were demographically limited to Asian women and children, thus constraining the models’ generalizability.

Although deep learning–based classification has been extensively explored for dermatological conditions, including hypopigmented dermatoses, no previous study has explicitly addressed the PIH using image-based techniques with visual interpretability. Several works have proposed visual explanation tools such as Grad-CAM, Grad-CAM++ [30], and Score-CAM [31] for skin cancer diagnosis. While these contributions have advanced the field of XAI in dermatology, none have applied

XSL•FO
RenderX

these frameworks specifically to distinguish between vitiligo and PIH using clinical images.

Complementing the classification-focused studies, other research has emphasized XAI as a means to foster trust in medical diagnostics. For example, Badhon et al [32] used Grad-CAM with transfer learning on a balanced dataset, achieving 97.07% accuracy while enhancing transparency through saliency maps. Zhong et al [22] incorporated class activation mapping (CAM) with Swin Transformer models [33], visually highlighting lesion areas, though not always aligning with clinical boundaries. Shorfuzzaman [34] proposed a Shapley additive explanations (SHAP)-enhanced stacked CNN ensemble for melanoma detection, while Wang et al [10] introduced a multimodal interpretability-based CNN incorporating Grad-CAM for image features and SHAP for patient metadata to improve clinical trust.

Despite these advancements, challenges remain concerning real-time feasibility, dataset diversity, and the robustness of explanation techniques. These gaps highlight the need for lightweight, interpretable, and clinically relevant deep learning workflows. Our study addresses this need by introducing a MobileNetV2-based model designed for efficient and real-time inference, coupled with an ensemble visual explanation framework that integrates Grad-CAM, integrated gradients, and SmoothGrad. To the best of our knowledge, this is the first attempt to differentiate vitiligo and PIH using explainable deep learning on clinical images, bridging a critical gap in dermatological AI.

Methods

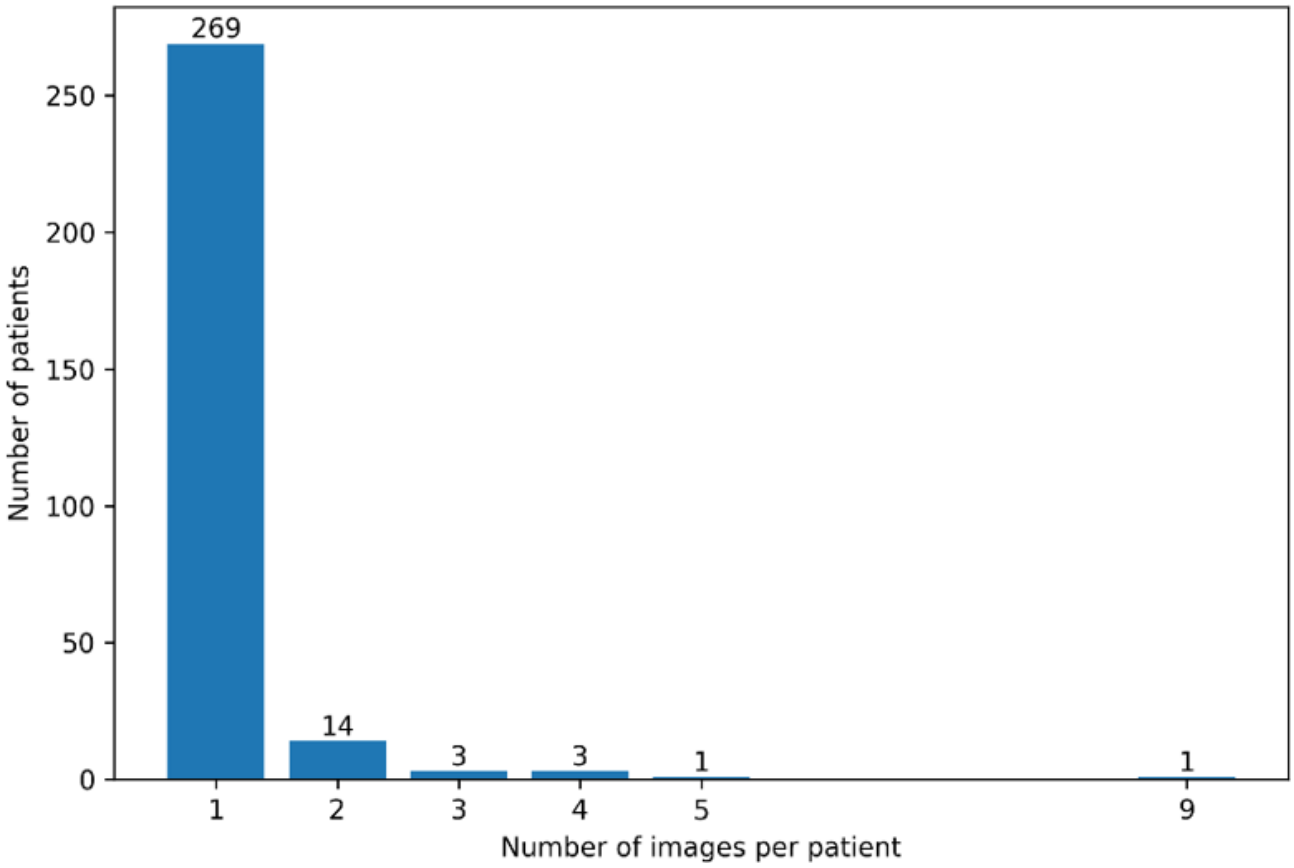
In this study, we developed a robust and interpretable deep learning framework for differentiating skin images of vitiligo and PIH, 2 conditions that are clinically and visually difficult to distinguish. The proposed workflow comprised three major stages: (1) preprocessing input images to meet model requirements, including resizing, normalization, and offline augmentation; (2) training and fine-tuning a MobileNetV2-based classifier using patient-wise 5-fold cross-validation; and (3) applying 3 explainability techniques—Grad-CAM, integrated gradients, and SmoothGrad—to provide interpretable visual explanations of the model's predictions.

Ethical Considerations

Ethical approval was granted by the King Abdullah University Hospital (KAUH) research ethics committees (approval number 50/161/2023, date: June 8, 2023). The requirement for informed consent was waived due to the retrospective nature of the study and the use of anonymized data.

Dataset Description and Preprocessing

The image dataset comprised 2 classes: vitiligo and PIH. A total of 332 clinical images were included, consisting of 176 vitiligo images obtained from KAUH in Irbid, Jordan, and 156 PIH images collected from KAUH and publicly accessible online sources. All images were labeled and verified by dermatologists.



The final dataset comprised 332 images obtained from 291 unique patients. Most patients contributed a single image (median=1 image per patient), while the mean number of images per patient was 1.14 (SD 0.66). The maximum number of images contributed by a single patient was 9. Figure 1 summarizes the full distribution of images per patient. These statistics indicate that the majority of patients were represented by only 1 image, although a small number of patients contributed multiple images from different anatomical sites.

To minimize potential source-related bias arising from mixed image origins, all images were processed using a unified preprocessing pipeline, including resizing to 224×224 pixels, pixel-value normalization, and identical augmentation operations. Although a metadata file was used to organize image labels and patient identifiers for patient-wise cross-validation, no metadata or acquisition-related variables were provided as input features to the model. The classifier was trained exclusively on image pixel data.

The dataset was organized at the patient level, with each image linked to a unique patient identifier. Multiple images from the same patient were retained when they captured anatomically distinct lesions or body regions. During model evaluation, a patient-wise 5-fold cross-validation strategy was employed, ensuring that all images from a given patient were assigned exclusively to either the training or validation subset within each fold. This prevented patient-level data leakage and provided a more rigorous estimate of generalization to previously unseen patients.

XSL•FO
RenderX

Figure 1. Distribution of the number of images per patient in the final dataset.

Offline data augmentation was applied exclusively to the training subset within each fold and included random rotations, horizontal and vertical flips, brightness adjustments, and zooming operations. For each original training image, 5 augmented variants were generated, resulting in a 6-fold increase in the effective training dataset size, including the original image. The corresponding validation images were left unchanged to ensure unbiased evaluation within each fold. Because of the limited dataset size, no separate holdout or external test set was used; all performance metrics were computed exclusively from the validation folds generated during the patient-wise 5-fold cross-validation procedure.

Model Architecture and Training Strategy

Given the need for a lightweight yet high-performing model, MobileNetV2 was selected as the backbone architecture. MobileNetV2 is a CNN optimized for mobile and embedded vision applications. The base model, pretrained on ImageNet [35], was adapted using transfer learning [36]. Initially, all backbone layers were frozen to leverage general visual features such as edges and textures. A subsequent fine-tuning phase was performed by unfreezing the final 30 layers of the network, specifically from block_13_expand to out_relu, enabling adaptation to dermatological features specific to vitiligo and PIH.

A custom classification head was appended to the convolutional base. This head consisted of a GlobalAveragePooling2D layer, followed by a fully connected dense layer with 128 units and ReLU activation, a dropout layer with a rate of 0.3 to reduce overfitting, and a final sigmoid-activated output layer for binary classification.

The model was trained using the Adam optimizer and binary cross-entropy loss. During the initial frozen training phase, the learning rate was set to 1×10^{4}. During fine-tuning, the learning rate was reduced to 1×10 to preserve pretrained features while enabling gradual adaptation of the unfrozen layers. Training was performed for up to 25 epochs with a batch size of 32 and early stopping based on validation loss (patience=5). Hyperparameters, including learning rate, batch size, and the number of trainable layers, were selected empirically.

Model performance was evaluated using patient-wise 5-fold cross-validation. Aggregated predictions across all validation folds were used to compute the final accuracy, precision, recall, F_1-score, and area under the receiver operating characteristic curve (AUC). This approach provided a robust estimate of the model's diagnostic performance on previously unseen patients. Hyperparameters used in the model are presented in Table 1.

XSL•FO
RenderX

Table . Hyperparameters used in the MobileNet model and their values[a].

Hyperparameter	Value	Description
Model architecture	MobileNetV2 (pretrained on ImageNet)	Lightweight convolutional neural network used as the backbone model
Input image size	224×224×3	Standard input dimensions for MobileNetV2
Epochs	25	Maximum number of training epochs
Batch size	32	Number of images processed per batch
Optimizer	Adam	Optimization algorithm
Learning rate	1×10 ^{4} (initial), 1×10 (fine-tuning)	Learning rates used during frozen training and fine-tuning
Loss function	Binary cross entropy	Loss function for binary classification
Early stopping patience	5	Training stopped if validation loss did not improve for five consecutive epochs
Preprocessing	MobileNetV2 preprocess_input	Scales pixel values to the range [–1, 1]
Data augmentation	Rotation, zoom, horizontal and vertical flips, brightness adjustment	Applied offline to training images only
Fine-tuning	Last 30 layers unfrozen	Layers from block_13_expand to out_relu were retrained
Dense layer units	128	Number of neurons in the fully connected layer
Dropout rate	0.3	Used to reduce overfitting
Evaluation strategy	Patient-wise 5-fold cross-validation	Prevents patient-level data leakage and provides robust performance estimates

[a]Name, value, and corresponding description of those hyperparameters are listed in the table.

Ensemble Explanation Framework

To enhance model interpretability, which is essential for the clinical deployment of AI systems, 3 complementary explanation methods were integrated: Grad-CAM [16], integrated gradients [17], and SmoothGrad [18]. Each method captures a distinct perspective of feature importance within the input image.

1. Grad-CAM generates coarse localization maps by computing the gradients of the predicted class score with respect to the activations of the final convolutional layer, thereby highlighting class-discriminative regions.
2. Integrated gradients attribute the model prediction by integrating gradients along a straight-line path from a baseline image to the input image, producing pixel-level attribution scores.
3. SmoothGrad improves the visual quality of gradient-based saliency maps by averaging gradients computed from multiple noisy perturbations of the input image.

To address the limitations of relying on a single explanation technique, an ensemble explanation map was constructed by combining the outputs of the 3 methods. For each input image, the saliency maps produced by Grad-CAM, integrated gradients, and SmoothGrad were resized to a common spatial resolution using bilinear interpolation and normalized to the range [0, 1]. For integrated gradients and SmoothGrad, the absolute magnitude of the attribution values was used prior to normalization to avoid cancelation effects arising from signed gradients and to ensure consistent comparison with the nonnegative Grad-CAM activation maps.

The final ensemble map was obtained by computing the arithmetic mean of the 3 normalized saliency maps, with equal weights assigned to each method:

$$M_Ensemble(x) = (1/3) \times M\hat{}_GradCAM(x) + (1/3) \times M\hat{}_IG(x) + (1/3) \times M\hat{}_SmoothGrad(x) \quad (1)$$

where x denotes the input image and M^_GradCAM(x), M^_IG(x), and M^_SmoothGrad(x) represent the normalized saliency maps generated by Grad-CAM, integrated gradients, and SmoothGrad, respectively. The ensemble explanation map M_Ensemble(x) is obtained by computing the arithmetic mean of the 3 normalized maps.

This equal-weight aggregation was adopted to preserve the complementary strengths of the 3 explanation methods while reducing method-specific noise and instability. No adaptive weighting or gating mechanism was applied; therefore, all 3 methods contributed equally to the final ensemble explanation.

Workflow Implementation

The workflow began with preprocessing the input images to satisfy the model's input requirements. After training and fine-tuning the MobileNetV2 classifier, Grad-CAM, integrated gradients, and SmoothGrad were applied independently to generate saliency maps for each image.

The 3 maps were subsequently normalized and averaged according to equation (1) to generate the ensemble explanation. The final output provided both the predicted class and a composite visual explanation highlighting the regions that most

XSL•FO
RenderX

strongly influenced the model's decision, thereby improving interpretability and clinical transparency.

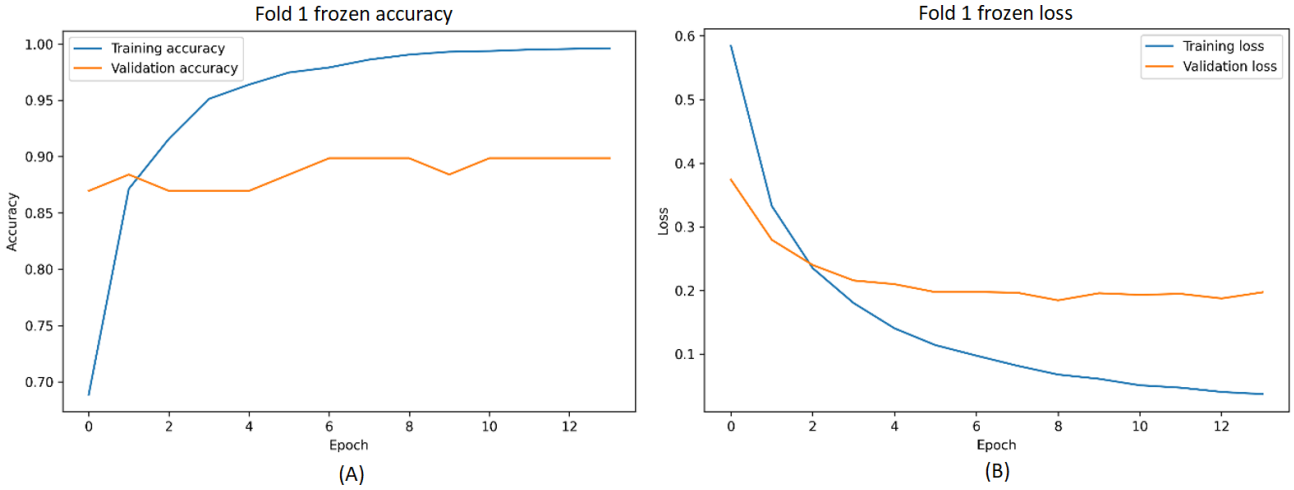
Results

Performance Improvement Through Fine-Tuning

Initially, the MobileNetV2 model, with all convolutional layers frozen, served as a strong baseline. Figure 2 presents representative training and validation curves for fold 1 during the frozen training phase, including both accuracy and loss. The corresponding training and validation curves for all 5 folds are provided in Multimedia Appendix 1. During this phase, the model demonstrated good discriminative ability; however, the extracted features remained largely aligned with generic ImageNet representations rather than dermatology-specific characteristics. Consequently, the model showed limitations in distinguishing subtle lesion patterns in visually ambiguous cases.

To improve domain adaptation, fine-tuning was performed by unfreezing the final 30 layers of the MobileNetV2 backbone, as described in the *Methods* section, specifically from the block_13_expand layer to out_relu. Figure 3 illustrates representative training and validation curves for fold 1 during the fine-tuning phase, while the corresponding curves for all 5 folds are included in Multimedia Appendix 1.

Figure 2. Representative training and validation accuracy and loss curves for fold 1 during the frozen training phase, in which all MobileNetV2 backbone layers were kept nontrainable. Panel (A) shows training and validation accuracy, and panel (B) shows training and validation loss.



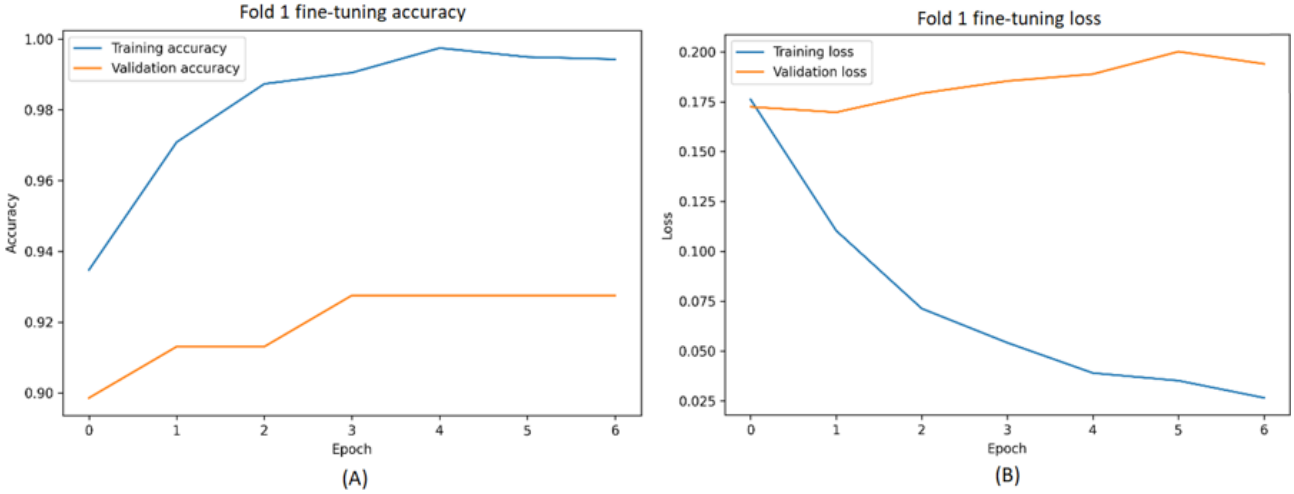


Figure 3. Representative training and validation accuracy and loss curves for fold 1 during the fine-tuning phase, after unfreezing the final 30 layers of the MobileNetV2 backbone. Panel (A) shows training and validation accuracy, and panel (B) shows training and validation loss.

A temporary increase in validation loss was observed at the beginning of the fine-tuning phase. This behavior is expected because the optimizer state was reinitialized and previously frozen layers were unfrozen, substantially increasing the number of trainable parameters and altering the optimization landscape. As a result, the model required several epochs to readjust the weights before achieving stable convergence.

Following fine-tuning, the model demonstrated improved qualitative and quantitative performance. In particular, the fine-tuned model showed enhanced discrimination between depigmented vitiligo lesions and hypopigmented PIH regions, even in clinically challenging cases. The model appeared to rely on diagnostically relevant features such as lesion border sharpness, pigment uniformity, and contrast with surrounding skin.

Table 2 summarizes the key improvements observed after fine-tuning compared to the frozen baseline.

Table . Comparative performance characteristics of the MobileNetV2 model before and after fine-tuning.

Metric	Frozen MobileNetV2	Fine-Tuned MobileNetV2
Feature representation	Generic (ImageNet-based)	Domain-specific (vitiligo vs PIH[a])
Clinical differentiation	Moderate	High
Validation loss	Higher	Reduced
Generalization performance	Good	Improved
Overfitting risk	Low	Low (stable convergence)

[a]PIH: postinflammatory hypopigmentation.

Model Evaluation and Performance Analysis

The final model was evaluated using patient-wise 5-fold cross-validation, ensuring that all images from a given patient were assigned exclusively to either the training or validation subset within each fold. This strategy provided a rigorous assessment of model generalization to previously unseen patients.

The number of validation images per fold ranged from 61 to 72, with no patient overlap between training and validation sets. Class balance was preserved across all folds, with each validation fold containing approximately 29 - 41 vitiligo images and 30 - 32 PIH images.

Across all 5 folds, the model generated 1 prediction for each of the 332 images. Aggregating these predictions yielded an overall accuracy of 94.88% and an AUC of 0.9885, indicating excellent discriminative performance. Table 3 summarizes the class-wise classification metrics. Fold-specific best-validation epochs and stopping epochs for both the frozen training and fine-tuning phases are provided in Table S1 in Multimedia Appendix 1.

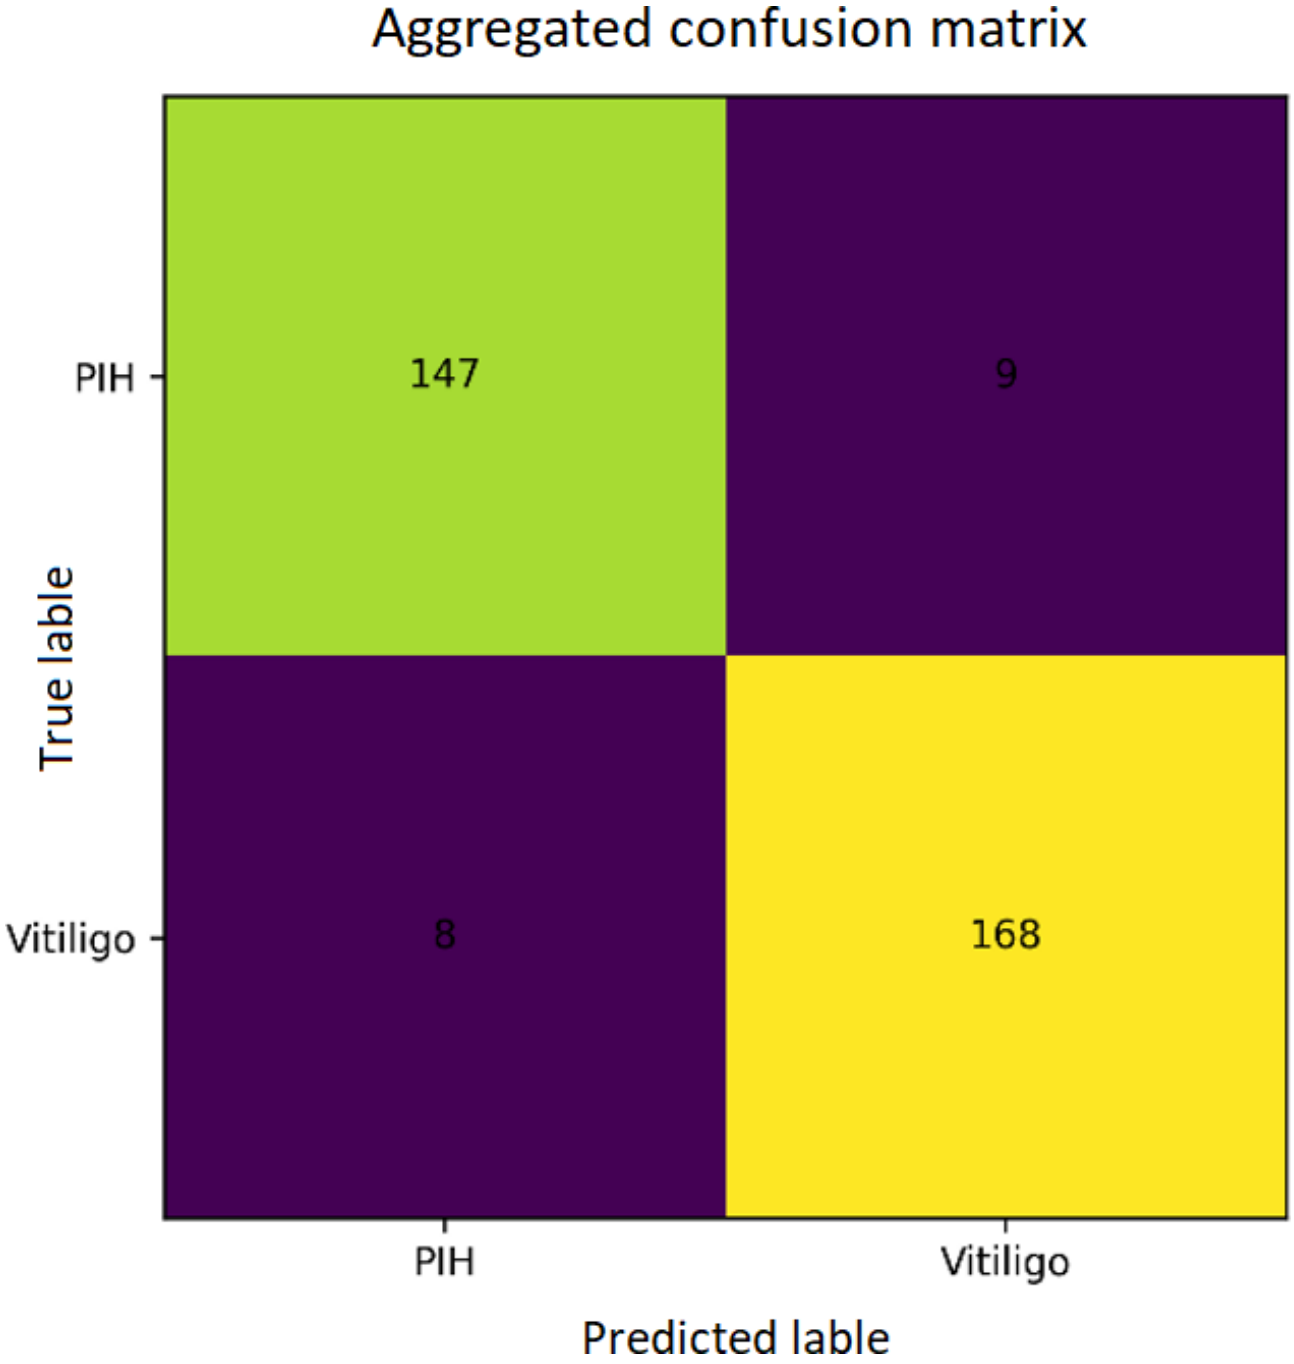
These results demonstrate strong and well-balanced diagnostic performance across both classes. The comparable precision and recall values indicate that the model does not exhibit a substantial bias toward either vitiligo or PIH.

Table . Classification performance of the fine-tuned MobileNetV2 model using patient-wise 5-fold cross-validation[a,b].

Class	Precision	Recall	F_1-score
PIH[c]	0.9484	0.9423	0.9453
Vitiligo	0.9492	0.9545	0.9518

[a]Overall accuracy: 0.9488.

[b]Area under the receiver operating characteristic curve: 0.9885.



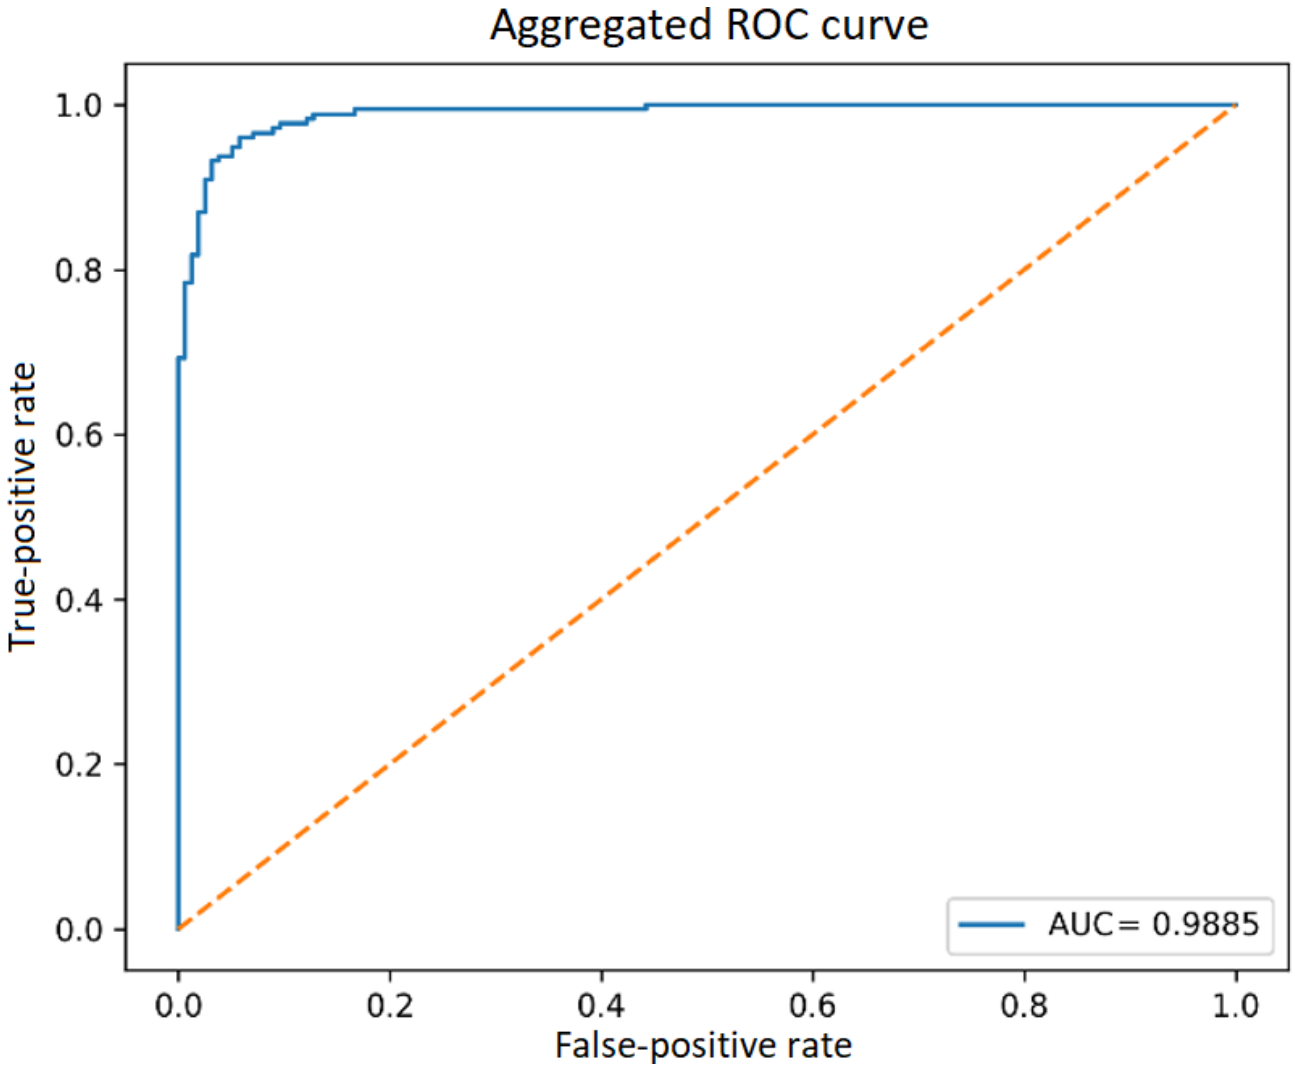
[c]PIH: postinflammatory hypopigmentation.

Classification Metrics and Diagnostic Performance

The aggregated confusion matrix (Figure 4) summarizes the predictions across all 5 validation folds, with each image contributing exactly once to the final evaluation.

XSL•FO
RenderX

Figure 4. Aggregated confusion matrix of the fine-tuned MobileNetV2 model for differentiating vitiligo from postinflammatory hypopigmentation (PIH). The matrix includes predictions from all 5 validation folds, with each image appearing exactly once.



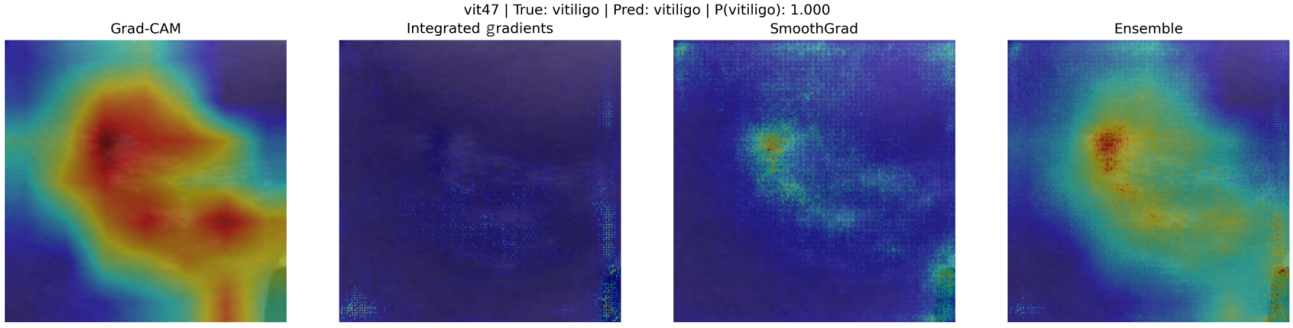
The model correctly classified 147 of 156 PIH images and 168 of 176 vitiligo images, resulting in only 17 misclassifications across the entire dataset. Specifically, 9 PIH images were incorrectly classified as vitiligo, whereas 8 vitiligo images were incorrectly classified as PIH.

The relatively small and nearly symmetric number of false-positive and false-negative predictions further confirms the balanced classification behavior of the model and supports its potential use for differentiating these visually similar pigmentary disorders.

The receiver operating characteristic (ROC) curve aggregated across all 5 validation folds (Figure 5) yielded an AUC of 0.9885, demonstrating excellent separability between vitiligo and PIH.

XSL•FO
RenderX

Figure 5. Aggregated receiver operating characteristic (ROC) curve of the fine-tuned MobileNetV2 model across all 5 validation folds. The dashed diagonal line represents random classification performance (area under the receiver operating characteristic curve [AUC]=0.50).



Model Interpretability Through Ensemble Explanation Methods

Overview

Interpretability analysis was performed using Grad-CAM, integrated gradients, SmoothGrad, and the proposed ensemble explanation framework. Four recurring interpretability scenarios were identified based on the degree of agreement and complementarity among the explanation methods. Representative examples are presented in Figures 6-9.

Figure 6. Representative example of scenario 1, where gradient-weighted class activation mapping (Grad-CAM), integrated gradients, smooth gradients (SmoothGrad), and the ensemble map consistently highlighted the same lesion region, demonstrating strong agreement across all explanation methods.

XSL•FO
RenderX

Figure 7. Representative example of scenario 2, where 1 explanation method produced a suboptimal attribution map, whereas the ensemble map remained robust and accurately localized the lesion. Grad-CAM: gradient-weighted class activation mapping; SmoothGrad: smooth gradients.

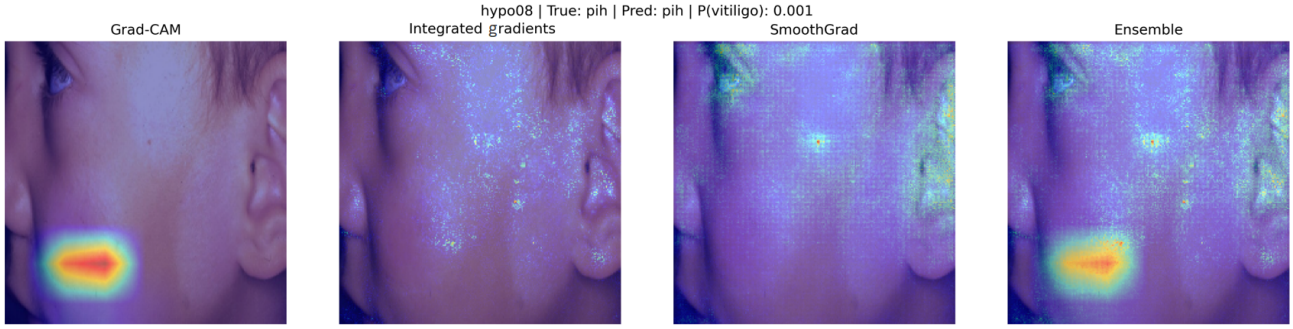


Figure 8. Representative example of scenario 3, where the individual explanation methods emphasized complementary lesion characteristics and the ensemble map integrated them into a unified interpretation. Grad-CAM: gradient-weighted class activation mapping; SmoothGrad: smooth gradients.

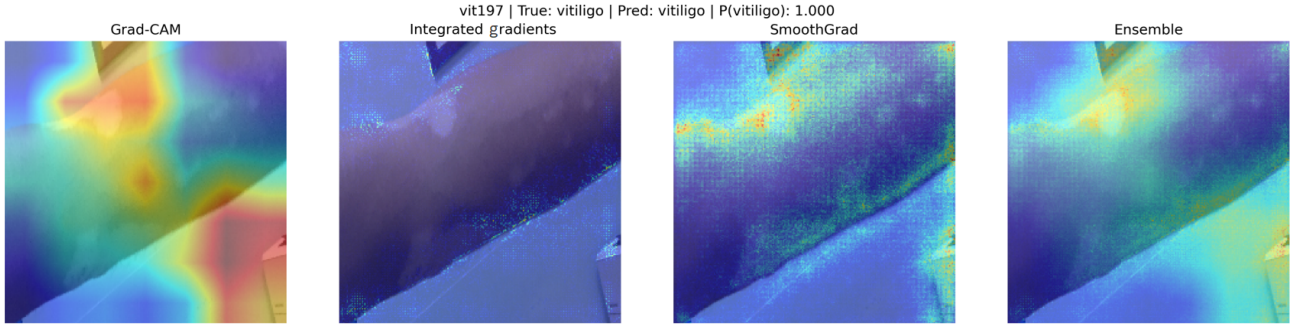

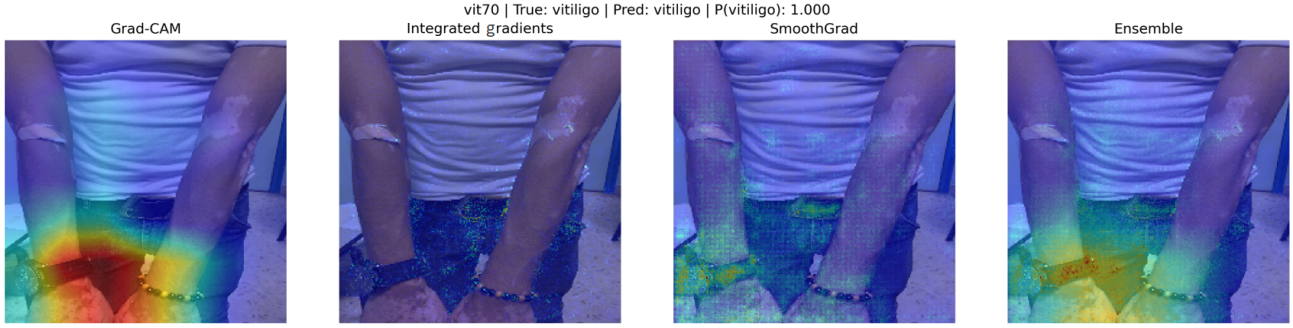

Figure 9. Representative example of scenario 4, where all explanation methods produced noisy or partially inconsistent saliency maps, resulting in a less informative ensemble map. Grad-CAM: gradient-weighted class activation mapping; SmoothGrad: smooth gradients.

Scenario 1: High Agreement Across All Methods

In the most common scenario, all 3 explanation methods generated highly consistent saliency maps, with each method focusing on the same clinically relevant lesion region. The resulting ensemble map (Figure 6) closely matched the individual explanations and reinforced the confidence in the model's prediction.

This scenario was observed in 36 of 66 (54.55%) validation images, indicating that the 3 methods frequently converged on similar and clinically meaningful attribution patterns.

Scenario 2: Failure of a Single Explanation Method

In this scenario (Figure 7), 1 explanation method produced a weak, noisy, or uninformative saliency map, while the other 2 methods successfully localized the lesion. Despite the failure of 1 individual method, the ensemble map remained accurate and clinically meaningful by integrating the informative signals from the remaining methods.

This pattern was observed in 25 of 66 (37.88%) images, demonstrating that the ensemble framework effectively mitigated isolated failures of individual explanation techniques.

Scenario 3: Complementary Information Across Methods

In a smaller subset of cases, the 3 explanation methods highlighted different but complementary aspects of the lesion. For example, 1 method emphasized lesion borders, whereas another focused on internal pigmentation changes. By combining these complementary signals, the ensemble map provided a more comprehensive and informative explanation than any single method alone (Figure 8). This scenario was identified in 4 of 66 (6.06%) images.

Scenario 4: All Methods Are Noisy or Partially Inconsistent

In 1 challenging case, all 3 explanation methods produced noisy or partially inconsistent saliency maps. The ensemble map remained similarly diffuse, providing limited improvement over the individual methods. Figure 9 illustrates this case.

XSL•FO
RenderX

This scenario occurred in only 1 of 66 (1.52%) images, indicating that the proposed framework generated clinically useful explanations in the vast majority of cases.

Quantitative Distribution of Interpretability Scenarios

To quantitatively assess the prevalence of these interpretability patterns beyond the representative examples shown in Figures 6-9, Table 4 summarizes the distribution of images across the 4 scenarios within a complete validation fold containing 66 images.

Table . Distribution of validation images across 4 interpretability scenarios (n=66).

Scenario	Description	Images, n (%)
1	High agreement across all methods	36 (54.55)
2	One method fails, but the ensemble remains robust	25 (37.88)
3	Methods provide complementary information	4 (6.06)
4	All methods are noisy or partially inconsistent	1 (1.52)
Total	—[a]	66 (100)

[a]Not applicable.

A single validation fold was selected as a representative subset of the dataset. This approach is consistent with established practices in explainable artificial intelligence, where qualitative and case-based interpretation analyses are commonly conducted on representative samples rather than the entire dataset because of computational costs and the inherently qualitative nature of visual assessment [37]. Furthermore, within the 5-fold cross-validation framework, each validation fold constitutes a statistically representative partition of the overall dataset, preserving class balance and lesion variability [16].

As shown in Table 4, the ensemble framework produced clinically meaningful explanations in 65 (98.48%) of 66 images, corresponding to scenarios 1 - 3. Scenario 1, representing strong agreement across all methods, was the most frequent outcome. Scenario 2 was also common, demonstrating that the ensemble remained reliable even when 1 individual method failed. Scenario 4 was rare, occurring in only a single image.

Discussion

Principal Findings

This study developed and validated an interpretable deep learning framework for differentiating vitiligo from PIH, 2 pigmentary disorders that are often difficult to distinguish because of their overlapping clinical appearance. Using a fine-tuned MobileNetV2 model evaluated with patient-wise 5-fold cross-validation, the proposed framework achieved an overall accuracy of 94.88%, a macroaveraged precision of 94.88%, a recall of 94.84%, and an F_1-score of 94.86%, demonstrating balanced classification performance across both classes, and an AUC of 0.9885.

Although patient-wise partitioning generally provides a more conservative estimate of performance, the revised pipeline also involved the reconstruction of the full preprocessing, metadata organization, fold generation, and model evaluation workflow. Because the original dataset already contained minimal patient overlap (mean 1.14, SD 0.66 images per patient; median 1, IQR 1-1, range 1-9 images per patient), patient-level leakage in the earlier image-wise protocol was likely limited. The observed performance difference, therefore, most likely reflects a combination of revised fold composition, random initialization effects, and improved stability of the rebuilt evaluation pipeline rather than leakage alone.

These results indicate that the model achieved high and well-balanced diagnostic performance for both classes. The aggregated confusion matrix demonstrated that 315 of 332 images were correctly classified, with only 17 misclassifications across all validation folds. This performance is particularly notable given that the evaluation protocol ensured that images from the same patient were never shared between training and validation subsets, thereby eliminating patient-level data leakage and providing a more rigorous estimate of generalization to previously unseen patients.

In addition to strong quantitative performance, the proposed framework incorporated an ensemble explainability strategy that combined Grad-CAM, integrated gradients, and SmoothGrad. The resulting explanation maps consistently highlighted clinically relevant features, including lesion border sharpness, pigment uniformity, and contrast with surrounding skin, indicating that the model based its predictions on diagnostically meaningful visual patterns rather than background artifacts or acquisition-specific cues.

From a clinical perspective, differentiating vitiligo from PIH is inherently challenging, particularly in early-stage lesions or in cases with subtle pigmentary changes. The strong performance achieved under a strict patient-wise validation strategy suggests that the model learned robust lesion-specific features that generalize beyond individual patients and image sources.

Impact of Fine-Tuning and Domain Adaptation

The initial frozen training phase provided a strong baseline by leveraging generic visual features learned from ImageNet pretraining. However, these features are not optimized to capture the subtle morphological and pigmentary characteristics that distinguish vitiligo from PIH.

XSL•FO
RenderX

Fine-tuning the final 30 layers of MobileNetV2 enabled the network to adapt to dermatology-specific patterns. This adaptation improved both quantitative performance and qualitative localization, as evidenced by the stable convergence behavior observed in the training curves and the enhanced focus on lesion-relevant regions in the saliency maps.

A transient increase in validation loss was observed at the beginning of the fine-tuning phase. This behavior is expected when previously frozen layers are unfrozen and the optimizer state is reinitialized, resulting in a temporary adjustment period before the model converges to a new optimum.

Cross-Validation Stability and Generalization

The patient-wise 5-fold cross-validation framework demonstrated consistent performance across all folds, supporting the robustness of the proposed approach. Because each validation fold contained images from entirely unseen patients, the resulting metrics provide a conservative and clinically realistic estimate of diagnostic performance.

The use of aggregated predictions across all validation folds further strengthened the analysis by enabling computation of final performance metrics from the complete set of 332 out-of-sample predictions rather than from a single fold. This approach reduced the influence of fold-specific variability and yielded a comprehensive assessment of model behavior.

Error Analysis

Although the overall performance was highly balanced, a small number of errors remained. Specifically, 9 PIH images were misclassified as vitiligo, and 8 vitiligo images were misclassified as PIH.

These errors likely reflect the substantial clinical overlap between the 2 conditions. Early vitiligo lesions may exhibit partial depigmentation or indistinct borders, whereas PIH lesions may present with sharply demarcated hypopigmentation that closely resembles vitiligo. Such borderline cases can be challenging even for experienced dermatologists.

Despite these difficult cases, the low number of misclassifications and the high AUC of 0.9885 indicate excellent discrimination across a wide range of decision thresholds.

Interpretability Analysis and Value of the Ensemble Framework

Interpretability analysis demonstrated that the ensemble explanation framework substantially improved the robustness of visual explanations.

A complete validation fold containing 66 images was manually reviewed and categorized into 4 predefined interpretability scenarios. In 36 (54.55%) images, all 3 explanation methods showed strong agreement (scenario 1). In 25 (37.88%) images, 1 method produced a weak or noisy map, but the ensemble remained robust by integrating informative signals from the remaining methods (scenario 2). In 4 (6.06%) images, the methods provided complementary information that enriched the final explanation (scenario 3). Only 1 (1.52%) image exhibited noisy or partially inconsistent maps across all methods (scenario 4).

Overall, the ensemble framework produced clinically meaningful explanations in 65 (98.48%) of 66 images. These findings confirm that combining multiple explanation techniques provides greater stability and reliability than relying on any single method alone.

Comparison With Prior Work

While explainability techniques such as Grad-CAM have been extensively explored in dermatological AI applications, particularly for skin cancer detection [10,22,32], their application to hypopigmented disorders remains limited. Previous studies have demonstrated the value of visual explanations for building clinical trust. For example, Badhon et al [32] and Shorfuzzaman [34] demonstrated increased trust via saliency maps but rarely benchmarked multiple explanation methods together or addressed conditions such as PIH. These studies typically relied on single explainability methods and did not systematically address their individual limitations or explore multimethod ensemble approaches. In contrast, this study integrates 3 complementary explanation methods into a unified ensemble framework and quantitatively evaluates their robustness through predefined interpretability scenarios.

The use of patient-wise cross-validation and the high diagnostic performance achieved under this stricter protocol further strengthen the clinical relevance of the proposed approach.

Clinical Implications

The combination of high classification performance and robust interpretability makes the proposed framework particularly attractive for clinical decision support.

The lightweight MobileNetV2 architecture offers computational efficiency suitable for deployment in resource-limited environments, mobile apps, and teledermatology platforms. At the same time, the ensemble explanation maps provide transparent visual evidence that can help dermatologists understand and verify the basis of model predictions.

Rather than replacing clinician judgment, the framework is intended to serve as an assistive tool that supports more consistent and objective differentiation between vitiligo and PIH.

Limitations

Several limitations should be acknowledged.

First, although the dataset size was sufficient to demonstrate proof of concept, it remains relatively modest for deep learning applications. Larger multicenter datasets would be valuable for further validation.

Second, most images were obtained from a single institution, supplemented by publicly available web images. Although all images were processed using a unified preprocessing pipeline, additional validation on external cohorts would strengthen generalizability.

Third, systematic subgroup analyses based on Fitzpatrick skin type, age, ethnicity, lesion location, and disease duration were not possible because these metadata were not consistently available.

XSL•FO
RenderX

Fourth, the model relied exclusively on image data and did not incorporate clinical information such as lesion history, preceding inflammation, or family history, which may further improve diagnostic performance.

Finally, while the explainability analysis was conducted on a representative validation fold, evaluation across all folds and formal assessment by dermatologists would provide additional evidence regarding explanation quality and clinical usefulness.

Future Directions

Several directions may extend the present work. First, multicenter studies involving larger and more diverse datasets are needed to validate the model across different imaging conditions, patient populations, and skin phototypes. Collecting structured demographic and clinical variables, such as Fitzpatrick skin type, age, ethnicity, lesion location, and disease duration, would enable subgroup analyses to assess fairness and generalizability.

Second, incorporating structured clinical metadata, including lesion onset, history of preceding inflammation, and family history, may improve diagnostic performance and better reflect real-world dermatological decision-making.

Third, the proposed ensemble explainability framework could be further refined by investigating adaptive weighting strategies and quantitatively validated against expert-annotated lesion boundaries and dermatologist assessments.

Fourth, future studies should compare MobileNetV2 with alternative architectures, including larger convolutional models such as ResNet and EfficientNet [38] and recent vision foundation models [39,40], to evaluate the trade-off between predictive performance and computational efficiency.

Finally, prospective clinical studies are needed to assess the impact of the proposed framework on diagnostic accuracy, clinician confidence, and workflow efficiency, particularly in teledermatology and resource-limited settings.

Conclusions

This study developed an interpretable deep learning framework for differentiating vitiligo from PIH using a fine-tuned MobileNetV2 model and an ensemble of Grad-CAM, integrated gradients, and SmoothGrad.

Under a rigorous patient-wise 5-fold cross-validation protocol, the model achieved excellent diagnostic performance, with an overall accuracy of 94.88%, an F_1-score of 95.18%, and an AUC of 0.9885. The ensemble explanation framework generated robust and clinically meaningful visual explanations in 98.48% of a representative 66-image validation subset used for interpretability assessment.

These findings demonstrate that combining lightweight deep learning architectures with complementary explainability methods can provide both high diagnostic accuracy and clinical transparency. The proposed framework has strong potential as a decision-support tool for dermatologists, particularly in settings where specialist expertise is limited.

Abstract

Background: Radiotherapy (RT) is a cornerstone of multimodal treatment for rectal cancer (RC); yet, substantial interindividual variability in treatment response persists. Deep learning (DL)–based radiomics offers potential for pre-RT response prediction to support personalized decision-making. **Objective:** This study aimed to develop and compare multiple DL radiomics models for predicting RT response in RC, with emphasis on the performance and clinical utility of Transformer architectures. **Methods:** In this single-center retrospective study, 2000 pathologically confirmed patients with RC who received standard RT were included. Pretreatment computed tomographic and dynamic contrast-enhanced magnetic resonance images and clinical variables were collected. Treatment response was categorized according to RECIST (Response Evaluation Criteria in Solid Tumors) version 1.1 as good (complete or partial response) or poor (stable or progressive disease). The primary analysis used magnetic resonance imaging (MRI)–only input; computed tomography (CT) was used for registration and quality control and evaluated in a late-fusion CT + MRI sensitivity analysis. Data were randomly split into training, validation, and test sets (8:1:1), with 5-fold cross-validation within the training set. Test set tumor masks were manually delineated, whereas a U-Net assisted segmentation was performed only within training to prevent data leakage. Convolutional neural network, graph convolutional network, and Transformer classifiers were compared. Class imbalance (approximately 65% vs 35%) was addressed using class weighting. Performance was evaluated using area under the receiver operating characteristic curve (AUROC) and accuracy with 95% CIs obtained by bootstrapping. AUROC differences were assessed using the DeLong test. Clinical usefulness was evaluated using decision curve analysis. Segmentation performance was quantified by Dice coefficient and intersection over union. Model interpretability was assessed using Gradient-Weighted Class Activation Mapping. **Results:** In the MRI-only primary analysis, the Transformer achieved the best performance on the independent test set, with accuracy of 87.0% (95% CI 84.2%-89.5%) and AUROC of 0.921 (95% CI 0.901-0.945), significantly outperforming the convolutional neural network (AUROC 0.881; *P*=.02) and graph convolutional network (AUROC 0.894; *P*=.041). Sensitivity and specificity were 89.2% and 82.9%, respectively. Decision curve analysis demonstrated higher net benefit across threshold probabilities of 0.3-0.7. U-Net segmentation achieved a mean Dice coefficient of 0.892 and intersection over union of 0.814. In sensitivity analysis, CT + MRI late fusion yielded a comparable AUROC to MRI only (0.926 vs 0.921; *P*=.36), with modest incremental net benefit at higher thresholds. **Conclusions:** In this large pre-RT imaging cohort, an MRI-driven Transformer-based DL radiomics model outperformed conventional architectures in predicting RT response in RC and demonstrated superior clinical net benefit. Late fusion of CT and MRI did not significantly improve overall discrimination but may provide incremental benefit in specific decision contexts. Multicenter external validation is warranted.

deep learning; radiomics; rectal cancer; radiotherapy; Transformer model

Introduction

Rectal cancer (RC) remains one of the leading causes of cancer-related incidence and mortality worldwide, with a particularly notable rise among middle-aged and older adult populations. Radiotherapy (RT) is a cornerstone of RC management; however, its therapeutic efficacy varies substantially among patients [1]. Current clinical indicators and conventional imaging approaches show limited ability to accurately predict individual responses to RT [2], often failing

XSL•FO
RenderX

to identify patients who are truly radiosensitive [3,4]. This variability poses a significant challenge in optimizing treatment strategies [2]. Consequently, there is a pressing need for robust predictive tools to guide personalized treatment and improve clinical outcomes.

The advent of radiomics has introduced the ability to extract high-dimensional quantitative features from medical images, uncovering latent biological information and offering novel insights into tumor behavior and treatment response. Unlike traditional imaging techniques, radiomics enables noninvasive prediction of therapeutic efficacy using imaging-derived biomarkers [5,6]. Nevertheless, conventional machine learning models often struggle to manage the complexity of radiomics data, particularly their high dimensionality and inherent nonlinearity [7,8]. This has led to a growing interest in the application of advanced deep learning (DL) algorithms, which offer superior capacity for feature representation and pattern recognition, to enhance the predictive power of radiomics analyses [9].

DL, particularly convolutional neural networks (CNNs), has achieved substantial advances in medical image analysis in recent years [10,11]. These models can automatically extract hierarchical features from imaging data and effectively recognize and classify complex patterns [12]. Compared with traditional approaches, DL offers notable advantages in handling high-dimensional data and performing intricate pattern recognition, making it especially well suited for analyzing radiomics data [13,14]. However, most existing studies have applied single DL algorithms in isolation, with few providing a systematic comparison of multiple models, particularly in the context of predicting RT response in patients with RC [15].

In recent years, the application of artificial intelligence (AI) in RT, cancer diagnosis, and clinical decision support has shifted from research exploration toward clinical deployment. Within the RT workflow, AI has been increasingly implemented in key steps such as organ autosegmentation, target delineation, (semi-)automated treatment planning, dose optimization, and image registration, yielding measurable time savings and improved plan consistency [16]. In the domain of cancer diagnosis, the integration of DL and radiomics has achieved substantial progress in RC lesion segmentation and feature quantification on magnetic resonance imaging (MRI). Such models can automatically localize tumor regions and characterize morphological and textural features of lesions, thereby facilitating earlier and more consistent assessment and diagnosis; this has been substantiated by both systematic reviews of RC lesion segmentation and specific studies on post–neoadjuvant chemoradiotherapy (nCRT) T2-weighted (T2W) MRI segmentation [17]. Moreover, AI models that integrate multimodal data have demonstrated practical value for personalized treatment strategies and risk prediction in clinical decision-making. For RC, a multicenter study showed that late-fusion models combining multiparametric MRI–derived DL or radiomics features with clinical variables outperformed unimodal approaches in predicting early recurrence risk and provided greater clinical net benefit as assessed by decision curve analysis (DCA) [18]. Against this background, this study integrates DL with radiomics to construct a predictive model aimed at accurately assessing the RT response in RC patients, thereby providing intelligent support for treatment optimization.

We systematically compared multiple state-of-the-art DL architectures, including CNNs, graph convolutional networks (GCNs), and Transformer models, for their ability to analyze and process radiomics imaging data in patients with RC. The Transformer architecture, in particular, exhibited superior capability in modeling complex image features through its self-attention mechanism, allowing it to effectively identify key regions relevant to RT response. By comparing these models in terms of feature extraction and predictive performance, this study investigated the potential of the Transformer model in predicting RT response in RC and evaluated its feasibility for clinical application. Unlike traditional applications of AI in tumor detection or initial diagnosis, this study focused on patients with pathologically confirmed RC. Our objective was to predict their responsiveness to RT based on pretreatment imaging, thereby enabling individualized treatment planning and minimizing unnecessary exposure to RT-related risks.

The key innovation of this study lay in the systematic application and comparison of multiple DL algorithms to enhance the accuracy of RT response prediction, with a particular emphasis on exploring the strengths of the Transformer model. By combining DL techniques with radiomics, we aimed to advance current predictive methodologies and develop a more precise model for RT response assessment. This work provides clinicians with a robust, data-driven tool to support personalized therapeutic strategies, ultimately contributing to the broader goal of precision medicine in oncology.

Methods

Ethical Considerations

This study was conducted in strict accordance with ethical standards. The use of imaging and clinical data was approved by the Medical Ethics Committee of Shanxi Provincial People's Hospital. As this was a retrospective analysis, all data were obtained from routine clinical records and were fully deidentified prior to analysis. The ethics committee confirmed that additional informed consent was not required. All data were anonymized before processing, and no identifiable patient images or information was included in the manuscript or supplementary materials. Data were stored on encrypted servers with access restricted to authorized investigators. Since this study did not involve prospective data collection or patient intervention, no monetary or nonmonetary compensation was provided to participants. For any future studies involving identifiable images, written informed consent will be obtained, and the relevant materials will be submitted with the manuscript.

Data Collection

This retrospective study included 2000 patients with RC who were treated at Shanxi Provincial People's Hospital between January 2015 and December 2023. All patients underwent standard RT and had complete paired pretreatment computed tomography (CT) and MRI data, along with follow-up assessments of RT response.

XSL•FO
RenderX

Inclusion criteria were (1) pathologically confirmed RC, (2) receipt of standard RT, (3) availability of complete pretreatment CT and dynamic contrast–enhanced MRI (DCE-MRI) data, and (4) documented RT outcomes with follow-up records. Exclusion criteria were (1) incomplete or poor-quality imaging data, (2) missing essential clinical information or outcome labels, (3) coexisting malignancies or severe systemic diseases, and (4) patients who did not receive standard RT protocols. Treatment regimens followed the Chinese Society of Clinical Oncology guidelines for RC and primarily consisted of long-course RT (50.4 Gy in 28 fractions). Some patients also received concurrent chemotherapy and subsequent surgical intervention, depending on clinical conditions.

To ensure transparency in patient selection, a CONSORT (Consolidated Standards of Reporting Trials)-style flowchart is provided in Figure S1 in Multimedia Appendix 1, detailing the inclusion process, exclusion criteria, final sample size, and classification of patients into RT-sensitive and RT-insensitive groups.

All imaging data were acquired from routine clinical scanning systems at a single institution (Shanxi Provincial People's Hospital), encompassing MRI and CT examinations performed across different years. Detailed information regarding scanner models and acquisition parameters is provided in Table S1 in Multimedia Appendix 2.

Data Preprocessing

Following data collection, the imaging data were preprocessed to ensure quality and consistency. The preprocessing steps included denoising, cropping, normalization, and resolution adjustment. All images were normalized to a range between 0 and 1 and resized to a resolution of 512×512 pixels. To enhance the model's generalization ability, data augmentation techniques such as rotation, flipping, and scaling were applied to generate more diverse training samples and effectively expand the dataset. In addition, clinical data were standardized to harmonize feature values with different units and ranges, ensuring compatibility with model input requirements. The complete data collection and preprocessing workflow is illustrated in Figure S1 in Multimedia Appendix 3.

To prevent data leakage, the statistical parameters required for image normalization (mean and SD) were computed exclusively from the training set and kept fixed for both the validation and test sets. The test set was not involved in estimating normalization parameters at any stage, thereby ensuring independence and rigor in both preprocessing and model evaluation.

All DL models used in this study were trained and inferred on 2D slices; thus, the input features were derived solely from spatial texture information within single images, without relying on voxel-level 3D volume information. During preprocessing, we did not perform volumetric resampling along the *z*-axis to reconcile slice thickness differences (3 mm vs 4 mm), in order to avoid interpolation-induced artifacts that could distort 2D texture features. Because model training and prediction were conducted at the single-slice level, and all patients' images were acquired using consistent scanning sequences and acquisition protocols, variations in slice thickness were expected to have limited impact on grayscale distribution or spatial structure of the input features. Nevertheless, we discuss the potential biases associated with differing slice thicknesses in the "Limitations" section, and we plan to explore full 3D volume resampling and the integration of 3D models in future work to further improve model robustness in cross-device settings.

Data Annotation and Quality Control

To ensure high-quality data for model training, strict annotation and quality control procedures were applied to all imaging data and RT response labels. For the imaging side, radiologists manually delineated tumor regions, with particular attention paid to tumor boundaries and clinically relevant areas. Semiautomated annotation tools were used to assist in the delineation process. All annotations were independently reviewed by 2 associate chief radiologists (ZW and ZH), each with more than 10 years of experience. All delineation results were further validated through random sampling to ensure the consistency and accuracy of boundary recognition.

RT response labels were assigned based on posttreatment MRI evaluations and classified according to the RECIST (Response Evaluation Criteria in Solid Tumors) version 1.1. Patients who achieved a complete response (CR) or a partial response (PR) were categorized as the "good response (GR) group," while those with stable disease or progressive disease were categorized as the "poor response group." All imaging evaluations were performed in a blinded manner, with evaluators unaware of treatment plans and clinical outcomes. Two independent reviewers (ZW and ZH) assessed the follow-up MRIs, and interobserver agreement was assessed using the Cohen κ coefficient, which reached 0.83, indicating good consistency. Final response classifications were determined through consensus and used as ground-truth labels for supervised model training.

In particular, all tumor masks in the test set were manually annotated by experts without reference to any DL model outputs, thereby avoiding error propagation and ensuring the independence and rigor of model evaluation. The U-Net model was used exclusively on the training set to generate tumor masks as auxiliary inputs for the classification models. Its outputs were not used in any segmentation or feature extraction tasks for the test set, minimizing the risk of information leakage.

DL Model Construction and Training

For the patient-level response prediction task, the model first performs independent inference on each 2D slice, producing a probability score indicating the likelihood of belonging to the "GR" category. Subsequently, the predicted probabilities of all slices from the same patient are averaged arithmetically to obtain an aggregated patient-level probability, and a threshold of 0.5 is applied to generate the final patient-level classification label. This aggregation strategy helps smooth slice-to-slice fluctuations caused by differences in imaging position, preventing any single atypical slice from disproportionately influencing the overall judgment. As a result, the stability and robustness of patient-level predictions are enhanced. This study used multiple DL algorithms to process radiomics imaging data and predict

XSL•FO
RenderX

patient responses to RT (Figure S1 in Multimedia Appendix 4). The models compared included CNNs, GCNs, and Transformer models. All models were trained and tested on the same dataset to ensure comparability.

The Transformer model served as the primary focus due to its self-attention mechanism, which enabled the capture of complex global features and provided unique advantages in tumor region recognition. In this model, input images were divided into 16×16 patches and processed with 8 multihead attention heads and 12 Transformer encoder layers. Standard sinusoidal positional encoding was incorporated to preserve spatial structure information. The model was trained using the Adam optimizer, with an initial learning rate of 1e-4 and a cosine annealing strategy for dynamic learning rate adjustment. Training was conducted over 100 epochs, with early stopping applied if validation loss did not decrease for 10 consecutive epochs.

As the comparative baseline, the CNN used a residual networks (ResNet-34) architecture, consisting of 34 residual convolutional layers organized into 4 residual stages with channel dimensions of 64, 128, 256, and 512, respectively. Feature extraction was performed on 2D patches of the input images. The output of the final global average pooling layer was fed into a 2-layer fully connected classification head (hidden layer size=256, activation function=ReLU) to generate predictions of RT response.

The GCN module adopted a 3-layer GCNConv structure, where nodes represented embedded features of image patches or regions of interest (ROIs). The adjacency matrix was constructed based on spatial proximity using a k-nearest neighbors approach (k=8). Each layer used a ReLU activation function, and dropout (P=.30) was applied between layers to mitigate overfitting. The aggregated node features after global pooling were passed to a classification layer. All models were trained under identical conditions, using the same loss function (weighted cross-entropy), optimizer (Adam, learning rate=1×10^{-4}), and training strategy (cosine annealing schedule with early stopping) to ensure a fair performance comparison. Hyperparameter tuning and L2 regularization were applied throughout training to reduce overfitting risks. The final model was independently evaluated on the test set and compared against other networks, with particular emphasis on its performance in feature extraction and classification accuracy.

Given the class imbalance in RT response labels (approximately 65% of patients in the GR group and 35% in the poor response group), a class weighting strategy was introduced during training. Specifically, inverse-frequency weights based on sample distribution were applied in the loss function to enhance the model's sensitivity to the minority class (poor response patients). This approach effectively mitigated the prediction bias caused by unequal class distribution and yielded higher sensitivity and overall stability in the validation set.

In the final implementation of this study, the Transformer architecture was used solely as an image-level classifier. The network consisted of multiple encoder layers and a classification head, without any decoder branch or explicit segmentation output (eg, a "Seg Head"). The tumor segmentation task was performed entirely by an independent U-Net model, and the 2 models operated independently throughout the training and evaluation processes.

Dataset Splitting and Cross-Validation

To evaluate the generalization ability of the models, the dataset was divided into training, validation, and test sets in a ratio of 8:1:1. Random sampling was used to ensure the representativeness of each subset. The 8:1:1 split was chosen based on the sufficiently large sample size (2000 patients), which supported the high-dimensional feature extraction needs of DL models. A larger training set enabled the model to better learn complex nonlinear patterns, while 200 patients each were retained for independent validation and testing. To further improve model stability and generalizability, 5-fold cross-validation was applied during training, with k set to 5. Stratified sampling was used to preserve consistent class distributions across all folds. All models were trained and evaluated on the same data splits, and the average performance metrics across the 5 folds were reported as the final results. This approach ensured robust evaluation, minimized bias, and enhanced the reproducibility of model performance across different subsets.

To evaluate model generalizability, the dataset was divided into training, validation, and testing subsets in an 8:1:1 ratio. All partitions were performed at the patient level, ensuring that all images, slices, and augmented samples from the same patient were assigned exclusively to a single subset to prevent information leakage. Stratified random sampling was applied to maintain consistent class distribution across subsets. To further enhance model robustness and generalization performance, 5-fold cross-validation (k=5) was conducted within the training cohort, also based on patient-level partitioning. This approach ensured the independence of the validation data and the reproducibility of the experimental results.

To avoid data leakage, data augmentation in this study was applied exclusively to the training set, while no augmentation was performed on the validation or test sets. All augmented samples were strictly linked to their original patients and existed only within the training subset, ensuring that none entered the independent test set. Consequently, each test-set patient corresponded to exactly 1 nonaugmented imaging input during inference, which explains why the total count in the confusion matrix matches the original number of patients (n=200).

Model Evaluation and Performance Analysis

Model performance was evaluated using multiple classification metrics, including accuracy, sensitivity, specificity, receiver operating characteristic (ROC) curves, area under the curve (AUC) values, and confusion matrices, to comprehensively assess the predictive accuracy of RT response in RC. Ninety-five percent CIs were calculated for all metrics to strengthen the robustness and interpretability of results.

To statistically compare model performances and verify the relative advantage of the Transformer model, pairwise bootstrap resampling (10,000 iterations) and DeLong's test were performed for AUC comparisons, with P values reported. ROC curves and their confidence intervals were used to visually and

XSL•FO
RenderX

quantitatively compare the classification performance of different models.

Calibration was evaluated on the independent test set by plotting a calibration curve (reliability diagram) using 10 equal-frequency bins (deciles). For each bin, we reported the mean predicted probability and the observed event rate. Overall calibration was quantified with the Brier score (the mean squared error between predicted probabilities and true labels). All calibration analyses were performed once on the test set without any retraining or post hoc recalibration to avoid information leakage. To ensure fairness, the bin boundaries and the evaluation pipeline were kept identical across input settings (MRI-only vs CT + MRI).

During evaluation, particular emphasis was given to evaluating the Transformer model's performance under varying segmentation input conditions. Its prediction results were further analyzed through Gradient-Weighted Class Activation Mapping (Grad-CAM) visualization to interpret attention regions and their clinical relevance. Tumor segmentation performance using the U-Net model was evaluated on the independent test set, with the Dice Similarity Coefficient (DSC) and the Intersection over Union (IoU) used as primary metrics. Manually delineated tumor regions, confirmed by 2 experienced radiologists, served as the gold standard. Failure cases were manually analyzed to identify potential factors contributing to segmentation inaccuracies, such as blurred tumor boundaries, low tissue contrast, or irregular tumor morphology. Detailed segmentation outcomes are shown in the "Results" section, and representative case images are provided in multimedia appendices.

Image Data Analysis Method

The image data analysis pipeline in this study consisted of 2 independent stages: tumor segmentation and image-level classification. First, a U-Net segmentation network was used to delineate tumor regions on the raw MRI or CT images, generating binary masks (Figure S1 in Multimedia Appendix 5). This segmentation model served solely to provide ROIs and did not participate in subsequent classification learning. Next, image patches or ROI features extracted from the masked tumor regions were fed into 3 types of classification models, CNNs, GCNs, and a Transformer classifier (Figure S1 in Multimedia Appendix 6), to predict patients' RT response.

It is important to emphasize that the Transformer model used in this study was a pure classification architecture composed only of an encoder and a multilayer perceptron classification head. It did not include any decoder structure, upsampling pathway, or segmentation outputs. Accordingly, it was entirely independent of the U-Net segmentation model used to generate masks; the 2 models shared no parameters and had no information exchange during training or inference. The GCN was used to model spatial relationships within the tumor region, further enhancing classification performance. The overall model evaluation and performance analysis workflow is shown in Figure S1 in Multimedia Appendix 7.

Input Modalities and Multimodal Fusion Strategy

In the primary analysis, the classifier used MRI-only inputs—pre-RT DCE-MRI and T2W sequences—and extracted features or patches or embeddings strictly within expert-annotated tumor masks, thereby minimizing bias from cross-modal acquisition heterogeneity and registration error. CT was used solely for quality control and, when necessary, rigid registration and was not provided to the classifier. Per reviewer request, we additionally implemented late fusion of CT + MRI under the same data split, loss function, class weighting, and hyperparameter settings as the primary analysis. Specifically, patient-level representations were extracted from CT and MRI with identical backbone encoders; after feature alignment and normalization, the representations were concatenated immediately before the classification head and trained or evaluated jointly (all other procedures unchanged). To ensure a fair comparison, the independent test set was kept fixed (n=200; good responders, n=130 and poor responders, n=70); only the input modality configuration was varied.

Statistical Analysis

This study applied various DL techniques to analyze radiomics imaging data from patients with RC. Initially, CNNs were used to extract features from the image data, capturing fine-grained details of tumor tissues. During image segmentation, deep segmentation networks such as U-Net and Mask R-CNN were used to identify and annotate tumor regions, ensuring accurate localization of key lesions. The self-attention mechanism of the Transformer model was used to manage complex spatial relationships, thereby improving the model's pattern recognition capabilities. GCNs were also applied to extract global and local spatial features from the images, effectively modeling both tumor and peritumoral tissue characteristics. By integrating multiple DL models, the study aimed to achieve accurate predictions of RT response and support personalized treatment recommendations.

During model evaluation, various statistical methods were used to comprehensively assess predictive performance. Metrics, including sensitivity, specificity, precision, and recall, were calculated to evaluate classification outcomes across different categories. Confusion matrices were plotted to visualize model performance in distinguishing between positive and negative RT responses. To assess predictive ability across varying thresholds, ROC curves and AUC values were generated for each model. These statistical analyses facilitated a detailed comparison of the strengths and limitations of each DL approach in predicting RT response in patients with RC.

Results

Dataset Sample Distribution Balance and Generalization Ability

In this study, radiomic imaging data from 2000 patients with RC were collected and randomly divided into training (1600 cases), validation (200 cases), and test (200 cases) sets using an 8:1:1 ratio. Approximately 65% (1300/2000) of patients exhibited a favorable response to RT and were classified as the "sensitive" group, while the remaining 35% (700/2000) were categorized as "nonsensitive." As shown in Table 1, we further compared baseline demographic and clinical characteristics—including age, sex, T stage, N stage, tumor

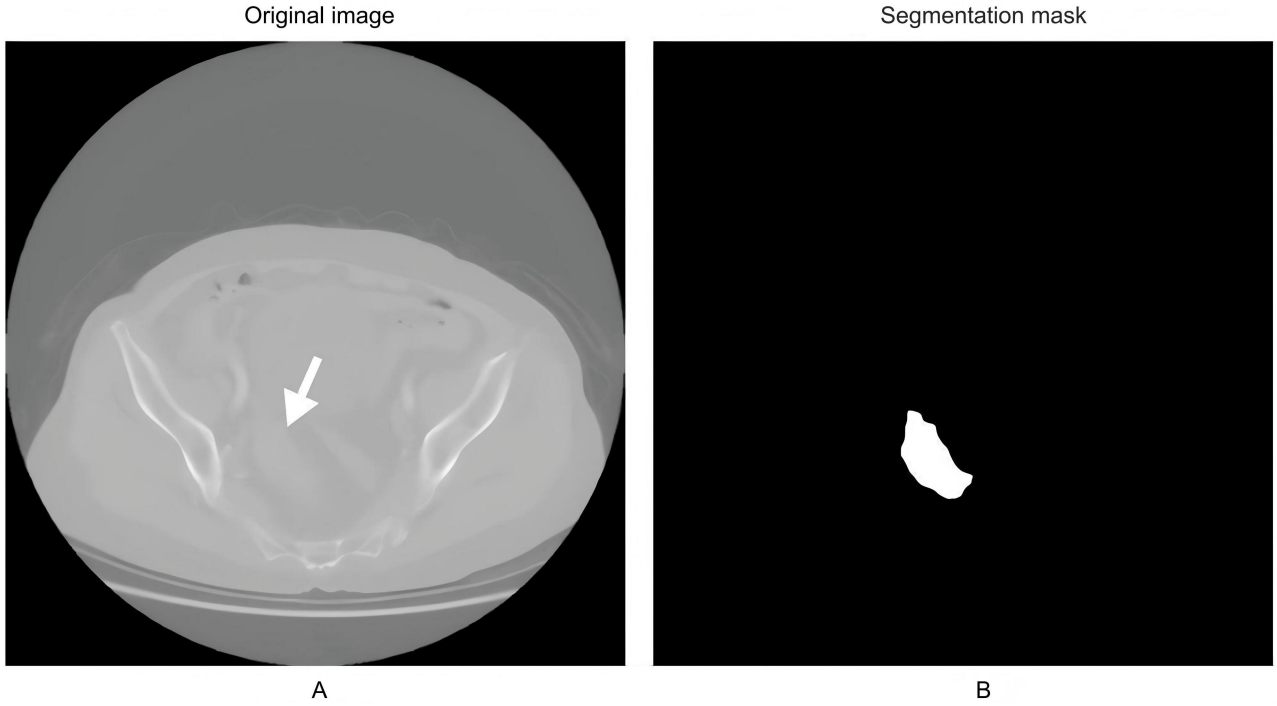
XSL•FO
RenderX

location, and carcinoembryonic antigen levels—between the training and test sets. None of the variables showed statistically significant differences (P>.05). These results indicate that the random partitioning of the dataset was unbiased and that the training and test sets were highly comparable. This balanced distribution provides a reliable foundation for model training and independent validation, thereby enhancing the generalizability and robustness of the proposed approach.

Table . Baseline demographic and clinical characteristics of patients in the training and testing cohorts[a].

Variable	Training cohort (N=1600)	Testing cohort (N=200)	*P* value
Age (years), mean (SD)	58.7 (10.9)	59.1 (11.2)	.62
Sex, n (%)			.53
Male	980 (61.3)	118 (59.0)	
Female	620 (38.7)	82 (41.0)	
T stage, n (%)			.78
T2	430 (26.9)	50 (25.0)	
T3	930 (58.1)	120 (60.0)	
T4	240 (15.0)	30 (15.0)	
N stage, n (%)			.67
N0	610 (38.1)	80 (40.0)	
N1	710 (44.4)	86 (43.0)	
N2	280 (17.5)	34 (17.0)	
Tumor location, n (%)			.79
Upper rectum	310 (19.4)	36 (18.0)	
Midrectum	860 (53.8)	112 (56.0)	
Lower rectum	430 (26.9)	52 (26.0)	
CEA[b] level (ng/mL), median (IQR)	3.6 (2.1-6.8)	3.8 (2.2-7.0)	.73
Response category, n (%)			>.99
Good response	1040 (65.0)	130 (65.0)	
Poor response	560 (35.0)	70 (35.0)	

[a]This table shows the baseline differences between the training and test sets in demographic characteristics (age and sex), tumor clinical staging (T stage and N stage), tumor location, and CEA level. Statistical comparisons were performed using independent-samples *t* tests, chi-square tests, or Mann-Whitney *U* tests, as appropriate. All *P* values were greater than .05, indicating no significant differences between the training and test sets. This demonstrates that the random allocation process was unbiased and that the cohorts were well matched and comparable.



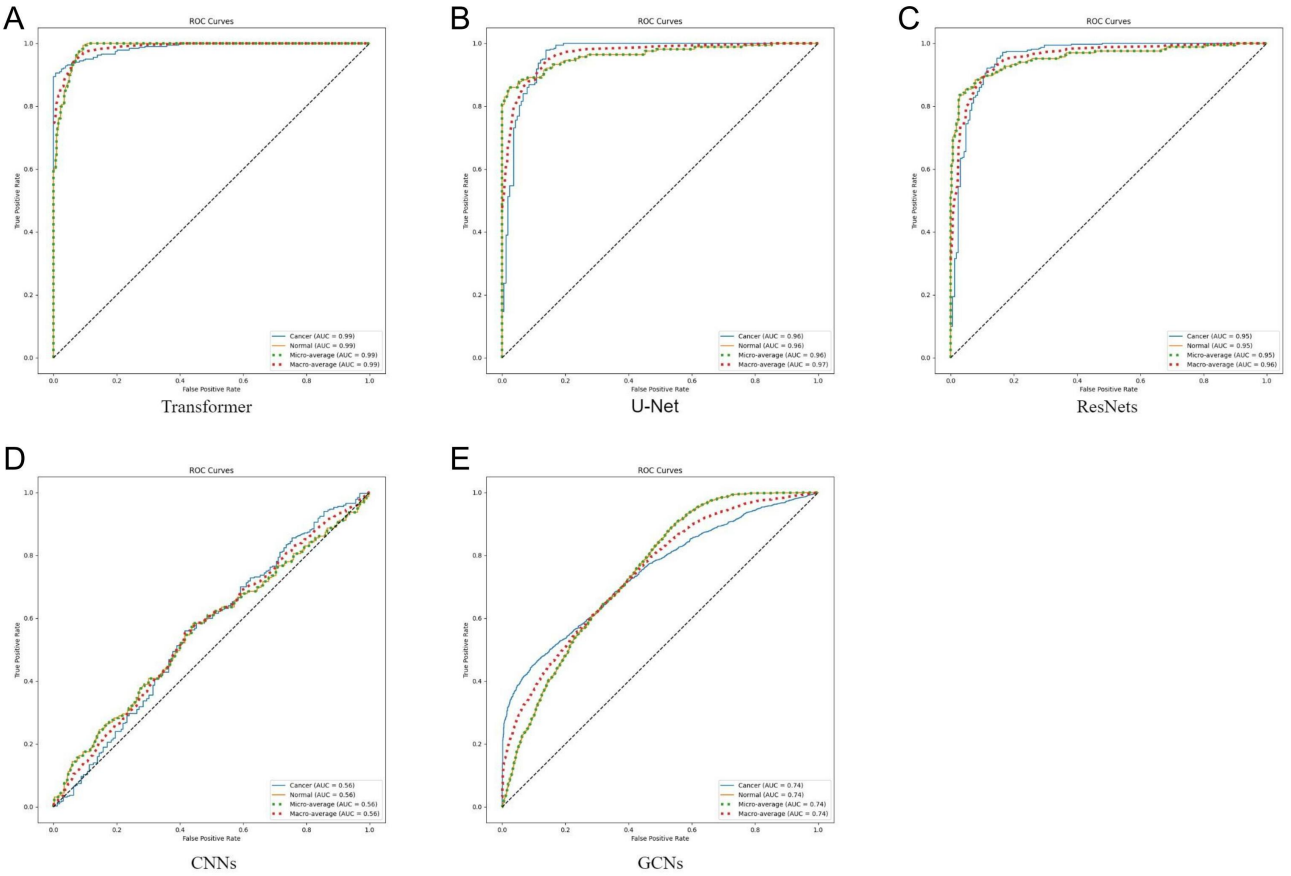
[b]CEA: carcinoembryonic antigen.

High Accuracy of U-Net Model in Tumor Region Segmentation

In this study, a U-Net segmentation network was applied to automatically segment tumor regions in the imaging data of patients with RC. The results demonstrated excellent performance of the model in tumor recognition and segmentation tasks. On the independent test set, the U-Net model achieved a mean DSC of 0.892 (95% CI 0.881 - 0.904) and a mean IoU of 0.814 (95% CI 0.800 - 0.829), indicating high segmentation consistency and robustness. The model precisely delineated tumor boundaries and clearly separated tumor regions from surrounding structures. The original image is shown in Figure 1A, and the corresponding segmentation mask generated by the U-Net model is shown in Figure 1B.

XSL•FO
RenderX

Figure 1. Tumor region segmentation results. (**A**) Original image. The white arrow indicates the rectal tumor lesion. (**B**) Model segmentation result image (tumor region highlighted).



When compared with manually annotated gold-standard segmentations by expert radiologists, the model showed a high degree of agreement in both boundary definition and tumor morphology. Notably, the U-Net model maintained strong performance even when segmenting tumors with irregular shapes or blurred margins. However, a small number of inaccurate segmentations were observed, primarily in cases characterized by indistinct tumor margins, low contrast with adjacent tissues, or atypical tumor morphology. These challenging cases provide directions for future model optimization.

Outstanding Performance of the Transformer Model in Predicting RT Response

This study compared the performance of several DL models in predicting the RT response in patients with RC. The results showed that the Transformer model achieved the highest overall performance, with an accuracy of 87%. As illustrated in Figure 2A, the Transformer leveraged its self-attention mechanism to effectively process complex patterns and fine-grained features within the radiomics imaging data, offering a distinct advantage in capturing global contextual information. In comparison, the CNN (Figure 2D) and GCN (Figure 2E) models achieved accuracies of 82% and 84%, respectively, both lower than that of the Transformer model. Analysis of ROC curves (Figures 2A-2E) further highlighted the Transformer model's superior discriminative ability, as reflected by its AUC value of 0.921 (95% CI 0.901 - 0.945), which exceeded that of the CNN (Figure 2D) and GCN (Figure 2E).

XSL•FO
RenderX

Figure 2. ROC curve comparison of different models. (A) Transformer, (B) U-Net, (C) ResNet, (D) CNN, and (E) GCN. AUC: area under the curve; CNN: convolutional neural network; GCN: graph convolutional network; ROC: receiver operating characteristic.

To enhance the robustness of the results, 95% CIs were calculated for all classification metrics across the models (Table 2). On the independent test set, the Transformer model achieved an accuracy of 87.0% (95% CI 84.2% - 89.5%), sensitivity of 89.2% (95% CI 85.3% - 92.4%), specificity of 82.9% (95% CI 79.2% - 88.1%), and an AUC of 0.921 (95% CI 0.901 - 0.945). In contrast, the CNN model reached an AUC of 0.881 (95% CI 0.854 - 0.906), while the GCN model achieved an AUC of 0.894 (95% CI 0.869 - 0.918).

Table . Performance comparison of deep learning models in predicting radiotherapy response[a].

Model	Accuracy	Sensitivity	Specificity	AUC[b]	*P* value vs Transformer
Transformer	87.0% (84.2%-89.5%)	89.2% (85.3%-92.4%)	82.9% (79.2%-88.1%)	0.921% (0.901%-0.945%)	—[c]
CNN[d]	82.0% (78.9%-85.0%)	83.7% (79.4%-87.6%)	80.2% (75.0%-84.6%)	0.881% (0.854%-0.906%)	.02
GCN[e]	84.0% (80.4%-87.2%)	85.9% (81.7%-89.7%)	82.1% (77.0%-86.4%)	0.894% (0.869%-0.918%)	.041

[a]This table compares the performance of 3 deep learning models (transformer, CNN, and GCN) in predicting radiotherapy response in rectal cancer using an independent test set. All metrics are reported as mean values with 95% CI. The primary evaluation metrics include accuracy, sensitivity, specificity, and the area under the curve (AUC). Differences in AUC were assessed using the DeLong test. The results demonstrate that the Transformer model outperformed both CNN and GCN models across all evaluation metrics, with the differences in AUC reaching statistical significance (P<.05).

[b]AUC: area under the curve.

[c]Not available.

[d]CNN: convolutional neural network.

[e]GCN: graph convolutional network.

To evaluate the statistical significance of AUC differences between the Transformer and other models, pairwise bootstrap resampling (10,000 iterations) and DeLong's test were conducted. The results showed that the Transformer model significantly outperformed both the CNN model (P=.02) and the GCN model (P=.041) in terms of AUC. These findings indicated that the Transformer model provided a statistically significant advantage in identifying imaging features associated with RT response.

RenderX

Confusion Matrix Reveals the Classification Capability of the Transformer Model

To further assess classification performance, a confusion matrix was constructed to evaluate the Transformer model's predictive ability. As shown in Table 3, among the 200 patients in the test set, the model correctly identified 89% of RT-sensitive patients. The false-positive rate, representing RT-insensitive patients incorrectly classified as sensitive, was only 8%. These results further validated the model's effectiveness across both classes, particularly in correctly identifying RT-insensitive patients. The Transformer model significantly reduced misclassification errors, a critical factor in clinical decision-making. Accurate identification of RT-insensitive patients was essential for enabling timely adjustments to treatment plans, avoiding ineffective RT, and ultimately improving patient prognosis and survival outcomes. On the independent test set, the Transformer's calibration curve closely followed the ideal 45° line, with only mild overconfidence observed in the high–predicted-probability region. The corresponding Brier scores were identical for both input settings: MRI-only, 0.145; and CT + MRI (late fusion), 0.145. Overall calibration was therefore comparable between modalities. Taken together with the AUCs (0.921 vs 0.927) and the DCA results, adding CT did not yield a meaningful improvement in global performance, but it produced a slight and consistent gain in net benefit within higher decision-threshold ranges (Figure 3 and Table 4).

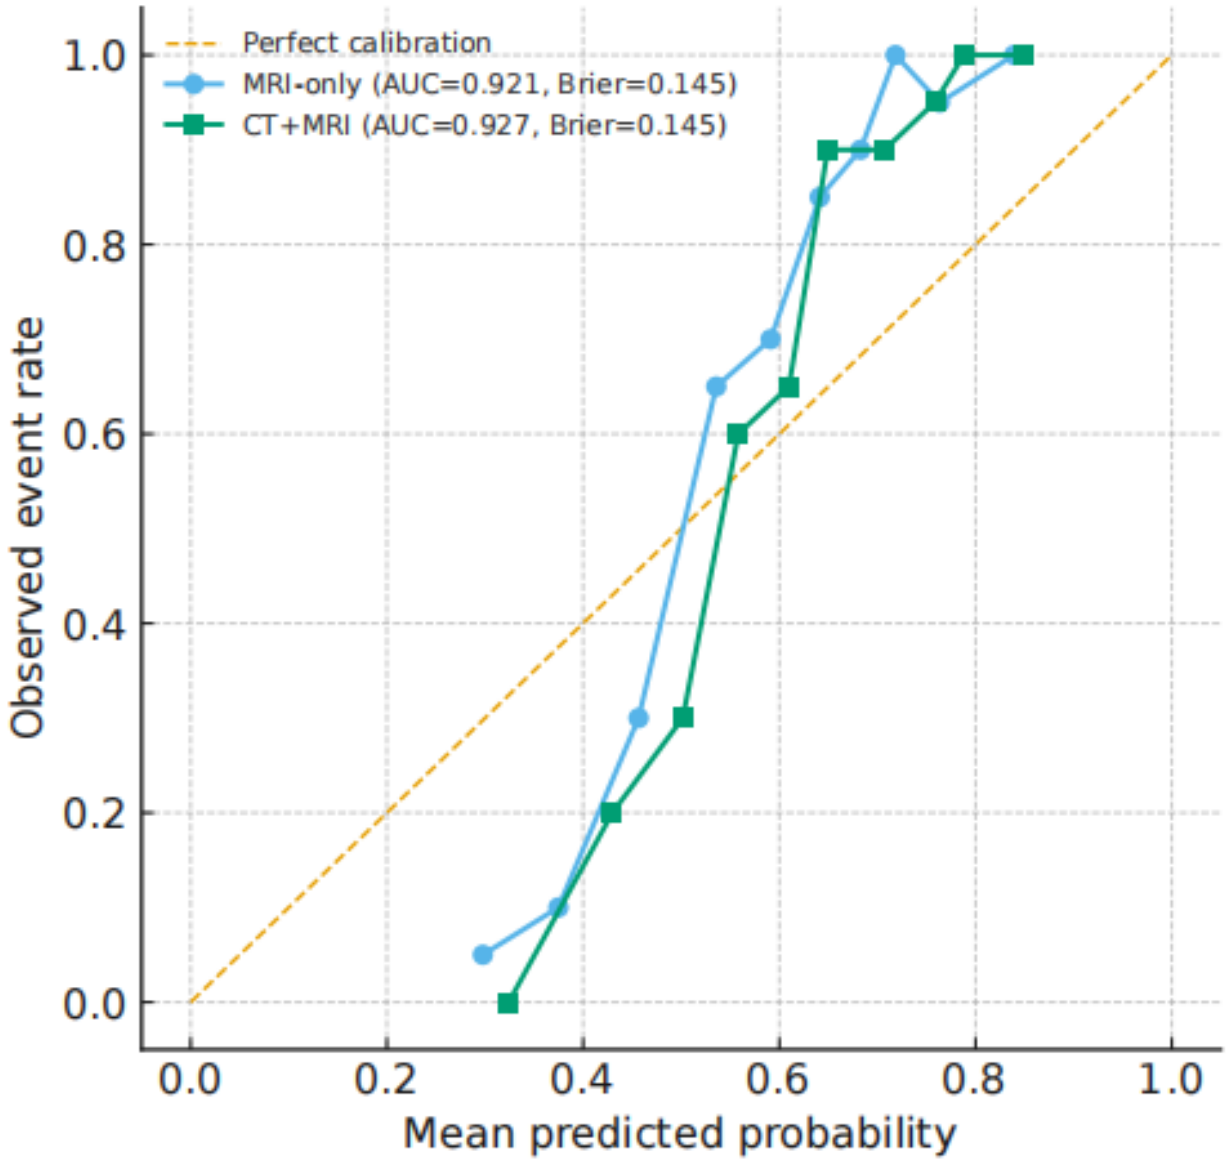

Table . Confusion matrix results for the Transformer model[a].

Category	Sensitive class (good response to radiotherapy)	Insensitive class (poor response to radiotherapy)
Predicted as sensitive class	116 (true positive)	12 (false positive)
Predicted as insensitive class	14 (false negative)	58 (true negative)

[a]This table shows the confusion matrix of the Transformer model on the independent test set (magnetic resonance imaging–only, n=200). True positives represent the number of patients correctly predicted as radiotherapy-sensitive (116 cases); false positives represent the number of patients incorrectly predicted as sensitive but actually nonsensitive (12 cases); false negatives represent the number of patients incorrectly predicted as nonsensitive but actually sensitive (14 cases); and true negatives represent the number of patients correctly predicted as radiotherapy nonsensitive (58 cases). Based on this matrix, the calculated performance metrics were as follows: accuracy=87.0%, sensitivity=89.2%, and specificity=82.9%.

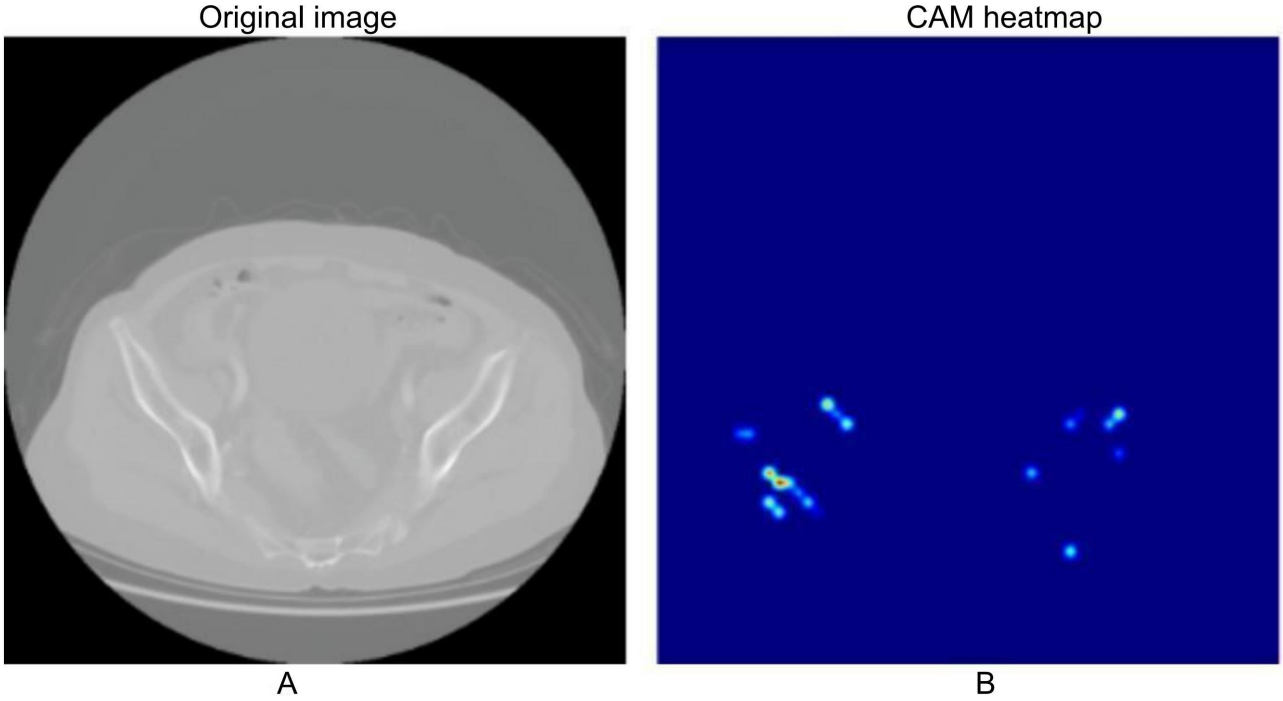
[a]MRI: magnetic resonance imaging.

[b]CT: computed tomography.



[c]This table shows the calibration binning results of the transformer model on the independent test set under 2 input settings: MRI-only and CT + MRI. The predicted probabilities (pred_mean) were divided into 10 equal-frequency bins (bin), each containing 20 samples. Obs_rate represents the observed positive rate (proportion of radiotherapy-sensitive patients), while pred_min and pred_max indicate the minimum and maximum predicted probabilities within each bin, respectively. The results show that both input settings exhibit calibration trends close to the ideal diagonal, indicating good agreement between predicted probabilities and observed rates. Notably, the CT + MRI setting demonstrated a slight improvement in net benefit within the higher threshold range.

Grad-CAM Visualization to Validate the Accuracy of Feature Extraction

The effectiveness of the Transformer model was reflected not only in its overall predictive performance but also in the depth and precision of its feature extraction. Grad-CAM was used to visualize the model's feature extraction process. The results revealed that the model primarily focused on tumor boundaries and high-density regions within the tumor. As shown in Figures 4A and 4B, the model was particularly adept at capturing complex structures in heterogeneous tumor areas and using them to predict RT response. The visualization results further demonstrated that the model effectively filtered out irrelevant background information and concentrated on diagnostically significant regions. This selective focus enhanced both the classification accuracy and the clinical interpretability of the model. The ability to highlight meaningful anatomical and pathological features supported the Transformer model as a reliable diagnostic aid for clinicians in treatment planning and response prediction.

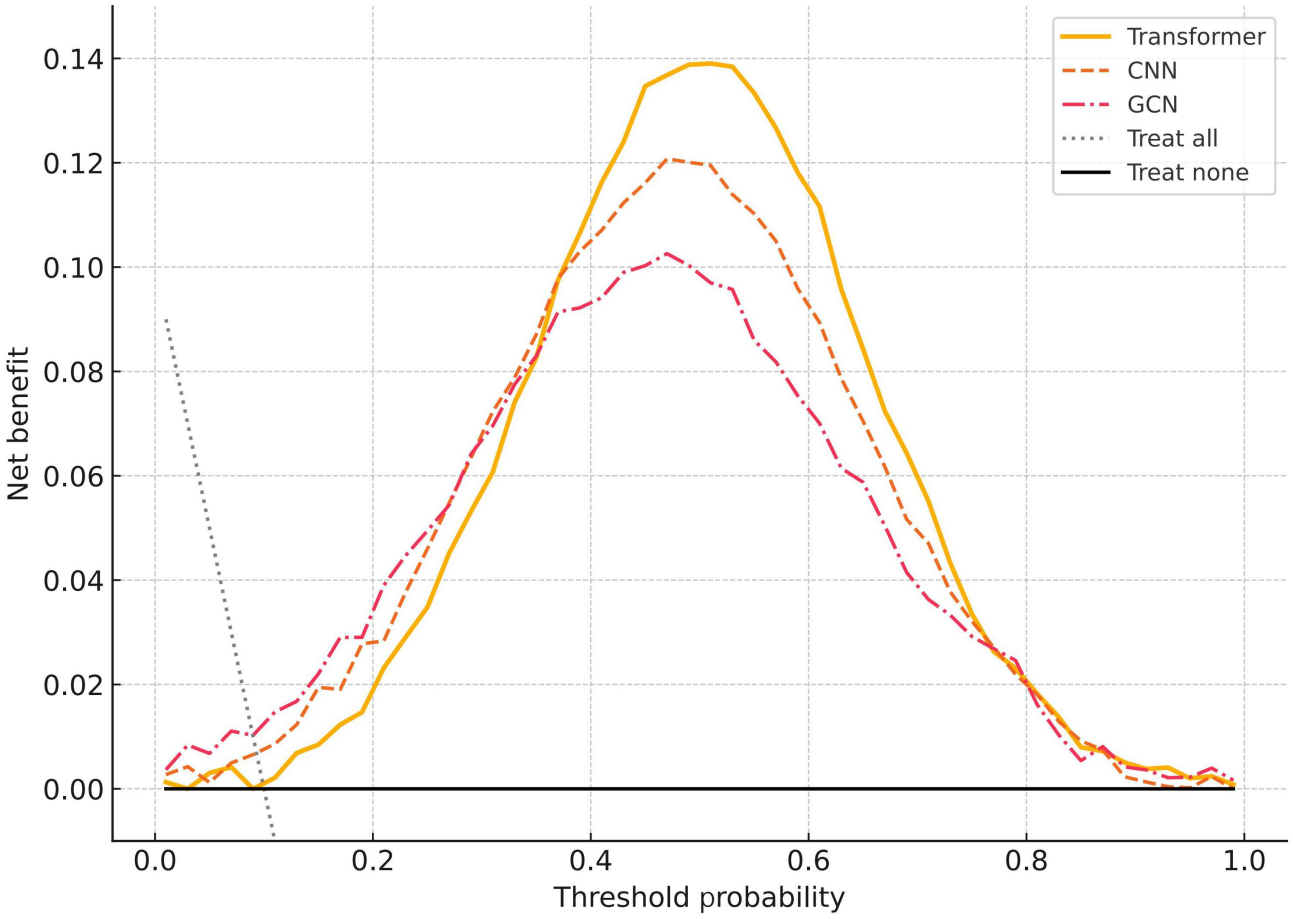
(B) Grad-CAM visualization image: displays the areas where the model focuses, particularly on tumor edges and high-density regions. Red areas represent the regions of high attention by the model. CAM: Class Activation Mapping.

Hyperparameter Optimization and Model Iteration Analysis

During model training and optimization, adjustments to hyperparameters such as learning rate, batch size, and regularization substantially improved the performance of the Transformer model. After 50 training epochs, the validation loss steadily decreased to 0.01, indicating good model convergence and stable training dynamics. As training progressed, the loss curves of the training and validation sets gradually converged, with no apparent signs of overfitting, further confirming the critical role of hyperparameter optimization in enhancing model performance (see Figure 5A for training loss and Figure 5B for validation loss). The model maintained consistently low validation loss and favorable convergence characteristics, establishing a solid foundation for subsequent testing and external validation.

Figure 5. Changes in loss and accuracy for training and validation sets. (A) Loss curve: the loss values for both the training and validation sets decrease gradually over 50 epochs. (B) The validation loss curve (Val loss) indicates that the model stabilized during the later training phase without signs of overfitting.



Clinical Benefit Analysis Based on DCA

To further evaluate the potential clinical use of the DL models in RT decision-making, DCA was performed to compare the net benefit of the Transformer, CNN, and GCN models across different probability thresholds (Figure 6). The results showed that across most threshold ranges—particularly between 0.3 and 0.7—the Transformer model achieved a higher net benefit than both the “treat all” and “treat none” strategies, as well as outperforming the CNN and GCN models. This suggests that the Transformer model provides greater decision support capacity in clinical practice.

XSL•FO
RenderX

Figure 6. Decision curve analysis. The figure shows the comparison of net benefit across different probability thresholds for the Transformer, CNN, and GCN models. The dashed lines represent the "treat all" and "treat none" strategies, respectively. The Transformer model demonstrated higher net benefits within the primary clinical decision-making range of 0.3 - 0.7, highlighting its clinical use in predicting radiotherapy sensitivity. CNN: convolutional neural network; GCN: graph convolutional network.

For example, when predicting RT-sensitive patients, the Transformer model maintained a high true-positive rate while significantly reducing the likelihood of unnecessary RT and associated side effects. These findings highlight the model's potential as a valuable tool for individualized RT decision-making.

Sensitivity Analysis of Imaging Input Settings (MRI-Only Versus CT + MRI)

To quantify the incremental value of CT, we compared MRI-only with late-fusion CT + MRI under identical training or validation procedures (same splits, loss, class weighting, and hyperparameters). Using the Transformer as an exemplar, overall discrimination on the independent test set was similar between modalities: Transformer (MRI-only): accuracy 87.0%, AUC 0.921 (95% CI 0.901 - 0.945), sensitivity 89.2% (true positive 116/130), specificity 82.9% (true negative 58/70), Brier score 0.145, and area under the precision–recall curve 0.900; Transformer (CT + MRI): accuracy 87.5%, AUC 0.926 (95% CI 0.905 - 0.948), sensitivity 90.0% (true positive 117/130), specificity 82.9% (true negative 58/70), Brier score 0.142, and area under the precision–recall curve 0.905.

DeLong's test indicated no significant difference in AUC between the 2 settings (P=.36). In DCA, CT + MRI yielded a slight and consistent gain in net benefit at higher threshold probabilities (>0.6), whereas curves largely overlapped within the primary clinical range (0.3 - 0.7). Overall, given a unified MRI acquisition protocol in this single-center cohort, MRI-only achieved robust performance; adding CT did not confer a statistically significant global improvement but may offer marginal clinical value at specific, higher decision thresholds. For completeness, test-set AUCs (95% CI) across all 3 architectures (CNN, GCN, and Transformer) under both input settings are summarized in Table 5, and full classification metrics for the Transformer are provided in Table 6.

XSL•FO
RenderX

Table . Comparison of the Transformer model performance under different input settings[a].

Input setting	Accuracy	AUC	95% CI (AUC[b])	Sensitivity	Specificity	Brier	AUCPR[c]	DeLong test *P* value
MRI[d]-only	87.00%	0.921	0.901 - 0.945	89.2% (116/130)	82.9% (58/70)	0.145	0.9	—[e]
CT + MRI (late fusion)	87.50%	0.926	0.905 - 0.948	90.0% (117/130)	82.9% (58/70)	0.142	0.905	.36

[a]This table compares the predictive performance of the Transformer model under 2 input settings: magnetic resonance imaging (MRI)–only and CT + MRI (late fusion). The main evaluation metrics include accuracy, area under the curve (AUC) with its 95% CI, sensitivity, specificity, Brier score, area under the precision–recall curve (AUCPR), and the DeLong test *P* value for AUC comparison. The results indicate that the overall discriminative performance of the 2 input settings was comparable (AUC difference, *P*=.36). The CT + MRI configuration showed slightly better Brier score and AUCPR at higher threshold ranges, suggesting a minor net benefit under certain clinical decision thresholds.

[b]AUC: area under the curve.

[c]AUCPR: area under the precision–recall curve.

[d]MRI: magnetic resonance imaging.

[e]Not available.

Table . Comparison of AUC[a] values across architectures under MRI[b]-only and CT[c] + MRI settings[d].

Architecture	MRI-only AUC (95% CI)	CT + MRI AUC (95% CI)	DeLong test *P* value
CNN[e]	0.881 (0.854 - 0.906)	0.888 (0.861 - 0.912)	.22
GCN[f]	0.894 (0.869 - 0.918)	0.899 (0.873 - 0.922)	.29
Transformer	0.921 (0.901 - 0.945)	0.926 (0.905 - 0.948)	.36

[a]AUC: area under the curve.

[b]MRI: magnetic resonance imaging.

[c]CT: computed tomography.

[d]This table compares the area under the curve (AUC) performance and corresponding 95% CI of 3 deep learning models—CNN, GCN, and Transformer—under 2 input conditions: MRI-only and CT + MRI. Differences in AUC were evaluated using the DeLong test. The results show that all 3 models exhibited slight improvements in AUC under the CT + MRI condition; however, none of the differences reached statistical significance (*P*>.05). Among the 3, the Transformer model achieved the highest AUC in both settings (MRI-only: 0.921; CT + MRI: 0.926).

[e]CNN: convolutional neural network.

[f]GCN: graph convolutional network.

Computational Efficiency and Inference Time Analysis

To quantitatively evaluate the computational overhead and deployment feasibility of different models in clinical scenarios, we further compared CNNs, GCNs, and Transformer-based models in terms of parameter count, theoretical computational complexity (Floating-Point Operations [FLOPs]), and inference time on an independent test set. Inference-time evaluation was conducted under a fixed hardware configuration (GPU: NVIDIA RTX 3090, 24 GB memory), using FP32 precision, with synchronized timing performed after model warm-up. The timing scope included model forward inference and patient-level probability aggregation (ie, arithmetic averaging of predicted probabilities across all 2D slices belonging to the same patient), while offline image preprocessing and data-loading overheads were excluded.

As summarized in Table 7, the Transformer model exhibits a larger parameter size (86.4 M) and higher FLOPs (17.8 G) than the CNN (ResNet-34) and GCN architectures, reflecting its increased model complexity. Nevertheless, on the test set, the Transformer model achieves an average per-slice inference time of 3.8 milliseconds. At the patient level (median number of slices: 20, IQR 16 - 24), the overall inference time is 78 (IQR 63-95) milliseconds per patient, which remains well within the acceptable range for real-time clinical decision support. By comparison, the patient-level inference times of the CNN and GCN models are 42 milliseconds and 55 milliseconds, respectively.

XSL•FO
RenderX

Table . Computational efficiency and inference latency of the evaluated models[a].

Model	Parameters, millions	FLOPs[b], billions	Inference time per slice (ms), mean (SD)	Average slices per patient, median (IQR)	Inference time per patient (ms)
CNN[c] (ResNet-34)	21.8	3.6	2.1 (0.3)	20 (16-24)	42 (34 - 50)
GCN[d]	28.5	5.2	2.7 (0.4)	20 (16-24)	55 (44 - 66)
Transformer	86.4	17.8	3.8 (0.5)	20 (16-24)	78 (63 - 95)

[a]Parameter counts and FLOPs were calculated based on a single region of interest input. Inference time was measured on an independent test set (n=200) and includes model forward inference as well as patient-level prediction probability aggregation, while offline image preprocessing and data-loading overheads were excluded. All results were obtained under identical hardware and software environments.

[b]FLOPs: Floating-Point Operations.

[c]CNN: convolutional neural network.

[d]GCN: graph convolutional network.

These results indicate that although the Transformer architecture incurs a higher computational cost than conventional convolutional models, its inference latency remains low. Moreover, when weighed against its substantial advantages in predictive performance and clinical net benefit, the increased computational overhead is acceptable for practical clinical applications.

Discussion

Principal Findings

In this study, a DL-based radiomics model was developed to predict RT response in patients with RC. A systematic comparison of multiple models, including CNNs, GCNs, and Transformers, revealed that the Transformer architecture demonstrated the best overall performance. By leveraging its self-attention mechanism, the Transformer effectively captured complex imaging features within key tumor regions, achieving an accuracy of 87% and an AUC of 0.921 on the test set. In addition to its predictive accuracy, the Transformer model demonstrated strong interpretability, as confirmed by Grad-CAM visualization, which highlighted its focus on clinically relevant tumor regions. These findings underscore the model's potential as a reliable and interpretable tool for supporting individualized RT planning in clinical settings.

During training, 5-fold cross-validation (k=5) was adopted based on the following considerations. First, it balanced statistical stability and sample efficiency. In this cohort (n=2000; class ratio ≈65%/35%), k=5 ensured approximately 200 validation cases per fold, providing sufficient positive and negative samples to stably estimate AUC, calibration, and DCA metrics. Larger k would yield smaller validation subsets, increasing variability in calibration and DCA estimates, whereas smaller k would raise estimation bias and reduce the resolution of hyperparameter selection. Second, it accounted for computational cost and practical reproducibility: compared with 10-fold cross-validation, 5 folds substantially reduced training time and resource requirements, making replication in a clinical research setting more feasible. To assess robustness, we conducted sensitivity analyses using k=3 and k=10 and repeated 5-fold cross-validation with different random seeds under the same patient-level stratification. Across all settings, the relative ranking of the Transformer and baseline models remained consistent, fold-to-fold AUC variability was comparable with the main analysis, and no systematic instability or overfitting was observed. Compared with 5 folds, 10 folds primarily increased training time and triggered more frequent early stopping without materially affecting final test performance. Three-folds showed slightly greater variance in validation metrics and reduced hyperparameter discriminability. In summary, k=5 provided an optimal balance among performance stability, computational feasibility, and methodological rigor. To avoid information leakage, cross-validation was performed exclusively within the training set using stratified, patient-level splits; all images, slices, and augmented samples from the same patient were confined to a single fold. The independent test set was reserved for a one-time final evaluation only.

Comparison With Prior Work

RT remains a cornerstone in RC treatment; however, predicting individual response to RT continues to be a major clinical challenge due to significant patient heterogeneity [19]. Radiomics, an emerging technology capable of extracting high-dimensional features from medical images, has opened new avenues for predicting treatment response [20]. However, traditional machine learning approaches have shown limited effectiveness in modeling the high-dimensional, heterogeneous nature of radiomics data [21]. The advent of DL, particularly CNNs, has markedly improved pattern recognition capabilities in this domain [7,9,22]. Unlike prior studies that applied single-model approaches, our work systematically compared 3 advanced DL architectures and identified the Transformer as the most effective model for complex image-based RT response prediction [23].

Several recent studies have attempted to integrate DL into tumor-imaging analysis and RT response prediction. For instance, Xu et al [24] applied CNNs for breast region segmentation using DCE-MRI in breast cancer, demonstrating strong performance in local feature extraction. However, their approach was limited to 2D analysis and failed to account for the complexity of 3D imaging data [24]. Similarly, Mzoughi et al [25] proposed a multiscale 3D CNN for glioma classification based on MRI, achieving approximately 85% accuracy, but still faced limitations in feature representation and generalizability.

XSL•FO
RenderX

Previous studies have systematically evaluated MRI-based radiomics and DL approaches for predicting response to nCRT in RC. A multicenter study published in *Radiology* demonstrated that MRI radiomics models could predict pathological complete response (pCR) with relatively high accuracy [26]. DL models based on post-nCRT T2W MRI also achieved discriminative performance for pCR or GR that was comparable to, or even surpassed, expert radiologist assessment [27]. Beyond single time point models, delta radiomics—which captures changes in features before and after treatment—showed superior performance in predicting nCRT response [28]. In terms of risk stratification and clinical translation, late-fusion multimodal models that integrated multiparametric MRI–derived DL or radiomics features with clinical variables outperformed unimodal models and provided greater clinical net benefit on DCA [18]. Furthermore, several systematic reviews and meta-analyses confirmed the robustness of imaging AI for predicting pCR, reporting pooled AUCs of approximately 0.90 - 0.91; models based on DL or clinical fusion generally outperformed conventional radiomics approaches [29]. These findings are consistent with the results of this study and support our design rationale of introducing more advanced architectures (eg, Transformers) and evaluating clinical use using tools such as DCA.

In contrast, our Transformer-based model achieved an accuracy of 87% and an AUC of 0.921, outperforming the CNN-based approaches in both precision and discriminative capacity. The multihead self-attention mechanism of the Transformer effectively captured global dependencies within tumor regions, demonstrating enhanced robustness and generalizability, especially in cases with complex morphology or blurred tumor boundaries. Compared with previously reported models, our approach offered distinct advantages in architectural innovation, predictive performance, and clinical interpretability, positioning it as a more reliable framework for RT response prediction.

Additionally, the U-Net model also demonstrated satisfactory performance in tumor segmentation, achieving a mean DSC of 0.892 and an IoU of 0.814 on the independent test set, indicating strong consistency with expert annotations. These results underscore the crucial role of accurate segmentation in radiomics workflows, as it ensures high-quality inputs for downstream feature extraction and classification, even in tumors with irregular edges.

Furthermore, Grad-CAM visualization revealed that the Transformer model concentrated on tumor edges and regions of heterogeneous density, areas known to correlate with RT sensitivity [20,21]. This interpretability enhanced the interpretability and clinical credibility of the model.

Limitations

Despite the promising results, this study had several limitations. First, the dataset was derived from a single center, with limited diversity in race, age, and pathological subtypes, which may have constrained the model's generalizability [20]. Although data augmentation and k-fold cross-validation were applied to mitigate this limitation, future studies should incorporate multicenter datasets to assess the model's robustness across broader populations. Second, the imaging data primarily consisted of DCE-MRI, without the integration of additional clinical variables such as genomic data, pathological classification, or treatment history. This single-modality approach may have limited the comprehensiveness of the predictive model [7]. Incorporating multimodal data in future models could improve both predictive accuracy and biological interpretability. Third, although Grad-CAM was used to enhance model interpretability, it functioned as a post hoc visualization method and did not directly reveal the underlying causal mechanisms driving model predictions. Future research that integrates molecular biomarkers and longitudinal follow-up data may help elucidate the biological basis of model outputs and strengthen their interpretability. Fourth, model performance evaluation was conducted on a single-center dataset and validated only on an internal holdout test set comprising 10% of the cohort. External multicenter validation was not performed. Although cross-validation and regularization techniques were used to reduce overfitting, radiomics models are known to be sensitive to cross-center variations—such as differences in imaging parameters, scanner models, and acquisition protocols—which may lead to substantial domain shift in real-world applications. Future studies should incorporate external datasets from multiple institutions to systematically assess robustness, generalizability, and clinical applicability. Fifth, expert-annotated tumor masks were used in the test set to avoid data leakage; however, this evaluation setup represents an "idealized" condition that does not fully reflect real-world clinical workflows. In practice, errors from automatic segmentation networks may propagate to the Transformer classifier, potentially leading to lower end-to-end performance than the manually masked results reported here. Future work will include validation of a fully automated pipeline and quantitative assessment of how segmentation inaccuracies affect downstream prediction tasks. Sixth, MRI slice thickness varied between 3 mm and 4 mm across patients. Although this study adopted a 2D slice–level modeling strategy, in which the inputs primarily rely on in-plane texture and morphological information, and volumetric resampling along the *z*-axis was intentionally avoided to prevent interpolation-induced artifacts, we acknowledge that differences in slice thickness and spatial resolution may still affect the statistical distributions of intensity and texture features, thereby constituting a potential confounding factor in radiomics-based analyses. We performed patient-level splitting for training, validation, and testing and used data augmentation and cross-validation to mitigate instability arising from acquisition-related heterogeneity; however, such effects cannot be completely eliminated. Future work will further explore standardized resampling strategies or explicit modeling of resolution differences (eg, stratification or covariate adjustment) and will incorporate 3D models and multicenter external validation to systematically evaluate the impact of slice thickness and scanner or protocol variability on model generalizability. Seventh, this study combined CR and PR patients into a single "GR" category to improve class balance, a strategy commonly used in statistical modeling. However, this grouping does not optimally reflect clinical practice: "watch-and-wait" strategies are typically suitable only for patients achieving clinical CR or pCR, whereas PR patients still require further treatment. While the binary classification

XSL•FO
RenderX

framework in this study aimed primarily to demonstrate the DL model's ability to predict overall RT response, future research should investigate multiclass models to enhance clinical interpretability and applicability. Eighth, although the Transformer model demonstrated superior predictive performance compared with CNN and GCN models, this improvement comes at the cost of increased computational burden. Transformers generally require larger parameter counts and higher floating-point computation, with the self-attention mechanism imposing substantial overhead when processing high-resolution image patches. To address this concern, we have supplemented the revised manuscript with a detailed comparison of model parameter counts, FLOPs, and patient-level inference time, thereby quantitatively assessing the computational efficiency of different architectures. The results demonstrate that despite its higher computational cost relative to ResNet-34 and the GCN model, the Transformer maintains a patient-level inference time within the acceptable range for real-time clinical decision support, indicating its practical feasibility for deployment under the current experimental settings. Nevertheless, in larger-scale datasets or resource-constrained clinical environments, model complexity and deployment cost may still pose limiting factors. Future work will therefore explore model compression strategies, such as knowledge distillation, structural pruning, and parameter sharing, to further reduce inference latency and computational resource consumption while preserving predictive performance, thereby enhancing the applicability of the model in real-world clinical workflows.

Future Directions

Future research should aim to extend the application of the Transformer-based radiomics model beyond RC, exploring its transferability and adaptability to other solid tumors such as cervical, lung, and esophageal cancers, in order to evaluate cross-cancer generalizability [15,30]. Another promising avenue involves integrating radiomics with additional data modalities, including genomic, transcriptomic, immunomic, and digital pathology features, to develop comprehensive multimodal fusion models. Such models have the potential to enhance predictive accuracy and provide deeper insights into the biological mechanisms underlying treatment response [21]. Furthermore, the development of lightweight and resource-efficient model versions suitable for deployment on edge devices will be critical for facilitating real-world clinical translation, enabling the routine use of DL-based radiomics models at the point of care to support individualized treatment planning and decision-making.

Conclusions

This study successfully constructed a Transformer-based DL radiomics model for predicting RT sensitivity in patients with RC. The results demonstrate that when using pre-RT MRI features as the primary input, the proposed model achieves superior performance in terms of predictive accuracy, interpretability, and model stability, thereby providing a feasible tool for pretreatment risk stratification and personalized RT decision-making. Supplementary analyses indicate that the multimodal integration of CT and MRI does not yield a statistically significant improvement in overall discriminative performance; however, it may offer a modest and consistent clinical net benefit at specific decision thresholds. Further validation using multicenter datasets is warranted, and future studies should more clearly delineate the potential value of multimodal information across different clinical application scenarios.

Funding

No external financial support or grants were received from any public, commercial, or not-for-profit entities for the research, authorship, or publication of this article.

Disclaimer

No generative AI tools were used in the preparation, writing, analysis, or submission of this manuscript.

Data Availability

To enhance the reproducibility of this study, the complete implementation code, including scripts for data preprocessing, feature extraction, model training, and inference, will be made publicly available on GitHub upon publication. All data processing workflows have been automated and standardized to ensure that external users can replicate the model training process under identical data conditions. Considering patient privacy and institutional policy restrictions, the trained model weight files will be provided only upon reasonable academic request and limited strictly to noncommercial research purposes.

Authors' Contributions

YL and HL contributed equally to this work. YL, HL, and QW designed the study and performed data analysis. ZW and ZH were responsible for data collection and curation. YL developed the deep learning models and conducted experiments. ZH supervised the project and provided critical revisions. All authors contributed to the manuscript writing and approved the final version.

Conflicts of Interest

None declared.

Patient inclusion flowchart for rectal cancer. The flowchart illustrates the inclusion and exclusion process. A total of 2450 patients were screened; 200 were excluded for missing imaging data, 120 for poor image quality, 80 for lack of radiotherapy outcome labels, and 50 for not receiving standard radiotherapy. Ultimately, 2000 patients were included for model analysis, with 1300 classified as radiotherapy-sensitive and 700 as radiotherapy-insensitive based on follow-up evaluations.

Multimedia Appendix 4
Workflow of deep learning model training and validation. This figure illustrates the overall framework of the deep learning analysis pipeline used in this study, including data preprocessing, tumor region segmentation, feature extraction, model training with cross-validation, and performance evaluation. First, preradiotherapy images were cleaned, normalized, and augmented to generate standardized inputs. Subsequently, a U-Net model was used for automatic tumor segmentation, and the resulting masks were used to extract tumor region features from the magnetic resonance images. The Transformer model then performed classification training based on patch embeddings, leveraging multihead self-attention to capture global feature patterns. Five-fold cross-validation was adopted during training to enhance model robustness and generalizability. Finally, performance metrics, including accuracy, sensitivity, specificity, and area under the curve, were computed. This workflow provides a comprehensive overview of the deep learning analysis pathway from raw imaging data to model prediction.

Multimedia Appendix 6
Schematic architecture of the transformer classification model. This figure illustrates the overall workflow of the Transformer-based classification model used to predict radiotherapy response in rectal cancer. First, pretreatment magnetic resonance images are processed using tumor-region masks (masked region of interest). The masked images are then divided into fixed-size 16×16 patches, which are linearly projected to obtain patch embeddings. The model consists of 12 Transformer encoder layers, where multihead self-attention mechanisms capture global contextual features. During classification, a dedicated classification token is passed through a multilayer perceptron (MLP head) to produce the final prediction of radiotherapy response (sensitive vs nonsensitive). This architecture operates exclusively at the image level and does not include any segmentation decoder, remaining fully independent from the U-Net segmentation model used elsewhere in the study.

Abstract

Background: Early life health risks can shape long-term morbidity trajectories, yet prevailing pediatric risk assessment paradigms are often fragmented and insufficiently capable of integrating heterogeneous data streams into actionable, individualized profiles.

Objective: This study aimed to design, implement, and validate an artificial intelligence–driven framework that fuses multimodal pediatric data and leverages advanced natural language processing and ensemble learning to improve early, accurate stratification of key pediatric health risks.

Methods: A retrospective dataset of over 40,000 pediatric participants aged 2 - 8 years was used to train and evaluate the framework. Data were split into training, validation, and test sets (70%, 15%, and 15%, respectively) with a temporally mindful partitioning strategy to approximate prospective evaluation. Baseline comparators included traditional statistical and machine learning models, and the statistical significance of area under the receiver operating characteristic curve (AUC-ROC) differences was assessed using the DeLong test.

Results: The proposed Bidirectional Encoder Representations From Transformers–based model achieved an AUC-ROC of 0.85 (95% CI 0.82 - 0.88), sensitivity of 0.78, specificity of 0.80, and F_1-score of 0.75 on the test set, outperforming multiple baseline models. In an additional manual comparison evaluation, automated and expert assessments aligned with 78% accuracy (78/100), and most discrepancies arose in “equivalent” cases.

Conclusions: This study provides a validated, artificial intelligence–driven, multimodal pediatric health risk stratification framework that translates heterogeneous child health data into clinically actionable risk profiles, demonstrating strong discriminative performance and meaningful agreement with expert assessment. The framework supports proactive, individualized pediatric care and offers a scalable foundation for further validation across broader populations and longitudinal follow-up.

Introduction

The assessment and early identification of health risks in children represent a critical area of research with profound implications for individual lifelong well-being and public health strategies. Establishing healthy developmental trajectories during childhood is fundamental, as health conditions and risk exposures in early life can significantly influence adult health outcomes and susceptibility to chronic diseases [1,2]. Traditional pediatric health surveillance often relies on periodic checkups, which may not fully capture the dynamic and multifaceted nature of health risks influenced by a complex interplay of genetic, environmental, and lifestyle factors [3,4]. Therefore, developing advanced, data-driven methodologies, such as those explored in recent research on artificial intelligence (AI) and machine learning (ML) for tasks like toxicity prediction and broader research applications, to proactively identify and stratify these risks is of paramount importance. Such systems, potentially incorporating guardian-interactive elements, can empower health

XSL•FO
RenderX

care providers and families with actionable insights for timely preventive interventions, ultimately contributing to a healthier future generation and optimizing health care resource allocation [5]. Global health initiatives increasingly emphasize the importance of leveraging innovative technologies, including advanced AI models, such as large language models adapted for specific domains [6], to enhance child health and well-being. The potential for deep learning to enhance diagnostic and prognostic capabilities in areas like child psychiatry further underscores this trend [7].

The rapid popularization of internet-based medical services, including telehealth, mobile health (mHealth) apps, and online consultation platforms, has significantly reshaped health care delivery and accessibility worldwide [8]. This digital transformation has not only provided patients and caregivers with more convenient access to medical advice and health information but also led to the generation of vast amounts of digital health data [9,10]. While much of the initial adoption has been observed in adult care, the principles of leveraging digital platforms for health monitoring, data collection, and remote consultation, often supported by automated systems for tasks like information synthesis [11], are increasingly recognized as valuable in pediatric care. The experience gained from the broader implementation of digital health solutions, including aspects of data security, interoperability, and user engagement, offers important lessons for developing effective and safe digital health tools specifically for children [12,13]. The expanding digital health infrastructure provides a rich ecosystem for collecting diverse health-related data that, if properly managed and ethically used with robust frameworks, can be invaluable for comprehensive risk assessment in pediatric populations [14,15]. Task-oriented dialogue systems, for instance, show potential for structured data gathering in such contexts. Despite progress in pediatric health surveillance, significant clinical voids persist, particularly in the settings of primary care and population health screening. Current risk assessment paradigms are often fragmented, struggling to effectively integrate heterogeneous data streams, such as structured electronic health record (EHR) data, unstructured clinical notes, parental reports, and real-time wearable sensor data, into a single, cohesive risk profile. This leads to a reactive, rather than proactive, approach to care, where risks are often identified only after they have manifested. This research addresses this gap by proposing a framework designed for the following specific end users: (1) pediatricians in primary care, who can use the system for point-of-care decision support; (2) public health officials, who can leverage population-level risk distributions for resource allocation and strategic planning; and (3) clinical care coordinators, who can manage and monitor high-risk pediatric cohorts more effectively.

The increasing availability of EHR data, administrative data, patient-generated health data, and other health-related information sources has fueled the application of health care big data analytics to improve service quality, operational efficiency, and patient outcomes [16-18]. Effective utilization of these data, supported by primers on data handling and the underlying principles of models like Bidirectional Encoder Representations From Transformers (BERT), can support evidence-based clinical decision-making, enhance population health management, facilitate epidemiological surveillance, and enable the development of personalized health care interventions [19]. To enhance clinical utility and facilitate shared decision-making, it is imperative that the reasons behind a child's risk stratification are transparent and interpretable. Shapley additive explanations (SHAP) are used due to their strong theoretical guarantee of consistency and local accuracy, which can provide a unified and reliable framework for model interpretation [20]. For a given prediction, SHAP assigns an importance value (SHAP value) to each input feature, and it is crucial for unlocking its full potential in transforming health care delivery, research, and policy.

AI algorithms can analyze complex, multidimensional datasets to identify subtle patterns, predict the likelihood of various health conditions, and stratify risk earlier and more accurately than traditional statistical methods [20,21]. Researchers have explored various AI-driven systems for health applications. For example, some systems focus on the early detection of developmental disorders using behavioral or imaging data, while others aim to predict adverse outcomes in neonatal intensive care units or identify children at risk for conditions like asthma, obesity, and mental health issues, sometimes using specific BERT-based approaches for analyzing medical records or predicting conditions like Alzheimer disease (AD-BERT), which, while not pediatric, demonstrates domain-specific adaptation [22]. Common approaches in developing such systems involve the curation of large, representative datasets; rigorous data preprocessing and feature engineering; the application of appropriate ML algorithms; and robust model validation using independent test sets and ideally prospective clinical evaluation [23]. For instance, deep learning models have shown promise in analyzing medical images for pediatric conditions, while ensemble methods and sophisticated scoring mechanisms like BERTScore for evaluating text generation quality [24] (analogous to assessing the quality of AI-generated health summaries) are often used to improve the robustness and accuracy of predictive models based on structured EHR data or textual information [25]. The primary contribution of our framework lies in its advanced natural language processing (NLP) capabilities, which distinguish it from prior AI systems in pediatric care that have largely relied on traditional NLP techniques. Methodologies, such as keyword matching, bag-of-words, and term frequency-inverse document frequency models, while useful, are fundamentally limited in their ability to interpret the complex and nuanced narratives found in clinical texts.

Therefore, this study aimed to design, implement, and validate a comprehensive, AI-driven framework for pediatric health risk stratification. We hypothesize that by integrating multimodal data, including EHRs, parental questionnaires, and wearable sensor data, and leveraging advanced NLP and ensemble learning models, our system can identify and stratify key pediatric health risks (eg, obesity and developmental delay) with greater accuracy and at an earlier stage than traditional assessment methods, thereby providing robust support for clinical decision-making and pre-emptive intervention. Methods

Pediatric Health Risk Stratification Framework and Data Foundation

This section addresses the critical, complex, and multifaceted aspects of multimodal data acquisition, encompassing the collection of diverse data types from various sources and the requisite, often intricate, data preparation processes. These preparation stages, including but not limited to data cleaning, normalization, transformation, and feature engineering, are indispensable for effectively fueling the advanced AI models that form the analytical core of this research, ensuring they operate on high-quality, meaningful inputs to generate reliable and actionable insights [29,30]. The overarching goal is to establish robust data and conceptual groundwork upon which sophisticated risk prediction and stratification can be built, ultimately aiming to transform pediatric health care through proactive and personalized interventions. Conceptually, the framework aims to map a complex set of input variables Xdata (representing multimodal pediatric data) through a series of transformations and AI modeling of fAI to an interpretable risk stratification outcome Yrisk :

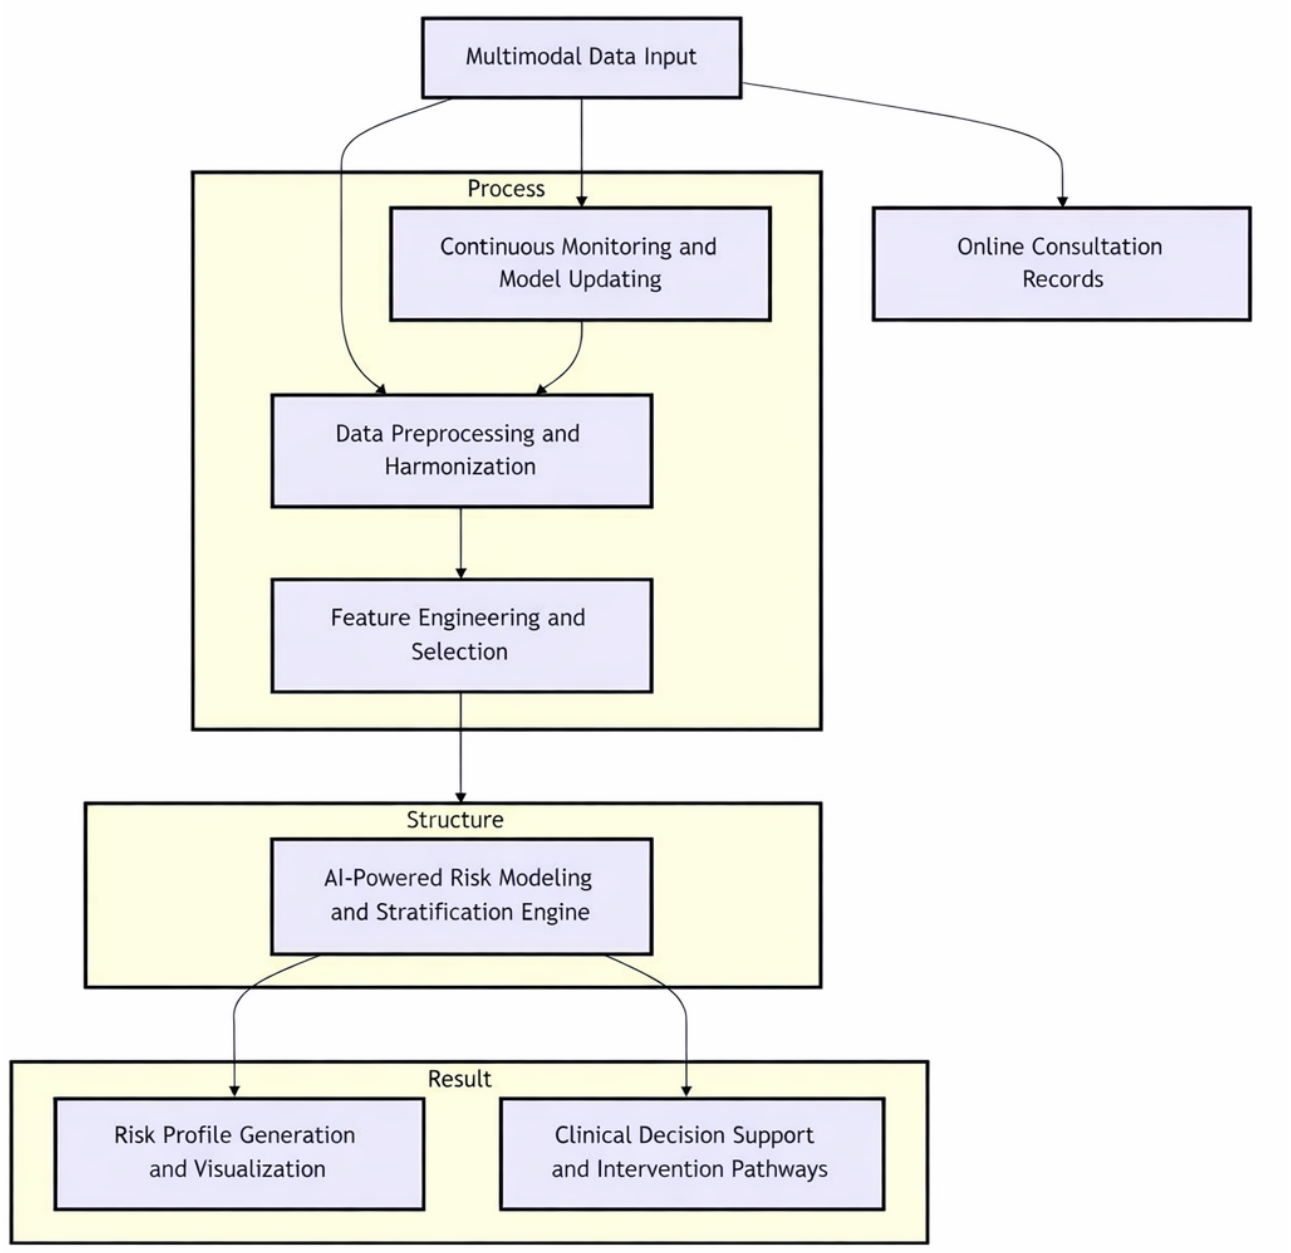
(1)Yrisk=fAI(Preprocessing(Xdata))

This high-level representation underscores the journey from raw data to actionable risk assessment.

Conceptual Framework for Pediatric Risk Stratification

The creation of a robust pediatric health risk stratification system requires a meticulously defined conceptual framework that delineates the core components, their interactions, and the overall data flow. As depicted in Figure 1, the proposed AI-driven framework is architected to be modular, scalable, and adaptable to diverse pediatric health contexts. Its primary objective is to convert raw, multisource pediatric data into actionable risk profiles, thereby facilitating proactive and personalized health care interventions.

Commencing with *multimodal data input*, the framework assimilates a wide array of data sources pertinent to child health. Subsequently, the *data preprocessing and harmonization* layer comes into play. Given the heterogeneity and potential quality issues inherent in real-world pediatric data, such as missing values, inconsistencies, and varying formats from different sources, this layer uses data cleaning, normalization, transformation, and integration techniques to create a unified and analysis-ready dataset.



Next is the *feature engineering and selection* module, which is dedicated to extracting meaningful features from the preprocessed data that are highly indicative of pediatric health risks. This process may involve creating composite variables, transforming existing features, or applying dimensionality reduction techniques to optimize the input for AI models. Domain knowledge from pediatric medicine is crucial in guiding this process to ensure clinical relevance.

At the core of the framework lies the *AI-powered risk modeling and stratification engine*. This engine uses advanced ML algorithms, with a particular focus on ensemble learning techniques, as discussed in the Introduction, to construct predictive models for various pediatric health risks. Trained on historical data, these models learn complex patterns and relationships between input features and health outcomes or risk states. The output of this engine is not merely a binary prediction but a nuanced risk stratification, which may encompass risk scores, probability estimates, or the identification of distinct risk phenotypes. The determination of weights for each data modality is a critical aspect of our ensemble model. Rather than assigning predetermined, fixed weights, our *stacking* framework uses a data-driven approach.

The final layers of the framework are devoted to *risk profile generation and visualization* and *clinical decision support and intervention pathways*. The generated risk profiles are designed to be interpretable by health care professionals and understandable by caregivers, often incorporating visual aids and clear explanations. This output is intended to seamlessly integrate with clinical workflows, offering evidence-based insights to support shared decision-making regarding preventive strategies, further assessments, or targeted interventions. *Continuous monitoring* and *model updating* are also integral to the framework, ensuring that the AI models maintain their accuracy and relevance as new information emerges and clinical knowledge evolves [31].

Identification of Key Pediatric Health Domains and Risk Factors

The primary pediatric health domains identified for this framework, as detailed in Table 2, cover a broad spectrum of child well-being. *Patient safety* focuses on risks, such as adverse drug events and medical errors, typically informed by EHR data and incident reports. *Continuous health monitoring* is crucial, tracking growth parameters and developmental milestones using EHR data and wearable sensor inputs. For children with ongoing conditions, *chronic disease management* addresses factors like glycemic control or asthma exacerbation frequency, primarily using EHR data and home monitoring device information. *Mental health* is a significant domain, evaluating behavioral indicators and emotional well-being via parental, teacher, and direct child assessments. Furthermore, *preventive care* adherence is monitored through risk factors, such as vaccination status and well-child visit compliance, drawing from EHR data and parental questionnaires [32]. The interconnected domains of *nutrition* and *growth* consider risks associated with nutritional intake and growth percentiles, also informed by EHR and parental questionnaire data. Lastly, *physical activity* levels and sedentary behavior duration, identified as critical risk factors, are assessed using wearable sensor data and parental questionnaires.

For each identified health domain, a set of specific, measurable risk factors and associated potential data sources is cataloged. This systematic identification ensures that the subsequent data acquisition and AI modeling efforts are focused and aligned with the goal of comprehensive risk assessment. The dynamic nature of these risk factors across different developmental stages (infancy, early childhood, middle childhood, and adolescence)

XSL•FO
RenderX

is also a key consideration in the framework's design and application.

Table . Key pediatric health domains, associated risk factors, and potential data sources.

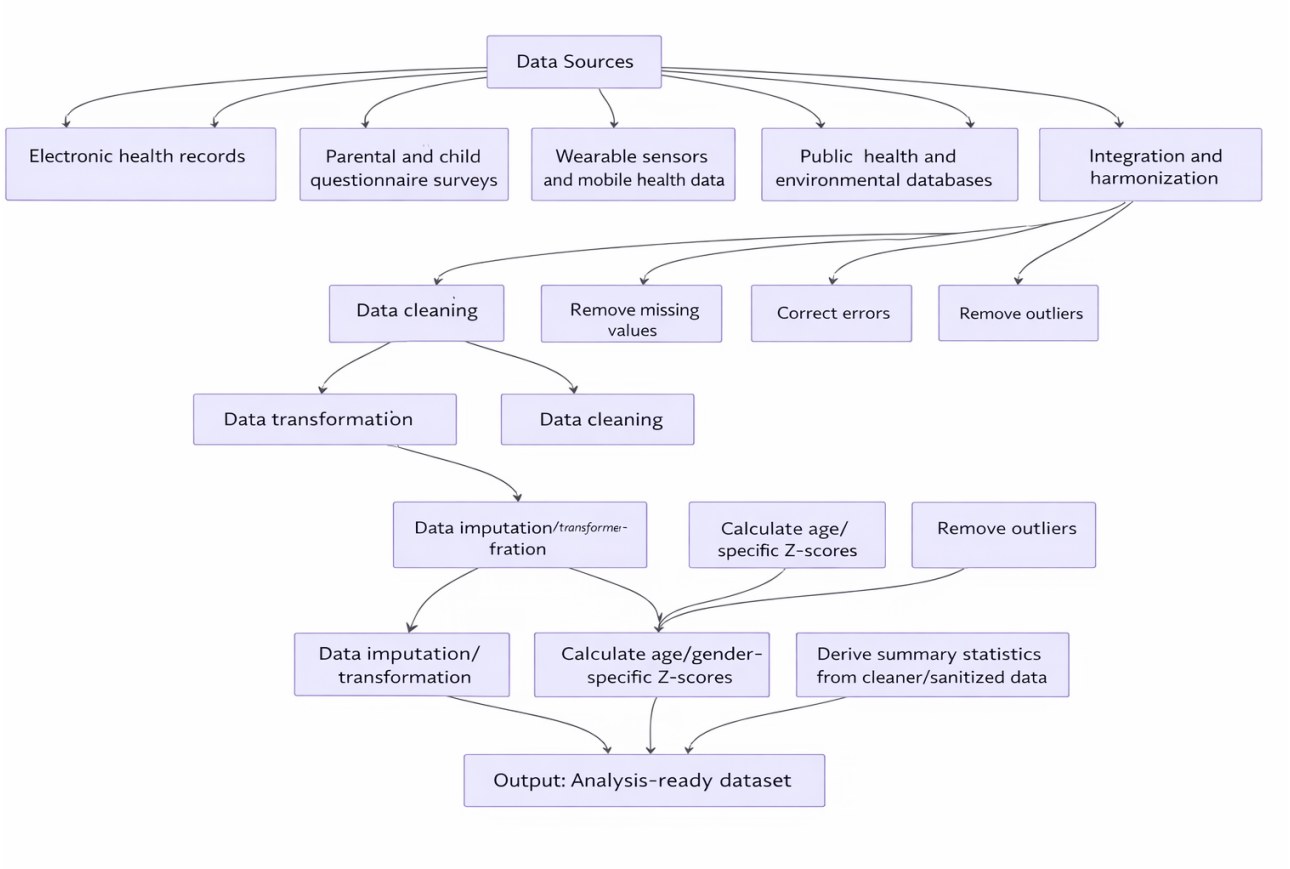
Key pediatric health domains	Associated risk factors	Potential data sources
Patient safety	Adverse drug events and medical errors	EHR[a] data and incident reports
Health monitoring	Growth parameters and developmental milestones	EHR data and wearable sensor data
Chronic disease management	Glycemic control and asthma exacerbation frequency	EHR data and home monitoring devices
Acute illness severity	Fever severity and respiratory distress indicators	EHR data and parental questionnaire responses
Mental health	Behavioral indicators and emotional well-being	Parental and teacher assessments, and direct child assessments
Preventive care	Vaccination status and well-child visit adherence	EHR data and parental questionnaire responses
Nutrition and growth	Nutritional intake and growth percentiles	EHR data and parental questionnaire responses
Physical activity	Activity levels and sedentary behavior duration	Wearable sensor data and parental questionnaire responses

[a]EHR: electronic health record.

Multimodal Data Acquisition and Preparation

The effectiveness of the AI-driven risk stratification framework is fundamentally dependent on the availability of comprehensive, high-quality, multimodal data that accurately reflect the various factors influencing child health. This section details the strategies for acquiring and preparing such data for input into the framework, emphasizing the critical importance of ethical considerations, including informed consent, data privacy, and security, in full compliance with relevant regulations, such as the General Data Protection Regulation (GDPR) and Health Insurance Portability and Accountability Act (HIPAA), adapted for pediatric populations.

The data sources for this framework are inherently multimodal, encompassing a variety of information types. EHRs serve as a primary source, offering longitudinal clinical data that include diagnoses (ICD codes), procedures, medications, laboratory results, growth chart data, and clinical notes. Access to both structured and unstructured EHR data is essential. *Parental and child questionnaires or surveys* are used to capture information often not systematically recorded in EHRs, such as detailed family history, socioeconomic status, lifestyle factors (diet, physical activity, and sleep), environmental exposures, and patient-reported outcomes or symptoms. *Wearable sensors and mHealth data* provide opportunities for continuous, real-world monitoring of physiological parameters (eg, heart rate, activity levels, and sleep patterns) and behavioral data. *School health records* can contribute information on immunizations, health screenings conducted at school, and potentially attendance or behavioral notes relevant to health [33]. *Public health and environmental databases* can offer community-level data on factors like air quality, neighborhood socioeconomic indicators, and access to health care or recreational facilities. *Genomic data*, when applicable and ethically sourced, can provide valuable genetic risk scores or specific genetic markers associated with pediatric conditions.



The data preparation pipeline, illustrated in Figure 2, involves several key steps to transform raw, multimodal data into an analysis-ready dataset. Initially, data from disparate sources must undergo integration and harmonization. This process includes mapping data elements to common terminologies, resolving inconsistencies, and creating a unified data schema. Data cleaning is then performed to address missing values, correct errors, and remove outliers. Data transformation may be necessary to convert raw data into formats suitable for analysis, such as calculating age-specific *z* scores for growth parameters or deriving summary statistics from time-series sensor data. For instance, if xraw is a raw measurement and μage,sex and σage,sex are the age- and sex-specific mean and SD, respectively, from a reference population, the *z* score can be calculated as follows:

$$z = x_{raw} - \mu_{age,sex} \sigma_{age,sex}$$

This normalization is crucial for enabling comparisons of measurements across different age groups and sexes. Finally, data anonymization or pseudonymization is rigorously applied to protect patient privacy before the data are used for model development. The resulting dataset provides the foundation for the feature engineering and AI modeling stages described in the subsequent part.(2)

XSL•FO
RenderX

Figure 2. Multimodal data acquisition and preparation pipeline.

Data Preprocessing and Feature Engineering

The integrity and utility of input data are paramount to the performance and clinical relevance of any AI model, particularly in the pediatric domain, where data can be sparse, longitudinal, and highly variable due to growth and development. Pediatric health data, often derived from multiple heterogeneous sources, such as EHRs, parental questionnaires, school health notes, and wearable sensors, typically present unique challenges, including systematically missing values (eg, developmental assessments not performed at certain ages), measurement noise (eg, variability in home-based measurements), and the presence of irrelevant or redundant information that can obscure true risk signals. Therefore, rigorous data preprocessing and thoughtful, domain-informed feature engineering are indispensable steps to prepare a high-quality dataset for subsequent AI modeling.

The initial phase of preprocessing involves comprehensive data cleaning. Missing data represent a pervasive issue in longitudinal pediatric health care datasets. For instance, growth parameters or developmental screening results might be missing for specific well-child visits. While simple imputation techniques like mean, median, and mode imputation can be applied for variables with a low percentage of missingness and random patterns, they often fail to capture the underlying data structure in pediatric cohorts. More sophisticated methods are typically required, such as k-nearest neighbors imputation, which identifies the k most similar pediatric cases (based on a suite of other observed features) and imputes the missing value for a feature Xj using a weighted average or majority vote from the neighbors [34]. Alternatively, model-based imputation, using algorithms like multivariate imputation by chained equations (MICE), can be used. MICE iteratively models each variable with missing values as a function of other variables in the dataset, cycling through variables until convergence is achieved. For a set of variables X1,…,Xp, MICE specifies a conditional model PXj ∣ X-j,φj for each Xj and iteratively samples from these conditional distributions.

Outlier detection and appropriate treatment are also critical in pediatric data, where extreme values might represent genuine clinical concern or measurement error. Statistical methods, such as the *z* score and IQR, are used. For a data point xi in a feature distribution, its *z* score is calculated as zi=(xi−μ)/σ, where μ is the mean and σ is the SD. Data points with |zi|>θoutlier may be flagged. The IQR method defines outliers as points falling below Q1-1.5×IQR or above Q3+1.5×IQR, where Q1 and Q3 are the first and third quartiles, respectively, and IQR=Q3-Q1. Decisions on handling outliers (removal, transformation, or winsorization) are made cautiously, considering the potential clinical significance of extreme values in child health.

Feature engineering in the pediatric context is a highly domain-driven process focused on creating new, informative features from raw data to capture developmental trajectories, critical exposure periods, and clinically relevant interactions. This enhances model performance and interpretability. In child health, this includes deriving age- and sex-adjusted *z* scores for growth parameters, such as height, weight, BMI, and head circumference, based on standardized pediatric growth charts like World Health Organization (WHO) and Centers for Disease Control and Prevention (CDC) growth standards. It also involves

XSL•FO
RenderX

creating features like developmental velocity, calculated as ΔD/Δt=Dt2-Dt1/t2-t1, reflecting the rate of change in developmental milestone scores between assessments. Additionally, it covers quantifying cumulative exposure to risk factors, such as days with poor air quality and screen time during early childhood, generating features for adherence to pediatric guidelines like vaccination completeness and well-child visit schedules, and creating interaction terms reflecting synergistic effects in child health, such as genetic predispositions interacting with environmental exposures.

To reduce dimensionality, mitigate the risk of overfitting (especially with potentially limited sample sizes in specific pediatric subpopulations), and improve model training efficiency and interpretability, various feature selection techniques are used. These are broadly categorized into filter methods, wrapper methods, and embedded methods. Filter methods evaluate features independently of the AI model, using statistical measures relevant to pediatric outcomes, such as the chi-square test for assessing associations between categorical risk factors (eg, maternal smoking during pregnancy) and a binary child health outcome, and the ANOVA *F* value for assessing the relationship between numerical predictors (eg, birth weight) and different risk groups. Wrapper methods, such as recursive feature elimination, use the performance of a specific AI model to iteratively build and evaluate models with different subsets of features. Embedded methods perform feature selection as an integral part of the model training process. For instance, tree-based algorithms like random forest and gradient boosting inherently provide feature importance scores based on how much each feature contributes to reducing impurity or error across the ensemble of trees. Regularization techniques, such as L1 regularization (Lasso), are particularly useful. The Lasso objective function for a linear model predicting a child's health outcome y based on features X and coefficients β is as follows:

$$(3) LLasso=\sum i=1n\ (yi-\beta 0-\sum j=1p\ xij\beta j)2+\lambda \sum j=1p\ |\beta j|$$

where λ is the regularization parameter that controls the penalty on the sum of absolute values of the coefficients, effectively shrinking less important feature coefficients to zero. The selection of λ is typically done via cross-validation.

To provide an overview of the preprocessing pipeline and feature engineering strategies across different data modalities, the key steps are summarized in Table 3.

Table . Summary of pediatric data preprocessing steps and feature engineering strategies.

Data type	Preprocessing methods	Feature engineering	Examples
Growth indicators	Missing data imputation (KNN[a] and MICE[b])	*z* score calculation and velocity features	Age- and sex-adjusted *z* scores
Early exposure	Outlier detection (*z* score and IQR)	Cumulative exposure and interaction terms	Poor air quality days and screen time
Questionnaires	Data cleaning and encoding	One-hot encoding and label encoding	Vaccination scores and visit adherence
School records	Data integration	Feature extraction	Immunization records and attendance
Wearables	Noise reduction and smoothing	Activity patterns and sleep metrics	Activity levels and sleep duration
Genomics	Data anonymization	Genetic risk scoring	Genetic predispositions

[a]KNN: k-nearest neighbors.

[b]MICE: multivariate imputation by chained equations.

Risk Stratification Algorithm

The process of risk stratification involves translating the continuous risk probabilities or composite risk scores generated by AI models into distinct, actionable risk categories that are meaningful in a clinical context. This is achieved by defining specific thresholds that convert model outputs into discrete risk strata. The thresholds are determined through a combination of clinical expertise, statistical methods, and decision theory principles, ensuring they are both clinically relevant and statistically valid. P(Risk / Xchild) represents the feature vector for a specific child. For a 4-tier stratification system, the risk categories can be defined as follows:

- Low risk: P(Risk /Xchild)<θ1
- Moderate risk: θ≤P(Risk / Xchild)<θ2
- High risk: θ2≤P(Risk / Xchild)<θ3
- Very high risk: P(Risk / Xchild)≥θ3

The selection of the thresholds θ1,θ2,θ3 is guided by clinical expertise, statistical methods, and decision theory. Pediatric specialists define thresholds based on established clinical guidelines, acceptable risk levels for specific age groups, and the availability and efficacy of preventive interventions. Statistical methods, such as using percentiles of the predicted risk distribution in a well-characterized pediatric reference population, can also be used. For example, thresholds might be set to correspond to the 50th, 80th, and 95th percentiles of this distribution. Decision theory principles can further refine threshold optimization by considering a utility function that balances the costs and benefits associated with true positives, false positives, true negatives, and false negatives. This might involve analyzing metrics like Youden J statistic (J=sensitivity+specificity−1) or finding points on the precision-recall curve that correspond to desired tradeoffs for pediatric screening or intervention programs.

XSL•FO
RenderX

When the system is designed to predict multiple distinct health risks for a child, such as the risk of obesity, developmental delay, or asthma exacerbation, the framework requires a mechanism to present these risks in a consolidated and understandable manner. This can be achieved by either displaying the stratified risk level for each condition independently or by developing a composite pediatric health vulnerability index (CPHVI). The CPHVI is calculated by assigning weights wi to each risk score *S*(Ri) based on factors, such as the clinical severity of risk Ri, its impact on long-term child development, its prevalence in the target pediatric population, and its responsiveness to an intervention. To translate the CPHVI into clinical practice, we propose a tiered intervention model based on predefined, clinically meaningful thresholds developed in collaboration with pediatric experts. For example, a CPHVI score exceeding a "high risk" threshold could automatically trigger an alert in the EHR system for the primary care physician, along with a recommendation for a direct referral to a relevant specialist. The formula for the CPHVI is as follows:

$$(4)\text{SCPHVI}=\sum i=1\text{N wi}\cdot\text{S(Ri)}\sum i=1\text{N wi}$$

The determination of the weights wi is a complex task, often requiring expert consensus or data-driven approaches. Another advanced approach involves using unsupervised learning techniques, such as clustering algorithms, applied to the vector of predicted individual risk probabilities for each child. This can help identify common co-occurring risk patterns or distinct pediatric subphenotypes that share similar multirisk profiles, guiding more tailored multifaceted interventions.

To enhance clinical utility and facilitate shared decision-making with families, the reasons behind a child's stratification into a particular risk category must be as transparent and interpretable as possible. Techniques, such as SHAP and Local Interpretable Model-Agnostic Explanations (LIME), are used. For a given prediction f(Xchild), SHAP assigns an importance value (SHAP value, φj) to each input feature j, representing its marginal contribution to pushing the prediction away from a baseline. The sum of SHAP values for all features plus the baseline prediction equals the model's output for that child:

$$(5)\text{fXchild} =\varphi 0+\sum j=1\text{M }\varphi j$$

This allows clinicians to understand which specific factors (eg, low birth weight, specific dietary patterns, and lack of physical activity) are most influential in determining a child's assessed risk level, thereby guiding targeted advice and interventions.

BERT-Based Knowledge Extraction and NLP Modeling

BERT-based NLP is used to extract informative representations from unstructured pediatric clinical text (eg, consultation records, clinical notes, and parental narratives), which are subsequently used as input features for pediatric health risk stratification models.

Pediatric medical journals serve as a vital source of pediatric disease knowledge, encompassing a wealth of information on pediatric diseases, including clinical symptoms, diagnostic methods, treatment approaches, and prognoses. These journals are written by pediatric experts and researchers and are based on extensive clinical practice and scientific research. They contain detailed case studies, research findings, and expert opinions, providing a solid foundation for the extraction and application of pediatric disease knowledge. The knowledge derived from these journals can help health care professionals better understand the characteristics and progression of pediatric diseases, thereby improving the quality of pediatric health care services [14].

The pediatric disease knowledge base is a structured repository that integrates information from pediatric medical journals and other authoritative sources. It includes various aspects of pediatric diseases, such as disease names, symptoms, signs, laboratory test results, imaging findings, treatment methods, and prognoses. This knowledge base is designed to provide comprehensive and accurate information on pediatric diseases, supporting clinical decision-making and research. By organizing and structuring the information from pediatric medical journals, the pediatric disease knowledge base enables efficient retrieval and utilization of pediatric disease knowledge, facilitating the application of this knowledge in clinical practice and research.

The process begins with the ingestion of pediatric medical journal data into our system. These textual data, rich in pediatric disease knowledge, undergo meticulous preprocessing to align with BERT's input requirements. The text is tokenized into a sequence of tokens [T1,T2,…,Tn], where each Ti represents a word or subword unit. Additionally, the pediatric disease knowledge base is incorporated to enhance the model's understanding of pediatric medical concepts. BERT's architecture consists of multiple transformer encoder layers, each equipped with self-attention mechanisms. The input tokens, enriched with special markers like [CLS] and [SEP], pass through these layers, generating a matrix of contextualized embeddings z={z1,z2,…,zn}. These embeddings capture intricate semantic relationships and contextual information within the text, forming the basis for subsequent knowledge extraction tasks.

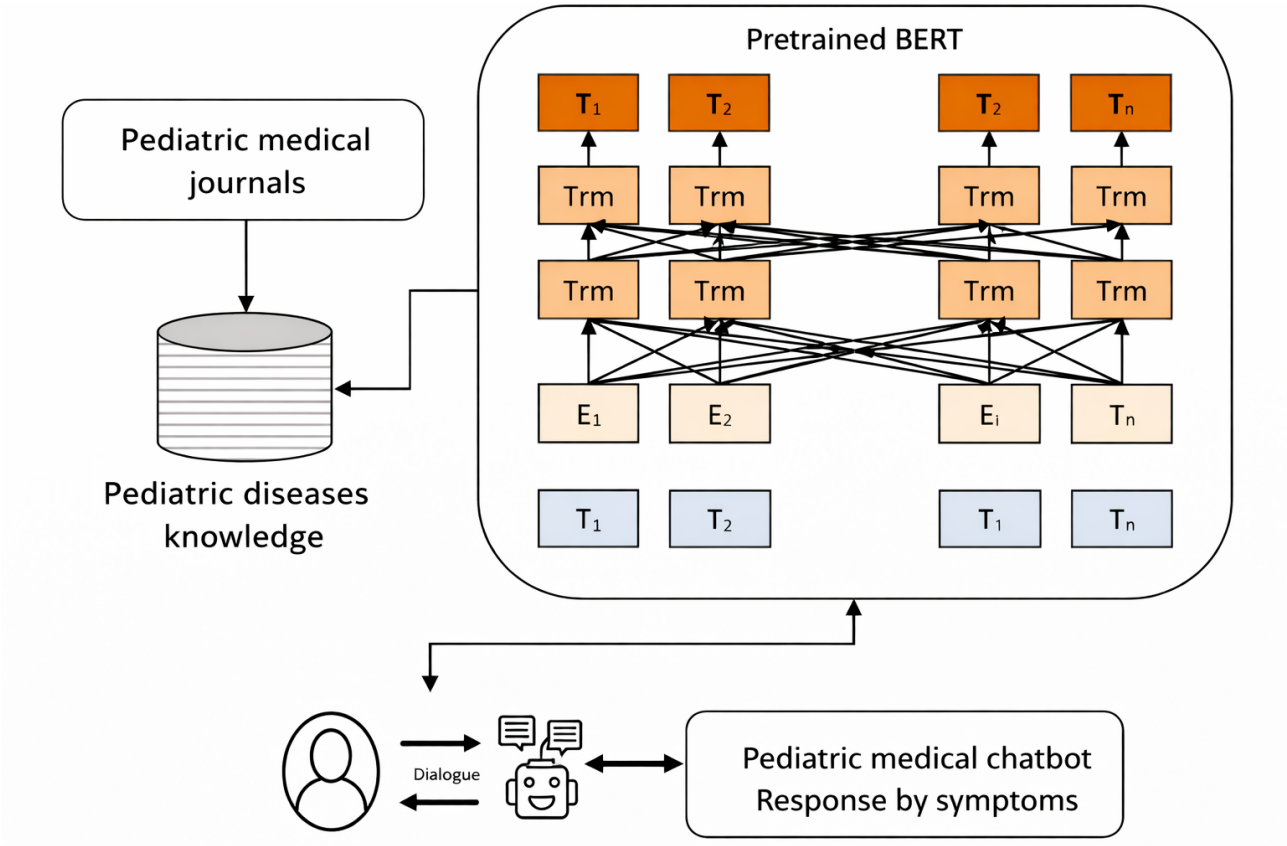
To identify key pediatric disease entities and their relationships within the text, named entity recognition and relation extraction techniques are applied to the BERT-generated embeddings. For named entity recognition, a linear layer combined with a conditional random field is used. The conditional random field loss function is defined as follows:

$$(6)\text{LNER}=-1\text{N}\sum i=1\text{NlogP(yi} \mid \text{Xi)}$$

where N is the number of samples and Pyi ∣ Xi is the probability of the true label sequence yi given the input sequence Xi. For relation extraction between entities, a classifier is trained using a cross-entropy loss function as follows:

$$(7)\text{LRE}=-\sum i=1\text{M }\sum j=1\text{C yi,jlogy}\hat{}\text{i,j}$$

where M represents the number of entity pairs, C is the number of relation types, and yi,j and y^i,j are the true and predicted probabilities for relation *j* between the entity pair *i*, respectively. The extracted entities and relationships are then integrated into the pediatric disease knowledge base. This knowledge base, enriched with entities and relationships from pediatric medical literature, serves to enhance a medical chatbot's responses. When users input symptoms, the chatbot leverages this



XSL•FO
RenderX

knowledge base to generate accurate and contextually relevant diagnostic suggestions and risk assessments.

Figure 3 illustrates a comprehensive workflow where BERT's robust language understanding capabilities are harnessed to extract valuable pediatric disease knowledge from medical texts. This knowledge is subsequently used to empower a medical chatbot, enabling it to deliver precise and informative responses to user inquiries regarding pediatric symptoms. The integration of BERT with pediatric medical journals and a pediatric disease knowledge base provides a powerful tool for advancing pediatric health care through improved diagnostic accuracy and personalized treatment recommendations.

Our knowledge extraction module is built upon BioBERT, a pretrained language model optimized for the biomedical domain. We chose BioBERT as our base model due to its demonstrated strong performance on various biomedical text mining tasks. For fine-tuning, we used a domain-specific corpus comprising over 50,000 articles from leading pediatric medical journals and over 100,000 deidentified clinical notes. The model was fine-tuned for 5 epochs with a learning rate of $2e^{-5}$. The performance of our fine-tuned model on key NLP tasks was rigorously evaluated on a manually annotated test set of 500 clinical notes, which were dual-annotated by pediatric domain experts to ensure quality.

BERT: Bidirectional Encoder Representations From Transformers.

System Architecture Design

The successful deployment, scalability, and usability of the AI-driven pediatric health risk stratification framework critically depend on a meticulously planned and well-engineered system architecture. This architecture must robustly support efficient multimodal data processing pipelines; reliable and timely execution of complex AI models; secure and compliant management of sensitive pediatric health data; and an intuitive, actionable interface for diverse end users, including pediatricians, specialist clinicians, public health officials, researchers, and potentially, with appropriate safeguards, parents or caregivers. A multitier, service-oriented architecture is proposed to ensure modularity, maintainability, and scalability. This typically comprises the following tiers:

1. Data tier: This foundational tier is responsible for the persistent storage and comprehensive management of all relevant pediatric health data. This includes raw input data from diverse sources (EHRs, wearables, and questionnaires), preprocessed and feature-engineered datasets, trained AI models (including their versions and metadata), generated risk profiles for individual children, and audit logs. This tier would likely involve a hybrid database strategy, combining relational databases (MySQL) for structured metadata, patient demographics, and well-defined clinical entities, with potentially NoSQL databases for handling large volumes of heterogeneous, unstructured, or streaming data (like continuous sensor readings). Robust data governance, backup, and recovery mechanisms are integral.
2. Application logic tier (backend services): This is the computational core of the system, housing the data

XSL•FO
RenderX

preprocessing pipelines, sophisticated feature engineering modules, the AI model inference engine, and the risk stratification algorithms. It handles all computational tasks, business logic for risk assessment, and interactions with the data tier. This tier would be developed using scalable and efficient programming languages and appropriate backend frameworks. It may be implemented as a set of microservices to enhance scalability and independent deployability of different functionalities.

3. Presentation tier (frontend interfaces): This tier provides the user interface and user experience for interacting with the system. This could manifest as a secure web-based application accessible via standard browsers, designed with responsive layouts for use on various devices. For specific user groups like parents or children (with age-appropriate design), a dedicated mobile app might be considered. The frontend allows authorized users to view individualized pediatric risk stratification results, explore interactive visualizations of risk factors and trends, access evidence-based decision support information or guideline recommendations, and potentially (for clinicians) trigger further diagnostic or intervention pathways.

Key functional system modules are designed to support the end-to-end pediatric risk stratification process (Figure 4).

1. Pediatric data ingestion and management module: It securely handles the import of data from diverse, often disparate, pediatric health information systems and sources. It performs initial data validation and schema mapping and manages data storage, versioning, and provenance tracking, which are crucial for longitudinal pediatric studies.
2. Preprocessing and pediatric feature engineering module: It implements complex algorithms described in the preceding section, tailored for pediatric data. This module needs to be highly configurable and extensible to accommodate new data types, evolving pediatric clinical knowledge, or updated feature definitions.
3. AI model execution and management engine: It loads versioned, trained AI models and performs inference on new or updated pediatric patient data to generate risk predictions. This engine must be optimized for performance and scalability, especially if real-time or near real-time risk assessment is required for acute pediatric conditions. It also manages the model lifecycle, including retraining triggers and performance monitoring.
4. Pediatric risk stratification and profiling module: It implements the sophisticated algorithms from the preceding section to convert raw model outputs into clinically interpretable risk strata and comprehensive, multidimensional pediatric risk profiles, potentially including age-adjusted interpretations.
5. Reporting, visualization, and alerting module: It generates customized reports, interactive dashboards (eg, showing population-level pediatric risk distributions and trends over time for specific age cohorts), and dynamic visualizations (eg, individual child risk timelines and feature importance charts for specific predictions). It may also include an alerting mechanism for clinicians when a child's risk profile crosses critical, predefined thresholds.
6. User authentication, authorization, and audit module: It ensures secure, role-based access to the system and its sensitive pediatric data, adhering strictly to privacy regulations (eg, HIPAA, GDPR, and Children's Online Privacy Protection Act [COPPA]). Comprehensive audit trails of data access and system actions are maintained.
7. Interoperability layer (application programming interfaces [APIs]): It provides well-defined APIs, possibly using standards like Fast Healthcare Interoperability Resources, to allow secure data exchange and interaction with other clinical systems (eg, pediatric EHRs, laboratory information systems, and clinical decision support tools embedded in existing workflows).

The data flow within the system begins with secure data ingestion from multiple sources into the *data tier*. The *application logic tier* then orchestrates the preprocessing and feature engineering pipelines. The processed features are subsequently fed into the *AI model execution engine* for risk prediction. These predictions are passed to the *risk stratification and profiling module*, and the final, interpretable pediatric risk profiles are stored and made available for secure access and visualization through the *presentation tier* or via the *API layer*. The technology stack will be carefully chosen based on criteria, such as scalability for large pediatric populations, real-time performance requirements, security mandates for child data, ease of development and maintenance, and compatibility with existing health care IT infrastructure. This might include Python with libraries like Pandas, NumPy, Scikit-learn, TensorFlow/Keras, and PyTorch for AI or ML development; web frameworks, such as Django/Flask (Python), Spring Boot (Java), and Node.js, for the backend services; modern JavaScript frameworks like React, Angular, and Vue.js for building responsive and interactive frontend interfaces; and a combination of SQL and NoSQL databases as described for the *data tier*. Containerization technologies like Docker and orchestration tools like Kubernetes may be used for deployment and scaling.

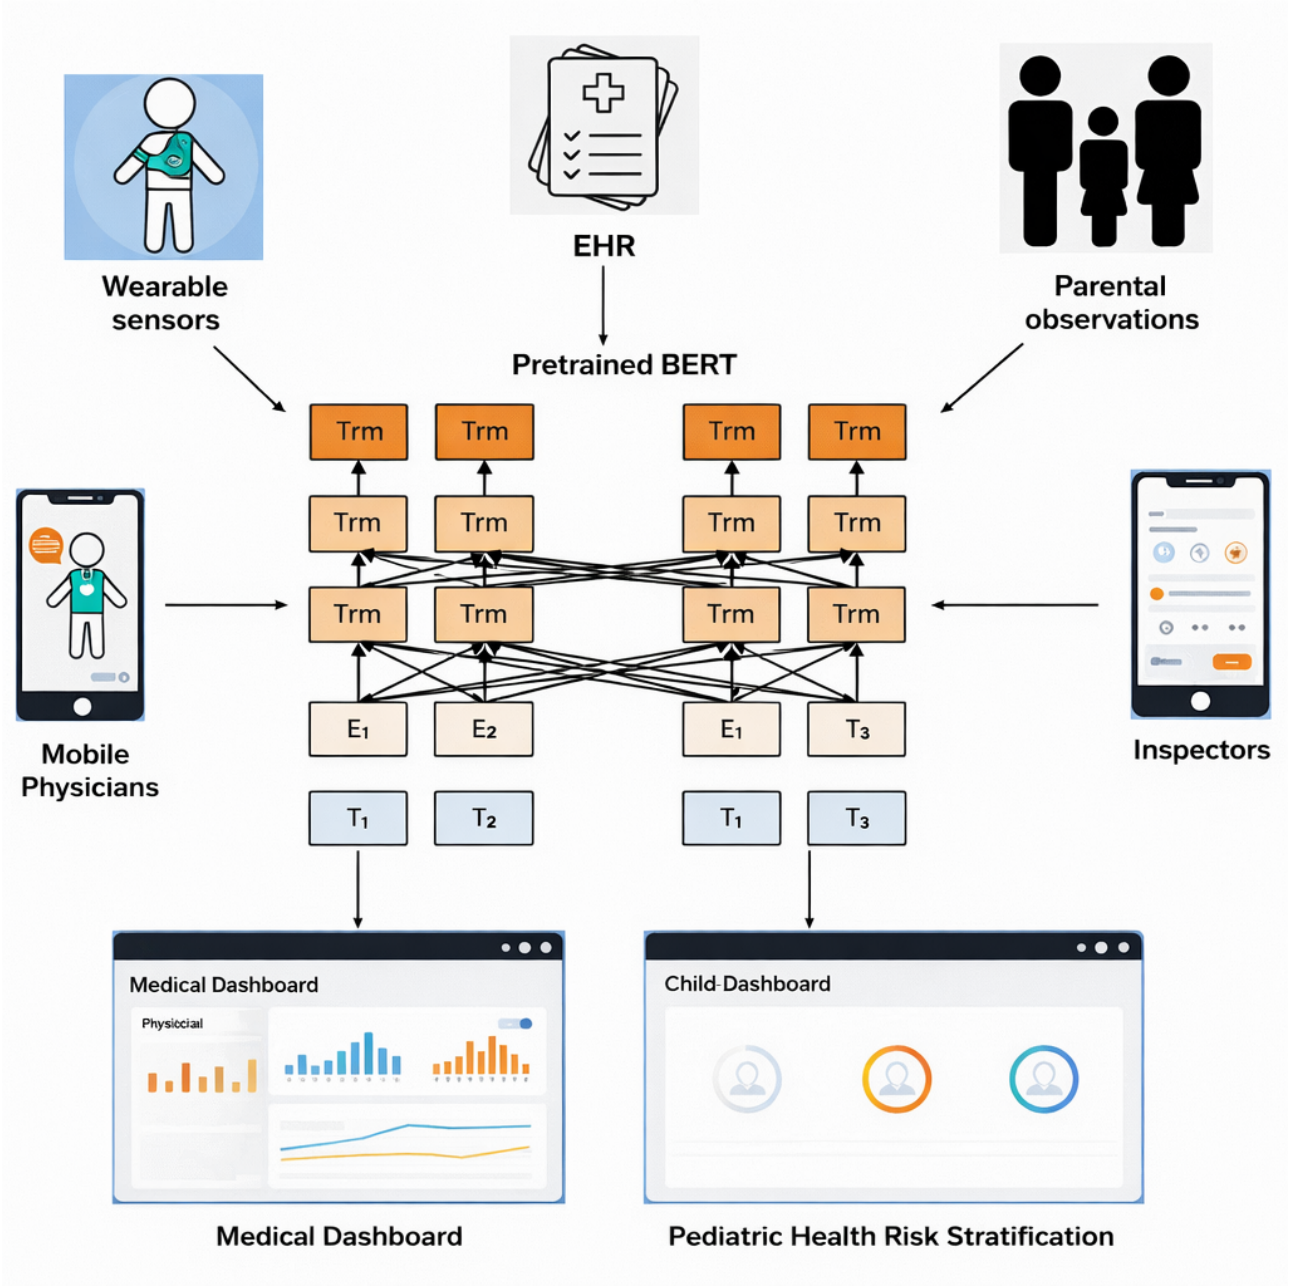
Prototype System Implementation

The pediatric health risk stratification prototype system integrates multisource data input with advanced AI models to deliver a comprehensive risk assessment platform. As illustrated in Figure 5, the system collects diverse data types, including patient demographics, clinical records, and parent-reported outcomes, which serve as the foundation for subsequent analysis and risk assessment. This integration ensures a holistic view of pediatric health, enabling more accurate and nuanced risk predictions.



At the core of the system is a pretrained BERT model, specifically fine-tuned to handle pediatric health terminology and context. The model processes input text data through multiple Transformer modules, which encode the text to capture complex linguistic patterns and semantic relationships. Feature extraction layers then distil these encoded representations into risk-relevant features. These features are passed to risk assessment components where the actual risk stratification takes place, transforming raw data into actionable insights regarding children's health risks.

The system's implementation leverages a robust technology stack to ensure efficiency, scalability, and user-friendliness. The backend, developed using Python and its rich library ecosystem, handles data processing and model execution. It uses microservices, potentially orchestrated by lightweight frameworks like Flask, to manage distinct functionalities such as data ingestion, preprocessing, and model inference. Data storage follows a hybrid approach, combining PostgreSQL for structured data with MongoDB for unstructured or semistructured content. The frontend, built with modern JavaScript frameworks, offers tailored interfaces for different users, including physicians and parents. It includes features like risk profile visualizations and population-level risk trend dashboards. Docker is used for containerization to ensure smooth deployment and scalability of the application components.

To illustrate the practical utility of the framework, consider a hypothetical clinical scenario. Dr Smith, a pediatrician, begins her day by logging into the system's dashboard. The system flags one of her patients, a 5-year-old child, for a significant increase in the composite risk score for developing obesity. Dr Smith clicks on the patient's profile and is presented with an interactive, multimodal dashboard. An explainable AI feature, using SHAP values, highlights the primary contributing factors: a recent decrease in physical activity levels captured by wearable data and parent-reported dietary logs indicating high consumption of processed foods. Based on these insights, the system provides Dr Smith with evidence-based, actionable recommendations, including a referral to a pediatric nutritionist and a set of tailored educational materials for the parents. This scenario demonstrates how the framework can transform raw data into clinically actionable insights to facilitate timely and personalized preventive care.

Experimental Setup

The primary dataset used for training and validating the AI models included data from over 40,000 pediatric participants, with an age range of 2 to 8 years at the time of data collection or follow-up. The dataset was partitioned into 3 mutually exclusive sets: a training set (70% of the data), a validation set (15%), and an independent holdout test set (15%). To ensure temporal validity if longitudinal data were used, the split was performed such that data from earlier time periods were used for training and validation, while data from later periods were reserved for testing, mimicking a prospective evaluation.

To benchmark the performance of the proposed AI-driven framework, a selection of robust baseline models was implemented and rigorously evaluated on an identical dataset and predictive task. These comparators included established traditional statistical models frequently used in pediatric risk prediction, specifically logistic regression for binary risk outcomes, where the probability of risk $P(Y=1 \mid X)$ is modeled as $P(Y=1 \mid X)=(1+e-(\beta 0+\sum i=1p \beta iXi))-1$, and Cox proportional hazards models in scenarios where time-to-event data for risk onset were available. Furthermore, simpler yet effective ML algorithms, namely support vector machine (SVM), configured with various kernels (linear and radial basis function), and standard single decision trees, were also incorporated as baselines. In instances where existing, validated pediatric risk scores or established rule-based systems were pertinent to the specific health outcomes under investigation and applicable to the dataset, these were also included in the comparative analysis to provide a comprehensive performance context. To rigorously

XSL•FO
RenderX

assess the statistical significance of our model's superior performance, we used the DeLong test to compare the area under the receiver operating characteristic curve (AUC-ROC) of our proposed model with that of each baseline model.

Ethical Considerations

This study involved research with human participants. The study protocol was reviewed and approved by the Institutional Review Board and Research Ethics Committee of Hunan University of Arts and Science (HUAS-20250504). All procedures were performed in accordance with the ethical standards of the responsible institutional committee and with the principles of the Declaration of Helsinki. Informed consent was obtained from all participants prior to their inclusion in the study. Participants were fully informed about the purpose of the study, the procedures involved, and their right to withdraw at any time without penalty. The privacy and confidentiality of all participants were strictly maintained throughout the study. All data were anonymized prior to analysis, and no personally identifiable information was collected, stored, or reported. No financial or material compensation was provided to participants for their participation in this study.

Results

This section reports the empirical performance of the proposed AI-driven pediatric health risk stratification framework evaluated on the independent test set, in comparison with multiple baseline models.

Table 4 summarizes the predictive performance of the proposed model and baseline methods across targeted pediatric health risks. The proposed model achieved an AUC-ROC of 0.85 (95% CI 0.82 - 0.88), an area under the precision-recall curve of 0.70 (95% CI 0.65 - 0.75), a sensitivity of 0.78, a specificity of 0.80, and an F_1-score of 0.75. In comparison, logistic regression, SVM, random forest, gradient boosting, and a conventional deep learning model yielded lower AUC-ROC and F_1-score values.

Table . Key performance metrics of the proposed artificial intelligence model and baseline models for targeted pediatric risks in the test set.

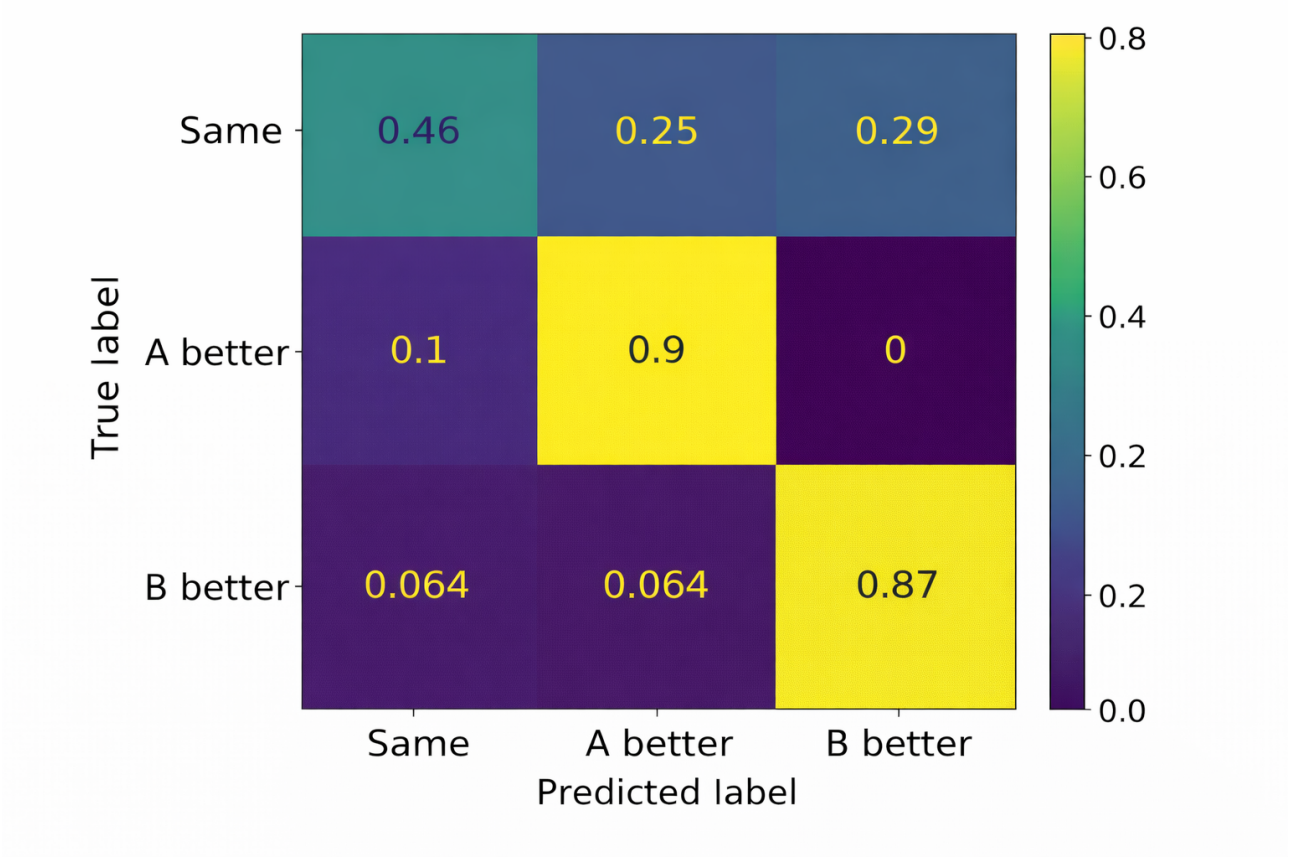
Model name	AUC-ROC[a], value (95% CI)	AUC-PR[b], value (95% CI)	Sensitivity	Specificity	F_1-score	Brier score
Proposed BERT[c] model	0.85 (0.82 - 0.88)	0.70 (0.65 - 0.75)	0.78	0.80	0.75	0.15
Logistic regression	0.72 (0.68 - 0.76)	0.60 (0.55 - 0.65)	0.65	0.70	0.62	0.20
SVM[d]	0.75 (0.71 - 0.79)	0.65 (0.60 - 0.70)	0.70	0.72	0.66	0.18
Random forest	0.78 (0.74 - 0.82)	0.67 (0.62 - 0.72)	0.72	0.75	0.69	0.17
Gradient boosting	0.80 (0.77 - 0.83)	0.69 (0.64 - 0.74)	0.75	0.76	0.72	0.16
Deep learning	0.83 (0.80 - 0.86)	0.72 (0.67 - 0.77)	0.76	0.79	0.74	0.14

[a]AUC-ROC: area under the receiver operating characteristic curve.

[b]AUC-PR: area under the precision-recall curve.

[c]BERT: Bidirectional Encoder Representations From Transformers.

[d]SVM: support vector machine.



The DeLong test demonstrated that the AUC-ROC of the proposed model was significantly higher than that of each baseline model (all $P<.05$). Paired t tests on F_1-scores similarly indicated statistically significant improvements in predictive accuracy for the proposed model relative to all comparators.

To further assess alignment with expert judgment, a manual comparison evaluation was conducted using 100 randomly selected pairs of online consultation cases. Automated predictions and expert assessments were concordant in 78 cases, corresponding to an agreement rate of 78%.

A confusion matrix (Figure 6) shows that most discrepancies occurred in cases manually labeled as "equivalent," whereas predictions for clearly differentiated cases exhibited higher agreement with expert assessments. Misclassifications were predominantly observed within the equivalent category, while the majority of nonequivalent cases were correctly identified.

XSL•FO
RenderX

Figure 6. Artificial intelligence prediction confusion matrix.

Model performance was further examined across predefined pediatric subgroups, including age categories, sex, and socioeconomic status (Table 5). Comparable AUC-ROC and F_1-score values were observed across all subgroups. For age-based stratification, the AUC-ROC values were 0.84 for children younger than 2 years, 0.85 for those aged 2 - 5 years, and 0.86 for those older than 5 years. Similar performance consistency was observed across sex and socioeconomic strata.

Table . Model performance across different pediatric subgroups for early childhood obesity.

Group	AUC-ROC[a], value (95% CI)	F_1-score
Age		
<2 years	0.84 (0.80 - 0.88)	0.74
2 - 5 years	0.85 (0.82 - 0.89)	0.75
>5 years	0.86 (0.83 - 0.89)	0.76
Sex		
Male	0.85 (0.82 - 0.88)	0.75
Female	0.84 (0.81 - 0.87)	0.74
Status		
Low SES[b]	0.83 (0.79 - 0.87)	0.73
Medium SES	0.85 (0.82 - 0.88)	0.75
High SES	0.86 (0.83 - 0.89)	0.76

[a]AUC-ROC: area under the receiver operating characteristic curve.

[b]SES: socioeconomic status.

Discussion

Conclusions

This study successfully designed and validated a novel AI-driven framework for comprehensive pediatric health risk stratification. The primary findings were threefold. First, the framework demonstrates the capability to effectively integrate heterogeneous, multimodal data sources to create a holistic view of a child's health status. Second, our proposed predictive model, which combines a fine-tuned BERT architecture with an ensemble learning strategy, significantly outperformed established baseline models, such as logistic regression and SVM, in predicting key health risks, achieving an AUC-ROC of 0.85 for early childhood obesity. Third, the prototype system's risk assessments showed substantial agreement with manual expert evaluations (78% accuracy), confirming its potential clinical utility and feasibility. The successful implementation of the prototype system, featuring intuitive dashboards for both clinicians and parents, further illustrates the practical applicability of this approach in facilitating early and personalized interventions, thereby contributing a novel and robust technological foundation for proactive pediatric health care.

Limitations and Future Work

While the presented framework shows considerable promise, certain limitations and avenues for future research warrant discussion. The current validation, though rigorous, was based on a specific dataset of over 40,000 pediatric participants aged 2 - 8 years. Broader validation across more diverse pediatric populations and longitudinal follow-up are essential to ascertain long-term predictive accuracy and generalizability. One limitation of our study is the observed slight dip in model performance for the subgroup of children aged 3 - 5 years, which we attribute to the relative scarcity of rich, unstructured text data for this age cohort. To mitigate this issue in future work, we plan to incorporate alternative text sources. A promising approach, as suggested, is the inclusion of open-ended responses from parental questionnaires. These narratives, which capture detailed parental concerns and observations, can be processed by our fine-tuned BERT model to generate rich semantic features, thereby enriching the feature set for younger children and addressing the data sparsity issue. A crucial direction for future work is the implementation of advanced bias mitigation techniques. We plan to further explore methods, such as adversarial debiasing, which involves training the model to make predictions that are invariant to sensitive attributes, thereby proactively enhancing the fairness and equity of our risk stratification framework.

Funding

The research project was supported by the Education Department of Hunan Province: Multidimensional Risk Assessment and Sports-Health Integrated Intervention Model Development for Postural Health in Children in Northwestern Hunan (project number: 24B0629), and the Aid Program for Science and Technology Innovative Research Team in Higher Educational Institutions of Hunan Province.

Abstract

Background: In large-scale clinical data analysis, CSV and traditional relational database management system–based approaches are widely used but impose substantial storage and processing constraints that delay research preparation and hinder multicenter collaboration. Although column-oriented storage formats such as Apache Parquet have gained attention in data science, systematic end-to-end evaluations in clinical environments remain limited, particularly regarding efficiency and scalability.

Objective: This study aimed to empirically evaluate whether a Parquet-based end-to-end pipeline could improve computational efficiency and scalability in large-scale clinical data analysis while preserving predictive performance and protecting privacy.

Methods: Electronic health record data comprising 13.76 million rows from a large academic medical center in Korea were analyzed using Parquet, CSV, PostgreSQL, and DuckDB environments. Standardized SQL workloads and multilabel classification models—implemented using graphics processing unit–accelerated Extreme Gradient Boosting and classifier chain (CC) ensembles to address class imbalance—were applied to evaluate storage efficiency, time to analysis, and predictive performance. Statistical equivalence testing with prespecified clinical margins and bootstrap resampling ensured rigorous comparison, while privacy risks were assessed through advanced membership inference attacks (MIA), including shadow MIA and likelihood ratio attacks.

Results: Compared with CSV, Parquet demonstrated enhanced computational efficiency by lowering disk access from 940.2 to 44.2 seconds (95.3% reduction). End-to-end processing latency was substantially reduced across feature transformation (15.0 vs 9.3 s) and model training (8.1 vs 6.7 s). To address complex clinical correlations, we implemented CC and one-vs-rest architectures, which effectively captured interdependencies between disease labels. Classification performance remained statistically equivalent across area under the receiver operating characteristic curve, area under the precision-recall curve, accuracy, and F_1-score, with all differences falling within prespecified clinical equivalence margins (P<.001). Notably, the CC ensemble demonstrated high technical rigor, minimizing Hamming loss (2.2×10^{-4}) and ensuring robustness even in imbalanced cohorts. MIA performed at chance level (area under the curve=0.500), suggesting no measurable increase in privacy risk.

Conclusions: By significantly mitigating data processing bottlenecks, a Parquet-based pipeline enabled high-throughput, large-scale clinical evidence generation without compromising model integrity or patient privacy. This framework provides a scalable and robust infrastructure for precision medicine, facilitating agile multicenter collaborations and real-world data analysis in resource-constrained clinical environments.

Introduction

Clinical data, including diagnostic reports, prescriptions, laboratory results, and imaging data, hold substantial potential for precision medicine, predictive modeling, and collaborative research. The volume of electronic health records (EHRs) generated in clinical practice has grown exponentially with the expansion of digital health systems [1-4]. However, as datasets expand, bottlenecks, such as storage overhead, transmission delays, and slow query execution, become increasingly common. These challenges cannot be resolved simply by expanding storage capacity; instead, they necessitate more efficient frameworks for data storage and processing.

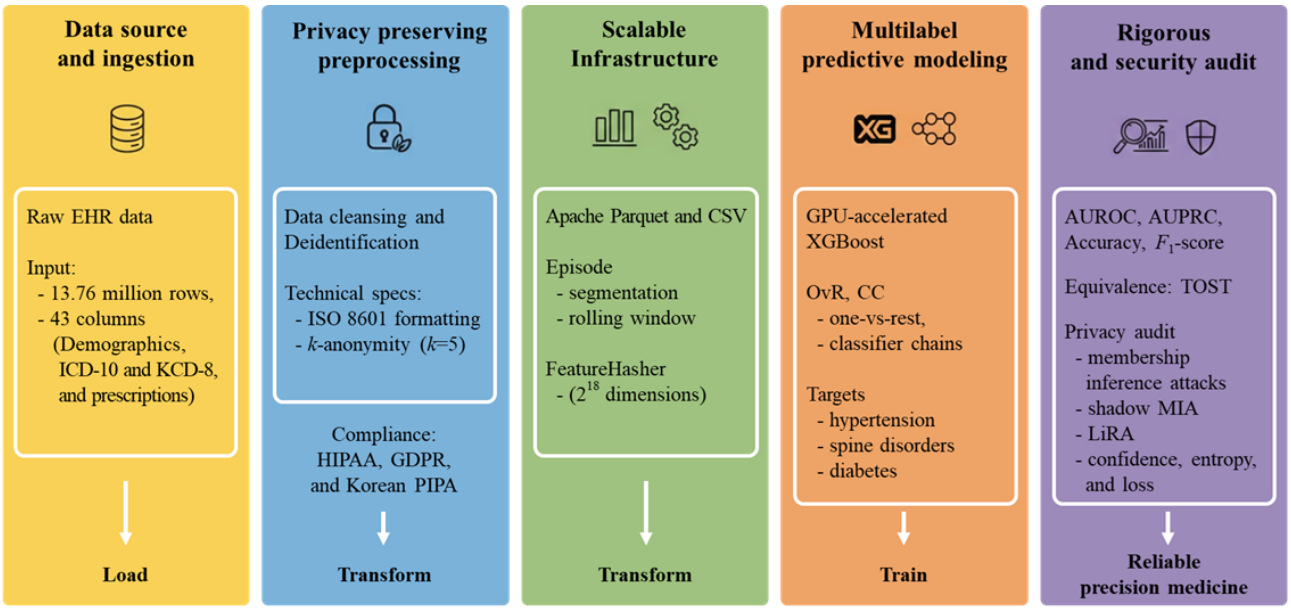
In medical informatics, data are most commonly stored in row-oriented formats, such as CSV files, spreadsheets, and relational databases. Although valued for their simplicity and interoperability, these approaches exhibit clear limitations in storage efficiency and analytic scalability. CSV files are uncompressed and large in size, restricting input and output throughput, while relational databases often underperform in column-level operations. In contrast, column-oriented formats offer high compression and selective input and output, making them well suited for high-volume and cloud-based environments. Among these, Apache Parquet is widely used as a standard solution owing to its scalability and interoperability [5,6]. However, few studies have systematically evaluated its end-to-end performance in clinical pipelines that incorporate deidentification procedures.

A further challenge in clinical data use is balancing privacy protection with data utility. Deidentification is mandatory in multicenter research and machine learning, but it may affect statistical distributions or compromise predictive performance. Understanding how storage architectures interact with deidentification to influence analytic outcomes is therefore of both academic and practical importance [7-13].

Unlike prior studies that focused solely on benchmarking computational efficiency, this work integrates privacy risk assessment and formal equivalence testing into a real-world end-to-end pipeline, thereby providing a clinically meaningful evaluation of Parquet as a foundation for precision medicine and collaborative research. Against this background, this study developed a scalable Parquet-based pipeline for high-volume clinical data and empirically assessed its storage efficiency, computational throughput, and preservation of predictive performance. This study also sought to establish a reliable infrastructure that enables cohort construction, secure data sharing, and clinical decision support in multicenter and precision medicine research [14-23].

Methods

Ethical Considerations



This retrospective observational study was conducted using real-world EHR data. The study protocol was approved by the institutional review board of Wonju Severance Christian Hospital (CR325065). The requirement for informed consent was waived by the institutional review board due to the retrospective nature of the study and the use of deidentified data. All data processing was performed within an independent honest broker system, and investigators had access only to deidentified data. No compensation was provided to the participants as there was no direct contact or intervention involved. The entire process complied with the Personal Information Protection Act of Korea, the Health Insurance Portability and Accountability Act Safe Harbor standard, and the General Data Protection Regulation [24-28].

Integrated End-to-End Clinical Data Processing Workflow

We developed an integrated pipeline connecting 5 core stages: raw EHR ingestion, privacy-preserving preprocessing (ISO 8601 and *k*-anonymity), scalable infrastructure using Apache Parquet, multilabel modeling via graphics processing unit (GPU)–accelerated Extreme Gradient Boosting (XGBoost), and rigorous statistical and privacy audits (Figure 1). To optimize analytic performance, we adopted a column-oriented storage format (Apache Parquet) over the traditional row-oriented structure (eg, CSV) [6]. For comparative evaluation, the same dataset was also maintained in CSV format. While row-oriented structures excel in transactional tasks, columnar storage significantly reduces input and output overhead and enhances compression efficiency for complex analytic queries. This architectural choice is specifically tailored for the high dimensionality and sparse distribution of clinical datasets, ensuring both system scalability and robust privacy protection across the entire workflow.

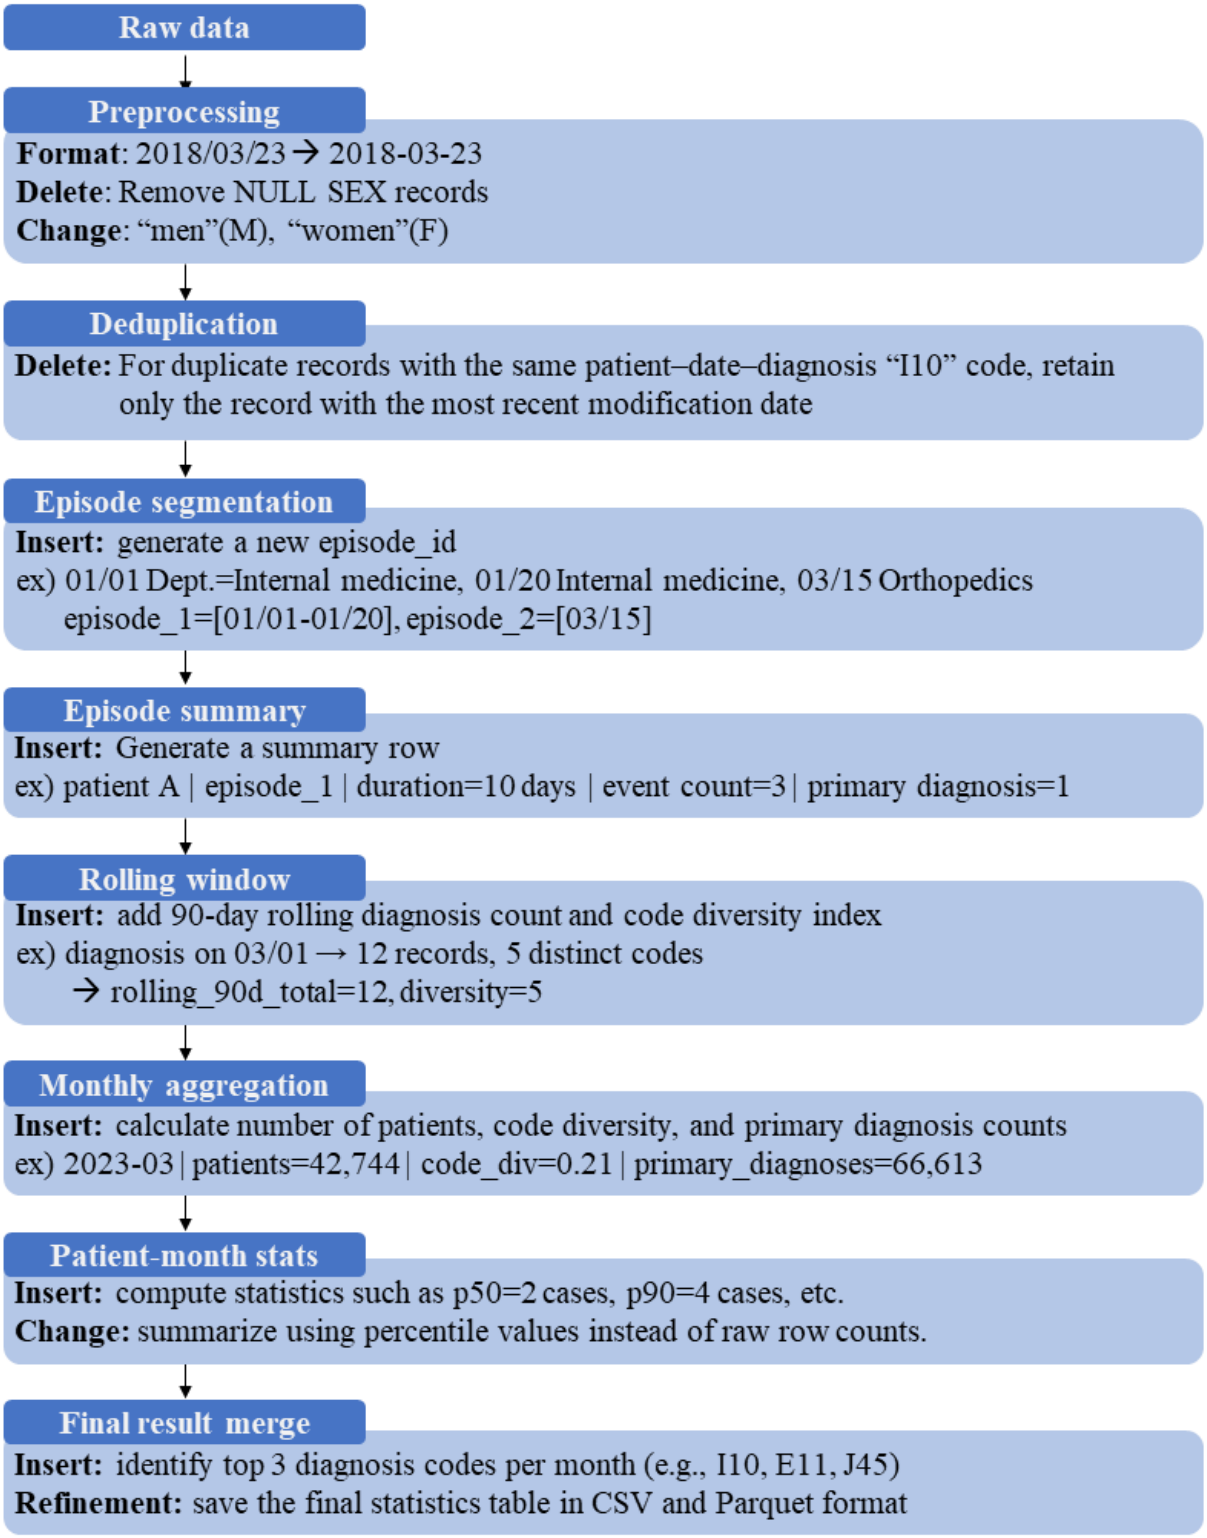
Data Preparation and Transformation



The dataset included patient demographics, diagnostic codes based on the International Classification of Diseases, Tenth Revision (ICD-10) [29-35] and the Korean Classification of Diseases, Eighth Revision (KCD-8), visit type, and prescription records. In total, the dataset comprised approximately 13.76 million rows (43 columns, approximately 3.2 GB), as detailed in Multimedia Appendix 1. After replacing patient identifiers with randomly generated surrogate IDs, quasi-identifiers were generalized to satisfy *k*-anonymity (*k*=5). Data cleansing further ensured quality control by standardizing date fields into the ISO-compliant format (YYYY-MM-DD).

Clinical Data Processing Pipeline

Clinical data processing followed a stepwise pipeline designed to reflect clinical context. In preprocessing, we standardized date formats, removed records with missing sex, and normalized sex codes (eg, “men” to M and “women” to F). Duplicate entries were resolved by retaining only the most recent record for identical combinations of patient, date, and diagnosis code. Visits were segmented into episodes by department changes or temporal gaps, and each episode was assigned an episode identifier. Episode-level summaries included episode duration, event count, and primary diagnosis status. To capture temporal continuity, a 90-day rolling window was applied to compute diagnosis counts and code diversity per patient. Monthly aggregates were then derived, including patient counts, code diversity, and primary diagnosis counts, with patient-month statistics summarized using quantiles (eg, p50 and p90). The diagnostic records for the targeted conditions—including I10.9, E10-E14, and M48.06—were identified and extracted to construct the final summary tables, which were then stored in both CSV and Parquet formats for comparative analysis. The stepwise process is illustrated in Figure 2.

XSL•FO
RenderX

Figure 2. Stepwise scenario of the clinical data processing pipeline.

Database Workload Benchmarking

To evaluate the efficiency of storage formats, scenario-based workloads were executed in DuckDB (DuckDB Labs) [36] and PostgreSQL (PostgreSQL Global Development Group) [37] environments. Synthetic example data are provided in Multimedia Appendix 2. Identical datasets were loaded into Parquet-based DuckDB and row-store PostgreSQL, and complex SQL queries—adapted from TPC-DS patterns [38,39] (eg, window functions, multidimensional aggregation, and ROLLUP)—were applied to compare performance. Resource use was further examined by varying chunk sizes (10,000-50,000 records) with detailed results in Multimedia Appendix 3.

Predictive Modeling and Multilabel Strategy

Predictive modeling assessed the impact of storage formats on classification performance for hypertension (I10.9), spinal disorders (M48.06), and diabetes (E10-E14). Patient-level

diagnostic histories were transformed into 2^{18} dimensional sparse vectors (approximately 262,000 features) via FeatureHasher (scikit-learn; Python Software Foundation) [40-42]. The dataset was randomly partitioned into training (65%), validation (15%), and test (20%) subsets with a fixed seed of 42. Classification models were implemented using GPU-accelerated XGBoost with positive class weighting to address imbalance [43-45]. Hyperparameter details are provided in Multimedia Appendix 4.

For multilabel classification, we applied one-vs-rest (OvR) [46] and classifier chains (CC) [47]. To mitigate label-order dependence and evaluate interlabel dependencies, we constructed ensembles of 5 strategically ordered chains encompassing a prevalence gradient—from high-prevalence anchors (hypertension and diabetes) to the sparse target, spinal stenosis (M48.06, 0.50%; Multimedia Appendix 5). Prioritizing M48.06, a domain-independent and sparse condition, served to demonstrate model robustness even without the clustering benefits of related disease families (eg, I-series codes). To ensure the rigorous prevention of label leakage and validate the integrity of the performance gains, all defining ICD-10 codes were strictly excluded from the feature space. This setup ensured that the model's predictive capability relied solely on statistical associations across hundreds of thousands of nondiagnostic features. Model performance was evaluated using area under the receiver operating characteristic curve (AUROC), area under the precision-recall curve (AUPRC), accuracy, and F_1-score, calculated for each label as well as macroaverages and microaverages.

Statistical Evaluation and Privacy Assessment

Model performance was evaluated using AUROC, AUPRC, accuracy, and F_1-score. To assess model reliability, calibration was further evaluated using the Brier score and expected calibration error (ECE), with detailed results provided in Multimedia Appendix 6. CSV and Parquet results were compared using paired runs with shared identifiers. Normality was assessed via the Shapiro-Wilk test, followed by paired 2-tailed *t* tests or Wilcoxon signed-rank tests with Bonferroni correction (P<.05) [48-50].

Equivalence was assessed via two 1-sided tests (TOST) [51] and 95% bootstrap CIs. Equivalence margins (δ) were prespecified at 0.02 for AUROC or AUPRC and 0.01 for accuracy or F_1-score. These thresholds were selected to be narrower than the 0.05 margin commonly used in clinical equivalence trials [52] and are more conservative than performance variances typically observed in the external validation of clinical artificial intelligence (AI) systems [53]. Such strict margins were intended to constrain observed differences to ranges generally regarded as clinically negligible, particularly for high-performing models operating within an elevated accuracy range (0.98-1.00).

To mitigate stochastic variation, a fixed random seed was applied across all experiments, ensuring that observed differences reflected data handling effects rather than algorithmic randomness. Privacy was further audited using membership inference attacks (MIA)—including confidence, entropy, loss-based (Yeom), shadow, and Likelihood Ratio Attack (LiRA) strategies—under patient-level stratified splits (train: 240,596; test: 240,597) to verify model robustness.

Experimental Setup and Reproducibility

All experiments were conducted on a Linux Ubuntu 22.04 server with a 24-core central processing unit (CPU), 128-GB memory, and an NVIDIA RTX 5090 GPU (CUDA 12.2, cuDNN 8.9, driver 550.54). Data processing used Python (version 3.10; Python Software Foundation) with Pandas 1.5.3, PyArrow 12.0.1, scikit-learn 1.3.2, and XGBoost 2.0.3 (GPU-hist). Multiprocessing was implemented using the standard Python multiprocessing module.

As specified in the modeling strategy, XGBoost was configured with a learning rate of 0.08, maximum depth of 6, and 1000 estimators. To handle class imbalance, task-specific *scale_pos_weight* and an ensemble of 5 CCs were used. All random operations used a fixed seed of 42 for reproducibility. For robust performance evaluation, we conducted 20 independent experimental runs and used 5000-iteration bootstrap resampling to compute 95% CIs. Detailed hyperparameters and the statistical framework for equivalence testing are provided in Multimedia Appendix 4.

Results

Storage and Pipeline Efficiency

Conversion to Parquet substantially improved storage efficiency, reducing file size by nearly 6.9-fold relative to CSV. As summarized in Table 1, Parquet also consistently outperformed CSV across the end-to-end pipeline. File loading (input and output) time decreased by more than 95%, and both feature transformation (FeatureHasher) and model training (XGBoost) were faster under Parquet. Although peak CPU memory was about 1.3 GB higher, GPU memory consumption decreased by 326 MB, resulting in stable overall resource use. Resource consumption remained stable at 9 to 10 GB across chunk sizes, reflecting consistent scalability, with efficiency varying by chunk size. The values in Table 1 represent peak use in end-to-end runs, with minor variations arising from measurement conditions, whereas CPU, memory, and disk input and output patterns remained consistent across chunk sizes (Multimedia Appendix 3).

XSL•FO
RenderX

Table 1. System performance comparison between CSV and Parquet formats.

Metric	CSV, mean (SD)	Parquet, mean (SD)	Difference[a] (95% CI)
Time (s)			
Input and output duration	940.2 (53.3)	44.2 (1.6)	−896.0 (−930.0 to −860.0)
Feature transformation	15.0 (0.9)	9.3 (0.7)	−5.7 (−7.0 to −4.5)
Model training	8.1 (1.2)	6.7 (0.9)	−1.4 (−2.5 to −0.3)
Resource use			
Memory maximum (GB)	21.2 (0.8)	22.5 (0.6)	1.3 (0.1 to 2.0)
GPU[b] memory maximum (MB)	4873.0 (582.6)	4547.0 (596.9)	−326.0 (−450.0 to −200.0)

[a]Calculated as the Parquet mean minus CSV mean.

[b]GPU: graphics processing unit.

Classification Performance and Calibration

Single-label results are presented in Table 2. All 3 tasks achieved AUROC values above 0.920, with AUPRC ranging from 0.488 to 0.580. Hypertension (I10.9) yielded the highest F_1-score (0.599), followed by spinal disorders (M48.06, 0.536) and diabetes (E10-E14, 0.521). Macroaveraged performance reached an AUROC of 0.920, an AUPRC of 0.545, an accuracy of 0.934, and an F_1-score of 0.552. Calibration analyses [54,55], reported in Multimedia Appendix 6, demonstrated excellent reliability for hypertension (Brier score 2.1×10^{-5}; ECE 6.0×10^{-6}), while spinal disorders (ECE=0.016) and diabetes (ECE=0.018) showed mild miscalibration but remained within recommended thresholds (ECE<0.020).

Table 2. Per-label classification performance using extreme gradient boosting.

Labels	AUROC[a]	AUPRC[b]	Accuracy	F_1-score
Hypertension	0.920	0.580	0.906	0.599
Spine disorder	0.941	0.488	0.982	0.536
Diabetes[c]	0.899	0.567	0.915	0.521
Macroaverage	0.920	0.545	0.934	0.552

[a]AUROC: area under the receiver operating characteristic curve.

[b]AUPRC: area under the precision-recall curve.

[c]Diabetes mellitus (International Classification of Diseases, Tenth Revision codes: E10-E14).

Table 2 evaluates label-specific discrimination under substantial class imbalance, whereas Table 3 summarizes overall multilabel prediction performance using microaveraged aggregation across all label–instance pairs. Specifically, Table 2 focuses on the predictive performance of individual sparse labels, while Table 3 reflects aggregated performance across all prediction events. Multilabel results in Table 3 confirmed high-performance consistency for both OvR and CC, with AUROC >0.999 and AUPRC >0.998. Subset accuracy was identical (0.999), but CC showed slight improvements in Hamming loss and Jaccard index [56], suggesting modest benefits from capturing label dependencies. A numerical gap was observed between per-label AUPRC (approximately 0.5; Table 2) and multilabel AUPRC (near 1.0; Table 3). This reflects the technical difference in aggregation: multilabel metrics were calculated using microaveraging to evaluate the overall model efficacy.

XSL•FO
RenderX

Table 3. Multilabel classification performance.

Models	AUROC[a]	AUPRC[b]	Hamming loss	Subset accuracy	Jaccard index
One-vs-rest					
Microaverage	0.999	0.998	2.4×10^{-4}	0.999	0.997
Macroaverage	0.999	0.998	—[c]	—	—
Classifier chains					
Microaverage	0.999	0.998	2.2×10^{-4}	0.999	0.997
Macroaverage	0.999	0.998	—	—	—

[a]AUROC: area under the receiver operating characteristic curve.

[b]AUPRC: area under the precision-recall curve.

[c]Not applicable.

Although discrimination remained high across all tasks, calibration analyses revealed modest overconfidence for diabetes and spinal disorder models. These deviations, while within accepted thresholds, emphasize the importance of calibration-aware adjustments when deploying predictive models in clinical workflows.

Database Benchmarking

As summarized in Table 4, DuckDB executed analytic workloads with an approximately 28-fold reduction in wall-clock time compared with PostgreSQL, which required 2546.4 seconds. DuckDB also exhibited higher CPU use (72.1% vs 39.6%), while memory consumption was comparable across systems.

Table 4. Performance comparison of DuckDB and PostgreSQL in scenario-based SQL workloads.

Metrics	DuckDB[a]	PostgreSQL[b]
Wall-clock time (s)	90.2	2546.4
CPU[c] use (%)	72.1	39.6
Memory use (GB)	13.7	14.8
Read throughput (MB/s)	554.7	365.2
Write throughput (MB/s)	1116.0	998.0

[a]DuckDB: column-oriented database optimized for analytical workloads.

[b]PostgreSQL: row-oriented relational database primarily designed for transactional workloads, with support for analytical queries.

[c]CPU: central processing unit.

Equivalence Analysis

Paired experiments (20 runs per condition) were conducted using shared run identifiers, with median and IQR values provided in Table S1 in Multimedia Appendix 7. Several metrics converged across all repetitions, producing zero IQR values and demonstrating high algorithmic stability. Overall, both formats achieved robust numerical consistency across all experimental iterations; for instance, mean AUROC was 1.000 for CSV and 0.984 for Parquet ($\Delta=-0.015$). While other metrics (AUPRC, accuracy, and F_1-score) were slightly higher under the CSV format, paired *t* tests and Wilcoxon signed-rank tests confirmed statistical significance after Bonferroni correction ($P<.001$; Table S2 in Multimedia Appendix 7). However, these numerical variations remained minimal.

Notably, all observed differences fell within the prespecified equivalence margins ($\delta=0.02$ for AUROC and AUPRC and $\delta=0.01$ for accuracy and F_1-score). TOST confirmed statistical equivalence ($P<.05$) across all evaluated metrics, and bootstrap 95% CIs for AUROC Δ (−0.016 to −0.015) further reflected near-zero variability consistent with asymptotic performance stability (Table S3 in Multimedia Appendix 7).

Privacy Assessment

The MIA evaluations, performed based on established methodologies [57-59] and summarized in Table 5, produced area under the curve (AUC) values of 0.501, 0.502, and 0.499 for confidence, entropy, and loss-based strategies, respectively. The maximum advantage did not exceed 0.007, and the gain over random guessing was ≤0.003. Attack performance was indistinguishable from random guessing, indicating no additional privacy risk. Additional shadow and LiRA [60,61] results are available in Multimedia Appendix 8, corroborating these findings.

XSL•FO
RenderX

Table 5. Membership inference attack results across different attack strategies.

Attack strategy	Attack AUC[a] (95% CI)	Advantage	Best accuracy	Gain vs baseline
Confidence	0.501 (0.501-0.503)	0.006	0.503	0.003
Entropy	0.502 (0.502-0.503)	0.007	0.503	0.003
Loss (Yeom)	0.499 (0.498-0.499)	0.002	0.500	0.001

[a]AUC: area under the curve.

Discussion

Principal Findings

This study successfully implemented an integrated end-to-end pipeline (Figure 1) that ensures a seamless transition from raw EHR data ingestion to predictive modeling. By leveraging Apache Parquet, the framework effectively addressed storage and processing bottlenecks—specifically, input and output latency—inherent in traditional row-oriented workflows, substantially enhancing data throughput and accelerating the analytic preparatory phase while maintaining high predictive fidelity. Furthermore, our findings indicate that the minor performance discrepancies between formats are attributable to systematic data handling effects under a strictly controlled environment. Beyond these computational efficiencies, privacy evaluations demonstrated that the optimized workflow maintains rigorous data protection standards, providing a secure foundation for multicenter research operations without introducing additional vulnerabilities.

Although paired statistical tests yielded highly significant *P* values ($P<.001$), this result reflects the sensitivity of paired testing under large-scale data and repeated bootstrap evaluation rather than clinically meaningful divergence. From an equivalence perspective, all performance differences remained well within the prespecified margins, confirming that the Parquet-based pipeline achieves practical performance equivalence to the traditional CSV workflow.

The substantial improvement in multilabel AUPRC compared with per-label performance highlights the system-level predictive advantage gained by explicitly modeling interlabel dependencies. While individual disease prediction remains challenging under substantial class imbalance, the multilabel formulation enables the model to capture clinically meaningful comorbidity structures, thereby reframing the observed performance gap as a reflection of holistic predictive efficacy rather than a metric artifact. This gap was also driven by the extreme class imbalance inherent in clinical datasets (eg, 0.50% prevalence for spinal disorders), where high AUROCs can coexist with lower F_1-scores. By integrating these dependencies within the CC architecture, the model leveraged frequent clinical co-occurrence patterns—such as hypertension and diabetes—to stabilize predictions for sparse conditions, including spinal stenosis. Importantly, the consistent performance observed despite the strict exclusion of all defining ICD-10 codes provided strong evidence against label leakage and underscored the model's reliance on nondiagnostic clinical associations.

Clinical Implications and Research Operations

The clinical implications were considerable. By substantially shortening preparatory phases and enabling analyses to be completed within hours rather than days, Parquet-based pipelines allowed investigators to progress more rapidly from raw data to actionable evidence. Such improvements not only accelerated study initiation but also facilitated the integration of predictive models into research and clinical workflows. In multicenter settings, scalability supported the efficient integration of heterogeneous patient populations without excessive computational cost, thereby enhancing reproducibility and advancing precision medicine initiatives. These efficiencies were directly relevant to clinical workflows and regulatory-grade analyses. They enabled interim analyses and timely regulatory submissions, supporting more responsive and efficient research operations.

Privacy and Security Safeguards

Privacy evaluation reinforced the suitability of this approach. Deidentification procedures satisfied k-anonymity, and MIA yielded chance-level performance. The chance-level performance of multiple MIA methods confirmed that computational gains do not compromise patient confidentiality, a prerequisite for secure collaboration across institutions. Patient-level stratification and consistent pipeline design acted as effective safeguards. While residual risks remain inherent to secondary data use, our findings suggested that Parquet does not introduce additional vulnerabilities. For collaborative research networks—where privacy assurances are essential for sharing—these results provide practical reassurance.

Interpretation of Predictive Performance and Label Dependencies

Classification analyses revealed stable performance for common conditions such as hypertension, whereas imbalanced disorders such as diabetes and spinal disease yielded lower scores. This pattern highlights the need to account for dataset structure and interlabel dependencies when interpreting predictive outputs. The elevated AUROC values likely reflect the combination of high-prevalence conditions and extensive diagnostic feature sets. Consistent with the modeling strategy, defining codes were excluded from the feature space; however, correlated diagnostic features may still have influenced performance estimates.

While performance convergence at elevated levels constrained the sensitivity to subtle comparative differences, it underscored the robustness and reproducibility of the pipeline, supporting its suitability for large-scale clinical research, where stability and reliability are critical. Predictive reliability was not compromised by storage structure, supporting Parquet as a

XSL•FO
RenderX

dependable option for secondary use of EHR data in diverse research settings.

Model Reliability and Calibration

Calibration analyses further showed that hypertension models were well aligned with observed risks, whereas diabetes and spinal disorder tasks exhibited modest miscalibration. These results underscore that even high-performing classifiers may generate overconfident probability estimates, a limitation directly relevant to clinical decision support. Future studies should evaluate calibration-aware techniques, such as temperature scaling or isotonic regression, to improve the reliability of probability estimates (Multimedia Appendix 6).

Beyond technical validation, the findings demonstrated practical value for clinical research operations. Large-scale trials and observational studies often face delays in cohort assembly and iterative validation; Parquet-based pipelines shorten these steps, enabling more adaptive study designs. In multicenter collaborations, they promote secure and efficient data exchange, reducing delays that commonly impede cooperative studies.

Limitations

Several limitations should be acknowledged. First, the datasets analyzed were derived from specific institutional cohorts, which may constrain generalizability to other health care systems. Second, the elevated performance baseline of the predictive models limited the sensitivity to subtle differences between CSV and Parquet formats. Third, while MIA offered a widely accepted proxy for privacy risk, broader adversarial evaluations were not included. Fourth, the evaluation was primarily conducted in on-premise settings, so the scalability of findings in distributed or cloud-based environments remains to be established. Finally, despite the clear efficiency advantages of Parquet, its adoption may introduce a technical learning curve for clinical researchers who are less familiar with column-oriented storage formats or big-data frameworks. Transitioning from traditional row-oriented workflows to optimized columnar architectures requires initial investments in technical training and infrastructure adjustment. However, these upfront efforts are likely to be offset by the long-term gains in scalability and processing speed demonstrated in our results, ultimately supporting more efficient and reproducible clinical evidence generation.

Future Work

Future research should extend the evaluation of Parquet-based pipelines to distributed and cloud-based environments, focusing on both scalability and cost-effectiveness. In addition, validation across hybrid and federated architectures will be important to confirm applicability in multicenter collaborations where data cannot be centralized. Beyond structured EHR data, future studies should also investigate applications to unstructured modalities, such as clinical narratives, imaging metadata, and time-series signals. Such efforts would test the versatility of Parquet-based pipelines in supporting multimodal learning and integrative analyses. Privacy assessments should likewise be expanded to encompass attribute inference, linkage, and other adversarial scenarios, ideally within federated or privacy-preserving analytic frameworks. Moreover, interoperability across international coding standards should be validated using external multicenter datasets to ensure global applicability. Pursuing these directions will enhance the technical robustness of Parquet-based infrastructures while reinforcing their clinical relevance, ultimately enabling secure collaboration and more efficient integration of evidence into patient care.

Conclusions

This study demonstrated that Parquet-based end-to-end processing effectively alleviated the storage and computational bottlenecks inherent in traditional row-oriented and relational database workflows while maintaining predictive fidelity and privacy safeguards. By improving computational efficiency and enabling the rapid preparation of analysis-ready cohorts, Parquet reduces the resources required for large-scale clinical data handling. These efficiencies translate into tangible research benefits, enabling earlier study initiation and more adaptive study designs across diverse clinical research settings.

The integration of efficiency with privacy safeguards further ensures that accelerated workflows remain suitable for secure data sharing across institutions. In parallel, these capabilities support regulatory-grade analyses and health technology assessments, where timely and reproducible evidence is critical. For clinicians and researchers, the central implication is that Parquet-based pipelines reduce the manual effort and computational overhead required to transform raw EHR data into analysis-ready cohorts. This capability not only strengthens multicenter collaboration but also facilitates the timely translation of evidence into clinical decision support.

Ultimately, by aligning computational efficiency with privacy-conscious infrastructure, Parquet-based pipelines reinforce the evidence base that informs clinical decision-making, positioning this approach as a robust foundation for sustainable precision medicine.

Abstract

Background: In the field of precision medicine, pan-cancer survival prediction is crucial for individualized oncology diagnosis and treatment. Although multimodal data fusion techniques have significantly improved prediction accuracy, existing studies generally overlook the sensitivity of medical data and the need for privacy protection.

Objective: To address the aforementioned problem, this study aims to propose a bilayer feature fusion framework based on the multihead attention mechanism and adaptive differential privacy, which balances precise feature extraction and sensitive data protection.

Methods: Specifically, the multihead attention mechanism was integrated into bilayer feature extraction and fusion. Layer-wise relevance analysis was used to calculate the correlation between features and outcomes, and Laplacian noise was adaptively added based on the calculation results to achieve collaborative optimization of precise feature extraction and sensitive data protection. Additionally, the concordance index (C-index) and 5-fold cross-validation were used to compare the proposed method with state-of-the-art approaches.

Results: The proposed model achieved superior performance in both pan-cancer and single-cancer survival prediction, validated via the C-index and 5-fold cross-validation. In pan-cancer scenarios, the trimodal combination of clinical data, messenger RNA data, and microRNA expression data achieved the highest C-index of 0.799, outperforming multiple existing multimodal survival prediction approaches. After adaptive Laplacian noise injection for privacy protection, the model's accuracy decreased by only 0.01-0.03 while satisfying -differential privacy. For single-cancer prediction, the proposed method achieved higher C-index values in 18 out of 20 cancer types compared with representative deep learning–based survival models, with 7 types showing significant improvements (C-index difference >0.1) and more stable performance distributions. Furthermore, pan-cancer–trained models generally outperformed single-cancer–trained counterparts in most cancer types, highlighting the value of shared predictive features across cancers.

Conclusions: This study provides a solution that balances prediction accuracy and privacy security for pan-cancer survival prediction, laying the foundation for the efficient use of medical data under privacy protection. Future work may further integrate pathological images and proteomics data to expand the model's applications in cancer subtype classification and biomarker discovery.

Introduction

In the era of precision medicine, pan-cancer survival prediction refers to the task of modeling and predicting patient survival outcomes across multiple cancer types simultaneously by leveraging shared and cancer-specific prognostic patterns. As a core component of individualized oncology diagnosis and treatment, pan-cancer survival prediction has been widely validated for its clinical value. Accurately estimating survival risk for patients with different cancer types not only enables clinicians to optimize treatment strategies and personalize follow-up schedules, but also facilitates risk stratification and more efficient allocation of medical resources [1].

Early survival prediction efforts were predominantly anchored in unimodal data paradigms, relying on either genomic features or clinical variables in isolation. Statistical models laid the foundational groundwork for this field: the random survival forest (RSF) [2], for instance, addressed key challenges in survival analysis (eg, right-censored data and missing values) through log-rank–based tree splitting and adaptive imputation, establishing a robust nonparametric framework. Meanwhile, the classic Cox proportional hazards model (CPH) [3] became a clinical staple for its interpretability via linear combinations of clinical indicators, though its inability to capture complex nonlinear biological mechanisms limited its predictive power in heterogeneous cancer cohorts. The advent of deep learning catalyzed a paradigm shift in unimodal modeling: approaches like DeepSurv [4] integrated neural networks with Cox regression to automatically learn nonlinear covariate–treatment relationships, outperforming traditional models on genomic datasets. Subsequent studies further validated deep learning's superiority in capturing complex variable interactions; for example, in clinical data for oral squamous cell carcinoma [5] and histopathological images for colorectal cancer [6]. Weakly supervised learning also emerged as a promising direction for leveraging unannotated whole-slide images across multiple cancer types [7], while transfer learning facilitated cross-dataset generalization in disease-specific prognostic tasks [8]. Despite these advances, unimodal models inherently suffer from incomplete information capture: genomic data alone overlooks the spatial heterogeneity of tumor microenvironments (eg, angiogenesis patterns in pathology slides), while clinical variables fail to reveal molecular-level prognostic markers, creating an inherent ceiling for predictive performance.

In response to these limitations, multimodal data fusion has emerged as a transformative research focus in pan-cancer survival prediction, driven by the recognition that complementary data modalities (omics, imaging, and clinical) can synergistically enhance prognostic accuracy. Early multimodal frameworks integrated clinical, transcriptomic (messenger RNA [mRNA]/microRNA [miRNA]), and pathological data to achieve cross-cancer prediction [9], while recent innovations have incorporated advanced techniques such as unsupervised learning and attention mechanisms to dynamically weight modality contributions [10]. A key trend in this space is the development of specialized fusion architectures: the Multimodal Affinity Fusion Network [11] and MultiCoFusion [12]; for example, use attention mechanisms and graph convolutional networks to model intermodal dependencies and gene-gene interactions, respectively. Furthermore, bilinear fusion approaches, such as the attention-based multimodal bilinear fusion [13] and hierarchical factorized models [14], have addressed the curse of dimensionality to enable deeper cross-modal interactions. Notably, methods like Dynamic-DeepHit [15] have pioneered the use of recurrent neural network–based attention to model longitudinal dependencies for dynamic risk prediction, while cross-modal translation and alignment (CMTA) [16] explicitly learn and aligns intra- and cross-modal representations between pathology and genomics via encoder-decoder structures. End-to-end multimodal models such as MultiSurv [17], which integrate up to 6 modalities (whole-slide images, clinical data, and multiomics), have demonstrated state-of-the-art performance (concordance index [C-index]=0.779) across 33 cancer types, validating the value of comprehensive data integration. Other frameworks have incorporated multitask learning [18] or alternating training [19] to jointly optimize survival prediction and auxiliary tasks (eg, cancer grading), further improving model robustness. Recent work by Flack et al [20] introduced a robust multimodal survival prediction framework that effectively handles data heterogeneity and missing modalities through a regularization-based fusion strategy, showing competitive performance across multiple cancer types. Despite these advancements, critical challenges persist: inefficient cross-modal information alignment, inadequate intramodal feature refinement, and unresolved issues of intermodal heterogeneity and noise propagation remain major barriers to achieving consistent performance across diverse cancer types at the pan-cancer scale. More critically, the majority of these state-of-the-art multimodal survival prediction models, including MultiSurv [17], HFBSurv [14], attention-based multimodal bilinear fusion [13], and MBFusion [18], operate under the implicit assumption of centralized, nonsensitive data. They fundamentally lack integrated mechanisms to protect the highly sensitive genetic and clinical information inherent in medical datasets, creating a significant gap between methodological advancement and real-world clinical applicability where privacy is paramount.

Although multimodal data fusion has significantly improved pan-cancer survival prediction accuracy, existing research generally ignores the sensitivity of medical data and the need for privacy protection. Medical data contain sensitive information such as patients' genomic data, pathological images, and clinical records, whose leakage may lead to ethical risks such as identity recognition and insurance discrimination. For instance, empirical studies have demonstrated that even aggregated genomic data remain vulnerable to linkage attacks using auxiliary public databases, potentially inferring an individual's identity with high confidence [21]. Additionally, during the training and sharing of deep learning models, gradients or intermediate features may inadvertently leak sensitive patterns of the original training data [22]. While Chen et al [23] proposed an optimized logistic regression model (batch gradient descent logistic regression and balanced differential privacy logistic regression based on hybrid feature selection (Pearson correlation test + random forest out-of-bag algorithm) and differential privacy (DP) protection to address the problems

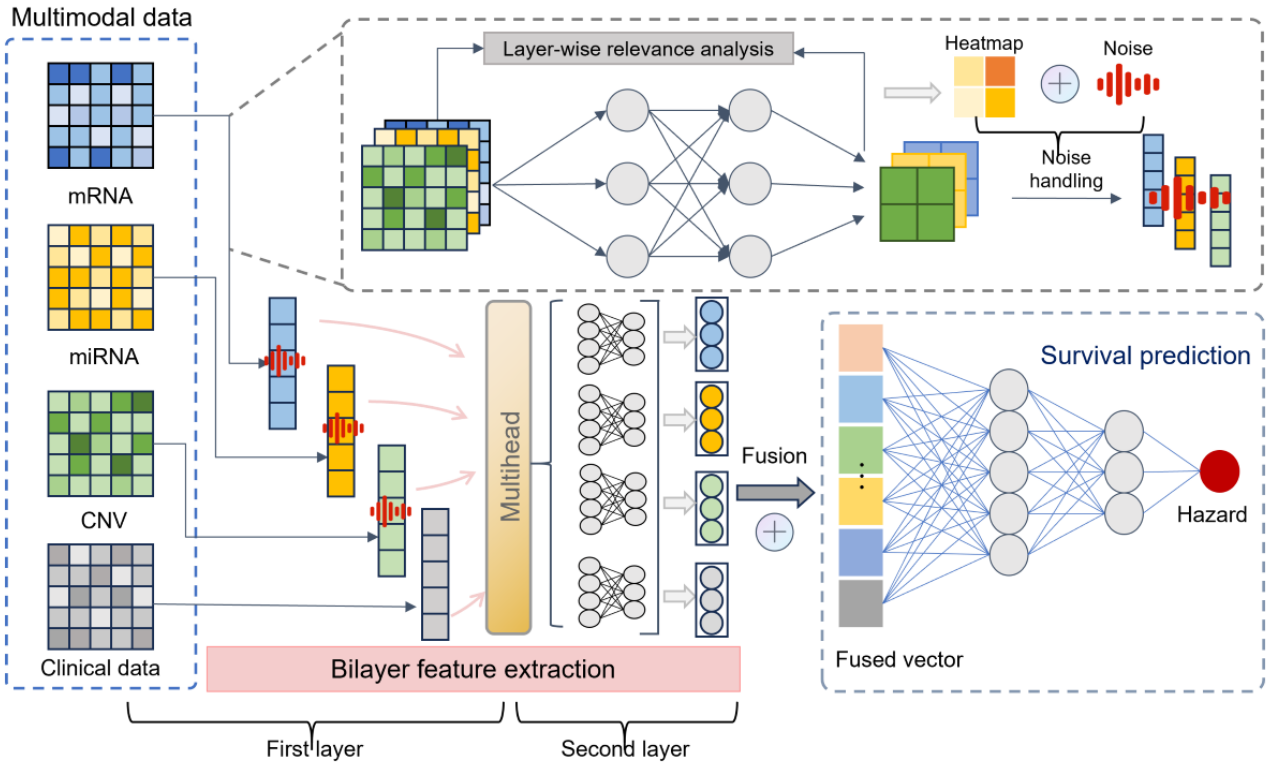
XSL•FO
RenderX

of insufficient prediction accuracy and privacy leakage in existing machine learning models for breast cancer prediction, and Chai et al [24] proposed the decentralized federated learning framework AdFed, combining regularization methods to train models without sharing raw data while achieving feature selection and privacy protection. To protect DNA data, Wu et al [25] proposed the DP-Motif Finding algorithm based on -DP, which uses closed frequent patterns to reduce redundant motifs, allocates privacy budget by constructing a perturbed extension tree, and uses best linear unbiased estimation postprocessing to optimize the noisy support. Wu et al [26] also proposed an adaptive federated learning scheme integrating DP, which adjusts the gradient descent process through an adaptive learning rate algorithm to avoid model overfitting and fluctuations, while introducing a DP mechanism to resist various background knowledge attacks, providing quantifiable privacy protection for the federated learning process. Wang et al [27] proposed a blockchain-based access control framework for genome-wide association studies in federated learning to protect the security of genetic data—this framework implements automated quality control to ensure training data quality, designs a blockchain-based authentication mechanism to filter malicious attackers, and adopts a periodic aggregation method combined with DP to accelerate cloud model training and resist multiple attacks [28]. Wang et al [29] proposed a method based on the ant colony optimization algorithm to detect gene interactions for genome-wide association studies—an intelligent privacy-preserving scheme. Current studies still suffer from problems such as single datasets and heavy reliance on data anonymization or centralized storage, failing to embed dynamic privacy protection mechanisms.

To solve the above problems, this study proposes a bilayer feature fusion framework based on the multihead attention (MHA) mechanism and adaptive DP, achieving collaborative optimization of precise feature extraction and sensitive data protection through technological innovation. Specifically, for feature fusion, traditional methods typically rely on fixed weights or simple concatenation to handle heterogeneous data. Simple concatenation, however, merely "physically stacks" feature vectors from different modalities, posing notable limitations. Multisource data (clinical, mRNA, miRNA, and gene copy number variation [CNV]) vary drastically in feature dimensions, semantics, and distributions; forcing them into a single-vector space postconcatenation overlooks inherent intermodal correlations; for example, links between specific mRNA expression and clinical survival time, or regulatory relationships between miRNA and CNV. Additionally, concatenation assumes "all features are equally important," failing to differentiate their contributions to survival prediction. This often buries key signals (eg, driver gene mutation sites) under redundancy, and may trigger the curse of dimensionality via rapid feature expansion, increasing computational complexity and overfitting risk. Given the aforementioned limitations of simple concatenation, our first contribution is the design of a structured bilayer feature extraction module. The first layer performs modality-specific feature extraction on clinical, mRNA, miRNA, and CNV data through fully connected (FC) networks and embedding layers. The second layer innovatively uses an MHA mechanism not merely as a fusion tool, but as a structured cross-modal interaction model that explicitly quantifies feature-level contributions. Unlike single-head attention, which models only single correlations, MHA captures differentiated correlations between features from different subspaces through parallelized independent attention heads and focuses on key survival-related features through dynamic weight allocation. Our second and primary contribution lies in the novel integration of adaptive DP directly into the multimodal feature extraction pipeline. At the privacy protection level, this study proposes adaptive DP based on layer-wise relevance analysis, balancing prediction accuracy and privacy security through a 2-step strategy. First, the layer-wise relevance propagation algorithm is used to quantify the association strength between neurons at each layer and survival prediction outcomes, identifying highly sensitive features (eg, driver gene mutation sites) in mRNA, miRNA, and CNV data; then privacy budgets are dynamically allocated based on correlation scores to inject Laplacian noise into the gradient update process—features with higher correlations receive less noise, preserving key prediction information while suppressing privacy leakage risks.

In summary, the novelty of our work is not merely the combination of MHA and DP, but the creation of a synergistic framework where (1) the bilayer MHA structure provides the granular feature importance signals necessary for adaptive noise allocation and (2) the adaptive DP mechanism, guided by layer-wise relevance analysis, protects privacy in a targeted manner that minimizes damage to the model's core predictive capability. This integrated solution addresses the specific limitations of prior multimodal models (which neglect privacy) and prior DP applications (which impair use in complex models), paving the way for clinically viable, privacy-preserving pan-cancer prediction tools.

Methods



Overview

As shown in Figure 1, the proposed model architecture consists of 2 parts: a bilayer feature extraction module based on MHA and an adaptive DP protection module based on layer-wise relevance analysis. The bilayer feature extraction part, based on MHA, first performs first-layer feature extraction through FC layers and embedding layers, and then uses the MHA mechanism in the second layer for further feature extraction and multimodal data fusion. By integrating the MHA mechanism, the bilayer feature extraction module fully uses the advantage of parallel heads to capture different correlations, comprehensively and deeply mining key information from multimodal data. Additionally, a privacy protection component is added during the first-layer feature extraction, integrating layer-wise relevance analysis into the FC layers to deeply analyze the correlation between features and survival prediction outcomes through backpropagation. Noise is adaptively added based on the obtained correlation results. This study introduces a bilayer feature extraction module into the multimodal survival prediction model to better mine data features and provides privacy protection, effectively preserving the privacy information in the training data. The data preprocessing and

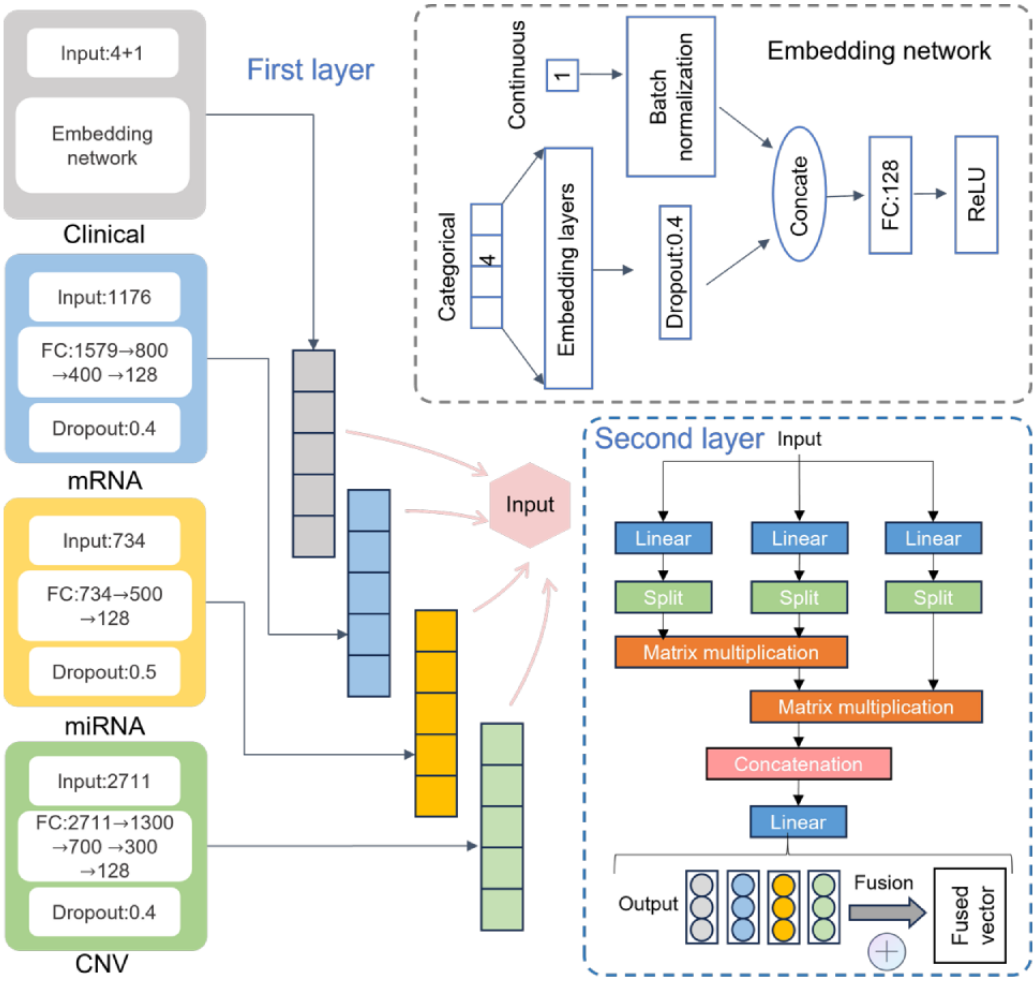
detailed method descriptions are presented in the following sections.

Figure 1. The architecture of the proposed model. CNV: gene copy number variation; miRNA: microRNA; mRNA: messenger RNA.

Data Preprocessing

In this study, 4 types of data were used: clinical data, gene expression (mRNA) data, miRNA data, and CNV data.

This section performs data screening for different data features. For clinical features, patient data with missing values and/or missing follow-up times were excluded. For gene expression data, a variance threshold method was used to select features with variances greater than a given threshold calculated from all patients [18,30]. In this study, the same thresholds as Fan et al [10] were used for mRNA and CNV modalities: 7 and 0.2, respectively. This processing retained 1579 mRNA features and 2711 CNV features. Subsequently, all continuous variables were normalized to the interval (0, 1) using minimum-maximum normalization [31].



Considering the variations in diagnosis and treatment methods across different cancer types, samples in the dataset may lack some required modalities. This study adopts zero-vector imputation for missing modalities, with its rationale mainly reflected in 2 aspects: first, zero vectors can explicitly indicate "no measured data for the modality," avoiding false biological signals introduced by statistical imputation methods. Second, zero-vector imputation ensures the consistency of feature dimensions across all samples, simplifies the model's input structure, and avoids additional computational overhead from complex missing-value processing modules, providing stability guarantees for gradient updates in the integration of adaptive DP mechanisms.

Bilayer Feature Extraction Based on MHA

To improve the accuracy and efficiency of feature extraction, this study designs a bilayer feature extraction method based on MHA, which can more comprehensively and deeply mine key information from multimodal data, as shown in Figure 2.

XSL•FO
RenderX

Figure 2. The architecture of bilayer feature extraction based on multihead attention. CNV: gene copy number variation; FC: fully connected; miRNA: microRNA; mRNA: messenger RNA; ReLU: rectified linear unit.

In recent years, neural networks with FC layers have been widely used for representation extraction [15]. In this study, different neural network settings with FC layers were used as the first-layer feature extraction to obtain representations from the raw numerical data of different modalities. Batch normalization was adopted to normalize the layer inputs and accelerate neural network training [30]. For the clinical data, we used categorical embedding layers for the 4 categorical variables, namely, cancer type, gender, race, and histological type, with dropout to encode the categorical variables into a numerical vector. The normalized continuous variables (ie, age) were then concatenated with these numerical vectors and fed into an FC layer with a fixed representation length. For miRNA, mRNA, and CNV modalities, 2-4 FC layers with rectified linear unit activation and batch normalization were used to extract fixed-length representations. The representation vectors  were obtained from modality-specific configurations to form the representation matrix  where m is the sample size and d is the feature dimension.

To effectively capture the complex interaction relationships between multimodal data and enhance feature representation capabilities, the MHA mechanism was introduced in the second-layer feature extraction stage.

The proposed MHA mechanism consists of 3 components similar to the self-attention in the transformer model: query (Q), key (K), and value (V). The matrix B is projected to generate keys K and values V. Specifically, V is processed using an identity function because the features extracted in the first layer already have sufficient representational power. For K, it is generated by:

Where  (d represents the feature dimension) is a trainable matrix randomly initialized from a standard Gaussian distribution and updated during training; B is the representation matrix obtained from the first-layer feature extraction. The dropout layer and rectified linear unit activation function are used to prevent overfitting and introduce nonlinearity. The query  is a learnable vector initialized randomly, with elements sampled from a uniform distribution .

The attention aggregation feature is calculated as:

Where A is the attention weight. After softmax normalization along the sample dimension, the sum of the attention weights

XSL•FO
RenderX

A for *N* samples is 1, enabling dynamic focusing on key survival-related features.

To capture multidimensional survival associations, the attention layer is extended to *H* heads. Specifically, *Q*, *K*, and *V* are split into blocks of size *d*/*H* along the embedding dimension. The attention for each head is calculated as:

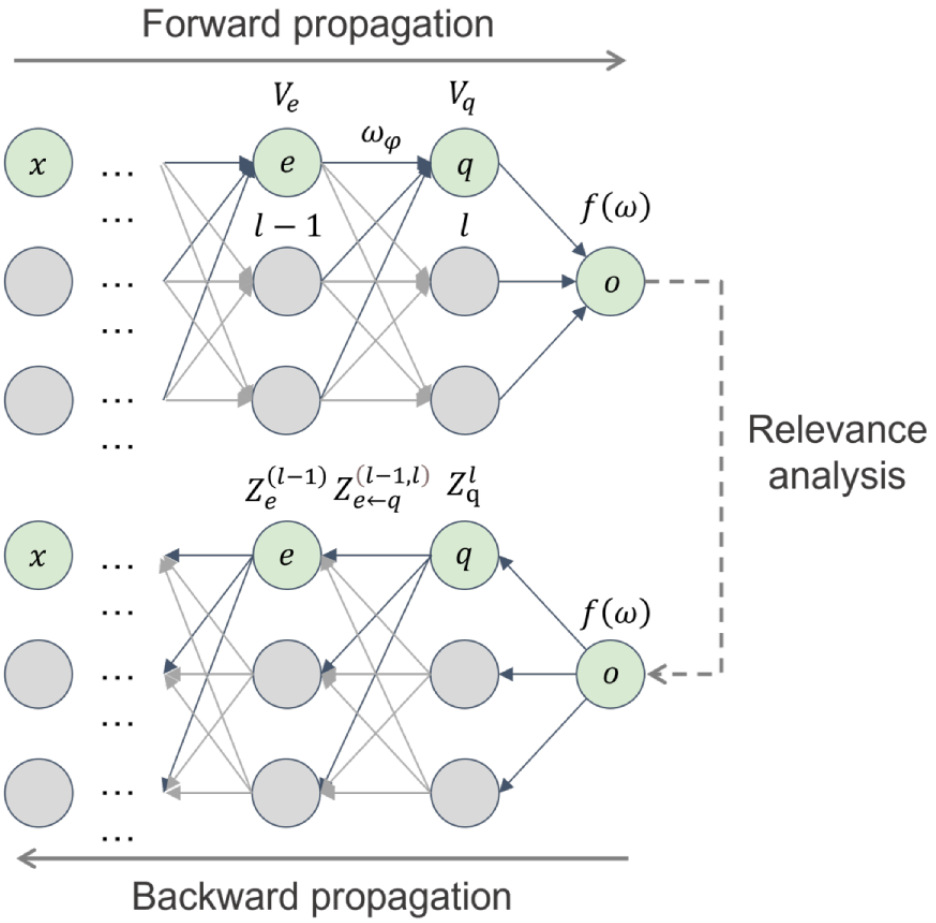
These heads are then concatenated into a multihead output:

This process allows different heads to capture interactions between different types of data separately.

Finally, the fused features are obtained by:

Where  is the weight of the last layer. In evaluation mode, the dropout layer is disabled. Thus, the fused feature *Y* can be written as:

The attention mechanism focuses on key information through dynamic weight allocation, efficiently handling long-range dependencies in sequence data and suppressing noise interference. However, its single-head structure has limitations in modeling multidimensional correlations. Therefore, based on the features extracted from the 4 modalities in the first layer, this study introduces the MHA mechanism. By parallelizing multiple independent attention heads, it captures differentiated correlations between features from different subspaces, providing more comprehensive feature representations for pan-cancer survival prediction. The above method achieves deep fusion of multimodal survival features, offering high-precision feature representations for pan-cancer survival prediction.



Adaptive DP Based on Layer-Wise Relevance Analysis

In the field of cancer survival prediction, privacy protection of medical data is of utmost importance. Genetic data, such as mRNA, miRNA, and CNV data, contain highly sensitive personal information, posing a risk of privacy leakage. Therefore, during the feature extraction process, this study designs a method based on layer-wise relevance analysis to construct a noise addition mechanism by adding Laplacian noise for privacy protection, ensuring data security.

First, during the extraction of mRNA, miRNA, and CNV features in the first layer, this paper adds appropriate Laplace noise to the training gradient of neurons based on analyzing the correlation between each neuron layer and the output layer. The core theoretical operation process is shown in Figure 3. Relevance analysis begins after forward and backward propagation, calculating the correlation results of each feature in a layer of neurons. Importantly, the correlation analysis results are adjusted with the forward and backward propagation processes until the propagation ends.

XSL•FO
RenderX

Figure 3. The process of the layer-wise relevance analysis method of the proposed model based on the backpropagation algorithm.

The correlation between each input feature x_{ij} and the output $Hx_i(0)$ is calculated by decomposing the neurons of the previous layer. Given $Z_e^{(l)}(x_i)$ as the correlation result between x_i and neuron e in layer l, define as the process of neuron e sending information to q. The neuron correlation is:

The decomposition rule for layer-wise relevance analysis is:

Where is a predefined stabilizer to address the unboundedness of $Z_e^{(l)}(x_i)$. R_q is the affine transformation of neuron e, defined as:

Where v_e is the value of neuron e,$_{eq}$ is the weight between neuron e and q,u_q is the bias term.

In the last hidden layer, for the output variable o, the correlation is calculated as:

This study directly calculates the correlation score $Z_j(x_{ij})$ between each feature x_{ij} inlayer j and the survival prediction result for mRNA, miRNA, and CNV features.

Next, a noise addition rule is defined. Through the above layer-wise relevance analysis, the value range of these correlation scores is divided into n nonoverlapping threshold intervals , and T_1 corresponds to the features with the highest relevance scores.

A privacy-budget mapping function is then defined, which assigns a specific privacy parameter $_k$ to each interval T_k. The function is designed to be strictly monotonic, satisfying the following condition: for any $g<h$,$\eta(T_g)<\eta(T_h)$, thereby ensuring that features with stronger predictive correlations are allocated a higher privacy budget (less noise), while features with weaker correlations receive a lower privacy budget (more noise).

Formally, for an interval index $k\in\{1,2,...,n\}$,the privacy parameter $_k$ is given by:

Where $_{max}$=0.5 and $_{min}$=0.1 define the permissible range of the privacy budget; $\delta_k \sim U(-\Delta,\Delta)$ is a bounded random perturbation term that preserves the strict monotonicity $_1 > _2 > ... > _n$.

XSL•FO
RenderX

Privacy budgets are adaptively allocated according to the function :

Where denotes the global privacy budget.

Laplacian noise is added to the training gradients of neurons, where is the total privacy budget for protecting mRNA, miRNA, and CNV features.

At the start of training, the gradient update objective function of the general optimization method is defined. In each training step, using a set of random training samples L from the genetic data feature set X (where $X = \{x_{11}, x_{12},..., x_{ij}\}$), starting from the initial point $_0$, the parameters are updated at step t as:

where is the learning rate at step t, is the regularization parameter, and  is the loss function.

Subsequently, the training gradients are perturbed to ensure the security of genetic data during training and sharing:

Where Y_t is the Laplacian noise.

After detailing the process of adding Laplacian noise to features based on layer-wise relevance analysis, this section proceeds to prove the implementation of -DP. The following proof shows how the proposed method satisfies -DP requirements:

Proof: assume L and L' are 2 adjacent batches, and $_{t+1(L)}$ and $_{t+1(L')}$ are the parameters for L and L', respectively. The formula is expressed as follows:

Then, the inequality for the difference between the 2 output results is:

From the above formula and DP, $_t$ is the sensitivity of the neural network **Inline graphic 27**. To protect the privacy information of the neural network, the gradient is perturbed based on relevance analysis, and the noise can be written as:

We have:

This proves that the method satisfies -DP, ie,

, where M is the model after adding Laplacian noise to features. It ensures that the model's noise addition mechanism is consistent with the definition of DP while protecting the privacy of mRNA, miRNA, and CNV features.

This method not only effectively reduces the risk of data leakage but also maximizes data usability, providing a more secure and reliable solution for cancer survival prediction and promoting the efficient use and sharing of medical data under privacy protection.

Ethical Considerations

All data used in this study were obtained from The Cancer Genome Atlas (TCGA), a publicly available database. The TCGA project obtained informed consent from all participants and received ethical approval from the appropriate institutional review boards. As this study involved only the use of deidentified, publicly accessible data, no additional ethical approval was required.

Results

Data

The clinical, mRNA, and miRNA data were downloaded from the Pan-Cancer Atlas of TCGA project (publicly accessible at the Genomic Data Commons), where more than 11,000 patient samples across 33 tumor types [32,33] were collected. The clinical dataset provides annotations for 11,160 patients, using 5 variables consistent with Silva and Rohr [17]: cancer type, gender, race, histological type, and age. The miRNA data set contains 743 miRNA feature records, and the mRNA dataset contains RNA sequencing counts for 20,531 mRNAs. The CNV data were downloaded from the University of California Santa Cruz Xena [34].

Table 1 describes the data information after preprocessing in detail. In this study, the pan-cancer datasets were partitioned into training (6656/11094, 60%), validation (2219/11094, 20%), and testing (2219/11094, 20%) subsets, with model performance evaluated using 5-fold cross-validation.

Experimental Settings

We conduct all experiments on a simulation environment equipped with a 64-bit Intel(R) Xeon(R) Silver 4210R CPU @ 2.40 GHz processor, 32 GB RAM, and an NVIDIA GeForce RTX 3080 GPU for accelerated computation. The experiments are implemented on the Windows 11 operating system, with Python (version 3.10; Python Software Foundation) as the primary programming language and PyTorch (version 2.6.0; Meta AI) as the deep learning framework.

For model training, the Adam optimizer is adopted with a fixed learning rate of 0.001. Key hyperparameters are configured as follows: sequence length is set to 128, batch size is 256, and total training epochs are 100.

Evaluation Metrics

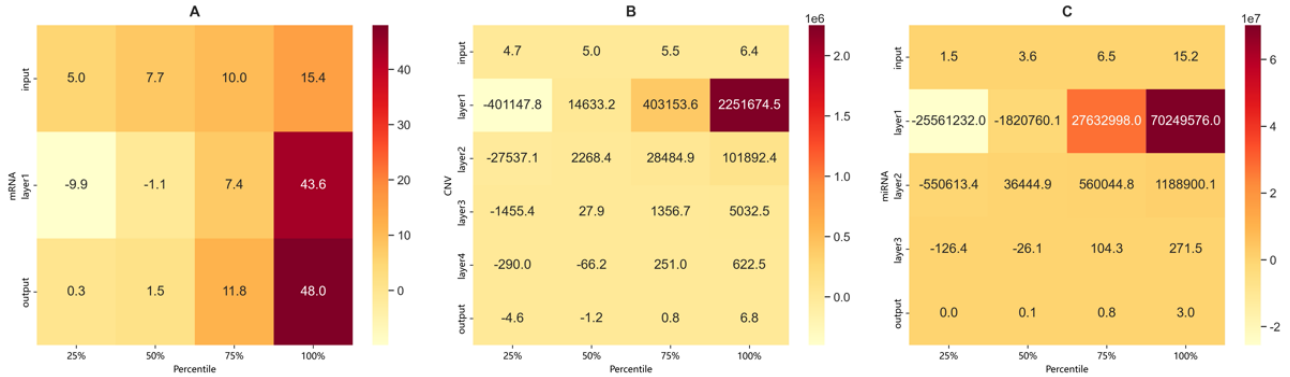
In this study, we assessed the performance of our model by using the C-index, a widely adopted metric for evaluating survival predictions in censored survival data [2,35]. The C-index measures the proportion of concordant pairs among all possible evaluation pairs, defined as:

where 1 is the indicator function of whether the expression in parentheses is true or false. The C-index ranges from 0 to 1. The closer the C-index is to 1, the closer the prediction order is to the real one; the closer the C-index is to 0.5, the closer the model's prediction is to a random prediction. Notably, the C-index focuses on the ordinal relationship of predictions rather than the accuracy of individual sample forecasts, making it particularly suitable for evaluating proportional hazards models.

Accuracy was also used for performance evaluation. The metric is evaluated as follows:

Layer-Wise Relevance Analysis

To evaluate the model's performance in privacy preservation, this study determines the privacy budget through hierarchical correlation analysis and subsequently adds Laplacian noise based on the results. Specifically, this study analyzed the strength of correlations between features and different FC layers using heatmaps for the 3 modalities: mRNA, miRNA, and CNV. The computed correlation scores are sorted in descending order, and the feature scores at the 25th, 50th, 75th, and 100th percentiles are visualized. The heatmaps show that higher correlation scores indicate stronger associations between the corresponding features and survival prediction outcomes.



A more detailed analysis of each modality's heatmap reveals that, as shown in Figure 4A, the output layer and mRNA layer 1 exhibit significantly higher correlation scores at the 100th percentile (48.0 and 43.6, respectively), with notable increases compared to the 25th, 50th, and 75th percentiles. This suggests that these 2 layers are particularly effective in capturing high-correlation features, which are strongly associated with survival outcomes. These findings indicate that privacy-preserving noise injection should focus on these layers to avoid the leakage of critical predictive information.

For the CNV and miRNA modalities, as illustrated in Figures 4B and 4C, layer 1 demonstrates markedly higher correlation scores at the 100th percentile compared to subsequent layers and the output layer. This suggests that the model primarily extracts key features from layer 1, with diminishing correlation strength in deeper layers. Therefore, noise injection strategies should prioritize high-correlation features in layer 1, enhancing privacy protection while maintaining the model's feature extraction performance.

Overall, the heatmaps of layer-feature correlations across the 3 modalities not only identify the core layers and key percentile-based features involved in the model's internal processing, but also provide empirical support for refining noise injection strategies. This contributes to achieving a better balance between privacy protection and model performance.

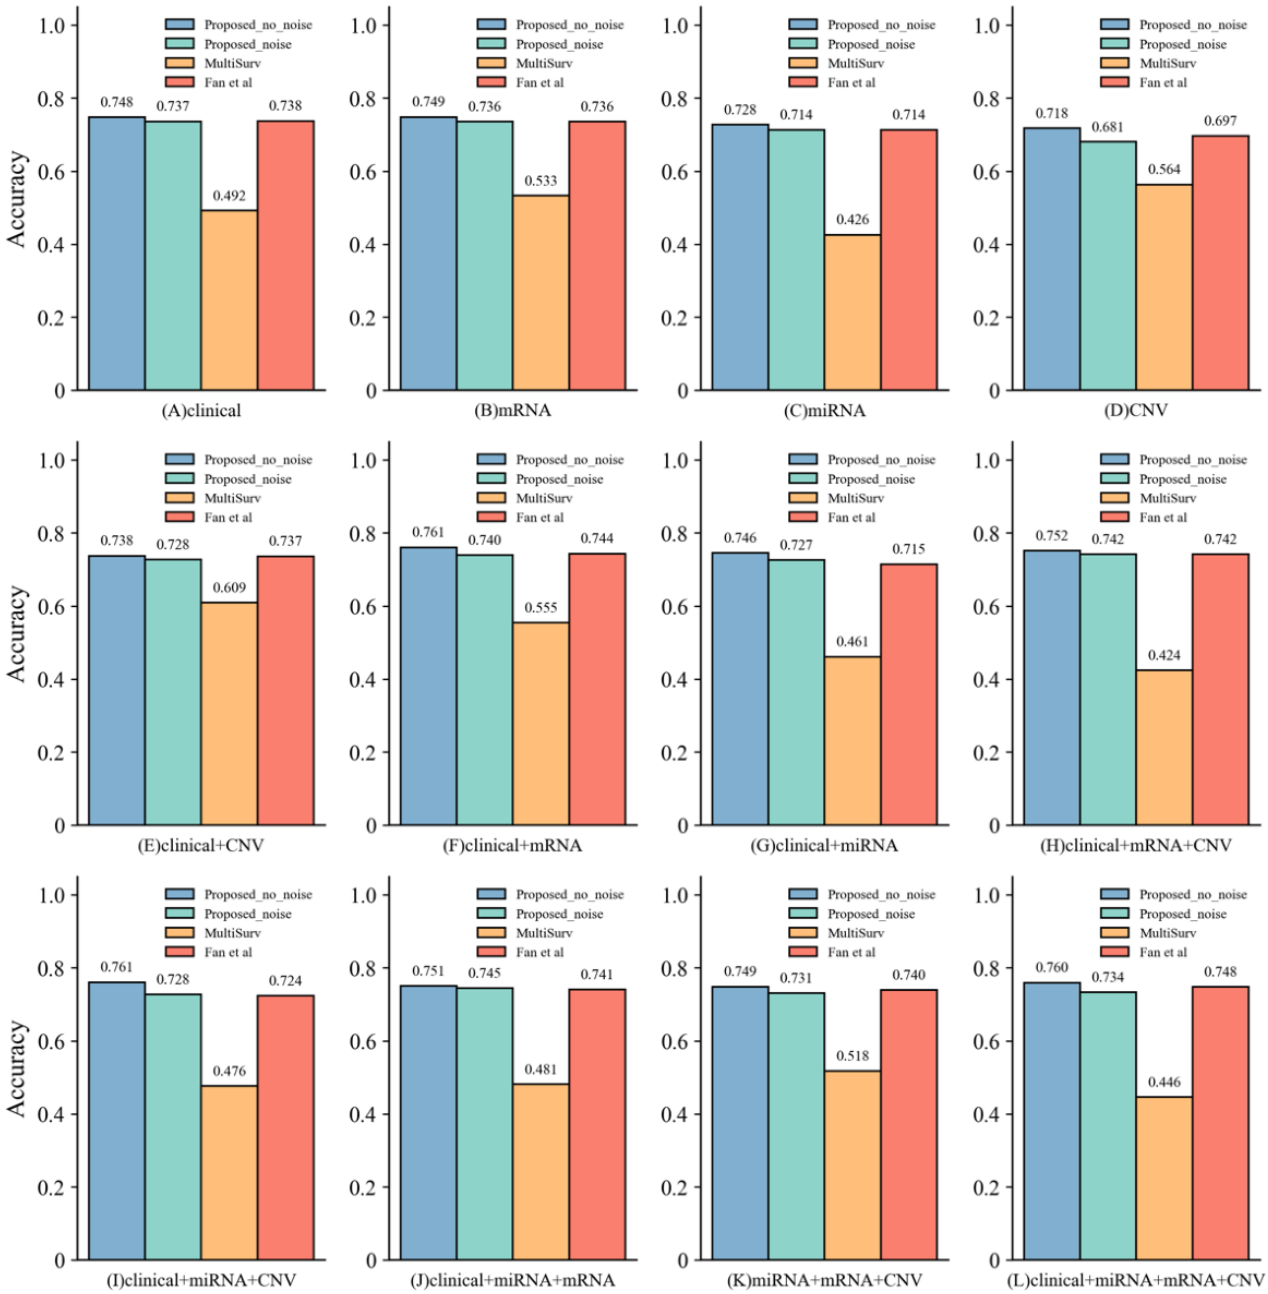
Privacy Protection Effect Comparison of Multimodal Methods



To further evaluate the impact of noise addition on model performance, this study uses accuracy as an auxiliary metric, with patients' survival status as the classification criterion (where deceased patients are labeled as 1 and surviving patients as 0), and implements the classification and prediction of survival status through a neural network with 3 FC layers. Leveraging the pan-cancer dataset, a systematic analysis is conducted on the model's survival classification performance across 4 data combinations: clinical data, mRNA, miRNA, and CNV. The proposed model is compared with 2 state-of-the-art attention-based models for pan-cancer survival prediction: MultiSurv [17] and Fan et al [10].

In unimodal settings, as shown in Figures 5A-5D, the proposed model demonstrates strong robustness. For instance, in the miRNA modality, accuracy slightly decreases from 0.728 before noise injection to 0.714 after; in the mRNA modality, accuracy drops modestly from 0.749 to 0.736.

Experiments involving multimodal combinations were conducted in dual-, tri-, and 4-modality settings. As shown in Figures 5E-5L, the model also maintains stable performance under multimodal conditions. For example, the clinical + miRNA + mRNA combination achieves an accuracy of 0.751 before noise addition and 0.746 afterward; for the clinical + mRNA combination, accuracy declines from 0.761 to 0.740 after noise injection.

Survival Prediction Using Pan-Cancer Training Dataset

To evaluate the survival prediction advantages of the proposed model across different modalities, this study adopted the C-index as the performance metric and compared it against 6 state-of-the-art models: the CPH [3], RSF [2], MultiSurv, DeepHit [15], CMTA [16], and Fan et al [10]. The experiments are conducted using clinical data, mRNA, miRNA, and CNV data in both unimodal and multimodal settings. All results were obtained via 5-fold cross-validation and are summarized in Table 2.

Clinical + CNV	—[h]	—	0.752 (±0.008)	0.747 (±0.006)	0.758 (±0.012)	0.753 (±0.005)	0.763 (±0.006)[d]
Clinical + mRNA	—	—	0.773 (±0.008)	0.764 (±0.011)	0.785 (±0.010)	0.784 (±0.007)	0.792 (±0.006)[d]
Clinical + miRNA	—	—	0.758 (±0.011)	0.760 (±0.008)	0.763 (±0.007)	0.766 (±0.010)	0.783 (±0.007)[d]
Clinical + mRNA + CNV	—	—	0.766 (±0.012)	0.768 (±0.013)	0.774 (±0.013)	0.779 (±0.007)	0.785 (±0.004)[d]
Clinical + miRNA + CNV	—	—	0.760 (±0.009)	0.761 (±0.010)	0.762 (±0.009)	0.764 (±0.007)	0.775 (±0.008)[d]
Clinical + miRNA + mRNA	—	—	0.771 (±0.014)	0.773 (±0.014)	0.779 (±0.013)	0.777 (±0.013)	0.799 (±0.012)[i]
miRNA + mRNA + CNV	—	—	0.747 (±0.013)	0.752 (±0.012)	0.770 (±0.007)	0.767 (±0.008)	0.778 (±0.010)[d]
Clinical + miRNA + mRNA + CNV	—	—	0.768 (±0.013)	0.770 (±0.010)	0.772 (±0.012)	0.779 (±0.010)	0.787 (±0.007)[d]

[a]CPH: Cox proportional hazards model.

[b]RSF: random survival forest.

[c]CMTA: cross-modal translation and alignment.

[d]$P<.05$ vs MultiSurv, DeepHit, CMTA, and Fan et al [10] (paired *t* test with Bonferroni correction, n=1000 bootstrap samples).

[e]mRNA: messenger RNA.

[f]miRNA: microRNA.

[g]CNV: gene copy number variation.

[h]Not available.

[i]$P<.01$ vs CMTA (top competitor; paired *t* test with Bonferroni correction, n=1000 bootstrap samples).

To substantiate claims of superiority despite modest C-index differences, statistical significance testing was performed using bootstrapped resampling and 2-tailed paired *t* tests. For each model and modality combination, 1000 bootstrap samples were generated from the test set. Paired *t* tests were conducted on the bootstrapped C-index values (n=1000) to test the null hypothesis that the mean performance difference is 0, with Bonferroni correction applied for multiple comparisons. Additionally, 95% CIs were derived from the bootstrap distributions. Nonoverlapping CIs are interpreted as indicating statistically significant differences ($P<.05$).

In unimodal prediction scenarios, the proposed model achieves C-index scores of 0.775, 0.779, 0.760, and 0.659 for clinical, mRNA, miRNA, and CNV data, respectively—significantly outperforming the CPH and RSF, which are limited to unimodal survival prediction. Notably, the proposed model yields the highest performance on mRNA data, with a C-index of 0.779, compared to 0.715 for CPH and 0.739 for RSF.

Furthermore, in the multimodal setting, this study compared the performance of MultiSurv, DeepHit, CMTA, Fan et al [10], and the proposed model across various combinations of data modalities. As shown in Table 2, the proposed model consistently achieves C-index values around 0.78 across different combinations. The highest performance is observed in the trimodal configuration (clinical + mRNA + miRNA), which yields a C-index of 0.799—surpassing MultiSurv (0.771),

XSL•FO
RenderX

DeepHit (0.773), CMTA (0.779), and Fan et al [10] (0.777). To statistically validate these performance improvements, paired significance testing with multiple-comparison adjustment was conducted. For each model and modality combination, 1000 bootstrap samples were generated from the test set. Paired *t* tests were performed on the bootstrapped C-index values (n=1000) with Bonferroni correction applied for multiple comparisons. The proposed model demonstrated statistically significant improvements over all competitors in the optimal trimodal configuration (clinical + mRNA + miRNA) after multiplicity adjustment: vs CMTA (*P*=.008), Fan et al [10] (*P*=.006), MultiSurv (*P*=.003), and DeepHit (*P*=.004). These adjusted *P* values (<.05) confirm that the observed C-index improvements (0.020, 0.022, 0.028, and 0.026 relative to CMTA, Fan et al [10], MultiSurv, and DeepHit, respectively) are statistically robust and not attributable to random variation.

This superior performance is attributed to the model's dual-layer feature extraction architecture, which, leveraging multiview parallel processing, enables finer-grained automatic weight adjustment. Notably, our proposed model further integrates an adaptive DP protection mechanism to safeguard sensitive medical data, while still achieving a higher C-index compared to existing state-of-the-art multimodal models that lack privacy-preserving designs. These findings reinforce the advantage of multimodal inputs over unimodal inputs, as multimodal data provide more comprehensive and informative cues for survival prediction.

Comparison With Standard Privacy Protection Methods

To comprehensively validate the superiority of the proposed adaptive DP framework in balancing privacy protection and predictive utility, this study adopted 2 core metrics—C-index for survival outcome ranking accuracy and classification accuracy for binary survival status prediction (deceased=1 and surviving=0)—and systematically compared it against 3 standard DP-aware baseline models: DP-Stochastic Gradient Descent (SGD) [36], DP-Adam [37], and Private Aggregation of Teacher Ensembles (PATE) [38]. The experiments were conducted under the optimal multimodal setting (clinical + mRNA + miRNA), with a fixed global privacy budget of = 0.8 (δ = 1e-5 for DP-SGD and DP-Adam, as per their standard implementations) to ensure a fair comparison of use under identical formal privacy guarantees. Consistent data preprocessing (zero-vector imputation for missing modalities, minimum-maximum normalization) and model training configurations (Adam optimizer, learning rate=0.001, batch size=256, and 100 epochs) were used across all methods to eliminate confounding variables. All results were derived from 5-fold cross-validation on the pan-cancer test set and supplemented with 1000 bootstrap resamples for statistical significance testing (paired *t* test with Bonferroni correction, *P*<.05). Detailed performance metrics and comparative analysis are summarized in Table 3.

Table 3 clearly shows that the proposed adaptive DP framework outperforms all standard DP baselines in maintaining predictive utility under the same formal privacy guarantee (=0.8). Regarding the C-index—the gold standard for survival prediction that assesses the ordinal consistency between predicted risk scores and actual survival times—the proposed model achieves 0.799 (±0.012), which is 4.3, 3.7, and 6.5 percentage points higher than DP-SGD (0.756 ± 0.015), DP-Adam (0.762 ± 0.014), and PATE (0.734 ± 0.016), respectively. Its utility loss compared to the non-DP counterpart (0.821 ± 0.008) is only 0.022, which is less than half of DP-SGD's loss (0.065) and about 1/3 of PATE's loss (0.087). This confirms that the layer-wise relevance propagation–guided targeted noise injection strategy more efficiently uses the privacy budget, preserving high-relevance prognostic features while satisfying -DP.

In terms of binary survival status classification accuracy, the proposed model maintains a high level of 0.745 (±0.013), outperforming the aforementioned baselines by 0.8, 1.0, and 1.4 percentage points, respectively. Its accuracy drop (0.006) is also significantly smaller than that of the baselines (0.014-0.020), further validating the efficiency of adaptive noise allocation in minimizing utility degradation for a given . Statistical analysis (paired *t* test with Bonferroni correction, n=1000 bootstrap samples) reveals that the proposed model's C-index and accuracy are significantly different from all baselines (*P*<.05), with nonoverlapping 95% CIs, confirming the robustness of the observed improvements.

Table 3. Use comparison of proposed model vs standard differential privacy (DP) baselines (multimodal: clinical + messenger RNA + microRNA; =0.8).

Modality	C-index[a]	Accuracy
Proposed_no_noise	0.821 (±0.008)	0.751 (±0.008)
Proposed model	0.799 (±0.012)	0.745 (±0.013)
DP-SGD[b]	0.756 (±0.015)	0.737 (±0.010)

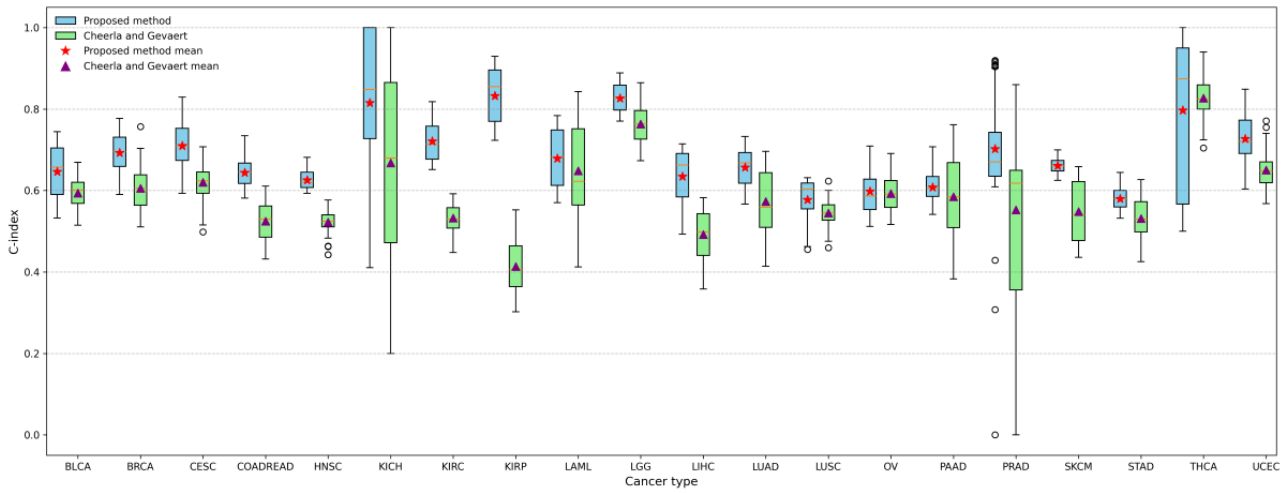
Analysis of Privacy Protection Effectiveness

The proposed adaptive DP mechanism is designed to satisfy -DP (=0.8) as formally proven in equation 20. Compared with traditional uniform noise injection methods (DP-SGD and DP-Adam) under the same global privacy budget, our method significantly improves the accuracy of survival prediction (with the C-index increased by 3.7-6.5 percentage points; Table 3). This result indicates that, for the same formal privacy guarantee ( ), our adaptive allocation strategy achieves higher predictive utility. The adaptive mechanism identifies features with high relevance to prediction and allocates a larger portion of the privacy budget to them (injecting less noise), thereby preserving critical prognostic information. Conversely, features with low predictive contribution receive a smaller budget (more noise), which theoretically enhances privacy protection for those elements without harming overall model utility. Therefore, the proposed method provides a stronger formal privacy guarantee for low-relevance features and achieves superior utility for high-relevance features under the same constraint, representing a more efficient use of the privacy budget.



Comparison of Survival Prediction Performance for Individual Cancer Types

To investigate the effectiveness of the proposed model in predicting survival outcomes for individual cancer types, this study conducted a comparison between our proposed model and the state-of-the-art deep learning–based model (Cheerla and Gevaert [9]) for single-cancer prediction using pan-cancer datasets. For consistency, this study adopted a multimodal input comprising clinical, miRNA, and mRNA data. The results are presented in Figure 6.

Compared with Cheerla and Gevaert [9], our proposed method achieved a higher C-index in the majority of cancer types—18 out of 20. Notably, in 7 of these 18 cancer types, the performance improvement was substantial, with C-index differences exceeding 0.1.

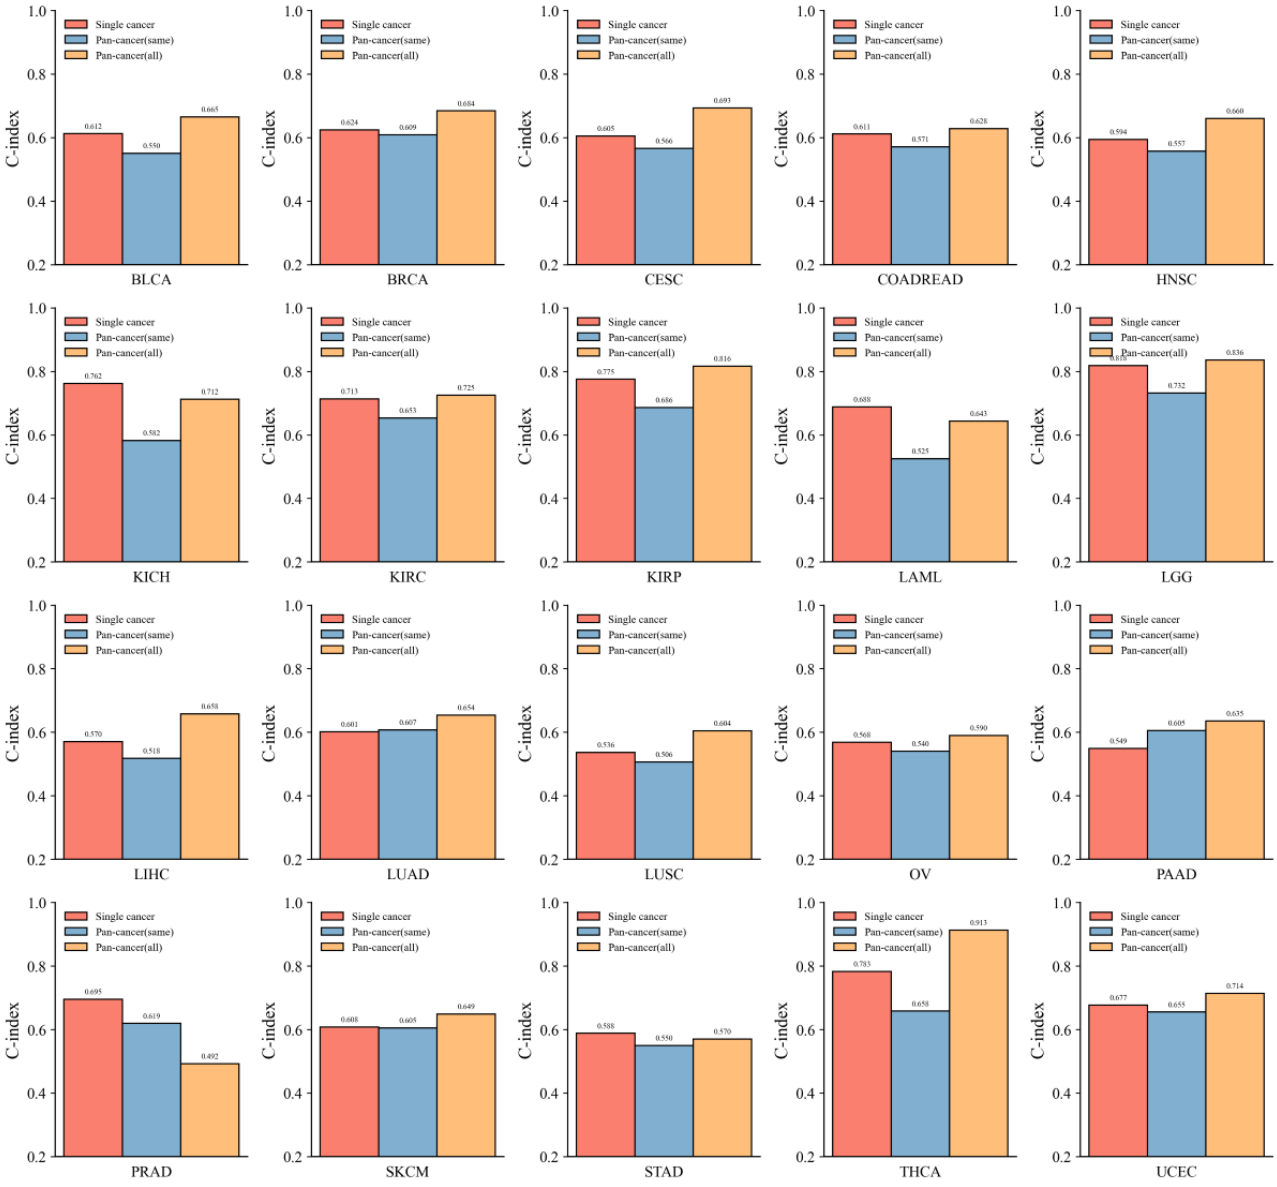
Furthermore, as illustrated in Figure 6, our model exhibits higher median C-index values for several cancer types and demonstrates more concentrated distributions in the upper range. This indicates both superior and more stable predictive performance. In contrast, Cheerla and Gevaert [9] show relatively lower C-index scores in some cancer types, with several boxplots revealing greater data dispersion and reduced stability.

Figure 6. Concordance index (C-index) of the proposed model (blue bars) and the previous work (Cheerla and Gevaert [9]; green bars) on the 20 cancer types using the modality combination of clinical, microRNA, and messenger RNA. BLCA: bladder urothelial carcinoma; BRCA: breast invasive carcinoma; CESC: cervical squamous cell carcinoma; COADREAD: colon adenocarcinoma/rectum adenocarcinoma; HNSC: head and neck squamous cell carcinoma; KICH: kidney chromophobe; KIRC: kidney renal clear cell carcinoma; KIRP: kidney renal papillary cell carcinoma; LAML: acute myeloid leukemia; LGG: low-grade glioma; LIHC: liver hepatocellular carcinoma; LUAD: lung adenocarcinoma; LUSC: lung squamous cell carcinoma; OV: ovarian serous cystadenocarcinoma; PAAD: pancreatic adenocarcinoma; PRAD: prostate adenocarcinoma; SKCM: skin cutaneous melanoma; STAD: stomach adenocarcinoma; THCA: thyroid carcinoma; UCEC: uterine corpus endometrial carcinoma.

Comparison Between Using Single-Cancer and Pan-Cancer Training Datasets

To further investigate the predictive performance of the proposed model across different types of datasets, this study conducted experiments using both pan-cancer and single-cancer datasets. The first objective was to examine whether training on pan-cancer data improves survival prediction accuracy for individual cancer types. In this study, we selected the same 20 cancer types as those used by Cheerla and Gevaert [9], where patients have significantly different survival patterns.

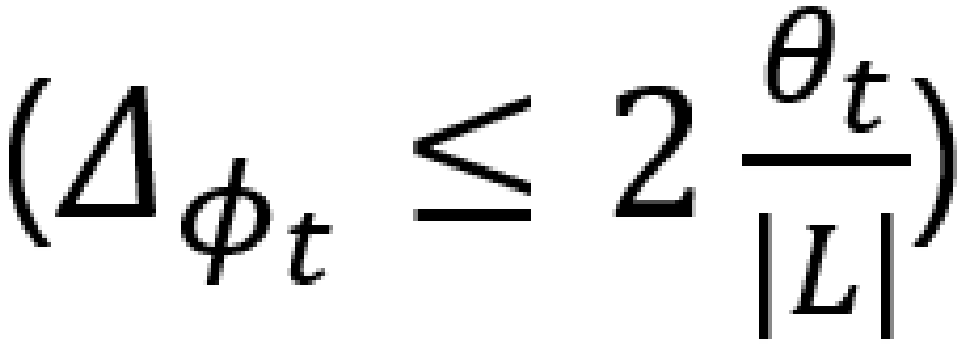
This study first compared the performance of models trained solely on single-cancer data with those trained on all pan-cancer samples, using consistent test sets for each cancer type. For single-cancer experiments, this study selected patients with the same cancer type in pan-cancer training-validation-test sets to form the single-cancer training-validation-test sets. The model was trained using integrated clinical, mRNA, and miRNA modalities, and the results are shown in Figure 7.



As shown by the bar plots labeled “Single cancer” and “Pan-cancer (all)” in Figure 7, the model trained on pan-cancer data generally outperformed the single-cancer–trained model

XSL•FO
RenderX

on the same test sets, with the exception of 4 cancer types: kidney chromophobe, acute myeloid leukemia, prostate adenocarcinoma, and stomach adenocarcinoma. For example, in the case of bladder urothelial carcinoma the pan-cancer–trained model achieved a C-index of 0.665, significantly higher than the 0.612 achieved by the model trained only on bladder urothelial carcinoma data.



To control for potential biases due to varying training sample sizes, this study further evaluated model performance when trained on an equal number of samples from the pan-cancer and single-cancer datasets. Specifically, we selected subsets of pan-cancer data matching the sample size of each individual cancer dataset. As illustrated by the bar plots labeled "Single cancer" and "Pan-cancer (same)" in Figure 7, the single-cancer–trained models generally outperformed the pan-cancer–trained counterparts under equal training size conditions.

Figure 7. Concordance index (C-index) scores of the proposed model trained on single-cancer and pan-cancer datasets on 20 cancer types using clinical, messenger RNA, and microRNA modalities. Red bars represent models trained on single-cancer datasets, where only patients with the same cancer type were used. Blue bars indicate models trained on pan-cancer datasets with sample sizes matched to each single-cancer dataset to control for sample size bias. Orange bars correspond to models trained on the full pan-cancer dataset. BLCA: bladder urothelial carcinoma; BRCA: breast invasive carcinoma; CESC: cervical squamous cell carcinoma; COADREAD: colon adenocarcinoma/rectum adenocarcinoma; HNSC: head and neck squamous cell carcinoma; KICH: kidney chromophobe; KIRC: kidney renal clear cell carcinoma; KIRP: kidney renal papillary cell carcinoma; LAML: acute myeloid leukemia; LGG: low-grade glioma; LIHC: liver hepatocellular carcinoma; LUAD: lung adenocarcinoma; LUSC: lung squamous cell carcinoma; OV: ovarian serous cystadenocarcinoma; PAAD: pancreatic adenocarcinoma; PRAD: prostate adenocarcinoma; SKCM: skin cutaneous melanoma; STAD: stomach adenocarcinoma; THCA: thyroid carcinoma; UCEC: uterine corpus endometrial carcinoma.

External Validation on Independent Cohorts

To address the critical question of generalizability beyond the TCGA dataset, we conducted an external validation on 2 independent cancer cohorts from the International Cancer Genome Consortium (ICGC) database [39]. Specifically, we selected the hepatocellular carcinoma (HCC; ICGC-HCC) and clear cell renal cell carcinoma (ccRCC; ICGC-ccRCC) projects, which provide clinical survival information and mRNA expression data compatible with our model's input requirements. To maintain consistency with our multimodal input configuration (clinical + mRNA + miRNA), the same zero-vector imputation strategy described in the Methods section ("Data Preprocessing") was applied to handle the missing miRNA modality and any mRNA features absent in the external data. The ICGC-HCC cohort comprised 242 patients with overall survival data, and the ICGC-ccRCC cohort comprised 530 patients. For each cohort, we preprocessed the mRNA expression data by aligning gene features to the 1579 mRNA features used in our TCGA training set. All continuous features were normalized using the minimum and maximum values derived from the TCGA training set to ensure consistent scaling.

This study applied our proposed model (trained on the pan-cancer TCGA dataset with clinical + mRNA + miRNA modalities) directly to the preprocessed ICGC cohorts without any retraining or fine-tuning. The model's survival prediction performance was evaluated using the C-index.

Our proposed model, trained on the pan-cancer TCGA dataset, achieved a C-index of 0.721 on the independent ICGC-HCC cohort and 0.708 on the ICGC-ccRCC cohort. This demonstrates that the model maintains its generalizable prognostic discriminatory power on unseen, external patient populations.

Discussion

Principal Results

In this study, we evaluated the model's classification performance in survival prediction across 4 data combinations—clinical data, mRNA, miRNA, and CNV—using the pan-cancer dataset. Compared with MultiSurv [17], the proposed model exhibits an approximately 0.3 improvement in prediction accuracy across all modality combinations after noise injection. When compared with Fan et al [10], the proposed model achieves higher accuracy in all settings before noise addition, and maintains comparable accuracy after noise injection, despite the latter model not incorporating any privacy-preserving mechanisms.

The improvement in survival prediction across different modalities stems from the model's ability to capture key information from different subspaces in parallel, thereby overcoming the representational limitations of single-attention mechanisms. By effectively integrating core features from each modality, the model enhances the flexibility and expressiveness of the fusion process. Notably, the inclusion of the CNV modality generally leads to a decline in predictive performance, suggesting that CNV data contain relatively fewer informative features relevant to patients' survival. This further underscores the value of multimodal data fusion in enhancing the generalizability of survival prediction models.

Comparisons in single-cancer survival prediction further demonstrate that the model achieves higher and more stable C-index values in 18 out of 20 cancer types compared with existing deep learning methods, highlighting its robustness in individualized survival prediction. Our study not only confirms the effectiveness and superiority of the proposed model in individualized cancer survival prediction but also demonstrates its ability to preserve patients' privacy. Collectively, these results provide a more reliable and privacy-conscious solution for precision oncology applications.

XSL•FO
RenderX

In addition, experiments conducted on both pan-cancer and single-cancer datasets show that the proposed model maintains strong predictive capability across diverse data settings, demonstrating robust generalization ability.

Challenges

While the model demonstrates strong privacy-preserving capabilities through DP, the integration of DP mechanisms into clinical artificial intelligence models introduces certain challenges. First, DP may impact the interpretability of the model, as the noise added to the gradients or model parameters can obscure the relationships between input features and predicted outcomes. This could reduce the transparency of the model, making it more difficult for clinicians to trust and understand the model's decisions, which is critical in medical applications. In addition, DP mechanisms may complicate auditability, as it becomes harder to trace the influence of individual data points on the model's predictions due to the noise injected for privacy protection.

Second, the integration of privacy mechanisms such as DP into clinical workflows or federated research environments can be practically challenging. In clinical settings, where data are highly sensitive, ensuring that privacy is preserved while maintaining the usability and accuracy of predictive models requires careful consideration of computational resources and model deployment strategies. In federated research environments, where data are distributed across multiple institutions, ensuring that DP mechanisms are applied consistently across all sites without compromising the model's predictive performance can be technically difficult. Moreover, adapting these privacy-preserving mechanisms to existing clinical systems and ensuring compliance with data protection regulations (eg, General Data Protection Regulation requires close collaboration with regulatory bodies and careful planning of data-sharing protocols.

These considerations highlight the need for further research into improving the balance between privacy protection, model interpretability, and practical integration in clinical and research settings.

Limitations

The proposed model has certain limitations. First, while we have demonstrated the model's effectiveness on the TCGA pan-cancer dataset and provided initial evidence of generalizability through external validation on ICGC cohorts, the performance on independent datasets shows a nonnegligible decline. This underscores the inherent challenge of translating models trained on 1 cohort (even a large and diverse one like TCGA) to others due to population, treatment, and technical variability. More extensive validation across multiple, prospectively collected cohorts is needed to fully establish clinical readiness. For example, training efficiency requires improvement. Analysis suggests that one possible reason is the introduction of the bilayer feature extraction module based on MHA and the adaptive DP protection mechanism, which increases algorithmic computational complexity. Additionally, the model exhibits increased inference time compared with simpler architectures such as CPH or RSF, due to the MHA mechanism and the privacy-preserving noise injection process. This may limit its deployment in real-time clinical settings where rapid predictions are required. Meanwhile, comparative experiments with other advanced models on larger-scale multimodal datasets are necessary. Indeed, in the era of big data and multimodal data fusion, new challenges lie ahead.

Future Work

Future work will expand in several directions. On the one hand, integrating pathological images and proteomics data will enhance multimodal feature fusion, extracting and fusing more information to further improve prediction performance. On the other hand, the model will be applied to additional tasks such as cancer subtype classification and biomarker discovery. Finally, research on other noise mechanisms based on DP is needed to protect sensitive information from multiple perspectives and ensure the security of model training and sharing. Moreover, efforts will be made to optimize the computational efficiency and reduce inference time through techniques such as model pruning, quantization, or lightweight attention mechanisms, thereby enhancing the model's practical applicability in clinical environments. To address potential limitations of zero-vector imputation, future work will also explore advanced missing-modality handling strategies, including masking strategies and missing-modality–aware attention mechanisms.

Conclusions

To address the key challenges of inefficient multimodal integration, insufficient privacy protection, and limited generalizability in pan-cancer survival prediction, this study proposes a bilayer feature fusion model integrating the MHA mechanism and adaptive DP. Innovatively, the framework uses modality-specific FC networks in the first layer to extract features from clinical, mRNA, miRNA, and CNV data. The second layer uses MHA to model cross-modal interactions through parallel attention heads, dynamically allocating weights to focus on survival-related features and overcoming the limitations of static fusion. Additionally, layer-wise relevance analysis is used during first-layer feature extraction to quantify the correlation between features and outcomes, enabling adaptive DP—injecting less Laplacian noise into the gradients of high-correlation features and more noise into low-correlation features to balance privacy and utility. Experimental results on pan-cancer datasets from TCGA demonstrate the feasibility and superiority of our proposed method. Furthermore, external validation on independent ICGC cohorts provided preliminary evidence of the model's generalizability, showing retained predictive power superior to clinical-only models despite expected performance attenuation due to cohort heterogeneity.

Abstract

Background: Augmented reality (AR) has emerged as a promising tool to enhance surgical precision during robot-assisted partial nephrectomy (RAPN), particularly by enabling the intraoperative overlay of 3D anatomical models. However, real-time AR implementation requires robust image segmentation of anatomical structures, such as the kidney, which remains technically challenging in dynamic laparoscopic environments.

Objective: This study aimed to develop and validate a large, annotated image dataset to train deep learning models for automated segmentation of the renal parenchyma during RAPN, as a prerequisite for real-time AR guidance.

Methods: We conducted a single-center, observational image annotation study using prospectively collected surgical videos from 131 RAPN procedures performed between 2022 and 2024. Patients had localized renal tumors, with 11 presenting with multifocal disease (160 tumors in total). A total of 48,000 frames were extracted based on image sharpness, diversity, and the exclusion of artifacts. A subset of 454 images was annotated by 9 contributors (surgeons, engineers, and nonexperts) after structured training. Interannotator agreement was assessed using the Dice similarity coefficient (DSC) and sensitivity against an expert reference. A convolutional neural network (AlbuNet-34) was trained using 12,546 annotated images and evaluated on a validation set of 3137 images. Model performance was analyzed overall and across surgical phases.

Results: Annotators achieved high agreement, with median DSC values ranging from 0.91 to 0.95 and sensitivity consistently more than 0.89. The deep learning model achieved a mean DSC of 0.75 (SD 0.23) and a sensitivity of 0.71 (SD 0.24) on the validation set. Segmentation accuracy varied significantly across surgical phases, with lower performance observed during tumor resection and tumor bed reconstruction due to increased visual complexity.

Conclusions: This study demonstrates the feasibility of automated renal parenchyma segmentation using deep learning in real-world intraoperative settings. Although current performance remains below that of expert-level annotations, the creation of

XSL•FO
RenderX

a large, annotated dataset and the implementation of a structured multiannotator workflow represent key milestones toward reliable AR-assisted surgery. Ongoing refinements in annotation quality, dataset diversity, and neural network optimization are expected to enhance future real-time AR applications in urology.

Introduction

Partial nephrectomy (PN) is the gold standard for the management of localized kidney tumors, allowing preservation of renal function while maintaining excellent oncological outcomes [1,2]. The introduction of minimally invasive techniques and robotic assistance has further improved perioperative outcomes by reducing blood loss, complications, and hospital stays [3,4]. However, robot-assisted PN (RAPN) remains technically demanding, particularly for complex tumors, for which precise identification of resection planes is essential to minimize ischemic injury and achieve complete tumor excision [5,6].

To enhance spatial understanding, high-resolution contrast-enhanced computed tomography (CT) enables the creation of patient-specific 3D virtual models [7-9]. Integrating these models intraoperatively, as in 3D image-guided RAPN (3D-IGRAPN) [10], improves surgical navigation. Augmented reality (AR) extends this approach by overlaying digital information directly onto the surgical field, supporting real-time localization of anatomical structures [11,12]. Unlike virtual reality (VR), which immerses users in a simulated environment, AR enhances the operative scene through image registration and tracking [13,14].

Surface-based registration facilitates alignment between preoperative 3D models and intraoperative images without requiring fiducial markers. This process relies on stereoscopic vision, in which 3D laparoscopic cameras triangulate corresponding points to reconstruct surface geometry. However, accurate registration depends on the prior recognition of the renal surface in intraoperative frames. Advances in computer vision and deep learning have made this possible by enabling automatic image segmentation and tracking of anatomical structures in real time [15]. Consequently, developing a robust AR system for RAPN requires training neural networks on large, diverse, and well-annotated datasets that capture the variability of intraoperative scenes. Figure 1 illustrates the overall workflow of an AR-guided RAPN procedure, in which intraoperative kidney segmentation forms the cornerstone for aligning preoperative 3D models with laparoscopic views.

Figure 1. Schematic representation of the augmented reality guidance process during robot-assisted partial nephrectomy. CT: computed tomography; OR: operating room.

Despite major advances in preoperative 3D modeling, intraoperative AR integration remains limited by the absence of large, multiannotator datasets that enable reliable real-time segmentation.

XSL•FO
RenderX

This study aimed to develop and validate a deep learning segmentation system for RAPN based on a large, multiannotator dataset. Specifically, we describe dataset construction, assess interannotator variability, and evaluate the performance of an automatic model designed to enable real-time kidney segmentation for AR-guided surgery.

Methods

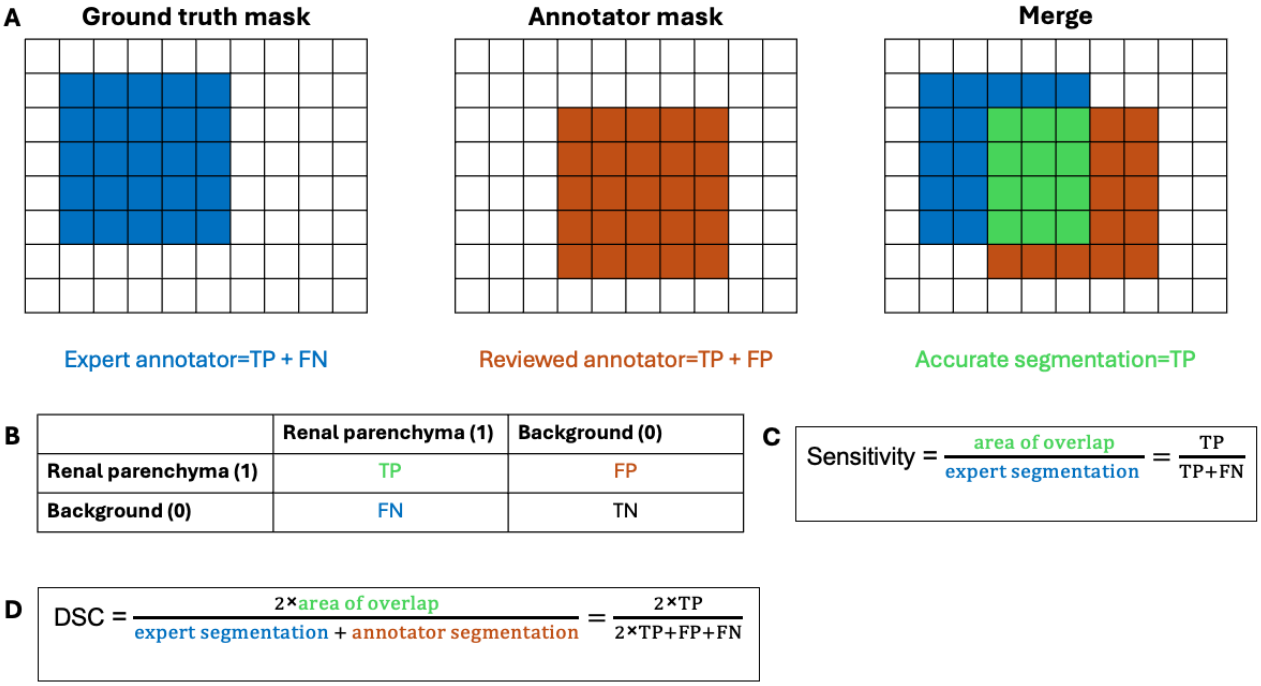
Study Design and Population

To train a neural network for accurately segmenting the renal parenchyma in intraoperative images, a high-quality dataset was constructed through the following steps: image collection, anonymization, preprocessing, annotation, and validation.

Between 2022 and 2024, surgical videos of RAPN performed with the da Vinci surgical system (Intuitive Surgical) were prospectively collected at an expert center (Bordeaux University Hospital, France). The inclusion criteria were as follows: (1) patients diagnosed with localized kidney tumors, either solitary or multiple, with varying complexity, location, and size and (2) patients eligible for RAPN who did not object to the collection of their data for the study. Videos were recorded using the MVR Pro system (MediCapture), ensuring that high-resolution video streams (1280×1024 pixels) were maintained.

Video Acquisition and Frame Extraction

Image extraction from the video footage was automated based on a predefined set of selection criteria to guarantee optimal quality and diversity. Image sharpness was assessed using Canny edge detection [16], which is based on the principle that sharp images exhibit a high density of well-defined contours. The sharpness score was computed as the ratio of detected edge pixels to the total image size, filtering out blurry or low-detail frames. A temporal spacing constraint was implemented to minimize redundancy by restricting frame extraction. This involved ensuring that frames were extracted only if the time interval between consecutive frames was >5 seconds. To achieve frame diversity, a Marr-Hildreth image hashing [17] algorithm was used. This technique computed the perceptual similarity between frames, discarding those with high redundancy based on a predefined Hamming distance threshold (set at 200). Extracted images were carefully reviewed to exclude artifacts and were subsequently annotated with metadata, including tumor location, size, and the RENAL (radius, exophytic/endophytic, nearness, anterior, location) nephrometry score [18]. The surgical procedures were divided into 5 critical phases: kidney release, tumor preparation, hilar dissection, tumor resection, and tumor bed reconstruction, each phase chosen for its relevance to AR-guided surgical improvements. All 131 RAPN procedures contributed usable images for each of the 5 predefined surgical phases (kidney release, tumor preparation, hilar dissection, tumor resection, and tumor bed reconstruction). Thus, every case was represented across all phases, ensuring a consistent phase-based distribution of annotated frames for training, validation, and testing.



Annotation Workflow and Quality Control

To achieve high-quality annotation, diverse annotator groups were defined: 2 junior urologists (regularly assisting in RAPN procedures), 2 physicians from other specialties (medical professionals without expertise in RAPN), 2 medical engineers (with technical backgrounds in the segmentation process), 2 external annotators (individuals without surgical or anatomical expertise), and 1 expert surgeon (professor of urology with extensive experience in performing RAPN). All annotators received uniform structured training, leveraging a detailed guidebook and the Supervisely software (Supervisely OÜ), initially focusing on basic annotation principles before advancing to the nuances of renal surgery images. Annotators were required to demonstrate proficiency by achieving scores of at least 80% in general training and at least 90% in renal-specific tasks, ensuring consistency and accuracy.

The reliability of annotated images was evaluated using sensitivity and the Dice similarity coefficient (DSC) [19] (Figure 2), compared to the ground truth provided by the expert surgeon. The DSC ranges from 0 to 1, with 1 indicating perfect agreement. Although no predefined threshold was set for an acceptable DSC in this study, values more than 0.8 are commonly considered indicative of good interannotator agreement.

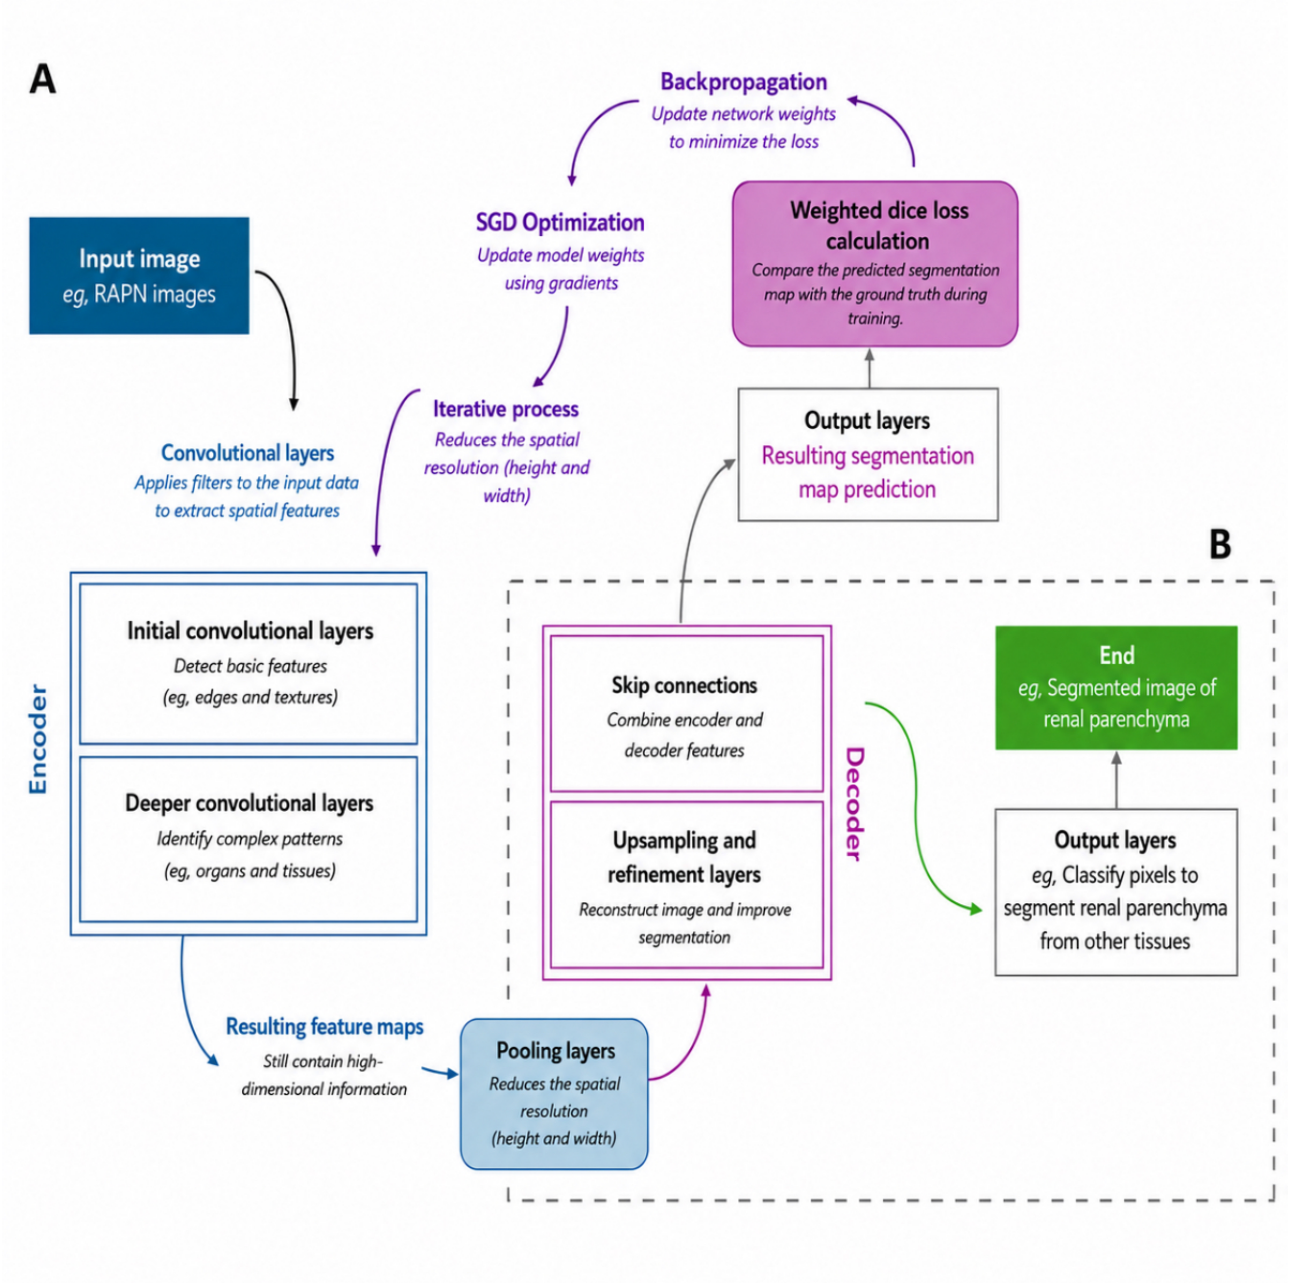
Renal parenchyma (1)	TP	FP
Background (0)	FN	TN

Consistency across annotators was ensured through an evaluative dataset featuring 454 images categorized into 3 complexity groups: simple, intermediate, and complex. Simple cases included images with an easily identifiable renal surface (97/454, 21.4%). Intermediate complexity was defined by the presence of significant fat on the renal surface (78/454, 17.2%); blood or clots (66/454, 14.5%); or instruments, compresses, clips, or loops in front of the renal surface (98/454, 21.6%). Complex cases involved the presence of at least 2 of these factors (115/454, 25.3%). The structural similarity index measure (SSIM) was used to confirm diversity, focusing on luminance, contrast, and structural features. SSIM scores, ranging from 0% to 100%, increase with greater similarity. The mean SSIM score for our dataset was 35.9%, indicating sufficient diversity to test the segmentation process while maintaining structural integrity and consistency. Heat maps were generated to visually represent areas of consensus and discrepancies across annotators.

Annotations from external contributors underwent statistical analysis to gauge accuracy before inclusion in the neural network dataset. For quality control, 9 surgeries were randomly selected to ensure balanced representation of surgical phases and annotator groups. Each segmentation was compared to expert reference masks to quantify labelling accuracy. A segmentation was considered correct when the predicted contour overlapped more than 70% with the expert-defined renal surface. A 30% error threshold was defined, based on prior internal validation experience, to trigger reannotation of uncertain or inconsistent cases. This relatively permissive threshold was selected as a pragmatic quality control criterion to identify clearly incorrect segmentations in complex intraoperative conditions, rather than to define optimal segmentation performance. This process allowed the quantification of overall annotation reliability and the identification of recurrent labelling errors before inclusion in the dataset. We calculated 95% CIs for the proportion of correctly annotated images.



To further assess annotation reliability, intraannotator variability analyses were conducted on a subset of the evaluation dataset. A total of 100 images were selected, including 20 images from each predefined complexity group. These images were annotated twice by the expert annotator.

Model Development and Training

AlbuNet-34 [20], a U-Net architecture–based [21] deep convolutional neural network (CNN), was implemented to automate renal parenchyma segmentation (Figure 3). The choice of the AlbuNet-34 architecture was guided by preliminary comparative experiments conducted during the development phase of the AR pipeline, prior to the present study. Conventional U-Net–based architectures and U-Net variants with different pretrained encoders (including ResNet-34, MobileNet-v2, and EfficientNet-B3) were evaluated under identical training conditions to assess convergence stability, segmentation accuracy, and computational efficiency in complex intraoperative scenes. AlbuNet-34 provided the most robust tradeoff between segmentation performance and computational cost, which motivated its selection for the present study. These comparisons focused on CNN-based architectures compatible with real-time intraoperative constraints. Although several architectures were explored during preliminary experiments, these comparisons were not conducted as part of a formal benchmarking framework and are therefore not reported quantitatively.

XSL•FO
RenderX

Figure 3. Schematic representation of the convolutional neural network architecture (AlbuNet-34), illustrating (A) the training phase and (B) the inference phase. SGD: stochastic gradient descent.

The annotated dataset was divided into a training set of 12,546 images and a validation set of 3137 images, with all images standardized to a resolution of 512×512 pixels. All frames from a given RAPN surgery were assigned to the same data subset to prevent data leakage. Consequently, no case contributed images to more than 1 partition. To address the strong class imbalance inherent to intraoperative images, a weighted Dice loss was applied to emphasize the minority class (renal parenchyma). Preliminary experiments without class weighting resulted in reduced sensitivity for renal parenchyma segmentation, which was detrimental to downstream surface tracking. The adopted loss function provided improved training stability and higher recall for the target organ.

The training process spanned 30 epochs, with a batch size of 8 to balance computational efficiency and convergence speed. Stochastic gradient descent (SGD) was used for optimization, starting with an initial learning rate of 0.001. To enhance convergence, an automatic learning rate scheduler reduced the learning rate by a factor of 0.1 every 5 epochs, preventing overshooting as training advanced. No explicit data augmentation strategy was applied during training. Preliminary augmentation experiments were conducted using standard techniques, including geometric transformations (rotations), photometric adjustments (brightness and contrast variations), and noise injection. However, these approaches did not yield consistent improvements in segmentation performance. Given the intrinsic variability of intraoperative images, including illumination changes, occlusions, bleeding, and tissue deformation, these strategies were not retained.

Model performance was rigorously assessed through sensitivity and DSC metrics, comparing its segmentation outputs to those of expert annotations.

XSL•FO
RenderX

Statistical Analysis

Segmentation performance was assessed using multiple complementary metrics: the DSC and the intersection over union (IoU) to quantify spatial overlap, sensitivity (recall) and specificity to evaluate pixel-wise detection performance, and precision (positive predictive value [PPV]) to characterize false-positive control.

For each image, all metrics were computed for each annotator. Results are summarized as both the mean (SD) and median (IQR) at the per-image level, as distributions were nonnormal (Shapiro-Wilk test: $P<.001$).

Interannotator agreement was analyzed by grouping annotators into four expertise groups: (1) senior surgeons ("Physicians"), (2) junior urologists, (3) medical engineers, and (4) external annotators without prior urological training.

To assess phase-specific performance, each annotated frame was assigned to a predefined surgical phase (kidney release, tumor preparation, hilar dissection, tumor resection, and tumor bed reconstruction). All 454 evaluated frames were mapped to one of these phases (n=215, 47.4% kidney release; n=91, 20% tumor preparation; n=50, 11% hilar dissection; n=42, 9.3% tumor resection; and n=56, 12.3% tumor bed reconstruction).

Statistical comparisons between groups were performed using the Kruskal-Wallis test.

Exact *P* values and effect sizes are reported. Statistical significance was defined as $P<.05$.

Analyses and plots were generated using R (version 4.4.2; R Foundation for Statistical Computing).

Ethical Considerations

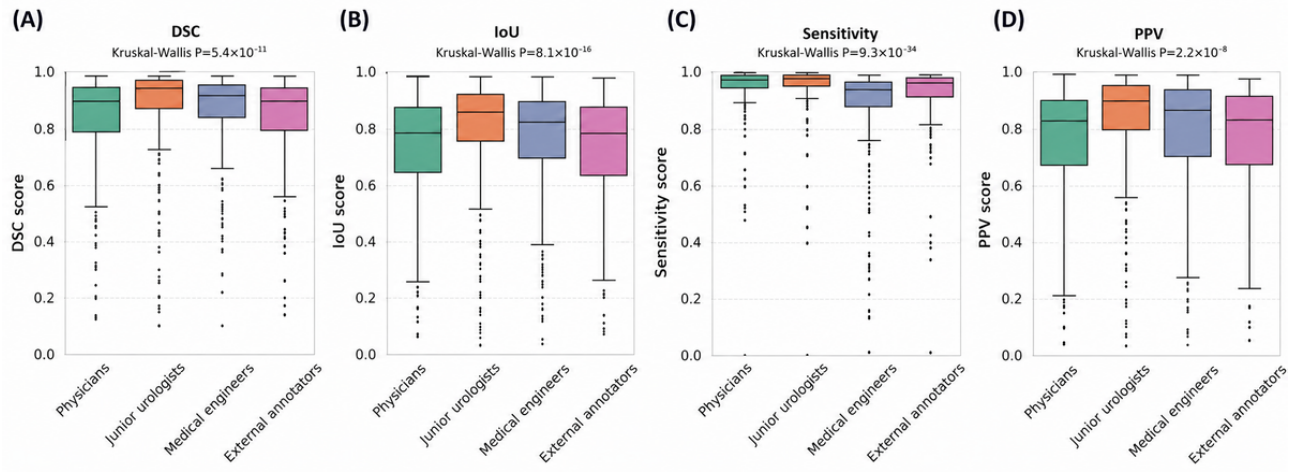
This study was approved under the UroCCR protocol 122 (ClinicalTrials NCT03293563), with data processing authorized by the CNIL (DR-2013-206). All patients provided written informed consent for the use of their surgical data for research purposes. Patient confidentiality was preserved through rigorous pseudonymization techniques implemented using the Scientific Python Development Environment (Spyder; version 5) and the *FFmpeg* library. This involved removing identifiable information and applying pseudonymization, with the resulting encrypted dataset stored securely with restricted access.

Results

Study Population and Dataset

To establish a comprehensive dataset for training an automated renal parenchyma recognition system, we gathered 131 RAPN surgical videos over 3 years. All surgeries provided usable annotated images for each of the 5 predefined surgical phases, resulting in a balanced dataset of 48,000 frames covering the full intraoperative workflow. A separate subset of 454 manually annotated frames was used exclusively for interannotator variability analysis and was not included in the training or validation datasets. Patient demographics are summarized in Table S1 in Multimedia Appendix 1. Among the included patients, 11 presented with multiple tumors, resulting in a total of 160 lesions. Detailed tumor characteristics (eg, location, size, proximity to critical structures, and RENAL nephrometry scores) are reported in Table S2 in Multimedia Appendix 2. A small subset of videos lacked patient identifiers and could therefore be used only for technical analysis, without linkage to individual clinical data.

Annotation Performance



Segmentation performance was evaluated across 4 annotator groups (n=454 manually annotated images): senior surgeons ("Physicians"), junior urologists in training, medical engineers, and external annotators without prior urological experience. Across all groups, DSC, IoU, sensitivity, and PPV varied significantly (Kruskal-Wallis $P<.001$ for all comparisons; Table 1; Figure 4).

Table 1. Percentage of annotations achieving Dice similarity coefficient (DSC), intersection over union (IoU), sensitivity, and positive predictive value (PPV) scores >0.8, stratified by annotator.

Annotators	Annotations with DSC >0.8, % (95% CI)	Annotations with IoU >0.8, % (95% CI)	Annotations with sensitivity >0.8, % (95% CI)	Annotations with PPV >0.8, % (95% CI)
Physician 1	73.1 (68.8-77.1)	70.8 (66.5-75.1)	93.8 (91.2-95.9)	81.2 (77.1-85.3)
Physician 2	72.3 (67.9-76.3)	69.7 (65.4-74.0)	92.3 (89.4-94.6)	80.4 (76.2-84.6)
Junior urologist 1	83.9 (80.2-87.2)	81.5 (77.6-85.3)	93.8 (91.2-95.9)	89.3 (86.0-92.6)
Junior urologist 2	77.1 (72.9-80.9)	75.0 (70.7-79.3)	93.4 (90.7-95.5)	85.7 (81.8-89.6)
Medical engineer 1	77.5 (73.4-81.3)	74.2 (70.0-78.4)	86.8 (83.4-89.6)	84.1 (80.2-87.9)
Medical engineer 2	77.3 (73.1-81.1)	73.5 (69.2-77.8)	85.7 (82.2-88.6)	83.2 (78.8-87.5)
External annotator 1	72.3 (67.9-76.3)	70.1 (65.8-74.4)	82.2 (78.4-85.4)	79.6 (75.1-84.0)
External annotator 2	70.0 (65.6-74.2)	67.9 (63.5-72.3)	92.9 (90.2-95.0)	80.2 (75.9-84.6)

XSL•FO
RenderX

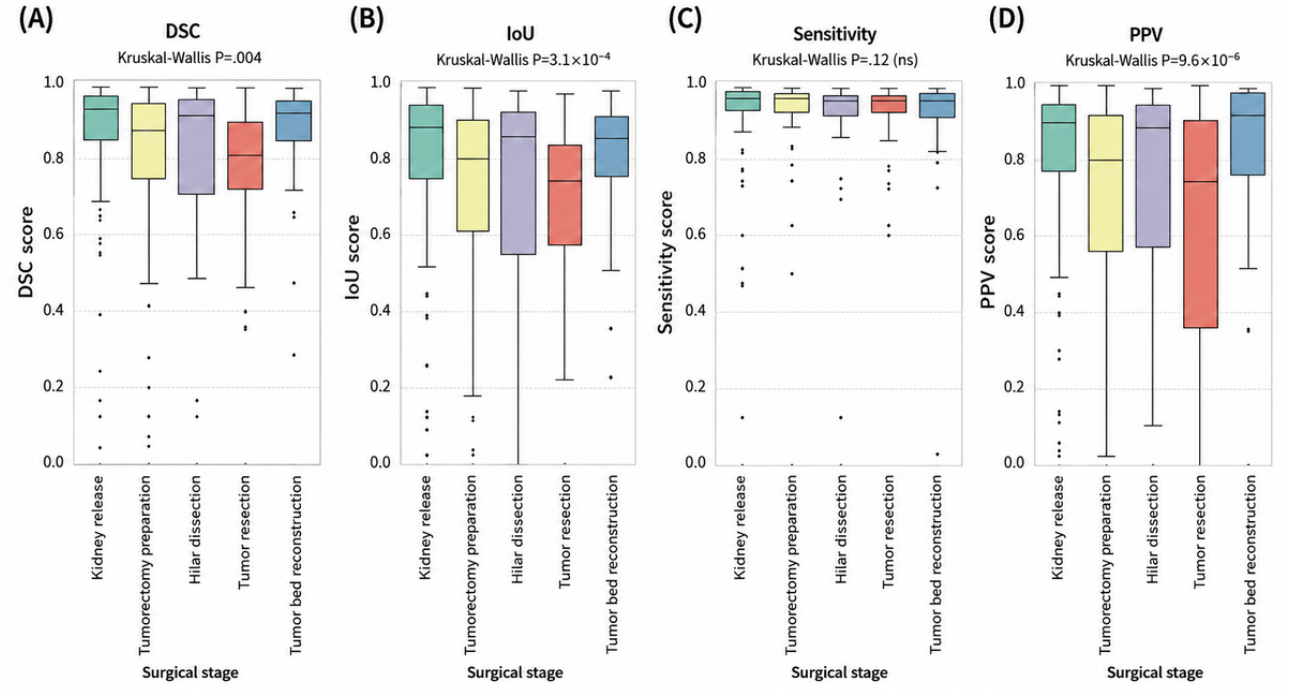


Figure 4. Boxplots of Dice similarity coefficient (DSC), intersection over union (IoU), sensitivity, and positive predictive value (PPV) across annotator groups. Boxes show median (IQR), and whiskers indicate 5th to 95th percentiles. Kruskal-Wallis *P*<.001 for all metrics.

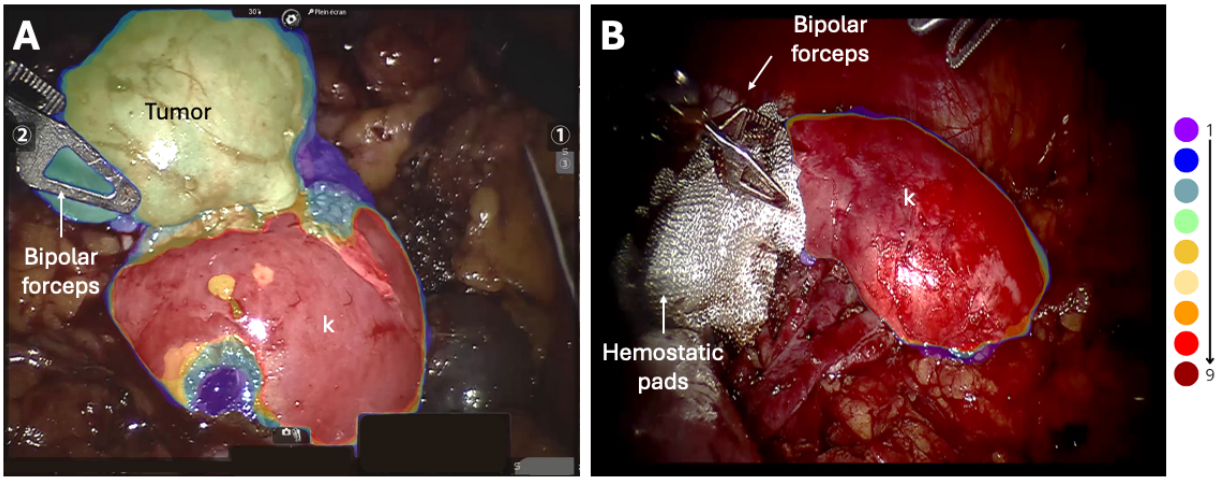
Junior urologists achieved the highest overall performance, with a median DSC of 0.95 (IQR 0.87-0.98), IoU of 0.91 (IQR 0.78-0.96), PPV of 0.93 (IQR 0.79-0.98), and sensitivity of 0.98 (IQR 0.96-0.99). Physicians achieved a median DSC of 0.91 (IQR 0.77-0.96), IoU of 0.83 (IQR 0.64-0.92), PPV of 0.86 (IQR 0.63-0.96), and sensitivity of 0.97 (IQR 0.95-0.99). Medical engineers achieved a median DSC of 0.92 (IQR 0.83-0.97), IoU of 0.86 (IQR 0.71-0.93), PPV of 0.91 (IQR 0.68-0.99), and sensitivity of 0.95 (IQR 0.88-0.97), while external annotators achieved a median DSC of 0.91 (IQR 0.78-0.96), IoU of 0.83 (IQR 0.64-0.92), PPV of 0.86 (IQR 0.64-0.95), and sensitivity of 0.97 (IQR 0.91-0.98; Table 1). Specificity remained uniformly high across all groups (≥0.97), confirming a low false-positive rate.

Between-group differences were significant for all metrics (Kruskal-Wallis *P*<.001 for DSC, *P*<.001 for IoU, *P*<.001 for sensitivity, and *P*<.001 for PPV). Overall, annotation accuracy was high (median DSC>0.90, IoU>0.80, and PPV>0.85), and trained junior urologists achieved the best balance between overlap and pixel-wise detection. Heat maps (Figure 5) provided visual overlays of segmentation overlap and discrepancies among the 9 annotators. Detailed per-annotator metrics (median and IQR for DSC, IoU, sensitivity, and PPV) are provided in Table S3 in Multimedia Appendix 3.

Figure 5. Boxplots of the Dice similarity coefficient (DSC), intersection over union (IoU), sensitivity, and positive predictive value (PPV) stratified by surgical phase (kidney release, tumorectomy preparation, hilar dissection, tumor resection, and tumor bed reconstruction). Boxes show median (IQR), and whiskers indicate 5th to 95th percentiles. Kruskal-Wallis *P*=.004 for DSC, and *P*=.12 for sensitivity.



Phase-based evaluation revealed differences in interannotator agreement across the 5 surgical phases (Figure 6). Median Dice scores relative to the expert reference were 0.94 (IQR 0.87-0.97) during kidney release, 0.90 (IQR 0.75-0.96) during tumor preparation, 0.92 (IQR 0.79-0.96) during hilar dissection, 0.90

XSL•FO
RenderX

(IQR 0.73-0.96) during tumor resection, and 0.95 (IQR 0.86-0.97) during tumor bed reconstruction.

Figure 6. Overlay of manual renal parenchyma segmentations during 2 surgical phases: (A) renal dissection and (B) tumor bed reconstruction, showing interannotator variability. Dark red indicates agreement among all 9 annotators, and purple indicates annotation by only 1 annotator.

Phase-based differences were statistically significant for most metrics (Kruskal-Wallis P=.004 for DSC, P<.001 for IoU, and P<.001 for PPV), whereas sensitivity remained stable across phases (P=.12), suggesting consistent pixel-wise detection even during technically demanding steps. Lower overlap metrics during the resection and preparation phases were consistent with occlusions, blood, and instrument interference, whereas the dissection and reconstruction phases maintained higher consistency. Full phase-specific results for each annotator group are summarized in Table S4 in Multimedia Appendix 4.

Intra-annotator variability analysis demonstrated high repeatability of expert annotations, with a median DSC of 0.94 (IQR 0.91-0.97) and a median IoU of 0.89 (IQR 0.84-0.94), depending on image complexity.

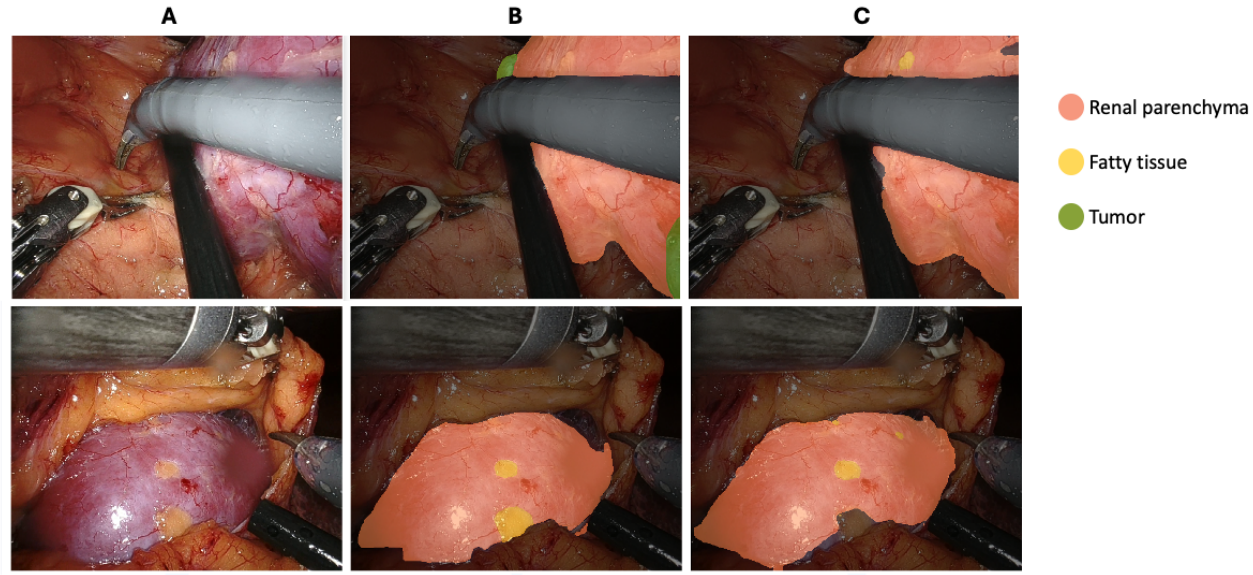
Annotation Efficiency and Quality Control

Annotation time varied markedly between groups (Kruskal-Wallis P<.001). External annotators required the most time (mean 4 minutes 24 seconds, SD 3 minutes 21 seconds per image) and medical engineers required the least time (mean 40, SD 23 seconds per image). High SDs (Table S5 in Multimedia Appendix 5) reflect substantial interparticipant variability, emphasizing the need for standardized annotation protocols.

External annotations were audited to ensure reliability. Despite their limited background, they achieved an average DSC of >0.81, contributing to the 48,000-image dataset. A targeted reevaluation of 9 surgeries (5459 images; Table 2) showed narrow 95% CIs for cases with ≥90% correct segmentation, supporting annotation precision. The global correct segmentation rate was 68.9% (SD 17.4%), with most errors arising from boundary misclassification and oversegmentation or undersegmentation. No correlation was found between the success rate and tumor characteristics.

Table 2. Assessment of external annotators' segmentation quality by expert review for 9 robot-assisted partial nephrectomy (RAPN) procedures[a].

Surgery (RAPN)	Segmentations judged correct by the expert reviewer, n/N (%; 95% CI)
RAPN 1	147/294 (50; 44-56)
RAPN 2	357/608 (58.72; 55-63)
RAPN 3	274/281 (97.51; 95-99)
RAPN 4	336/646 (52.01; 48-56)
RAPN 5	910/1005 (90.55; 89-92)
RAPN 6	530/759 (69.83; 66-73)
RAPN 7	437/618 (70.71; 67-74)
RAPN 8	449/864 (51.97; 49-55)
RAPN 9	301/384 (78.3-9; 74-82)



[a]Mean number of images per surgery 607 (SD 251); mean number of segmentations judged correct by the expert reviewer, 51.92% (216/416).

XSL•FO
RenderX

Model Performance

Using the manually annotated dataset, the AlbuNet-34 CNN achieved a mean DSC of 0.75 (SD 0.23) and a mean sensitivity of 0.71 (SD 0.24) against the expert ground truth. Figure 7 illustrates these comparisons across images of varying complexity. The model was trained on 12,546 images and validated on 3137 images, requiring approximately 10 hours and 24 minutes of computation.

Figure 7. Visual comparison of manual and automatic renal parenchyma segmentations. (A) Examples of intraoperative images, (B) corresponding expert manual segmentations, and (C) automatic segmentations generated by the AlbuNet-34 model.

Although these results confirm the feasibility of automatic renal parenchyma segmentation, model performance remains below that of expert-level segmentation, particularly during complex surgical phases, such as tumor resection and tumor preparation, where occlusions, bleeding, and instrument interference affect visual clarity.

Discussion

Principal Findings

In this study, we developed and validated a large multiannotator dataset to enable automatic kidney segmentation during RAPN. This work represents one of the first feasibility demonstrations of intraoperative segmentation for AR guidance, bridging preoperative 3D virtual modeling with near–real-time surgical vision. Importantly, the objective of this study was not to establish a state-of-the-art segmentation benchmark but to assess the feasibility and robustness of intraoperative kidney segmentation as a functional component of an AR pipeline. Given the growing evidence supporting the benefits of 3D virtual models in RAPN [10,22], our study specifically addresses the remaining gap: the intraoperative application of AR to achieve dynamic anatomical guidance.

Integrating AR into RAPN represents a shift from traditional imaging, overcoming the limitations of 2D modalities, such as ultrasound, CT, and magnetic resonance imaging (MRI), which fall short in dynamic surgical settings. AR offers real-time, 3D visualization, enhancing spatial understanding and decision-making [23]. This innovation is particularly critical for complex tasks, such as endophytic tumor localization and the preservation of critical structures, showing AR's potential to improve surgical precision, safety, and patient outcomes. Beyond preoperative 3D-IGRAPN, which has already demonstrated clinical benefits [10,22], our dataset and segmentation model address this intraoperative gap by providing quantitative validation of their feasibility.

Accurate real-time segmentation is crucial for the seamless overlay and alignment of digital models onto the surgical field. Surface-based registration plays a key role in enhancing the localization of renal surfaces and enabling image fusion without the need for physical markers. This capability is achieved through advanced stereoscopic vision and 3D camera technology, which facilitates precise spatial triangulation and the creation of an intraoperative 3D model derived from the renal surface topography. This intraoperative model is aligned with the virtual 3D model generated from preoperative CT scans. Surgical guidance using AR benefits from the combination of detection and tracking of the renal parenchyma, and the successful implementation of these processes relies on the initial recognition of the renal surfaces within intraoperative images using a trained neural network.

The development of a reliable parenchyma segmentation system relies on extensive datasets that are critical for accurate near–real-time organ segmentation. Our work highlights the time-consuming nature of manual segmentation, corroborating the findings of De Backer et al [24], who reported that 1248 hours were required to segment 15,100 frames in a study on real-time instrument delineation. Similarly, our time analysis highlighted substantial variability in the time annotators spent per image, with high SDs across groups (Table S5 in Multimedia Appendix 5). This variability likely contributed to the absence of statistically significant differences in segmentation performance between annotator groups. These findings reflect

XSL•FO
RenderX

the labor-intensive and cognitively demanding nature of the segmentation task, particularly given the large number of images involved. Together, these findings reinforce the importance of optimizing annotation workflows and potentially developing semiautomated tools to alleviate annotator burden.

Using nonexpert annotations effectively expands the dataset, alleviating the burden on medical professionals. Interannotator variability remains a challenge, with DSC scores often less than 0.70 for complex organs [25,26]. Additionally, recent studies underscore reduced identifiability for retroperitoneal organs, such as the kidneys, compared with intraperitoneal organs [27]. Despite these challenges, in our study, we obtained DSC scores higher than those reported in the existing literature [25,26], suggesting that trained nonexperts can contribute meaningfully to data annotation. However, the observed variability highlights the need for careful supervision and training to ensure annotation reliability. Importantly, quality control analysis confirmed that expert oversight remains essential, with approximately 69% of segmentations judged to be correct according to predefined quality control criteria based on expert overlap assessment.

To optimize nonexpert contributions, structured training and advanced annotation tools are critical. Providing clear guidelines and feedback loops through expert review enhances annotation accuracy, provides valuable learning opportunities for nonexperts, and improves dataset quality. Expanding the image source beyond a single expert center will increase dataset variability, making the dataset more representative of different clinical conditions and enhancing the AR system's utility and reliability in real-world surgical environments.

Phase-specific analysis revealed that segmentation performance varied significantly across surgical steps. Kidney release and reconstruction phases showed the highest agreement, while tumor resection and tumor preparation phases were more challenging due to occlusions, bleeding, and tissue deformation. These results highlight that the segmentation output is most reliable during the exposure and reconstruction phases, whereas selective activation during resection may optimize usability and reduce cognitive load.

Real-time performance remains challenging because rapid data processing is crucial for continuous updates during surgery. Preliminary integration experiments conducted during the development of the AR framework suggest that CNN-based renal parenchyma segmentation is compatible with near–real-time deployment on graphics processing unit (GPU)–based systems. However, these experiments were performed outside the scope of the present study and under different experimental conditions; therefore, a formal evaluation of latency and frame rate within an end-to-end AR pipeline is required to confirm real-time feasibility and clinical usability. Addressing latency [28], reducing equipment bulk, and improving user interfaces are essential steps toward broader adoption and practical application in surgical environments. Precise initial model positioning on organs is crucial for accurate alignment and tumor localization but remains a challenge due to difficult-to-identify anatomical landmarks on radiological and laparoscopic images [29]. Kidney appearance varies among patients, which can affect landmark visibility. Currently, manual registration is required; however, automating this process would streamline surgical workflows, allowing surgeons to focus entirely on the procedure. These real-time and integration constraints currently favor lightweight CNN-based architectures over more computationally demanding model families.

Our rigid registration framework highlights the need for models that accommodate soft tissue deformation. Addressing this limitation can significantly improve real-time modeling of organ dynamics, thereby refining the precision of AR tools. Our findings revealed phase-dependent variability in segmentation accuracy, highlighting the dynamic challenges of maintaining consistent AR performance throughout RAPN. Segmentation performance was highest during kidney release and reconstruction, whereas tumor resection and tumor bed reconstruction were more challenging because of increased visual complexity, including bleeding, instrument occlusion, and rapid anatomical changes. In this context, similar to ultrasound, AR guidance may be most effective when applied on demand at critical moments rather than continuously, thereby enhancing visualization when needed while minimizing unnecessary cognitive or technical burden. These phase-specific limitations also emphasize the importance of refining annotator training protocols and annotation tools for visually complex stages, as well as implementing ongoing quality control to improve dataset consistency and robustness.

More broadly, few robust studies have successfully segmented kidney structures from laparoscopic videos, underscoring the complexity of such imagery and the lack of standardized benchmarks in this domain. In this context, architectural choices were guided by robustness and computational efficiency under intraoperative constraints rather than by exhaustive benchmarking against multiple model families. A more systematic comparison of modern architectures, including lightweight CNNs and transformer-based models, would be valuable for further optimizing segmentation performance and should be addressed in future studies. The relatively low DSC score of our neural network, compared to those reported in CT- or MRI-based studies [30], arises from the unique challenges of laparoscopic images, such as lower resolution, variable lighting, and motion artifacts. These challenges present opportunities for innovation in improving segmentation accuracy. Although our model currently underperforms compared to human annotators, we anticipate that the performance of AlbuNet-34 will improve with time. Enhanced by data from the UroCCR network and our guidebook, which highlights annotator challenges, continuous training and additional data are expected to elevate the model's performance toward human-level accuracy. The AlbuNet-34 architecture was selected based on preliminary comparative experiments conducted during the development phase of the AR framework, in which several U-Net–based variants were evaluated under identical conditions. These comparisons aimed to identify a robust and computationally efficient solution compatible with intraoperative deployment, rather than to optimize performance on generic segmentation benchmarks.

The development of AR systems for RAPN exemplifies interdisciplinary collaboration, merging expertise in medicine, engineering, and computer science to enhance clinical viability

XSL•FO
RenderX

and technological sophistication. Real-life trials are crucial to validate the effectiveness of AR systems and ensure that they translate into tangible improvements in renal oncology surgery, culminating in better patient outcomes.

This study has several limitations. First, its single-center design and the absence of external validation may limit the generalizability of our findings. Second, although the reference standard was defined by a single expert annotator, intraannotator variability analysis demonstrated high repeatability (IoU>89% and DSC>93%). However, this analysis does not fully capture interexpert variability, and the lack of multiexpert consensus annotations may introduce systematic bias. Third, model evaluation was performed on a validation set without an independent held-out test set, which may lead to optimistic performance estimates. Fourth, segmentation performance varied across surgical phases, reflecting differences in visual complexity, and real-time feasibility was not formally assessed, particularly regarding latency and frame rate. Finally, although architectural choices were guided by robustness and computational efficiency, systematic benchmarking and ablation studies were not exhaustively performed, and some redundancy may persist in the dataset despite frame selection strategies. Future work should address these limitations through multicenter validation, multiexpert annotation, independent test datasets, and more comprehensive model comparisons.

Conclusions

This study presents the initial steps toward developing an AR system for RAPN, emphasizing interdisciplinary collaboration to enhance surgical precision. It validates the feasibility of intraoperative kidney segmentation based on a large multiannotator dataset and outlines the next step toward multicenter, real-time validation. Despite challenges related to segmentation variability and real-time processing, leveraging deep learning together with structured training for nonexpert annotators demonstrates promising potential. Future efforts will focus on model optimization, latency measurement, and clinical validation.

Data Availability

The datasets generated and analyzed during the current study are not publicly available because of patient confidentiality and institutional restrictions but are available from the corresponding author on reasonable request and subject to ethics approval.

Funding

As part of the Digital Urology 3D project [31], this work was supported by a government grant managed by the French National Research Agency under the third Investment for the Future Program, part of France 2030 (grant ANR-21-RHUS-0015).

Authors' Contributions

GM, JCB, AB, and NB conceived the study. KC, MP, AP, AK, JD, and FR-B contributed to data curation and methodology. GM, AP, and AK supervised the annotation protocol. GM drafted the manuscript. AB, NB, and LR provided technical validation. All authors reviewed and approved the final manuscript.

Conflicts of Interest

NB is Chief Executive Officer of SurgAR, a company developing artificial intelligence and augmented reality solutions for surgery. This role represents a potential conflict of interest relevant to the present work. The other authors declare no competing interests.

Abstract

Background: The Global Burden of Disease (GBD) study provides the most comprehensive global burden estimates available, but translating GBD data downloads into structured analyses requires an integrated, multimethod workflow spanning trend estimation, changepoint detection, demographic decomposition, frontier benchmarking, and health inequality measurement. Existing tools cover portions of this workflow, but none integrate it end-to-end in a code-free interface, creating a substantial technical barrier, particularly for investigators in resource-limited settings.

Objective: This study aimed to develop and release the GBD Analysis Suite, an open-source R Shiny dashboard that consolidates 11 commonly used analytical modules for GBD-style burden-of-disease research into a single, code-free, web interface supporting user-uploaded data, and to describe its underlying architecture, analytical methodology, and intended applications.

Methods: The application was built using R 4.5.3 and the Shiny framework, integrating established statistical packages, including *forecast*, *segmented*, *openxlsx*, *ggplot2*, *plotly*, and others, into modules covering data import, choropleth mapping, estimated annual percentage change, joinpoint regression, Kitagawa and Das Gupta decomposition, multimodel time-series forecasting, descriptive visualization, sociodemographic index–based frontier analysis, descriptive age-period-cohort visualization, slope and relative indices of inequality, and batch export. The application accepts Global Health Data Exchange (GHDx)–formatted CSV or Excel files, automatically detects standard variable names, and enforces internal consistency through built-in validation checks. Kitagawa decomposition uses the symmetric mid-point formulation to ensure exact additivity. The three ensemble forecast models (autoregressive integrated moving average [ARIMA], exponential smoothing state-space [ETS], and a feed-forward neural network [NNETAR]) apply Box-Cox log transformation, with an explicit nonnegativity floor applied to the point forecast and prediction intervals of every model.

Results: The application is publicly deployed and can be accessed through any modern web browser without requiring local installation. On the bundled 196-country, 34-year demonstration dataset, exporting the full set of outputs completes in approximately 12 seconds at a peak memory footprint of approximately 600 MB. A feature comparison against 5 existing tools (GBD Compare, GBD Foresight, NCI Joinpoint, BAPC, and NordPred) across 14 capability dimensions confirms that the GBD Analysis Suite is

XSL•FO
RenderX

the only reviewed platform combining user-uploaded data input with code-free access to all 6 core analytical methods of modern GBD papers. Source code is publicly available under the MIT license.

Conclusions: The GBD Analysis Suite lowers the technical barrier to reproducible, multimethod burden of disease analyses. It is designed particularly for researchers in low- and middle-income countries where biostatistical support, commercial software licenses, and high-performance computing are often unavailable. The modular architecture supports flexibility across disease areas, geographies, and time windows, subject to input data compatibility. Community contributions, feature requests, and collaborative extensions are welcomed through the project's public GitHub repository.

KEYWORDS

global burden of disease; R Shiny; web application; dashboard software; open-source software; reproducible research; data visualization; epidemiology; EAPC; estimated annual percentage change; joinpoint regression; time-series forecasting; health inequality; decomposition

Introduction

The Global Burden of Disease (GBD) study, coordinated by the Institute for Health Metrics and Evaluation (IHME), provides the most comprehensive global estimates of disease incidence, mortality, and disability-adjusted life-years available, covering 204 countries and territories from 1990 to the present [1]. Its public data portal, the Global Health Data Exchange (GHDx), hosts extensive standardized datasets freely downloadable in CSV format [2]. Translating these downloads into export-formatted outputs (manuscript tables, formatted figures, and reproducible methods text) requires a multimethod workflow spanning at least 6 analytical domains: temporal trend analysis (estimated annual percentage change [EAPC]), changepoint detection (joinpoint regression), demographic decomposition, multimodel forecasting, frontier benchmarking, and health inequality measurement. Executing these methods reproducibly within a single project typically requires integrating multiple software packages, each with separate installation, documentation, and output formats, a substantial technical barrier for research teams with limited computational resources.

Existing tools address parts of this workflow, but none integrates the complete pipeline. Visualization portals such as IHME's GBD Compare [3] and its companion GBD Foresight tool [4] enable exploration of precomputed estimates but provide no reanalysis capability. Analytical packages, including the National Cancer Institute (NCI) Joinpoint Regression Program [5], the R *forecast* package [6], and Bayesian age-period-cohort modeling tools such as BAPC [7] and NordPred [8], each address a single method and, in most cases, require local installation and programming fluency. No currently available free tool integrates EAPC estimation, joinpoint regression, decomposition, multimodel forecasting, frontier analysis, and inequality measurement in a single code-free interface. Previously published open-source R Shiny applications in epidemiology have typically targeted a single disease area or analytical task, such as cancer-registry analytics [9] or spatial and spatio-temporal disease mapping [10], rather than the integrated multimethod GBD workflow.

This fragmentation creates a substantial and disproportionate barrier for investigators in low- and middle-income countries (LMICs), where GBD data are most urgently needed to inform health policy, but biostatistical expertise, institutional computing infrastructure, and commercial software licenses are least available. Documented structural barriers to research capacity and analytical participation for investigators based in LMICs compound this gap [11]. For such investigators, a browser-based, user-uploadable, multimethod analytical platform would substantially lower the barrier between data availability and peer-reviewed publication.

This paper describes the GBD Analysis Suite: an open-source R Shiny dashboard implementing 11 commonly used analytical modules that together support the complete workflow of a GBD burden of disease study. The application requires no programming skills beyond data upload, runs in any modern web browser, and is freely deployable to shinyapps.io without institutional infrastructure. We describe its software architecture, data pipeline, analytical modules, output formats, and intended use cases, and compare its capabilities against 5 established tools covering parts of the GBD analytical workflow.

Methods

Data Input Model

The application accepts any dataset downloaded from the GHDx [12] in CSV or Microsoft Excel (.xlsx) format. Users may upload a single file or combine multiple disease-specific GHDx exports. A companion sociodemographic index (SDI) file, also available from the GHDx portal, may be uploaded separately to activate SDI-dependent modules (EAPC versus SDI correlation, frontier analysis, and global inequality).

The application's automatic column-detection algorithm identifies standard GHDx variable names case-insensitively (location name, year, value, upper, lower, measure name, metric name, sex name, age name, and cause name), requiring only that location name, year, and value be present for core modules to function. Additional variables unlock specific analyses automatically. For example, the presence of both number and rate metrics activates Kitagawa decomposition. The presence of age-stratified rows additionally activates Das Gupta 3-component decomposition. A preformatted SDI template is available for download from within the application.

Software Architecture

The GBD Analysis Suite was developed in R version 4.5.3 [13] using the *shiny* [14] and *shinydashboard* [15] frameworks. The

XSL•FO
RenderX

interface is organized as an 11-tab sidebar dashboard. Core dependencies include *dplyr* [16], *tidyr* [17], and *data.table* [18] for data manipulation, *ggplot2* [19] and *plotly* [20] for visualization, *forecast* [6] for time-series modeling, *segmented* [21] for joinpoint regression, *maps* [22] for world polygon layers, *openxlsx* [23] for Excel export, and *officer* [24] and *flextable* [25] for Word-compatible methods-text generation. Complete version information for all packages is provided in Multimedia Appendix 1. All interactive charts are rendered via *plotly*, ensuring cross-browser compatibility without client-side R installation. The application is deployed as a Shiny app [26] and is fully operational when run locally via shiny::runApp(). Source code, bundled demonstration data, and a package-installation script are publicly available at the GitHub repository [27].

Analytical Modules

Module 1: Data Import and Validation

Users can upload any GHDx-formatted CSV or Excel file via a browser-based file picker or load a bundled demonstration dataset with a single click. The demonstration dataset contains GBD 2023 meningitis estimates for incidence and mortality, reported as numbers, rates, and percentages, for both sexes combined and for males and females separately, across four age bands together with age-standardized estimates, spanning 1990 to 2023 across 196 countries and territories (599,760 rows). The dataset forms a complete factorial grid and contains no missing values by design. A small number of observations (1277 of 599,760) carry a value of exactly zero. These are retained on import and are excluded only by the positivity filter applied in the modules that require logarithmic transformation. Upon upload, the application automatically detects column mappings, verifies required fields, aggregates observations by measure, metric, sex, and age group, and generates a structured data-quality report.

Module 2: Choropleth Maps

Age-standardized rates are plotted as interactive choropleth world maps using *maps* package polygons joined to GHDx location names by a standardized name-matching table. Three map types are available: single-year age-standardized rate (ASR), EAPC magnitude, and percentage change between two user-selected years. Color scales use the *viridis* sequential palette for rate magnitude and percentage change displays, and the *RColorBrewer* RdYlGn diverging palette for EAPC magnitude, with user-adjustable breakpoints. Location names that do not match the bundled polygon set are left unfilled (rendered in neutral grey) without interrupting rendering, and subnational entries are not aggregated to the national level. Users should therefore verify that uploaded location names follow GBD standard naming conventions.

Module 3: EAPC

For each location, a log-linear model is fitted to age-standardized rates over the selected year range: ln (ASR) = alpha + beta × year. The EAPC is computed as 100 × (exp(beta) – 1) and its 95% confidence interval as 100 × (exp (beta +/– 1.96 × SE) – 1), following the partitioning method commonly applied in international cancer and burden of disease statistics [28]. The regression is fitted to the point estimate of the age-standardized rate only. Where a dataset supplies upper and lower uncertainty bounds, these columns are detected and retained but are not propagated into the EAPC estimate or its confidence interval, so the reported interval reflects sampling variability around the fitted log-linear trend rather than the underlying uncertainty of the GBD estimates themselves. Trend classification follows established conventions: a statistically significant positive EAPC (ie, confidence interval lower bound >0) is classified as increasing, while a statistically significant negative EAPC (ie, confidence interval upper bound <0) is classified as decreasing. Otherwise, the trend is classified as stable. This increasing/decreasing/stable classification assumes approximately independent annual observations. In the presence of strong temporal autocorrelation, it should be corroborated with methods that explicitly model serial dependence, such as joinpoint regression. Results are displayed as a sortable data table, a forest plot, a scatter of EAPC against baseline ASR, and, when an SDI file is provided, a scatter of EAPC against SDI with a loess smoothing line.

Module 4: Joinpoint Regression

Joinpoint regression is implemented using the *segmented* package [21]. Four selection methods are available: fixed (user-specified, 0-5 joinpoints), Bayesian information criterion (BIC), default and recommended, Akaike information criterion (AIC), and permutation test (Monte Carlo). The method is selected via a dropdown in the module interface. Three model families are supported: log/multiplicative, linear/additive, and square root. For each segment, the application reports the annual percentage change (APC), its 95% CI, a 2-tailed *t* test, *P* value, and a significance flag. An overall average APC (AAPC) is computed as the segment-length-weighted mean of segment-specific APCs [5].

Module 5: Decomposition

Two decomposition methods are applied automatically based on data availability. When both number and rate metrics are present, Kitagawa 2-component decomposition [29] partitions the change in total case counts between 2 time points into a population-growth effect (mean rate multiplied by change in population) and an epidemiological effect (change in rate multiplied by mean population), using symmetric mid-point averages to ensure exact additivity. The 2 components sum to the observed change as an algebraic identity, holding to machine precision. When age-stratified rate rows are additionally present, Das Gupta 3-component decomposition [30] augments this with a population-aging component, applying proportional rescaling to preserve exact additivity. Both methods produce country-level waterfall charts showing the sign and magnitude of each component.

Module 6: Multimodel Time-Series Forecasting

Prior to model fitting, observations with missing or nonpositive rate values are excluded, because the Box-Cox log transformation is undefined at zero. This filter is applied consistently across the forecasting, EAPC, and joinpoint modules. Users analyzing rare diseases or low-count settings should be aware that this step may remove valid zero-count

XSL•FO
RenderX

observations, and that the time-series index is built from the retained years in sequence, so any internal temporal gaps are treated as consecutive and are not interpolated. Three models are fitted for ensemble averaging: autoregressive integrated moving average (ARIMA; auto.arima), exponential smoothing state-space (EST, est), and a feed-forward neural network (nnetar) with a fixed random seed for reproducibility. Three additional models are computed and displayed as individual comparators but are not included in the ensemble: TBATS (tbats), Theta (thetaf), and Holt double-exponential smoothing (holt). The Ensemble model combines the ARIMA, ETS, and NNETAR forecasts using weights inversely proportional to their root-mean-square error (RMSE) in a 20% holdout, averaging both the point forecasts and the 80% and 95% prediction intervals. Equal weights are applied as a fallback when the series is too short for holdout evaluation or when a candidate model fails to converge. All 3 ensemble models, ARIMA, ETS, and NNETAR, apply Box-Cox log transformation with lambda=0. Bias-corrected back-transformation is enabled for ARIMA; ETS and NNETAR use the default back-transformation without bias adjustment. Among the comparators, Holt applies the same log transformation with bias-corrected back-transformation, Theta is fitted on the untransformed scale, and TBATS is fitted without an explicit transformation argument, so that any Box-Cox transformation is selected internally by the tbats implementation. An explicit nonnegativity floor, pmax(0, .), is applied to the point forecast and to all four prediction-interval bounds of every model, so that nonnegativity does not rely on the transformation alone. The ensemble output is floored in the same way and is in addition intrinsically nonnegative because it averages only log-transformed model outputs [6]. The forecast horizon is user-selectable from 5 to 30 years. Both 80% and 95% prediction intervals are displayed. Out-of-sample predictive accuracy of the candidate models is assessed by a 20% holdout cross-validation reporting RMSE, mean absolute error (MAE), and mean absolute percentage error (MAPE). Very short series or series containing abrupt structural breaks should be forecast and interpreted with particular caution.

Module 7: Descriptive Statistics

Seven commonly used exploratory chart types support exploratory analysis: time-trend lines, heatmaps, boxplots, sex comparison scatters, butterfly charts, 3D scatter, and treemaps.

Module 8: Health Frontier Analysis

The SDI-based health frontier is estimated by fitting a loess regression (span=0.8) of age-standardized mortality rate on SDI for all countries, using the most recent available SDI year per country [31]. The empirical frontier is defined as the loess-fitted value offset by a user-specified lower percentile of residuals (default: 10th). Country efficiency is reported as the ratio of frontier value to observed rate, expressed as a percentage. The loess-percentile frontier is intended as a descriptive, exploratory benchmark rather than a formal production-function estimate. Parametric methods such as data envelopment analysis and stochastic frontier analysis impose structural assumptions (eg, convexity or a specified inefficiency distribution) that are difficult to justify for cross-national burden data. The term efficiency here denotes relative position against the empirical frontier, not a normative or causal judgment. The smoothing span and residual percentile are user-adjustable, and analysts requiring formal efficiency scores should apply dedicated packages to the exported data.

Module 9: Descriptive APC Visualization

This module provides descriptive visualizations only and does not implement a formally identified APC framework. Marginal incidence rate ratios (IRR) are computed as the mean age-, period-, or cohort-specific rate divided by the overall mean. The period net drift, the one formally identified APC parameter [32], is estimated as 100 x (exp(beta) - 1) from a linear regression of log(rate) on period. Age and cohort marginal ratios are descriptive visualizations and must not be interpreted as independent or causal APC effects. Users requiring formal APC identification are directed to the NCI APC Web Tool or the *apcR package*.

Module 10: Health Inequality (Slope Index of Inequality and Relative Index of Inequality)

The slope index of inequality (SII) is estimated annually by assigning each country a fractional rank based on SDI and regressing the age-standardized rate on that rank using ordinary least squares. Population weighting by country size is identified as a planned methodological enhancement and is not applied in the current version. The relative index of inequality (RII) follows the Kunst-Mackenbach formulation [33] and is computed as the ratio of the model-predicted rate at the most disadvantaged (lowest-SDI) rank to that at the most advantaged (highest-SDI) rank, yielding a positive relative measure in which values above 1 indicate a greater burden among lower-SDI populations. Both indices are plotted over the selected period.

Module 11: Batch Export

All tabular results can be exported as a multisheet Excel workbook using the *openxlsx* package. Figures are exported as high-resolution PNG or PDF files via *ggplot2*. A structured methods-text paragraph, which carries a disclaimer reminding users to review and adapt it to their specific analysis before any publication use, is auto-generated in plain text and Word-compatible format (*officer*).

Internal Consistency Safeguards

Three design decisions enforce internal consistency of output by construction. First, Kitagawa additivity: the symmetric mid-point formulation ensures that population-growth and epidemiological components sum exactly to the observed change in counts as an algebraic identity, holding to machine precision. A PASS or FAIL additivity check is reported alongside every decomposition output. Second, forecast nonnegativity: the 3 ensemble models (ARIMA, ETS, and NNETAR) apply Box-Cox log transformation with lambda=0, and every model, including the comparators, applies an explicit nonnegativity floor to its point forecast and to both prediction intervals, so that no negative rate can be reported. Third, frontier input restriction: the frontier module silently restricts input to rate-metric, age-standardized rows, preventing accidental frontier estimation on mixed metrics. Additional robustness features include reproducible neural-network forecasts via a fixed random seed,

XSL•FO
RenderX

explicit user control over joinpoint count, and automatic dataset auditing on upload.

Licensing, Source Code, and Deployment

The GBD Analysis Suite is released under the MIT open-source license. Source code, a bundled 196-country demonstration dataset (1990 to 2023), and a one-line package-installation script are publicly available at the GitHub repository [27]. The deployed application is accessible at the Shiny app [26]. A complete sessionInfo() output from the deployed environment is provided in Multimedia Appendix 1.

Ethical Considerations

This paper describes an open-source software tool and does not involve primary human participant research. The dashboard operates exclusively on publicly available, de-identified, population-level aggregate outputs from the GBD study. (1) Formal ethics review was not required because no human participants were enrolled, no patient data were accessed, and no individual-level information is handled at any stage. (2) Informed consent is not applicable. (3) No personal or identifiable data are processed. (4) No participants were involved. Compensation is not applicable. (5) All figures depict only aggregate population-level data. No identifiable individuals appear. Users retain full ownership of any data they upload. The deployed instance processes uploaded data only in active-session memory and does not persist user-uploaded files beyond session termination.

Results

Application Availability and Deployment

The GBD Analysis Suite is deployed and publicly accessible at the Shiny app [26]. Source code, the bundled 196-country demonstration dataset, and installation instructions are available at the GitHub repository [27] under the MIT license. The application loads and executes in any modern web browser (Chrome, Firefox, Safari, and Edge) without requiring a local R installation, Java runtime, or institutional software license.

Module Coverage

Table 1 summarizes the 11 modules, the primary *R package* each relies upon, the required input columns, and the outputs produced. Every module produces at least one tabular output and at least one figure, all of which are included in batch exports.

XSL•FO
RenderX

Table 1. Analytical modules of the GBD Analysis Suite.

	Module	Analytical use[a]	Main statistical procedure	Primary R packages	Key references
1	Data import and validation	Upload, auto-detect columns, validate structure, and audit dataset composition	Column alias detection, structured data-quality tabulation by measure, metric, sex, and age	*readxl*, *readr*	None
2	Choropleth maps	Map age-standardized rates, EAPC[b] magnitude, or percentage change across countries	Name-matched polygon join to a standardized world layer, sequential/diverging color scaling	*maps*, *plotly*	None
3	EAPC	Quantify and classify the average annual trend in age-standardized rates	Log-linear regression of ln(rate) on year, EAPC = 100 × (exp(beta) – 1) with 95% CI	*stats (lm)*	[28]
4	Joinpoint regression	Detect changepoints and estimate segment-specific trends	Segmented (broken-line) regression, segment APC[c] and length-weighted AAPC[d], fixed, BIC[e], AIC[f], or permutation selection	*segmented*	[5,21]
5	Decomposition	Partition the change in total counts into population and epidemiological components	Kitagawa 2-component and Das Gupta 3-component decomposition with mid-point/proportional balancing	*dplyr*	[29,30]
6	Multimodel time-series forecasting	Project future rates with prediction intervals and compare candidate models	ARIMA[g]/ETS/NNETAR inverse-RMSE weighted ensemble plus TBATS, Theta, and Holt comparators, Box-Cox (lambda = 0) on ensemble members and Holt, nonnegativity floor on all models, 20% holdout RMSE[h]/MAE[i]/MAPE[j]	*forecast*	[6]
7	Descriptive statistics	Provide exploratory visual summaries across years, sexes, ages, and locations	Seven exploratory chart types, including trend lines, heatmaps, boxplots, scatters, and treemaps	*ggplot2*, *plotly*	None
8	Health frontier analysis	Benchmark country rates against an empirical SDI[k]-based frontier	Locally weighted regression (LOESS, span 0.8) shifted by a user-specified residual percentile	*stats (loess)*	[31]
9	Descriptive APC visualization	Display descriptive age, period, and cohort patterns and the period net drift	Marginal incidence-rate ratios (descriptive), period net drift = 100 × (exp(beta) – 1) from log(rate) on period	*ggplot2*	[32]
10	Health inequality (SII[l] and RII[m])	Summarize the cross-national socioeconomic gradient in rates	Slope and relative index of inequality from fractional-rank regression (unweighted OLS)	*stats (lm)*	[33]
11	Batch export	Export all tabular and figure outputs plus an auto-generated methods paragraph	Multisheet workbook writing, high-resolution figure rendering, templated methods-text generation	*openxlsx*, *officer*	None

[a]Analytical use summarizes each module's intended descriptive or analytical purpose. The main statistical procedure lists the principal computation performed. References indicate the key methodological source for the procedure, where applicable. Modules built primarily on general-purpose visualization or data-handling packages are listed as “None.” All modules operate on the core input fields (location, year, and value) and use additional fields where available.

[b]EAPC: estimated annual percentage change.

[c]APC: annual percentage change.

[d]AAPC: average annual percentage change.

[e]BIC: Bayesian information criterion.

[f]AIC: Akaike information criterion.

[g]ARIMA: autoregressive integrated moving average.

[h]RMSE: root mean square error.

[i]MAE: mean absolute error.

[j]MAPE: mean absolute percentage error.

[k]SDI: sociodemographic index.

[l]SII: slope index of inequality.

XSL•FO
RenderX

[m]RII: relative index of inequality.

Feature Comparison With Existing Tools

Table 2 compares the GBD Analysis Suite against 5 established tools covering parts of the GBD analytical workflow. Across 14 capability dimensions spanning data input, the 6 core analytical methods of modern GBD papers, and output and deployment features, the GBD Analysis Suite is the only platform supporting all analytical dimensions without requiring programming expertise. Two rows at the bottom of the table, peer-reviewed methodology validation and maturity of established user base, note dimensions on which competing tools currently have an advantage over this newly released suite.

These comparisons should be read in context: the comparator tools differ in primary intent (eg, GBD Compare is an IHME visualization portal of official estimates; NCI Joinpoint is a single-method analytical program). The suite's contribution is integration breadth, not replacement of any individual specialist tool. Comparator tools were selected against three criteria: publicly available or academically published tools designed for population-level epidemiological data, tools capable of accepting user-uploaded GBD-format input files, and tools addressing at least two of the analytical domains covered by the suite. This comparison is not exhaustive, and specialized packages exist for individual methods.

[a]GBD: Global Burden of Disease.

[b]NCI: National Cancer Institute.

[c]NCI Joinpoint binary is freely distributed, but the source is not public.

[d]Accessible via shinyapps.io in any modern browser.

[e]Windows desktop client only.

[f]Three-model inverse root mean square error–weighted ensemble (autoregressive integrated moving average [ARIMA], ETS, NNETAR) plus three individual comparators (TBATS, Theta, Holt).

[g]GBD Foresight provides Institute for Health Metrics and Evaluation (IHME)–produced forecasts only. No user-configurable models.

[h]BAPC and NordPred focus on Bayesian APC forecasting for cancer incidence. Single-model approach.

[i]Activates automatically when age-stratified number and rate data are provided.

[j]SII: slope index of inequality.

[k]RII: relative index of inequality.

[l]SDI: sociodemographic index.

[m]APC: annual percentage change.

[n]NordPred produces APC-structured forecasts but does not offer separate APC visualization.

[o]Image export only. No multisheet workbook or structured methods text.

[p]This manuscript constitutes the first formal description. Methodology not previously peer-reviewed.

[q]New release. User base is limited at time of publication.

Performance Characteristics

Runtime performance was measured on the bundled 196-country, 34-year demonstration dataset (599,760 observations of GBD 2023 meningitis estimates) on a four-core, eight-thread workstation with 30 GB of RAM running R 4.5.3 under Windows 10. Interactive modules, including data import validation, descriptive visualization, EAPC estimation, joinpoint regression, and inequality computation, completed in under 2 seconds per user action, with a measured range of 0.1 to 1.9 seconds. Forecasting was the most computationally intensive module, with the 3-model ensemble (ARIMA, ETS, and NNETAR) plus 3 individual comparators (TBATS, Theta, and Holt), requiring approximately 9 seconds per country at a 15-year horizon. Exporting the complete set of outputs took approximately 12 seconds in total, comprising approximately 1 second for a 10-sheet Excel workbook, whose sheets are written according to which analyses have been run, approximately 10 seconds for the high-resolution figures, which are saved individually at 300 dpi in PNG or PDF format, and under 0.1 seconds for the auto-generated methods text file. Peak memory footprint during full-dataset operations was

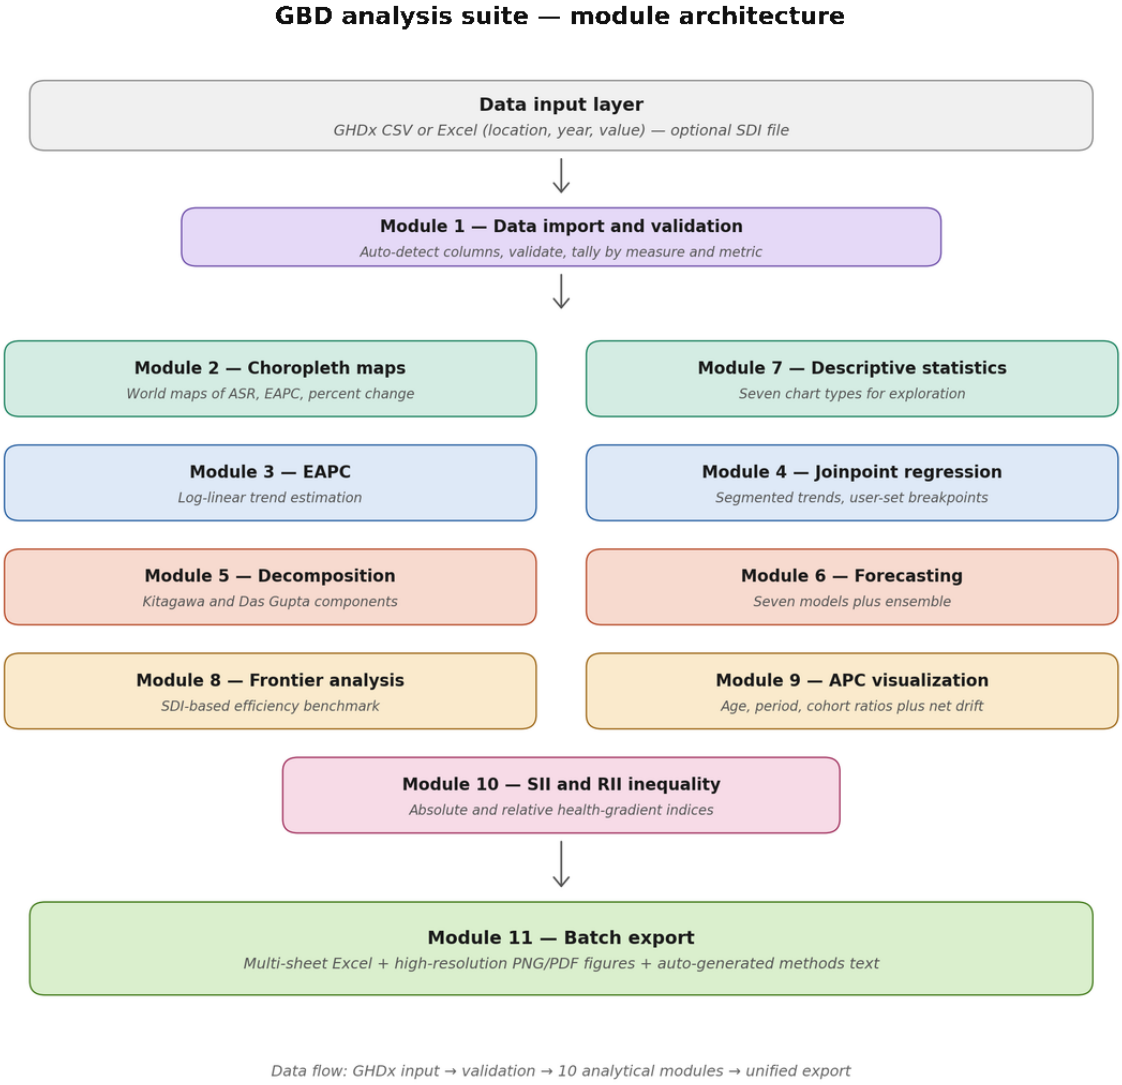
XSL•FO
RenderX

approximately 600 MB. The free shinyapps.io tier did not complete loading the full demonstration dataset within 60 seconds in our testing, so users working with full multicountry datasets are advised to run the application locally via shiny::runApp() on a machine with at least 4 GB of available memory rather than relying on the shared public instance. Smaller datasets (single-country or single-cause extracts, typically 1000 to 10,000 observations) executed all modules in under 1 second sequentially, at the memory footprints reported in Table 3. The application has been exercised with input datasets up to approximately 1 million rows without structural failure, completing descriptive and EAPC computation on 1 million rows in approximately 5 seconds at a peak footprint of approximately 800 MB. Response times scale approximately linearly with row count.

Table 3. Performance benchmark of the analytical engines across input sizes (median of three runs).

Rows[a]	Countries	File size (MB)	Load + parse (s)	Analysis (s)	Peak memory (MB)
1000	1	0.15	0	0.11	252.7
5000	2	0.72	0	0.12	253.2
10,000	4	1.38	0.01	0.61	341.0
50,000	17	6.43	0.04	0.86	415.2
100,000	33	12.66	0.07	1.19	434.2
599,760	196	88.63	0.39	5.94	582.7

[a]Subsets were genuine head-N samples of the demonstration dataset written to disk as CSV. Load + parse covers data.table reading plus the application column parser. Analysis covers the chained descriptive, estimated annual percentage change, inequality, slope index of inequality (SII), and frontier engines. Peak memory is the maximum R memory observed during load and analysis. The 1000- and 5000-row tiers contain only one to two countries, so the inequality, SII, and frontier engines (which require three or more countries) do not execute at those sizes.



To characterize this scaling formally, the application's analytical engines were benchmarked on genuine subsets of the demonstration dataset ranging from 1000 to 599,760 rows. Table 3 reports the median of 3 runs per size tier. This benchmark times data loading and parsing plus the core analytical pipeline (descriptive statistics, EAPC, health inequality, SII, and frontier computation). It does not include the heavier figure-rendering and workbook-writing steps of a full batch export, which account for the longer end-to-end export time noted above. Load and parse time scaled approximately linearly with file size, while analytical time scaled sub-linearly with row count and approximately linearly with the number of countries, because the inequality, SII, and frontier engines operate on per-country and per-year aggregates rather than on raw row count. The complete 599,760-row file (88.6 MB across 196 countries) was processed by the analytical pipeline in approximately 5.9 seconds at a peak memory footprint of approximately 583 MB.

Demonstration Outputs

The bundled 196-country demonstration dataset allows new users to execute the full 11-module workflow with a single button click, producing all tabular and figure outputs within one session. Figure 1 presents the application's module architecture. Figure 2 shows the main dashboard interface. Figures 3-9 present representative outputs from the choropleth mapping (Figure 3), EAPC estimation (Figure 4), joinpoint regression (Figure 5), Kitagawa decomposition (Figure 6), ensemble forecasting (Figure 7), frontier analysis (Figure 8), and descriptive APC (Figure 9) modules, all computed on the demonstration dataset. Figure 10 presents the descriptive statistics panel (Module 7) and Figure 11 the health inequality output (Module 10), both computed on the same dataset.

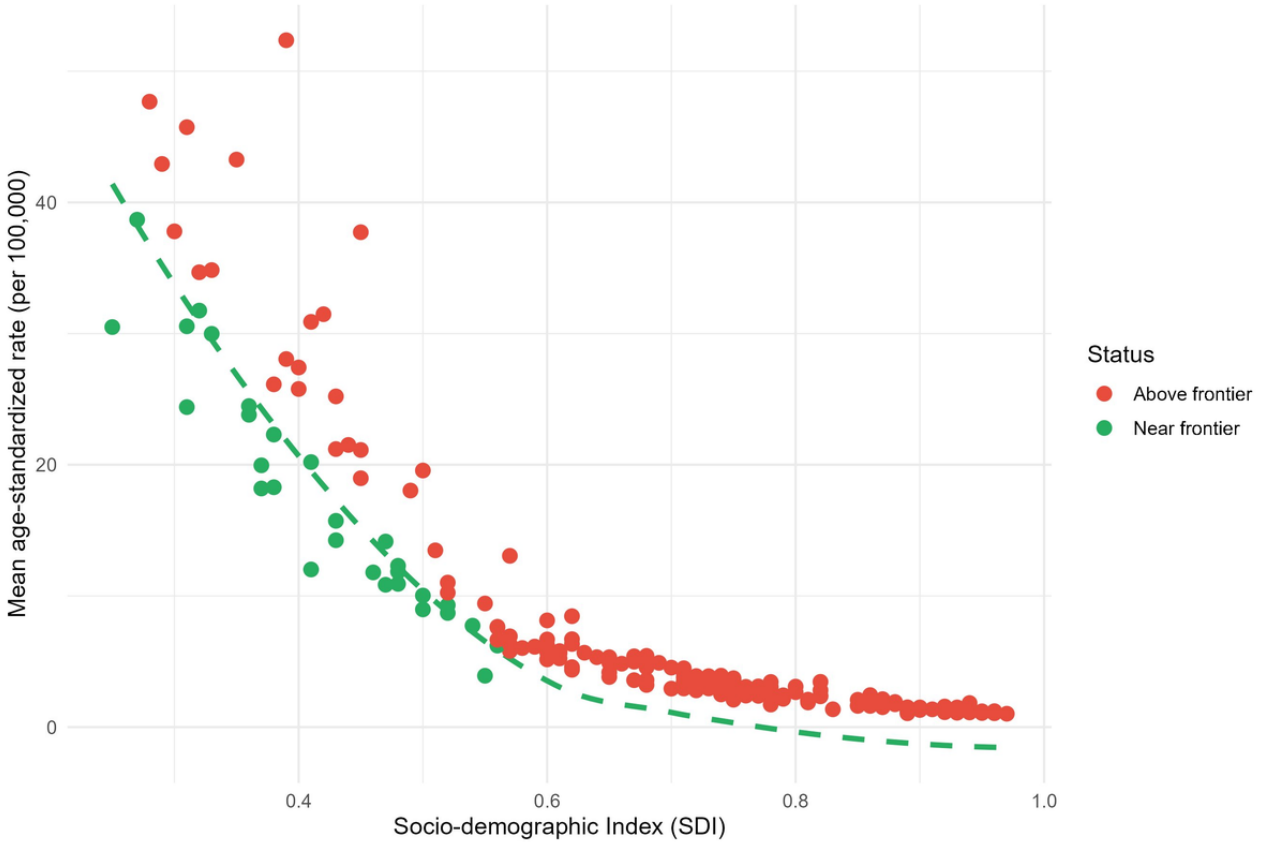

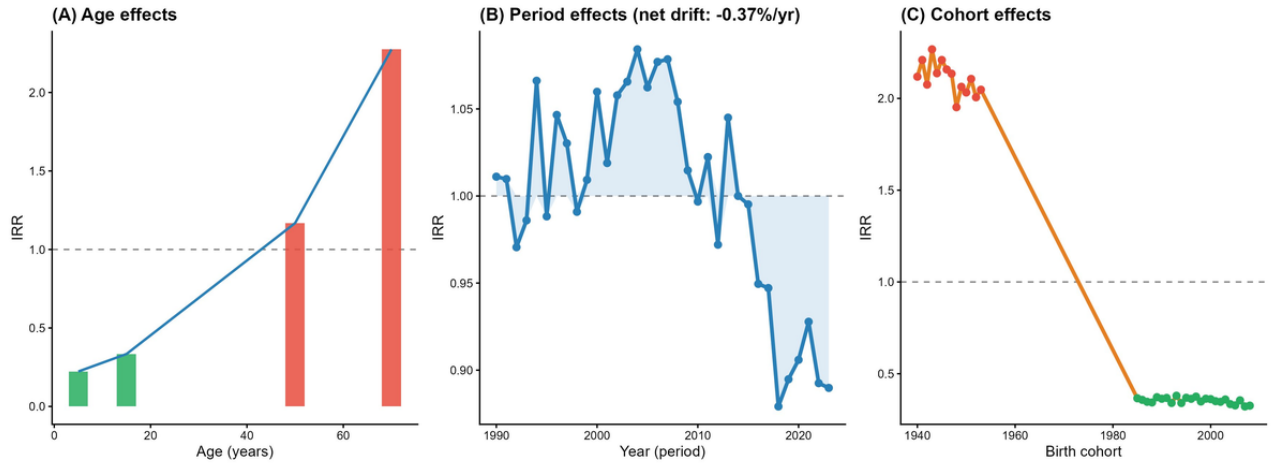

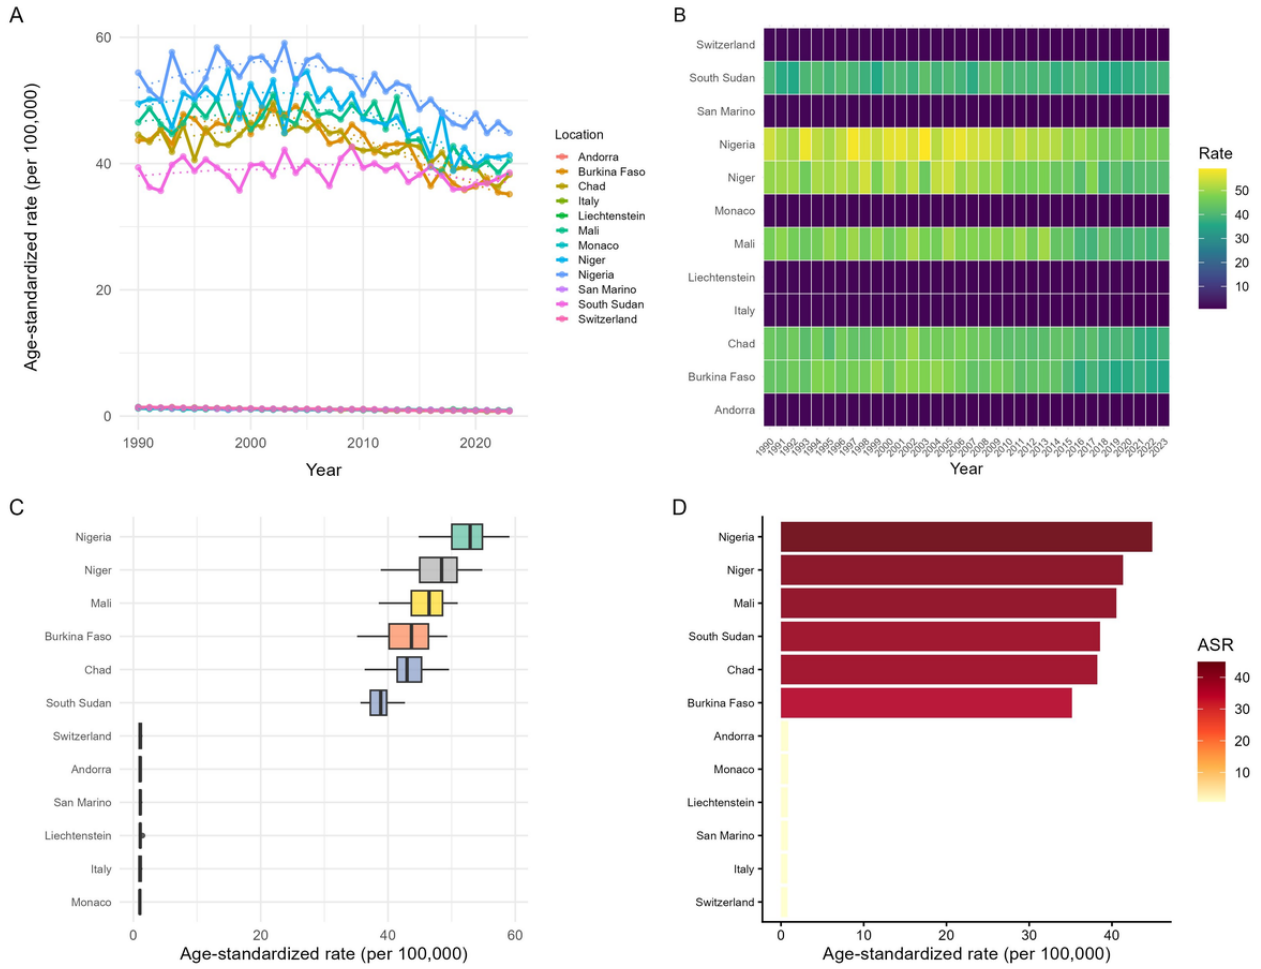

Figure 9. Descriptive annual percentage change visualization for a demonstration country, showing age effects, period effects with net drift, and cohort effects. IRR: incidence rate ratio.

The descriptive statistics module (Module 7) generates a panel of commonly used exploration chart types from a single uploaded dataset. Figure 10 illustrates four of these for the bundled demonstration dataset: temporal trend lines of age-standardized rates across selected countries, a country-by-year rate heatmap that summarizes the full panel at a glance, rate-distribution boxplots that compare the spread of values across locations, and an age-standardized burden ranking bar chart for the most recent year. The module additionally offers sex comparison scatters, a 3D scatter, and a treemap, giving seven exploratory chart types in total. Each chart is rendered interactively and can be exported as a high-resolution image. The panel is intended for rapid visual screening of a dataset before formal analysis, and the figures shown here required no programming beyond uploading the data file.

XSL•FO
RenderX

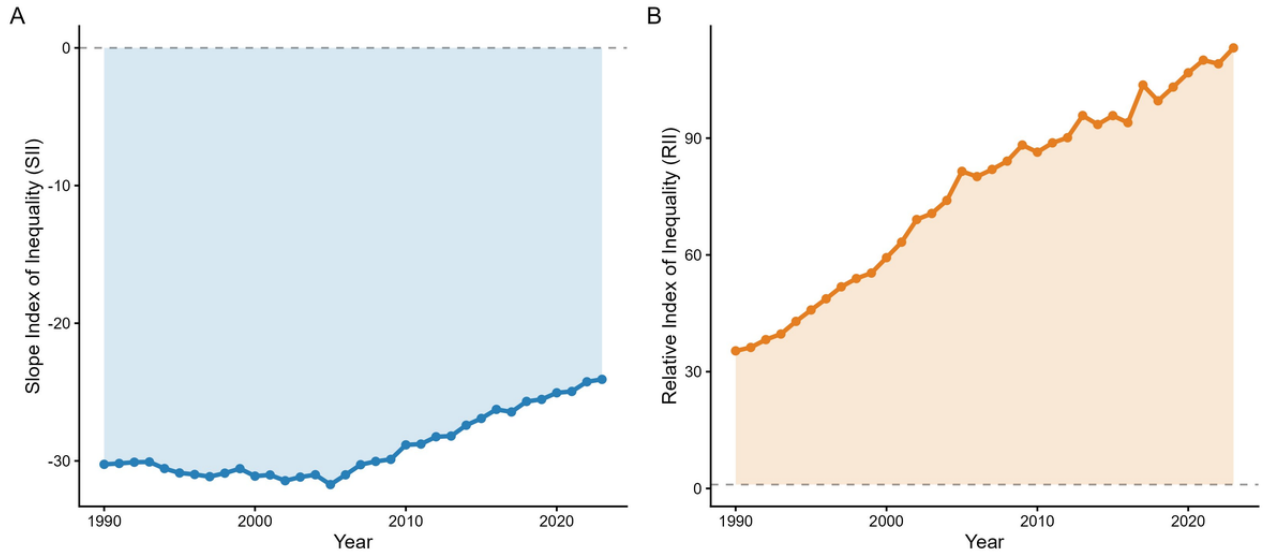

Figure 10. Module 7 descriptive statistics panel for the bundled demonstration dataset, illustrating four of the module's exploratory chart types: temporal trend lines across selected countries, a country-by-year rate heatmap, rate-distribution boxplots, and an age-standardized burden ranking for the most recent year. ASR: age-standardized rate.

The Health Inequality module (Module 10) quantifies the cross-national socioeconomic gradient in burden using the SII and the RII, derived from regression of age-standardized rates on the fractional rank of the SDI across all available countries. Figure 11 shows both indices over the full 1990 to 2023 period for the demonstration dataset. The SII is negative throughout, reflecting that the highest burden is carried by the lowest-SDI countries, and its magnitude narrows over time, consistent with a gradually attenuating absolute gradient. Both indices are computed with unweighted ordinary least squares as described in the Methods. Population-weighted estimation is identified as a planned enhancement.

XSL•FO
RenderX

Figure 11. Health inequality output for the bundled demonstration dataset, showing the (A) SII and (B) RII over time, with countries ranked by sociodemographic index. Negative slope index of inequality values indicate that burden is concentrated in lower-sociodemographic index countries.

Extensibility

The module-level architecture is designed to be flexible across cause, country set, and time window, subject to input data compatibility. Each module operates on the subset of uploaded data matching its required columns, with no hard-coded assumptions about which countries, years, or causes are present. The application has been exercised on single-cause datasets (cancer incidence, cardiovascular mortality, and infectious disease burden), multicause noncommunicable disease extracts, single-country historical trend analyses, and multicountry regional comparisons, across time horizons ranging from 10 to 34 years. New analytical methods can be added as additional Shiny tabs following the existing module pattern. Contributions via the public GitHub repository are welcomed.

Discussion

Principal Contribution

This paper describes the GBD Analysis Suite, an open-source R Shiny dashboard that integrates 11 commonly used analytical modules for GBD-style burden of disease research into a single, code-free web interface. The application fills a structural gap in the existing tool ecosystem: platforms optimized for exploration (GBD Compare [3], GBD Foresight [4]) do not support user-uploaded data or analytical recomputation, while platforms optimized for analysis (NCI Joinpoint [5], BAPC [7], NordPred [8]) are single-method tools requiring local installation and, in most cases, programming fluency. The GBD Analysis Suite occupies the unfilled niche of a browser-accessible, user-uploadable, multimethod analytical platform that supports the complete analytical workflow of a modern GBD paper.

Design Principles

Three design principles guided development. First, accessibility: the application runs in any browser without a local R installation, commercial software license, or specialized infrastructure, removing barriers that disproportionately affect investigators in low- and middle-income countries. Second, reproducibility: the application enforces internal consistency by construction (Kitagawa additivity, forecast nonnegativity, frontier input validation), uses fixed random seeds for stochastic components, and exports a structured methods-text paragraph alongside numerical output. Third, transparency: all source code is public, all statistical procedures are documented with literature citations in both the application interface and the exported methods text, and every export includes software version and dependency information.

Intended Use Cases

The application is designed for the analyst who has downloaded a GHDx cause-country-year extract and wants to produce export-formatted trend, decomposition, forecast, frontier, and inequality outputs without assembling and maintaining a bespoke R codebase. Typical workflows include cause-specific burden papers for single-country or multicountry analyses, regional or multicountry comparisons with within-region frontier and SII/RII computation, methodological teaching and training using the bundled demonstration dataset, and rapid secondary analysis as GHDx data are updated, supporting reproducible reruns across GBD releases. Conversely, the platform is intended for descriptive and exploratory analysis of population-level, aggregate GHDx-format data. It is not a substitute for primary statistical software where formal inferential guarantees are required, and it is not appropriate for individual-level data, small-area analyses, or studies requiring formal inference from an identified APC model. Users working with sparse data or non-GHDx datasets should treat outputs as preliminary.

Implications for Low- and Middle-Income Country Research

A primary design motivation was to lower the technical barrier to GBD-style analyses for investigators in LMIC settings, where biostatistical support, commercial software licenses, and access to high-performance computing are often limited [11]. The application runs entirely in the browser, requires no local R

XSL•FO
RenderX

installation, and accepts GHDx CSV files directly, the same freely distributed format used by every GBD publication. The batch-export feature produces an export-ready methods paragraph alongside numerical outputs, reducing the preparation burden for peer-reviewed submission. Given the dual constraint of high burden of disease needs and limited analytical infrastructure that characterizes much of the LMIC research environment, a browser-native, code-free platform addresses a practical gap that code-based tools do not fill.

Limitations

Several limitations bear consideration. First, the application operates on GBD estimates, which themselves carry uncertainty from data sparsity, garbage-code redistribution, and the IHME modeling assumptions that generate them [1]. The application detects upper and lower uncertainty interval columns in uploaded data but does not propagate them through analyses. All computations use point estimates only. Second, EAPC is calculated from age-standardized rates using the IHME age-standard, which differs from the Segi world standard commonly used in cancer-registry analyses. Comparisons across the literature using different standards require care. Third, the APC module computes only descriptive marginal ratios plus the identified period net drift. Formal identifiable APC inference requires constraint-based estimation and is not provided. Users needing this are directed to dedicated packages. Fourth, forecast prediction intervals reflect parametric uncertainty within each model family and do not fully capture model-selection uncertainty beyond the ensemble averaging provided. Fifth, although the joinpoint module now provides automated BIC (default, recommended), AIC, and permutation-test selection methods, analyses requiring strict cross-study replicability should use the fixed mode with an explicitly stated breakpoint count, as BIC and permutation methods may yield different optimal breakpoints across software versions. Sixth, while the application has been exercised on a range of disease, country, and time-window configurations during development, formal performance benchmarking across the full space of possible GBD queries has not been conducted, and formal unit-test coverage with continuous integration is currently limited. Users are encouraged to verify outputs against known reference datasets before publication. Seventh, the application currently supports GHDx data exports only. Extensions to accept cancer-registry (IARC/CI5), vital registration (World Health Organization [WHO] mortality database), or other burden data sources would require additional column-mapping logic. Eighth, uploaded data in the deployed instance are held in session memory only and are not persisted beyond the active session, but users with formal data-governance requirements, for example those handling restricted-access extracts under institutional data-use agreements, should deploy the open-source code on local or institutional infrastructure rather than using the public shinyapps.io instance. Finally, long-term sustainability depends on continued maintenance by the project's contributors. The MIT-licensed codebase and public GitHub repository allow for community forks or handover should active development pause.

Strengths

Despite these limitations, the developed platform has several strengths. To our knowledge, it is among the first freely available, browser-accessible platforms to integrate the full multimethod workflow of a modern GBD burden of disease study in a code-free interface. The design emphasizes reproducibility through enforced internal consistency (Kitagawa additivity, forecast nonnegativity, frontier input restriction), fixed random seeds, and auto-generated methods text that accompanies every export. Deployment to shinyapps.io requires no institutional infrastructure, making the tool immediately accessible to researchers in LMIC settings where commercial software licenses and high-performance computing resources are often unavailable. All source code is released under the MIT license on a public GitHub repository, supporting community forks, contributions, and independent audit of methodology.

Future Directions

Planned extensions include support for additional data sources beyond GHDx (particularly IARC CI5 cancer registry data and WHO Mortality Database exports), a comparison mode displaying side-by-side outputs from two uploaded datasets (for example, two GBD releases, or model versus registry data), integration with bibliographic tools (Zotero, Mendeley) to auto-import relevant citations into the exported methods text, a server-side caching layer for faster response on large multicountry datasets, and progressive expansion of unit-test coverage toward a continuous-integration pipeline. Contributions from the community are welcomed via the public GitHub repository.

Conclusions

The GBD Analysis Suite integrates 11 commonly used analytical modules for GBD-style burden of disease research into a single, open-source, code-free web interface. The platform fills a structural gap between exploration-only visualization portals and single-method analytical packages and is freely deployable without institutional infrastructure. By lowering the technical barrier to a reproducible, multimethod analytical workflow, the application aims to expand the community of researchers able to conduct structured, reproducible GBD-style analyses. Translating these outputs into peer-reviewed evidence requires appropriate epidemiological expertise and critical interpretation.

Acknowledgments

All authors declared that they had insufficient funding to support open access publication of this manuscript, including from affiliated organizations or institutions, funding agencies, or other organizations. JMIR Publications provided article processing fee (APF) support for the publication of this article.

Funding

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors. The GBD Analysis Suite was developed as an independent open-source research tool.

Data Availability

This paper describes software methodology. No new empirical data were generated. The application source code and bundled demonstration dataset are publicly available at GitHub repository [27] under the MIT license. The deployed application is accessible at the Shiny app [26]. A complete sessionInfo() output is provided in Multimedia Appendix 1. Underlying GBD data are available through the Global Health Data Exchange (GHDx) [12].

Abstract

Background: The early detection of diseases is one of the tasks of general practice. Artificial intelligence (AI)–based technologies could be useful for identifying diseases at an early stage in general practices. As approximately 90% of the population regularly consults a general practitioner during one year, this could increase the percentage of citizens who take part in meaningful screening measures.

Objective: This study aimed to evaluate the level of trust among citizens in rural and urban areas in AI-supported early detection measures in general practice.

Methods: This cross-sectional study was conducted in the federal state of Schleswig-Holstein, Germany, from November 2023 to December 2023, on the topic of early detection measures with AI in general practice care, among other things. For this purpose, 5000 adult residents of rural areas (Ostholstein, Pinneberg, and Nordfriesland) and urban areas (the city of Kiel) were invited to take part in the survey. Data analysis was carried out using descriptive statistics, subgroup analysis, and linear and stepwise regression analysis to identify the factors that influenced trust in AI-based diagnoses.

Results: Most respondents (787/1790, 44.0%) considered the introduction of an AI-based screening measure to be a sign of modern medicine. Moreover, 21.7% (n=388) of respondents feared that the introduction of such services could lead to a deterioration in the physician-patient relationship. The role of AI in future care was rated as very important by 35.4% (n=634) of respondents. The stepwise regression analysis showed that a positive attitude toward AI in medicine was the strongest predictor (ß=0.420) of trust in AI-based diagnoses. In contrast, trust in physician diagnoses was associated with lower age (ß=–0.111) and shorter waiting times for test results (ß=0.077).

Conclusions: Trust in general practitioner–based diagnoses was approximately 6 times greater than trust in AI applications. Despite concerns about their impact on the physician-patient relationship, approximately one-third of participants believed that the role of AI in health care will grow.

KEYWORDS

artificial intelligence; AI; citizens; cross-sectional study; diabetic retinopathy; general practice; trust

Introduction

The basic care of all patients in emergency, acute, and long-term care, as well as in prevention and rehabilitation, constitutes a central responsibility of general medicine [1]. Therefore, the early detection of diseases represents an important aspect of secondary prevention in a general practitioner (GP) practice. Appropriate measures can be initiated through early detection, which can considerably improve the course of an individual illness. GPs are often the first to diagnose diseases such as diabetes, hypertension, and cardiovascular diseases [2].

More than 90% of the population regularly consults their GP per year [1], which offers a significant opportunity to increase the proportion of citizens who take part in appropriate screening measures.

Screening for eye diseases is a promising extension of these early detection measures. Diabetic retinopathy (DR), in particular, can lead to severe visual impairment or even blindness if it is not detected and treated early. The number of people in Germany who become blind as a result of DR is approximately 15,000 per year [3]. DR is therefore the second most common cause of blindness [4]. According to a European study, 48% of patients with diabetes do not undergo the recommended screening examination [5].

The current diagnosis of these diseases requires a referral to an ophthalmologist, which can lead to long waiting times, especially in rural areas with limited access to specialists [6].

XSL•FO
RenderX

In this context, artificial intelligence (AI)–supported technologies could play an important role by complementing and extending traditional screening approaches. For example, in general practice, these technologies may include AI-assisted analysis of skin lesions for cancer screening or algorithms that identify abnormal heart rhythms in long-term electrocardiograms. In this study, we focused on DR as an illustrative example.

AI-assisted diagnostic tools could be used to analyze retinal images without requiring the presence of an eye specialist [7,8]. At the same time, recent studies indicate good diagnostic performance of deep learning algorithms. For example, in a study conducted in 2019, the detection of DR was analyzed on 25,326 retinal images of diabetes patients from Thailand. The algorithm showed a sensitivity of 97%, higher than the 74% observed for human experts, and a specificity of 96%, compared with 98% of specialists [9].

The implementation of AI-supported technologies could enable screening for DR directly in the GP practice as part of disease management programs. In this way, suspicious findings could be detected early, and patients could be referred to ophthalmologists accordingly.

It is still unknown whether trust in AI-supported technologies for early disease detection varies across population groups. However, significant variations in attitudes toward eHealth were observed between urban and rural respondents, highlighting a potential disparity in the future implementation of these technologies in general practice across demographic areas [10,11]. Therefore, the aim of the study was to evaluate the level of trust citizens in rural and urban areas have in AI-supported early detection measures in general practice.

Methods

This cross-sectional study was conducted in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines [12].

Study Design and Participants

A cross-sectional study on early detection measures using AI in GP care was conducted in the federal state of Schleswig-Holstein, Germany, from November 2023 to December 2023. To this end, 5000 adult citizens from Schleswig-Holstein were invited to take part in the survey. The citizens were randomly selected from the databases of the local registration office.

Following the first invitation, 2 reminders to participate in the study were sent out at 3-week intervals. A stamped and preaddressed return envelope was included in all mailings to facilitate participation. A short version of the questionnaire was enclosed with the third reminder letter. This approach, which is consistent with the Tailored Design Method in survey research, was chosen to maximize the response rate and reduce the participation barrier for citizens who had not yet responded, by minimizing the time required.

Data Collection and Questionnaire

Data were collected using a self-constructed questionnaire in paper form. The development of the questionnaire was rigorously based on the findings of a qualitative study that served as a formal pilot phase and informed the generation of items [13]. This preceding qualitative study explored the determinants of AI implementation for DR screening in primary care. In addition, a subset of items—especially those assessing trust in AI vs physician diagnosis and general attitudes toward AI—was pilot-tested in a small qualitative pretest with GPs (1 female GP and 3 male GPs) to ensure clarity and face validity.

To account for different levels of respondent burden, 2 versions of the questionnaire were used:

- The long version consisted of 35 items, covering all conceptual domains in depth (telemedicine use, attitudes toward AI, perceived impact of AI-supported screening, importance ratings for screening attributes, expectations about examination duration, trust in diagnoses, and sociodemographic variables).
- The short version was reduced to 5 core study-related items, capturing only the core constructs (general attitude toward telemedicine, general attitude toward AI in medicine, trust in AI diagnosis, trust in physician diagnosis, age, gender, and region).

The use of long and short questionnaire versions was chosen because shorter instruments in postal surveys can increase response rates and reduce dropout, especially when sent as reminders [14].

The long questionnaire consisted of five sections:

1. Telemedicine experience and attitudes
2. Attitudes toward AI in health care
3. Perceived impact of AI-based screening in general practice
4. Importance of specific aspects of AI-assisted eye disease screening
5. Trust in AI-based diagnosis vs diagnosis by physicians

The participants' general attitude toward AI applications in general practice was assessed using a 6-point Likert scale ranging from "very positive" to "very negative." In addition, questions were asked about the expected future role of AI in their own health care and the potential impact of integrating AI into general practice.

Participants were asked to rate from a list of options what impact the use of AI-based screening measures would have on their everyday life and care, such as improving or worsening patient care and physician-patient relationships. In addition, specific aspects were asked about the importance of performing AI-based screening tests. The importance of these aspects was rated on a 6-point scale, ranging from "very important" to "very unimportant." Finally, respondents were asked about their trust in diagnoses made by AI compared with diagnoses made by GPs.

The questionnaire also included sociodemographic parameters such as age, gender, and regional origin. Sociodemographic information (age, gender, and regional origin) was collected at the end of the instrument. Regional origin was dichotomized

XSL•FO
RenderX

into rural (Ostholstein, Pinneberg, and Nordfriesland) and urban (Kiel).

Statistical Data Analysis

The analyses were carried out using the SPSS software (version 29.0; IBM Corp). The sociodemographic characteristics of the sample (full and short versions of the questionnaire) were analyzed descriptively. Variables with continuous values were summarized using mean values and SDs. Variables with categorical values were represented by absolute (n) and relative (%) frequencies. The regional origin was dichotomized: the regions Ostholstein, Pinneberg, and Nordfriesland were assigned to the rural area, and the Kiel region to the urban area.

The sociodemographic characteristics of the sample (full and short versions of the questionnaire) were analyzed descriptively. Variables with continuous values were summarized using mean values and SDs. Variables with categorical values were represented by absolute (n) and relative (%) frequencies. The regional origin was dichotomized: the regions Ostholstein, Pinneberg, and Nordfriesland were assigned to the rural area, and the Kiel region to the urban area.

The nonparametric Mann-Whitney *U* test was used to compare the full and short versions of the questionnaire regarding the general preferences of telemedicine and AI. Furthermore, a subgroup analysis was performed by using the nonparametric Mann-Whitney *U* test to assess whether the regional origin (0=rural region and 1=urban region) differed concerning the preferences for telemedicine and AI.

Moreover, linear correlations between trust in diagnosis with AI and trust in diagnosis through physicians, the sociodemographic variables, and various influencing factors were calculated using Spearman correlation coefficient. Testing for connections using a correlation is a common procedure to reduce the number of variables for subsequent model calculations. In a further step, significant correlations identified in this way were taken into account in the linear regression models.

Afterward, 2 stepwise regression analyses were performed to evaluate which factors were strongly associated with the outcome variables. Trust in diagnosis with AI and trust in diagnosis through physicians were the outcome variables, while other aspects, such as preferences for telemedicine and AI, attitudes to early detection measures, and some characteristics of participants (such as gender, age, regional origin), were considered potential predictors and handled as covariates. Additionally, the possibility for multicollinearity was considered in both models. The variance inflation factor (VIF) and the tolerance value were reported for the final step of the regression models. Values for VIF should not exceed 5.0, and tolerance values should not be lower than 0.25 [15]. Statistical significance was set at $P<.05$.

Ethical Considerations

The ethics application for conducting the study was approved by the ethics committee of the University of Lübeck in March 2023 (2023-258_1). All participants provided informed consent prior to participation and were informed that their participation was voluntary and that they could withdraw from the study at any time without consequences. The study involved only the analysis of data collected within the scope of the approved protocol; no additional data were evaluated beyond those covered by the original ethical approval. All data were anonymized prior to analysis, and no personally identifiable information was accessible to the researchers. Appropriate technical and organizational measures were implemented to ensure data protection and confidentiality in accordance with applicable data protection regulations. No incentives were offered for participation.

Results

Description of the Sample

Of the 5000 citizens contacted, 1790 (35.8%) took part in the survey, corresponding to a response rate of almost 36%. Of the participants, 785 (43.9%) were male and 972 (54.3%) were female. A total of 10 participants (0.6%) identified themselves as diverse, while 23 (1.3%) did not specify their gender. Of these participants, 352 (19.7%) chose the short version of the questionnaire. Of these, 160 (44.1%) were male, 189 (52.1%) were female, 3 (0.8%) were diverse, and 7 (1.9%) had missing data for this variable. The average age of all participants was 56 years (range 18-96 years).

Of the 1790 participants, 764 (42.7%) lived in the city and 979 (54.7%) lived in a rural area. Most participants lived in Kiel (764/1790, 42.7%), followed by 520 (29.1%) in Ostholstein, 335 (18.7%) in Pinneberg, and 124 (6.9%) in Nordfriesland districts. Table 1 provides further details on the comparison between the long version and the short version of the questionnaire.

XSL•FO

Table . Sociodemographic characteristics of participants (n=1790).

Characteristics[a]	Long version questionnaire (n=1427)	Short version questionnaire (n=363)	*P* value
Gender, n (%)			.64
Female	783 (54.9)	189 (52.1)	
Male	625 (43.8)	160 (44.1)	
Diverse	7 (0.5)	3 (0.8)	
Age (y), mean (SD; range)	55.8 (16.8; 18 - 96)	57 (16.4; 18 - 91)	.11
Regional origin, n (%)			.09
Kiel (urban)	606 (42.5)	158 (43.5)	
Ostholstein (rural)	406 (28.5)	114 (31.4)	
Pinneberg (rural)	275 (19.3)	60 (16.5)	
Nordfriesland (rural)	109 (7.6)	15 (4.1)	
Assessment of local medical care[b], mean (SD)	2.97 (1.43)	2.93 (1.32)	.88

[a]The n values vary due to missing data.

[b]Ranging from 1 (very good) to 6 (very bad).

General Attitude, Future Role of AI, and Trust in Diagnosis Through AI and Physicians

A descriptive analysis of general preferences regarding telemedicine and AI in health care was carried out (Table 2). The variables analyzed included general attitudes toward telemedicine and AI, as well as specific aspects such as trust in diagnoses by AI and the future role of AI in one's own health care.

Table . General preferences for telemedicine and artificial intelligence (AI)—descriptive analysis.

Variables	Long version, mean (SD)	Short version, mean (SD)	*P* value
General attitude to the topic of telemedicine[a]	3.44 (1.50)	3.58 (1.37)	.06
General attitude to applications of AI in medicine[a]	3.35 (1.49)	3.47 (1.47)	.19
Future role of AI for own health care	2.91 (1.48)	—[b]	—
Trust in diagnosis through AI[c]	3.53 (1.43)	—	—
Trust in diagnosis through physician[c]	1.96 (0.82)	—	—

[a]Ranging from 1 (very positive) to 6 (very negative).

[b]Not available.

[c]Ranging from 1 (very small) to 6 (very big). These items were not asked in the short version.

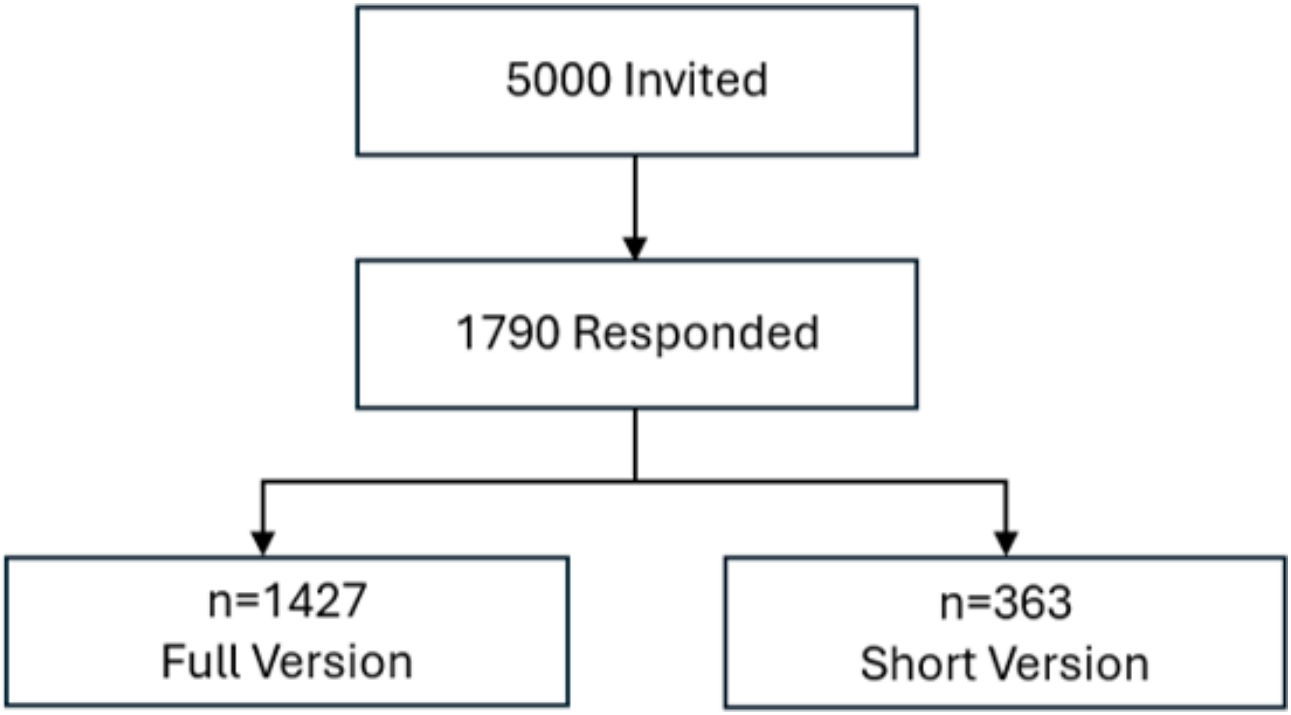
For the general attitude toward applications of AI in medicine, a mean value of 3.35 (SD 1.49) was observed for the long version of the questionnaire, and a mean value of 3.47 (SD 1.47) was observed for the short version.

The assessment of the future role of AI in personal health care had a mean value of 2.91 (SD 1.48). The SD of 1.48 suggests a wide distribution of responses. It was rated important by 35.4% (n=634) of respondents.

Trust in diagnoses by AI is rated with a mean value of 3.53 (SD 1.43). In comparison, trust in diagnoses by physicians had a mean value of 1.96 (SD 0.82).

Subgroup Analysis Concerning Regional Origin and General Preferences to Telemedicine and AI

Participants from urban regions were more positive toward telemedicine ($mean_{urban}$ 3.26, SD 1.5; $mean_{rural}$ 3.56, SD 1.5; $P<.001$) and toward applications of AI in medicine ($mean_{urban}$ 3.11, SD 1.4; $mean_{rural}$ 3.52, SD 1.5; $P<.001$) than participants from rural regions. Moreover, for respondents from urban regions, AI was perceived to play a bigger future role for own health care ($mean_{urban}$ 2.65, SD 1.4; $mean_{rural}$ 3.09, SD 1.5; $P<.001$), and they reported greater trust in diagnoses made by AI ($mean_{urban}$ 3.38, SD 1.4; $mean_{rural}$ 3.63, SD 1.5; $P<.001$) than participants from rural regions. No significant difference was



XSL•FO
RenderX

observed for trust in diagnosis through physicians (mean$_{urban}$ 1.99, SD 0.80; mean$_{rural}$ 1.93, SD 0.81; *P*=.14).

Relevance of AI-Based Screening Measures in the GP Practice

Participants were asked to rate the use of AI-based screening measures in GP practices (Figure 1). Respondents had the opportunity to select several statements that applied.

Figure 1. Response rates for the long version vs short version of the questionnaire.

The analysis of the survey results showed a differentiated perception of the AI-based screening measures, which reflected both potential benefits and concerns among the citizens surveyed.

Out of the 1790 respondents, the most frequently mentioned statement was “signs of modern medicine,” selected by 787 (44.0%) participants. The statement “improved patient care” was selected by 618 participants (34.5%), followed by “easing everyday life” with 445 (24.9%) responses. In contrast, 388 (21.7%) participants stated that they would expect a “worsened doctor-patient relationship,” and 270 (15.1%) respondents described the measure as “intensifying uncertainty.”

The statements “improved doctor-patient relationship” (n=167, 9.3%), “signs of unnecessary technologization” (n=162, 9.1%), “deterioration in patient care” (155, 8.7%), and “difficulty in everyday life” (n=37, 2.1%) were selected less frequently (Multimedia Appendix 1).

Aspects of the Implementation of Screening Examinations for Eye Diseases Using AI in GP Practices

In the data received from the long version of the questionnaire, the most important factors from the citizens’ perspective were trust in the GP (mean 1.78, SD 1.24) and the reliability of the examination (mean 1.43, SD 1.01), followed by data security (mean 2.19, SD 1.52).

With regard to organizational factors, the accessibility of the practice (mean 2.14, SD 1.31) and the waiting time for an ophthalmologist appointment (mean 2.13, SD 1.26) were also rated as relevant. The protection against additional examination costs (eg, Individual Health Services; mean 2.30, SD 1.42) was rated as moderately important.

Factors considered less important from the citizens’ perspectives included not having their pupils dilated (mean 3.24, SD 1.65), the duration of the examination (mean 2.93, SD 1.45), and the distance to the nearest ophthalmologist (mean 2.50, SD 1.39).

The results showed that trust in the GP conducting the examination, the reliability of the examination, and data security were the most important aspects considered by the participants when implementing such technologies in GP practices (Table 3).

XSL•FO
RenderX

Table . Evaluation of the aspects of artificial intelligence–supported screening for eye diseases in general practitioner practices.

Variables[a]	Factors, mean (SD; 95% CI)
Trust in general practitioner	1.78 (1.24; 1.71 - 1.86)
Duration of the examination	2.93 (1.45; 2.84 - 3.02)
Waiting time until the test results are available	2.44 (1.29; 2.37 - 2.52)
Data security	2.19 (1.52; 2.10 - 2.29)
Reliability of the examination	1.43 (1.01; 1.37 - 1.49)
Not having the pupils dilated	3.24 (1.65; 3.14 - 3.35)
Accessibility of the practice	2.14 (1.31; 2.06 - 2.22)
Distance to the nearest ophthalmologist	2.50 (1.39; 2.41 - 2.58)
Waiting time for an eye specialist appointment	2.13 (1.26; 2.05 - 2.21)
Waiting time in an ophthalmologist's practice	2.49 (1.31; 2.41 - 2.57)
Protection against additional examination costs	2.30 (1.42; 2.22 - 2.39)
Performance of the examination by medical assistants	2.12 (1.30; 2.04 - 2.20)

[a]Scale from 1=very important to 6=very unimportant.

Factors Associated With Trust in Diagnosis With AI

The stepwise regression analysis is presented in Table 4 and reports only coefficients with statistical significance at the $P<.05$ level. A 9-step model was fitted and explained more than 60% ($R^2=0.602$) of the variance in the dependent variable, "trust in diagnosis through AI." In the first step of the stepwise regression analysis, the variable "general attitude to applications of AI in medicine" showed the highest explained variance ($R^2=0.509$). A higher positive level of attitude toward applications of AI in medicine was strongly associated with higher level of trust in diagnosis through AI. Individual characteristics were not included in the regression model, as $P>.05$. Collinearity statistics ranged between 2.112 (VIF value) and 0.473 (tolerance value) for "general attitude to applications of AI in medicine" and 1.140 (VIF value) and 0.877 (tolerance value) for "improved patient-physician relationship."

Table . Associations of individual characteristics, general preferences for telemedicine and artificial intelligence (AI), and attitudes toward early detection measures in general practitioner care with general trust in AI (results of stepwise linear regression analysis).

Variables[a]	β	*P* value
General attitude to applications of AI in medicine	0.420	<.001
Intensifying uncertainty	0.136	<.001
Future role of AI for own health care	0.164	<.001
Signs of unnecessary technologization	0.120	<.001
Improved physician-patient relationship	−0.063	.003
Providing security	−0.091	<.001
Duration of the examination	0.063	.004
Worsened physician-patient relationship	0.066	.004
Reliability of the examination	0.053	.02

[a]Last step was reported.

Factors Associated With Trust in Diagnosis Through Physicians

The stepwise regression analysis is presented in Table 5 and reports only coefficients with statistically significances at the $P<.05$ level. A 5-step model was fitted and explained more than 4.8% ($R^2\approx.048$) of the variance in the dependent variable, "trust in diagnosis through physicians." For example, a higher positive level of trust in diagnosis through physicians was strongly associated with lower age and greater importance attributed to the waiting time until the test results were available. Collinearity statistics ranged between 1.308 (VIF value) and 0.765 (tolerance value) for "distance to the nearest ophthalmologist" and 1.007 (VIF value) and 0.993 (tolerance value) for "providing security."

XSL•FO
RenderX

Table . Associations of individual characteristics, general preferences for telemedicine and artificial intelligence, and attitudes toward early detection measures in general practice care on general trust in diagnosis through physicians (results of stepwise linear regression analysis).

Variables	β	*P* value
Age of the participants	−0.111	<.001
Waiting time until the test results are available	0.077	.03
Providing security	0.093	.003
Local general medical care	0.089	.005
Distance to the nearest ophthalmologist	0.090	.01

[a]Last step was reported.

Discussion

This study examines citizens' attitudes toward the use of AI in general practice, particularly in the context of early detection measures. The study showed that the introduction of AI-supported technologies is met with mixed reactions.

Differences Between Rural and Urban Areas

Significant differences emerged between urban and rural participants. People from urban areas were significantly more positive about the use of AI in medicine than those from rural areas.

Differences in access to medical services between urban and rural areas are deeply rooted and reflect a complex mix of infrastructural, socioeconomic, and cultural factors [16,17]. While urban areas often provide a wide range of medical services and specialists, some rural areas experience a shortage of physicians, greater distances to health facilities, and limited access to specialized treatment [17].

The introduction of AI and telemedicine is often promoted as a solution to these inequalities by extending access to care. However, emerging research suggests that these technologies are not always met with acceptance [10,11]. The reasons for this are varied and include technological barriers, a lack of trust in digital diagnostic methods, and a preference for in-person physician-patient interactions [12,18,19].

To ensure equal access to care, a deeper understanding of the specific needs and concerns of the rural population is needed. This means not only providing technology but also taking into account the cultural and psychological aspects that influence attitudes toward technology.

Dynamics of Trust in General Practice Care and Technology

This study pointed to a trust deficit in AI-supported technologies. Trust plays an essential role both in interpersonal interactions and in the use of technology. The patient-physician relationship is built on trust, particularly in the physician's commitment to voluntary responsibility and compassionate judgment [20]. This dimension of trust is crucial, as patients in vulnerable health situations depend heavily on the expertise and care of their treating physicians.

This trust is primarily shaped by the quality of the physician-patient relationship, in particular effective communication, interpersonal care, and the physician's knowledge of the patient's individual needs. The study emphasized that these factors play an important role in strengthening patient trust, while other aspects, such as the duration of registration at a practice or the frequency of visits, had less influence on trust [21].

Interpersonal interaction and trust in the treating physician are essential for patient satisfaction and adherence to treatment [20]. Research also highlighted that perceived empathy and individualized care are particularly important to patients, reinforcing the importance of these qualities in maintaining trust in medical professionals [21].

Central to this trust is the concept of continuity of care, particularly relational continuity, in which patients consistently see the same physician over time.

The association between continuity of primary care and patient mortality has been described by categorizing continuity into 3 types: relational continuity, informational continuity, and management continuity. A review of 13 quantitative studies found that greater continuity of care is significantly associated with lower all-cause mortality, particularly among older patients and those with chronic conditions. This protective effect was explained by improved physician knowledge, increased patient confidence, and better adherence to medical advice [22].

Therefore, in an increasingly digitalized world, it is essential that new digital health applications are designed from a patient-centered perspective.

Trust in technologies is predominantly based on functional aspects, such as reliability, security, and predictability [23]. From the perspective of the citizens in our study, the reliability of the examination was the most important factor.

Trust in technology is a construct that is strengthened by a combination of experiences with the technology, trust in users, and trust in regulators. Each of these components plays a critical role in maintaining and fostering trust over time. Past experiences, especially the reliability of the technology, had a significant impact on user trust [24]. In addition, trust is strengthened by the integrity and competence of those who use the technology, especially in the medical field [25], as well as by trust in regulatory authorities responsible for the safety and effectiveness of the technology [26].

The ways in which AI technologies work are currently incomprehensible to the public. This technological opacity requires a certain degree of explainability and interpretability

XSL•FO
RenderX

[27]. This lack of transparency means that damage caused by interaction with an AI system cannot be easily proven or clearly attributed [28]. This poses a major challenge and underlines the urgency of developing mechanisms that clearly regulate responsibility and liability in connection with AI decisions.

AI is often seen as a potential solution to current challenges in the health care system, such as relieving the burden on physicians and promoting a person-centered physician-patient relationship [29,30]. In a systematic analysis of 45 studies, the impact of AI on the person-centered physician-patient relationship was investigated. The researchers identified various ways in which the use of AI tools could promote person-centered care. One of these ways was the use of AI tools in a supportive role [31].

The rising interest in AI for medical applications should not overshadow the need for proper scientific review and evaluation. It is crucial that the medical field maintains its high standards of evidence and ethical responsibility to ensure both the credibility and effectiveness of patient care in an increasingly digital world.

While a large body of research demonstrates the benefits of primary care, there is comparatively less evidence for the use of AI technologies in health care. This discrepancy has substantial implications for evidence-based medicine, where clinical decisions should be based on solid scientific research [32].

A lack of uniform evaluation protocols introduces several challenges, such as doubts concerning the long-term effectiveness, safety of patients, security of data, and ethical dilemmas. To integrate telemedicine and AI into health care systems responsibly and effectively, we need flexible and comprehensive evaluation methods that conform to clinical objectives and regulatory guidelines [33].

The literature highlights that the factors influencing health are complex and influenced by a variety of factors [34,35]. Future studies should continue to explore how aspects beyond technology influence health to ensure that the design of new health systems considers a balanced integration of digital and human resources.

Future Role of AI in Medical Care

While concerns remain about the integration of AI in health care, a significant proportion of participants believed that AI-based early detection measures in general practice could enhance patient care. The application of patient-specific medical data combined with AI assistance systems has the potential to improve treatment outcomes by facilitating prevention, early diagnosis, and individualized therapies. Such advancements could lead to the identification of new medical correlations and innovative approaches to prevention [36].

However, despite these potential benefits, significant challenges and concerns remain. The use of AI necessitates access to substantial amounts of sensitive medical data, raising concerns about data privacy and security. Robust security protocols are essential to safeguard patient privacy and prevent data misuse [37].

The development and integration of AI in health care also bring significant ethical considerations, particularly around accountability for poor decisions or unexpected outcomes. Establishing clear guidelines and defining responsibilities are essential to address these ethical concerns and build trust with patients [38].

In this context, the European Union's "AI Act" represents a critical step toward creating uniform regulations for AI use within the European Union to ensure safety and trustworthiness. This regulation uses a risk-based approach, categorizing AI applications into different risk levels, with high-risk applications, such as those often found in the medical field, subjected to strict requirements. These requirements include transparency, security, and the avoidance of discrimination, all aimed at ensuring that AI systems in the health care sector adhere to high-quality standards and guarantee patient safety [39].

Strengths and Limitations

With a response rate of approximately 36%, the study provides a robust insight into the attitudes and opinions of the population of Schleswig-Holstein on the use of AI in GP practices.

The study was limited to Schleswig-Holstein, which could limit the generalizability of the results to the whole of Germany. Furthermore, the sample could be biased by self-selection of participants who may have had a greater interest in or familiarity with digital technologies. Future studies should therefore aim for a broader geographical spread to improve the representativeness and applicability of the results to the entire German population.

Conclusions

These findings suggest that despite the growing importance of AI in some areas of health care, the traditional physician-patient relationship is seen as absolutely essential. This emphasizes the enduring value of the human elements in health care—personal interaction, empathy, and understanding—features that AI cannot replicate.

Nevertheless, the introduction of AI is still recognized as a sign of modern medicine. People in urban areas are somewhat more open to AI technologies in health care. The integration of AI into health care raises crucial considerations regarding the principles of evidence-based medicine. Balancing technological innovation with the fundamentals of patient-centered care will be crucial in navigating the future landscape of health care.

Funding

This work was supported by grants from the Joachim Herz Foundation as part of the PASBADIA (smartphone-based point-of-care diagnostics) Project.

Abstract

Background: AI-enabled voice electronic medical records (EMRs) are increasingly promoted as tools to reduce clinician documentation burden; however, empirical evidence from multilingual, resource-constrained health systems in sub-Saharan Africa remains limited.

Objective: This study examined health care professionals' perceptions, anticipated benefits, and concerns regarding AI voice-enabled EMRs in Ethiopia to inform context-sensitive implementation strategies.

Methods: We conducted a qualitative, multisite study using semistructured written responses from 43 Ethiopian health care professionals recruited via purposive and maximum variation sampling between April 11, 2026, and April 21, 2026. Data were analyzed in Taguette using a hybrid deductive-inductive approach integrating 3 complementary frameworks: the Consolidated Framework for Implementation Research (CFIR), the technology acceptance model (TAM), and Normalization Process Theory (NPT). Analytical rigor was strengthened through independent dual coding, structured reconciliation, reflexive memos, and a version-controlled audit trail.

Results: Four overarching themes were identified. First, participants anticipated clear clinical benefits, including reduced typing burden, improved documentation continuity, and enhanced patient interaction, yet expressed substantial concerns about automation errors, accent-related transcription failures, and persistent infrastructural instability. Second, usability barriers, including interface complexity, inadequate training, and digital anxiety, shaped technology acceptance across cadres. Third, participants anticipated shifts in workflow, task distribution, and clinical collaboration as documentation practices evolved. Finally, ethical and governance concerns, particularly regarding data confidentiality, unclear consent procedures, and fear of surveillance, emerged as major determinants of trust. Cross-framework synthesis revealed that adoption readiness was jointly shaped by organizational capacity, usability perceptions, emotional and cognitive responses, and evolving workflow expectations.

Conclusions: Successful implementation of AI voice-enabled EMRs in Ethiopia requires coordinated investments in digital infrastructure, locally adapted language models, strengthened data governance, and iterative user onboarding. These findings underscore the urgency of context-sensitive and ethically grounded approaches when deploying speech-based AI in low-resource health systems.

KEYWORDS

artificial intelligence; AI; voice electronic medical records; digital health; multilingual speech recognition; low- and middle-income countries; sociotechnical systems; health information systems

Introduction

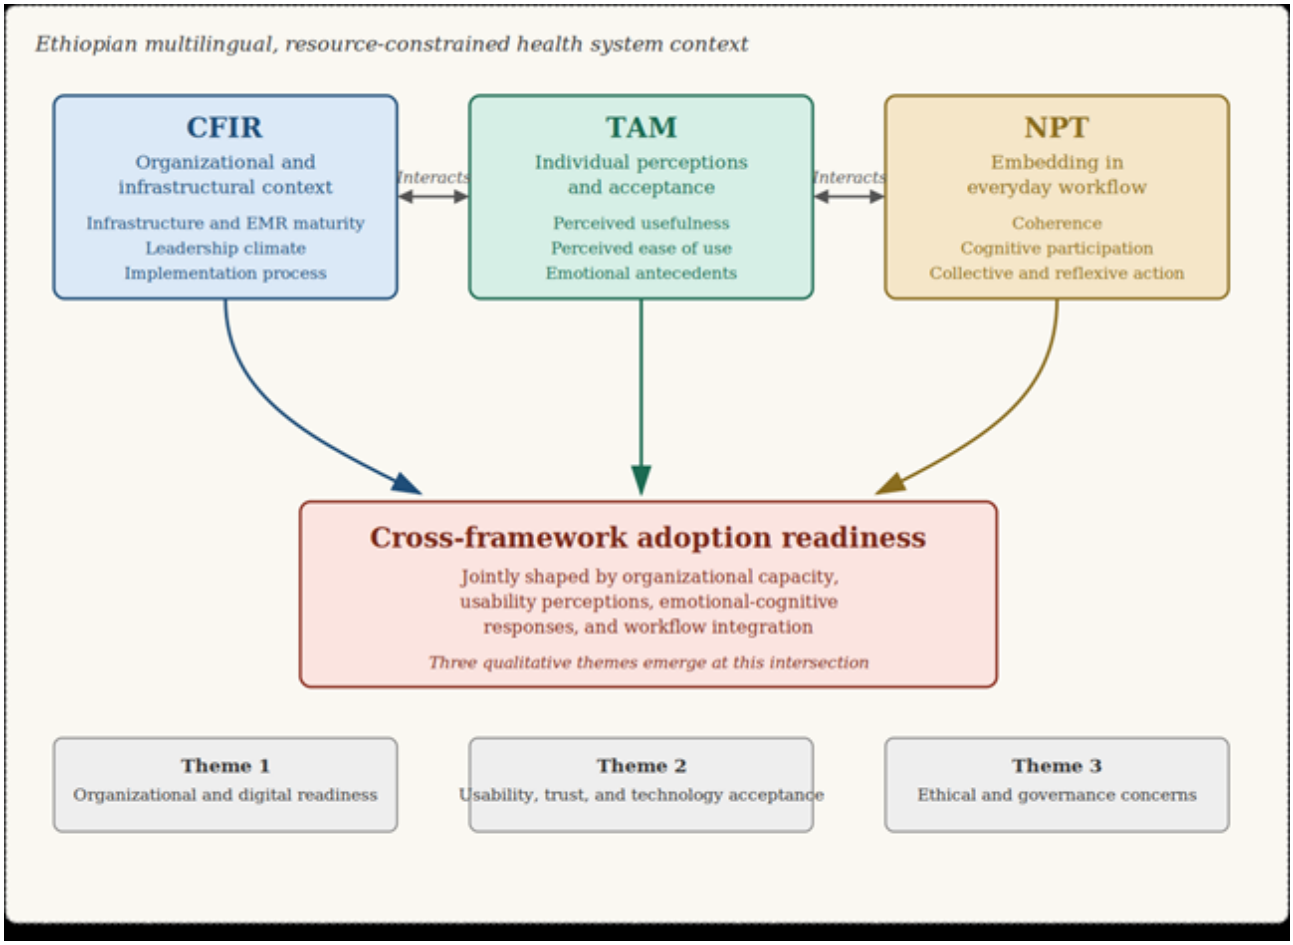
Health care systems worldwide are undergoing rapid transformation driven by digital health technologies. The World Health Organization's Global Strategy on Digital Health 2020-2025 recognizes electronic medical records (EMRs) as foundational to achieving universal health coverage [1]. EMRs facilitate structured data storage, retrieval, and communication among health care professionals, improving clinical accuracy and reducing duplication of effort. Recently, AI, particularly voice-based and natural language processing (NLP) technologies, has emerged as a promising complement to conventional EMRs, with the potential to reduce the documentation burden and allow clinicians to focus on patient care.

The integration of AI voice technologies into health care is not without challenges. Key concerns include accurate recognition of diverse accents and multilingual speech, ensuring patient privacy during ambient recording, interoperability with existing EMR platforms, and addressing ethical issues related to data ownership and algorithmic bias [2]. These concerns are amplified in low- and middle-income countries (LMICs), where health information systems are fragmented, digital infrastructure is unreliable, and clinical communication frequently occurs in multiple languages simultaneously.

Although EMR implementation challenges in LMICs are well documented [3,4], little empirical attention has been paid to AI voice-enabled EMR systems, which represent a qualitatively distinct sociotechnical paradigm from typing-based records. Unlike conventional EMRs, AI voice systems rely on real-time speech recognition, NLP, and clinical concept extraction [5]. Ethiopia offers a particularly instructive context for this inquiry. Guided by the Ethiopian Digital Health Blueprint (2020-2024) and the Health Sector Transformation Plan II, the Ministry of Health has made substantial investments in EMR infrastructure across hospitals and health centers. Despite this progress, EMR adoption remains inconsistent, with many facilities operating hybrid paper-digital workflows [3]. Ethiopian clinical communication further complicates adoption: clinicians frequently code-switch among Amharic, *Afaan Oromo*, Tigrinya, English, and local dialects, presenting challenges that most commercial speech recognition systems are ill-equipped to handle.

Existing Ethiopian digital health research has examined EMR usability, digital readiness, and system fragmentation [3,6]; however, no published studies have examined AI-driven voice documentation or its implications for workflow, ethics, and data governance. This study addresses that gap by integrating the Consolidated Framework for Implementation Research (CFIR) [7], the technology acceptance model (TAM) [8], and Normalization Process Theory (NPT) [9] to provide the first multidimensional analysis of how organizational context, individual perceptions, and workflow dynamics shape clinicians' readiness for AI voice-enabled documentation.

The specific study aims were to generate contextually grounded insights into health care professionals' perceptions, experiences, and patterns of anticipated use regarding AI-enabled voice EMR systems; to identify infrastructural, organizational, and workforce readiness gaps alongside key facilitators of implementation, with a view to informing national policy and procurement decisions; and to critically examine both enthusiasm and skepticism surrounding AI voice EMRs, elucidating conditions under which these technologies are perceived as trustworthy, usable, and sustainable in routine practice.



Methods

Study Design

This was a qualitative, multisite study using semistructured written responses, conducted between April 11, 2026, and April 21, 2026. The analytic approach combined reflexive thematic analysis [10] with a framework matrix informed by CFIR, TAM, and NPT (Figure 1). Reporting followed the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist [11].

XSL•FO
RenderX

Figure 1. Integrated analytical framework for AI voice-enabled electronic medical record (EMR) adoption. CFIR: Consolidated Framework for Implementation Research; NPT: Normalization Process Theory; TAM: technology acceptance model.

Study Setting and Sampling

The study was conducted across Ethiopian tertiary hospitals, regional hospitals, and health centers representing varied geographic locations (urban and rural) and EMR maturity levels. Eligible participants included clinicians (general practitioners, residents, nurses, and radiologists), health information officers, IT personnel, facility managers, and public health experts. Purposive sampling, with an intended maximum-variation approach across roles, facility types, and geographic settings, was used via institutional networks to recruit 43 participants. Information power was judged sufficient given the study's narrow focus on AI voice-enabled EMRs, high participant relevance, strong theoretical scaffolding (CFIR-TAM-NPT), data richness, and iterative analytic approach [12]. The realized sample skewed toward male, younger (aged 20-39 years), and government-facility participants; we therefore characterize the sampling strategy as an approximation of maximum variation rather than a fully achieved one and interpret findings that depend on demographic stratification with corresponding caution. A total of 12 of the 58 (21%) invitees did not complete the questionnaire, and 3 of the 46 (7%) respondents with incomplete core qualitative items were excluded, yielding a final completion rate of approximately 74% (43/58). Detailed role- and facility-level characterization of noncompleting invitees was not systematically captured during data collection, which we note as a limitation.

Data Collection

Data were collected via an English-language Google Forms (Alphabet Inc) questionnaire containing open-ended items covering participant demographics, EMR experience, awareness and perceptions of AI voice EMRs, and perceived readiness, barriers, and facilitators. Participants completed the form anonymously at their convenience. The instrument was pretested with 3 to 5 comparable participants, and minor revisions were made to improve clarity, item flow, and alignment with the CFIR-TAM-NPT constructs. No standardized prototype, video demonstration, or product description of an AI voice-enabled EMR was provided during data collection; participants therefore responded based on individually constructed mental models of a hypothetical system rather than a shared reference point, a constraint we return to in the Limitations section. Written, semistructured responses via Google Forms were chosen over in-depth interviews or focus groups primarily for feasibility, given the geographic dispersion of participants across tertiary hospitals, regional hospitals, and health centers, and to allow anonymous participation without requiring synchronous scheduling. We recognize that this modality typically yields shorter, less reflexive accounts than spoken interviews, and the resulting data should be interpreted as a distinct qualitative format rather than as equivalent in interpretive depth to interview-based inquiry.

XSL•FO
RenderX

Data Management

Digital informed consent was obtained within the Google Form prior to participants accessing the qualitative items, following a detailed information sheet covering study purpose, confidentiality, and the right to withdraw. Responses were stored on a secure institutional Google Drive (Alphabet Inc) with restricted access. Deidentified datasets were subsequently exported to encrypted, password-protected local folders for analysis and long-term archiving, consistent with institutional data protection and ethical requirements.

Data Analysis

All responses were in English and analyzed in Taguette using a hybrid semantic-latent, line-by-line coding strategy. Deductive parent codes were derived from CFIR (inner setting, outer setting, and implementation process), TAM (perceived usefulness and perceived ease of use), and NPT (coherence, cognitive participation, collective action, and reflexive monitoring). Inductive subcodes captured emergent concepts, including multilingual accent mismatch and fear of misinterpretation or surveillance. Two coders independently coded all responses; discrepancies were resolved through side-by-side comparison, reconciliation meetings documented in a decision log, and, when necessary, arbitration by a third reviewer. An audit trail comprising a versioned codebook, reflexive memos, and procedural logs supported transparency.

The integration of CFIR, TAM, and NPT was theoretically motivated: CFIR sensitized the analysis to inner-setting conditions (infrastructure, EMR maturity, and leadership climate); TAM to perceived usefulness, ease of use, and emotional antecedents of adoption; and NPT to the embedding of new documentation routines in everyday practice. Because participants' accounts of organizational readiness, usability, and workflow integration were substantively interrelated, resulting themes were structured around these overlapping domains of participant experience rather than around single frameworks in isolation; each theme therefore draws on constructs from >1 framework where participants' own accounts crossed conceptual boundaries.

Trustworthiness

Trustworthiness was enhanced through methodological and analyst triangulation. Interview findings were compared with contextual documents, including the Ethiopian Digital Health Blueprint and facility EMR guidelines. Independent first-cycle coding by 2 analysts, followed by refinement with a third reviewer, strengthened interpretive credibility. An audit trail, version-controlled codebook, and documented analytic decisions supported dependability. Reflexive memos and peer debriefing enhanced confirmability. Detailed contextual descriptions of the setting, participants, and the Ethiopian digital health context were provided to support transferability.

Ethical Considerations

Ethics approval was obtained from the institutional review board (IRB) of Yonsei University on April 9, 2026 (1041849-202603-SB-057-02). The study was conducted in accordance with the principles of the Declaration of Helsinki. Participation was voluntary, and participants were informed about the purpose and procedures of the study, the voluntary nature of their participation, their right to decline participation or withdraw, and the intended use of the information they provided. Informed consent was obtained from all participants before participation.

No personally identifiable information was collected. All data were anonymized, securely stored on password-protected and access-restricted drives, and used solely for academic research and health policy purposes. Access to the study data was restricted to authorized members of the research team. Participants received no financial or material compensation for their participation in the study. No photographs, images, or other materials that permitted the identification of individual participants were included in the manuscript.

Given that the study involved no clinical intervention or identifiable patient data and included voluntary, anonymous participation by adult professionals with full rights of withdrawal, ethical oversight was provided by the Yonsei University IRB throughout the study. Retrospectively, ethics approval was also obtained from the IRB of Mekelle University College of Health Sciences–Ayder Comprehensive Specialized Hospital (MU-IRB 2874/2026; expedited approval granted).

Researcher Positionality

The lead researcher has professional experience in digital health and health systems in Ethiopia, providing contextual depth while simultaneously creating the potential for interpretive bias. To mitigate this, the study incorporated independent dual coding, structured reconciliation procedures, and detailed analytic memos documenting assumptions and decisions. Peer debriefing with colleagues outside the research team further challenged emergent interpretations, ensuring that findings reflected participants' perspectives rather than the researchers' a priori expectations.

Results

Participant Characteristics

Forty-three health care, IT, and administrative professionals participated, representing diverse roles, educational backgrounds, facility types, and years of experience (Table 1). Most participants were male (n=36, 84%), aged 20 to 39 years (n=37, 86%), and employed in government hospitals (n=34, 79%). Professional roles spanned residents; general practitioners; radiologists; nurses; and a substantial proportion of EMR administrators, IT staff, and public health experts (n=24, 56%). This diversity provided a broad range of perspectives on digital health readiness and EMR familiarity. Participants' prior exposure to AI-based tools or voice transcription software specifically was not systematically captured in the survey instrument; we note this as a limitation, as baseline familiarity likely shaped how participants interpreted and evaluated the hypothetical system described in this study.

Theme 1: Organizational and Digital Readiness (CFIR)

Participants consistently identified substantial organizational and infrastructural readiness gaps that shaped their assessments of implementation feasibility. Infrastructure limitations were the most frequently cited barrier: frequent power outages, unreliable internet connectivity, and insufficient hardware, particularly in regional and rural facilities, led many participants to question the viability of cloud-dependent or AI-augmented systems.

Anticipated Clinical Benefits

Despite these concerns, participants expressed strong optimism about the potential clinical value of voice-enabled documentation. Reduced administrative burden was the most anticipated benefit, particularly among clinicians managing high outpatient volumes. One participant responded as follows:

> *Voice documentation is faster and easier for busy clinics. It removes the stress of rushing through notes.* [Nurse]

Participants also anticipated improvements in documentation accuracy and completeness. Typing was seen as conducive to

XSL•FO
RenderX

abbreviations and clinical shortcuts, whereas dictation was perceived to enable richer, more descriptive narratives. One participant responded as follows:

> *Structured transcribed notes would improve follow-up care. The next clinician would know exactly what happened.* [Public health officer]

Usability Barriers and Skills Gaps

Usability concerns were substantial. Participants described complex or nonintuitive interfaces as sources of anxiety, particularly among less digitally experienced clinicians. Interface navigation barriers were expected to slow adoption and increase the risk of errors. One participant expressed as follows:

> *Some of us are not used to complicated screens. If the system is not simple, people will give up quickly.* [Nurse]

Training emerged as a critical theme shaping perceived ease of use. Participants emphasized that digital health tools in Ethiopia were frequently introduced without structured onboarding, phased learning curves, or refresher sessions. The majority advocated repeated, hands-on, iterative training, citing high staff turnover and wide variation in baseline digital skills:

> *People forget. Training must be repeated until everyone is comfortable.* [Senior resident physician]

Emotional factors also influenced adoption readiness. Clinicians described anxiety about their confidence, fear of appearing incompetent, and reluctance to seek assistance, particularly among older or less digitally literate staff:

> *Some colleagues feel shy to ask for help. They pretend to understand but struggle.* [Resident]

Theme 2: Usability, Trust, and Technology Acceptance (TAM)

Reliability and System Trust

Trust in AI voice-enabled EMRs was highly variable. Although many clinicians associated AI tools with modernization and global innovation, reliability and linguistic accuracy emerged as equally prominent concerns. Fear of misinterpretation, particularly when AI mistranscribed medical terminology or locally accented speech, was pervasive. One participant responded as follows:

> *If the system misinterprets one word, it may affect patient care.* [Physician]

Participants also expressed concern about system crashes and operational overdependence in settings with unstable power and network infrastructure.

Linguistic Challenges in a Multilingual Context

Linguistic challenges were particularly salient in Ethiopia's multilingual clinical environment. Clinicians routinely code-switch among Amharic, *Afaan Oromo*, Tigrinya, English, and local dialects; many doubted whether any existing commercial system could accurately process such variation:

> *Many of us mix Amharic and English when we talk. If the system doesn't understand both, we will spend more time fixing errors.* [Radiologist]

This theme demonstrates that perceived usefulness is not determined solely by anticipated efficiency gains but is jointly shaped by historical experience with technology failure, organizational memory of prior EMR rollouts, and expectations of sustained institutional commitment.

Theme 3: Workflow Integration and Implementation Dynamics (NPT)

Workflow Adaptation and Professional Role Boundaries

Participants expected AI voice-enabled EMRs to reduce manual data entry; however, many anticipated unintended tasks shifting as documentation workflows changed. Some predicted redistribution of documentation responsibilities toward nurses or junior staff, potentially blurring established professional boundaries:

> *If the system writes as we speak, some roles may change. We must be clear about responsibilities.* [Public health officer]

Communication, Collaboration, and Continuity of Care

Participants anticipated that real-time transcription could strengthen interdepartmental communication, reduce duplication of clinical findings, and enhance continuity of care:

> *Everyone from the lab to the pharmacy can see the same note instantly.* [Health information officer]

Resistance, Change Fatigue, and Institutional Trust

Resistance to new digital tools was common, especially among older staff or clinicians who had experienced prior EMR implementations that were subsequently abandoned or inadequately supported. Past failures had generated skepticism about whether new systems would be maintained long enough to justify the learning investment. One participant responded as follows:

> *Older staff feel this is for young people; they prefer handwriting.* [Administrator]

Impact on Patient-Provider Interaction

Many clinicians believed that voice documentation could enhance patient engagement by reducing time spent typing during consultations. Speaking while examining was perceived as enabling a more natural and attentive clinical interaction. One participant responded as follows:

> *Speaking while examining keeps you with the patient, not the computer.* [Subspecialist]

Theme 4: Ethical, Governance, and Linguistic Equity Concerns

Data Privacy and Informed Consent

Ethical and governance concerns were expressed by nearly two-thirds of participants. Key issues included data confidentiality, uncertainty regarding server location and data

XSL•FO
RenderX

ownership, unclear consent procedures, and fear of surveillance or misuse. One participant responded as follows:

> *If stored on external servers, confidentiality could be compromised.* [Health information officer]

Participants stressed the need for explicit, multilingual, and culturally appropriate informed consent, noting that audio recording was perceived as inherently more sensitive than typed documentation. Fear of managerial surveillance and concern that voice systems might capture unintended content or be repurposed for performance monitoring were also expressed:

> *There are no strong laws for digital data here. That makes people anxious.* [Physician]

Weak national data protection frameworks and unclear accountability structures intensified these concerns, highlighting the need for transparent communication regarding data retention policies, access controls, and audit mechanisms.

Linguistic Equity and Accent Bias

Linguistic equity was identified as one of the most significant implementation challenges. Participants feared that accent-related or code-switched speech would produce transcription errors, compromising patient safety and increasing clinician workload. These concerns underscore the ethical importance of developing locally trained models, collecting Ethiopian speech corpora, and ensuring accent-inclusive tuning. Without such measures, voice-enabled EMRs risk reproducing existing digital inequities and further eroding clinician trust.

Discussion

Principal Findings

This study provides one of the first in-depth qualitative examinations of health care professionals' perceptions of AI voice-enabled EMRs in Ethiopia. Four overarching findings emerged. First, clinicians expressed genuine optimism about the potential clinical and operational benefits of voice documentation, framing efficiency gains as directly linked to care quality and patient safety rather than mere administrative convenience. Second, substantial usability, trust, and linguistic barriers constrain readiness for adoption, and these barriers are deeply embedded in Ethiopia's broader digital health landscape. Third, participants anticipated that voice-enabled documentation would reshape workflow patterns and professional role boundaries, requiring deliberate management of task redistribution and interdepartmental coordination. Fourth, ethical and governance concerns, particularly regarding data confidentiality and linguistic equity, represent critical determinants of trust that implementation strategies must proactively address.

Perceived Usefulness and Clinical Value

Participants' strong expectations that AI voice-enabled EMRs could reduce documentation burden and improve workflow efficiency mirror emerging evidence from LMIC digital health studies. Research has demonstrated that digital documentation tools in resource-constrained settings substantially reduce administrative load and increase perceived productivity [4], findings closely paralleling clinicians' views in this study. Our participants described improved documentation not merely as an efficiency gain but as an enabler of clinical adequacy, particularly relevant in Ethiopia's high-volume outpatient settings, where staffing is limited and caseloads are large.

These findings are consistent with global reviews of speech-based AI in health care, which demonstrate that voice interfaces reduce task switching, manual data entry, and cognitive overload, thereby supporting clinical focus [5]. Participants also believed that voice-enabled systems could improve documentation accuracy and completeness: typing was seen as conducive to abbreviations and shortcuts, whereas dictation was perceived to allow richer clinical narratives. This aligns with evidence from high-income settings suggesting that speech-based documentation can improve continuity of care and interdepartmental communication [12], although this association has not yet been empirically tested in the Ethiopian context and is offered here as a plausible parallel rather than a confirmed finding.

Usability, Skills, and Trust Barriers

Despite their optimism, participants expressed significant concerns about usability and digital readiness. Interface complexity, unfamiliar navigation pathways, and fear of error emerged as major barriers, echoing global literature, largely drawn from high-income settings, emphasizing the importance of intuitive interfaces for speech AI systems in clinical environments [12]; the extent to which these findings are transferable to Ethiopia's clinical environments remains to be empirically established. In settings where digital experience is uneven, even moderate interface complexity can produce cognitive overload and impede adoption. These findings align with recent systematic work on human-centered AI agent design in health care and education, which emphasizes that trust and usability are shaped as much by interface transparency and adaptive onboarding as by underlying model performance [13], suggesting that implementation recommendations for AI voice EMRs in Ethiopia should draw explicitly on human-centered design principles rather than treating usability as a secondary concern to technical accuracy.

Training deficits were among the strongest barriers identified. Clinicians repeatedly described the need for structured, phased, and iterative training, reflecting LMIC research demonstrating that digital health tools commonly fail when training is superficial or delivered as a 1-time event [4]. In Ethiopia's context of wide variation in digital literacy, training is not simply a capacity-building mechanism but an equity imperative enabling all clinical cadres to participate meaningfully in digital transformation.

Emotional and trust-related barriers further shaped usability perceptions. Clinicians described shame, embarrassment, and reluctance to seek help, particularly among older or less digitally literate staff. These findings echo research demonstrating that emotional responses such as anxiety and hesitation strongly influence automation adoption in clinical settings [2]. In Ethiopia, these emotions are amplified by prior experiences of EMR failure, which have generated skepticism about system longevity and institutional commitment. Because the sample was heavily concentrated among younger clinicians (37/43,

XSL•FO
RenderX

86%; aged 20-39 years; Table 1), with older clinicians who are described here as experiencing greater digital anxiety substantially underrepresented, this finding should be interpreted as suggestive rather than representative of age-related variation in digital anxiety across the Ethiopian health workforce more broadly.

Concerns about reliability and the risk of clinical errors from mistranscription were also prominent. The fear of system crashes in facilities with unstable power and connectivity raised doubts about operational feasibility. Studies in African and Asian settings similarly report that mistranscription of non-Western accents and medical terminology remains a persistent challenge for automated speech recognition (ASR) technologies [14]. Ethiopia's multilingual clinical communication, frequently involving code-switching among Amharic, *Afaan Oromo*, Tigrinya, and English, presents unique challenges that current commercial AI systems are not equipped to handle. These concerns, while theoretically plausible and consistent with the broader literature, are based on participants' anticipated rather than observed transcription failures, since no live ASR testing on Ethiopian languages was conducted in this study. A recent non–peer-reviewed letter to the editor proposing retrieval-grounded evaluation of conversational AI in clinical risk-assessment contexts offers a useful conceptual template, rather than empirical precedent, for testing these anticipated failure modes in future research [15]. These linguistic risks nonetheless constitute a major trust barrier that future implementation must explicitly address.

Workflow Integration and Labor Dynamics

Participants described how AI voice-enabled EMRs could reshape workflow patterns, labor distribution, and clinical coordination. Many anticipated improvements in patient flow, reduced documentation backlogs, and faster consultation turnaround, consistent with evidence that speech-based tools reduce administrative delays [5]. However, concerns about unintended task shifting were equally prominent: clinicians worried that nurses or junior staff might inadvertently become default scribes, a dynamic observed in LMIC digital health projects where technology introduction unintentionally redistributes documentation labor [16]. Explicitly clarifying role expectations and monitoring labor equity are therefore essential preconditions for ethical implementation.

Participants also highlighted the potential of real-time transcription to improve interdepartmental communication, continuity of care, and reduce the duplication of clinical findings, consistent with global EMR research demonstrating the value of interoperable documentation [17]. However, these benefits depend heavily on system interoperability. Ethiopia's current digital landscape is characterized by hybrid paper-digital workflows, uneven EMR adoption, and limited system integration. Participants warned that adopting AI voice tools without equivalent investment in interoperability could worsen existing digital fragmentation.

The impact of voice documentation on patient-provider interaction was also discussed. Many clinicians felt that voice interfaces could reduce typing distractions and restore clinical presence, echoing findings reported from high-income settings [12]; however, this contextual transfer is not empirically confirmed for Ethiopia and should be treated as a plausible hypothesis rather than an established parallel, given substantial differences in infrastructure, patient volume, and clinical workflow. However, participants recognized that high error rates or frequent need for correction could paradoxically increase cognitive burden and interrupt consultations, a tension noted in the global literature [17]. Resistance to change, particularly among staff who had experienced failed digital implementations, further shaped workflow expectations, underscoring the importance of stable infrastructure and sustained institutional support [18].

Ethical, Governance, and Linguistic Equity Considerations

Ethical and governance concerns emerged as major cross-cutting findings. Clinicians expressed uncertainty about where voice data would be stored, who would control it, and whether external server involvement would compromise confidentiality. These concerns mirror global AI governance debates emphasizing data sovereignty, transparency, and accountability [1]. In Ethiopia, where national data protection regulations are still evolving, unclear governance structures amplify fears of vulnerability to misuse, unauthorized secondary use, or data breaches. Recent work on institutional AI governance argues that external regulatory frameworks alone are insufficient and must be complemented by internal, organization-level governance mechanisms such as vendor accountability structures and internal audit capacity [19]; this distinction is particularly salient in the Ethiopian context, where institutional governance capacity may need to substitute for, rather than simply await, external regulatory maturity.

Consent emerged as a particularly sensitive dimension. Participants stressed that voice recordings were perceived as inherently more intrusive than typed data, necessitating explicit, multilingual, and culturally appropriate consent processes. This aligns with global ethical frameworks emphasizing meaningful, context-sensitive consent in AI-mediated clinical interactions [2]. Fear of managerial surveillance and concern that voice systems might capture unintended content or be repurposed for performance evaluation were also expressed, underscoring the need for transparent data boundary policies, retention controls, and audit mechanisms.

Linguistic equity represents perhaps the most distinctive implementation challenge in Ethiopia's context. Participants consistently anticipated that commercial ASR systems would misrecognize their accents and code-switched speech, a concern broadly consistent with emerging evidence drawn mainly from preprint studies of general-purpose ASR performance in African and other underresourced-language settings, suggesting that commercial systems can disproportionately misrecognize non-Western accents and languages with limited training data [14,20]. This literature has not yet directly evaluated Ethiopian languages or Ethiopian-accented clinical speech, so whether these patterns hold in Ethiopia specifically remains an empirical question rather than an established finding. Clinicians' concerns about accent-based errors and code-switched speech nonetheless highlight the ethical imperative of developing locally trained

XSL•FO
RenderX

models, collecting Ethiopian speech corpora, and ensuring accent-inclusive system tuning.

Without such investments, voice-enabled EMRs risk reproducing and deepening existing global digital inequities.

Strengths and Limitations

This study is among the first qualitative inquiries into AI voice-enabled EMR adoption in Ethiopia and provides context-specific insights into an underresearched area. The multiframework approach (CFIR-TAM-NPT) offered a comprehensive lens encompassing infrastructure readiness, usability, and workflow integration. Participant diversity across roles, departments, and facility types enhanced the richness and credibility of the findings. Rigorous qualitative procedures, including independent dual coding, structured reconciliation, and thematic mapping, supported dependability and trustworthiness.

Several limitations warrant consideration. First, the study did not involve real-time testing of an operational AI voice-enabled EMR; participants' responses were based on anticipatory perceptions rather than direct experience, potentially introducing perceptual bias in both directions (overestimating risks such as surveillance or overemphasizing expected efficiency gains). Second, patient and caregiver perspectives were not included; future research should examine how voice-based documentation and ambient audio capture are experienced by those receiving care. Third, and most consequentially given this study's central focus on linguistic equity, requiring exclusively English-language responses created a direct tension with the study's own themes: participants who routinely code-switch among Amharic, *Afaan Oromo*, Tigrinya, and English in clinical practice were required to respond in English alone, likely introducing self-selection bias that systematically underrepresents the clinicians most affected by accent-related ASR failure, namely those with lower English proficiency working in lower-resource regional facilities. A follow-up study incorporating multilingual data collection would be needed to represent these voices directly. Fourth, ethics approval from the Mekelle University IRB (MU-IRB 2874/2026; expedited approval granted September 4, 2026) was obtained retrospectively, after data collection had concluded, rather than prior to recruitment; although ethical oversight for the study was maintained throughout via the Yonsei University IRB, we acknowledge that prospective dual-country review is preferable and recommend it as standard practice for future studies recruiting Ethiopian health professionals at scale. Fifth, because this study was conducted in a single country, any transferability of these findings to other African health systems is analytic rather than statistical; readers should treat cross-national relevance as conceptual guidance to be tested locally rather than as a representative generalization across the region. Finally, the cross-sectional design limits the ability to capture longitudinal adoption dynamics.

Implications for Policy, Practice, and Research

The recommendations below are derived from participants' anticipatory perceptions of a hypothetical system rather than from evidence of an operational deployment and should accordingly be read as priorities for context-sensitive piloting and empirical validation rather than as directly evidenced operational mandates. These findings underscore the need for a coordinated national strategy for AI-enabled documentation within Ethiopia's broader digital health agenda. Policymakers should prioritize strengthening digital infrastructure, standardizing EMR maturity across facility levels, and ensuring interoperability before any large-scale deployment of voice-based tools, with these priorities tested through phased, evaluated pilots rather than implemented at scale based on this study alone. Ethiopia's emerging data protection frameworks would likely benefit from expansion to include explicit provisions for voice data governance, algorithmic transparency, and vendor accountability, although the specific form this should take requires further empirical and legal analysis beyond the scope of this study. The development of national Ethiopian language speech corpora and locally adapted speech recognition models is suggested here as a strategic public-good investment worth piloting to mitigate linguistic inequities and improve contextually appropriate AI performance.

For health facilities and implementing partners, the findings highlight the importance of embedding AI voice-enabled EMRs into existing workflows rather than overlaying them onto fragile systems, a principle that should be tested and refined through phased implementation rather than assumed. Effective adoption likely requires phased rollouts, continuous hands-on training, and accessible troubleshooting mechanisms that accommodate diverse digital competency levels, although the specific design of these mechanisms should be informed by piloting rather than derived directly from this study's anticipatory data. Clear communication about data boundaries, consent procedures, and intended system use appears important for building trust and reducing fear of surveillance based on participants' expressed concerns. Facilities should consider proactively managing potential labor redistribution by establishing explicit role expectations and monitoring the equity impact of AI documentation tools on nursing and junior clinical staff, as this concern was raised by participants but not observed directly.

Future research should prioritize real-world evaluation of ASR accuracy across Ethiopian languages, dialects, and multilingual code-switching. Longitudinal implementation research is needed to examine adoption trajectories, workflow changes, and organizational resilience in hybrid paper-digital contexts. Mixed methods and controlled studies can assess the clinical impact of voice-based documentation on decision-making, patient safety, and care continuity. Finally, comparative research across African and multilingual health care systems will advance global understanding of linguistic equity, data sovereignty, and ethical governance in AI-mediated clinical environments.

Conclusions

This study provides one of the first comprehensive qualitative examinations of how health care professionals in Ethiopia perceive the feasibility, value, and risks of AI voice-enabled EMRs. Across diverse clinical cadres and facility types, participants expressed genuine optimism about the potential of voice documentation to reduce administrative burden, improve workflow efficiency, and strengthen continuity of care, benefits

XSL•FO
RenderX

that are particularly salient in high-volume, resource-constrained environments. At the same time, participants identified substantial usability challenges, linguistic limitations, infrastructural fragility, and ethical concerns that substantially constrain adoption readiness.

Integrating CFIR, TAM, and NPT demonstrates that successful implementation depends not only on technological performance but equally on organizational maturity, digital literacy, workflow integration, and trust in governance systems. Participants' reflections reveal that AI voice-enabled EMRs are experienced as sociotechnical innovations: their value is coproduced through interactions among infrastructure conditions, emotional and cognitive responses, professional identities, and the wider policy environment.

These findings highlight the promise and precarity of speech-based AI in LMIC health systems. Although clinicians recognize significant clinical and operational advantages, this technology will not succeed without sustained investment in local language adaptation, robust data protection frameworks, iterative training, and interoperable digital infrastructure. Strengthening these foundations is essential to ensure that AI-enabled voice EMRs enhance, rather than undermine, equity, safety, and trust in Ethiopia's digital health transformation.

Acknowledgments

The authors express their sincere gratitude to all health care professionals who participated in this study and generously shared their experiences and perspectives. The authors also acknowledge the institutions and professional networks that facilitated communication with potential participants and supported the recruitment process. During the preparation and revision of this manuscript, the authors used ChatGPT (version GPT-4o; OpenAI) to assist with language editing, grammatical refinement, clarity, and organization of selected sections. All AI-assisted content was critically reviewed, verified, and revised by the authors, who take full responsibility for the accuracy and integrity of the final manuscript. Generative AI was not used for participant recruitment, data collection, or data analysis.

Funding

The ANCHOR (Accelerating New Careers in Health Outcomes Research) Program supported this research through the Gangwon ANCHOR Center, funded by the Ministry of Education and Gangwon State, Republic of Korea (grant 2026-ANCHOR-10-006).

Data Availability

The datasets generated and analyzed during this study are not publicly available because they contain potentially identifiable and sensitive information obtained from qualitative interviews with health care professionals. Deidentified data may be made available by the corresponding author upon reasonable request, subject to ethical and institutional requirements and approval.

Abstract

Background: Many digital health and AI initiatives show promising results in pilot settings but do not progress to sustainable services. Pilots can operate within a predefined collaboration, whereas operational services must accommodate changes in participating organizations, available resources, and analytical capabilities while preserving established governance and technical arrangements.

Objective: This study examines the pilot-to-service transition as a problem of governed federation evolution and evaluates whether Open Health can admit new forms of participation while preserving bounded capabilities, organizational sovereignty, and auditable decision evidence.

Methods: Open Health applies federated computing (FC) as a governance model separated from the analytical runtime. A governed federation context is established before execution, participants receive holder-bound capabilities, and an admission gateway produces explicit ALLOW or DENY decisions before requested operations proceed. The proof of concept uses the Flower federated learning framework and the Pathology Modified National Institute of Standards and Technology (PathMNIST) dataset from the MedMNIST collection with an initial federation comprising hospitals A and B. Mode 1A introduces hospital C as a sponsored contributor permitted to submit locally computed training updates but not invoke the resulting federated model for inference. Mode 1B examines bounded AI-agent participation, where restricted results may be transformed through policy-authorized operations into derivatives whose consumption is governed independently from the source. Evaluation considers admission conformance, signed decision evidence, analytical effects of the additional contribution, and admission overhead.

Results: The demonstrator admitted valid member operations and hospital C's sponsored contribution (mode 1A) while denying model consumption outside hospital C's capability, scope violations, holder-binding mismatch, and federation-envelope mismatch. Mode 1B extended the same bounded-governance pattern to AI-agent participation, admitting bounded inference and governed transformation but denying unauthorized source consumption and privileged governance access. Under matched training conditions, cancer-related macro recall increased from 50.2% in the A+B control to 67.4% in A+B+C (+17.2 percentage points), while noncancer macro recall changed from 85.5% to 86.3% (+0.8 percentage points). Recall increased from 19.5% to 39.9% for cancer-associated stroma and from 80.9% to 94.9% for colorectal adenocarcinoma epithelium. Median (IQR) full admission latency was 1.210 (1.141-1.333) ms for ALLOW, 1.195 (1.136-1.273) ms for capability-scope DENY, and 0.884 (0.837-0.921) ms for holder-binding DENY. Each evaluated request generated signed decision evidence recording the decision, reason, participant and request bindings, governance context, and related model run.

Conclusions: Open Health demonstrates how a federated health-data collaboration can evolve through differentiated participation while preserving membership boundaries and bounded capability relations. The principal contribution is an executable governance boundary preserving capability relations and producing independently verifiable decision evidence separately from the federated-learning runtime. The analytical experiment showed that governed admission of an additional contributor produced a measurable effect on the intended cancer-related classes while preserving noncancer performance. The proof of concept establishes governance behavior under controlled conditions; clinical effectiveness and production-scale performance require further evaluation.

Introduction

Background

Digital health and clinical AI increasingly depend on access to diverse, multimodal, and representative data distributed across organizations and care settings. Models developed or validated within a single institution may not perform consistently across different populations or operational contexts, whereas broader cross-organizational collaboration can improve robustness and generalization by reducing dependence on narrowly defined local datasets [1-3].

Despite substantial investment in digital health and AI, many initiatives that show promising results in pilot settings do not progress to sustainable operational services [4,5]. Explanations commonly emphasize model performance, data quality, clinical validation, and local implementation barriers, but operationalization may also require the collaboration itself to change. Adding an organization can entail further contracting, governance review, technical integration, and assurance, and large-scale health-data programs have identified organizational and technical integration as important sources of delay [6].

Pilots can usually operate within a predefined collaborative arrangement in which participating organizations, datasets, analytical objectives, and responsibilities are established before execution and remain relatively stable. Operational services must accommodate changes in participation, available data, and analytical capabilities as needs and circumstances evolve. Scaling concerns not only the execution of distributed computation but also the ability of a governed collaboration to evolve without reconstructing its governance and technical arrangements for each new activity. Recent system-level evidence from the National Health Service AI Lab similarly identifies the pilot-to-scale gap, with fragmented governance and lack of system orchestration among the mutually reinforcing mechanisms constraining the scaling of health care AI [7]. In this study, scalability refers to the capacity of the governed collaboration to accommodate changes in participants, resources, and operations without altering its governance conditions. Computational throughput and deployment scale are outside this definition.

Existing health-data infrastructures address important parts of this problem at different boundaries. Centralized platforms provide common custody and access mechanisms, trusted research environments (TREs) provide controlled analytical access to governed datasets, federated learning (FL) frameworks coordinate computation across organizational boundaries, keeping raw data local, and dataspace or policy frameworks establish requirements for participation and data sovereignty. Their functions remain necessary, yet the decision that a participant may enter a particular federated activity under a defined authority, purpose, and set of capabilities can remain distributed across contracts, accreditation, identity systems, application configuration, and operational controls.

Open Health addresses the transition from fixed collaboration to evolving service through federated computing (FC), which represents collaboration as a governed structure within which autonomous organizations retain sovereignty over local data and systems for participating under shared governed rules [8,9]. FC complements health-data platforms, identity systems, FL frameworks, and organization-local security controls by providing the governance structure through which participation becomes legitimate within an existing federation.

Session-bound admission is one mechanism for establishing such participation [10]. Admission is evaluated for a specific governed activity, purpose, and bounded set of capabilities. Different participation relations can coexist within the same federation. An organization may, for example, submit locally computed model updates to federated training, without exposing its underlying local data, under a bounded contribution relation while retaining a status distinct from existing federation members. Contribution and model consumption are governed through separate capabilities, where a capability denotes an explicitly granted permission to perform a specified federation operation. Collaboration growth can proceed through purpose-specific and asymmetric participation relations, preserving the governance conditions of the federation.

The Open Health demonstrator examines this proposition in a multisite FL setting using Pathology Modified National Institute of Standards and Technology (PathMNIST) [11,12]. PathMNIST provides a biomedical benchmark derived from colorectal histopathology, but the federation-level partitioning used in this study is experimentally constructed and is not intended to reproduce the full clinical, organizational, or technical heterogeneity of operational health institutions.

An initial federation comprising hospitals A and B is extended through the governed participation of hospital C as a sponsored contributor. Hospital C may contribute to federated training but may not consume the resulting model only by virtue of that contribution. The implementation enables examination of whether federation participation can expand and preserve explicit authority, capability boundaries, session binding, and auditable decision evidence. This study, therefore, addresses the following research question: Can an open federated health data collaboration support governed evolution through new forms of participation and preserve bounded capabilities and auditable decision evidence?

The paper makes 3 contributions: First, it reframes the transition from pilot to service as a problem of governed federation evolution beyond computational or data scale. Second, it presents an Open Health implementation of FC in which session-bound admission, capability separation, and auditable decision evidence are integrated with a conventional FL runtime.

XSL•FO
RenderX

Third, it evaluates governed federation evolution through controlled organizational and computational participation scenarios, together with the analytical consequence and admission overhead of the implemented mechanisms.

The remainder of the paper is organized as follows: the Methods section reviews existing approaches to collaborative health-data infrastructure and their governance boundaries, introduces the FC and federation-admission principles used by Open Health, and describes the system implementation, experimental scenarios, and evaluation criteria. The Results section reports the admission, analytical, AI-agent conformance, and admission-overhead results. The Discussion section discusses the principal findings, their relationship to existing health-data infrastructure, the role of decision evidence and governed AI-agent participation, and the limitations and directions for future work.

Existing Solutions and Related Work

Collaborative Health-Data Infrastructures

Health-data collaboration is supported by several classes of infrastructure, including centralized data platforms, TREs, proprietary federated platforms, open-source FL frameworks, and policy or data-sovereignty frameworks. They are not direct substitutes because each establishes a different boundary around data custody, computation, participation, and governance.

Centralized data platforms simplify integration by bringing data under a common technical and administrative environment, where repository-level identity, access control, and data-management mechanisms can govern users and datasets [13,14]. Such an arrangement is effective when common custody is organizationally and legally acceptable but is less suitable when participating organizations must retain direct sovereignty over sensitive health data. TREs adopt a different boundary by providing controlled environments in which approved researchers or projects analyze specified datasets under explicit governance and disclosure controls. OpenSAFELY (Bennett Institute for Applied Data Science) [15] is a prominent example. TREs provide strong mechanisms for research approval, controlled access, and accountability, principally governing access to approved data and projects. The evolution of a federation of autonomous organizations and operational relationships constitutes a separate governance problem.

Proprietary integration and federated platforms, including Rhino Health [16], Syntropy [17], and the Mayo Clinic Platform [18], support cross-site analytics allowing participating organizations to retain local data. Their governance, deployment, and operational mechanisms are defined within the corresponding platform environment. Open-source FL frameworks such as Flower (Flower Labs GmbH) [19], NVIDIA FLARE (NVIDIA Corporation) [20], Intel OpenFL [21], PySyft (Andrew Trask) [22], and Substra (Owkin) [23] similarly provide computational mechanisms for coordinating distributed machine-learning workflows, keeping raw data local. In both cases, FC can be technically coordinated, and authority to participate remains represented through platform governance, deployment configuration, or surrounding organizational processes. Hybrid cloud architectures provide another mechanism for retaining organizational control over sensitive data for performing distributed computation. Brown and Randall [24] evaluated a secure record-linkage architecture in which identifiable information remained on premises, but privacy-preserving computation was performed in cloud infrastructure. Open Health addresses a complementary boundary by governing whether and under what conditions a participant may invoke a federated activity, independently from where the computation is executed.

Cross-organizational collaboration also depends on semantic interoperability because participating institutions may represent clinically equivalent concepts through different data structures, terminologies, coding systems, or information models. Rosenau et al [25] developed an intermediate query representation to bridge heterogeneous repository-specific query languages within a federated German health research infrastructure. Shared vocabularies and ontologies can make distributed data interpretable across organizational boundaries. Entitlement to contribute a resource, consume a resulting model, or perform an operation under a particular authority is established separately through federation governance. Semantic interoperability and federation governance address complementary requirements.

Policy-oriented dataspace initiatives, including Gaia-X [26], the European Health Data Space (EHDS) [27], and Towards the European Health Data Space [28], address trustworthy exchange, organizational eligibility, interoperability, and data sovereignty at the ecosystem level. Their emphasis on organizational control is closely aligned with cross-organizational health-data collaboration. Conversely, an operational federation-level admission decision cannot replace the regulatory, contractual, ethical, or organizational conditions that established eligibility.

AI-agent frameworks introduce a further implementation layer by coordinating how computational participants invoke tools, services, workflows, memory, or other runtime resources. Tool restrictions, isolation, approval mechanisms, and monitoring can constrain execution, but such controls do not determine whether an AI-driven process is entitled to participate in a federated health-data activity, under whose authority it acts, or which federation capabilities it may exercise. Open Health treats the agent framework as an execution mechanism whose implementation may vary independently of the federation's governance semantics.

Governance Boundaries in Cross-Organizational Collaboration

Cross-organizational infrastructures depend on established identity and access-control mechanisms. Federated identity systems can authenticate principals across organizational boundaries. Open authorization (OAuth)–based mechanisms, cloud identity and access management (IAM), role-based access control (RBAC), and attribute-based access control (ABAC) can control access to services and resources [29-32]. Such technologies provide necessary deployment foundations by establishing whether an identity can be trusted, whether a service account may invoke an API, or whether an actor possessing specified attributes may access a resource. Participation in a shared activity raises a different question because the relevant decision must be established across organizational boundaries.

XSL•FO
RenderX

In operational deployments, the effective participation decision may be distributed across cloud IAM policies, platform configuration, central policy services [33-35], contractual arrangements, and checks embedded in orchestration code. Heterogeneous identity and infrastructure stacks can make integration increasingly bespoke as collaborations evolve, but configuration changes can alter effective participation semantics and complicate reconstruction of earlier decisions. Organization-local access control and cross-organizational admission address different governance boundaries. The former controls activity within an administrative domain, whereas the latter establishes whether a participant may enter a specified collaborative activity under the applicable federation conditions.

Cross-silo FL illustrates the separation between computational coordination and participation governance. A federated learning (FL) framework can coordinate model distribution, local training, update submission, aggregation, and evaluation, leaving the authority for participation external to the learning procedure. Prior work on auditable session admission has shown that requests can be evaluated against session-specific capabilities and holder identity before reaching the FL runtime, producing explicit ALLOW or DENY decisions and structured decision evidence [10]. The underlying training and aggregation procedure remains unchanged. Open Health adopts the separation between governance boundary and analytical runtime, applying it to the broader problem of federation evolution.

Table 1 summarizes the principal approaches according to the boundary at which governance is exercised, and the extent to which changes in participation become explicit operational decisions. The comparison is functional: the different approaches may coexist within the same health-data infrastructure. Open Health introduces a complementary boundary at the transition from institutional eligibility or agreement to participation in a particular governed federated activity. Authentication, regulatory or dataspace eligibility, FL-platform interoperability, and valid local permissions establish the necessary preconditions. Entitlement to a particular federation activity is determined separately through federation admission for the specified purpose and bounded capability. Open Health addresses that transition by making the participation decision explicit, session-bound, and auditable, leaving data custody, local identity, operational authorization, semantic interoperability, and analytical execution to the mechanisms suited to those functions.

Table . Functional comparison of approaches supporting cross-organizational health-data collaboration.

Approach	Primary governance boundary	Data remain under organizational control	Controls operational access	Establishes purpose-specific participation	Participation decision externally auditable	Supports governed change of participation
Centralized data platforms: enterprise cloud data lakes [14]	Repository or data controller	Usually no	Yes	Deployment dependent	Deployment dependent	Through repository governance
TREs[a] [15,36,37]	Approved project or research environment	Often logically controlled by custodian	Yes	Yes, for approved research	Yes	Primarily through new project or governance approval
Proprietary federated platforms [16-18]	Platform federation	Yes	Yes	Platform dependent	Platform dependent	Platform dependent
Open-source FL[b] frameworks [19-23]	Federated computation	Yes	Runtime dependent	Usually external to FL framework	Usually external	Usually external
Dataspace or sovereignty frameworks [26-28]	Ecosystem eligibility and exchange	Yes	Implementation dependent	At policy or ecosystem level	Governance dependent	Yes, principally at ecosystem level
Open Health or federated computing [9]	Governed federation activity	Yes	Complementary local or runtime mechanisms	Explicit and session-bound	Explicit decision evidence	Through bounded participation relations

[a]TRE: trusted research environment.

[b]FL: federated learning.

Methods

Dimensions of Collaboration Growth

Scaling a collaboration requires changes not only in the number or type of participants but also in the resources available to the federation, and the operations participants may perform. The 3 dimensions are related but governed through different relations. New participants establish participation relations, new datasets or models extend the federation's resource base, and new analytical capabilities extend the set of permitted operations. Distinguishing them avoids collapsing heterogeneous entities and activities into a single category of objects to be admitted (Table 2).

XSL•FO
RenderX

Table . Dimensions of collaboration growth and their associated governance questions.

Dimension of evolution	What changes	Governance question
Participation	Organizations and human or computational participants, including AI agents	Under whose authority may they participate?
Resources	Datasets, models, compute, and analytical services	Under what conditions may they be contributed, exposed, or used?
Operations	Training, inference, validation, and analysis	Which activities are permitted, and for which purpose and scope?

Open Health treats scaling as governed evolution across participants, resources, and operations. Rights remain specific to the relation in which they are established, providing the conceptual basis for the asymmetric participation relations examined in the experimental implementation.

FC and the Governed Federation Context

Open Health applies FC to the problem of evolving cross-organizational health-data collaboration and treats the federation as a governed relational structure. Participating organizations retain sovereignty over their local data, infrastructure, identities, and internal access mechanisms; the federation embodies the shared conditions agreed among the participating organizations under which cross-organizational participation becomes legitimate. The resulting boundary is complementary to organization-local IAM, RBAC, or ABAC, TREs, FL frameworks, and other operational controls because those mechanisms continue to govern activity within their respective administrative or computational domains.

The constitutive governance conditions originate in the agreements established among the participating organizations rather than in the capabilities of the technical implementation. A governed federation context is established before operational execution. The context identifies the authorities participating in the collaboration, the applicable constitutional and policy state, the purpose of the activity, and the conditions under which participation may occur. Open Health represents the bounded context through a federation envelope, allowing later capability and admission decisions to be interpreted relative to the governance state under which they were made. Authentication establishes identity, and prior organizational eligibility establishes eligibility to participate. Federation admission separately establishes entitlement to a specified activity.

A federated service is an operational function exposed within a governed federation and retained under the control of the organization that provides it. The service and its underlying resources remain within that organizational domain. The federation governs the relations under which participants may invoke it, including authority, purpose, capability, scope, and federation context. FL model inference, data transformation, and other analytical functions may be exposed as federated services and remain operational functions outside the federation's constitutive governance.

FC as Code (FCaC) [9] provides the machine-processable representation through which these governance relations are expressed and evaluated. In Open Health, the governed federation context, participant authority, capabilities, purpose, scope, and related constraints are represented as executable artifacts that can be tested at the admission boundary. We separate governance establishment and capability expression from operational execution: FC models the relations governing participation, FCaC renders those relations machine-processable, admission evaluates them for a requested activity, and the corresponding federated service performs the admitted operation. Keeping these concerns distinct allows the participation structure to evolve independently of the analytical runtime and organization-local security mechanisms. Federation governance remains represented in its own constitutive artifacts, and operational configuration changes leave the conditions of participation unchanged.

FC provides a structure in which collaboration can evolve through changes in relations among participants, resources, and operations. A new organization does not need to acquire the rights of an existing member; a newly contributed resource need not become available to every participant, and permission to perform one operation need not imply permission to perform another. The relevant governance question is not whether an entity has been globally admitted to the federation, but whether a particular participation relation is legitimate within the governed context.

Session-Bound Admission

Overview

Session-bound admission operationalizes the transition from an established governance context to a requested federated activity [10]. In the earlier FL-specific formulation, that governed context was exposed as a session identifier, retaining the semantics of the underlying federation envelope. Open Health makes the federation-context semantics explicit and applies the same boundary-oriented principle to participation relations that may change over time. The admission decision asks whether a specific participant may perform a specified operation, for a defined purpose and scope, within the current governed context. An admission decision with the value ALLOW or DENY is produced before the requested activity reaches the corresponding analytical or operational runtime.

Capabilities used at the admission boundary are contextual, not global. A capability issued for one governed context is not a reusable entitlement to arbitrary future activities, and possession of a capability is not equivalent to federation membership. Admission evaluates the holder, requested operation, purpose, resource, and scope against the capability and the governance state associated with the federation envelope. The analytical runtime remains responsible for executing an admitted activity. Legitimacy of the preceding participation relation is established separately at the federation boundary.

XSL•FO
RenderX

Admission of Participants

A participant may be a human actor or a conventional software process acting within the federation under an accountable organizational relationship. The issuer expresses the participant's permitted federation activity through a bounded capability associated with the current federation envelope. Holder binding connects the capability to the participant for whom it was issued, while purpose, operation, resource, and scope delimit the activity that may subsequently be requested. The gatekeeper then evaluates the presented capability against the current governed context, with issuance and admission remaining separate decisions.

Separating issuance from admission supports differentiated participation. An established member may hold capabilities for both training and model use, whereas another organization may receive only a contribution capability for a specified federated training activity. Sponsorship provides an accountable route for establishing bounded participation while preserving the sponsor's rights as a separate governance relation. Delegation and federation membership remain in separate governance relations.

The same separation applies across capability categories. Contribution and consumption are governed through separate capabilities. Admission authorizes only the specified operation and scope. Provenance similarly records where a participant, credential, model, or other artifact originates, whereas accountability concerns the authority under which participation occurs, and the party responsible for that relationship. Treating provenance and accountability as separate relations avoids inferring federation rights from technical origin or organizational association alone.

Admission decisions also produce explicit governance evidence. The evidence associates the participant, governed context, requested activity, capability, purpose, decision outcome, and reason for the decision. These boundary-generated artifacts provide the information needed to reconstruct successful and denied requests independently of application logs and historical system configurations. They also link governance intent to operational participation and preserve the decentralization of organization-local policy mechanisms.

Admission of AI Agents

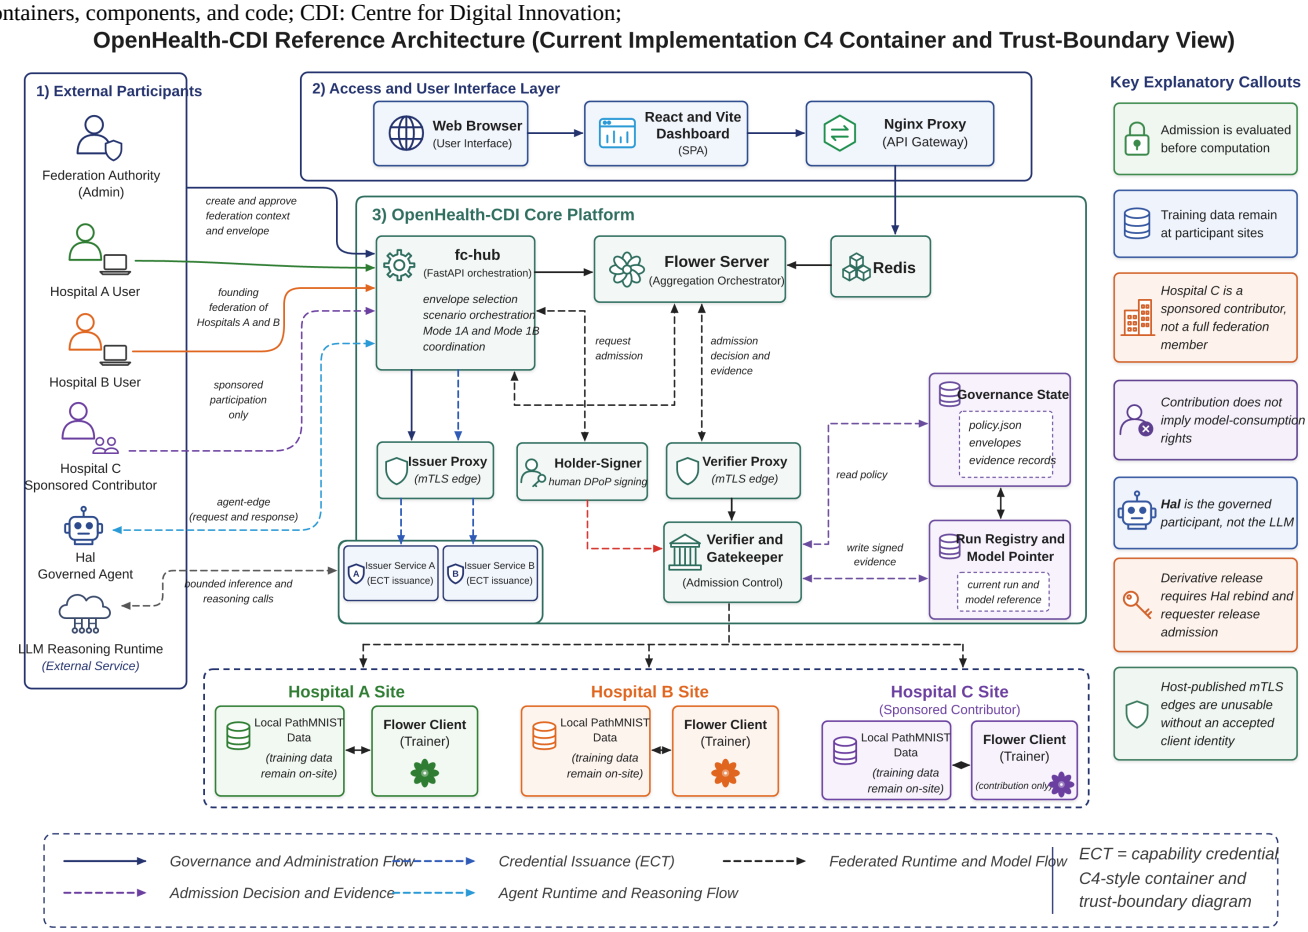
AI agents do not require a separate constitutive governance category. From the perspective of FC, an AI agent is a form of computational participant acting under an accountable organizational relationship. The model provider, planning strategy, memory architecture, tool framework, or execution runtime may affect how the agent behaves, but none of those implementation properties independently determines its federation rights. Admission remains governed through the same relations of authority, purpose, capability, holder binding, and federation context that apply to other participants.

Agent participation nevertheless introduces an additional operational distinction between runtime capability and federation capability. An agent runtime may expose file access, network communication, tools, APIs, or other execution mechanisms. Federation entitlement is established independently through admitted capabilities. Admission authorizes the specified federation operation and scope, while local runtime and external-environment permissions remain governed by their respective controls. The federation governs boundary crossing, and the agent runtime governs how admitted execution is carried out.

Admission cannot certify that an AI agent will behave correctly after execution begins. In this study, agent containment denotes complementary runtime controls such as sandboxing, network isolation, tool policies, approval mechanisms, and monitoring that restrict what the agent can do after admission. Federation participation remains defined by the admitted capability relations, and the execution framework must not expose federation operations beyond those relations. Assurance therefore depends on conformance between the agent's effective execution possibilities and the capabilities established by the governed admission decision. The bounded AI-agent scenario evaluates this requirement under the same federation-governance model used for human and conventional computational participants.

Threat and Trust Boundary

The threat model considered in this study concerns unauthorized enlargement of federation participation or capability relations. Attacks on the FL algorithm itself are outside its scope. The evaluated boundary includes capability or scope violations, holder-binding mismatch, federation-envelope mismatch, unintended propagation of rights through sponsorship or contribution, and attempts by a computational participant to exercise authority outside its admitted execution path. Model poisoning, membership inference [38], gradient leakage, model inversion [39], Byzantine aggregation, and related attacks on the analytical runtime remain outside the admission-governance mechanism evaluated here and require complementary protections at the FL and organization-local security layers [2].



Open Health System Implementation

System Architecture

The Open Health demonstrator implements a governed FL environment in which participation is established before execution of the corresponding distributed computation. The architecture separates the governance and admission plane from the analytical runtime so that the conditions under which an organization or computational participant acts can be evaluated independently from the technology executing the work. Figure 1 summarizes the implementation as four interacting areas comprising the federation-authority and participant interfaces, the Open Health governance and orchestration services, the FL runtime, and the participating hospital sites. The proof of concept is implemented as a local containerized Docker deployment. The conditions the architecture must satisfy are stated independently as a conformance criterion for FCaC [40]. All cross-boundary operations in the demonstrator traverse this admission boundary before reaching the corresponding federated service. No path into a participating site bypasses it.

XSL•FO
RenderX

Figure 1. Open Health proof-of-concept architecture. The governance and admission layer establishes session-bound participation before execution by the federated learning runtime. Hospitals retain their Pathology Modified National Institute of Standards and Technology data locally. The Flower runtime exchanges model updates rather than raw data. Hospital C participates as a sponsored contributor with a capability restricted to federated training; model-consumption rights are governed separately. A bounded AI agent participates through the same governed admission path but may exercise only the capabilities granted within the active federation context. ECT: envelope capability token; LLM: large language model. C4: context, containers, components, and code; CDI: Centre for Digital Innovation;

Flower remains responsible for distributed model training and aggregation [19]. Open Health governs participation at the federation boundary. Each hospital retains its PathMNIST partition locally and exchanges only model updates through the Flower workflow, so raw images remain within the originating site. This separation confines the Open Health contribution to participation governance and leaves the learning algorithm and analytical runtime unchanged.

Governance and Admission Workflow

Before a federated activity begins, the federation authority establishes a governed context represented by an envelope. Creation, binding, and approval of the envelope associate the activity with the applicable constitutional and policy state. The Key Your Organization (KYO) procedure establishes the envelope through mutual transport layer security (mTLS)–authenticated organizational approvals and the required federation quorum. The resulting envelope_id is the admission binding for subsequent participation decisions and remains distinct from the operational model run created after admission [9].

Participants receive envelope capability tokens (ECTs) through the Open Health issuer service. Each ECT expresses the bounded resource, operation, purpose, and scope available to its holder and associates that capability with the governed federation context [10]. Its signature is verified against a public trust anchor associated with an issuer authorized in that context. Capability issuance, admission, and federation membership are established independently, allowing a participant to hold a narrowly scoped capability while other federation activities remain outside its authorization. For each governed request, the holder presents a request-bound demonstrating proof-of-possession (DPoP) proof signed with the key associated with the ECT. The proof binds the credential presentation to the evaluated request and establishes control of the holder key [41].

Constitutional and policy artifacts are compiled into machine-evaluable constraints for the admission boundary. The verifier and gatekeeper evaluate the ECT, holder proof, envelope_id, requested operation, purpose, resource, and scope against the current compiled governance state. Admission evaluation is stateless and fail-closed. A missing, malformed, expired, or unverifiable artifact yields DENY. No discretionary path or operator override is available at the admission boundary.

Runtime, State, and Decision Evidence

The web interface is built with React 18 (Meta Platforms) and Vite 7.3.5 (VoidZero), the gateway runs Nginx (F5, Inc), and the backend services are implemented with FastAPI (Sebastián Ramírez). Participant and federation-authority operations are exposed through this interface and routed through the Nginx

XSL•FO
RenderX

gateway to the OpenHealth services. The fc-hub FastAPI service coordinates. The fc-hub FastAPI service coordinates the governed workflow and maintains the association between the current federation context and the operational FL run, but policy evaluation remains the responsibility of the verifier and gatekeeper. The interface and orchestration services expose governance state and invoke governed operations, while governance semantics remain defined by the federation's constitutive artifacts.

Constitutional and policy artifacts, active federation envelopes, and admission evidence are maintained separately from the Flower runtime. Each evaluated request produces a structured decision record containing the relevant participant, governed context, requested capability, purpose and scope, decision outcome, and reason.

The run registry maintains a traceable association between the governed federation context and the model run executed by Flower, preserving them as distinct objects. Capability credentials remain bound to the federation envelope and do not extend automatically to future model runs. A decision concerning a particular executed run may record the corresponding run association when applicable. Governance context, capability, admission decision, and model run remain distinct artifacts connected through explicit relations.

Experimental Scenarios

The experimental design uses PathMNIST [11,12] to examine governed evolution of an initially fixed federation. Hospitals A and B establish the baseline federation. The scenarios then change the governed participation relations without changing the analytical runtime, first by admitting hospital C as a sponsored contributor and then through bounded AI-agent participation. Governance and analytical outcomes are evaluated independently. Admission correctness is established through preservation of the specified capability relations, whereas model performance is evaluated through the resulting analytical outcomes.

A+B Baseline

Hospitals A and B constitute the initial federation and participate as established members under the same governed federation context. Each hospital retains its local PathMNIST partition and operates a Flower client that performs local training and submits model updates to the federated aggregation process. Raw images remain within the corresponding hospital environment, and the shared model is produced through conventional federated training after the required participation has been admitted.

PathMNIST contains nine classes comprising adipose tissue, background, debris, lymphocytes, mucus, smooth muscle, normal colon mucosa, cancer-associated stroma, and colorectal adenocarcinoma epithelium. Background was excluded from the publication experiment because it represents image background rather than a histological tissue category and is therefore outside the scope of the tissue-specific analytical comparison. The active noncancer classes were adipose tissue, debris, lymphocytes, mucus, smooth muscle, and normal colon mucosa, while cancer-associated stroma and colorectal adenocarcinoma epithelium formed the cancer-related group.

The federation partition was experimentally constructed. Hospitals A and B each received 30% of the observations allocated to every active noncancer class and 5% of those allocated to each cancer-related class. Consequently, the A+B control contained 60% of the allocated observations for every active noncancer class and 10% for each cancer-related class. The remaining observations were assigned to hospital C.

Two roles of the A+B configuration are distinguished in the evaluation. The initial A+B run establishes the governance and system baseline in which the federation consists only of its existing members. For the analytical comparison, an A+B control is trained under conditions matched to the A+B+C configuration, preserving the same model architecture and learning procedure so that the comparison isolates the effect of the additional admitted contribution rather than differences in training configuration.

Mode 1A: Governed Expansion With a Sponsored Contributor

Hospital C is admitted to federated training as a sponsored contributor under a participation relation distinct from federation membership. Sponsorship establishes an accountable, bounded participation relation for hospital C. Its capability is restricted to the submit_update operation for the specified federated-training purpose and remains bound to the current governed federation context. Admission authorizes that specific activity while preserving hospital C's sponsored-contributor status and the separation from member capabilities.

Model consumption is represented independently from contribution and is absent from the capability granted to hospital C. The implementation permits hospital C to contribute model updates to an admitted federated-training activity, remaining unable to query or otherwise consume the resulting model. Contribution and consumption are governed as distinct relations not inferred from participation or organizational association.

Hospital C contributed 40% of the observations allocated to each active noncancer class and 90% of the observations allocated to each cancer-related class. Accordingly, the A+B+C configuration contained the full set of allocations for every active class. Mode 1A produces two independent evaluation dimensions. The governance dimension examines whether contributions are admitted, while operations outside hospital C's granted capability, including model consumption, remain denied. The analytical dimension compares the matched A+B control with the A+B+C model to determine whether the admitted contribution produces an observable analytical consequence.

Mode 1B: Bounded AI-Agent Participation

Mode 1B introduces an AI agent as a computational participant acting within the same governed federation context as the human participants. The agent has a dedicated identity and holder-bound capabilities that permit narrowly scoped inference operations but do not confer federation membership or unrestricted access to model outputs. Its execution environment is isolated from

XSL•FO
RenderX

privileged governance services so that technical reachability cannot enlarge the participation relation established through admission.

The scenario considers a requester seeking cancer-related information whose unrestricted form lies outside the requester's authorized consumption scope. Direct source consumption is therefore denied. The agent may invoke an explicitly governed rebind operation, transforming the restricted result into a policy-authorized derivative representation, which the demonstrator implements as a blurred image accompanied by a qualitative indication of model accuracy. The federation policy determines the transformation. The term rebind is retained throughout this paper in its broader operational sense of placing a derived representation under a new governance relation. This terminology emphasizes the governed outcome of the operation. In the stricter formalization of [8], the value-changing transformation V→W constitutes an Unbind, whereas Rebind preserves the value while tightening its governance envelope. Source and derivative consumption are governed independently. The agent performs the transformation under its own admitted authority, and the requester's access to the resulting derivative is evaluated under a separate derivative-consumption capability. The transformation and subsequent consumption remain distinct governed operations within the same federation context, preserving the distinction between the capabilities of the computational participant and those of the requesting participant.

AI-Agent Participation and Governance Invariants

The mode 1B design makes explicit a set of governance invariants that remain independent from the agent framework used to implement the computational participant. An agent runtime may determine how tasks are planned and tools are invoked, but the execution mechanism cannot redefine the authority under which the participant entered the federation (Table 3).

Table . Federated computing governance invariants for AI-agent participation. These invariants are the agent-participation case of the general conformance criterion for federated computing as code [40].

Governance invariant	Operational consequence for AI-agent participation
Admission is governed	Technical reachability is insufficient; the computational participant must be explicitly admitted to the requested federation activity.
Authority is explicit and bounded	The agent acts only within the authority, purpose, operation, resource, and scope represented by the admitted capability.
Sponsorship is distinct from delegation	A sponsoring organization establishes an accountable participation route; its federation capabilities remain with the sponsor.
Provenance is distinct from accountability	The agent participates under an explicitly established authority relation, independent of the origin of its model, framework, runtime, or provider.
Credentials remain bound to the federation envelope	A capability issued for one governed context remains valid only within that federation envelope and its associated activity.
Contribution and consumption are independently governed	Contribution capabilities and model-query or model-use capabilities are established as separate relations.
Execution cannot redefine governance	Tools, network paths, or runtime functions that are technically available cannot enlarge the participation relation established by the admission decision.
Derivative consumption is distinct from source consumption	A policy-authorized rebind may create a derivative that can be consumed under a capability relation different from that governing the source representation.

For an admitted computational participant, conformance requires the effective operational possibilities exposed by the execution environment to remain within the capabilities established by the governed admission decision. The criterion evaluates whether runtime behavior remains within the admitted capability boundary, including when execution is variable or fallible. It does not require the computational participant to be predictable; it makes preservation of the asserted governance boundary observable and testable even when the internal behavior of that participant varies.

Evaluation Criteria

The demonstrator is evaluated along complementary governance and analytical dimensions. Governance behavior is assessed through positive and negative admission tests covering valid session admission, capability mismatch, holder-binding mismatch, sponsorship-based contribution, denial of model consumption to a contribution-only participant, and preservation of federation-context binding. Decision evidence is examined for the ability to associate ALLOW and DENY outcomes with the participant, requested operation and purpose, governed context, reason, and relevant model run when applicable.

- Mode 1A evaluates the analytical effect of governed federation expansion by comparing the matched A+B control with A+B+C. Cancer-related macro recall is the unweighted mean recall of classes 7 and 8. Noncancer macro recall is the unweighted mean recall of active classes 0, 2, 3, 4, 5, and 6. Class-specific recall for cancer-associated stroma and colorectal adenocarcinoma epithelium is also reported. Global macro recall and overall accuracy are reported descriptively. Analytical outcome and governance correctness are evaluated independently.

XSL•FO
RenderX

- Mode 1B evaluates conformance between the capability relations specified for the computational participant and the effective execution possibilities exposed to it. General claims about agent safety, autonomy, or model reliability fall outside the evaluation.

Admission Overhead

Admission overhead is evaluated through a request-level microbenchmark of the admission gateway. Three decision paths are exercised: a valid ECT and holder proof with a permitted capability (ALLOW), a valid ECT and holder proof with a capability or scope mismatch (DENY-Cap), and a valid ECT presented with a mismatched holder proof (DENY-Holder). Each iteration uses a fixed valid federation context and capability credential for generating a fresh request-bound DPoP proof [41]. Per-request timings are recorded inside the admission gateway using a monotonic high-resolution clock. Measurements are retained in memory during the benchmark and written to a JavaScript Object Notation Lines (JSONL) log after the run, excluding filesystem I/O from the measured request path. The benchmark uses 1000 requests per decision path under no concurrent load, and latency is summarized as the median with the 25th and 75th percentiles.

Ethical Considerations

This study involved no human participants or identifiable personal data. All experiments used PathMNIST, a publicly available, anonymized dataset [11,12], and hospitals A, B, and C were simulated participants. Under University College London guidance, research using anonymized public-domain datasets is minimal risk and does not require ethical approval [42], and Health Research Authority guidance generally excludes research using previously collected, nonidentifiable information from research ethics committee review [43]. Ethics review and informed consent were therefore not sought.

Results

Admission Behavior and Decision Evidence

The Open Health implementation produced explicit admission decisions for permitted and rejected requests at the federation boundary. In this study, evidence denotes the signed, machine-generated decision artifact emitted by the admission mechanism for each evaluated request. It is distinct from the capability credential presented by the requester, from application logs, and from the analytical artifacts produced by the FL runtime. The approach follows earlier session-admission work in treating the decision outcome, its reason, and the bindings required to reconstruct the evaluated request as first-class experimental outputs [10].

Each Open Health decision record identifies the admission event and timestamp, records the ALLOW or DENY outcome and reason, and associates the requester and holder-binding result with the relevant organizational and sponsorship information. The record also captures the requested action, purpose, and tissue scope, the governing federation envelope, the policy hash, and the related model run when applicable. Request and credential identifiers bind the decision to the specific presentation that was evaluated. An independent evidence signature protects the integrity of the resulting artifact.

The resulting evidence is independently verifiable and not merely observable. A verifier possessing the federation's public trust anchor can check the signature and inspect the recorded outcome, reason, request bindings, and governance state independently of mutable dashboard state and historical Flower-runtime configuration. Evidence establishes the governance decision and the conditions under which it was made. Clinical correctness of the subsequent analytical result is evaluated separately (Table 4).

Table . Principal elements of an Open Health admission-evidence record.

Evidence element	Representative content	Audit role
Decision	Decision identifier, timestamp, ALLOW or DENY, and reason	Identifies the outcome produced at the admission boundary and why it was reached.
Principal and accountability	Subject, actor type, issuing organization, sponsorship relation, and requester-binding result	Associates the decision with the participant and the authority relation under which the request was made.
Requested activity	Operation, purpose, resource, and requested tissue scope	Records the activity against which the presented capability was evaluated.
Governed context	Federation envelope, policy hash, and related model run when applicable	Binds the decision to the governance state and operational context in which it was valid.
Request and credential binding	Request identifier and capability-credential fingerprint	Distinguishes the evaluated presentation from other requests or credentials.
Integrity	Signed decision artifact and evidence-key identifier	Allows later verification that the recorded decision has not been modified.

Positive and negative tests were used to determine whether the admission boundary preserved the capability relations specified by the federation. Table 5 summarizes the principal cases. Ordinary member participation, hospital C's sponsored contribution, attempted model consumption outside hospital C's capability, scope violations, holder-binding failure, and federation-envelope mismatch are evaluated independently. Each case produces its own decision record. Each DENY is recorded as an explicit governance event.

XSL•FO
RenderX

Table . Admission and capability-conformance results.

Test condition	Expected	Observed	Decision evidence
Established member requests an operation within the admitted capability	ALLOW	ALLOW	Capability match
Hospital C submits an update for the admitted federated training purpose	ALLOW	ALLOW	Capability match under sponsored contribution
Hospital C requests model consumption outside its granted capability	DENY	DENY	Capability violation
Requested pathology scope exceeds the capability scope	DENY	DENY	Capability scope exceeded
Presented proof does not match the credential holder binding	DENY	DENY	Holder-binding mismatch
Presented capability is bound to a different federation envelope	DENY	DENY	Envelope mismatch

Governed Expansion From A+B to A+B+C

The A+B configuration established the initial federation with 2 existing members participating in federated training under the same governed context. Mode 1A then introduced hospital C through sponsorship, preserving the status and capabilities of hospitals A and B and leaving the Flower training and aggregation procedures unchanged. Hospital C was admitted for the submit_update operation associated with the federated-training purpose, and the corresponding admission evidence remained associated with the governed context and executed model run.

The complementary negative test preserved the asymmetric relation established for hospital C. A request to query or otherwise consume the resulting model was denied because model consumption was absent from the sponsored contributor's capability set. Successful contribution combined with unsuccessful model consumption provides the primary governance result for mode 1A. Federation growth occurred by adding a bounded participation relation instead of promoting hospital C to an equivalent member or transferring the capabilities of its sponsor.

Analytical Effect of the Additional Contribution

PathMNIST model performance was measured to verify that hospital C's admitted contribution produced an observable analytical consequence and not a purely administrative change. The analytical comparison uses an A+B control trained under conditions matched to the A+B+C run. An earlier A+B baseline used during development is not treated as the comparative reference because its training duration differs from that of the governed-expansion experiment (Table 6).

Table . Matched analytical comparison between A+B control and governed A+B+C expansion.

Metric	A+B control (%)	A+B+C expansion (%)	Change (pp)[a]
Cancer-related macro recall	50.2	67.4	+17.2
Noncancer macro recall	85.5	86.3	+0.8
Cancer-associated stroma recall	19.5	39.9	+20.4
Colorectal adenocarcinoma epithelium recall	80.9	94.9	+13.9
Global macro recall	76.7	81.6	+4.9
Overall accuracy	82.0	86.4	+4.5

[a]pp: percentage points.

Admission of hospital C increased cancer-related macro recall from 50.2% to 67.4% (+17.2 percentage points), while noncancer macro recall remained similar at 85.5% and 86.3%, respectively. Within the cancer-related classes, recall increased from 19.5% to 39.9% for cancer-associated stroma and from 80.9% to 94.9% for colorectal adenocarcinoma epithelium. Global macro recall increased from 76.7% to 81.6%, and overall accuracy from 82.0% to 86.4%.

These analytical results establish that hospital C's admitted contribution had an observable effect on the workload. Governance correctness is established separately through preservation of the admitted capability relations and their signed admission records. Model-performance improvement is therefore not treated as evidence that admission was correctly governed.

AI-Agent Conformance and Rebind

Mode 1B introduces an AI agent as a computational participant with its own identity and holder-bound capabilities. A requesting participant may lack authority to consume an unrestricted source result. Direct consumption of the restricted source must remain

XSL•FO
RenderX

denied to a requester lacking the corresponding source-consumption capability.

The requester is not authorized to consume the unrestricted cancer-related source result. The agent may nevertheless perform bounded inference and invoke the governed rebind operation, which converts the restricted result into a policy-authorized derivative consisting of a blurred tissue image and a qualitative indication of prediction accuracy. The requester may consume this derivative only under a separate derivative-consumption capability. The agent performs the transformation under its own admitted authority, and federation policy determines the permitted transformation. The Mode 1B scenario follows the conformance requirements summarized in Table 7, which define the required decisions across source consumption, bounded inference, policy-authorized rebind, derivative consumption, and access to privileged governance paths.

Table . Mode 1B conformance requirements and observed decisions for bounded AI-agent participation.

Governed operation	Required decision	Observed decision	Governance requirement
Requester asks for unrestricted cancer-related source output	DENY	DENY	Source-consumption capability remains absent
The agent performs inference within its bounded capability	ALLOW	ALLOW	Agent authority remains explicit and holder-bound
The agent invokes the policy-authorized rebind operation	ALLOW	ALLOW	Transformation is determined by federation policy
Requester consumes the derived representation under the corresponding capability relation	ALLOW	ALLOW	Derivative consumption is evaluated independently from source consumption
The agent attempts a privileged governance path outside the admitted execution route	DENY	DENY	Execution cannot enlarge federation authority

Admission Overhead

Admission adds cryptographic verification, capability matching, evidence signing, and evidence persistence to the request path.

Table 8 reports the completed request-level benchmark for the current Open Health implementation.

Table . Server-side admission latency by decision path.

Operation	ALLOW[a], median (IQR) ms[b]	DENY-Cap[c], median (IQR) ms	DENY-Holder[d], median (IQR) ms
ECT[e] verification	0.150 (0.143 - 0.171)	0.148 (0.143 - 0.160)	0.150 (0.144 - 0.161)
DPoP[f] verification	0.112 (0.110 - 0.120)	0.114 (0.111 - 0.120)	0.144 (0.139 - 0.151)
Capability match	0.0051 (0.0048 - 0.0053)	0.0051 (0.0049 - 0.0054)	NA[g]
Full admission check	1.210 (1.141-1.333)	1.195 (1.136 - 1.273)	0.884 (0.837 - 0.921)

[a]ALLOW denotes a valid capability and holder proof.

[b] Values are median (IQR) ms, from 1000 requests per case.

[c]DENY-Cap denotes a capability or scope mismatch.

[d]DENY-Holder denotes a holder-binding mismatch.

[e]ECT: envelope capability token.

[f]DPoP: demonstrating proof of possession.

[g]NA indicates that capability matching was not reached because holder validation failed first.

Median full admission latency was 1.210 (IQR 1.141 - 1.333) ms for successful admission, 1.195 (IQR 1.136 - 1.273) ms for capability-scope denial, and 0.884 (IQR 0.837 - 0.921) ms for holder-binding denial. ECT verification, DPoP verification, and capability matching individually remained submillisecond. Capability matching is reported as not applicable for the holder-binding denial because the request fails closed during DPoP verification and evaluation terminates before the capability-matching stage. The shorter full latency for this path is consistent with that early termination. For ALLOW, decision-evidence signing and persistence had median latencies of 0.065 (IQR 0.063-0.069) ms and 0.164 (IQR 0.159-0.172) ms, respectively, with comparable values for the denial paths.

The full admission measurement includes cryptographic verification, capability evaluation, decision-evidence signing and persistence, and the surrounding admission-gateway processing. The benchmark is intended as a deployability check rather than a throughput study and reports single-request latency under no concurrent load. The relevant systems question is whether explicit admission and signed decision evidence introduce material overhead relative to the federated activity they govern; throughput and tail latency under concurrent requests remain outside the current evaluation.

XSL•FO
RenderX

Discussion

Principal Findings

The Open Health demonstrator supports the central proposition of the study by representing federation growth as a governed change in participation relations, with technical onboarding remaining subject to explicit governance conditions. Positive and negative admission decisions remain tied to the federation envelope and are retained as signed evidence. Mode 1B extends the same structure to computational participation by separating the agent's execution capability from the rights of the human participant requesting the result.

Model accuracy is a secondary outcome in the current evaluation. Under matched training conditions, cancer-related macro recall increased from 50.2% to 67.4% after hospital C's admitted contribution, while noncancer macro recall remained similar at 85.5% and 86.3%. This establishes an observable analytical consequence of the governed contribution but neither establishes nor measures governance correctness. The primary result is preservation of the capability relations asserted before execution, including contribution-specific capabilities, holder-bound admission, federation-context binding, and independent governance of source and derivative consumption.

From Fixed Collaboration to Governed Federation Evolution

Many collaborative infrastructures are designed around an initially established set of organizations, resources, and analytical operations. Their technical mechanisms may scale effectively once those assumptions are fixed, yet movement from pilot to operational service can require the collaboration itself to change. Open Health addresses that transition by treating participation, resources, and operations as separable dimensions whose relations can evolve under an existing governance context.

The concept of a federated service follows from the same separation. An operational function can be exposed within the federation while remaining under the control of its provider, with the federation governing the authority, purpose, capability, scope, and context under which it may be invoked. Flower-based training and inference provide the concrete services used in the demonstrator. The governance structure is runtime-independent and can in principle accommodate other analytical or data-processing services as operational functions outside the federation's constitutive layer.

Relationship to Existing Health-Data Infrastructure

Open Health is not intended to replace TREs, identity federation, IAM, RBAC, or ABAC, dataspace governance, or FL frameworks. Each addresses a different boundary. Organization-local controls remain responsible for identities, infrastructure, users, and resources within an administrative domain, while analytical runtimes remain responsible for executing admitted computation. The additional FC boundary establishes whether a participant may enter a particular federated activity under the current shared governance conditions.

The distinction becomes important when collaborations evolve asymmetrically. Conventional onboarding may be sufficient when every new organization is intended to receive the same role and operational privileges as existing members. Hospital C represents a different case because the desired relation is deliberately narrower. Sponsorship enables accountable, differentiated participation while preserving delegation and membership as separate governance relations.

AI-Agent Participation and Governed Transformation

Mode 1B illustrates that an AI agent fits within the existing constitutive categories of the federation. The agent acts as a computational principal with its own identity, holder binding, and bounded capabilities. Its planning strategy or runtime determines how an admitted operation is executed. Runtime isolation constrains execution paths; federation authority is established through governed admission. Rebind extends this structure with an additional governed relation.

The agent may transform a restricted result into a policy-authorized derivative; the recipient's rights to that derivative are evaluated independently from rights to the source. The blurred representation used in the demonstrator is not treated as a differential-privacy mechanism or as an agent-defined judgment that an output is safe. Its significance lies in the governed transformation and the independent capability relation attached to subsequent consumption. The construction provides an operational connection to the earlier value-identity model, in which transformations of data and their governance bindings are considered jointly [8].

The same layering limits the claim that can be made about agent safety. Admission establishes legitimate participation at a federation boundary, whereas sandboxing, tool restrictions, network isolation, monitoring, and approval mechanisms constrain behavior within the execution environment. Neither layer can substitute for the other. The Open Health result concerns conformance between federation admission and runtime execution; agent predictability lies outside the scope of the study.

Limitations and Future Work

The demonstrator is a proof of concept implemented outside a production health-data infrastructure. PathMNIST provides a biomedical benchmark for reproducibly exercising governance relations and class-specific analytical effects. Clinical effectiveness and performance across heterogeneous operational health systems remain subjects for subsequent evaluation. The current proof of concept includes 3 participating hospitals and focuses on technical federation governance. Institutional processes required to establish real cross-organizational agreements remain outside its scope. The implementation will be ported to Amazon Web Services as part of the University College London Centre for Digital Innovation Impact Accelerator Program beginning in September 2026. The resulting cloud deployment will provide an environment for evaluating operational deployment and scaling and for verifying preservation of the governance invariants examined in this study.

The admission benchmark characterizes single-request latency in the current implementation and deployment environment

XSL•FO
RenderX

under no concurrent load and does not establish throughput, tail-latency, or scale-out performance. Key rotation, revocation, recovery, long-duration policy evolution, and operational incident handling require further evaluation. History-dependent controls such as cumulative disclosure limits belong to a procedural layer beyond the per-request admission mechanism evaluated here.

Mode 1B is restricted to a deliberately bounded agent interaction, with arbitrary autonomous behavior, unrestricted tool use, and unsupervised clinical decision-making outside its scope. Further work should examine multiagent and multisponsor participation, where computational participants operate under distinct accountable sponsorship relations and interact through bounded federation capabilities, with authority remaining specific to each participant. Deployments across different analytical frameworks and health-data environments would also test whether the governance boundary remains portable when the underlying execution substrate changes.

Conclusion

Open Health reframes the transition from federated pilot to operational service as a problem of governed federation evolution. The demonstrator separates the establishment of a federation context, expression of bounded capabilities, admission of specific participation, execution by a conventional analytical runtime, and production of signed decision evidence. Federation growth can occur through differentiated participation relations that preserve membership boundaries and bounded capability relations.

The hospital C scenario demonstrates contribution under a dedicated capability, with model consumption governed separately. The AI-agent scenario extends the same semantics to a computational participant producing a policy-authorized derivative under its own admitted capability, while recipient access remains independently governed. Together, the scenarios show how participants and operations can evolve while preserving explicit authority and capability boundaries.

The principal contribution is not a new FL algorithm or a claim of improved clinical model performance. It is a machine-evaluable admission boundary through which an existing collaboration can change while retaining auditable evidence of the conditions under which participation was allowed or denied. Such a boundary provides one route from fixed federated health-data demonstrations to services that can evolve while preserving organizational sovereignty.

Acknowledgments

We would like to extend our heartfelt thanks to Professor Ibrahim Abubakar, Professor Nora Colton, and the University College London (UCL) Health Partnership team for their steadfast support and belief in our vision for Open Health development. Their leadership and encouragement have been fundamental to this work. We are also deeply grateful to Professor Geraint Rees and the UCL Innovation & Enterprise teams for their financial support and commitment to technological innovation, which have been essential in advancing this project. We also thank the UCL Centre for Digital Innovation (UCL CDI), powered by Amazon Web Services (AWS), and the CDI Impact Accelerator team for their expertise, guidance, and support in accelerating the development of Open Health and strengthening its pathway towards real-world implementation and impact.

Generative AI Use

Generative AI tools were used as interactive computational interlocutors during manuscript and software development, including counterfactual explanations, critical challenges, iterative language revision, exploratory programming, and analysis support. Generated suggestions were treated as provisional alternatives rather than authoritative outputs. Research decisions, technical design choices, verification, interpretation of results, and final manuscript content remained under the responsibility of the authors.

Funding

Open Health has received funding and institutional support from the University College London (UCL) Innovation & Enterprise Knowledge Exchange Account, the UCL Health Partnerships team, and the UCL Centre for Digital Innovation (UCL CDI). We are deeply grateful for their investment in the development of Open Health and their continued support in advancing the initiative from concept towards implementation and impact.

Data Availability

Pathology Modified National Institute of Standards and Technology, the pathology dataset of MedMNIST v2 (a collection of standardized biomedical images modeled on the MNIST digit dataset), is publicly available [11,12]. A frozen, versioned archive of the implementation, study configurations, governance artifacts, tests, and generated evidence supporting the reported results is available at Zenodo [44].

Abstract

Background: Cardiovascular diseases (CVDs) and type 2 diabetes (DM2) are influenced not only by biomedical risk factors but also by social determinants of health (SDOH). While the inclusion of SDOH in predictive models is increasingly advocated, few studies have quantified their specific contribution in a high-risk clinical cohort using robust statistical and machine-learning approaches.

Objective: This study aims to quantify the added predictive value of SDOH in predicting CVD or DM2 disease onset within 5 years, within 10 years, and at any time during follow-up among individuals already at elevated risk and to compare this added value across multiple modeling setups and frameworks.

Methods: We used a large, linked dataset of over 58,000 inclusion events from the Extramural Leiden University Medical Center Academic Network data warehouse in the Netherlands, combining structured coded diagnosis and medication records from general practitioners with individual-level socioeconomic data from Statistics Netherlands. Individuals aged 30 years and older without prior DM2 or CVD were followed to assess disease progression. We trained Cox proportional hazards (CPH) and Extreme Gradient Boosting (XGBoost) models to predict progression to DM2 or CVD within 5 and 10 years and overall. All analyses were performed using the R programming language. Experiments included comparisons of Systematic Coronary Risk Evaluation 2, CPH, and XGBoost models; evaluation of time-bound and survival-based formulations; and quantification of SDOH impact using feature subset XGBoost models and Shapley additive explanations (SHAP)–based importance.

Results: For the 5-year prediction of CVD or DM2, the combined XGBoost model using biomedical and SDOH predictors achieved an area under the receiver operating characteristic curve (AUC) of 0.738, significantly outperforming the biomedical-only model (AUC=0.728; *P*=.01) and the SDOH-only model (AUC=0.691; *P*<.001). For 10-year CVD prediction, XGBoost achieved an AUC of 0.729, outperforming CPH (AUC=0.718; *P*=.02) and Systematic Coronary Risk Evaluation 2 (AUC=0.697; *P*<.001). For overall event prediction, XGBoost again performed best (AUC=0.719), significantly higher than CPH (AUC=0.704; *P*<.001). SHAP analyses showed that biomedical predictors contributed most strongly on a per-feature basis, while a subset of SDOH variables, particularly income- and benefit-related indicators, provided complementary predictive signal and ranked among the most influential predictors.

Conclusions: Incorporating SDOH improved the prediction of CVD and DM2 onset in a clinically defined high-risk cohort. Across hundreds of linked predictors, SDOH provided measurable incremental discrimination beyond biomedical risk factors, and income- and benefit-related variables ranked among the most influential features. SHAP analyses indicated that this added value was largely driven by a limited subset of highly informative social predictors. These findings support integrating structured SDOH into clinically actionable risk stratification models.

Introduction

The risk of developing cardiovascular disease (CVD) and type 2 diabetes (DM2) is related to a combination of interrelated metabolic anomalies (eg, insulin resistance, dyslipidemia, and hypertension), which are themselves socially patterned [1-3]. This is closely aligned with the clinical metabolic syndrome (MetS), a group of interrelated risk factors such as obesity, hypertension, dyslipidemia, and insulin resistance that together raise the risk of chronic cardiometabolic diseases [3,4]. MetS is widely recognized as a predictor of both DM2 and CVD, with formal definitions established by institutions such as the World Health Organization, the Joint Interim Statement, and the National Cholesterol Education Program Adult Treatment Panel III [5,6]. Although MetS definitions are typically based on biometric thresholds such as waist circumference, such measurements are not consistently available in routine health care data. In real-world primary care settings, the identification of cardiometabolic risk often depends on structured diagnosis codes and prescription records.

Therefore, extensive work has been done on the development of prediction models for the onset of DM2 and CVD, focusing predominantly on biomedical risk factors such as BMI, blood pressure, lipid levels, and comorbidities [7]. For CVD, notable examples include Systematic Coronary Risk Evaluation (SCORE) [8] and QRESEARCH cardiovascular risk algorithm (QRISK)-like statistical models [9-11]. For DM2, these models include SCORE2-Diabetes [12,13], the Australian DM2 risk model [14], and the QDScore algorithm [15]. These models typically rely on traditional statistical techniques such as the widely used Cox proportional hazards (CPH) models [16] and generally do not explicitly include social determinants of health (SDOH), despite growing evidence that sociodemographic factors significantly influence the risk development and progression of CVD and DM2.

The exclusion of variables such as income, education level, ethnicity, and household structure has raised concerns about the applicability of the models across diverse populations. For example, a study evaluating the SCORE2 model's performance in an ethnically and socioeconomically diverse Dutch cohort found that the model underestimated CVD risk, particularly among individuals of low socioeconomic position and the Surinamese minority group [17]. The researchers suggested that incorporating socioeconomic position and ethnicity into CVD risk models could improve prediction accuracy and lead to fairer health care interventions.

While widely used, traditional statistical approaches such as CPH may not fully capture the complexity of disease progression, particularly when incorporating large multidimensional datasets that include SDOH and medical determinants. In this context, machine learning (ML) can offer significant added value. Unlike conventional statistical models, ML algorithms are capable of handling nonlinear relationships and large sets of data with high dimensionality. In direct comparison, ML models have been shown to be able to outperform logistic regression and proportional hazards models for the prediction of cardiovascular risk, in the right circumstances [18-26]. Over the years, several alterations to the Cox model have been proposed to make it more robust toward a relatively large number of predictors, including regularization techniques such as Least Absolute Shrinkage and Selection Operator (LASSO), Ridge, and Elastic Net regression. These methods help by shrinking the regression coefficients, reducing overfitting, and enabling variable selection [27].

However, these alterations do not eliminate the need for a linear relationship between predictors and log-hazard. Furthermore, the models are still unable to detect interactions between variables, as these will be ignored if they are not explicitly prespecified. To overcome these limitations, ML approaches offer a more flexible alternative. These algorithms can process large, high-dimensional datasets and identify hidden patterns without requiring predefined relationships between variables. It should be said that these models are regarded to perform up to standard only when sufficient meaningful predictors and events are present to train the models, and traditional models have been shown to work comparably or better in low-dimensional contexts, which is an important argument in favor of traditional models, due to their low cost of implementation, ease of use, and better explainability [19,28-30].

To address the aforementioned challenges, we aimed to assess the predictive value of SDOH when estimating risks of disease progression to DM2 and CVD. This involved creating a dataset of primary and secondary care determinants and then comparing models that use only biomedical risk factors with those that use both medical and social factors, with a specific focus on understanding how the addition of SDOH influences performance. We evaluated traditional statistical approaches, such as the CPH model, alongside more advanced ML algorithms that can better accommodate complex, high-dimensional data. For quantifying the added value of SDOH, we focused on binary risk prediction within clinically actionable time windows, particularly 5-year risk, which balances decision relevance, data quality, and robustness to censoring. Survival models were included as benchmarking analyses rather than as primary analytical framework.

Through this work, we aim to clarify whether and to what extent SDOH provide incremental predictive value beyond established biomedical risk factors in routine care data. By benchmarking statistical and ML models on 5-year CVD prediction, we motivate the use of Extreme Gradient Boosting (XGBoost) for subsequent analyses and examine the added value of SDOH within clinically meaningful and implementable fixed-horizon risk prediction settings.

Methods

Ethical Considerations

This study was approved by the Scientific Committee of the Department of Public Health and Primary Care at the Leiden University Medical Center (LUMC; reference WSC-2023 - 55/SP). Furthermore, the study "HealthBox, Metabolic Syndrome Risk Stratification Patient Segmentation" (reference 24 - 3005) was reviewed by the non-WMO (Medical Research Involving Human Subjects Act) Review Committee

XSL•FO
RenderX

of LUMC Division 3. The committee concluded that the study does not fall under the scope of the WMO and is therefore exempt from review by a Medical Ethics Review Committee. The non-WMO committee raised no objections to the study.

In addition, the study received approval from the Scientific Committee of the HagaZiekenhuis (reference T24-030), as well as the Scientific Committee of the Haaglanden Medisch Centrum (reference 2024 - 039 HealthBox).

In accordance with the Dutch Medical Treatment Contracts Act, patients were informed about the use of their health data for scientific research. The institutions involved operate under an opt-out system, whereby patients can indicate that their data should not be used for research purposes. Only data from patients who did not opt out were included in this study. Because this was a retrospective secondary analysis of routinely collected health care and administrative data, and because the non-WMO Review Committee determined that the study was not subject to the WMO, additional individual informed consent was not required.

Health care data from the Extramural Leiden University Medical Center Academic Network (ELAN) data environment were linked to socioeconomic and administrative data from Statistics Netherlands (CBS; *Centraal Bureau voor de Statistiek*) and analyzed through the CBS Remote Access environment. This secure environment provides controlled access to pseudonymized data. Researchers had access only to pseudonymized and deidentified data, and no directly identifiable patient information was available to the researchers during analysis. No individual-level results are reported in this paper, and all outputs were checked to prevent disclosure of identifiable information. Data handling complied with institutional data governance procedures and applicable Dutch and European privacy regulations, including the General Data Protection Regulation.

No participants were recruited directly for this study, and no financial compensation or other incentives were provided.

Data and Dataset

ELAN Infrastructure

The data for this study were retrieved from the ELAN data infrastructure [31,32], which comprises 734,000 individuals registered in practices across the province of South Holland, the Netherlands. The ELAN general practitioner (GP) records span from the year 2000 to 2023. However, for the purposes of our study, we include preinclusion data only up to 2018 to ensure that there exists a minimum of 5 years of follow-up time available to assess the occurrence of outcomes.

ELAN was developed as part of an initiative to facilitate health care research on the key challenges of sustainable health care in the Netherlands. ELAN includes routine health care data collected from GPs and multiple hospitals located in the province of South Holland, the Netherlands. These primary and secondary care records include diagnoses, laboratory test results, prescribed medications, and treatment histories, providing a rich source of clinical information. Furthermore, ELAN is linked at the individual level to national datasets from CBS, expanding its scope well beyond medical data.

By integrating medical and socioeconomic data at the individual level, ELAN provides researchers with a unique opportunity to explore how medical and social factors interact to influence health outcomes. This is particularly useful for complex multifactorial conditions, such as CVD and DM2, where environmental factors and access to health care services have been shown to significantly influence disease progression along with biological risk factors.

Participants

Patients were included in the dataset if they were aged 30 years or older at the time of entering the cohort and had been assigned one or more of the following International Classification of Primary Care (ICPC) diagnosis codes, corresponding to relevant conditions, excluding CVD or DM2 outcomes:

1. A91.05: glucose intolerance
2. T82: obesity
3. T83: overweight
4. W84.02: diabetes gravidarum
5. W81: gestational hypertension, preeclampsia, and hemolysis, elevated liver enzymes, low platelet count
6. T99.06: polycystic ovary syndrome
7. Y07: erectile dysfunction
8. A29.01: family history of diabetes
9. K85: elevated blood pressure
10. T93: elevated cholesterol levels

For each of these inclusion criteria, we extracted data registration dates per patient. Each inclusion event was recorded as a separate entry in the dataset, which means that a single patient can have multiple entries corresponding to different inclusion events.

We selected this event-based design rather than a single-record per-patient structure to avoid reliance on a single, potentially arbitrary entry moment for each patient. In routine care, CVD and DM2 risk factors are recorded at different time points, and the availability and values of predictors depend on when a patient enters the cohort. Restricting the dataset to a single record per patient would therefore require selecting one moment of available information, which may discard relevant measurements.

In addition, patients may qualify for the risk group through different inclusion events at different time points. If only one record per patient was used, this would assume a single entry point, potentially oversimplifying the patient's risk profile and possibly leading to inaccurate risk estimation. By recording multiple inclusion events, we can independently assess the predictive value of different inclusion criteria, providing insight into which diagnostic codes or medications contribute most significantly to CVD or DM2 risk.

Because the event-based structure allows repeated observations per individual, inclusion events are not fully independent. To prevent biased estimation and optimistic performance due to within-patient correlation, all model development and evaluation procedures used train-test splits at the individual level, ensuring

XSL•FO
RenderX

that no patient contributed inclusion events to both the training and test sets. To further test robustness to this design choice, we conducted sensitivity analyses using alternative dataset constructions in which only a single inclusion event per patient was retained (first or last inclusion event). These sensitivity analyses are described in the "Experiments section.

To ensure that our dataset only includes individuals at substantial risk of developing CVD or DM2, we excluded patients with a CVD or DM2 diagnosis that occurred prior to their first inclusion in the risk group. Furthermore, we considered these CVD and DM2 diagnoses as outcomes (events) that we aimed to predict per inclusion event. The following ICPC codes were used:

1. T90: diabetes mellitus (DM2)
2. K47: angina pectoris (CVD)
3. K75: myocardial infarction (CVD)
4. K76: other ischemic diseases (CVD)
5. K89: transient ischemic attack (CVD)
6. K90: cerebral infarction (CVD)
7. K92.01: peripheral artery disease (CVD)

Cardiovascular mortality was deliberately not included as a separate outcome in this study because the primary objective of our modeling framework is to support early, clinically actionable prevention rather than late-stage fatality prediction. From a preventive care perspective, the most meaningful target is the first occurrence of nonfatal CVD, as this represents the stage at which risk-modifying interventions can still meaningfully alter the disease trajectory. For the same reason, we also do not include heart failure as an outcome. To reduce the influence of competing mortality during follow-up, cohort inclusion was restricted to individuals aged ≤70 years at entry.

Biomedical Determinants

Biomedical data were extracted from the electronic health records of the GPs and supplemented by secondary care data.

1. Height in cm and weight in kg, from which BMI can be derived. Obesity (BMI ≥30 kg/m²) is one of the strongest predictors of both DM2 and CVD, with extensive evidence linking excess weight to insulin resistance, hypertension, and dyslipidemia.
2. Hemoglobin A_{1c} in percentage: a marker of long-term blood glucose control. It has been shown to increase the risk of CVD at higher levels.
3. Blood glucose level in mmol/L: used to diagnose impaired fasting glucose and diabetes, as sustained hyperglycemia is a key indicator of insulin dysfunction.
4. Low-density lipoprotein (LDL) cholesterol in mmol/L: often referred to as "bad cholesterol," high LDL levels (>3 mmol/L) are associated with increased CVD risk.
5. High-density lipoprotein (HDL) cholesterol in mmol/L: the "good cholesterol" that has a protective effect against CVD. Low HDL levels (<1 mmol/L in men and <1.2 mmol/L in women) are associated with a higher cardiovascular risk.
6. Triglycerides in mmol/L: elevated triglyceride levels (>1.7 mmol/L) are closely associated with metabolic syndrome, diabetes, and increased cardiovascular risk.
7. Total cholesterol level in mmol/L: a composite measure of LDL, HDL, and triglycerides, often used in CVD risk calculations.

For each inclusion event, we extracted the most recent laboratory values prior to that event, ensuring the dataset reflects the patient's state at inclusion. Additionally, we captured the maximum historical value of each measurement before the study period to account for past extremes (eg, spikes in glucose or LDL) that may indicate long-term risk. We supplemented these GP-based laboratory values with hospital records from 2 ELAN-affiliated hospitals, located within ELAN's operating area. Measurements from primary and secondary care were stored in separate columns, allowing models to adjust for potential biases between care-setting sources.

These laboratory values, combined with inclusion codes and dates, form the core of our biomedical dataset. However, since ELAN data are only available from the point of registration, individuals may have met the inclusion criteria before any records exist. Additionally, switching GPs can lead to batch data entries, creating nonexisting clustering of events.

CBS Data

In this paper, results are based on calculations by LUMC in project number 9002 using nonpublic microdata from CBS. The linkage of microdata from CBS enabled access to national demographic information, mortality data, insurance records on prescription medications, and SDOH. These datasets include a wide range of indicators such as personal characteristics, household structure, socioeconomic position, and mortality records. Incorporating these variables allowed for a more comprehensive analysis of how medical and social factors jointly influence the progression to CVD or DM2. Specifically, we included variables such as the country of birth of the individual and their parents, migration generation, primary and spendable income, and household head, as well as household size and number of children.

Outcomes SCORE2 and Cardiovascular Risk Models

The SCORE2 risk prediction algorithms were developed with the objective of estimating 10-year fatal and nonfatal risk of CVD in individuals without a prior diagnosis of CVD or DM2 [28]. Within SCORE2, key risk factors for CVD were recorded at the point of study inclusion, including age, sex, smoking status, blood pressure, and cholesterol. Although SCORE2 is primarily designed for cardiovascular risk assessment rather than for more comprehensive profiling, its models and outputs have been incorporated into broader cardiometabolic research, for example, by serving as input features in models applied to MetS patient populations [33-35].

SCORE2, like traditional CPH models, assumes a linear relationship between predictor variables and the log-hazard of CVD risk. This means that each risk factor is expected to have a fixed and proportional effect on the outcome, which can oversimplify complex nonlinear interactions between variables, if present. For example, the effect that income has on CVD risk may reach a maximum at a certain value, meaning risk does not increase beyond a certain (high) income threshold, indicating a strong nonlinear relationship that these models are not able

XSL•FO
RenderX

to handle well. Similarly, the impact of education on CVD risk could vary depending on factors such as access to health care or dietary habits, which also introduce nonlinearity in risk prediction. ML approaches offer a promising alternative by being able to detect such nonlinear interactions and relationships.

ML for Survival (XGBoost)

Among the various ML methods used in survival analysis research, tree-based ensemble models have been shown to be particularly effective, especially in settings with complex, high-dimensional predictor spaces [36]. One prominent class of such methods is gradient boosting, which concerns first fitting a weak classifier to the data at hand and then continuously fitting new classifiers with the goal of reducing the loss of the previous classifier as much as possible. This is done via the use of a technique called gradient descent, which is used iteratively to find the next step that minimizes the outcome of a certain function, in this case, the loss function that corresponds to the model error.

One of the most well-regarded implementations of gradient boosting is XGBoost [37], which has been widely adopted across various ML tasks, including disease progression modeling [38,39]. In XGBoost, every classifier along the way is a type of decision tree, for which features from the data are chosen based on a greedy approach where a split is made that reduces the error the most. This approach to feature selection, combined with regularization techniques to prevent overfitting and parallelization at the node level to enhance performance, makes XGBoost highly efficient and accurate.

XGBoost also ranks feature importance based on gain, coverage, and frequency metrics, allowing researchers to identify the most influential predictors. This can be used to quantify the difference in importance between biomedical risk factors and SDOH in determining the risk of disease progression.

For survival analysis, XGBoost can be extended by incorporating loss functions adapted to time-to-event data. These include the CPH loss function, which allows XGBoost to estimate hazard ratios similarly to Cox models, and the accelerated failure time loss function, which models survival time directly. Using these adaptations, XGBoost can handle censored data efficiently, particularly in high-dimensional, complex datasets where interactions between medical factors play a crucial role.

In addition to XGBoost, we evaluated random forest models as a complementary tree-based ML approach. Random forests construct ensembles of decision trees using bootstrap aggregation and random feature selection, providing a nonparametric baseline that captures nonlinear effects without relying on further boosting [40]. Including random forest allows us to assess whether observed performance differences compared to other models can be attributed to the boosting framework rather than to general tree-based modeling. Random forest results are therefore reported as a comparative baseline rather than a primary modeling approach.

Experiments

Overview of Experiments

To systematically assess the predictive value of SDOH in disease progression to CVD or DM2, we conducted four linked prediction experiments:

1. 10-year CVD risk prediction: the first experiment served as a benchmark, focusing on the prediction of 10-year CVD risk. We compared 3 modeling approaches: the SCORE2 algorithm, a CPH model, and our random forest and XGBoost models.
2. Overall event prediction (CVD or DM2): in the second experiment, we applied CPH and XGBoost to a broader prediction task that involves predicting CVD or DM2 without a fixed time frame. This allowed us to evaluate the general risk of progression to CVD or DM2 and helped determine which model is most suitable for subsequent analyses, as we used the best-performing model in the remainder of our experiments.
3. Time-bound prediction tasks (5-year and 10-year): in the third experiment, to reflect practical clinical decision-making, we assessed predictive performance in fixed-time binary classification settings. Here, the outcome is defined as the occurrence of CVD or DM2 within 5 or 10 years after entry into the cohort. These experiments allowed us to evaluate how our prediction models perform across different time windows. From this experiment, we chose a clinically relevant model for use in the next experiment to evaluate the added value of SDOH.
4. Contribution of SDOH: finally, we explicitly investigated the impact of SDOH. We trained and evaluated a clinically relevant model from the third experiment on three distinct feature sets: (1) medical predictors only, (2) social predictors only, and (3) the top 10 medical and social predictors. This design enabled us to quantify the added value of social variables in predicting disease progression.

Together, these experiments provided a framework for understanding the predictive utility of SDOH in both survival-based and fixed-time risk prediction settings. In the next section, we will go over how we implemented and tested our models on our dataset.

Model Implementation and Evaluation

To carry out our experiments, we implemented 4 types of models: the SCORE2 risk algorithm, a CPH model, random forest, and the XGBoost ML model. This section elaborates on how each model was adapted and applied within our experimental framework.

All trainable models in this study were developed using a random split at the individual level, where 80% of the individuals in the dataset were used for training and the remaining 20% were reserved for model evaluation. Since our dataset is based on inclusion events, where each individual can have multiple events, splitting on the row level could result in data from the same person appearing in both the training and test sets. This would violate the assumption of independence between training and test data and could lead to overly optimistic performance estimates, as the model may effectively be “tested”

XSL•FO
RenderX

on patterns it has already seen during training. This approach enhanced the generalizability and validity of our model evaluation and ensured that performance metrics more accurately reflect how well the model would perform on unseen individuals in practice. To ensure consistency between experiments, the same train-test split was applied across all models and prediction tasks.

In addition, we performed sensitivity analyses using a single-event-per-patient dataset (first and last inclusion event). These analyses were used to assess whether predictive performance was driven by repeated observations per individual rather than by model overfitting and are reported in the "Results" section. To distinguish dataset effects from model effects, we also performed cross-evaluation in which models trained on the multievent dataset were evaluated on single-event test sets and vice versa.

We applied the SCORE2 10-year CVD risk model in the first experiment using the medical variables available in our dataset. Where possible, the input variables were aligned with those required by SCORE2. Smoking status was not included because it was not consistently available in a structured form in ELAN. SCORE2 was therefore implemented using the subset of required predictors available in the dataset (age, sex, systolic blood pressure, total cholesterol, and HDL cholesterol). SCORE2 results should be interpreted as an approximate benchmark rather than a fully specified clinical implementation. For SCORE2, CVD events were defined according to the same criteria used throughout the study, ensuring consistency between experiments.

For the CPH model, we used a regularized Cox model with LASSO (L1) penalty, implemented via the *glmnet* package in R. The L1 penalty enabled feature selection, which was especially valuable given the high-dimensional nature of our dataset. The model was trained on our dataset with survival data, with time-to-event recorded in days and event status coded as 1 (event) or 0 (censored). Ten-fold cross-validation within the training set was used to select the optimal penalty parameter λ based on model deviance. Because *glmnet* does not support clustered variance estimation, we refit the final Cox model using the *coxph* function (*survival* package) and apply a patient-level clustering term to obtain more robust SEs that account for within-patient correlation arising from repeated inclusion events. For time-specific risk estimation (eg, 10-year CVD risk), we derived individual survival probabilities from the refit *coxph* model using the estimated baseline survival function and the individual linear predictor. Specifically, the baseline survival curve was obtained from the training data using *survfit*, and the predicted 10-year risk was computed as $1 - S(t|x)$ at t=10 years. These risk estimates were then used for the area under the receiver operating characteristic curve (AUC) evaluation. Separate models were trained for each prediction task, and model performance was evaluated on the common test set. For comparability across modeling frameworks, survival models were evaluated using AUC on the corresponding binary event end points by converting predicted survival probabilities to fixed-horizon event risks.

Random forest models were included as a comparative tree-based ensemble baseline. They were implemented using the *ranger* package in R and trained using the same feature sets and the same individual-level train-test split as the other models. Model performance was evaluated using the same discrimination metrics on the held-out test set.

XGBoost was implemented using the *xgboost* package in R. For time-to-event prediction tasks, we used the accelerated failure time survival objective with a log-logistic distribution. For binary classification tasks, such as overall event prediction and 5-year or 10-year disease onset, we used the "binary:logistic" objective. Hyperparameter tuning was performed using random search over the predefined grid shown in Table 1, combined with 10-fold cross-validation within the training set. For each sampled hyperparameter configuration, models were trained for up to 2000 boosting rounds while monitoring cross-validated performance at each iteration. Early stopping was applied such that training was terminated if AUC did not improve for 50 consecutive rounds. The optimal number of boosting rounds was selected based on the best cross-validated performance, after which a final model was trained on the full training set using the selected hyperparameters and number of rounds, again using early stopping rounds on a validation subset of the training set (20%). After training, the model is evaluated on the held-out test set.

For both CPH and XGBoost, input feature matrices were constructed using one-hot encoding for categorical variables. For variables with many categories (eg, country of birth and income bracket), only the 10 most frequent categories were one-hot encoded, and the remaining categories were grouped into an "other" category to reduce sparsity.

Missing values were handled as follows. For time-related variables, such as days since a measurement or diagnosis, missing values were imputed with zero under the assumption that missingness reflects the absence of a prior event or that no measurement had been recorded. For continuous variables such as laboratory values, missing entries were imputed using the median of the respective variable to reduce the influence of outliers while preserving representative values. For categorical variables, we imputed a dedicated "Missing" category. Because missingness in routine care data may itself carry predictive information, we additionally included binary missingness indicators for each variable. This allowed models to learn whether the presence or absence of a measurement (eg, a laboratory test) was informative, rather than forcing missing values to be treated as purely random noise. The imputation and indicator strategy was applied consistently across modeling frameworks to ensure comparability of feature matrices. In addition, tree-based models such as XGBoost can natively handle missing values by learning a default split direction for missing observations at each node, reducing reliance on complex imputation. We nevertheless applied a consistent imputation strategy across models to ensure comparability across modeling frameworks.

In addition, implementing multiple imputation by chained equations is computationally challenging in high-dimensional settings such as ours (>550 predictors, mixed variable types, and ~58,000 inclusion events). In preliminary attempts, multiple imputation by chained equations did not complete reliably due to memory and runtime constraints when including the full predictor set. Developing and validating a scalable multiple imputation pipeline for this linked dataset, including appropriate sensitivity analyses for nonrandom missingness, was outside the scope of this prediction-focused study. For transparency, we report the extent of missingness per variable group in Multimedia Appendix 1.

Model performance was evaluated primarily using the AUC metric, with 95% CIs provided. All metrics were computed using standard packages in R, including *survival*, *glmnet*, and *pROC*. In the second experiment, we determined via AUC which model performs best on the task of event prediction and then used the respective model in further experiments to quantify the added value of SDOH in the task of disease progression in risk patients.

To enhance the interpretability of the final ML models, we applied Shapley additive explanations (SHAP) to the selected models in the third experiment and beyond. SHAP values provide additive, locally accurate explanations that quantify both the direction and magnitude of each predictor's contribution to an individual prediction [41]. For global feature importance, we summarized SHAP values using the mean absolute SHAP value per predictor across a held-out evaluation set. This metric reflects the average magnitude of a feature's contribution to the model output, irrespective of direction, and enables a stable ranking of influential predictors. To support interpretability beyond ranking alone, we used a beeswarm plot to additionally examine the sign and distribution of SHAP values for key predictors in order to assess whether respective higher values were associated with increased or decreased predicted risk. To quantify the contribution of SDOH, SHAP values were further aggregated across predefined variable groups (medical vs social predictors), supporting interpretation of how these domains jointly influence predicted CVD and DM2 disease progression.

Results

Participant Characteristics

Table 2 presents baseline characteristics of the study population, consisting of 58,627 records from 48,687 unique individuals, of whom 6592 (13.5%) experienced a DM2 or CVD event during follow-up. Women comprised 53% (25,687/48,687) of the overall cohort, with a significantly higher proportion in the nonevent group (22,634/42,095, 54%) compared to the event

XSL•FO
RenderX

group (2826/6592, 43%; *P*<.001). The mean age at inclusion was higher among individuals who experienced an event (59.68, SD 11.92 years) than among those who did not (53.55, SD 12.37 years; *P*<.001).

Age distributions also differed markedly between groups: individuals in the event group were more likely to be older, particularly aged 60 - 70 years (28.87% vs 21.44%) and 70 years and older (21.95% vs 10.64%), whereas younger individuals (aged 30 - 50 years) were more prevalent in the nonevent group. Among the most prevalent outcomes were codes T90 (25.02%), K75 (21.44%), and K89 (19.96%). The average time to event was 5.6 (SD 4.5) years across all outcomes.

Socioeconomic position differed significantly between groups. Individuals who experienced an event had lower household income indicators, including lower primary household income and lower standardized disposable income (both *P*<.001). Additionally, their households were smaller (mean household size 2.23, SD 1.12 vs 2.57, SD 1.64) and had fewer children (0.47, SD 0.88 vs 0.79, 1.08), with the children also being older at inclusion. These differences were all statistically significant (*P*<.001).

Biomedical profiles also differed substantially. Prior to inclusion, individuals in the event group had significantly worse metabolic profiles: higher mean hemoglobin A_{1c} levels (41.4, SD 9 vs 44.6, SD 12 mmol/mol), fasting glucose (6.30, SD 1.65 vs 5.83, SD 1.12 mmol/L), and triglycerides (1.92, SD 1.48 vs 1.68, SD 1.29 mmol/L), all with *P*<.001. LDL cholesterol levels were slightly lower in the event group, though the difference was small. BMI values showed only minor differences, with the most recent value slightly lower in the event group (30.1, SD 5.4 vs 30.3, SD 5.8 kg/m²; *P*=.07).

Overall, nearly all characteristics showed statistically significant differences between individuals who did and did not experience a CVD or DM2 event, highlighting the disparities between groups in socioeconomic, household, and clinical domains.

Experiment 1: 10-Year CVD Prediction

The SCORE2 model achieved an AUC of 0.704 (95% CI 0.697 - 0.711) on the full dataset and 0.697 (95% CI 0.680 - 0.713) on the test set. The CPH model showed a significantly better performance (*P*<.001), reaching an AUC of 0.718 (95% CI 0.702 - 0.733).

Among ML approaches, the binary random forest model achieved an AUC of 0.709 (95% CI 0.692 - 0.724), performing comparably to SCORE2 but below CPH. XGBoost achieved the highest performance, with the survival model achieving an AUC of 0.727 (95% CI 0.711 - 0.742) in the test set, statistically significantly outperforming the CPH model (*P*=.03). The binary XGBoost model achieved an AUC of 0.729 (95% CI 0.714 - 0.745), which was not statistically different from the XGBoost survival model (*P*=.39). These findings indicate that ML-based approaches, such as XGBoost, can significantly improve risk discrimination for 10-year CVD compared to both regression and rule-based baselines, and also outperform a nonboosted tree ensemble baseline.

For the binary XGBoost model, we report the random search hyperparameters that yielded the highest performance in the 10-year CVD event prediction task. The best-performing configuration used a maximum tree depth (*max_depth*) of 9, a learning rate (η) of 0.1, a subsample ratio of 0.7, a column subsample ratio per tree (*colsample_bytree*) of 0.7, a minimum child weight of 1, and regularization parameters set as follows: γ=1, λ=1, and α=1.

Experiment 2: Overall Event Prediction

The CPH model achieved an AUC of 0.704 (95% CI 0.691 - 0.717) in predicting time-to-event for the combined outcome of DM2 and CVD, illustrating its strength in handling censored survival data and modeling the temporal aspect of risk. The XGBoost survival model yielded a higher AUC of 0.715 (95% CI 0.701 - 0.728), significantly outperforming CPH (*P*<.001), indicating that the survival-based boosting framework was able to capture additional predictive signal in this high-dimensional dataset.

The random forest model achieved an AUC of 0.705 (95% CI 0.691 - 0.718), performing similarly to CPH (*P*=.81), but significantly below both XGBoost variants (both *P*<.001)

When reformulated as a binary classification task, predicting whether an event occurs at any point during the study period rather than modeling its timing, the XGBoost model significantly outperformed both survival models, achieving an AUC of 0.719 (95% CI 0.706 - 0.733), although the absolute difference between the XGBoost variants was modest. This highlights the advantage of boosted tree-based ML methods in high-dimensional, nonlinear feature spaces when the outcome is event occurrence, rather than precise event timing.

As our comparison focuses on the discriminative ability of our models, how well each model stratifies risk between those who do and do not experience an event, our findings illustrate that while CPH remains robust and interpretable for time-to-event analysis, binary XGBoost offers superior performance for overall event prediction in complex datasets. Based on this, we proceeded with the binary XGBoost model in subsequent experiments, including our analysis of the added value of SDOH. This model was trained using the best-performing hyperparameters identified in our earlier random search.

RenderX

Experiment 3: Time-Bound Prediction Tasks (5- and 10-Year Event Prediction)

The 5-year overall event model achieved an AUC of 0.738 (95% CI 0.721 - 0.755), significantly outperforming the 5-year CVD model (AUC 0.722, 95% CI 0.702 - 0.743), while the difference was with the 5-year DM2 model (AUC 0.786, 95% CI 0.758 - 0.814). The 5-year DM2 model performed significantly better than the CVD 5-year model.

For the 10-year window, the overall model achieved an AUC of 0.722 (95% CI 0.708 - 0.736), which is significantly lower than both the 10-year CVD model (AUC 0.729, 95% CI 0.714 - 0.745) and the 10-year DM2 model (AUC 0.760, 95% CI 0.735 - 0.785). The differences between the CVD and DM2 models could be explained by the wider definition of CVD, which constitutes 6 of the 7 total event ICPC.

Experiment 4: Contribution of SDOH

For the last set of experiments, we selected the 5-year overall binary XGBoost model to evaluate the added predictive value of biomedical risk factors versus SDOH. This model was chosen because it achieved strong performance and represents an interpretable and clinically relevant prediction task. To reduce multicollinearity and simplify interpretation, we tested a feature set excluding 2 highly correlated income variables (standardized disposable household income and gross household income) and replacing floored age with a single continuous age feature (days since date of birth). This reduced set slightly improved performance in the 5-year overall event model (AUC 0.734 vs 0.739; P=.02), with minimal effects on other models. We therefore adopted this reduced set for our main SDOH analysis.

Table 3 presents the predictive performance of models trained on different subsets of features to evaluate the added value of SDOH. The combined 5-year binary model from the previous experiment achieved an AUC of 0.738 (95% CI 0.721 - 0.755). The model using only biomedical risk factors performed slightly lower, with an AUC of 0.728 (95% CI 0.711 - 0.746), although the difference was statistically significant (P=.01), indicating that the inclusion of social determinants provides incremental improvement in the task of predicting disease onset in patients with elevated risk.

In contrast, the model trained exclusively on social determinants achieved an AUC of 0.691 (95% CI 0.683 - 0.709), significantly lower than the medical-only model (P<.001), but still showing a meaningful predictive signal. A minimal baseline model containing only inclusion code and age performed worst, with an AUC of 0.659 (95% CI 0.641 - 0.678), and was significantly outperformed by all other models.

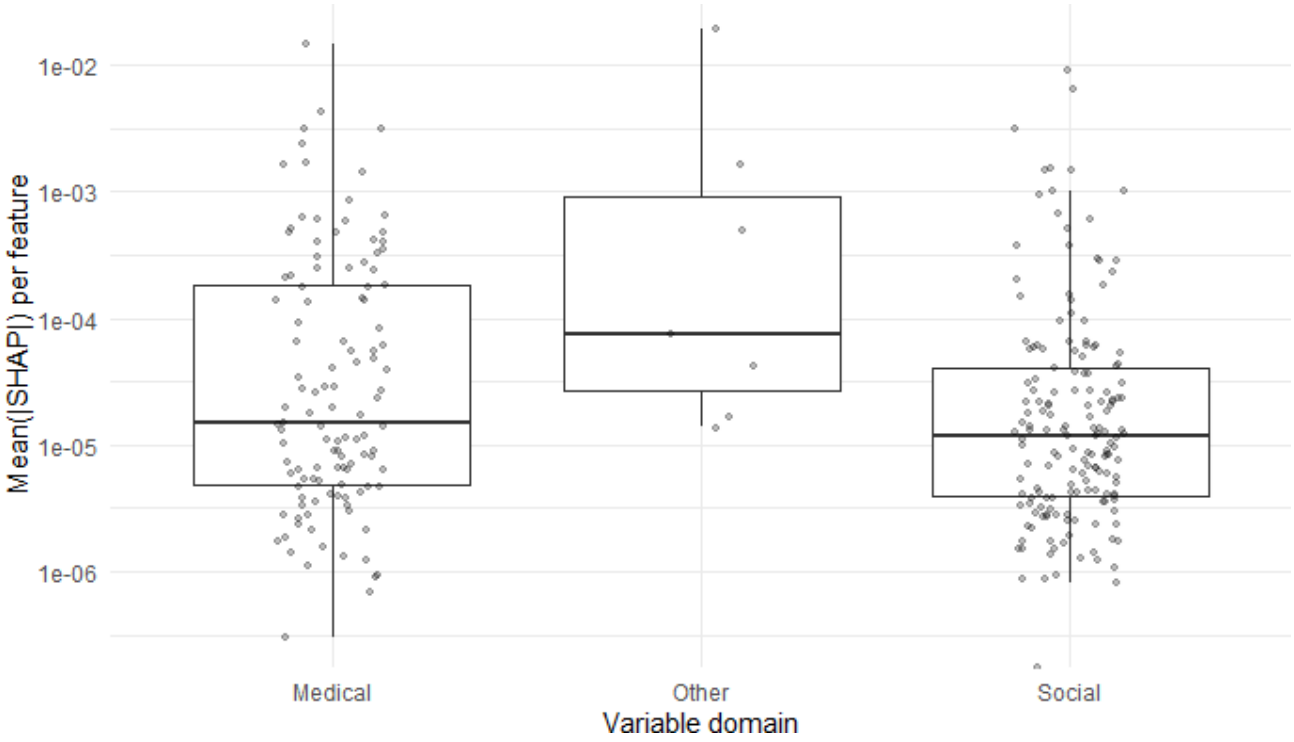
To explore the impact of the most informative features, we also evaluated models using only the top 10 medical and/or social predictors, determined by mean absolute SHAP values in the overall 5-year binary model. The top 10 biomedical risk factors alone achieved an AUC of 0.729 (95% CI 0.712 - 0.746), while the top 10 social determinants only reached 0.687 (95% CI 0.668 - 0.705).

Table . XGBoost[a] performance on different contexts relating to subsets of features.

XGBoost model	AUC[b] (95% CI)
Overall 5-year binary model	0.738 (0.721 - 0.755)
Only biomedical risk factors	0.728 (0.711 - 0.746)
Only SDOH[c]	0.691 (0.683 - 0.709)
Only inclusion code and age	0.659 (0.641 - 0.678)
Only the top 10 biomedical risk factors	0.729 (0.712 - 0.746)
Only the top 10 social determinants of health	0.687 (0.668 - 0.705)
Top 10 biomedical + top 10 social determinants combined	0.738 (0.721 - 0.755)

[a]XGBoost: Extreme Gradient Boosting.

[b]AUC: area under the receiver operating characteristic curve.



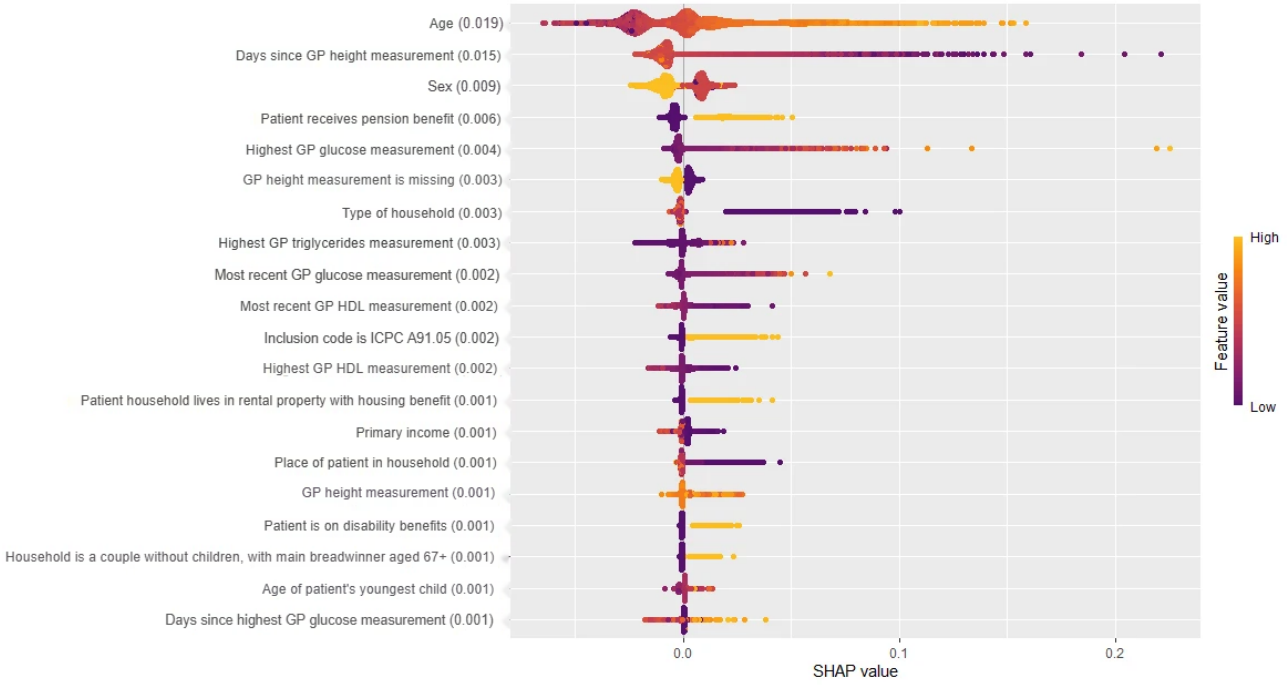
[c]SDOH: social determinants of health.

Notably, combining the top 10 biomedical and top 10 social predictors restored performance to the level of the full combined model. This finding suggests that the added predictive value of SDOH is not driven by a large number of weak social predictors, but can be captured by a small subset of highly informative social features that complement biomedical risk factors.

To further interpret the role of biomedical and social predictors in the final 5-year binary XGBoost model, we analyzed SHAP values at both the global and individual levels. First, we summarized feature contributions by computing the mean absolute SHAP value per predictor and aggregating these values across predefined feature groups (biomedical, SDOH, and baseline characteristics), which we visualized in a box plot in Figure 1 below.

XSL•FO
RenderX

Figure 1. Boxplot of feature importance by variable domain, showing spread in mean absolute Shapley additive explanations values of the predictors in the 5-year Extreme Gradient Boosting model. SHAP: Shapley additive explanations.



Biomedical predictors have substantially higher per-feature importance, with a higher median SHAP magnitude and a broader upper tail compared to SDOH. In contrast, SDOH features show lower average contributions per feature but still include a subset of variables with relatively large SHAP values, indicating that a small number of social predictors contribute meaningfully to risk discrimination. This pattern aligns with the model performance findings earlier in this experiment, where SDOH provided incremental predictive value when combined with biomedical determinants, despite being weaker as a stand-alone feature set. This is consistent with the observation that combining merely the top 10 biomedical and top 10 social predictors recovered the full model performance, suggesting that SDOH contribute primarily through a relatively small set of highly informative variables.

While the domain-level SHAP distributions summarize the relative contribution of biomedical and social predictors, they do not indicate which specific variables drive model predictions or whether their effects are associated with increased or decreased risk. To address this, Figure 2 presents a SHAP beeswarm plot of the top 20 predictors ranked by mean absolute SHAP value. Each point represents an inclusion event, with the SHAP value on the *x*-axis indicating the direction and magnitude of a feature's contribution to the predicted risk of CVD or DM2 disease progression. Point color reflects the feature value, with higher values shown in lighter colors.

XSL•FO
RenderX

Figure 2. Beeswarm plot of Shapley additive explanations values among the top 20 predictors with the highest mean absolute Shapley additive explanations value within the 5-year Extreme Gradient Boosting event prediction model. The respective mean absolute Shapley additive explanations values are denoted in parentheses. GP: general practitioner; HDL: high-density lipoprotein; ICPC: International Classification of Primary Care; SHAP: Shapley additive explanations.

Age is the most influential predictor, with higher age consistently associated with increased predicted risk. Sex also contributed meaningfully, with male sex generally shifting predictions toward higher risk.

Several features related to clinical measurement patterns emerged as influential. In particular, lower values of "days since GP height measurement" were associated with increased predicted risk, suggesting that more recent clinical measurement activity coincided with higher risk profiles. Consistent with this, a missingness indicator for height measurement also contributed to predictions, indicating that the presence or absence of routine measurements carried predictive signal beyond the measured value itself.

Multiple socioeconomic and household-level variables appeared among the most influential predictors. Receipt of pension benefits was associated with increased predicted risk, likely reflecting its strong correlation with older age and retirement status. Housing-related variables also showed clear patterns: living in rental housing with housing benefit was associated with higher predicted risk, consistent with socioeconomic disadvantage. Similarly, disability benefit status shifted predictions toward higher risk, suggesting that disability and work limitations capture an additional vulnerability signal not fully explained by biomedical measurements alone.

Finally, household composition variables contributed to risk prediction in a more heterogeneous way. The categorical "type of household" feature showed a distinct pattern in which the "unknown" category was associated with increased risk in combination with other predictors. The other household types did not exhibit much predictive power, further highlighting the importance of this type. This suggests that missing or unclassified household registration may itself act as a proxy for instability or unmeasured social complexity, which the model uses when estimating CVD and DM2 risk.

Together, these patterns reinforce the findings described above that the added value of SDOH is driven primarily by a limited set of informative social variables that complement biomedical variables, rather than by meaningful contributions across a large number of weak predictors.

Sensitivity Analysis: Single-Event Versus Multievent Dataset Construction

To assess whether the multievent dataset structure influenced predictive performance through within-patient dependence, we conducted sensitivity analyses using alternative dataset constructions in which only a single inclusion event per patient was retained. Specifically, we evaluated XGBoost models trained on datasets containing either the first or last inclusion event per individual and compared their performance with the primary multievent model. The task at hand was 5-year event prediction.

Using a single inclusion event per patient, the XGBoost model trained on first inclusion events achieved an AUC of 0.746 (95% CI 0.727 - 0.764) for 5-year overall event prediction, while the model trained on last inclusion events achieved a slightly lower AUC of 0.735 (95% CI 0.717 - 0.753). This difference was not statistically significant (P=.41), indicating comparable discrimination between first- and last-event representations.

To further distinguish the effects of dataset structure from model behavior, we performed cross-evaluation analyses. When the model trained on first inclusion events was evaluated on the multievent test set, it achieved an AUC of 0.738, which was identical to the performance of the model trained and evaluated on the multievent dataset (AUC 0.738; P=.71). Furthermore,

XSL•FO
RenderX

when the model trained on the multievent dataset was evaluated on the first-event test set, it again achieved the same AUC as the first-event-trained model evaluated on that test set (both AUC 0.746; *P*=.99)

These findings indicate that observed differences in performance between single-event and multievent analyses are driven primarily by differences in test set composition rather than by model overfitting or inflation due to repeated observations per patient. Overall, model discrimination and comparative conclusions were stable across dataset constructions, supporting the robustness of the primary multievent modeling approach, which is maintained in the other experiments.

Discussion

Principal Results

This study demonstrates that adding SDOH on top of biomedical data significantly improves the prediction of disease progression to CVD and DM2. In our best-performing model, a binary XGBoost classifier predicting 5-year progression to either DM2 or CVD, several socioeconomic variables (including income and social benefit indicators) ranked among the top predictors, performing equally or outperforming traditional biomedical features such as laboratory values and diagnosis codes. Although models trained solely on social data underperformed compared to those using only biomedical data, the integration of both domains produced superior results, confirming the complementary value of SDOH, which we directly quantified using the XGBoost gain metric.

In the construction of our dataset, we used routine care data actively recorded by health care professionals within ELAN-affiliated practices and hospitals. This allowed us to define a clinically grounded high-risk cohort based on structured diagnosis and prescription records, reflecting how risk is typically identified in real-world primary care settings. We first compared the performance of SCORE2, CPH, and XGBoost models on the task of predicting 10-year progression to CVD. Although smoking status was unavailable, the model achieved performance comparable to the SCORE2 ELAN validation by Kist et al [17], supporting its use as a reference baseline.

Across experiments, we observed differences in performance between modeling frameworks. For overall event prediction, CPH, survival XGBoost, and binary XGBoost were all evaluated using AUC on the binary event end point. In this setting, survival XGBoost achieved slightly higher discrimination than CPH, while binary XGBoost achieved the highest AUC overall. This suggests that, in this high-dimensional dataset, boosted tree models can capture predictive signal beyond proportional hazards regression for clinically actionable risk stratification. Random forest provided a competitive tree-based baseline but did not match the performance of boosted trees, indicating that the observed gains were not solely attributable to nonlinear modeling but also to the sequential boosting framework.

The added value of SDOH was further supported by SHAP-based interpretability analyses. Biomedical predictors showed higher average contribution on a per-feature basis, but a subset of social predictors consistently ranked among the most influential features in the full model. Notably, combining only the top 10 biomedical and top 10 social predictors recovered the full model performance, suggesting that the predictive contribution of SDOH is driven primarily by a limited number of highly informative social variables rather than diffuse contributions across many weak predictors. Together, these findings support the inclusion of SDOH in modeling CVD and DM2 risk and suggest that a compact set of social and biomedical indicators may be sufficient to achieve strong discrimination in routine-care prediction settings.

Comparison With Prior Work

Our findings align with growing evidence that integrating SDOH significantly enhances the prediction of CVD and DM2 outcomes. Prior studies, such as those by Xia et al [42] and Cooper et al [43], have demonstrated improved model performance when including socioeconomic or area-level indicators. However, many of these studies used smaller, survey-based cohorts or relied on aggregated SDOH data, such as area-level income or education, which limits precision and generalizability.

More recent studies using larger datasets and advanced ML methods further underscore the added predictive value of SDOH. For example, Teshale et al [44] incorporated self-reported SDOH alongside traditional clinical risk factors in ML and deep learning models trained on a cohort of over 12,000 older adults (aged ≥70 years) from Australia and the United States. Their findings showed that SDOH, such as social network, living situation, and education, were as predictive as, or more predictive than, clinical variables, particularly among women. Similarly, Howell et al [45] demonstrated that including self-reported SDOH modestly improved the predictive performance of diabetes risk models in a cohort of nearly 10,000 American adults aged 45 years and older, all without DM2 at baseline. Socioeconomic and behavioral variables such as health insurance status, income, and health literacy contributed meaningful information. Our study differs in scale from these studies, with a larger dataset, but also in the use of objectively registered SDOH, rather than self-reported, enhancing data reliability and creating a more comprehensive view of the added value of SDOH in estimating the risk of developing CVD and DM2.

Segar et al [46] also showed that SDOH can enhance prediction in large-scale clinical settings. In their study, which used a large training set of 123,000 American patients with heart failure, incorporating SDOH data into ML models significantly improved the prediction of in-hospital mortality. However, again, this study, like many others, relied on aggregated, area-based social measures rather than individual-level data.

A recent non-Western example is the study by Hu et al [47], which used ML to predict DM2 incidence among over 26,000 adults from Fujian province in China. Their model, based on a feature set of 18 self-reported variables, including age, BMI, education, income, marital status, smoking status, and self-rated health, achieved an AUC value of 0.723. The study found that SDOH, such as rural residence, low income, and low education levels, were strongly associated with increased risk of

XSL•FO
RenderX

developing DM2, underscoring the relevance of social factors beyond Western health care contexts.

It is important to note that most of the existing studies were conducted in the United States, where the health care system differs substantially from that of the Netherlands in terms of access, financing, and the role of socioeconomic factors. The Dutch health care system offers universal coverage and more standardized access to primary care, potentially altering how social determinants affect health outcomes. Nevertheless, European research supports the broader relevance of SDOH even within universal care systems. For example, analysis of data from the Survey of Health Ageing and Retirement in Europe study (~14,000 participants aged 50 - 75 years in Belgium and France) showed that socioeconomic conditions, including education and social network measures, independently predicted mortality and major cardiovascular events [48]. These findings reinforce the idea that SDOH remain important predictors even when basic health care access is guaranteed, a conclusion that is consistent with the results of this study.

We further distinguish our approach by comparing multiple predictive models, including ML (XGBoost) techniques, trained with and without SDOH. This systematic comparison allows us to directly quantify the added value of social data beyond medical predictors alone, a dimension that is often overlooked or only partially explored in prior research.

Moreover, by applying SHAP in the third experiment and beyond, we provide interpretable insights into both global and individual-level contributions of biomedical and social predictors. We furthermore show directionality and domain-level aggregation plots, creating a basis for further research and clinical prioritization.

Strengths and Limitations

This study benefits from several methodological and data-related strengths. Most notably, we constructed a large, real-world dataset comprising more than 58,000 inclusion events from nearly 49,000 individuals. By linking primary care, secondary care, and CBS data at the individual level, we were able to include a wide range of SDOH, such as gross and disposable income, household structure, and migration background. Crucially, unlike previous studies that rely on self-reported (social) data, our social variables are drawn from mandatory national registries, including municipal population databases that include all legal Dutch residents. This eliminates self-report bias, improves completeness, and allows for consistency over time through annually updated information, independent of survey timing or participant response, achieving a level of precision and coverage not previously demonstrated in related literature.

By comparing models trained with and without SDOH, we provide both robust predictive performance and interpretable insights into the relative contribution of biomedical and social factors. The inclusion event-based design ensures alignment with actual clinical decision points, reinforcing the practical utility of our predictive models.

The scale and objectivity of our data allow for a comprehensive and nuanced quantification of the individual contribution of social factors in predicting CVD and DM2 outcomes. Moreover, the breadth of SDOH included in our study, many of which are unavailable or sparsely measured in prior studies, allows for more comprehensive modeling of social conditions affecting CVD and DM2 risk than prior studies that do not make use of such an extensive feature set. The broader coverage helps to isolate unique effects of individual social factors, improves the accuracy in selecting the most relevant predictors, and provides a stronger foundation for investigating potential causal relationships in future research.

A further key strength of our study lies in its clinically grounded definition of CVD and DM2 risk. In consultation with clinical experts, we identified high-risk individuals using structured diagnostic records, closely mirroring real-world identification in primary care. While this approach may limit strict comparability to studies based solely on metabolic syndrome criteria, it enhances practical relevance and replicability across real-world health care settings.

Despite these strengths, several limitations should be acknowledged to contextualize the findings of this study. For example, in the construction of our dataset, we were limited to routine care data that were actively recorded by health care professionals within ELAN-affiliated practices and hospitals. This means that we only have information from points in time when patients interact with the health care system, for example, through GP visits or hospital consultations. As a result, we lack visibility into the health of patients during periods when they do not interact with the health care system. This introduces a substantial systematic bias toward people who are more likely to seek care and have risk factors recorded. Furthermore, since our dataset is structured around inclusion events rather than unique individuals, patients with higher health care involvement can contribute multiple entries to training data. This may further amplify the bias by overrepresenting those who have more frequent interactions, skewing model learning toward more medically active subpopulations, and possibly leaning toward more severe cases. We tried to mitigate potential data leakage by not allowing the same patients to appear in both the training and test sets; however, this does not fully address the bias introduced by the overrepresentation of highly engaged patients. This bias can have several important implications. First, it may lead to an underrepresentation of people who have difficulties accessing medical care, including those with a lower socioeconomic position. These same individuals may be at elevated risk due to unmeasured or unaddressed medical and social vulnerabilities. Moreover, these individuals may seek care only when conditions become more severe, meaning the available data on these patients may disproportionately reflect more advanced disease stages.

On the other hand, patients who frequently interact with the health care system may appear to have more complete risk profiles, potentially increasing the predictive power of features such as laboratory values or diagnosis codes that are only available when recorded. This could create overfitting to data patterns that may not generalize well to less engaged patient populations. Future research could help quantify and address this bias by comparing model performance across specific, clinically relevant patient subgroups.

XSL•FO
RenderX

This limitation demonstrates a larger challenge in retrospective clinical data research and is difficult to fully mitigate. Addressing it would require more continuous population-based data collection, such as through wearable devices or patient-reported outcomes. When such data are not available, future work could explore model performance across population subgroups, for example, stratified by ethnicity or practice location, to better understand disparities in prediction performance among different populations. However, in this study, we show that it is feasible to determine the risk of disease progression when evaluating inclusion events.

Cardiovascular mortality was deliberately not included as a separate outcome in this study because the primary objective of our modeling framework is to support early, clinically actionable prevention rather than late-stage fatality prediction. We acknowledge, however, that death occurring before a recorded CVD diagnosis represents a competing event that may prevent observation of the nonfatal outcomes studied here. Cause-specific cardiovascular mortality was not modeled separately, and competing-risk modeling was outside the scope of the current work. To reduce the likelihood that mortality dominates follow-up and to maintain focus on prevention-relevant risk stratification, we restricted cohort inclusion to individuals aged ≤70 years at entry. Future work could extend this framework by incorporating mortality outcomes and competing-risk methods when appropriate linkage and outcome registration are available.

In addition, our SHAP analyses indicated that variables reflecting measurement patterns, especially the presence of a recorded height measurement and the number of days since the last height measurement, were among the most influential predictors. These features likely capture aspects of health care use and clinical monitoring intensity (eg, height being recorded as part of weight management or cardiometabolic screening) rather than solely reflecting underlying physiology. Consequently, the model may partly learn patterns of clinical attention (ie, who is monitored more closely) rather than only underlying disease risk. This could inflate predictive performance in routine-care data and reduce generalizability to individuals with fewer recorded measurements or less frequent health care contact.

Due to the large number of linked variables used in our analysis and our dataset, we are able to offer a comprehensive view of which social and biomedical risk factors are impactful in predicting the onset of CVD and DM2. However, despite this extensive scope, certain variables known to influence CVD and DM2 risk were not available. Most notably, we were unable to include smoking status, substance abuse, physical activity, and dietary habits, all of which are established lifestyle factors associated with CVD and DM2. These factors are typically not captured in ELAN routine care data in a structured format, and unstructured data were also unavailable for this study. Although our models compensate for some of the missing factors through related variables, such as income as a potential (although shallow) indicator of socioeconomic position, the absence of these factors might harm the predictive accuracy of the models. Future research could aim to integrate lifestyle and behavioral data, that is, through free-text clinical notes [49], to further enhance model performance and understanding of CVD and DM2 risk. Nevertheless, our models achieved robust predictive performance comparable to or exceeding that reported in existing literature, even without direct lifestyle and behavioral data.

An additional consideration is that several high-ranking SDOH variables are inherently correlated with age and life stage. For example, receipt of pension benefits, household indicators related to retirement age, and the age of children are strongly age-dependent and may partly reflect the dominant role of age in CVD and DM2 risk prediction. However, other influential SDOH features, such as disability benefits and housing-related indicators (eg, rental housing and housing benefit), are less directly tied to age and likely capture complementary vulnerability signals.

We compared both survival-based and binary modeling formulations. In our experiments, survival XGBoost achieved discrimination comparable to, and slightly higher than, CPH when evaluated on a common binary event end point, but absolute performance differences between survival and binary formulations were modest. This suggests that, in high-dimensional routine-care data, direct optimization of binary event prediction may be advantageous for fixed-horizon clinical risk stratification, even when time-to-event information is available.

Importantly, although CPH and survival XGBoost were trained using time-to-event objectives, our primary evaluation focused on discrimination for clinically actionable binary end points (eg, event occurrence within 5 or 10 years), rather than survival-specific metrics such as time-dependent AUC or concordance. As a result, the reported AUC values reflect performance for fixed-horizon risk stratification and may not fully capture the potential advantages of survival models for modeling event timing. Future work could evaluate survival models using survival-specific metrics and calibration at clinically relevant time horizons.

At the same time, this study should be interpreted as a model development and internal validation study within a single regional health care infrastructure. Although our evaluation was performed out of sample within this setting and patient-level splitting prevents direct leakage, model performance and calibration may not fully generalize to other regions or health care systems with different population characteristics, care pathways, coding practices, or availability of SDOH variables. Importantly, comparable datasets with similarly extensive linked SDOH are currently uncommon, which makes immediate external validation challenging. Nevertheless, external validation and recalibration in independent cohorts remain essential steps before clinical deployment.

Clinical Implications

While our dataset contains a presenting bias, data being available only when patients interact with the health care system, this limitation is also a key opportunity for clinical application. Predictive models like the ones developed in this study are most useful at moments when patients present themselves. By making use of routinely collected data from primary care and hospitals,

XSL•FO
RenderX

enriched with SDOH, our models can assist health care providers in identifying patients at elevated risk for CVD and DM2 disease progression in real time.

Such models could support primary care workflows, where time constraints limit comprehensive risk assessment, if externally validated. Here, a risk prediction tool integrated into electronic health record systems could flag high-risk individuals at the point of care, possibly enabling earlier interventions. Notably, the added value of SDOH, measured via the clinically interpretable SHAP method, supports the idea that socially vulnerable individuals may benefit from more tailored approaches. By capturing these signals, predictive models can also help clinicians identify patients who may not present with abnormal laboratory values but who are nonetheless at elevated long-term risk. Given that our approach was rooted in real-world clinical data and is scalable to similar infrastructures, it provides a foundation for integrating these predictive analytics into routine care, contributing to more data-informed health care.

However, the integration of SDOH into existing clinical systems remains a practical challenge. Many health care systems do not currently capture detailed social data in a structured or standardized format, and the inclusion of such data may require changes in infrastructure and an ethical discussion. For this reason, biomedical-only models, like the one evaluated in this study, can still offer meaningful improvements over existing practices and may serve as an intermediate or fallback solution when SDOH data are unavailable. Although these models perform slightly worse than combined models, they remain clinically valuable and are more readily implementable in most care settings. Future research could explore how such models can be validated and implemented, including pilot implementations and usability studies with clinicians.

Conclusions

This study demonstrates the added value of incorporating SDOH into predictive models for progression to CVD or DM2. Using a clinically grounded, high-risk cohort identified through structured diagnosis records in ELAN-affiliated practices and linking these to individual-level sociodemographic data from CBS, we created a uniquely comprehensive dataset to examine the interplay between medical and social risk factors. While biomedical features remained dominant predictors, social characteristics substantially enhanced model performance when combined with clinical data, underscoring their value as complementary signals in personalized risk prediction.

Using XGBoost in a high-dimensional setting enabled robust prediction across hundreds of linked predictors, while SHAP-based interpretability analyses provided transparent insight into the relative contribution of biomedical and social factors. Notably, the combined predictive value of SDOH was largely captured by a limited subset of highly informative social variables, as reflected by the strong performance of models trained on the top-ranked medical and social predictors.

Although the integration of SDOH into clinical practice remains logistically challenging due to infrastructure and data standardization and ethical issues, our findings suggest that predictive models using routine biomedical data alone still provide meaningful insights and could serve as an effective starting point for implementation. Altogether, our study highlights the potential of socially informed risk models to support personalized prevention strategies and more equitable care, and offers a replicable framework for future applications in real-world clinical settings.

Abstract

Background: Irregularly sampled data, as a common data structure in the medical field, is frequently observed in emergency clinical datasets. It poses problems such as unequal sampling time intervals and frequencies, making it difficult to align the data without losing information for input into models. Meanwhile, due to information loss in the dataset, it is also difficult for the model to effectively analyze the overall data variation and predict the complex and dynamic conditions of emergency patients in the future.

Objective: This study aimed to address the impact of issues such as missing values and irregularly sampled time intervals on prediction results. This paper proposes a method that converts time-series data into a graph network structure and develops a prediction model for graph data to better support complex tasks.

Methods: In this paper, feature channels and measurement times in time-series data are constructed as nodes, and feature measurements at time points are constructed as edge weights. The point feature space and edge weight space are extracted by a graph convolutional neural network and a gated convolutional attention mechanism network, respectively, and feature fusion is carried out under the action of the learnable head.

Results: The proposed method was tested on 4 datasets and compared with both irregularly sampled time-series predictors and state-of-the-art methods for complete data. In addition, a dedicated analysis was conducted leveraging data from 5 key clinical treatment phases. In single-target classification and single-target regression tasks, the method proposed in this study outperforms other comparative methods in most experiments (accuracy=0.74 - 0.88, area under the curve=0.70 - 0.87, and mean absolute error=0.038 - 0.061). Meanwhile, this study constructs clinical phenotypes during patients' hospitalization as multitarget prediction tasks, and the proposed model also outperforms comparative methods in multitarget classification tasks (mean accuracy=0.75 - 0.91 and mean area under the curve=0.70 - 0.75). Ablation experiments verify the effectiveness of fusion between the node feature space and the edge feature space. The interpretability analysis of time points identifies key features that require focused attention for patients across different target tasks and time periods.

Conclusions: The proposed model can effectively analyze medical data with missing values and uneven sampling. It achieves high prediction accuracy in both regression prediction tasks and classification tasks. The graph network-based model structure endows the model with better interpretability, enabling effective exploration of factors that trigger changes.

Introduction

Irregularly sampled time-series data is a common data pattern in fields such as medicine, meteorology, and transportation. Due to issues such as unequal sampling time intervals and different sampling frequencies between different features, models often use a method of sampling data at certain time intervals to align the overall data queue and fix the time interval of the sequence during the analysis and prediction of irregularly sampled time-series data [1]. For missing values in data series, existing models often use adjacent values or mean values to fill in the gaps [2]. This will cause loss of fine-grained information in time-series data and also discard the time-scale information in time-series data, which will reduce the prediction accuracy of the model when predicting and analyzing complex multiobjective downstream tasks and make it difficult to handle different types of prediction tasks simultaneously. The model constructed in this way is often difficult to solve complex and changing prediction tasks faced in the real world, especially for time-series data analysis in the medical field, which requires models with high prediction accuracy. In the medical field, it is often necessary to perform complex multitask analysis on a large amount of feature data generated in a short period of time for emergency patients, providing information for clinicians to construct treatment plans from multiple dimensions [3]. By constructing targeted treatment plans based on multiple prediction results, the mortality rate of patients can be effectively reduced.

Retrospective studies on patients' time-series data in medicine have always been an important means to promote the development of basic medicine and explore changes in disease courses. Medical researchers can construct targeted treatment plans by discovering the changing patterns of characteristic data. The analysis methods for time-series data initially used statistical methods to analyze factor changes. With the proposal of machine learning and deep learning algorithms, researchers have built various artificial intelligence models for the classification and regression prediction of medical data [4-6]. However, due to the subjectivity of patients' willingness to go to the hospital in reality, the sampling time interval of medical time-series data is often uneven, and there are missing values at some time points. At the same time, such data characteristics will also make the model face the problem of uneven input data. In machine learning models, researchers use the method of temporal sampling to align the data. Missing values are processed by zero-value filling or adjacent-value filling. For example, Yoon et al [7] constructed a machine learning model for time-series data of hypotension in intensive care unit patients to explore the relationship between hypotension data and patient mortality. To address the issue of unequal sampling intervals, they aligned the overall data by performing mean sampling every 5 minutes. Delahanty et al [8] predicted the Sequential Organ Failure Assessment scores of patients to assess the onset time of sepsis. For missing data at certain time points, the authors filled in missing values using neighboring values. Wu et al [9] developed a machine learning model to classify the severity levels of chest pain in emergency patients. They used zero padding to handle missing values in the data. While this method introduces a significant amount of noise and homogenizes the original patient features, it allows the model to achieve reasonable accuracy for single-task applications. However, it struggles to maintain high predictive accuracy in multitask scenarios.

With the advancement of model construction methods and the introduction of deep learning algorithm frameworks, the increased flexibility in acceptable input structures has led to the development of various methods for handling missing values in medical time-series data. Lee et al [10] input each patient's time-series data through three channels: measurement type, measurement value, and measurement behavior. They used an attention mechanism network to fuse and extract overall features, which was applied to predict patient mortality. Bardak and Tan [11] used medical order text data generated from patient clinical treatments to extract features, which were then used to supplement missing values in patients to meet the data requirements for subsequent model training. Xu et al [12] constructed a graph network data structure by applying regular sampling to patient clinical time-series data to address the impact of missing values on model training. They ultimately extracted features and fitted downstream tasks using a gated mechanism and a graph attention network. A comparative analysis of the processing methods of various deep learning models shows different strategies for handling missing values. Encoding the data into a graph network structure improves interpretability and meets the needs of medical research while minimizing the impact of missing values on the model to the greatest extent.

Aiming at the above problems, this paper proposes a data construction method based on a graph network. The feature channels of clinical time-series data of each patient and the recording time points constitute nodes in the graph network. The feature vector of the patient's feature channel node is composed of the Kullback-Leibler (KL) divergence formed by data distribution in the feature channel, and the generated features are embedded into the feature correlation space for distribution. The patient's clinical time-series data is input into the model for training after passing the above rule-based diagram network transformation. In the model, the point weight and edge features are extracted from the corresponding space through the model respectively, and fused under the action of a learnable head. The fused features are matched with multiobjective tasks required in clinical practice through the decoder, and the loss function is constructed according to the classification task and the regression task, respectively.

Graph network data structure is a type of data structure that can simultaneously encode spatial information and temporal change information in time-series data, which is widely used in the field of traffic and weather prediction analysis. In the early stage of research, researchers mainly focused on node features and connection relationships for classification and prediction tasks. Lu et al [13] constructed a dual-attention mechanism based on node information in traffic flow data to adaptively predict situations where nodes in the graph network change with time and space simultaneously. Jin et al [14] constructed a set of spatio-temporal prediction model of a graph network for the change of particulate matter 2.5 and predicted the change of node characteristics with time through node clustering in graph

XSL•FO
RenderX

network. Sun et al [15] constructed the temperature of the ocean surface as the node feature in the graph network and constructed the transportation direction of ocean currents as the connection edge between nodes and used long short-term memory model to predict the changes of the sea surface temperature.

With the development of more model structures and computer computing power, researchers have added more information such as edge weights, edge connection directions, and point features to the graph network, which improves the final prediction accuracy of the model and can be adapted to more target downstream tasks. For example, Yin et al [16] constructed a dynamic graph network structure for traffic flow data and integrated the edge features and point features in the data into the model at the same time, so that the model could make correct predictions when the network structure changed and better fit the real changes. Feng et al [17] established the graph network of the data at each time point and also established the relationship graph network between different time points, which was used to use the delay data to guide the original data for prediction and analysis. He et al [18] proposed a multilevel fusion spatio-temporal analysis network, which fuses feature extraction from different dimensions in graph networks to adapt to downstream multiobjective tasks. Therefore, this paper uses the data structure of graph network to encode the medical clinical time-series data and makes full use of the point feature space and edge connection weights in the graph network structure to construct the features contained in the clinical time-series data. Based on the data structure of graph network, a time-series analysis and prediction model of multiobjective tasks is constructed to meet the clinical needs.

The data structure of a graph network can retain the fine-grained information and short-term feature change-in information in the patient time-series data to the greatest extent and will not bring additional noise information to the model. The construction of multiobjective tasks can enable the model to meet the needs of clinicians in the process of clinical practice, help doctors predict multidimensional changes in patients' conditions, and formulate treatment plans for patients. The innovation points proposed in this paper can be summarized as follows:

1. This paper proposes a method to transform medical clinical time-series data into a graph network structure, which preserves the fine-grained information in the data to the greatest extent while reducing the introduction of noise information. The model avoids the problem of missing values and unequal sampling intervals in medical time-series data.
2. This paper proposes a training model for a graph network composed of time-series data, which extracts feature vectors from point feature space and edge weight space, respectively, and fuses them under the action of a learnable head to fit downstream target tasks. Both the classification task and the regression task achieve high prediction accuracy.
3. By extracting feature weights at different time points, this paper provides an interpretable analysis of critical features influencing patient survival over time, thereby assisting clinicians in making targeted and informed decisions at each stage.

Methods

Overview

In this section, we will introduce the method of constructing a graph network data structure for time-series data proposed in this paper. In the constructed graph network data, the point features and edge weights are respectively extracted and fused to construct the overall features of the patient time-series graph network. Finally, we will introduce the classifier and the overall model training framework built for the downstream multiobjective task. The overall symbols are summarized in Table 1.

XSL•FO
RenderX

Table . Explanation of object names used in the calculation formula.

Symbols name	Definition
t	Measurement time
f	Measurement feature
v	Measurement value
Tm	Calculated time range
Fm	Calculated number of feature channels
Vm	Total number of measured behaviors
Pt	Time node
Pf	Feature node
Ew	Connection edge weight
Spf	Overall spatial feature set
Fbpf	Feature vector of a feature node
Spt	Overall spatial feature set
Fapt	Feature vector of a time feature node
Xf	Feature matrix of the nodes
Aw	Edge weight matrix
Fp	Overall feature of the node feature space
WE	Feature value matrix
WEF	Partially forgotten feature matrix
AE	Output of multihead attention mechanism layer
Fe	Feature obtained from the edge weight space
Ftotal	Final total features

Graph Network Construction

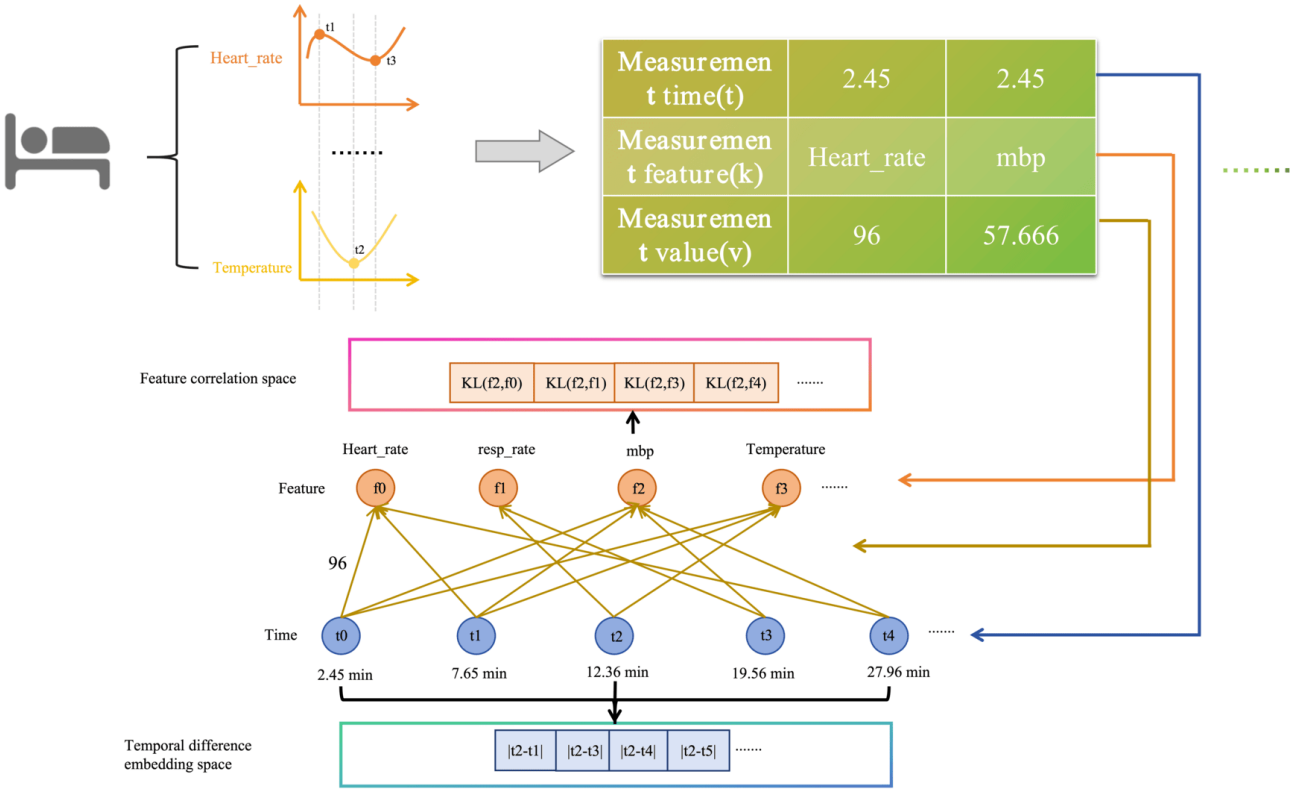
To retain the fine-grained information in the patient time-series data to the greatest extent and reduce the introduction of noise information, this paper constructs the clinical time-series data as a graph network structure to input into the model calculation. In the construction of the graph network data structure, the feature space of nodes is first constructed. By disassembling the clinical time-series data, it is found that each data measurement behavior can be divided into three dimensions: measurement time (*t*), measurement feature (*f*), and measurement value (*v*). Based on the calculated time range (T_m), the calculated number of feature channels (F_m), the total number of measured behaviors (V_m), and the overall time-series data of the patient can be expressed as {(t1,f1,v1),(t1,f2,v2),....(ta,fb,vc)}a≤Tm,b≤Fm,c≤Vm. Among them, the measurement time and the measurement feature constitute the time node (P_t) and the feature node (P_f) in the graph network data, respectively, and the measurement value is constructed as the connection edge weight (E_w) between the time node and the feature node. The feature space of the feature node (P_f) is mapped in the feature correlation space and composed of the KL divergence values calculated between the original data within the computational time range across the F_m feature channels of each patient. This study references multiple studies on feature space construction based on KL divergence [19,20]. The use of KL divergence to measure distributional differences between distinct physiological variables (eg, heart rate and temperature) may indeed appear counterintuitive from a clinical perspective. However, it is important to clarify that KL divergence is not used here to infer causal or biological relationships between different features. Instead, it serves as a similarity metric to construct the feature node embeddings in the graph network. Specifically, it quantifies the distributional alignment between different physiological time series within the same patient, which may reflect the degree of systemic physiological integration or dysregulation—a key characteristic of critical illness progression. This approach is supported by prior work in multivariate time-series analysis, where distributional similarity is used to capture latent coordination among physiological systems. The specific construction method is as follows: first, select feature *f*; second, compute the KL divergence values between feature (f) and all other features to form the point feature vector for this feature; repeat this process until the point feature vectors for all features are constructed. The feature distributions used for a specific prediction time point are calculated strictly using data recorded strictly before that (T_m) time. For example, when constructing the graph network for prediction at time (T_m), only measurements with time stamps < T_m are used to compute the KL divergence and edge weights. No future information is incorporated, thereby preventing temporal data leakage. The feature space integrates the information correlation and distribution correlation between

XSL•FO
RenderX

feature channels and establishes the relationship between the edge weight value and the point feature space. At the same time, the KL divergence values in the overall feature space are normalized to ensure that the feature distribution is in the feature correlation space and reduce the impact on model training. The calculation method of the feature space (P_f) is as follows:

(1)Spf={F1pf,F2pf.....Fbpf}b≤Fm

(2)Fbpf=[KL(fb,f1),KL(fb,f2).....KL(fb,fFm)] b≤Fm



Probability distribution construction for KL divergence under sparse data: for each feature channel, let its available measurements before prediction time be {v1,v2,...vn}. This paper constructs a discrete probability distribution over a fixed set of M bins spanning the global range of all features. When n=2, we use kernel density estimation with a Gaussian kernel; when n=1, the distribution is a Gaussian centered at that single value; and when n=0, we assign a uniform distribution. The KL divergence between 2 features is then computed on these discrete distributions. Where, S_{pf} represents the overall spatial feature set, and F^{pf}_b represents the feature vector of a feature node. Meanwhile, the feature space mapping of the time mode P_t is in the temporal difference embedding space, built by the difference between the time node and the measured time of the remaining nodes. The feature space is used to reflect the correlation of the time values in the measured time series. The calculation time point is strictly limited within the calculation time range. The information provided by the time node can assist the model in mining the time scale between different measurements and provide the change information of the time scale for the model training. The calculation method of the feature space P_t is as follows:

(3)Spt={F1pt,F2pt,…,Fapt}, a≤Tm

(4)Fapt=[− ‖ (ta,t1) ‖ ,− ‖ (ta,t2) ‖ ,…,− ‖ (ta,tm) ‖], a≤Tm

Where, S_{pt} represents the overall spatial feature set, and F^{pt}_a represents the feature vector of a time feature node. The connection edge E_w of the graph network is composed of v_c in the measurement behavior, and the existence of the connection edge is directly related to the existence of the measurement behavior. In this way, the fine-grained information in the data is retained to the greatest extent, and the introduction of noise information is eliminated. The construction method of the graph network is shown in Figure 1.

Figure 1. Graph network data structure construction figure: the feature channels and time in each patient's clinical time-series data record constitute nodes, and the record values constitute edge weights. The Kullback-Leibler (KL) divergence and the time difference form the point features.

Model Construction

After constructing a graph network with time-series data, this paper proposes the construction of a graph convolutional network (GCN) by using the point feature space and the edge weight connection relationship to extract the overall features in the point feature space. At the same time, a multihead attention mechanism network with a gated mechanism connecting multiple layers is proposed for feature extraction in the edge weight feature space. Finally, a learnable weight head is added to the features of the 2 dimensions for feature fusion to meet the downstream multiobjective tasks.

First, in the GCN, the feature spaces S_{pf} and S_{pt} are jointly constructed as the feature matrix X_f of the nodes. The collected values of each feature for an individual patient at different time points are normalized, and the connection values corresponding to time nodes and feature nodes form the edge weight matrix

XSL•FO
RenderX

A_w, and the learnable parameter Wis added. The GCN [21] network with L) layer input edge weights is used to construct and calculate the overall feature F_p of the node feature space. The calculation is as follows:

(5)H(1)=σ(AwXfW0)

(6)Fp=H(L)=σ(AwH(L−1) WL−1)

Second, during the computation process of the GCN network, the model primarily focuses on the intrapatient variations, and the edge features tend to gradually weaken as the training depth increases. To fully express the features in the edge weight space, this paper proposes a targeted approach. First, each feature of the edge weight (E_w) is independently normalized across the entire set of patient samples. This normalized edge weight data is then used to construct the feature value matrix (W_E). Finally, (W_E) is input into the convolutional gated attention mechanism network.

During the computation process of the convolutional gated attention mechanism network, first, W_E is fed into the forgetting gate to construct the partially forgotten feature matrix (W_{EF}). Then, W_{EF} and W_E are input into the 2D convolution layer at the same time, and the multidimensional data (C_{EF}) and (C_E) are generated after convolution and input into the multihead attention mechanism layer [22] to obtain $A_E(1)$. It is constructed as shown in the following formula:

(7)WEF=Sigmoid(h1WE+b1)

(8)CEF=Conv2d(WEF)

(9)CE=Conv2d(WE)

(10)AE(1)=Attention(CEF,CE,CE)

Here, (h_1) represents the weight matrix of the first layer and (b_1) represents the bias term of the first layer. The feature $A_E(1)$ obtained from the first layer is reinput into the convolutional gated network to generate the C_{AE} after passing through the average pooling layer. C_{AE}, $A_E(1)$, and C_E are again input into the multihead attention mechanism layer. Repeat the operation of feature extraction through (L) layers, and finally obtain the extracted feature weight (F_e) of the edge feature space. The overall calculation formula is as follows:

(11)CAE(L)=Conv2d(Sigmoid(hLAveragePooling(AE(L−1))+bL))

(12)AE(L)=Attention(CAE(L),AE(L−1),CE)

(13)Fe=AveragePooling(AE(L))

Finally, the feature (F_p) obtained from the point feature space and the feature (F_e) obtained from the edge weight space were added to the learnable weight head (H_{fp}) and (H_{fe}), respectively, to form the overall feature extracted from the time-series data graph network space. The features are computed as follows:

(14)Ftotal=HfpFp+HfeFe

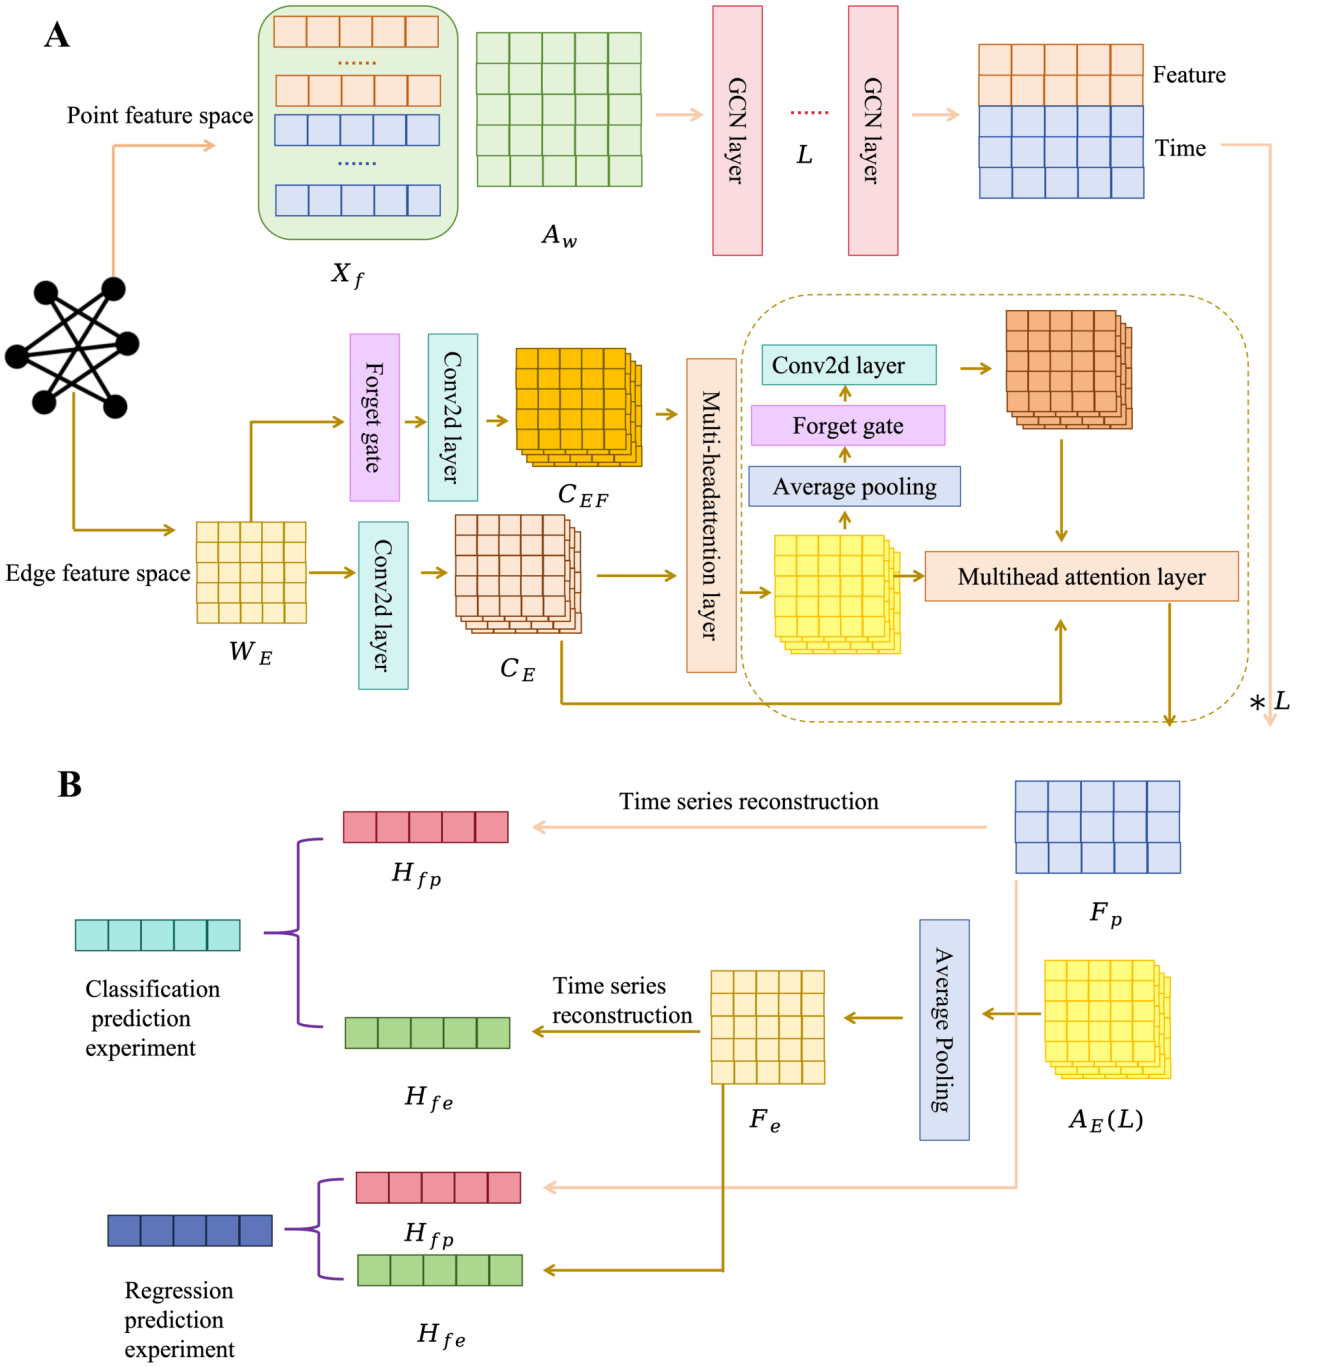
Model Training

After obtaining the overall features extracted from the temporal graph network, we build different decoders to satisfy the downstream multiobjective task. For the classification prediction task, it is necessary to trace the overall feature changes of patients and conduct a comprehensive analysis. For the 2 different classification tasks of patient mortality and patient clinical representation, the overall feature matrix (F_{total}) is decomposed and arranged by time and mapped to the corresponding dimension through the feedforward neural network for training. The binary cross-entropy loss function is used to calculate the task loss value, and the calculation formula is as follows:

(15)BceLoss=−1N∑i=0Nyi log (p(yi)) +(1−yi) log (1−yi)

For the regression task, the key consideration is the feature vector of patients at the final time point. For regression prediction tasks such as predicting the future length of hospital stay or the future change of different physical sign data, this paper uses the features of the last dimension of the point feature space and edge weight space, which are weighted by H_{fp} and H_{fe} and then mapped to the corresponding dimension by the feedforward neural network for training. The calculation formula is as follows:

(16)L1loss=1N∑i=0N|yi-f(yi)|



The length of hospital stay was normalized before model training using minimum-maximum scaling. Specifically, let (y_{st}) denote the original stay time in hours. The normalized value (y_{norm}) is computed as:

ynorm=yst-yminymax-ymin

The overall model construction and training are shown in Figures 2A and 2B.

Figure 2. Model and training structure figure. (A) Features are extracted by building models for the point feature space and the edge weight space, respectively. A multilayer graph convolutional network (GCN) is used for the point feature space, and a multilayer gated convolutional attention mechanism layer is used for the edge weight space. (B) Feature fusion and extraction of different dimensions of data for training downstream tasks. Here, * represents the multiplication sign, X_f represents the feature matrix of the nodes, A_w represents the edge weight matrix, L represents the number of GCN layers, W_E represents the feature value matrix. C_E represents the matrix obtained by convolving the variable weight matrix, C_{EF} represents the matrix obtained by convolving and applying the forget gate to the variable weight matrix, H_{fp} and H_{fe} represent temporal features extracted from graph network data, F_p represents feature matrix constructed based on graph network data, F_e represents feature matrix constructed based on edge weight data, and $A_E(L)$ represents feature matrix obtained after the L-th GCN layer.

Ethical Considerations

This research was conducted in accordance with the Declaration of Helsinki and was approved by the Ethics Committee of the First Affiliated Hospital of Wenzhou Medical University (approval KY2023-R061). The requirement for written informed consent was waived by the Institutional Review Board due to the retrospective nature of the study. The study data are anonymous or deidentified. Meanwhile, no identification of individual images in the paper or additional material is possible.

Dataset Introduction

In the experimental data part of this paper, the time-series data of patients extracted from the public datasets Medical

XSL•FO
RenderX

Information Mart for Intensive Care (MIMIC) III [23,24] and MIMIC-IV [25] are used. Under the guidance of the clinical practice experience of clinicians, this paper selects 42 important features of concern in clinical practice for model construction. Meanwhile, the patient's survival, length of hospital stay, and clinical phenotypes are constructed as the outcome variables of the model. Since the recording time of the MIMIC-IV dataset is in the transition period of characterizing the coding rules, it is split into two parts: *ICD-9 (International Classification of Diseases, 9th Revision)* and *ICD-10* (*International Classification of Diseases, 10th Revision)*. The data of patients collected by the Critical Care Medicine Department of the First Affiliated Hospital of Wenzhou Medical University from 2012 to 2021 are also used to verify the effectiveness of the model. The data of 2000 patients in each dataset are selected in a 1:1 ratio of death to survival to explore the effectiveness of the proposed model in a balanced and fair way. Overall statistics for the data are provided in Table 2. Among them, the format of categorical data is expressed as "number of patients to number of nonpatients," and the format of numerical data is expressed as "mean (SD)." To verify the stability and effectiveness of the model, the proposed model was evaluated on an expanded dataset of 4000 samples with a 1:1 ratio of death to survival, analyzing temporal feature data more than 6-hour and 12-hour time windows. The results were compared with those of state-of-the-art methods, and the detailed comparison is provided in Multimedia Appendix 1.

Classification Prediction Experiment

In this paper, the proposed model is compared with advanced time-series prediction models in two single- and multi-objective tasks: predicting the final death of a patient and predicting whether multiple phenotypes of a patient occur. The study explores the advantages and scope of application of the proposed model. The experimental equipment adopted in this paper includes an Intel(R) Xeon(R) Silver 4210R CPU running at 2.40 GHz, an NVIDIA GeForce RTX 3090 graphics card with 24 GB of video memory, and 16 GB of system memory. The proposed model in this paper is compared with state-of-the-art time-series prediction models designed for irregularly sampled data, including time-aware long short-term memory [26], gated recurrent unit with decay [27], multitime attention networks for irregularly sampled time series [28], and ContiFormer [29]. Additionally, we adopt time-series analysis methods such as fully convolutional networks [30], temporal convolutional networks [31], neural basis expansion analysis for interpretable time series forecasting [32], Crossformer [33], and DSformer [34], which are trained on regularly sampled data with missing values imputed by the mean. The final comparison results provide a more multidimensional perspective for evaluating time-series prediction performance. For the time range of data length, this paper refers to the experience in the clinical practice process to construct 5 important time period lengths for training and comparison. The hyperparameter tuning of the model refers to multiple state-of-the-art hyperparameter optimization methods [35-39], and the optimal training parameters for each model are obtained. Detailed data are provided in Multimedia Appendix 2. The accuracy and area under the curve for predicting death for each model are provided in Tables 3 and 4.

From the results, it can be seen that the proposed model is in a leading position in most tasks of the 4 datasets, and the results of the proposed method are equal to or slightly inferior to the results of the comparison methods in some time periods of some datasets. Meanwhile, the proposed model demonstrates accuracy in predicting mortality on a larger-scale dataset. The detailed comparison results are provided in Multimedia Appendix 1. From the analysis, it can be found that death is a simple binary classification task, and most of the time-series analysis methods can effectively capture the change law of time-series data to make the correct judgment. The wrong part of the judgment may be due to changes in the patient's condition, resulting in the patient's condition getting better or suddenly worse. Moreover, in the public datasets, the clinical time-series data of patients are collected with high frequency and high data density, and the results of various time-series prediction methods are basically similar. However, in the private dataset, due to different clinical policies, the data collection frequency of patients is relatively sparse, and there are many missing values in the normal time-series arrangement, which leads to poor and unstable prediction results. The proposed algorithm can predict stably and efficiently even when there are many vacant values.

For the multitarget classification task of predicting whether a patient's phenotype occurs, the average accuracy, area under the curve, and precision-recall area under the curve (PRAUC) of each target are used as evaluation metrics. PRAUC is particularly suitable for imbalanced classification tasks, as it focuses on the model's performance on the minority class—a common scenario in clinical phenotype prediction where positive cases are often rare. The prediction performance of each model is summarized in Tables 5-7.

From the Tables 5 and 6, it can be seen that the proposed model has achieved superior results in different datasets and different time periods, which fully reflects the advantages of the proposed algorithm in the face of complex downstream tasks. As shown in Table 7, the proposed method consistently achieves the highest PRAUC across most datasets and time windows, indicating its robustness in handling severe class imbalance. Meanwhile, the proposed model demonstrates accuracy in predicting multiple clinical phenotypes on a larger-scale dataset. The detailed comparison results are provided in Multimedia Appendix 1. Comparing different time-series analysis algorithms, the sampling-and-filling method does cause the loss of fine-grained information. However, the data input structure of the graph network proposed in this paper can meet the required input of the model while retaining the fine-grained information in the time-series data to the greatest extent. At the same time, the experimental results show that the simpler the model structure may produce better results when computing time-series data with sampling and filling.

Regression Prediction Experiment

In the experimental architecture of this paper, predicting the length of hospital stay of a patient is set as a regression prediction analysis task to explore the prediction accuracy of the model in the face of different types of downstream tasks. At the same time, the model can provide multidimensional information required by clinical practice. In this paper, the normalized length of hospital stay of patients is set as the prediction target, and the mean absolute error (MAE) value between the true value and the predicted value is used as the standard to evaluate the quality of the model. The comparison of regression predictions is shown in Table 8. For each dataset, the corresponding minimum and maximum values were used for scaling. Detailed dataset-specific normalization parameters are provided in Multimedia Appendix 3.

From the analysis of the table, it can be found that the prediction accuracy of the model proposed in this paper is in the leading position in most datasets and time periods and is slightly inferior to the best prediction results in a small number of time periods. This finding fully reflects the stability of the model proposed in this paper in the face of different downstream tasks. Meanwhile, the proposed model demonstrates accuracy in predicting the length of hospital stay on a larger-scale dataset. The detailed comparison results are provided in Multimedia Appendix 1. Compared with other models, it can be found that some time-series analysis models have good accuracy in classification experiments, but have large deviation values in regression prediction tasks. In this paper, the prediction indicators of different time periods of each dataset are averaged, and the regression prediction and classification prediction are projected into the same set of score space to verify the stability of the model in the face of multitask learning.

Ablation Experiment

In the ablation experiment of the model, the point feature space and edge weight space proposed in this paper are experimented on using the above 3 regression and prediction analysis tasks (death, phenotype, and stay time) on 4 datasets with different time lengths, and the contribution of feature vectors extracted from different feature spaces to the overall model is explored. Meanwhile, this paper also analyzed the connection results of 2 feature spaces under the learnable head and the direct connection results of 2 feature spaces. Results from top to bottom, the accuracy for predicting death, the average accuracy for predicting the occurrence of different representations of patients, and the MAE for predicting the length of hospital stay were arranged. The values are given in Table 9.

From the analysis of the table, it can be found that both the point feature space and the edge weight space can achieve certain prediction accuracy in the classification task. However, due to the characteristics of the graph network space and the fact that the GCN network is easy to fall into local graph space, the features extracted from the point feature space lead to unstable prediction results. The lack of measurement time information in the edge weight space also leads to low prediction accuracy of the extracted features. The combination of the two can effectively construct a stable and high-accuracy prediction model. In regression prediction analysis, the information provided by the point feature space is limited, and the results of regression prediction have large deviations. Under the action of the learnable head, it can effectively fuse with the feature vector extracted from the edge weight space. It improves the prediction accuracy and prediction stability of the model. Meanwhile, a single-head attention mechanism network and a single-layer GCN are supplemented to verify the effectiveness of hyperparameter configuration and the construction of the multilevel network framework. The results are shown in Table 10.

Discussion

Principal Findings

Aiming at the problem of uneven sampling time intervals and a large number of missing values in medical time-series data, this paper proposes to transform medical time-series data into a graph network structure for input. The feature vectors are extracted by constructing algorithms respectively for the point feature space and the edge weight space in the graph network data structure and are fused to form the feature vector of the graph network space under the action of the learnable head. The fused features are then decoded by the decoder to cope with different downstream tasks. In the exploration of model interpretability, this study extracts each feature at different time points from the trained model. The extracted features are fitted to different target tasks using logistic regression, and Shapley Additive Explanations analysis is used to obtain the changes in the contribution of features to the final target task across various time points. Figure 3 illustrates the variation of feature contributions to mortality prediction at different time scales based on 48-hour data from the MIMIC-IV *ICD-10* dataset. Results for the entire dataset are provided in Multimedia Appendix 4.

XSL•FO
RenderX

Figure 3. Shapley Additive Explanations (SHAP) analysis figure: variation of feature contributions across different time points.

As analyzed from Figure 3, heart rate and glucose indicators are important factors affecting patient survival in the early stage of hospitalization. With the passage of time, carbohydrate metabolites and patient age gradually become the dominant factors.

Comparison to Prior Work

In this paper, the proposed model is tested in 5 different data time ranges in 4 datasets, and it is found that the proposed model has good prediction accuracy and prediction stability in classification and regression prediction tasks. Meanwhile, paired DeLong tests were performed on the mortality probability prediction results of the proposed model and comparative models in the MIMIC-IV *ICD-9* and private datasets. The results showed that the *P* value of the test in MIMIC-IV *ICD-9* was <0.001 and that in private data was <0.05. Additionally, paired *U*-tests were conducted on the MAE values of the regression predictions for length of hospital stay, revealing that *P* values in both MIMIC-IV *ICD-9* and private data were <0.05. The specific value of *P* is provided in Multimedia Appendix 5. These findings fully demonstrate the effectiveness of the proposed model in improving prediction performance. Moreover, this paper conducts ablation experiments on the point feature space model and the edge weight space model and finds that the accuracy and stability of the classification prediction of the model come from the simultaneous contributions of the 2 spaces. The accuracy of regression prediction comes from the adjustment and fusion of the 2 spatial feature vectors by the learnable head.

In comparing our proposed model with existing methods, it is important to acknowledge a confounding factor in the baseline experimental design. Our graph-based model operates directly on raw, irregularly sampled time-series data without any imputation, whereas standard deep learning models, such as a fully convolutional network and temporal convolutional network, are trained on data that have been preprocessed with mean imputation to enforce regular sampling intervals. This design choice conflates 2 distinct sources of potential performance gain: the architectural advantage of the graph network and the representational benefit of avoiding information loss due to imputation. The primary rationale for this comparison was to reflect a realistic clinical deployment scenario, where missing values are prevalent, and imputation remains the default preprocessing step for conventional models. As such, the current benchmark captures the end-to-end practical advantage of a model that inherently accommodates irregular data without the need for imputation. However, we acknowledge that this setup does not isolate the contribution of the graph architecture alone. Despite this limitation, we believe the current comparison remains clinically meaningful, as it reflects the performance gap between models that require imputation and those that do not in real-world settings.

XSL•FO
RenderX

Limitations

The model proposed in this paper also has the following limitations: (1) since the method proposed in this study fully uses the information in the data to construct nodes and edges and uses both nodes and edges for computation simultaneously, it imposes certain requirements on the training space; and (2) as the number of computational features and the scope of computation time increase, the demand for computational space grows exponentially.

Future Directions

In the future, this study intends to develop a graph network construction paradigm with a more compact structure, which can be compatible with longer time-series data and more features, thereby enabling the tracking and monitoring of patients' overall disease progression. While the proposed model demonstrates strong predictive performance on irregularly sampled medical time-series data, its scalability to large-scale clinical databases remains a challenge. As noted in the Limitations subheading, the current graph construction and joint computation over node and edge feature spaces impose significant memory overhead that grows exponentially with the number of features and time points. To facilitate real-world deployment in hospital informatics environments that routinely handle tens of thousands of patients, several optimization strategies can be explored. First, sparse graph representations could be adopted to retain only clinically meaningful edges, reducing the memory footprint. Second, feature or temporal down-sampling techniques may help control the node count while preserving essential information. Third, distributed computing frameworks or graph mini-batching strategies could partition the computation across multiple devices, enabling parallel processing of large patient cohorts. Finally, memory-efficient graph convolution operators, such as those based on neighborhood sampling or low-rank approximations, offer promising avenues for scaling graph networks to larger datasets. In future work, we aim to investigate these directions to enhance the scalability and clinical utility of the model without compromising predictive accuracy.

Conclusions

Based on the model's prediction results, analyzing patients' clinical time-series data from the early time period can reveal the disease progression for many patients. In addition to carefully examining the characteristic representations of patients identified by the model as having higher mortality risk, it is also possible to focus on predicting treatment regimens that are likely to be misapplied to a given patient. Through the similarity of the patient's graph network to form the edge and through the hierarchical clustering method, a good treatment plan is mined, and the wrong treatment plan is excluded. Overall, this paper proposes a deep learning–based temporal data analysis model for accurately predicting the survival outcomes of critically ill patients, while also providing critical features that require close attention at various time points.

Abstract

Background: Atrial fibrillation (AF) is a common arrhythmia associated with an increased risk of stroke and heart failure. To improve prevention, recent studies have used deep learning models to identify at-risk individuals early from normal sinus rhythm (NSR). However, studies using mobile electrocardiogram (mECG) in outpatient, real-world settings remain underexplored.

Objective: The study aimed to develop and evaluate deep learning models using a real-world limb-lead mECG database to predict the short-term occurrence of AF from NSR recordings.

Methods: mECG data were collected from real-world users of commercially available handheld mECG devices capable of capturing 6 limb leads. AF occurrence was defined as an AF event within a predefined time window (7, 14, or 31 d) from the date of the NSR recording. Transformer-based prediction models were developed for limb-lead and lead I input configurations using a multistage training approach with self-supervised pretraining and domain adaptation, drawing on both open, large-scale clinical 12-lead ECG and proprietary real-world mECG databases. The models were evaluated in an internal real-world cohort and explored in an external cohort as a proof of concept via time-to-event analysis.

Results: Between March 2023 and November 2024, 386,519 mECGs were acquired from 8206 users. There were 18,949, 25,206, and 33,524 AF incidences within the 7-, 14-, and 31-day time windows. The models were pretrained with 787,257 12-lead ECGs and 202,689 mECGs, then fine-tuned to predict AF occurrence using 97,447 labeled mECGs. The limb-lead models achieved areas under the receiver operating characteristic curves (AUROCs) of 0.793, 0.785, and 0.787 for 7-, 14-, and 31-day predictions on the internal cohort, respectively, with a user-level AUROC of 0.702 for the 31-day prediction. These models significantly outperformed the lead I models (P<.001), supporting the value of multilead configurations. The multistage pretraining was essential, as single-source pretraining yielded lower AUROCs of 0.555 with mECGs only and 0.761 with 12-lead ECGs only for the 31-day prediction. In the subgroup analysis, AUROC values were consistent across age, PR interval, and corrected QT interval, but showed disparities (P<.001) by sex (0.713 in females vs 0.794 in males) and by QRS duration (0.583 in ≥120 ms vs 0.796 in <120 ms). In the external cohort (n=144), the 31-day model stratified all 5 new-onset AF events, showing significantly different survival functions between the positively and negatively predicted groups (P=.03); Cox proportional hazards regression yielded a hazard ratio of 1.49 (95% CI 1.06 - 2.09) per 0.1 increase in model output.

Conclusions: Our findings elucidate the feasibility of deep learning–based AF risk prediction using single-NSR recordings from mobile devices, highlighting the potential for remote AF management in real-world populations. The model output may serve as a risk indicator to support opportunistic AF screening, prompting further clinical evaluation and informing decisions about more intensive monitoring.

Introduction

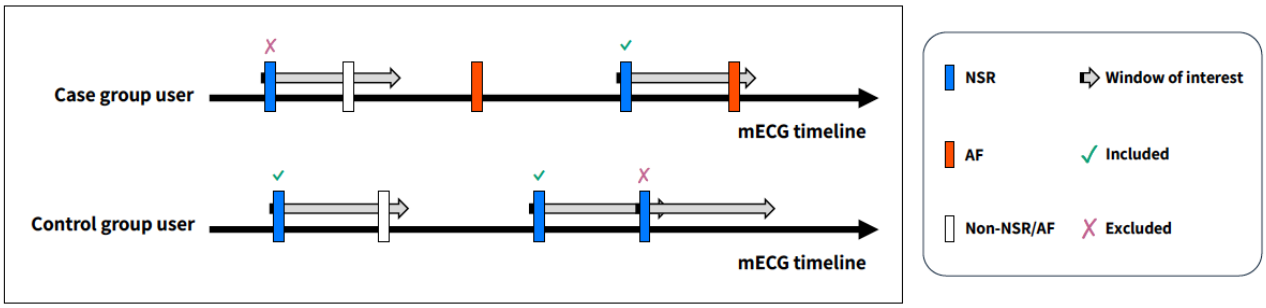
Atrial fibrillation (AF) is a common arrhythmia and a major cause of stroke and heart failure. Early identification of individuals at risk is crucial for timely intervention, yet current strategies rely on symptom-driven visits or periodic electrocardiogram (ECG) assessments in clinical settings, which may miss paroxysmal or asymptomatic events.

Mobile electrocardiogram (mECG) devices offer an alternative by enabling user-initiated rhythm monitoring outside clinical environments. Randomized trials have shown that handheld or wearable ECGs improve AF detection compared with standard care [1]. However, most screening methods still depend on directly capturing an AF episode and may miss paroxysmal cases that occur outside the recording window.

Predicting short-term AF risk during normal sinus rhythm (NSR) could enable earlier identification of high-risk individuals. AI algorithms have been increasingly applied to 12-lead and Holter ECGs recorded during NSR, with several studies demonstrating their ability to detect latent signatures indicative of underlying or impending AF [2-9]. More recently, AF prediction has been extended to mECG data collected via smartphone-connected handheld devices and wearable patches [10,11], thereby demonstrating that AI models can estimate near-term AF risk in real-world ambulatory settings. Yet most of these models have been developed and evaluated on single-source datasets, leaving their robustness in independent populations uncertain.

Predicting future AF from NSR recordings is an inherently challenging task, as it requires the model to identify subtle arrhythmogenic signatures hidden within otherwise normal waveforms. This challenge is magnified when using mECGs, which often exhibit greater signal variability and noise artifacts compared with clinical 12-lead ECGs. To overcome these limitations, a robust methodological approach is required. Self-supervised learning (SSL) offers a compelling solution by enabling models to learn powerful, generalizable representations from large pools of unlabeled data [12]. This approach is well-suited for enhancing downstream performance on complex tasks, even with limited annotated samples. Various studies have shown the promise of SSL applications in biomedical time-series tasks, including ECG analysis [13-15]. Furthermore, SSL has been shown to facilitate effective domain adaptation [16,17], allowing models pretrained on one data type (eg, clinical ECGs) to be effectively transferred to another that has different statistical characteristics (eg, mECGs).

In this study, we developed deep learning models that estimate near-term AF risk, potentially useful for aiding clinicians in screening candidates for closer rhythm surveillance, using a real-world mECG database. Specifically, we trained deep learning models to predict AF occurrence within 7, 14, and 31 days following NSR mECGs recorded by a commercially available handheld device. To enhance generalizability, a multistage training pipeline was used as follows: (1) self-supervised pretraining on large-scale clinical ECGs, (2) further pretraining on mECGs for domain adaptation, and (3) supervised fine-tuning for AF prediction. The models were evaluated internally, including subgroup analyses on demographic and ECG-specific variables, and were further tested for new-onset AF risk stratification as an additional proof-of-concept assessment in a clinically distinct external cohort.



Methods

Study Design

We designed a retrospective study to develop and validate deep learning models that predict AF occurrence within short-term windows from a single mECG recorded during NSR. The AF occurrence labeling and exclusion scheme is detailed in Figure 1. Each NSR mECG was considered a potential model input and retrospectively labeled based on the rhythm observed in subsequent recordings within predefined follow-up windows of interest. Labeling was conducted separately for 3 distinct windows: 7, 14, and 31 days. Specifically, an mECG was labeled as positive if AF was detected in any follow-up recordings within the respective window, and negative otherwise. Rhythm classification (eg, NSR or AF) was determined by the device-generated diagnostic output at the time of user-initiated recordings. To be eligible for labeling, an mECG had to be classified as NSR and have at least one follow-up mECG within the corresponding prediction window; all ineligible recordings were excluded from the labeled dataset. Due to this requirement, the labeled sets for 7- and 14-day windows are subsets of the 31-day set, as they exclude recordings that cannot be labeled within the shorter time windows.

XSL•FO
RenderX

Figure 1. Atrial fibrillation (AF) occurrence labeling and exclusion scheme. Users were classified into a case group or a control group based on the presence of at least one AF recording in the mobile electrocardiogram (mECG) database. For the case group, normal sinus rhythm (NSR) recordings with a subsequent AF recording within a specific time window of interest (eg, 7-d, 14-d, or 31-d) were labeled as AF occurrence positive. For the control group, NSR recordings with a subsequent non-AF recording were labeled as AF occurrence negative. Recordings that did not meet these criteria (eg, NSR without any follow-up recording, NSR followed by non-AF recordings in the case group, or non-NSR ECGs) were excluded from the labeled sets and retained as part of the unlabeled set used for self-supervised pretraining.

Data Collection

This study used 3 ECG datasets with distinct roles in model development and evaluation: (1) real-world mECGs collected from the general population, (2) a large-scale public 12-lead ECG dataset, and (3) mECGs from individuals without prior AF history but at elevated clinical risk of AF. Each dataset was preprocessed and used according to the specific objectives of model pretraining, training, or testing. No formal a priori sample size calculation was performed; the study used all available recordings.

The first dataset consisted of mECGs recorded from real-world users of HATIV P30 (VUNO Inc; Figure 2), a commercially available handheld mobile device capable of capturing 6 limb leads (I, II, III, aVR, aVL, and aVF). Recordings were collected between March 2023 and November 2024 from real-world device users in South Korea. Only leads I and II were directly measured; the remaining 4 leads were derived using standard transformations. Each mECG was recorded over a 30-second duration, and a clean segment of 15 to 30 seconds was extracted using the signal filtering rule of the device. We excluded mECGs with invalid or missing values to ensure reliable analysis, those classified as noise by the device's algorithm to maintain adequate signal quality, or recordings with only a single lead to preserve consistent multilead input across the dataset. mECGs were labeled and split at the user level into training, validation, and test sets to prevent user overlap. The training and validation sets were used for supervised learning and model selection, while the test set served for internal performance evaluation. To prevent label noise, mECGs were excluded from the AF labeling process if they were not measured by the device owner (ie, third-party recordings) or were recorded by excessive users. Excessive users were defined as those with an average of 5 or more daily measurements, presumed to be institutional accounts. These excluded recordings were then used only for self-supervised pretraining as part of the unlabeled set. All AF mECGs in the test set were additionally reviewed by a board-certified electrophysiologist with over 10 years of post-board electrophysiology experience at Chonnam National University Hospital, to confirm label quality.

XSL•FO
RenderX

Figure 2. HATIV P30 handheld mobile electrocardiogram device used for data acquisition. The device captures leads I and II directly through 2 electrodes on its top surface, which are held in the user's hands, and a third electrode on its bottom surface, which is placed on the left leg. The remaining limb leads (III, aVR, aVL, and aVF) are then computationally derived from the measured lead I and II signals using standard transformations. The device performs automatic signal-quality checks during acquisition and prompts the user to rerecord when input quality is inadequate. Validated recordings are then processed by the device's on-board algorithm for arrhythmia detection, including atrial fibrillation identification. The image is provided courtesy of VUNO Inc.

The second dataset was MIMIC-IV-ECG [18], a large-scale public 12-lead ECG database. It consisted of ECGs collected in a clinical setting at Beth Israel Deaconess Medical Center (Boston, United States) from 2008 to 2019, representing a broad spectrum of patients with diverse demographics and cardiac conditions. This dataset was used for large-scale self-supervised pretraining of the model before domain-specific fine-tuning, using only the 6 limb leads or lead I for compatibility with the mECG data.

The third dataset consisted of HATIV P30 mECGs acquired for an ongoing prospective study from patients at Hallym University Dongtan Sacred Heart Hospital who had no prior diagnosis of AF but were stratified as high risk, with a C_2 HEST (coronary artery disease or chronic obstructive pulmonary disease, hypertension, elderly, systolic heart failure, and thyroid disease) [19] or HATCH (hypertension, age, transient ischemic attack or stroke, chronic obstructive pulmonary disease, and heart failure) [20] score of ≥4. We used the recordings collected between May 2024 and February 2025. Only the first NSR mECG per patient was available and paired with clinician-reviewed AF incidence, solely to evaluate the model's risk stratification performance. Enrolled patients were instructed to record mECGs at least weekly and whenever they experienced symptoms, with AF events determined from these recordings. Each AF event in the external cohort, based on review of follow-up mECG waveforms, was confirmed by 1 of 4 board-certified cardiologists at Hallym University Dongtan Sacred Heart Hospital, with a median of 16 (range 10 - 33) years of clinical experience.

Data Preprocessing

All signals underwent a standardized preprocessing pipeline prior to model input. Recordings were resampled to 250 Hz and filtered using a fifth-order Butterworth bandpass filter (0.67 - 40 Hz). Distinct segment extraction methods were then applied for training and evaluation. During training, a single, random 9-second segment was cropped from each recording for data augmentation to improve generalizability [21]. This length was selected to approximate the standard 10-second clinical ECG strip while capturing multiple cardiac cycles (≈9 - 12 beats at typical heart rates). Each extracted segment was then standardized to have a zero mean and unit variance. During evaluation, each recording was divided into overlapping 9-second segments with a stride of 0.5 seconds. This stride was chosen to provide dense temporal coverage while maintaining computational efficiency during inference. Each segment was individually standardized, and the model's final prediction was obtained by averaging the outputs across all segments.

Deep Learning Model Development

The entire deep learning framework was implemented using the *PyTorch* library (PyTorch Foundation). We adopted a multistage training pipeline for developing deep learning models capable of predicting future AF occurrences from NSR. Masked autoencoder (MAE) [13] was used for SSL with a vision transformer [22] as the backbone, motivated by the strong arrhythmia classification performance demonstrated in previous studies [14,15]. The vision transformer takes an ECG signal as input, divides it into sequential segments, and analyzes them through multiple layers using an attention mechanism that

XSL•FO
RenderX

weighs how different segments relate to one another, capturing both local waveform features and broader patterns to produce its output. During MAE pretraining, portions of the input ECG signal were randomly masked, and the model learned to reconstruct these hidden portions from the visible remainder, thereby acquiring meaningful representations of cardiac electrical patterns from unlabeled data without requiring outcome labels. An overview of the pretraining framework is illustrated in Figure S1 of Multimedia Appendix 1.

Initial self-supervised pretraining was performed on the MIMIC-IV-ECG limb-lead or single-lead (lead I) signals, enabling the model to learn generalized spatiotemporal ECG representations across a wide range of clinical contexts [14]. To adapt the pretrained model to the mECG domain, we conducted further MAE-based pretraining [16,17] on the mECG pretraining set. This stage aimed to bridge the distributional gap between clinical 12-lead ECGs and recordings from real-world mobile device users.

The pretrained encoder was then fine-tuned using the labeled training set for the supervised AF occurrence prediction task. A balanced focal loss [23] was used to handle class imbalance. We used a strong data augmentation policy using RandAugment [24], which involved a set of transformations inspired by prior ECG augmentation research [25], to improve model generalization and robustness. This was motivated by the inherent difficulty of the task (ie, detecting latent signatures of future AF within NSR recordings) and the noisy nature of recordings collected in real-world settings. The augmentation set used in this study is listed in Table S1 of Multimedia Appendix 1.

AdamW optimizer [26] and a cosine annealing learning rate schedule [27] were used for both the pretraining and fine-tuning stages, and layer-wise learning rate decay [28] was used for fine-tuning. Model selection was performed using the validation set, and the best-performing checkpoint was evaluated on the test set. Hyperparameters were tuned for the 31-day prediction setting; the configurations used in this study are listed in Table S2 of Multimedia Appendix 1.

Model Evaluation

Model performance was evaluated across 6 separately trained models, defined by combinations of input lead type (limb leads vs lead I only) and prediction window (7, 14, and 31 d). The area under the receiver operating characteristic curve (AUROC) was used as the primary metric. We also reported sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) for greater clinical interpretability. These metrics were calculated using a decision threshold chosen to equalize sensitivity and specificity on the validation set. This balanced threshold reflects equal clinical priorities in the mobile device user setting: early AF detection to enable timely follow-up (sensitivity) and avoidance of false alarms that could cause unnecessary user anxiety in self-monitoring (specificity). We additionally evaluated classification performance at a high-sensitivity threshold (sensitivity=0.9 on the validation set).

We also conducted subgroup analyses of the 31-day prediction model to identify potential performance disparities. Stratified AUROCs were reported by age (<60 vs ≥60 y), sex (male vs female), and key ECG features, including PR interval (<200 ms vs ≥200 ms), QRS duration (<120 ms vs ≥120 ms), and corrected QT interval (QTc; <460 ms vs ≥460 ms). These numeric features were obtained from the device-generated, automated ECG interpretation and were binarized based on clinically defined cutoffs.

For exploratory external evaluation, we applied the trained 31-day limb-lead model to the external cohort. Each patient was assigned a model output and then stratified into a “positively predicted” group or “negatively predicted” group based on the decision threshold previously established on the validation set (where sensitivity equals specificity). We then performed a 31-day time-to-event analysis to compare the cumulative incidence of new-onset AF between these 2 stratified groups. In addition, we estimated the association between the continuous model output and time to incident AF using Cox proportional hazards regression. The model output was entered as a single predictor and scaled per 0.1-unit increase to facilitate clinical interpretation.

Additional Analyses

We performed 3 sensitivity analyses. First, to assess the contribution of each pretraining stage, we compared three pretraining configurations: (1) MAE pretraining on MIMIC-IV-ECG only, (2) MAE pretraining on mECGs only, and (3) sequential MAE pretraining using MIMIC-IV-ECG followed by mECGs (the default setting in the main experiments). Second, to assess the relative contribution of physically measured versus computationally derived leads, we compared a model trained using only the physically measured leads (leads I and II) against the default configuration using the full set of limb leads (leads I, II, III, aVR, aVL, and aVF). Third, to evaluate model performance independent of within-user contributions, we also performed a user-level analysis, deriving a single per-user prediction by randomly selecting a recording and aggregating outputs. Additionally, we visualized the Transformer model’s attention weights for representative test examples to qualitatively assess model interpretability.

Statistical Analyses

Statistical analyses were conducted to compare baseline characteristics and evaluate model performance. Baseline demographic and clinical features were compared across the mECG training, validation, and test sets using a one-way ANOVA for continuous variables and the chi-square test for categorical variables. To compare model performance, we used the DeLong method [29] to test for significant differences between AUROCs and to calculate CIs. For sensitivity, specificity, PPV, and NPV, CIs were estimated using the Clopper-Pearson exact method [30]. For the time-to-event analysis in the external cohort, Kaplan-Meier survival curves were generated to estimate the cumulative incidence of new-onset AF in the model-stratified groups, and the difference was tested for significance using the log-rank test. Hazard ratios were reported with 95% Wald CIs. Calibration was assessed using the observed-to-expected (O/E) ratio. A significance level of .05 was used for all analyses. We used Python with

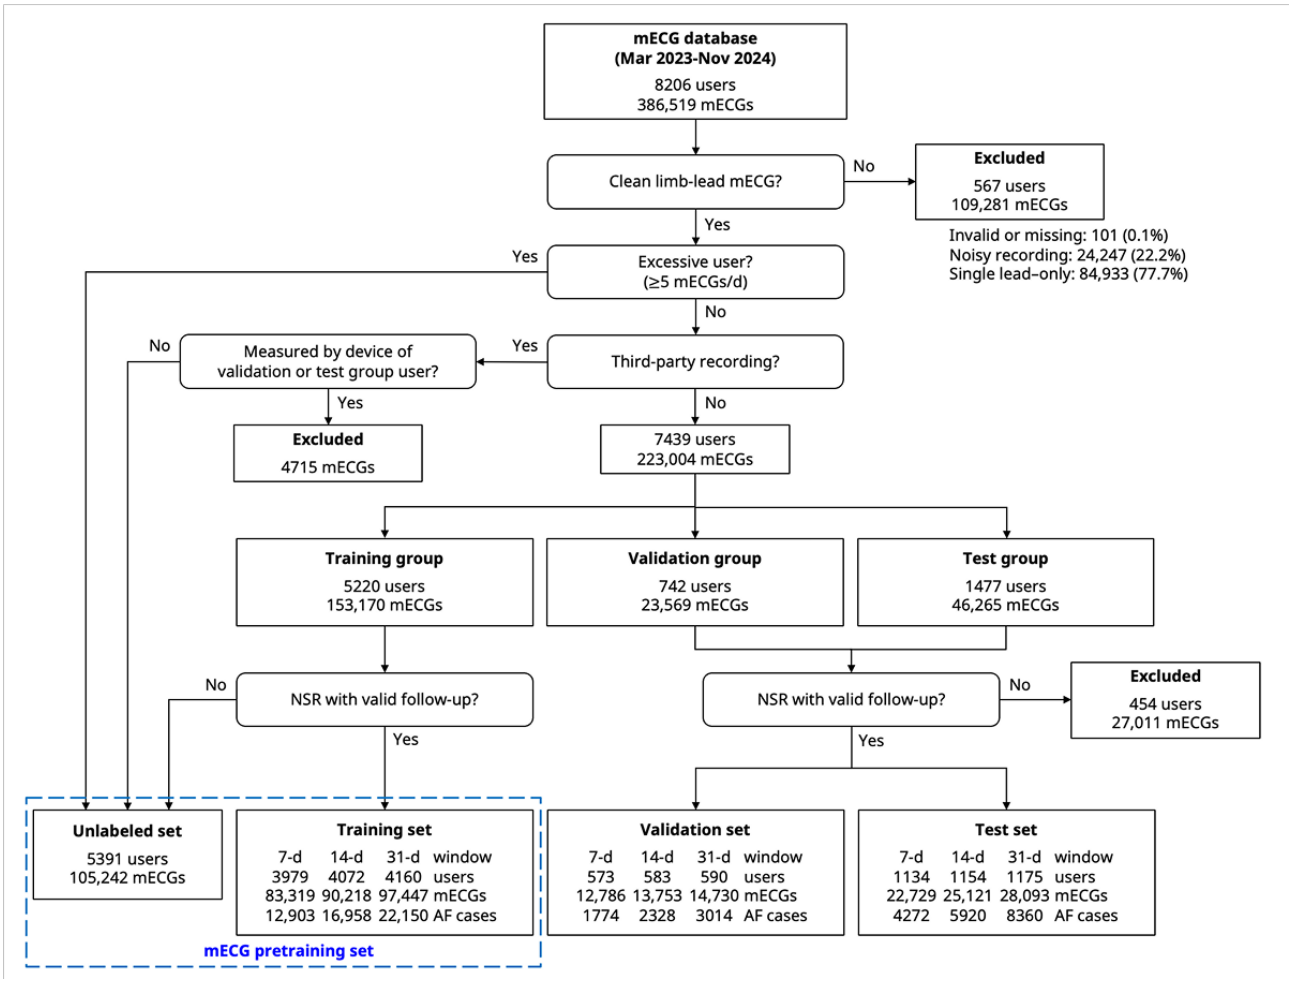
open-source libraries, including *SciPy*, *scikit-learn*, *scikit-survival*, and *lifelines*.

Ethical Considerations

This study was conducted in accordance with ethical standards and was approved by the Institutional Review Board (IRB) of Chonnam National University Hospital (IRB: CNUH-2025 - 127). Users provided informed consent for the use of their deidentified data (eg, ECGs, age, and sex) for research purposes during registration on the mobile application platform. The external cohort was collected as part of a prospective observational study registered with the Clinical Research Information Service, Korea (registration: KCT0009304, date of registration: April 5, 2024, IRB: HDT 2023-12-003). In addition, the study used the publicly available MIMIC-IV-ECG v1.0 dataset, which is deidentified and openly accessible via PhysioNet [18]. The MIMIC-IV-ECG project was approved by the IRBs of Beth Israel Deaconess Medical Center and the Massachusetts Institute of Technology, with a waiver of individual patient consent. Formal patient and public involvement was not incorporated, given the retrospective nature of the analysis and the use of pre-existing deidentified data.



Results

Study Population and Dataset Split

Between March 2023 and November 2024, 386,519 mECGs were acquired from 8206 mobile device users. Figure 3 illustrates the construction of the mECG dataset. Quality-based exclusions removed 28.3% (109,281/386,519) of mECGs, including 101 with invalid or missing signal values, 24,247 with noise, and 84,933 with only a single lead, leaving 277,238 mECGs. After further setting aside 54,234 recordings from excessive users and third-party users, the cleaned database comprised 223,004 mECGs (7439 users). User - level stratification yielded training, validation, and test groups containing 153,170 mECGs (5220 users), 23,569 mECGs (742 users), and 46,265 mECGs (1477 users), respectively. After the AF occurrence labeling procedure, the training, validation, and test sets for the 31-day prediction model included 97,447 mECGs (4160 users), 14,730 mECGs (590 users), and 28,093 mECGs (1175 users), respectively, with AF occurrences of 22.7% (22,150/97,447), 20.5% (3014/14,730), and 29.8% (8360/28,093); the numbers of mECGs for the 7- and 14-day prediction models decreased according to the shortened prediction time window and are detailed in Figure 3. Upon review by an electrophysiologist, all AF recordings in the test set were confirmed as AF, with no device-clinician discordance. In addition to these labeled sets, 105,242 mECGs from 5391 users were used as an unlabeled set for mECG pretraining, comprising recordings from excessive users, third-party recordings not measured on devices of users in the validation or test groups, and training group recordings without NSR or valid follow-up. Separately, 1.2% (4715/386,519) third-party mECGs recorded on devices of users in the validation or test groups were excluded entirely to prevent cross-cohort data leakage.

RenderX

Figure 3. Flow diagram of the mobile electrocardiogram (mECG) dataset construction. Initial data were curated by excluding invalid, low-quality, and single lead–only signals. To prevent data leakage, users were partitioned into training, validation, and test groups. Excessive users (≥5 mECGs/d) and third-party recordings not associated with the validation or test groups were reserved as unlabeled data. Users with at least 1 atrial fibrillation (AF) episode were defined as cases; all others were defined as controls. Final labeled datasets included only normal sinus rhythm (NSR) recordings with valid follow-ups within 31 days: an AF episode for cases and any subsequent recording for controls. The mECG pretraining dataset combined all labeled training data and the unlabeled data.

The training, validation, and test sets showed comparable baseline demographics, with no significant differences in mean user age (52.2, 52.1, and 51.6 y, respectively; *P*=.41) or in the proportion of male users (2117/4160, 50.9%; 306/590, 51.9%; and 621/1175, 52.9%; *P*=.48) in the 31-day setting, as shown in Table 1. Meanwhile, AF prevalence differed was variable depending on whether the analysis was at the user level (710/4160, 17.1%; 98/590, 16.6%; and 205/1175, 17.4%; *P*=.90) or the sample level (22,150/97,447, 22.7%; 3014/14,730, 20.5%; and 8360/28,093, 29.8%; *P*<.001). All measured ECG parameters (eg, heart rate, PR interval, QRS duration, and QTc) showed statistically significant differences across the sets (*P*<.001). The 7- and 14-day settings showed similar findings (Tables S3 and S4 in Multimedia Appendix 1).

[a]Continuous variables are summarized as means (SDs) and categorical variables as numbers (%). A one-way ANOVA and a chi-square test were performed to compare the continuous variables and categorical variables, respectively. Demographic statistics were computed at the user level, while statistics for ECG parameters were calculated at the sample level.

[b]Not available.

[c]AF: atrial fibrillation.

[d]ECG: electrocardiogram.

[e]bpm: beats per minute.

[f]QTc: corrected QT interval.

The 12-lead ECG pretraining set constructed from the MIMIC-IV-ECG database [18] for multistage training included 787,257 ECGs from 160,771 patients after the exclusion of invalid signals. The external set comprised 144 mECGs from 144 individuals. There were 3.5% (5/144) new-onset AF events that occurred within the 31-day follow-up window in the external set (Table S5 in Multimedia Appendix 1).

Model Performance

Model performance for the 3 (7-, 14-, and 31-d) time windows is shown in Table 2. For models trained on limb-lead input, the AUROCs were consistent across the time windows: 0.793 (0.785 - 0.801) at the 7-day window, 0.785 (0.778 - 0.792) at the 14-day window, and 0.787 (0.781 - 0.793) at the 31-day window. The narrow CIs indicate that the available sample size provided adequate statistical precision. Using thresholds with equal sensitivity and specificity, the NPV remained above 0.842 across all time windows, while the PPV increased with the prediction window length: 0.432 (0.420 - 0.444), 0.481 (0.470 - 0.492), and 0.548 (0.538 - 0.558), respectively. The results with high-sensitivity thresholds are presented in Table S6 of Multimedia Appendix 1.

Time window	AUROC[b] (95% CI)	Sensitivity (95% CI)	Specificity (95% CI)	PPV[c] (95% CI)	NPV[d] (95% CI)
Limb-lead model					
7-day	0.793 (0.785 - 0.801)	0.651 (0.636 - 0.665)	0.802 (0.796 - 0.807)	0.432 (0.420 - 0.444)	0.908 (0.904 - 0.913)
14-day	0.785 (0.778 - 0.792)	0.662 (0.650 - 0.674)	0.780 (0.774 - 0.785)	0.481 (0.470 - 0.492)	0.882 (0.877 - 0.887)
31-day	0.787 (0.781 - 0.793)	0.659 (0.648 - 0.669)	0.770 (0.764 - 0.776)	0.548 (0.538 - 0.558)	0.842 (0.836 - 0.847)
Lead I model					
7-day	0.737 (0.728 - 0.746)	0.619 (0.604 - 0.633)	0.737 (0.731 - 0.744)	0.353 (0.342 - 0.364)	0.893 (0.888 - 0.898)
14-day	0.727 (0.719 - 0.735)	0.586 (0.573 - 0.598)	0.753 (0.747 - 0.759)	0.422 (0.411 - 0.433)	0.855 (0.849 - 0.860)
31-day	0.678 (0.671 - 0.685)	0.547 (0.536 - 0.558)	0.722 (0.716 - 0.728)	0.455 (0.445 - 0.464)	0.790 (0.784 - 0.796)

[a]The decision thresholds were selected such that sensitivity equaled specificity on the validation set. CIs were computed using the DeLong method for the areas under the receiver operating characteristic curves and the Clopper-Pearson exact method for sensitivity, specificity, positive predictive value, and negative predictive value.

[b]AUROC: area under the receiver operating characteristic curve.

[c]PPV: positive predictive value.

[d]NPV: negative predictive value.

The lead I models consistently showed suboptimal performance compared to the limb-lead models. AUROCs were 0.737 (0.728 - 0.746), 0.727 (0.719 - 0.735), and 0.678 (0.671 - 0.685) for the 7-, 14-, and 31-day time windows, respectively, which are significantly below those of their counterparts trained on limb-lead signals (P<.001; Table S7 in Multimedia Appendix 1).

Subgroup Analyses

Subgroup performance for the limb-lead 31-day prediction model is summarized in Table 3. AUROCs were consistent across subgroups defined by age, PR interval, and QTc. Performance varied by sex, with AUROCs of 0.794 (0.788 - 0.801) in male participants and 0.713 (0.698 - 0.728) in female participants (P<.001). In users with a QRS duration ≥120 ms, AUROC decreased to 0.583 (0.489 - 0.677).

Table . Subgroup analysis of the prediction of 31-day AF occurrence using the limb-lead model[a].

Group	Samples, n	Prevalence of AF[b], n (%)	AUROC[c] (95% CI)	*P* value
Total	28,093	8360 (29.8)	0.787 (0.781 - 0.793)	
Sex				<.001
Male	19,554	6855 (35.1)	0.794 (0.788 - 0.801)	
Female	8539	1505 (17.6)	0.713 (0.698 - 0.728)	
Age (y)				.47
≥60	8564	4012 (46.8)	0.768 (0.758 - 0.778)	
<60	19,529	4348 (22.3)	0.763 (0.755 - 0.771)	
PR interval (ms)				.25
≥200	345	189 (54.8)	0.755 (0.701 - 0.809)	
<200	27,748	8171 (29.4)	0.786 (0.780 - 0.792)	
QRS duration (ms)				<.001
≥120	552	60 (10.9)	0.583 (0.489 - 0.677)	
<120	27,541	8300 (30.1)	0.796 (0.790 - 0.802)	
QTc[d] (ms)				.66
≥460	370	189 (51.1)	0.796 (0.751 - 0.842)	
<460	27,723	8171 (29.5)	0.786 (0.780 - 0.792)	

[a]*P* values assess statistical differences in the AUROCs between subgroups within each category (eg, male vs female). The DeLong method was used to compute the 95% CIs for the AUROCs and the corresponding *P* values.

[b]AF: atrial fibrillation.

[c]AUROC: area under the receiver operating characteristic curve.

[d]QTc: corrected QT interval.

Additional Analysis Results

Table 4 compares the AF prediction performance across the 3 pretraining configurations. The full sequential pretraining pipeline using MIMIC-IV-ECG followed by mECGs consistently yielded significantly higher performance (*P*<.001) compared to the models pretrained only on mECGs or MIMIC-IV-ECG, which showed AUROCs of 0.761 (0.754 - 0.767) and 0.555 (0.548 - 0.562) in the 31-day prediction setting. Further sensitivity analysis results, including input lead configuration, user-level evaluation, and attention visualizations are presented in Tables S7 and S8 and Figures S2 and S3 in Multimedia Appendix 1.

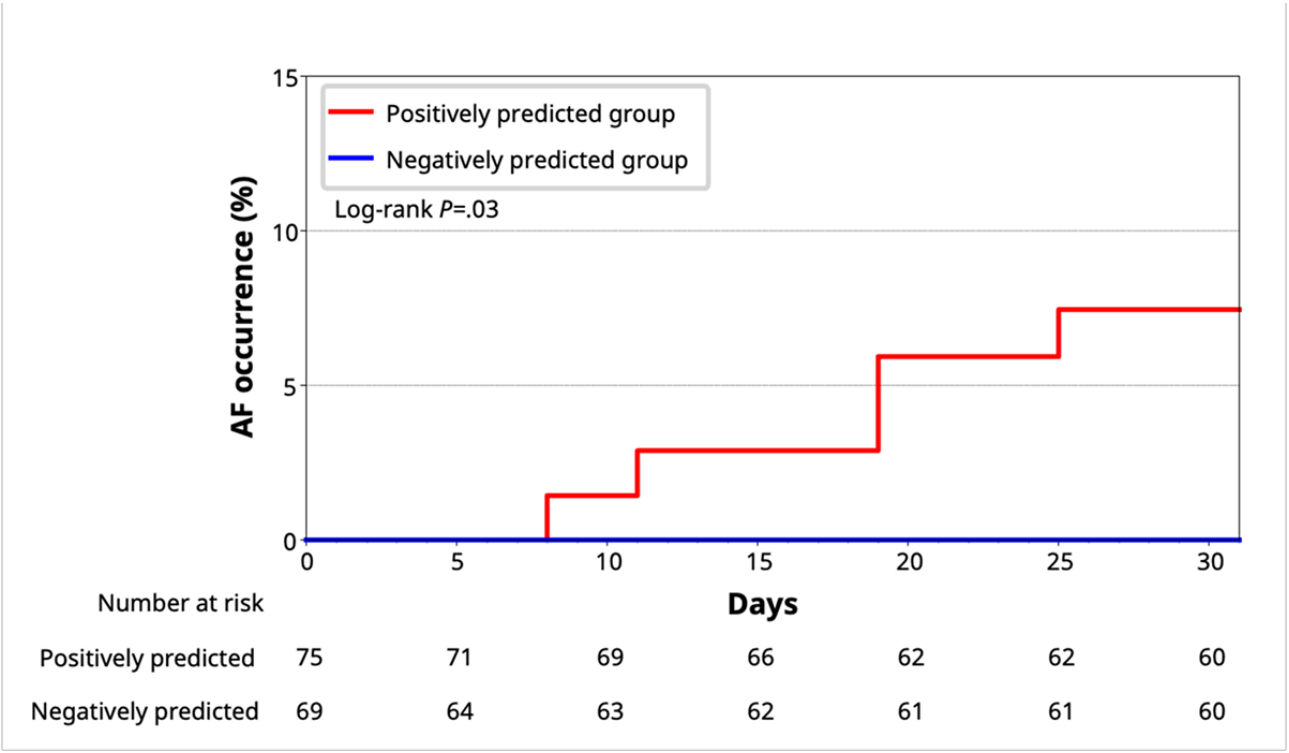
Table . Atrial fibrillation predictive performances under different self-supervised pretraining configurations[a].

Pretraining set	AUROC[b] (95% CI)		
	7-day window	14-day window	31-day window
mECG[c]	0.687 (0.679 - 0.696)	0.643 (0.635 - 0.652)	0.555 (0.548 - 0.562)
MIMIC-IV-ECG	0.764 (0.756 - 0.772)	0.752 (0.745 - 0.760)	0.761 (0.754 - 0.767)
MIMIC-IV-ECG→mECG	0.793 (0.785 - 0.801)	0.785 (0.778 - 0.792)	0.787 (0.781 - 0.793)

[a]Three configurations were considered: (1) mECG dataset alone, (2) MIMIC-IV-ECG alone, and (3) a multistage scheme that first pretrains on MIMIC-IV-ECG and then adapts to mECG data (MIMIC-IV-ECG→mECG). CIs were computed using the DeLong method. Models pretrained with the multistage scheme consistently yielded significantly higher performance (*P*<.001; DeLong test) than those pretrained with single-stage schemes.

[b]AUROC: area under the receiver operating characteristic curve.

[c]mECG: mobile electrocardiogram.



New-Onset AF Incidence Analysis

The limb-lead 31-day prediction model was applied to the external NSR cohort with elevated AF-related risk scores. All 5 new-onset AF episodes were in the positively predicted group (5/75, 6.7%); no events were observed in the negatively predicted group (0/69, 0%). Kaplan-Meier survival curves are shown in Figure 4. A significant difference was observed in cumulative AF incidence between the groups (log-rank *P*=.03). Cox proportional hazards regression on the continuous model output (scaled per 0.1-unit increase) yielded a hazard ratio of 1.49 (95% CI 1.06 - 2.09; *P*=.02). The O/E ratio for the model

XSL•FO
RenderX

outputs was 0.11 (5 observed vs 45.6 expected events), indicating overconfident predictions.

Figure 4. Kaplan-Meier curves for new-onset atrial fibrillation (AF) in the external cohort. The patients were stratified into positively predicted and negatively predicted groups based on the 31-day AF occurrence prediction model applied to each patient's initial normal sinus rhythm recording, which was collected as part of a prospective study. Survival functions were estimated using the Kaplan-Meier method, based on the time to the first AF occurrence over the 31-day follow-up. The difference in survival distributions was assessed using the log-rank test.

Discussion

Model Performance and Comparison With Prior Works

In this study, we developed deep learning models to predict short-term occurrence of AF from mECGs recorded during NSR. Leveraging large-scale, real-world data and a multistage self-supervised pretraining framework, our limb-lead models demonstrated consistent predictive performance across 7-, 14-, and 31-day prediction windows, achieving AUROCs of 0.793, 0.785, and 0.787, respectively. The persistently high performance suggests that our models identify a stable arrhythmogenic substrate rather than transient AF triggers. Notably, these results surpass traditional clinical risk scores, such as the HATCH (AUROC=0.669) and C_2HEST (AUROC=0.69) [31,32], highlighting the potential of AI-driven mECG analysis to significantly improve AF screening. Furthermore, our results are comparable to a prior study that reported an AUROC of 0.760 for paroxysmal AF prediction from NSR mECG within a 30-day window [11]. The model's predictions appeared to rely on physiologically meaningful ECG features: visualization of attention weights showed that the model tended to assign the highest weights to P-wave regions, followed by the QRS complex and T-wave regions (Figure S3 in Multimedia Appendix 1), consistent with the P-wave being the ECG signature of atrial electrical activity and the atrial origin of AF.

Because the dataset included multiple mECG recordings per user, we also evaluated the model's performance at the user level by deriving a single prediction per-user. The user-level AUROC was 0.702 in the 31-day prediction setting, lower than the corresponding recording-level value of 0.787, indicating that recording-level metrics were modestly inflated by within-user contributions. Nevertheless, the user-level performance remained meaningful, supporting the model's utility for per-user risk stratification. These findings further suggest that aggregating multiple recordings over time may enhance the reliability of individual-level predictions, consistent with the model's intended use as a serial, opportunistic monitoring tool rather than a single-measurement diagnostic test.

The limb-lead model achieved PPVs of 0.432, 0.481, and 0.548 for the 7-, 14-, and 31-day prediction windows, respectively. While these values could be viewed as indicating that approximately half of positively flagged individuals would not progress to clinically detected AF within the corresponding window, the monotonic increase in PPV with longer prediction horizons is consistent with an early-alarm interpretation: a subset of individuals flagged as positive but not yet meeting the outcome at 7 days may progress to AF over longer intervals. Reported PPVs in AF prediction studies vary widely depending on cohort prevalence, operating point, and prediction window, generally falling in the 0.2 to 0.7 range across studies [2,10,11]. Deployment thresholds can be tuned toward higher PPV when minimizing false positives is prioritized.

XSL•FO
RenderX

While model performance was consistent across age groups (P=.47), it differed significantly by sex, with a lower AUROC in the female subgroup (P<.001). A similar performance discrepancy between males and females was reported in a previous study of mECG-based AF prediction [11]. This sex-based gap may reflect differences in AF prevalence as well as baseline ECG differences between the sexes. Lower performance was also observed in the wide QRS subgroup with an AUROC of 0.583 (0.489 - 0.677), possibly because QRS-widening conditions (eg, bundle branch block, pre-excitation, ventricular pacing) alter the morphology that the model relies on. Model output should be interpreted with caution in these patients, though the small subgroup size (n=552, 60 AF events) and the wide CI limit its reliability; it should be confirmed in larger datasets.

Significant performance differences were observed between the limb-lead and single-lead models (P<.001 across all time windows), reaffirming the added value of a multilead configuration even in handheld ECG devices [33]. Sensitivity analysis of input lead combinations in Table S7 of Multimedia Appendix 1 showed that this improvement originated primarily from the inclusion of lead II, reflecting the additional independent information provided by this physically measured channel. The other derived limb leads (III, aVR, aVL, and aVF) contributed only a small additional improvement, likely reflecting their role in supporting model optimization rather than providing additional discriminative information.

When compared to models trained on 12-lead ECGs, our results were relatively modest. For instance, a study by Kim et al [6] achieved AUROCs of 0.812, 0.813, and 0.803 for 7-, 14-, and 28-day AF prediction, respectively, from 12-lead NSR recordings. The performance gaps can be attributed to the richer diagnostic information provided by the precordial leads, which are absent in the mobile setup, as well as the inherent variability and noise present in real-world mobile data compared to the clean, standardized data typically collected in a clinical setting [34,35].

Effectiveness of Multistage Self-Supervised Pretraining

The effectiveness of our multistage pretraining framework was confirmed through a stepwise analysis. Models trained exclusively on the mECG database had limited predictive ability, achieving an AUROC of 0.555 in the 31-day prediction setting, indicating the difficulty of detecting subtle changes in waveforms related to AF occurrence. Incorporating a large-scale clinical 12-lead dataset (MIMIC-IV-ECG) for initial pretraining led to a substantial performance gain, increasing the AUROC to 0.761. The best performance was achieved with the full sequential approach, pretraining first on MIMIC-IV-ECG and subsequently on the in-domain mECG data, which yielded a final AUROC of 0.787. This stepwise improvement demonstrates the importance of layered representation learning: building foundational knowledge from a large clinical dataset and then refining it through domain adaptation on the mECG data distribution [17].

Time-to-Event Analysis on an External Cohort

The 31-day prediction model was further evaluated in an external prospective cohort of patients with NSR who had no prior AF, selected on the basis of elevated risk scores (C_2HEST or HATCH ≥4). The observed stratification of new-onset AF risk suggests that the model retains discrimination in this clinically distinct cohort, even within a population already identified as high-risk by the traditional scores. This highlights the potential of the model for hierarchical application, possibly to identify individuals who require the most intensive surveillance. Given the small number of events observed, however, these findings should be interpreted as preliminary and hypothesis-generating rather than as definitive evidence of external generalizability. An adequately powered evaluation in a larger multicenter cohort is warranted to confirm these initial observations. In addition, the model was developed to optimize discrimination, and its continuous output is most appropriately interpreted as a relative risk score for ranking individuals by AF likelihood. The overconfident predictions in the external cohort (O/E ratio=0.11) are consistent with this discrimination-focused training. Because the external cohort consisted of high-risk patients (C_2HEST or HATCH≥4) substantially older than the internal cohort (mean 75.1 vs 51.6 y), this overconfidence may have been further amplified. Where absolute event probabilities are required for clinical communication, standard recalibration procedures (eg, Platt scaling, isotonic regression) can be applied as a final step at deployment without retraining the model [36].

Prevalence of AF in Collected Data

The 17.4% (205/1175) user-level prevalence of AF in the internal cohort is consistent with findings from other large studies of mobile device users and is comparable to the 25.3% (18,661/73,861) prevalence of paroxysmal AF reported by Raghunath et al [11] and the 21.1% (1089/5170) prevalence among patients with a documented history of AF in the work by Kim et al [10]. The high prevalence reflects the user-initiated nature of data collection in real-world settings. Such datasets are often enriched with individuals actively managing a known condition or investigating symptoms, as mobile platforms provide a practical tool for inexpensive, long-term rhythm monitoring necessary for conditions like AF.

The observed 31-day AF incidence of 3.5% (5/144) in the external cohort aligns with previously reported rates in populations with elevated clinical risk. In the REVEAL trial [37], patients with a $CHADS_2$ score of ≥3 or ≥2 with additional risk factors had a 6.2% AF incidence within the first 30 days of monitoring using insertable cardiac devices. Similarly, a retrospective study of patients undergoing 30-day ambulatory ECG monitoring reported a 3.4% (78/2326) incidence of newly diagnosed AF among individuals with a comparable risk profile, with a mean (SD) CHA_2 DS_2 -VASc score of 3.2 (1.8) [38]. Given the nature of our external data, which includes a cohort of individuals with elevated risk scores and follow-up monitoring with self-measured recordings, the observed short-term incidence is clinically plausible. Moreover, the clear separation in AF incidence between positively predicted (5/75, 6.7%) and negatively predicted (0/69, 0%) groups highlights

XSL•FO
RenderX

the model's ability to stratify short-term AF risk even within a population already at elevated risk.

Clinical Implications

This study marks a conceptual shift from the detection of arrhythmic episodes to the estimation of short-term AF risk using only NSR signals. This approach is particularly valuable because early-stage AF is often paroxysmal and asymptomatic, making it difficult to capture on an ECG even when a patient seeks care for symptoms. Our model addresses this diagnostic challenge by identifying the underlying risk from a readily available NSR recording.

In a real-world clinical pathway, the model's output could function as a risk score, enabling clinicians to select high-risk individuals for more extensive diagnostic workups, such as long-term continuous monitoring. Given the observed PPV, however, the model's output should be interpreted as a risk indicator that prompts further evaluation rather than as a standalone AF diagnosis. Interpreting it otherwise could subject patients to unnecessary diagnostic workups, with associated financial costs and anxiety. Because device users access the system for self-monitoring without specialized medical training, they should receive a recommendation to seek follow-up evaluation rather than a definitive diagnostic statement, while clinicians should integrate the model's output with additional clinical information from the electronic medical record to inform subsequent management decisions [39].

Our study was designed from the outset around an mECG device-user population, and the model's intended use is correspondingly scoped to this opportunistic monitoring setting rather than general-population screening. While prior studies have focused on identifying silent AF or predicting long-term risk using clinical 12-lead ECGs [2-8], our model leverages mECGs from a commercially available device, supporting the feasibility of short-term, device-based AF risk stratification outside a clinical environment. The time-to-event analysis in the external cohort provides preliminary evidence of the model's potential as a tool to inform proactive management, although broader generalizability across populations and care settings remains to be established.

Methodological Considerations

We highlight 3 design choices. First, users with ≥5 mECGs per day were excluded to avoid label noise from potentially shared institutional devices, which could not be distinguished from individual frequent monitoring. However, the excluded subset was small (53 users, 0.7%), making the practical impact minimal, even if some clinically relevant individuals (eg, anxious patients monitoring frequently) were inadvertently removed. Second, third-party recordings retained in the unlabeled pretraining set carry a theoretical risk of overlap with validation or test users, but such overlap is improbable, given the small fraction of these users and the fact that AF labels were not used during pretraining. Third, the labeling strategy depends on AF incidence in future recordings, implying that users with more frequent recordings have a higher likelihood of being categorized as AF-positive. The lower user-level performance (Table S8 in Multimedia Appendix 1) compared with recording-level performance suggests that some surveillance bias may exist. Daily measurement frequency, however, did not differ significantly between AF and non-AF groups, suggesting that frequency-driven bias at the group level may be limited.

Limitations and Future Work

We acknowledge several limitations in this study. First, we did not have access to detailed clinical information, such as comorbidities relevant to AF development, race, ethnicity, or socioeconomic status, because such sensitive personal information is not captured by the commercial device used for data acquisition. Their absence precluded both adjustment for potential confounding and direct benchmarking against comorbidity-based clinical risk scores. The model's incremental value over established risk scores, therefore, remains to be determined. Second, outcome labels for the internal cohort relied on device-generated rhythm classifications. Only AF recordings in the test set were reviewed by an electrophysiologist, while the NSR labels and all training and validation set labels were not, resulting in partial verification bias and introducing label noise. Third, in terms of evaluation, the external cohort was insufficient to guarantee adequate statistical power. While the results were significant, they should be interpreted with caution pending confirmation in larger studies. Fourth, the model exhibited sex-based algorithmic bias, with a lower AUROC in the female subgroup, indicating a need for fairness-aware training strategies in future development. Finally, the testing cohorts were limited to users of a commercial mECG device, who likely represent a predominantly Asian population with sufficient purchasing power, potentially introducing selection bias and limiting representation across diverse racial and socioeconomic groups. The exclusion of single lead–only recordings may additionally contribute to this bias if such usage correlates with specific user demographics or behaviors. Furthermore, user-initiated, intermittent recordings may leave asymptomatic AF episodes unrecorded, introducing censoring bias that may inflate apparent specificity and NPV through false-negative labels. Specifically, our labeling convention treated a single non-AF recording within the prediction window as confirmation of AF-free status for the entire window, allowing unrecorded AF episodes to be misclassified as negative.

Future research should address these limitations through several complementary directions. First, integrating model outputs with comorbidity-based clinical risk scores and electronic medical record data may enhance predictive performance and clarify the model's incremental value over established tools. Second, as the mECG dataset continues to grow, temporal split evaluation using more recently accumulated data will enable the assessment of model robustness against potential temporal drift and evolving user behavior patterns. Third, fairness-aware training strategies, such as sex-balanced sampling or class-weighted loss functions, could help mitigate the observed sex-based performance disparity. Finally, validation in larger and more diverse external cohorts that span racial, ethnic, and socioeconomic backgrounds, ideally with denser monitoring modalities such as continuous patch–based ECG or longer-term Holter recordings, would confirm generalizability, support model fairness across populations, and characterize the impact of user-initiated intermittent sampling and surveillance bias.

RenderX

Conclusions

In conclusion, this study successfully developed and validated deep learning models that can predict the short-term occurrence of AF from a single NSR recording obtained with a handheld mECG device. Our models demonstrated robust and consistent predictive performance across 7-, 14-, and 31-day windows and successfully stratified new-onset AF risk in an independent clinical cohort. The effectiveness of a multistage pretraining framework, which leveraged both large-scale clinical and real-world mECG data, was critical to these achievements. These findings highlight the feasibility of using AI-powered mECG analysis for opportunistic, remote screening, shifting the paradigm from arrhythmia detection to proactive risk stratification.

The authors have no generative AI use to disclose. Only Grammarly's basic grammar and spelling check function (not a generative AI feature) was used. No generative AI tools were used to generate or substantially revise any manuscript content.

Funding

This research was supported by a grant from the Korea Health Technology R&D Project through the Korea Health Industry Development Institute, funded by the Ministry of Health and Welfare, Republic of Korea (grant: RS-2023-00265466); a grant (BCRI25041) from the Chonnam National University Hospital Biomedical Research Institute; and, in part, a grant from the Gwangju AI Healthcare Ecosystem Establishment Project funded by the Ministry of Science and ICT (MSIT, Korea) Balanced National Development Account (Project: H0401-26-1001). The funders played no role in the study design; data collection, analysis, or interpretation of the data; or the writing of this manuscript.

Data Availability

The mobile electrocardiogram dataset generated and analyzed during this study is not publicly available due to privacy and ethical restrictions stipulated by the Institutional Review Boards of Chonnam National University Hospital and Hallym University Dongtan Sacred Heart Hospital. However, it is available from the corresponding author upon reasonable request. The MIMIC-IV-ECG dataset used for pretraining in this study is publicly available on the PhysioNet repository [18]. The code implementations for this study, including the model development, evaluation protocol, and statistical analyses, are publicly available on Zenodo [40].

Abstract

Background: Online health care consultation provides patients with broad access to physicians, but also presents the challenge of selecting a suitable doctor in the absence of triage guidance. Patients have multifaceted needs, prioritizing not only recommendation accuracy but also physician service quality, and diversity of physician expertise. Furthermore, the sparsity of patient interaction data intensifies the difficulty of providing balanced and effective recommendations.

Objective: This study aims to develop a multiobjective physician recommendation method that simultaneously optimizes recommendation accuracy, service quality, and diversity of physician expertise while addressing the data sparsity challenge inherent in online health care platforms.

Methods: We propose dynamic graph–based bacteria colony optimization for multiobjective physician recommendation (DyGMO-PR), a dynamic graph–based multiobjective optimization method. It integrates bacterial colony optimization with an evolving physician relationship graph. Our approach features a novel graph–based encoding scheme, a chemotaxis-inspired graph-walking strategy for stable search, and a dynamic graph evolution mechanism that learns implicit physician relationships to enhance recommendation quality under sparse data conditions.

Results: Evaluation on a real-world dataset comprising 10,493 consultation records from 1256 patients and 1377 physicians demonstrates the effectiveness of DyGMO-PR. Our method consistently outperforms 6 state-of-the-art multiobjective recommendation algorithms. Using a recommendation list length of 6 as an example, DyGMO-PR achieves an accuracy of 0.876, a service quality of 0.873, and a diversity of 0.720, surpassing the best-performing baseline by 7.4%, 3.1%, and 8.1%, respectively. DyGMO-PR also attains the highest hypervolume value (0.696 at K=6) and the highest recall (0.380 at K=6). Case studies and graph analysis further demonstrate the method's effectiveness in generating interpretable and balanced recommendation lists.

Conclusions: DyGMO-PR offers an effective solution for multiobjective physician recommendation. It provides a flexible and practical foundation for building more responsive and reliable recommender systems in online health care.

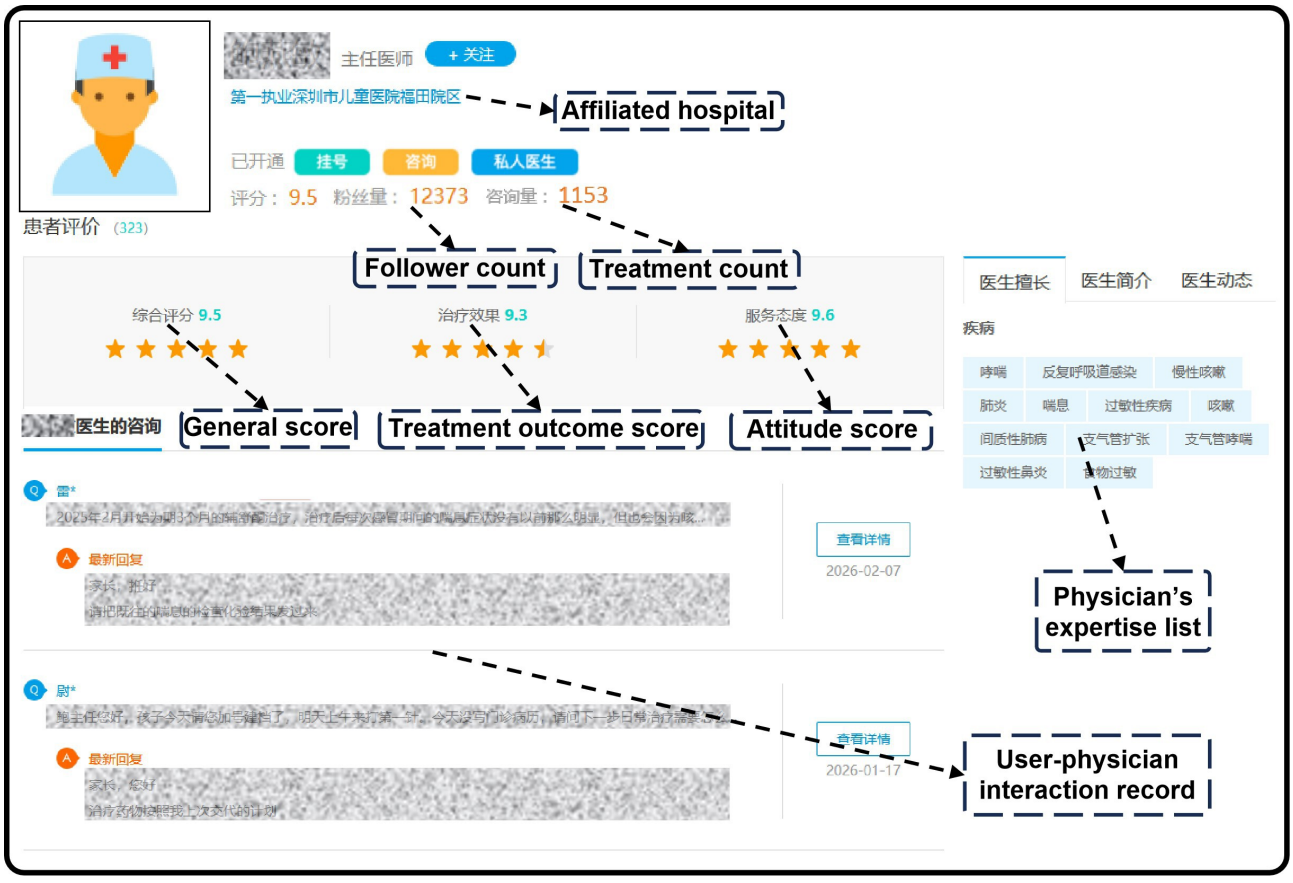
KEYWORDS

physician recommender system; multiobjective optimization; dynamic physician graph; data sparsity; online health care

Introduction

Online health care consultation services have emerged as one of the most promising solutions for mitigating health disparities and improving access to health care services [1,2]. Notably, China, one of the global leaders in online health care, has upheld it as a national health priority to reduce health care costs and improve access in rural areas [3]. In the United States, investors view online health care consultation as the new backbone of the future health care system [4]. The European Union has also embraced online health care, integrating it into its Regional Digital Health Action Plan [5].

One notable feature of online health care consultation is its ability to overcome geographical and time constraints, which encourages more medical professionals to provide services online [6]. For instance, HaoDaiFu, one of China's largest online health platforms, provides access to over 910,000 physicians. Another feature of online health care consultations is that patients typically do not have access to triage services commonly available in offline health care settings. This challenge is further compounded in certain countries and regions (eg, China) where patients do not have a primary care physician and must directly choose a specialist. For individuals with limited medical knowledge, even after identifying the appropriate type of specialist, the sheer number of available physicians remains overwhelming [7]. Furthermore, patients may have diverse preferences and expectations. Without an effective matching mechanism, discrepancies between patient expectations and the services provided by physicians can lead to dissatisfaction, delay



XSL•FO
RenderX

timely treatment, and adversely affect the overall reputation of online health care platforms [8,9].

Physician recommender systems are crucial techniques that help patients receive personalized physician recommendations that align with their preferences [10]. Especially in the online context, these systems play a crucial role in reducing the time and effort patients spend searching for physicians [11]. They are essential for improving patient satisfaction, clinical outcomes, and overall efficiency within online health care platforms [12].

Most existing physician recommender systems learn from patients' explicit descriptions and historical consultation records to perform patient-physician matching [13]. However, they often fail to account for the full complexity of patient preferences. In the online context, patients' needs extend beyond merely identifying a physician with relevant expertise. As depicted in Figure 1 [14], physician information displayed in an online consultation platform is multifaceted, and all this information collectively influences patients' selection choices. Therefore, besides the recommendation accuracy goal in conventional system design, we integrate 2 more objectives in our recommendation framework, including physician service quality (derived from the physician's attitude score, treatment outcome score, affiliated hospital tier level, average reply time, etc) and expertise diversity (derived from the physician's expertise list, estimating the physician's capability in tackling patients' multidisciplinary inquiries). The diversity of physician expertise is particularly valuable when patients are uncertain about their condition or lack clear medical knowledge [15]. It should be noted that these objectives may conflict with one another, making it challenging to simultaneously satisfy all of them in a single recommendation list.

Figure 1. Physician information from an online consultation platform [14].

Early physician recommender systems primarily focused on improving recommendation accuracy as a single objective. They typically rely on historical patient-physician interaction data, using collaborative filtering or deep learning models to estimate the alignment between physicians and patient needs. For instance, Zheng et al [16] and Lu et al [17] combined Bidirectional Encoder Representations from Transformers (BERT) with attention mechanisms to learn representation vectors from patient-physician dialogues and profiles. Then they generate recommendations by computing matching scores. To alleviate the cold-start problem caused by data sparsity, Mondal et al [18] constructed a multilayer graph database to model patient-physician trust relationships. Zhang and Li [13] integrated medical knowledge graphs with deep networks to enhance recommendation reliability. Although these studies have effectively improved accuracy, they remain limited to single-objective optimization. These accuracy-oriented studies fail to address the multidimensional needs of patients in online health care consultation scenarios.

In recent years, some researchers have begun to explore multiobjective physician recommendation in online health care settings. Wang et al [19] considered recommendation accuracy and hospital diversity as optimization objectives. They use matrix factorization to estimate physician competency and use heuristic algorithms to enhance diversity during the ranking

XSL•FO
RenderX

stage. Fei and Li [20] used the entropy-weighted method to fuse symptom matching, professional qualifications, patient preferences, and resource equity into a single score for ranking in their system design. Zhao et al [21] maximized patient satisfaction and physician disease-type preferences by adopting linear weighting to convert the multiobjective problem into a single-objective model. Cui et al [22] estimated the uncertainty of matching scores and ranked physicians based on the lower bounds of confidence intervals, thereby indirectly balancing accuracy and risk. Although these studies have broadened the objective dimensions of physician recommendation, they still convert multiobjective problems into a single composite indicator or ranking and therefore fail to capture the inherent trade-offs among conflicting objectives.

Multiobjective evolutionary algorithms can generate a Pareto front that offers decision makers a set of nondominated solutions that balance multiple conflicting objectives [23,24]. These algorithms have been successfully applied in recommender systems. For instance, Jain et al [25] enhanced nondominated sorting genetic algorithm II (NSGA-II) for collaborative filtering, and Geng et al [26] developed a trajectory-reinforced bacterial colony optimization (BCO) approach for multiobjective recommendation. However, their application to online physician recommendations remains limited. A significant challenge of physician recommender system design in an online consultation context is the inherent sparsity of patient health records. Since online consultations typically serve as a supplement to in-person health care, they represent only a small fraction of a patient's medical history [27]. Thus, the historical patient-physician interactions only reveal partial patient preferences. The sparse solution space may lead to poor convergence and suboptimal performance. How to achieve multiobjective recommendations that balance patients' diverse needs under such sparse data conditions thus remains an underexplored research challenge.

To address the research gap identified above, this study seeks to answer the following research question (RQ):

RQ1: How can a multiobjective optimization method be developed to simultaneously optimize recommendation accuracy, physician service quality, and diversity of physician expertise?

RQ2: How to develop a graph-based optimization framework that mitigates data sparsity in patient-physician interactions and provides interpretable guidance for decision-making?

To address these challenges, this study proposes a novel approach named dynamic graph–based bacteria colony optimization for multiobjective physician recommendation (DyGMO-PR). The main contributions of this study are 2-fold.

First, we introduce a novel multiobjective optimization method for physician recommendation for online health care consultations. This method leverages an evolutionary algorithm specifically designed to address the issue of sparse patient data in online health care consultations. The objective is to achieve an optimal balance among 3 critical goals, including recommendation accuracy, physician service quality, and the diversity of physician specialties in the recommendation list. The strength of our approach lies in its ability to incorporate multiple criteria, enabling a more balanced and comprehensive physician recommendation process.

Second, within this method (1) we develop a physician relationship graph-based encoding technique that effectively captures implicit relationships between physicians, thereby enhancing recommendation quality even with limited patient data. This approach addresses the challenge of sparse patient records; (2) we propose a graph walking–based search and graph evolving method to improve the stability of the heuristic optimization process. This method dynamically updates the physician graph structure, allowing the system to evolve and adapt, resulting in enhanced recommendation performance; and (3) by integrating these techniques with a multiobjective bacteria colony optimization algorithm, we create a novel multiobjective recommendation system that offers a new approach to managing the complexities of sparse patient data and patients' multidimensional needs.

Extensive experiments on a real-world physician recommendation dataset are conducted to evaluate the performance of our proposed method. The results demonstrate that our method outperforms existing state-of-the-art methods. Furthermore, we conducted case studies to validate the effectiveness of the proposed method in improving recommendation performance and enhancing explainability, thereby providing actionable insights for both patients and online consultation platforms.

Methods

Problem Formulation

We formalize the physician recommendation problem as a discrete multiobjective optimization problem. Let U={u1,u2,...,uM} denote the set of patients on an online health care consultation platform, and P={p1,p2,...,pN} denote the set of physicians. For each patient $u \in U$, we have the physicians they previously selected on the platform, denoted by a list of physicians Pu={pu1,pu2,..,pul}. Additionally, each physician is associated with a set of diseases they specialize in treating S={s1,s2,...,sD}, a hospital tier level $q^{hospital}$, an average physician service score q^{score}, and the number of endorsements (thumbs-up) received from colleagues $q^{colleague}$. Our objective is to generate a list of physicians for a target patient u that achieves Pareto-optimal performance across 3 key objectives, namely prediction accuracy, physician service quality, and diversity in the diseases treated by the physicians. The formal definition of the recommendation problem and Pareto dominance rule are provided below.

Definition 1

The recommendation problem with 3 objectives and K decision variables is given by

minimize F(x)={f1(x),f2(x),f3(x)}

where x is the decision vector and $F(x)$ is the objective vector.

XSL•FO
RenderX

Definition 2

Let x_A and x_B denote 2 decision vectors in the solution space. x_A dominates x_B if and only if

$$\forall i=1,2,3:fi(xA)\leq fi(xB)\exists i=1,2,3:fi(xA)<fi(xB)$$

The Pareto optimal front consists of nondominated decision vectors in the solution space. For each solution on the Pareto front, no objective can be further improved without compromising others. Therefore, the Pareto front provides a set of optimal solutions, each offering a different trade-off between the 3 objectives, thus presenting a wide range of performance options for the physician recommendation task.

Optimization Objectives

This work simultaneously optimizes recommendation accuracy, physician service quality, and diversity of physicians' areas of expertise. It is important to note that these different objectives can vary depending on the specific recommendation system. In the context of patients selecting physicians on an online health care consultation platform, we defined our 3 objectives based on the goals that patients commonly consider. Moreover, these 3 objectives often conflict with one another.

The accuracy objective ensures the accuracy of recommendations. It uses the widely recognized metric for recommendation systems [28], which compares the recommendation results with patients' ratings while accounting for both the relevance and ranking position of physicians:

$$(1)DCG=\sum i=1Kru,ilog2(i+1)$$

$$(2)NDCG=DCGIDCG$$

where K represents the number of physicians included in the recommendation list, and $r_{u,i}$ represents the predicted rating of i^{th} physician by user u. Ideal discounted cumulative gain (IDCG) represents the ideal rating of discounted cumulative gain (DCG), which reflects the highest value when the most relevant physicians are ranked at the top. The $r_{u,i}$ is defined based on patients' historical consultations. Specifically, for physicians with whom a user has interacted, we set $r_{u,i}=1$ whereas for unrated physicians, we used extremely simple graph contrastive learning (XSimGCL) [29] to estimate the missing ratings. In our work, XSimGCL is trained using the historical interactions between users and physicians. XSimGCL is a popular contrastive learning method for recommendation. It has demonstrated superior performance in both recommendation accuracy and training efficiency, particularly on highly sparse datasets.

Given similarly accurate recommendations, patients generally prefer to choose doctors who offer higher-quality services. The measurement of physician service quality is a composite index that incorporates the physician service scores, the tier level of the physician's affiliated hospital, and endorsements from colleagues.

Physician service scores include the average reply time score, attitude score, treatment quality score, productivity score, and comment score, all of which are recorded by online health care consultation platforms.

The tier level of the physician's affiliated hospital is used to reflect service quality because our data source is from a platform based in China, where the hospital's tier generally indicates the physician's level of expertise. Physicians in higher-tier hospitals are often associated with higher service quality. In China, hospitals are classified into 4 tiers (0-3), with level 3 representing the highest service quality.

The endorsements (thumbs-up) from colleagues reflect the outcomes of peer reviews and can indirectly indicate the quality of a physician's services.

For a recommendation list with K physicians, we design a score to calculate the physician service quality:

$$(3)Quality=1K(\sum i=1K(qihospital+qiscore+qicolleague))$$

where $q_i^{hospital}$, q_i^{score}, and $q_i^{colleague}$ are normalized. This comprehensive measure provides a good representation of a physician's service quality.

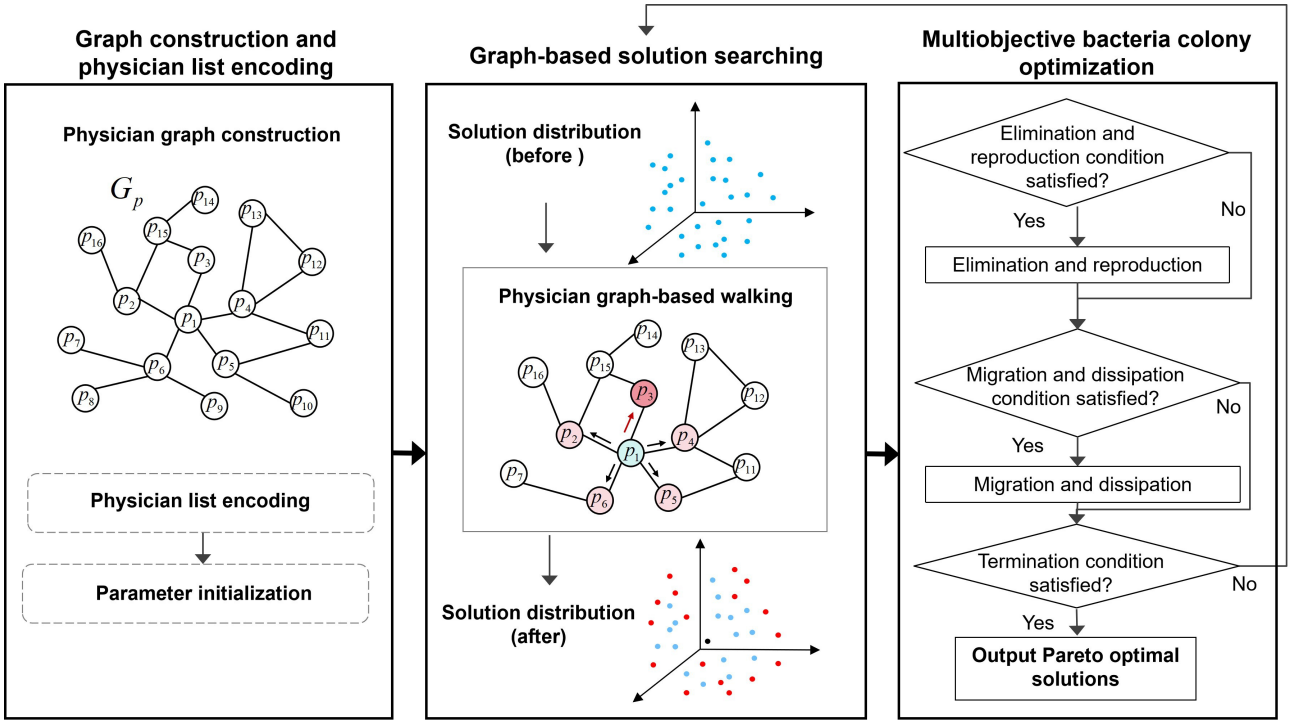
If the accuracy of recommendations and the quality of the physicians' services are comparable, the diversity of diseases in which the recommended physicians specialize can further enhance the likelihood of successful recommendations. In our research context, patients, as nonexperts, must independently select their physician without the assistance of triage or referral services. When presenting a list of recommendations, ensuring that the physicians are relevant to the patient's condition while also maximizing the breadth of diseases they are skilled at treating can significantly enhance the patient's ability to choose from a broader range of options. This, in turn, increases the likelihood of a successful recommendation.

For a recommendation list with K physicians, the diversity of physician expertise is measured as

$$(4)Disease_diversity=sKc*stop_l$$

where $|^SK|$ represents the total number of diseases treated by the recommended K physicians, $|^Stop_l|$ denotes the total number of diseases treated by the top l most skilled physicians, which is used to normalize the diversity measure, and c is a constant that sets the range of diversity measure.

Model Development



We propose a novel approach, DyGMO-PR, which incorporates several key algorithmic innovations. BCO [30] is a bio-inspired algorithm known for its strong global search capability and fast convergence in multiobjective tasks [26,31,32]. Our method introduces a multiobjective optimization framework based on BCO that simultaneously balances recommendation accuracy, physician service quality, and the diversity of physician expertise in the recommendation results. Within this framework, we present two novel algorithmic components that distinguish our approach from prior studies: (1) We construct a physician graph and propose a new graph-based encoding and updating method for physician recommendation lists. This technique enhances the stability of both heuristic and stochastic optimization processes, leading to more robust recommendation outcomes. Furthermore, this encoding strategy serves as the foundation for the subsequent dynamic graph search. (2) We develop a dynamic graph evolution mechanism that adaptively refines the

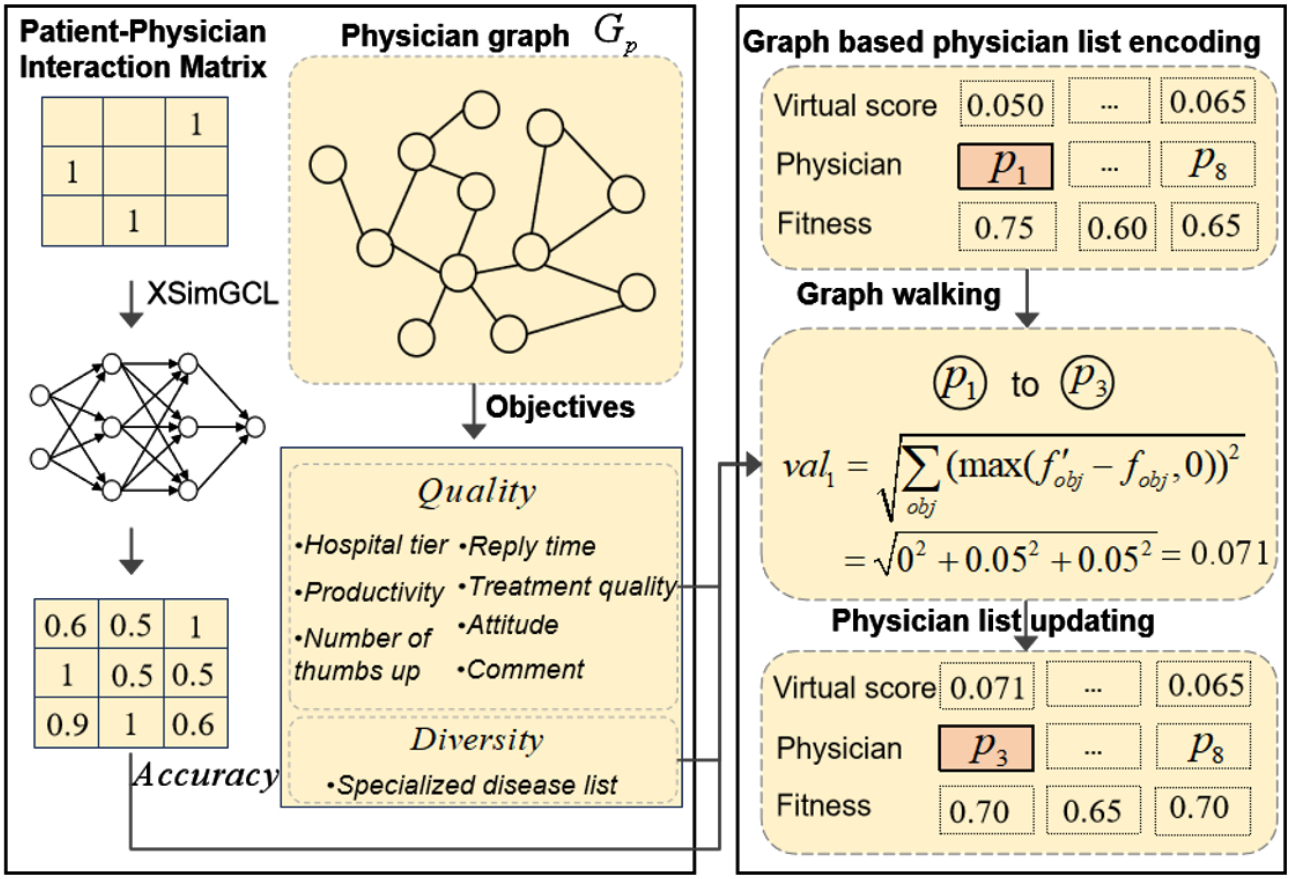
XSL•FO
RenderX

physician graph structure by uncovering implicit relationships among physicians. This enables the identification of high-quality recommendation candidates beyond those explicitly known to the system.

The details of the research design are elaborated below. Figure 2 provides an overview of the proposed DyGMO-PR framework.

Figure 2. The dynamic graph–based bacteria colony optimization for multiobjective physician recommendation (DyGMO-PR) framework; P: physician.

Physician Graph Construction and Physician List Encoding



DyGMO-PR first constructs a physician graph to represent the relationships between physicians and proposes a novel method for encoding physician lists, where each list serves as a candidate for physician recommendation.

The physician graph, G_p=(P,E), is defined as follows: each node P represents a physician, and an edge e exists between 2 physicians if they share expertise in treating at least one disease. The graph G_p captures relationships in physicians' areas of medical expertise, and the edges serve as heuristic pathways for identifying candidate physicians.

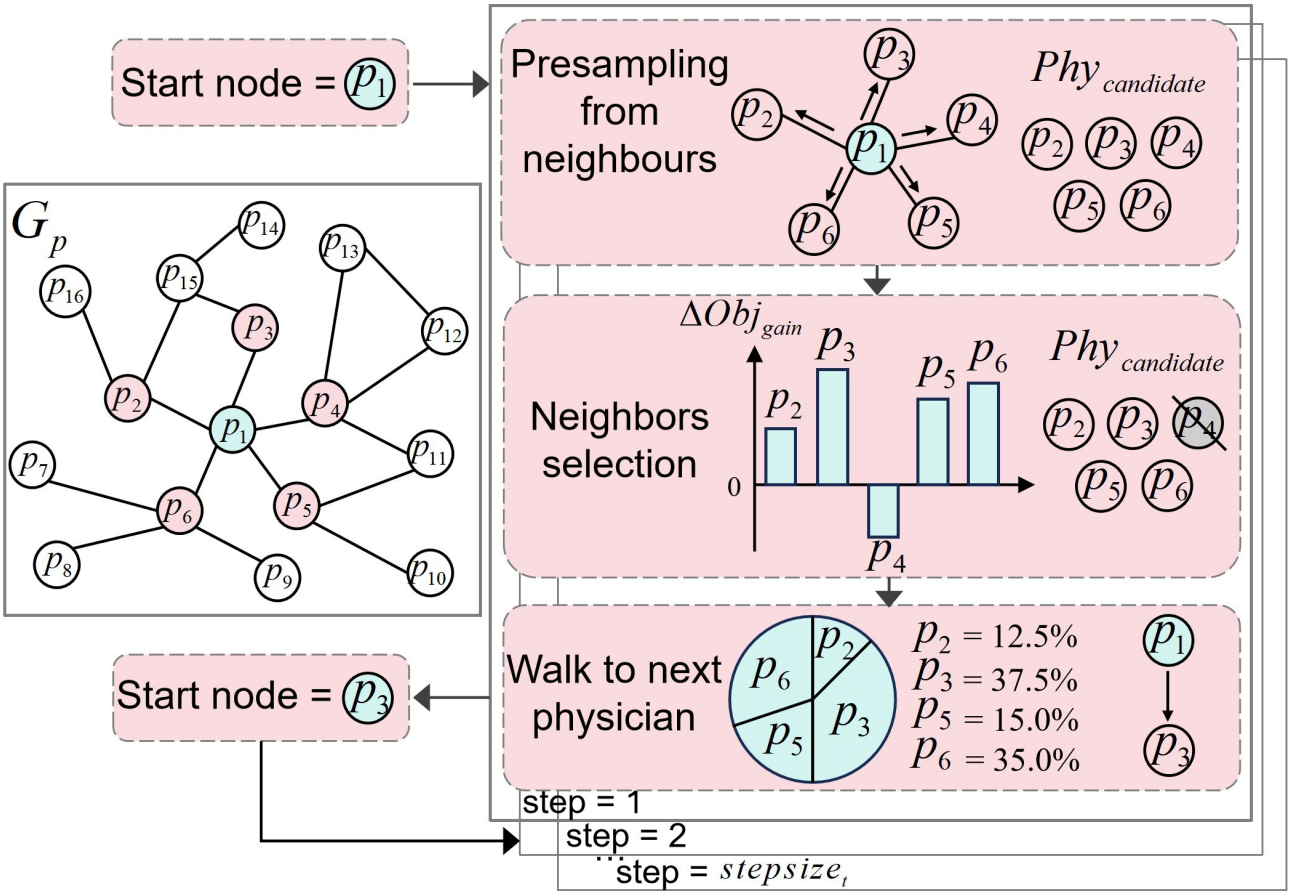
Based on G_p, we propose a new physician list coding scheme in the bacteria colony algorithm, as illustrated in Figure 3. Each bacterium $bacteria_{u,j}$ (j^{th} bacteria for user u) represents a physician recommendation list for recommendation results. The coding of $bacteria_{u,j}$ contains three key elements: (1) a list of recommended physicians $\{p_1, ...,p_K\}$, (2) a set of virtual scores measuring individual physician contributions to recommendation objectives $\{val_1, ...,val_K\}$, and (3) fitness values corresponding to the 3 recommendation objectives: $Accuracy_{u,j}$, $Quality_{u,j}$, and $Diversity_{u,j}$. The fitness values are computed using Equations 1-4. A physician's virtual score quantifies their contribution to the overall fitness of the bacterium (see Equation 5). This virtual score determines the probability (see Equation 6) of their replacement during the bacterial chemotaxis process (see next section).

XSL•FO
RenderX

Figure 3. Graph-based physician list encoding and updating. P: physician; XSimGCL: extremely simple graph contrastive learning.

(5)vali=∑obj∈ {accuracy,quality,diversity}(max(f′obj−fobj,0))2

(6)probreplace=1−vali∑i=1K(1−vali)



f'_{obj} in Equation 5 represents the fitness value of the current physician list after graph walking to the i^{th} physician node and f_{obj} is the fitness value before the graph walking (see the next section) in the previous round of searching. The $prob_{replace}$ is lower for physicians with higher service quality, better alignment with patient preferences, and greater contribution to the diversity of diseases represented in the physician list. This graph-based coding scheme enables the bacteria colony algorithm to search along the graph paths more effectively and converge more rapidly toward the Pareto front.

Physician Graph Walking Inspired by Bacteria Chemotaxis

The second component (see Figure 4) is a graph-walking technique inspired by bacterial chemotaxis. In graph theory, graph walking refers to traversing a sequence of nodes *P* (ie, physicians), where consecutive nodes are connected by an edge *e*. Our proposed method includes a presampling and node-searching strategy to identify the most suitable physician candidate within the physician graph. This strategy ensures consistent performance improvements during traversal. We further design a physician relationship learning and graph structure evolution strategy. Edges between physicians are added or removed based on their contribution to recommendation performance. The updated graph is then fed back into the first component for subsequent iterations.

XSL•FO
RenderX

Figure 4. Physician graph walking–based bacteria chemotaxis. P: physician.

Formally, the physician graph G_p=(P,E) defines the solution space for physician recommendation and serves as the foundation for graph walking. For a bacterium $bacteria_{u,j}$, a physician Pi is selected from its physician list according to the physician's virtual score (Equation 6). The selected physician becomes the starting point for the graph-walking process. Subsequently, we introduce a neighbor node selection method that leverages presampling. Specifically, a walk step size is set for each random graph walk process. During each random walk, the neighboring physician nodes are included in a candidate list $Phy_{candidate}$={p_1, ...,p_{num}}. The objective gain contributed by each physician on the candidate list is then calculated. Assuming that p_i is replaced by physician p_{can} in $Phy_{candidate}$, the objective gain from this replacement is:

(7)Δobjcan=max{objcan−obji,0}

(8)gaincan=ΔobjcanΣcan=1PhycandidateΔobjcan

where obj_{can} is the objective function value, randomly chosen from *Accuracy*, *Quality*, and *Diversity*, for the updated physician recommendation list with p_{can}. The larger $gain_{can}$, the higher the probability that p_{can} will be selected to update the recommendation list. The algorithm for this graph-walking method, inspired by bacterial chemotaxis, is presented in Figure 4 (the pseudo-code is shown in Multimedia Appendix 1).

For bacterium $bacteria_{u,j}$, the chemotaxis process performs a random walk on G_p to update the physicians in its recommendation list. After each random walk, the bacterium updates its virtual score according to Equation 5. The extent of the random walk is controlled by the step size that is initially set as a constant. As the algorithm converges, step size gradually decreases to narrow the exploration scope, thereby enhancing the use of historical exploration information. This approach enables the bacterium to explore a wide range of recommendation combinations during the early iterations, while in later stages, a smaller parameter value helps accelerate the algorithm's convergence. The step size is updated as below:

(9)stepsizet=S0∗(1−tT)2

where t represents the current iteration number, $stepsize_t$ represents the step size of the iteration t, S_0 represents the initial step size, T represents the maximum iterations. The final value is calculated by taking the ceiling of the computed result.

After the chemotaxis process, a trajectory reinforcement strategy is used to track the bacteria positions and store the nondominated new solutions using a trajectory document [26]. By merging the bacteria in the trajectory document with the current bacteria positions, the global exploration ability and convergence efficiency of the optimization algorithm are enhanced. The nondominated bacteria positions in the merged population are retained for subsequent operations.

Bacteria Elimination, Reproduction, Migration, and Dissipation

The third component involves bacterial elimination, reproduction, migration, and dissipation. These operations help preserve a high-quality bacteria population (ie, high-quality

XSL•FO
RenderX

physician lists for the recommendation task) and facilitate the selection of Pareto-optimal outcomes.

Specifically, when the current bacteria population size exceeds a predefined size *Pop*, bacteria with the smallest crowding distances are removed until the population size equals *Pop*. Conversely, if the current bacteria population size is smaller than *Pop*, bacteria with the largest crowding distance will be reproduced to expand the population size to *Pop*. These operations allow the proposed method to search extensively in the solution space in order to find the optimal solution areas.

Formally, a crowding distance measure is used to evaluate the closeness of a bacteria to its neighbors in the 3D objective space:

$$(10) cro_dis=\sum b\in N\sum obj\in\{accuracy,quality,diversity\}(objb-obju,j)2$$

where N contains the 2 nearest neighbor bacteria of $bacteria_{u,j}$. Bacteria with smaller crowding distance are located in denser environments and are more likely to be eliminated to maintain population diversity.

Dynamic Physician Relationship Learning and Graph Evolving

The last component is designed for dynamic physician relationship learning. We propose a new physician relationship learning and graph evolution mechanism to capture the dynamics of inter-physician relationships.

When constructing the physician graph $G_p=(P,E)$, an edge e is established between 2 physicians if they share common expertise as indicated in their individual profiles. However, this approach may not sufficiently capture the complexity of implicit associations among physicians. For example, a pediatrician and a neurologist are both specialized in treating cephalgia according to their personal profiles, and an edge, e, exists between them in the initial physician graph. However, their target patient populations may differ significantly. Therefore, relying solely on the existing edges in G_p for recommendations may limit the framework performance.

To address this, we allow the graph edges in G_p to dynamically evolve and learn valuable node connections throughout the recommendation process. Specifically, let $bacteria_{u,j}$ and $bacteria_{u,j+stepsize}$ represent the bacterium before and after a graph walking, respectively. Each bacterium represents a physician recommendation list. The graph-walking mechanism traverses the physician graph, allowing a bacterium to replace a physician in its current list with an adjacent node. Let $obj_{p_accracy}$, $obj_{p_quality}$, and $obj_{p_diversity}$ denote the objective gains in accuracy, service quality, and diversity resulting from this graph walk. The graph edge between $bacteria_{u,j}$ and $bacteria_{u,j+stepsize}$ will be updated according to the following rules:

- Rule 1: if $obj_{p_accracy}>0$, $obj_{p_quality}>0$, $obj_{p_diversity}>0$, and no directed edge from *PA* to *PB* exists, this directed edge is added
- Rule 2: if $obj_{p_accracy}>0$, $obj_{p_quality}>0$, $obj_{p_diversity}>0$, and a directed edge from *PA* to *PB* exists, this directed edge is removed
- Rule 3: if there are both positive and negative objective gains among $obj_{p_accracy}$, $obj_{p_quality}$, and $obj_{p_diversity}$, the graph structure remains the same.

It is important to note that these new edge updates are directional. While the initial graph is undirected, the evolutionary process captures asymmetric improvement in objectives when walking from *PA* to *PB*. Therefore, Rule 1 adds a directed edge from *PA* to *PB* to reinforce the productive direction, and Rule 2 removes the directed edge *PB* to eliminate unproductive direction. This design ensures that the evolving graph structure reflects the directional value of physician relationships in the context of multiobjective optimization.

The updating rules refine the physician graph by evaluating whether adding or removing an edge improves the 3 objectives. This process forms the basis for the evolving physician graph G_p. As the graph continuously evolves in alignment with the recommendation goal, it becomes increasingly refined and better suited to generating more effective recommendation results.

Experiment Design

Dataset

The dataset used in this study is derived from a real-world online consultation platform. We retain only patients with at least 5 historical consultation records, thereby reducing noise from patients with limited medical knowledge who cannot always choose the most appropriate physician and thus improving the stability and reliability of model training. After this filtering, the final dataset comprises 10,493 online consultation instances, each representing an online physician-patient interaction. The dataset also contains background information about physicians (with private information anonymized), including their service quality scores, areas of disease specialization, professional titles, genders, and affiliated hospitals. These consultation records are organized chronologically. The dataset exhibits a sparsity rate of 99.39%, suggesting a high likelihood of encountering the cold start problem in recommendation tasks and highlighting the challenging nature of physician recommendation in real-world online consultation scenarios.

This study simultaneously optimizes 3 recommendation objectives, including accuracy, service quality, and diversity of physicians' specialized diseases. Service quality and diversity can be directly computed from physicians' static information (see Equations 3 and 4). Accuracy requires the user-physician rating $r_{u,i}$ (see Euqation 1). For physicians with whom a user has no interaction history, the rating is not directly observable and is predicted by the XSimGCL [28]. To train XSimGCL, we sort each patient's interaction records chronologically and use the last 20% as the testing set, with the first 80% as the training set. To ensure a valid evaluation, we remove from the testing set any interactions involving physicians who did not appear in the training set. This ensures that all users and physicians in the testing set have been observed during training. The final training set comprises 9178 interactions, and the testing set comprises 1315 interactions. The physician relationship graph is also constructed using the disease specialization information of these 1377 physicians.

XSL•FO
RenderX

Benchmark Methods

We compare our proposed method with 6 state-of-the-art multiobjective optimization-based recommendation methods. Below is a brief description of these methods.

- NSGA-II [33]: it uses nondominated sorting and crowding distance to evaluate and select solutions, aiming to provide high-quality Pareto front solutions. It is widely used in various multiobjective optimization problems.
- Multiobjective particle swarm optimization (MOPSO) [34]: it simulates particle movement in the solution space and uses nondominated sorting and an external archive to maintain solution diversity. It is known for its strong global search and convergence capabilities.
- Multiobjective firefly algorithm (MOFA) [35]: it is based on the firefly algorithm, which simulates the light-emitting behavior of fireflies to guide the search process and balances solution quality and diversity by adjusting light intensity.
- Strength Pareto evolutionary algorithm 2 (SPEA2) [36]: it is based on strength Pareto optimization and evaluates solutions using strength metrics and maintains an elite archive of nondominated solutions. Density estimation is used to ensure solution diversity.
- Multiobjective evolutionary algorithm based on decomposition (MOEA/D) [37]: it decomposes the recommendation problem into multiple single-objective subproblems using different weight vectors for trade-offs. It optimizes these subproblems collaboratively, which helps in effectively approximating the Pareto front.
- Trajectory reinforcement-based multiobjective bacterial colony optimization (TRMOBCO) [26]: it proposes an improved multiobjective BCO algorithm that integrates trajectory reinforcement–based chemotaxis, elimination and reproduction based on spatial dependence, and energy-based adaptive migration.

In our evaluations, to ensure fairness, the optimization objectives of these benchmarks are aligned with those of our proposed method, including accuracy, service quality, and diversity in the diseases that physicians specialize in treating within the recommendation results, as defined by Equations (2)-(4).

Performance Measurement

We first evaluate the performance of Pareto-optimal solutions. Following the evaluation metrics commonly used in existing studies, we assess and compare performance based on the mean, SE, and maximum (max) values of the objective functions across the Pareto-optimal solutions.

Additionally, to comprehensively assess the search capability of our method and benchmarks, we adopt the hypervolume metric [38], which measures the volume of the space dominated by the obtained Pareto front relative to a reference point. Hypervolume reflects both the convergence and diversity of the solution set, with a larger value indicating that the algorithm finds a broader and better trade-off among the 3 objectives.

Moreover, in online health care consultation, patients often return to the same physician due to their long-term health care needs and preference for consistent service. Therefore, beyond optimizing the 3 objectives, it is also critical for the recommendation system to retrieve physicians that patients have previously consulted. To assess this capability, we report the Recall@*K* metric, which measures the proportion of historically consulted physicians that appear in the top-*K* recommendation list.

Parameter Setting

The parameter settings for the benchmarks are tuned and reported in Multimedia Appendix 2. The length of the recommendation list *K* is set to vary over the range [6,8,10,12,14,16,18,20]. For comparison, the top 50% of solution sets obtained from each method were selected. Each method was executed 5 times, and the average performance was calculated to ensure stability.

Ethical Considerations

This study was conducted in compliance with relevant national data protection regulations through localized data processing on the source institution's server, strict anonymization, and access control protocols. The use of online consultation data was approved by the collaborative online consultation service platform and Shenzhen University Ethics Committee (approval number PN-202500098).

Results

Overview

Table 1 presents the performance comparison between our proposed method and all benchmarks for the online health care physician recommendation task, evaluated across various recommendation list lengths (*K* values). The bolded values highlight the best results. Among all the comparison methods, DyGMO-PR achieves the highest mean accuracy, mean service quality, and mean diversity, as well as the highest max accuracy, max service quality, and max diversity for these 3 objectives across different values of *K* values. These results indicate that DyGMO-PR consistently generates recommendation results with superior average performance in terms of the 3 recommendation objectives. Furthermore, DyGMO-PR demonstrates a clear advantage over other benchmarks in identifying the best-performing recommendation results.

[a]NSGA-II: nondominated sorting genetic algorithm II.

[b]MOPSO: multiobjective particle swarm optimization.

[c]MOFA: multiobjective firefly algorithm.

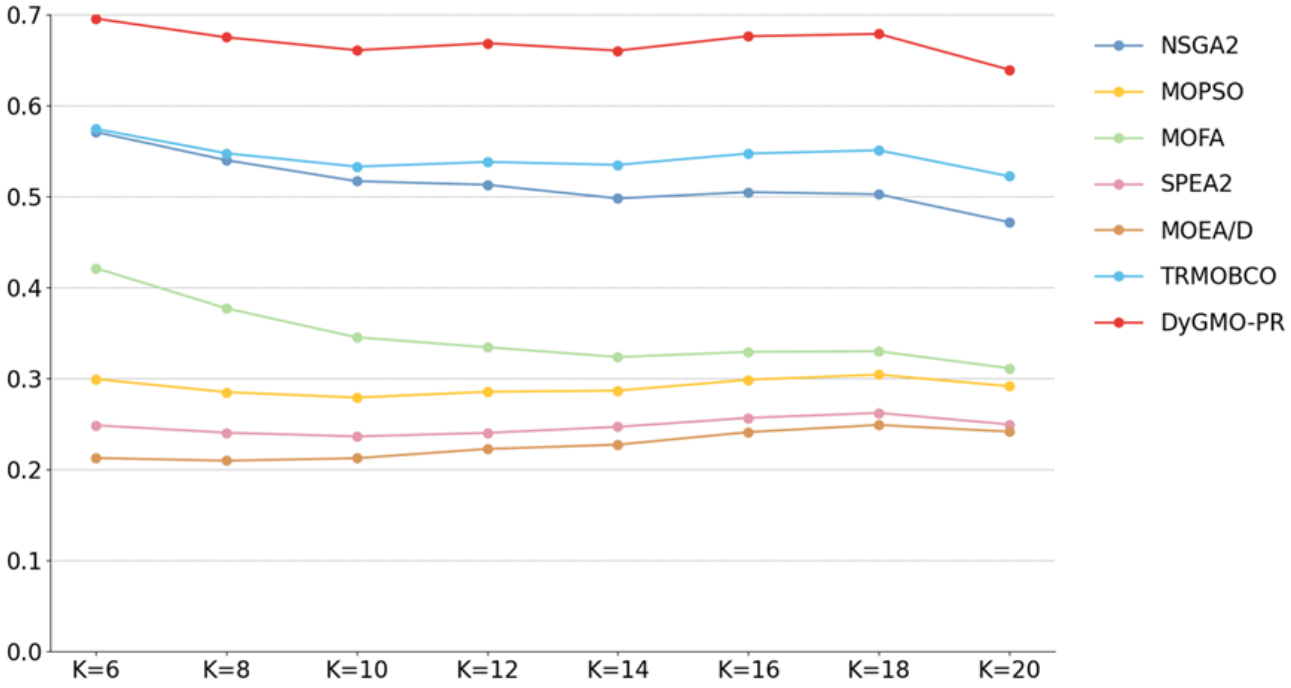
[d]SPEA-2: strength Pareto evolutionary algorithm 2.

[e]MOEA/D: multiobjective evolutionary algorithm based on decomposition.

[f]TRMOBCO: trajectory reinforcement–based multiobjective bacterial colony optimization.

[g]DyGMO-PR: dynamic graph–based bacteria colony optimization for multiobjective physician recommendation.

[h]NDCG: normalized discounted cumulative gain.



The SDs of DyGMO-PR are higher than those of some baselines. This allows for broader coverage of the Pareto front and enables the algorithm to offer a more diverse set of high-quality trade-off solutions.

To statistically verify the significance of observed improvements, we performed a one-sided Wilcoxon signed-rank test [39]. Specifically, for a given *K* and a given objective, we compared DyGMO-PR with one baseline at a time using the paired results from the 5 independent runs. The test examined whether DyGMO-PR significantly outperforms the baseline against the possibility that it does not. In all 5 runs, DyGMO-PR outperformed the baseline in every pairwise comparison. Consequently, the sum of positive ranks reached its maximum possible value (W=15), yielding an exact one-sided *P* value of .03. Thus, we reject the null hypothesis at the $P<.05$ significance level, confirming that DyGMO-PR significantly outperforms each baseline in every configuration. Because the result is uniform across all comparisons, we omit individual significance markers in Table 1 for simplicity.

In addition, as shown in Figure 5, DyGMO-PR achieves the highest hypervolume value among the compared methods, demonstrating its capability to balance recommendation accuracy, service quality, and diversity of physician expertise. Its superior performance remains stable across different recommendation list lengths (eg, various *K* values).

Figure 5. Hypervolume values of compared algorithms. DyGMO-PR: dynamic graph–based bacteria colony optimization for multiobjective physician recommendation; MOEA/D: multiobjective evolutionary algorithm based on decomposition; MOFA: multiobjective firefly algorithm; MOPSO: multiobjective particle swarm optimization; NSGA2: nondominated sorting genetic algorithm II; SPEA2: strength Pareto evolutionary algorithm 2; TRMOBCO: trajectory reinforcement–based multiobjective bacterial colony optimization.

Results in Table 2 report the Recall@*K* of compared algorithms. Notably, DyGMO-PR achieves the highest recall among the algorithms. We also conducted the same one-sided Wilcoxon signed-rank test as in Table 1 confirms that DyGMO-PR significantly outperforms all baselines, with $P<.05$ in every case. Additionally, DyGMO-PR also recommends physicians with a wider range of professionalized skills, offering patients a broader choice of options together with their familiar physicians.

Sensitivity Analysis

The proposed DyGMO-PR algorithm has 2 important parameters: recommendation list length *K* (which determines the number of recommended physicians displayed to patients) and the initial graph walking step size S_0 (which controls the scope of the physician graph search). We empirically investigate the effectiveness of different parameter settings for these 2 parameters. The value of parameter *K* is chosen from the array

XSL•FO
RenderX

[6,8,10,12,14,16,18,20] and S_0 is chosen from the array [2,4,6,8]. Additionally, we also compare the proposed step size decay strategy against using a constant step size to validate the effectiveness of the decay strategy.

Figure 6 illustrates the performance in terms of mean and max values of the 3 recommendation objectives, including accuracy, service quality, and diversity, respectively. Overall, DyGMO-PR demonstrates a competitive advantage across multiple recommendation objectives and various recommendation list lengths *K*. As the recommendation list length *K* increases, the mean accuracy performance of the algorithms remains relatively stable, while the max accuracy of the algorithms slightly decreases. It suggests that a longer recommendation list may introduce less qualified physicians. In contrast, the mean and max diversity gradually increase as *K* increases until *K*=18, after which the diversity begins to decline with a further increase in *K*. These results indicate that recommending too many physicians to patients is not effective. For patients, the physicians who best match their needs typically appear near the top of the recommendation list. Expanding the list by including more physicians may reduce overall accuracy and service quality, although it can enhance diversity within a reasonably limited list length.

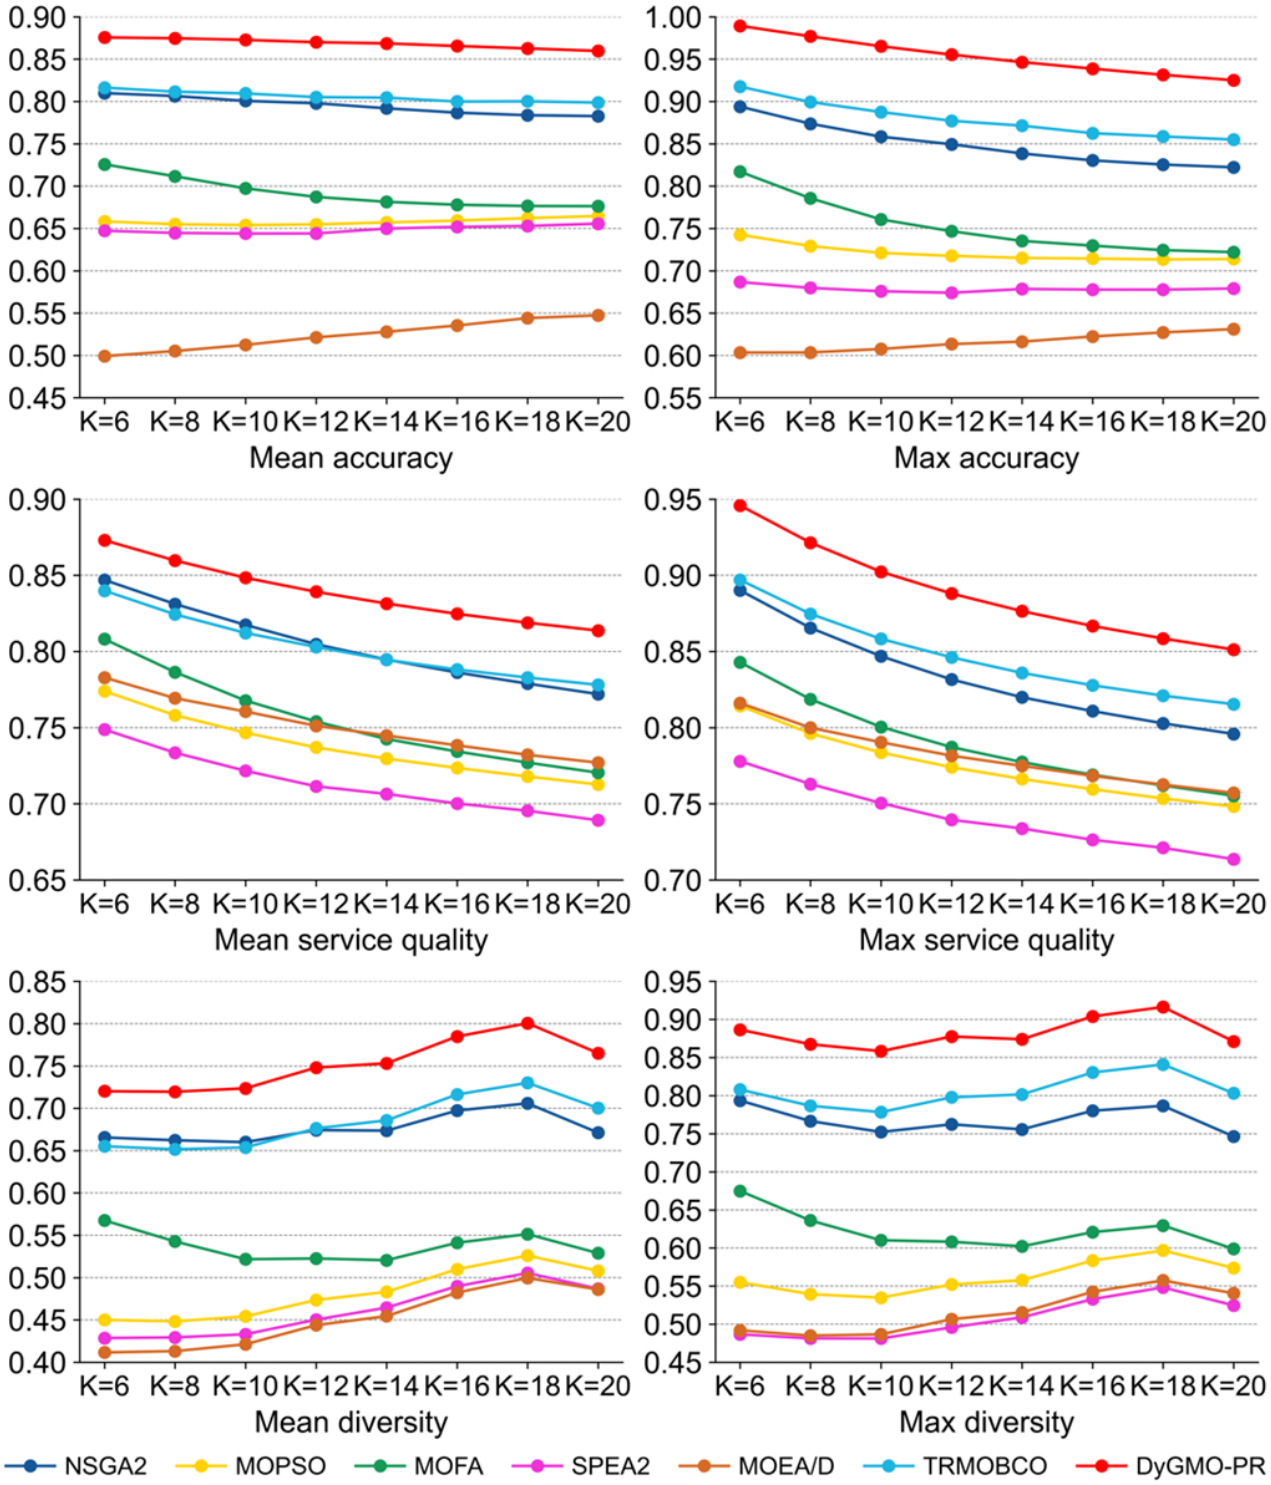
RenderX

Figure 6. The mean and max performance of compared algorithms. DyGMO-PR: dynamic graph–based bacteria colony optimization for multiobjective physician recommendation; MOEA/D: multiobjective evolutionary algorithm based on decomposition; MOFA: multiobjective firefly algorithm; MOPSO: multiobjective particle swarm optimization; NSGA2: nondominated sorting genetic algorithm II; SPEA2: strength Pareto evolutionary algorithm 2; TRMOBCO: trajectory reinforcement–based multiobjective bacterial colony optimization.



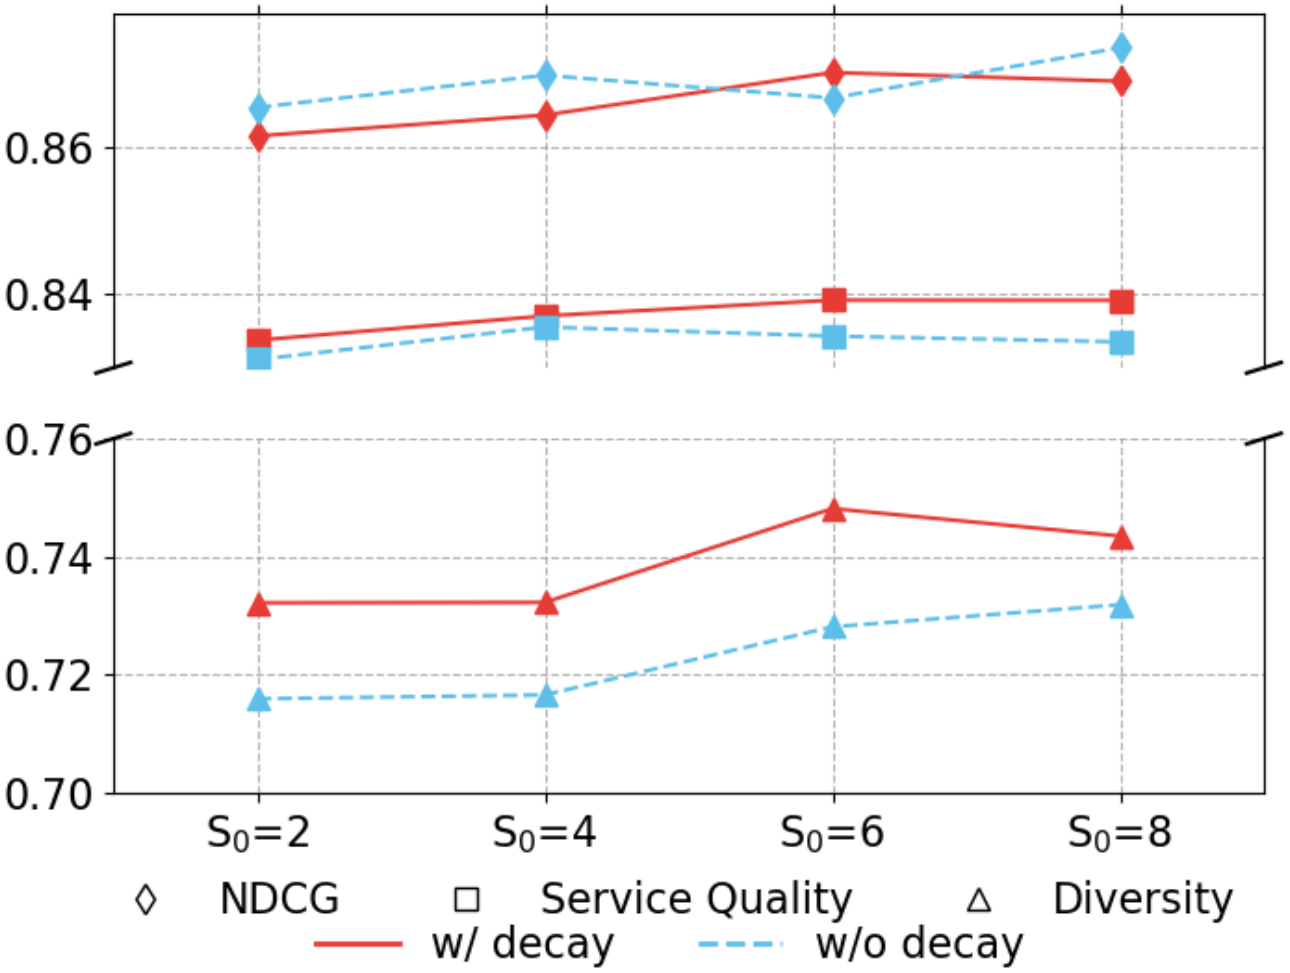


Figure 7 and Figure 8 depict the performance of DyGMO-PR with different step size settings. The step size decay strategy in Equation 9 is compared with an alternative strategy in which the step size remains constant. As shown in Figure 7, our proposed decay strategy outperforms the alternatives in terms of service quality and diversity performance. The hypervolume comparison results in Figure 8 show that the constant step size strategy performs better when the initial step size is small (ie, S_0=2 and S_0=4), whereas our decay strategy is more effective for a larger initial step size (ie, S_0=6 and S_0=8). Notably, when the S_0 is set to 6, our decay strategy achieves the best overall performance. These results indicate that the proposed step size schedule facilitates rapid convergence in the early stages of the optimization process while enabling fine-tuning in later stages.

Case Studies

To assess the interpretability of DyGMO-PR, we randomly selected a patient for case studies. The analysis first examines the physician recommendation lists, then investigates the evolution of the physician graph.

The focal patient for the case studies is a premature infant with twelve online consultation records on the online health care consultation platform. This patient has consulted 8 different physicians, with one physician (ID: 14) being consulted 4 times. The consultations spanned multiple departments, including pediatrics, rehabilitation, gastroenterology, otolaryngology, dermatology, and others.

As shown in Multimedia Appendix 3, the recommendations generated by DyGMO-PR outperform those produced by the benchmark methods across all 3 recommendation objectives. To provide a deeper insight, we randomly selected 2 recommended physician lists from the Pareto front obtained by DyGMO-PR (see Multimedia Appendix 3). Recommendation list 1 exhibits optimal accuracy performance with lower diversity of physician expertise (accuracy=0.944, service quality=0.793, and diversity=0.489). In this list, the diseases that the other 6 physicians specialize in treating are closely related to those that can be treated by Physician ID 14. In contrast, recommendation list 2 demonstrates a more balanced performance across the 3 recommendation objectives, including accuracy (0.788), service quality (0.814), and diversity (0.625). Here, 3 of the recommended physicians have been consulted previously, with Physician ID 14 once again ranked first. The remaining physicians specialize in a broader and less directly related range of diseases compared to those in recommendation list 1, clearly illustrating the inherent trade-off between recommendation accuracy and diversity of physician expertise.

The dynamic graph learning strategy updates the graph structure to better align with the recommendation objectives. We further examined the evolution of the physician graph during the optimization process. Multimedia Appendix 4 presents the properties of the initial and converged graph for this patient. Although the number of nodes remains constant, the number of edges increases substantially, with the average node degree rising by 27.145 and graph density increasing by 0.009.

To investigate graph local structural changes, we randomly selected 2 physician nodes (ID 25 and ID 971) and analyzed their connections in both the initial and converged physician graphs. Physician ID 25 specializes in treating neonatal jaundice, pneumonia, and pediatric enteritis, while Physician ID 971 focuses on anorexia, asthma, recurrent respiratory infections, common cold, cough, precocious puberty, and indigestion. As detailed in Multimedia Appendix 5, Physician ID 25 gains 8 new neighbors in the converged graph, and the diseases treated by these new neighbors are closely aligned with the patient's historical consultations. For Physician ID 971, 5 initial

XSL•FO
RenderX

neighboring physicians are removed, and 3 new neighbors are added. The newly connected physicians specialize in a broader range of diseases than those removed, which not only aligns more closely with the patient's historical conditions but also enhances the diversity of diseases covered in the recommendation list.

Moreover, we analyzed the structural changes of the entire physician graph before and after evolution (detailed results are provided in Multimedia Appendix 6). In the initial graph, all physicians had equal in-degree and out-degree. After evolution, we stratified physicians by their in-degree/out-degree ratio, which reflects a physician's relative attractiveness as a target in the evolved directed graph. The results show that physicians ranked in the top 50 by this ratio achieved substantially higher accuracy, service quality, and diversity of physician expertise compared to other groups. Among the 8 physicians the patient had actually consulted, 7 exhibited an in-degree/out-degree ratio well above 1. This finding corroborates that the graph evolution enhances the prominence of physicians relevant to the patient's historical conditions. This indicates that the graph evolution process effectively reshapes the network structure to improve recommendation performance. These findings provide global-level interpretability and validate the effectiveness of the proposed dynamic graph learning mechanism.

The above case studies demonstrate the effectiveness and interpretability of the DyGMO-PR algorithm. The analysis of 2 selected lists from its Pareto front illustrates the algorithm's ability to produce diverse, high-quality options that balance the patient's need for accuracy, service quality, and disease coverage. Furthermore, the physician graph analysis reveals that the dynamic graph evolution actively reshapes the relationships between physicians. Adding and removing directed connections enables the heuristic searching process to uncover specialists whose expertise aligns more closely with the patient's personalized needs. The resulting graph provides an interpretable map of why certain physicians are recommended, thereby improving the transparency and trustworthiness of the system.

Discussion

Physician recommender systems in online health care consultation assist patients in navigating the challenge of selecting a physician from an overwhelming number of available options. In this research, we proposed a novel DyGMO-PR. DyGMO-PR simultaneously optimizes the recommendation accuracy, physician service quality, and the diversity of physician expertise. This new method introduces a dynamic physician relationship learning mechanism that mitigates data sparsity and stabilizes the search process for recommendation lists.

The contributions of this research can be summarized in 3 main aspects. First, we propose a multiobjective physician recommendation framework grounded in BCO. Unlike conventional methods that optimize a single objective, we define 3 objectives that reflect patients' key concerns: accuracy, service quality, and diversity of physician expertise. DyGMO-PR effectively balances these objectives and can be readily extended to other multiobjective recommendation scenarios by customizing the objective functions. Second, we propose a physician graph-based encoding scheme that assigns virtual scores to quantify each physician's potential contribution. This design enhances the stability and convergence of heuristic optimization in sparse and discrete solution spaces. Third, we propose a dynamic physician graph evolution mechanism that learns new physician relationships and refines the physician graph to support interpretable recommendations.

The proposed method offers substantial practical value for online health care platforms, physicians, and patients. For platforms, DyGMO-PR provides a flexible and tunable foundation for physician recommendation. By generating a Pareto-optimal set of solutions, platforms can assign different weights to the 3 objectives according to user needs. For instance, they may prioritize accuracy for new users, emphasize service quality for premium services, or enhance diversity for users with unclear symptoms. This adaptability allows platforms to tailor recommendations according to user characteristics or platform development stages. For physicians, the method increases the visibility of high-quality specialists who might otherwise be overlooked due to sparse interaction data. For patients, DyGMO-PR delivers personalized and interpretable recommendation lists that balance accuracy, service quality, and disease coverage. This is particularly valuable for patients with limited medical knowledge or complex conditions, as it broadens their access to relevant and trustworthy specialists.

The DyGMO-PR framework is designed to be generalizable to other domains involving multiobjective recommendation in the presence of sparse interaction data. The method requires three types of input data: (1) user-item interaction history, (2) item attribute information, and (3) a relational structure among items. These data requirements are commonly met across various real-world scenarios. Within the health care domain, beyond physician recommendation, the method can be applied to hospital referral recommendation, where patients are matched to hospitals based on specialty strength and service quality. Beyond health care, the proposed approach is also well-suited for e-commerce product recommendation (eg, balancing relevance, product ratings, and category diversity) and content platform recommendation (eg, news or videos, balancing content matching, quality, and topic diversity). In each case, the approach can be adapted by redefining the optimization objectives and constructing domain-specific relational graphs.

There are several promising directions for future research. First, DyGMO-PR could be extended to address other real-world problems that require identifying multiple optimal solutions. Second, the accuracy objective relies on patients' historical consultation records as ground truth. However, these records may contain noise because some patients with limited medical knowledge do not always choose the most appropriate physician. We mitigated this noise by retaining only patients with at least 5 consultations and using XSimGCL, a robust contrastive learning model for rating prediction. Nonetheless, some noise inevitably remains, and future research could incorporate more precise feedback signals (eg, postconsultation satisfaction ratings) or external medical knowledge to eliminate noise and improve rating accuracy. Third, incorporating deeper medical domain knowledge, such as disease comorbidity relationships

XSL•FO
RenderX

or symptom-disease co-occurrence networks, may further enhance the reliability of the physician graph and improve recommendation performance. Such external knowledge could provide a more robust foundation for dynamic graph learning. We hope this study will inspire future research in optimization-based multiobjective recommender systems.

Abstract

Background: Long-term garment-type wearable Holter electrocardiographic (ECG) monitoring is frequently affected by noise contamination, which complicates automated atrial fibrillation (AF) detection in real-world recordings. Although deep learning has shown high performance for AF detection, relatively few studies have evaluated explicit strategies for handling noise-included wearable ECG data. An alternative representation using the R-R interval (RRI) time series may reduce the dependence on waveform morphology and provide an alternative pathway for AF screening in noisy recordings.

Objective: This study aimed to develop and evaluate a 3-class, noise-aware RRI-based AF screening framework that explicitly separated AF, non-AF, and uninterpretable noise windows, and to assess the impact of analysis window length on model performance.

Methods: Single-lead garment-type wearable Holter ECG data from 117 patients at the University of Osaka Hospital were analyzed after exclusion of patients with documented atrial tachycardia, flutter, or paced rhythm according to the predefined task definition. R-peaks were automatically detected, and the resulting RRI segments were converted into 2D histogram images, with time on the x-axis and RRI-derived heart rate on the y-axis, for 1.5-, 3-, and 6-minute windows. A ResNet-34–based 2D convolutional neural network was trained for 3-class classification. Model performance was evaluated using 5-fold interpatient cross-validation on the institutional dataset and independent external testing on the MIT-BIH (Massachusetts Institute of Technology–Beth Israel Hospital) AF Database (AFDB). In the external validation, atrial flutter–annotated intervals were excluded to match the training task definition. Patient-level AF burden was evaluated by comparing reference AF burden with model-estimated AF burden using Pearson and Spearman correlation coefficients, and linear regression.

Results: Of 129 monitored patients between March 1, 2023, and November 20, 2025, 117 were analyzed. In the internal validation, the 3-class model (non-AF, AF, and noise) showed similarly high performance for the 1.5- and 3-minute windows, both with an accuracy of 96.6%. In independent external validation, the 3-minute window showed numerically the highest overall performance (accuracy: 97.3%; AF sensitivity: 96.9%; and AF specificity: 97.7%), although the differences across window lengths were modest. At the patient level, AF burden correlation was high across all window lengths, with Pearson r of 0.995, 0.991, and 0.989 and Spearman ρ of 0.988, 0.982, and 0.979 for the 1.5-, 3-, and 6-minute models, respectively.

Conclusions: The RRI-based 2D convolutional neural network achieved high AF classification accuracy and strong patient-level correlation with reference AF burden. Using RRI features and a 3-class framework, which explicitly separated noise from AF and non-AF rhythms, a 3-minute RRI window provided a favorable balance of performance for AF screening in a garment-type Holter ECG.

Introduction

Atrial fibrillation (AF) is a common arrhythmia and a major cause of cardioembolic stroke [1,2]. Early and accurate detection of paroxysmal AF (PAF), which may manifest asymptomatically or transiently, is important for timely anticoagulation and rhythm control strategies. Given the unpredictable onset of PAF, long-term Holter electrocardiographic (ECG) monitoring has been extensively used to capture AF episodes [3-7]. Garment-type wearable Holter ECG devices, which integrate electrodes into shirts or belts, have garnered attention for their ability to facilitate long-term continuous recording during daily activities with minimal burden on the wearer [8-10].

In garment-type wearable Holter ECG monitoring, the characteristics of noise contamination differ from those of conventional adhesive or patch-type recordings. As the garment can be removed and reworn, recordings may contain not only intermittent contact artifacts during wear, caused by body motion, variable electrode contact, and changes in skin-electrode impedance, but also off-body periods, signal loss intervals, and segments acquired during unstable reattachment [9,11-13]. These heterogeneous segments are ultimately included in the long-term recordings submitted for clinical review, making manual analysis by clinical technologists or physicians time-consuming and labor-intensive [3,14,15]. Therefore, the practical challenge in diagnostic support using automated analysis is not limited to improving AF detection accuracy in relatively low-noise ECG segments but also includes avoiding forced classification into AF or non-AF in windows in which rhythm interpretation is unreliable. Recent studies, including the PhysioNet or Computing in Cardiology Challenge 2017, have emphasized the importance of AF classification from noisy single-lead ECG recordings and have advanced algorithm development in this setting [7,16,17]. However, corresponding evidence in long-term garment-type wearable Holter ECG remains limited.

Automatic ECG analysis using AI, particularly deep learning (DL), has recently emerged as a promising approach to address these challenges. Although DL architectures that directly process raw ECG waveforms, including 1D convolutional neural networks (1D-CNNs) [14-18], have demonstrated high performance, their performance may deteriorate in the presence of waveform noise in wearable recordings. In contrast, approaches based on the R-R interval (RRI) focus on the beat-to-beat irregularity, which is fundamental to AF and may be relatively tolerant of waveform contamination [19-22]. Moreover, converting the RRI time series into 2D images allows AF rhythm characteristics to be represented as structured visual patterns, making this approach highly compatible with analyses based on 2D convolutional neural networks (2D-CNNs) [23-25]. In noise-controlled patch-type Holter recordings, such RRI-based 2D-CNN approaches have achieved high accuracy with short segment windows of approximately 90 beats [4,24].

However, a suitable RRI-based DL framework for noise-prone garment-type monitoring remains unclear. In particular, it is uncertain how analysis window length influences diagnostic performance when analyzable rhythm portions and uninterpretable artifact-contaminated portions coexist within long-term recordings. Therefore, this study aimed to develop and evaluate an RRI histogram-based 3-class AF screening framework for wearable Holter ECG recordings, in which visually uninterpretable or unreliable segments were treated as an independent noise class, separate from AF and non-AF rhythms. By examining multiple analysis window lengths, we sought to identify an approach that could support efficient and reliable AF screening in real-world wearable monitoring.

Methods

Study Design

Task Definition

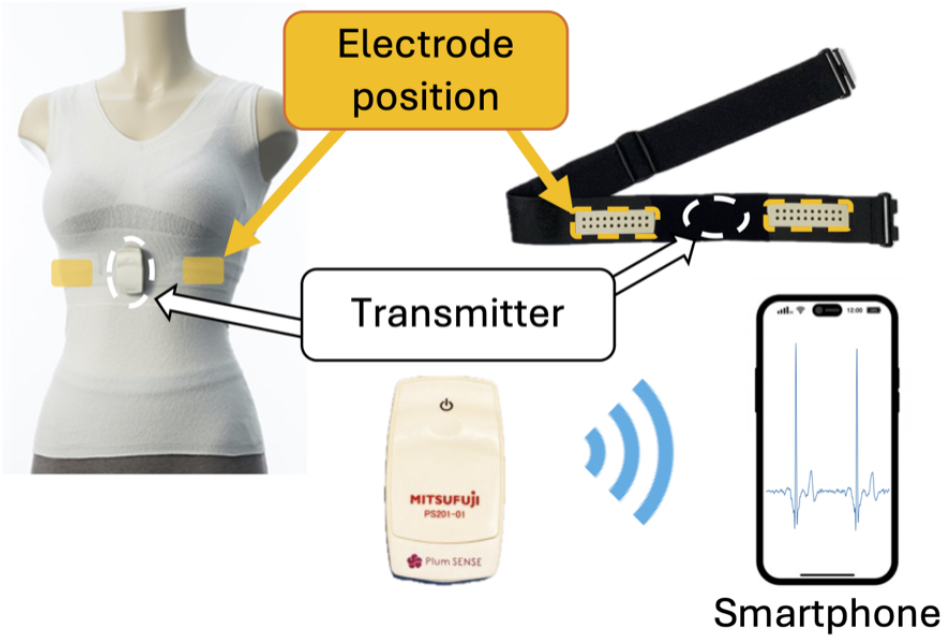
This study aimed to develop a machine learning framework for AF screening based on RRI irregularity while explicitly separating uninterpretable segments as noise. Atrial tachycardia (AT) and atrial flutter (AFL) typically exhibit regular RRIs and lack the irregular characteristics of AF, thus representing distinct physiological rhythmic phenotypes [26]. Therefore, AT/AFL episodes were excluded from both the training and validation datasets to preserve the clinical coherence of the task rather than to optimize model performance. The diagnosis and characterization of AT/AFL constitute a separate clinical challenge and are considered beyond the scope of this analysis.

In addition, this study was designed to systematically evaluate the impact of window length as part of a sensitivity analysis of the performance of the RRI-based AF detection model in the context of long-term garment-type wearable Holter ECG monitoring, which is susceptible to noise contamination. Therefore, noise was treated as a distinct label to reflect real-world data quality and enable the model to explicitly separate uninterpretable segments from AF and non-AF rhythms. Three window lengths were examined: 1.5-, 3-, and 6-minute windows.

Study Population

The study population comprised patients who underwent monitoring using a wearable Holter ECG device (PS201-01; Mitsufuji) at the University of Osaka Hospital between March 1, 2023, and November 20, 2025. Examinations were performed to evaluate suspected or known arrhythmias or symptoms such as palpitations.

Ethical Considerations



This study was approved by the Ethics Committee of the University of Osaka Hospital on March 1, 2023 (approval 22449) and was conducted in accordance with the Declaration of Helsinki. Written informed consent was obtained from all participants prior to study enrollment. All study data were deidentified before analysis to protect participant privacy and confidentiality. No financial compensation or other incentives were provided to the participants. No images in the manuscript or supplementary material contain information that could identify individual participants.

XSL•FO
RenderX

ECG Recording and Data Collection

ECG data were acquired using a PS201-01 wearable Holter ECG device [10] with either shirt-type or belt-type garment electrodes (Figure 1).

Figure 1. Configuration of the garment-type wearable Holter ECG system. The shirt-type garment (left) uses electrodes incorporating silver fiber AGposs, whereas the belt-type garment (right) uses electrodes incorporating both AGposs and the silver-containing paste DuraQ. The orange frames indicate the electrode positions. The transmitter was attached within the white dotted-line area and transmitted electrocardiogram data via Bluetooth to a smartphone app, where the signals were stored.

Device Configuration

The PS201-01 system uses silver fibers (AGposs; Mitsufuji) as the electrode material. The shirt-type garment used AGposs alone, whereas the belt-type garment combined AGposs with electrodes made from a silver-containing paste (DuraQ; Sumitomo Bakelite). Both garments share an equivalent electrode configuration, enabling the acquisition of a single-lead ECG corresponding to lead I of a standard 12-lead ECG.

Data Acquisition Specifications

The ECG waveforms acquired using the PS201-01 device were transmitted via Bluetooth to a dedicated smartphone app (wearable Holter ECG management; Mitsufuji) and stored in the Medical Waveform Format Encoding Rules format. The device is a class II long-term ECG recording system approved under the Japanese Pharmaceuticals and Medical Devices Act. The ECG signal was directly sampled by the built-in analog-to-digital converter at 250 Hz and stored at the same sampling frequency without downsampling; no analog-to-digital converter (ADC) internal digital filter or digital low-pass filter was applied before storage. According to manufacturer-provided circuit simulation data, the analog front end was designed to provide band limiting for antialiasing before ADC sampling. The relative gain compared with the passband was −2 dB at 100 Hz, −4.5 dB at 125 Hz, −10 dB at 250 Hz, −20 dB at 700 Hz, and −33 dB at 1000 Hz; the −3 dB, −20 dB, and −40 dB frequencies were approximately 105 Hz, 700 Hz, and 1.25 kHz, respectively. The sampling frequency of 250 Hz was identical to that used in the MIT-BIH AFDB.

Data Preprocessing and Annotation

For model development, the RRI segments were extracted from raw ECG waveforms and annotated by a cardiologist.

RRI Data Generation

For ECG data stored in the Medical Waveform Format Encoding format, an automatic R-peak detection algorithm based on the Hamilton method [27], as implemented in the Python BioSPPy library, was applied to generate the RRI time series data. No subsample interpolation, dedicated artifact-rejection procedure, or additional peak refinement technique was applied after automatic detection. Baseline correction was performed using a bandpass filter as a part of the preprocessing pipeline. In noise-labeled segments, R-peak detection was not uniformly reliable and could result in excessive false detections, absent or insufficient detections, or temporally heterogeneous detection patterns, depending on the type and severity of artifact. As the accuracy of R-peak detection critically influences model performance in RRI-based AF diagnosis, this step serves as the foundation of the entire analysis workflow. To support the practical validity of this preprocessing step under 250 Hz sampling, we performed a supplementary quality assessment of R-peak detection described in the following section.

Quality Assessment of R-Peak Detection

As a supplementary quality check of the preprocessing pipeline, we performed a manual review of randomly sampled 30-second

XSL•FO
RenderX

ECG segments from the institutional dataset used for model development and internal validation. This assessment was performed to evaluate the practical reliability of the Hamilton-based R-peak detection step in the same data source used for training and testing, but it was not used to select, exclude, or reassign segments for model training or testing. All windows were handled according to the predefined label aggregation rules and patient-level cross-validation splits, regardless of the quality assessment results. The review set consisted of 100 pure non-AF segments, 100 pure AF segments, 50 pure noise segments, and 50 noise-containing segments. A cardiologist visually reviewed each segment to determine whether reliable reference R-peaks could be identified. A segment was defined as *annotatable* when R-peaks could be reliably confirmed for at least 20 of the 30 seconds. For annotatable segments, automatic R-peak detection was graded as *acceptable* when >90% of automatically detected peaks appropriately corresponded to visually identified R waves, having *minor errors* when the proportion was >70% to ≤90%, and *unreliable* otherwise. For noise and noise-containing segments, readability was also recorded.

Annotation Procedure

The generated RRI plots and the corresponding raw ECG waveforms were visualized using an in-house ECG annotation tool. A cardiologist reviewed the continuous ECG recordings in chronological order and assigned labels at 10-second intervals, taking the surrounding rhythm context into account. AF was defined as a rhythm showing irregular RRIs without discernible P waves, occupying more than half of a given 10-second interval. When multiple rhythms occurred within a single interval, the rhythm occupying the majority of the interval was assigned as the representative label. Thus, transitions between rhythms were handled by majority labeling within each 10-second interval.

A cardiologist classified the data into 3 classes:

- Non-AF: normal sinus rhythm and non-AF arrhythmias, excluding AT/AFL
- AF: atrial fibrillation
- Noise: a 10-second interval in which reliable rhythm interpretation was not possible because of severe artifact, unstable electrode contact, signal loss, or periods during which the garment was not worn

The following ECG patterns were excluded from the analysis: regular supraventricular tachycardia (AT/AFL) and segments containing paced waveforms.

Annotations were created independently of model training and evaluation. To further assess annotation robustness, supplementary intrarater and independent interrater agreement analyses were performed, as described in the “Annotation Agreement Assessment” section.

Annotation Agreement Assessment

We performed a supplementary annotation verification analysis using randomly sampled ECG segments from the institutional dataset used for model development and internal validation. A custom program was developed to randomly sample segments and display the corresponding ECG data for manual review. Using this procedure, 150 segments were randomly selected, comprising 50 non-AF, 50 AF, and 50 noise segments according to the original study annotations. The sampled segments were then reassessed in 2 ways: first, by the cardiologist who had created the original annotations, using the dedicated review program, and second, by an additional independent cardiologist. Agreement of each reassessment with the original study annotations was evaluated using percentage agreement and Cohen κ. This supplementary analysis was designed to examine the robustness of the original annotations and was not used to select, exclude, relabel, or reassign segments for model training or testing. The original study annotations remained the reference labels for model development and evaluation, and all windows were handled according to the predefined label aggregation rules and patient-level cross-validation splits.

Patient-Level Rhythm Burden Assessment

To characterize the rhythm composition of the institutional cohort, patient-level AF burden was calculated using the original 10-second annotations. AF burden was defined as the proportion of AF-labeled intervals among analyzable intervals after excluding noise-labeled intervals from the denominator. The distribution of AF burden across patients was summarized to assess whether the cohort contained a broad range of PAF patterns or was dominated by sustained AF and non-AF recordings.

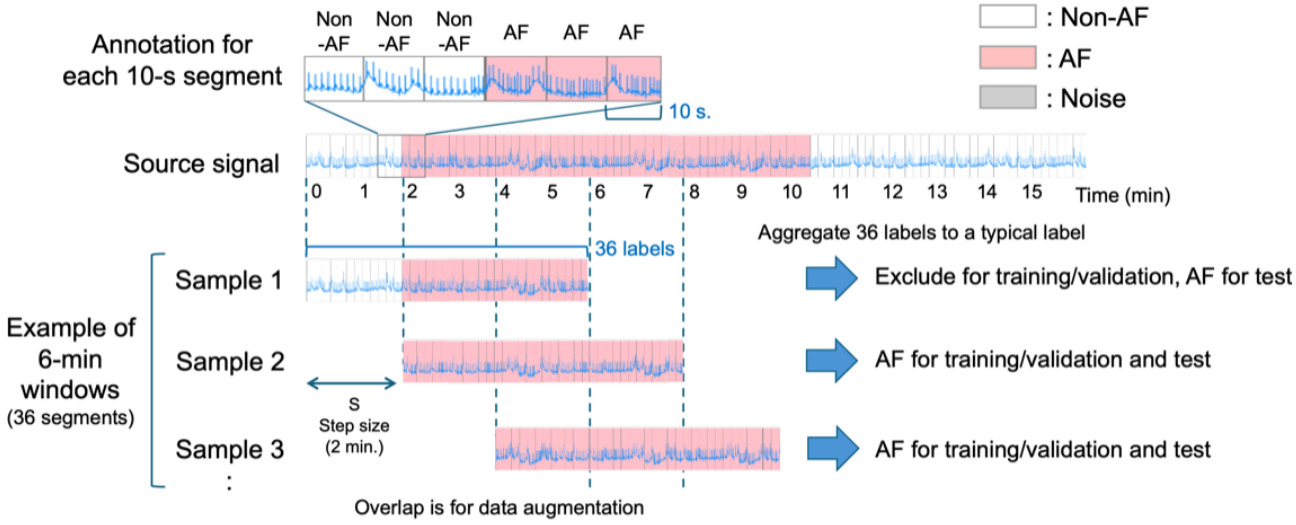
To address the concern that the non-AF class might consist predominantly of clean sinus rhythm, we performed a rudimentary ectopic burden estimate in patients with an AF burden of 0%. This subgroup was selected because all analyzable intervals in these patients were annotated as non-AF, allowing assessment of ectopy in non-AF recordings without contamination by AF-to-non-AF transition periods. As exhaustive ectopic beat annotation across the full dataset was not feasible and could be affected by noise, representative ECG segments were sampled for manual review. For each eligible patient, six 3-minute segments were selected from the available analyzable non-AF recordings, and ectopic beats were visually identified. Ectopic burden was calculated as the proportion of ectopic beats among all visually assessable beats in the reviewed segments. Patients were categorized according to estimated ectopic burden as <1%, 1% to <5%, 5% to <10%, or ≥10%. This analysis was intended to provide a descriptive estimate of ectopy within the non-AF class rather than a comprehensive beat-level annotation of the entire dataset.

Feature Extraction and Training Data Generation

Two-dimensional feature images used as inputs to the DL model were generated from the RRI time series data to construct the training and evaluation datasets.

Segmentation of RRI Data

The RRI time series data were segmented into fixed-length analysis windows. Window lengths of 1.5, 3, and 6 minutes were used, and model performance was evaluated for each setting. These window lengths were selected to cover clinically and methodologically relevant time scales. A 1.5-minute window approximately corresponds to 90 beats at a heart rate of 60 beats



XSL•FO
RenderX

per minute, which is similar to the segment length used in prior Lorenz/Poincaré plot–based AF detection studies [23-25]. A 6-minute window was included because 6 minutes have been used as a clinically relevant threshold in studies of atrial high-rate episodes [28,29]. A 3-minute window was evaluated as an intermediate setting to assess the trade-off between temporal resolution with shorter windows and classification stability with longer windows.

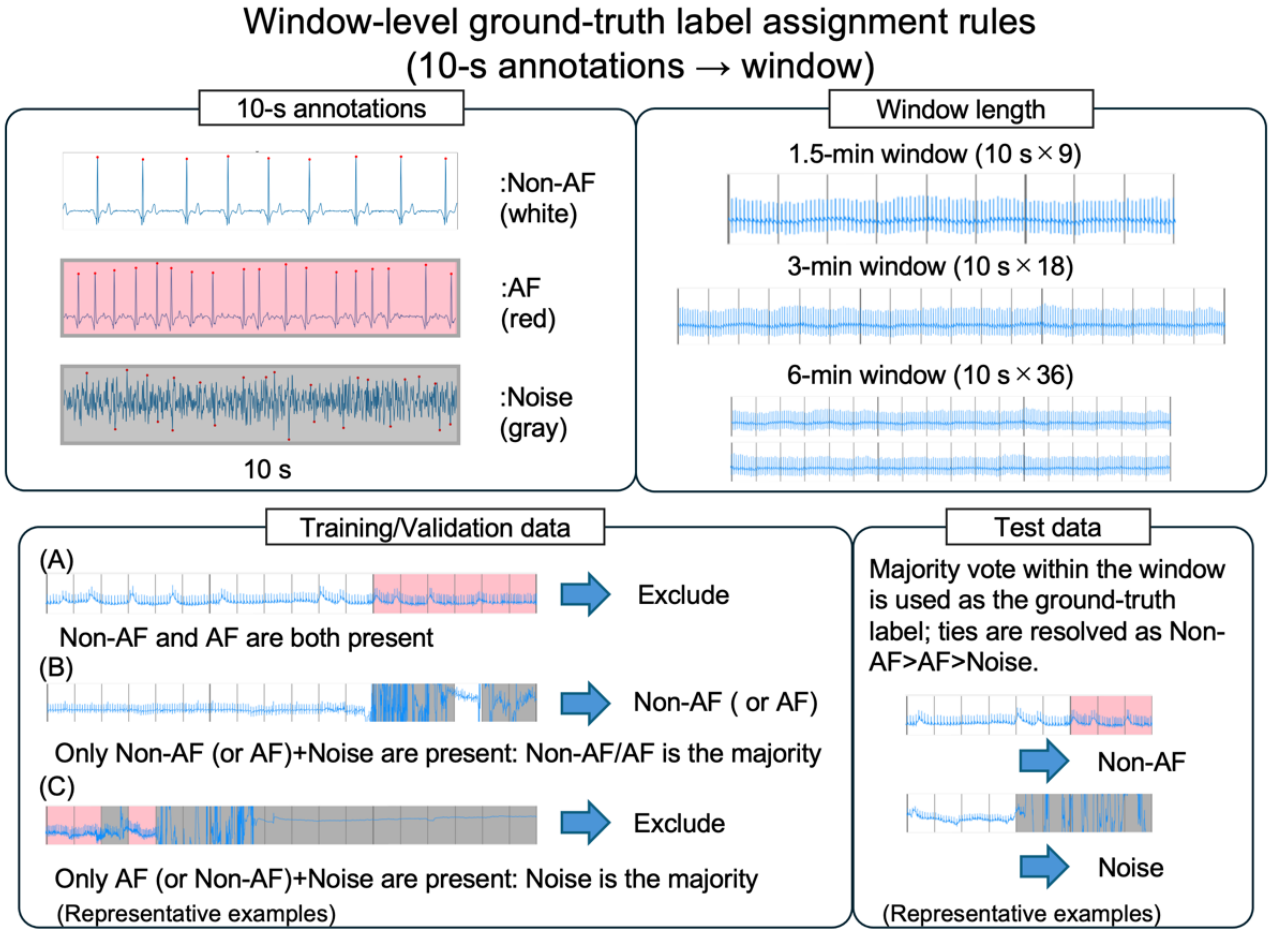
Data Augmentation (Sliding Window)

To improve model generalization and increase the volume of training data, a sliding window approach was applied to all window length settings (Figure 2). To standardize the augmentation strategy across models while preserving a similar relative degree of overlap, the step size was set to one-third of the target window length. Accordingly, step sizes of 30 seconds, 1 minute, and 2 minutes were used for the 1.5-minute, 3-minute, and 6-minute models, respectively. Cross-validation was performed per patient to prevent interpatient data leakage caused by the sliding window procedure. Thus, overlapping windows derived from the same patient were contained within the same data split and were not shared across training, validation, and test sets. No additional procedure was applied to reduce correlation among overlapping samples within the same split; rather, the sliding window approach was used as an intended augmentation strategy within the training framework.

Figure 2. Schematic overview of sliding window data augmentation and segment-level label assignment used for model development. Ground-truth annotations were provided at 10-s intervals and aggregated to a single segment label (36 labels for a 6-min window; 18 labels for a 3-min window; and 9 labels for a 1.5-min window). Segments containing both atrial fibrillation (AF) and non-AF labels were excluded from the training or validation dataset but handled according to the test time rule (The detailed label aggregation rules are provided in the "Label Aggregation Rules" subsection).

Conversion to 2D Images (Histogram Processing)

Rather than using the raw 1D RRI sequence directly as input, each segment was transformed into a 2D histogram image to represent rhythm irregularity in a structured form. AF is characterized not only by variability in interval length itself but also by the temporal pattern and density distribution of beat-to-beat fluctuations. A 2D representation was therefore adopted to capture both the overall distribution of interval-derived values and their sequential variation, conceptually similar to Lorenz/Poincaré-based rhythm analysis [23-25]. In addition, this representation allowed noisy or visually uninterpretable segments to appear as scattered and unstable patterns. Histogram binning aggregates neighboring values and may reduce the influence of minor timing fluctuations or isolated R-peak detection errors. Heat maps were generated as 2D histograms from each RRI segment using the window-level R-peak positions on the x-axis and heart rate derived from the RRI on the y-axis. Specifically, heart rate was calculated as 60,000 divided by the RRI in milliseconds, and the histogram was computed as a count-based density map without additional count normalization. Thus, the present input representation was a time–heart rate density histogram rather than a recurrence plot or a ΔRRI map. The y-axis represented RRI-derived heart rate and was predefined to range from 30 to 400 beats per minute, uniformly divided into 200 bins for all window lengths. Thus, RRIs longer than 2.0 seconds, corresponding to heart rates below 30 beats per minute, and extremely short RRIs below 150 milliseconds, corresponding to heart rates above 400 beats per minute, were outside the predefined heart rate range of the histogram representation. These out-of-range intervals were not encoded as separate overflow bins or dedicated features in the model input. For the x-axis, the number of bins was scaled according to segment duration to maintain comparable temporal density across models: 25 bins for 1.5-minute windows, 50 bins for 3-minute windows, and 100 bins for 6-minute windows. Accordingly, the resulting histogram image sizes were 25×200, 50×200, and 100×200 bins, respectively. Histogram counts were used as pixel intensities, and no additional smoothing or interpolation was applied before input into the 2D-CNN. An enlarged representative RRI histogram image is provided in Figure S1 in Multimedia Appendix 1 to improve visual interpretability of the histogram format. As noise-labeled segments were defined by visually uninterpretable or nondiagnostic ECG quality rather than by a single R-peak detection failure mode, their RRI-derived histograms were



XSL•FO
RenderX

heterogeneous. Representative noise-labeled examples included excessive false R-peak detections, absent or insufficient detections, and temporally heterogeneous artifact patterns within the same window. Real ECG waveforms with automatically detected R-peak positions and the corresponding RRI-derived heart rate histograms are shown in Figure S2 in Multimedia Appendix 1.

Label Aggregation Rules

As annotations were assigned at 10-second intervals, each segment corresponded to 9 labels for a 1.5-minute window, 18 labels for a 3-minute window, and 36 labels for a 6-minute window. The final window label was determined using separate rule sets for the training/validation and test datasets, as illustrated in Figure 3.

Figure 3. Window-level ground-truth label assignment rules for the 3-class classification task. Annotations were assigned in 10-s intervals. Consequently, each segment corresponded to 9 labels for a 1.5-min window, 18 labels for a 3-min window, and 36 labels for a 6-min window. The figure illustrates the rules for handling windows containing multiple labels, together with representative electrocardiogram (ECG) examples for both training/validation and test data. Ten-second labels are indicated by background color: red for atrial fibrillation (AF), gray for noise, and white for non-AF. The Noise example shown in the figure represents an actual artifact-contaminated waveform recorded using the garment-type wearable Holter ECG device, not simulated Gaussian noise.

Training or Validation Data

The data used for training or validation were handled according to the following rules:

- For supervised training, windows containing both AF and non-AF labels were excluded because assigning a single representative label to such windows would introduce ambiguous supervisory signals. This rule was adopted to preserve clear label definitions during model training rather than to deny the existence of rhythm transitions in real-world recordings. This approach may reduce the representation of transitional or mixed rhythm segments in the training dataset and is therefore considered a limitation of the present framework.

- For supervised training, windows containing both AF and non-AF labels were excluded because assigning a single representative label to such windows would introduce ambiguous supervisory signals. This rule was adopted to preserve clear label definitions during model training rather than to deny the existence of rhythm transitions in real-world recordings. This approach may reduce the representation of transitional or mixed rhythm segments in the training dataset and is therefore considered a limitation of the present framework.

Test Data

The data used for test were handled according to the following rules:

XSL•FO
RenderX

- The most frequently used label within a window (majority vote) was used as the reference label.
- In the event of a tie, the reference label was determined using a predefined priority order (non-AF > AF > noise) solely to ensure deterministic label assignment. This priority order was an operational convention for uncommon edge cases and was not intended to represent a clinically motivated hierarchy among rhythm classes.

DL Model and Validation Protocol

A supervised DL model was constructed to classify the generated 2D RRI images into non-AF, AF, and noise classes.

DL Model

We adopted ResNet-34, a 2D-CNN architecture with residual learning that enables stable training in deep networks and has shown strong performance in image recognition [30]. ResNet-34 was selected as a practical compromise between representational capacity and model complexity within the ResNet family. In the context of the present wearable ECG dataset, we considered shallower models potentially insufficient to capture the diversity of rhythm patterns, whereas deeper models could increase the risk of overfitting without a clear advantage. To accommodate the present input representation, the initial convolutional layer was modified to accept single-channel inputs, and the final pooling layer was replaced with an adaptive global average pooling layer. As a result, the model could accept the native histogram image sizes (25×200, 50×200, and 100×200) without resizing to a fixed square resolution. The model was initialized from scratch, and no pretrained weights were used. No additional systematic hyperparameter optimization was performed beyond the predefined training settings and early stopping. The model was trained to classify the histogram images derived from the RRI segments into 3 classes: non-AF, AF, and noise. Training was performed using the Adam optimizer (learning rate 1×10^{-4}), with cross-entropy loss as the objective function.

Internal Validation

Internal validation was performed using 5-fold cross-validation on an institutional dataset. To avoid leakage of patient information between the training and test sets, we used an interpatient paradigm, splitting data at the patient level. Patients were randomly divided into 5 mutually exclusive groups based on their identifiers. For each fold, approximately one-fifth of the patients were assigned to the test set, and the remaining four-fifths were used for model development, with the development set further divided into training and validation subsets at a 9:1 ratio. The training split within the nontest patients was also performed at the patient level by random sampling without stratification; therefore, all sliding window samples derived from a given patient were assigned exclusively to either the training or validation subset. No explicit balancing was applied for patient characteristics, such as age, AF burden, or signal quality across folds. The training and evaluation were repeated for each fold using the same procedure. Given the relatively limited size of the institutional dataset, early stopping was used as the primary measure to reduce overfitting. Specifically, training was halted if the validation loss did not improve for 5 consecutive epochs. No additional formal hyperparameter search was performed. As an exploratory post hoc subgroup analysis by garment type, we evaluated the 3-minute model using the same 5-fold cross-validation splits as those used in the primary internal validation. As the shirt-type subgroup had a limited sample size and included few AF cases, separate garment-specific model training was not performed. Instead, in each fold, the model was trained using mixed shirt- and belt-type recordings, and pooled out-of-fold predictions from the corresponding test folds were stratified by garment type.

External Validation

To evaluate the generalization performance of the predefined model framework, external validation was conducted using the MIT-BIH AFDB, a widely used benchmark for AF detection. The AFDB was completely independent of the institutional dataset and was used exclusively as an external test dataset; it was not used for model training, validation, or tuning. The AFDB contains 25 two-channel ECG recordings, each approximately 10 hours in duration and sampled at 250 Hz. Two recordings (00735 and 03665) were excluded due to missing signals. As the sampling frequency of 250 Hz matched that of the wearable Holter device, resampling was not required. To match the single-lead configuration of the wearable device, only the channel labeled ECG1 was used for all AFDB recordings; the 2 channels were neither averaged nor randomly selected.

The AFDB contains annotations comprising 4 rhythm categories: atrial fibrillation (AFIB), atrial flutter (AFL), junctional rhythm (JR), and normal rhythm (NR). Each event was annotated with a sample-level onset position and corresponding label. For comparison with the proposed method, these annotations were converted into 10-second interval labels. When multiple labels occurred within a 10-second interval, the label with the longest duration was assigned as the representative label.

As AT/AFL episodes were excluded from the institutional training and validation datasets, AFL-annotated intervals were excluded from the primary external validation analysis to ensure consistency between the training task definition and the external test framework. Intervals corresponding to AFIB were mapped to the AF class, whereas those corresponding to JR and NR were mapped to the non-AF class. No additional supraventricular rhythm categories were separately annotated in the AFDB; therefore, no further rhythm-specific remapping was performed. As the database lacked explicit noise labels, intervals containing visually apparent noise were newly annotated and assigned to the noise class. Noise was defined as a visually uninterpretable ECG segment in which reliable rhythm assessment was not possible because of artifact. These annotations were confirmed by 2 cardiologists. As a secondary analysis, we also evaluated an alternative framework in which AFL intervals were mapped to the AF class, reflecting a broader clinical grouping of atrial tachyarrhythmias.

For external validation, the final model was retrained using the full institutional development dataset with the same predefined architecture and training settings used in the internal validation. A 9:1 training:validation split was used for early stopping only. This approach was chosen so that all available institutional

XSL•FO
RenderX

development data contributed to the final model before testing on the completely independent AFDB. The same early stopping strategy was used, in which training was halted if the validation loss did not improve for 5 consecutive epochs. This model was then used to segment the RRI data from the AFDB into segments of each window length, convert them into 2D images, and generate predictions. The same core preprocessing pipeline was used for both the institutional data and AFDB, including R-peak detection from the full recording and generation of window-level RRI histogram images. The main AFDB-specific preprocessing steps were exclusion of nontarget intervals before window generation and remapping of the public annotation labels as described earlier. The reference label for each window was defined as the label of the longest rhythmic region in that window.

To evaluate the clinical relevance of aggregated model outputs across an entire recording, we assessed the correlation between the reference AF burden and the model-estimated AF burden on a per-patient basis. In the external validation implementation, AFL-annotated intervals were first excluded in accordance with the primary task definition. The reference AF burden was then calculated for each patient, based on the AFDB annotations, as the proportion of AF-labeled 10-second intervals among analyzable intervals after excluding noise-labeled intervals from the denominator. Model-estimated AF burden was similarly calculated as the proportion of windows classified as AF among windows classified as either AF or non-AF, thereby excluding windows classified as noise from the denominator. Mixed-rhythm windows were handled according to the predefined label assignment and window aggregation rules and were not subjected to an additional exclusion step during patient-level burden calculation.

Accuracy Evaluation and Statistical Analysis

Diagnostic Performance Metrics

Model performance was evaluated at the window level using overall accuracy and class-wise sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), F_1-score, and area under the receiver operating characteristic curve (AUROC) for the 3 classes (AF, non-AF, and noise). Overall accuracy was defined as the proportion of correctly classified windows among all evaluated windows. For each class, sensitivity, specificity, PPV, NPV, and F_1-score were calculated using a one-versus-rest framework, in which the target class was treated as positive and the other 2 classes were combined as negative. For the internal validation, these metrics were calculated separately for each of the 5 cross-validation test folds and then summarized across folds. Macroaveraged F_1-score and macroaveraged AUROC were additionally calculated to provide an overall assessment that was less affected by class imbalance. AUROC was calculated using a one-versus-rest approach for each class.

For AF burden, the association between reference and model prediction was assessed at the patient level. Pearson correlation coefficient was used as the primary measure to assess the linear association between the reference and model-estimated AF burden values. As AF burden may show a skewed distribution, Spearman rank correlation coefficient was additionally calculated as a supplementary nonparametric measure. Linear regression was also performed to characterize the relationship between the 2 methods.

Statistical Analysis Environment

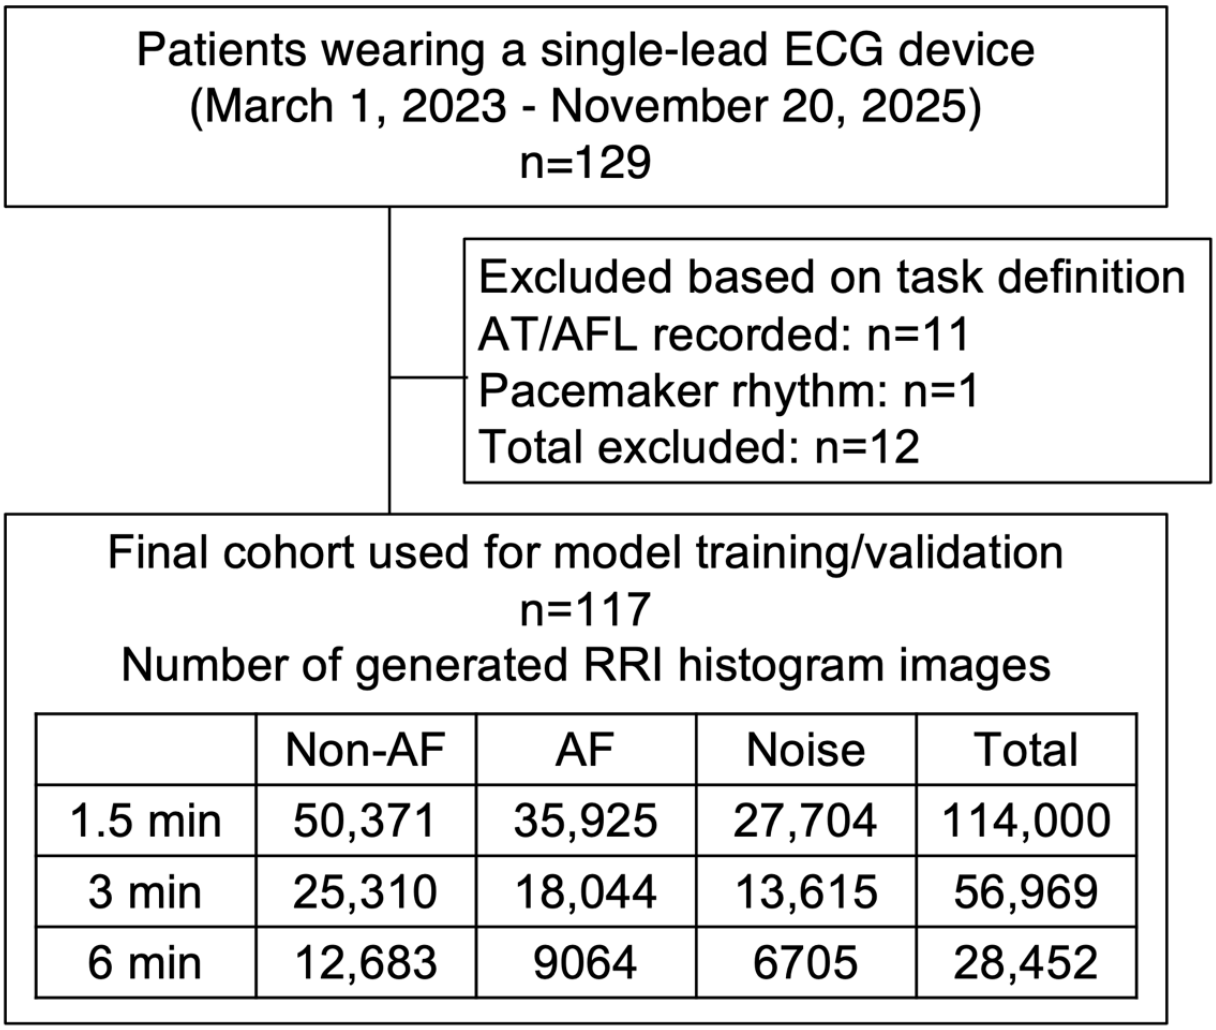
All analyses were performed using Python 3.8.8 on the Windows 11 platform. The computational environment comprised a 3.6 GHz 12-core Intel Core i7 CPU, 32 GB DDR5-4800 memory, and an ASUS GeForce RTX 3080 Ti GPU (12 GB). The ECG annotation was performed using a custom-built ECG annotation tool (GitHub). AI-assisted tools were used only for code drafting and refactoring. Specifically, ChatGPT (OpenAI; during 2025, JST) and GitHub Copilot (GitHub; during 2025, JST) assisted in the Python boilerplate generation and readability improvements. All scripts were reviewed, tested, and finalized by the authors, who took full responsibility for the analyses. No confidential or patient-identifiable information was entered into the tool.

Results

Study Population and Baseline Characteristics

Between March 1, 2023, and November 20, 2025, 129 patients underwent monitoring with a single-lead garment-type wearable Holter ECG device. Of these, 12/129 (9.3%) patients with documented AT/AFL or paced rhythm were excluded according to the predefined task definition. Consequently, 117/129 (90.7%) patients were included in model development and internal validation. Their baseline characteristics are summarized in Table 1.

Table . Baseline characteristics of the institutional cohort included in model development and internal validation at the University of Osaka Hospital (N=117).



Characteristic	Value
Age (y), mean (SD)	69.6 (12.5)
Sex (male), n (%)	77 (65.8)
Height (cm), mean (SD)	163.5 (9.4)
Weight (kg), mean (SD)	65.2 (14.9)
BMI (kg/m²), mean (SD)	24.2 (4.0)
History of AF[a], n (%)	99 (84.6)

[a]AF: atrial fibrillation.

XSL•FO
RenderX

The institutional dataset comprised a total of 2850 hours of ECG recordings from 117 patients. After segmentation and label aggregation, the number of unique window-level samples before data augmentation for the 1.5-, 3-, and 6-minute settings was 114,000, 56,969, and 28,452, respectively (Figure 4). Across all window length settings, non-AF windows were the most frequent class, whereas noise windows were the least frequent, indicating class imbalance in the generated datasets.

Figure 4. Study cohort selection and dataset generation for model development and validation in garment-type wearable Holter ECG monitoring at the University of Osaka Hospital between March 1, 2023, and November 20, 2025. Flow diagram showing patient selection from the institutional cohort, exclusion of atrial tachycardia/atrial flutter (AT/AFL) and pacemaker cases according to the predefined task definition, and the number of generated R-R interval (RRI) histogram images for model development and internal validation. The number of generated RRI histogram images represents unique window-level samples before sliding window augmentation and corresponds to the total number of test windows across the 5 cross-validation folds. ECG: electrocardiogram.

	Non-AF	AF	Noise	Total
1.5 min	50,371	35,925	27,704	114,000
3 min	25,310	18,044	13,615	56,969
6 min	12,683	9064	6705	28,452

Rhythm and Signal Quality Characteristics in the Institutional Cohort

To characterize the rhythm composition of the institutional cohort, patient-level AF burden was calculated from the original 10-second annotations as the proportion of AF-labeled intervals among analyzable intervals. The AF burden distribution was bimodal: 53 (45.3%) patients had an AF burden of 0%, whereas 49 (41.9%) patients had an AF burden of ≥80%; patients with intermediate AF burden were relatively infrequent (Table S1 in Multimedia Appendix 2).

In the rudimentary semiquantitative review of ectopic burden among 53 patients with an AF burden of 0%, estimated ectopic burden was <1% in 36 (67.9%) patients, 1% to <5% in 8 (15.1%) patients, 5% to <10% in 3 (5.7%) patients, and ≥10% in 6 (11.3%) patients. This review suggested that the non-AF recordings were not limited to exceptionally clean sinus rhythm. The distribution is summarized in Table S2 in Multimedia Appendix 2.

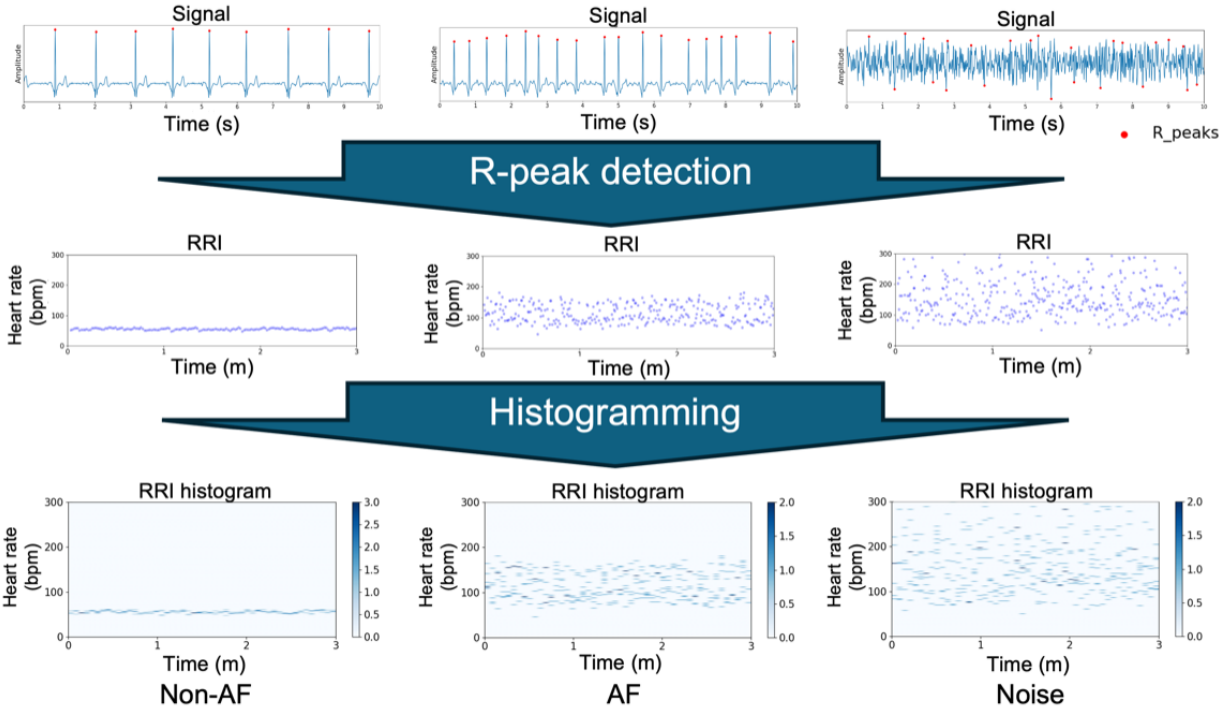
Noise-labeled intervals were commonly observed in the institutional recordings. The total number of noise-labeled 10-second intervals was 249,285, corresponding to approximately 692.5 hours of noise-labeled recording. At the patient level, the median noise burden was 17.6% (IQR 7% - 36%), and only 2 of 117 patients had a noise burden of 0%. These findings indicate that uninterpretable or unreliable

XSL•FO
RenderX

segments were commonly present in long-term garment-type wearable Holter ECG recordings. The detailed distributions of noise burden are provided in Table S3 in Multimedia Appendix 2.

Quality Assessment of R-Peak Detection

In the supplementary review of 300 randomly sampled 30-second ECG segments, 238 (79.3%) were considered annotatable. All pure non-AF segments and all pure AF segments were annotatable, and all these were graded as acceptable. Almost all pure noise segments (49/50, 98%) were judged nonannotatable and unreadable. Among noise-containing segments, 37 (74%) of 50 were annotatable and readable. Across the 238 annotatable segments, 237 (99.6%) were graded as acceptable, and 1 (0.4%) was graded as minor errors, whereas none were graded as unreliable.



Annotation Agreement Assessment

In the supplementary annotation verification analysis, 150 randomly sampled ECG segments from the in-house dataset were reassessed, including 50 non-AF segments, 50 AF segments, and 50 noise segments. Agreement with the original study annotations was high for both the reevaluation by the original annotator and the independent review by an additional cardiologist. Cohen κ was 0.91 for the comparison between the original annotations and the reevaluation by the original annotator and 0.95 for the comparison between the original annotations and the independent cardiologist, with corresponding agreement percentages of 94% and 96.7%, respectively. Detailed pairwise agreement (Cohen κ) and class-stratified agreement by label are provided in Table S4 in Multimedia Appendix 2.

Performance of the 2D-CNN Model in Internal Validation

The RRI histogram images were generated for each window length. Representative images of each class are shown in Figure 5. The proportion of candidate training windows excluded because they contained both AF and non-AF labels was less than 0.1% of all candidate windows. Exact ties requiring the application of the predefined tie-breaking rule were uncommon in the test data label aggregation process, occurring in 0% of 1.5-minute windows, 0.4% of 3-minute windows, and 0.3% of 6-minute windows. These low frequencies indicate that the tie-breaking rule had minimal influence on the overall evaluation. The mean performance metrics across the 5 cross-validation folds for each window length are presented in Table 2, and the detailed class-wise metrics, calculated in a one-versus-rest manner for the non-AF, AF, and noise classes, are provided in Table S5 in Multimedia Appendix 2.

Figure 5. Generation of R-R interval (RRI) histogram images and representative examples used for 3-class classification. Schematic of the transformation from the RRI time series to 2D histogram images, together with representative examples of non–atrial fibrillation (AF), AF, and noise windows. The noise example represents an actual artifact-contaminated waveform recorded using the garment-type wearable Holter ECG device and the corresponding RRI-derived heart rate histogram, not simulated Gaussian noise.

Table . Window-level performance metrics across the 5 cross-validation folds for the 1.5-, 3-, and 6-min models in the internal validation cohort.

Window	1.5 min, mean (SD)	3 min, mean (SD)	6 min, mean (SD)
Accuracy	0.9656 (0.0116)	0.9664 (0.0110)	0.9610 (0.0106)
Macro F_1-score	0.9633 (0.0115)	0.9641 (0.0109)	0.9582 (0.0120)
Macro AUROC[a,b]	0.9958 (0.0026)	0.9961 (0.0025)	0.9955 (0.0022)
AF[c]_Sensitivity	0.9675 (0.0318)	0.9666 (0.0268)	0.9489 (0.0418)
AF_Specificity	0.9800 (0.0090)	0.9817 (0.0081)	0.9835 (0.0037)
AF_PPV[d]	0.9558 (0.0220)	0.9591 (0.0214)	0.9636 (0.0109)
AF_NPV[e]	0.9859 (0.0135)	0.9849 (0.0112)	0.9761 (0.0187)

[a]Calculated using a one-versus-rest approach across the 3 classes.

[b]AUROC: area under the receiver operating characteristic curve.

[c]AF: atrial fibrillation.

[d]PPV: positive predictive value.

[e]NPV: negative predictive value.

The 1.5- and 3-minute windows achieved similarly high overall performance, with mean (SD) cross-validation accuracies of 96.6% (SD 1.2) for both models, macro F_1-scores of 96.3% (SD 1.2) and 96.4% (SD 1.1), and macro AUROCs of 99.6% (SD 0.3) and 99.6% (SD 0.3), respectively. For the AF class, the 3-minute model showed slightly better balance than the 1.5-minute model, with comparable sensitivity of 96.7% (SD 2.7) versus 96.7% (SD 3.2), and slightly higher specificity of 98.2% (SD 0.8) versus 98.0% (SD 0.9) and PPV of 95.9% (SD 2.1) versus 95.6% (SD 2.2). In contrast, the 6-minute model showed slightly lower overall accuracy of 96.1% (SD 1.1), macro F1-score of 95.8% (SD 1.2), and AF sensitivity of 94.9% (SD 4.2), although AF specificity remained high at 98.4% (SD 0.4). Performance for the non-AF class was also consistently high across window lengths, indicating stable discrimination of AF from non-AF rhythms in the 3-class framework. Noise class performance appeared favorable in the internal validation, although its interpretation should remain cautious in light of the lower external noise sensitivity discussed in the following paragraph. Receiver operating characteristic curves for each window length are shown in Figure S3 in Multimedia Appendix 1.

In an exploratory post hoc subgroup analysis by garment type using pooled out-of-fold predictions from the 3-minute model, performance was similar between shirt-type and belt-type recordings. Accuracy was 96.8% in shirt-type recordings and 96.5% in belt-type recordings, and AF sensitivity was 97.4 and 96.7, respectively. However, the shirt-type subgroup included fewer patients and showed substantial class imbalance; therefore, definitive conclusions regarding garment-specific performance differences cannot be drawn. The detailed subgroup results are provided in Table S6 in Multimedia Appendix 2.

Performance of the 2D-CNN Model in External Validation

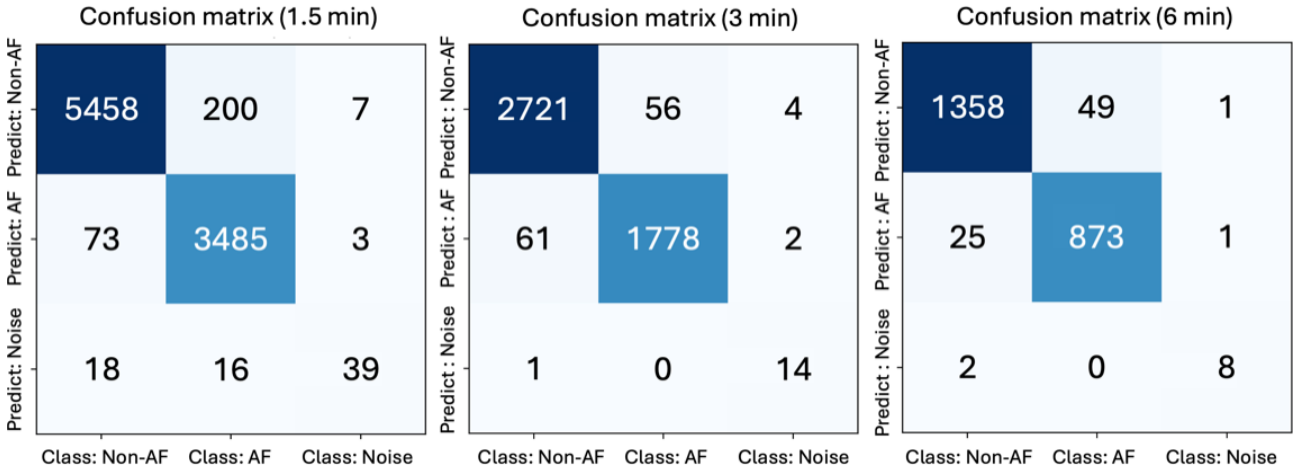
The final DL models, trained using the 117-patient institutional dataset, were evaluated using the MIT-BIH AFDB to assess their generalizability. In the primary external validation, AFL-annotated intervals were excluded to align the test-label definition with the training task, in which AT/AFL episodes had been excluded. The results are summarized in Table 3.

Table . Window-level performance metrics in the primary external validation analysis using the MIT-BIH[a] Atrial Fibrillation Database (AFDB).

MIT-BIH AFDB	1.5-min window model	3-min window model	6-min window model
Accuracy	0.9659	0.9731	0.9663
Non-AF[b]_Sensitivity	0.9836	0.9774	0.9805
AF_Sensitivity	0.9416	0.9695	0.9469
Noise_Sensitivity	0.7959	0.7000	0.8000
Non-AF_Specificity	0.9448	0.9676	0.9464
AF_Specificity	0.9864	0.9772	0.9814
Noise_Specificity	0.9963	0.9998	0.9991

[a]MIT-BIH: Massachusetts Institute of Technology–Beth Israel Hospital

[b]AF: atrial fibrillation.



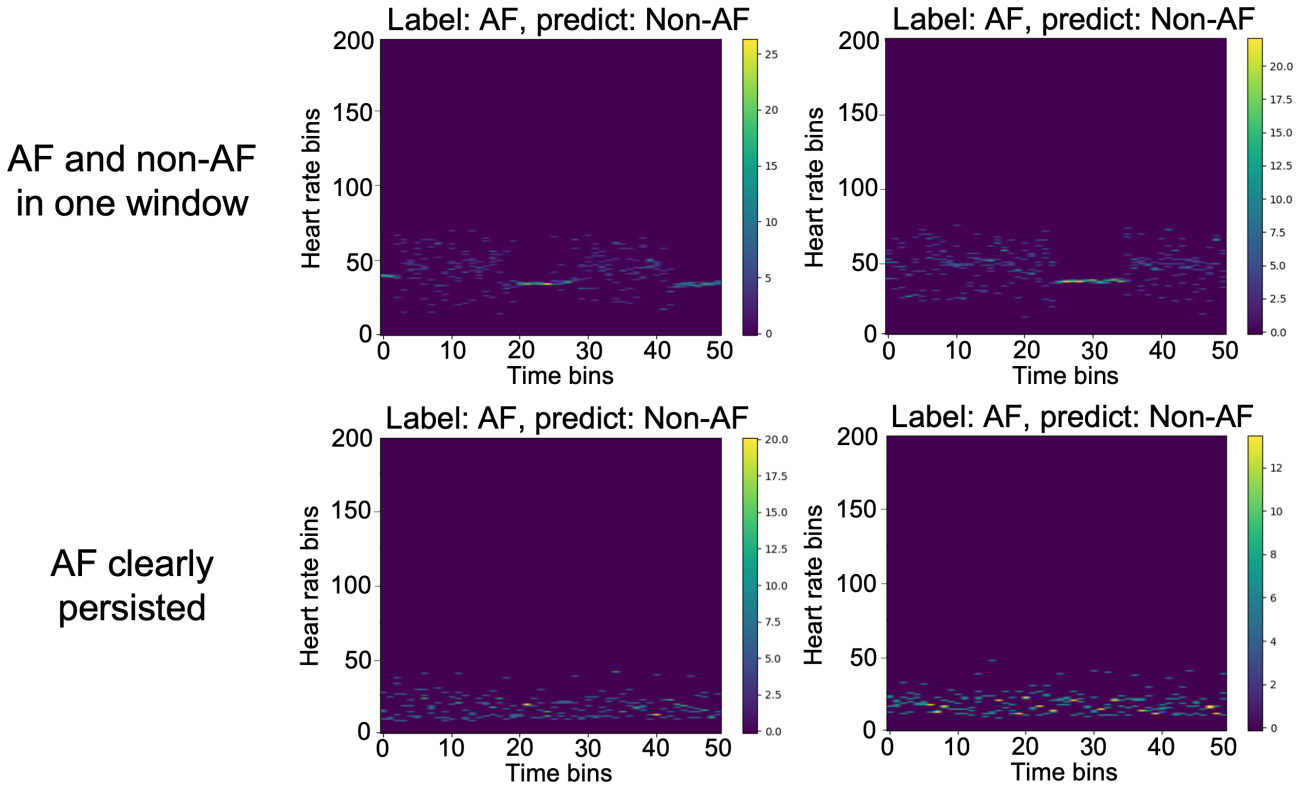
The external validation dataset consisted of 23 independent AFDB recordings (approximately 230 h in total). As the AFDB did not originally include an explicit noise label, visually uninterpretable windows were additionally annotated as noise.

XSL•FO
RenderX

The resulting reference-label distribution was imbalanced across all window length settings: for the 1.5-minute setting, 5549 non-AF (59.7%), 3701 AF (39.8%), and 49 noise (0.5%) windows; for the 3-minute setting, 2785 non-AF (60%), 1834 AF (39.5%), and 20 noise (0.5%) windows; and for the 6-minute setting, 1385 non-AF (59.8%), 922 AF (39.8%), and 10 noise (0.4%) windows.

In the AFDB, the 3-minute model achieved the window-level accuracy of 97.3%, with an AF sensitivity of 96.9% and AF specificity of 97.7%. The 1.5-minute model achieved an overall accuracy of 96.6%, AF sensitivity of 94.2%, and AF specificity of 98.6%, representing a modest reduction in overall accuracy and AF sensitivity compared to the 3-minute model. The 6-minute model showed overall accuracy of 96.6%, AF sensitivity of 94.7%, and AF specificity of 98.1%, which were slightly lower than those of the 3-minute window. Accordingly, in the external dataset, the 3-minute window showed the highest overall accuracy and AF sensitivity while maintaining high AF specificity, although the differences across window lengths were modest and no formal statistical comparison was performed. Across all window lengths, however, sensitivity for the noise class was low: 79.6% (39/49), 70% (14/20), and 80% (8/10) for the 1.5-, 3-, and 6-minute models, respectively. This result should be interpreted cautiously because the number of noise-labeled windows in the external dataset was small and the noise characteristics in the AFDB may not have fully matched those in the institutional wearable dataset. Consistent with the class-wise metrics, the confusion matrices showed that AF and non-AF were generally well discriminated, whereas noise windows were relatively infrequent and more often misclassified than the other classes (Figure 6).

Figure 6. Confusion matrices for external validation of the 3-class classification task in the Massachusetts Institute of Technology–Beth Israel Hospital (MIT-BIH) Atrial Fibrillation Database (AFDB). Confusion matrices for the primary external validation analysis using 23 independent MIT-BIH AFDB recordings, with atrial flutter–annotated intervals excluded to match the institutional training task. The x-axis indicates reference labels, and the y-axis indicates model predictions for non–atrial fibrillation (AF), AF, and noise across the evaluated window lengths.

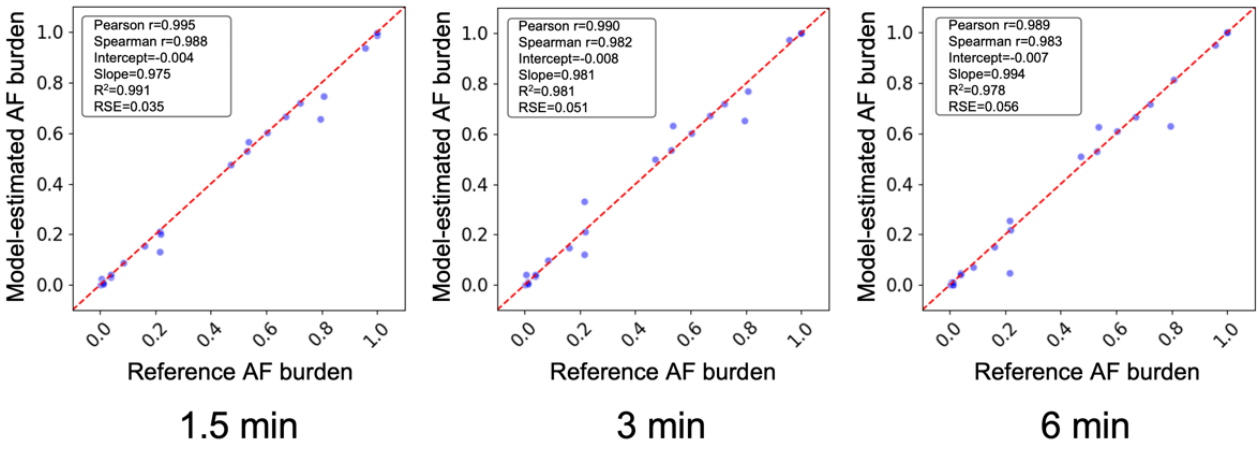


To further characterize the low noise sensitivity, we reviewed the false-negative noise windows in the 3-minute external validation analysis. Among the 20 noise-labeled windows, 6 were misclassified as non-AF or AF. Visual review of the corresponding ECG waveforms and RRI histograms suggested 2 common patterns. In 3 windows, the ECG waveform was visually nondiagnostic for rhythm interpretation, but the automatic R-peak detection algorithm generated structured RRI sequences, resulting in RRI histograms that did not show a typical scattered noise pattern. In the remaining 3 windows, visually noisy ECG portions were mixed with analyzable rhythm portions within the same 3-minute window, leaving structured RRI features in the model input despite the window-level noise label. Representative examples are shown in Figure S4 in Multimedia Appendix 1.

We visually inspected the windows misclassified by the 3-minute model to characterize common patterns in the corresponding images. Among the AF windows misclassified as non-AF, 87.5% (49/56) corresponded to images in which AF and non-AF rhythms coexisted within the same 3-minute window, whereas windows in which AF clearly persisted beyond 3 minutes but was not detected accounted for 12.5% (7/56) of the cases. These findings indicate that most AF-to-non-AF misclassifications were associated with mixed-rhythm windows. Representative misclassified images are shown in Figure 7.

XSL•FO
RenderX

Figure 7. Representative misclassified atrial fibrillation (AF) windows in the primary external validation analysis. Representative examples from the 3-min model showing AF windows misclassified as non-AF in the MIT-BIH Atrial Fibrillation Database. The figure highlights cases in which AF and non-AF rhythms coexisted within a single window, as well as cases in which AF persisted beyond 3 min but was not detected.



The results of the secondary analysis in which AFL intervals were mapped to the AF class are provided in Table S7 in Multimedia Appendix 2. Across all window lengths, performance in this secondary analysis was slightly lower than in the primary AFL-excluded analysis; for example, for the 3-minute model, accuracy decreased from 97.3% to 96.1%, and AF sensitivity decreased from 96.9% to 93.3%.

Evaluation of AF Burden

When AF burden was treated as a continuous patient-level variable derived from aggregated window-level classifications, the model showed a strong correlation with the reference AF burden across all 3 window length settings (Figure 8). Pearson correlation coefficients were 0.995 (R^2=0.991), 0.991 (R^2=0.982), and 0.989 (R^2=0.979) for the 1.5-, 3-, and 6-minute models, respectively, and the corresponding Spearman rank correlation coefficients were 0.988, 0.982, and 0.979. Overall, patient-level AF burden correlation was high across all window lengths, with only small differences between models.

Figure 8. Patient-level atrial fibrillation (AF) burden correlation in the MIT-BIH Atrial Fibrillation Database external validation cohort. Scatter plot and regression line comparing reference AF burden with model-estimated AF burden for each of the 23 external validation recordings included in the primary atrial flutter–excluded analysis. AF burden was evaluated at the patient level by aggregating reference intervals and model predictions across each recording. RSE: residual standard error.

Discussion

Principal Findings

In this study, we developed a DL model that classifies RRI-derived 2D histogram images into non-AF, AF, and noise classes using a 2D-CNN. Internal and external validation suggested that the 3-minute window provided a clinically reasonable balance across the evaluated window lengths, although the differences were modest and should be interpreted as exploratory rather than definitive. In the external validation, the model also showed high correlation with the reference AF burden at the patient level. The contribution of this study lies not in the use of a novel network architecture, but in the application and evaluation of an RRI-based 3-class classification framework that explicitly incorporates noise in real-world garment-type wearable Holter ECG recordings.

Comparison to Prior Work

For automated AF diagnosis, DL approaches can be broadly grouped into waveform-based models, RRI/heart rate variability (HRV)–based models, and multimodal frameworks that combine ECG-derived features with additional clinical information. Waveform-based models trained directly on raw ECG signals have shown high diagnostic performance in a variety of datasets, including residual network–based approaches, but their performance may depend substantially on recording format, window length, and dataset characteristics [18-22,31]. In contrast, RRI/HRV-based approaches focus on the beat-to-beat irregularity that is fundamental to AF and have been explored using transition-matrix features, entropy-based indices, multivariate classifiers, visual irregularity mapping, Lorenz/Poincaré-type representations, and image-based DL frameworks [4,23-25,32-34]. Recent multimodal work has further suggested that combining ECG with HRV and demographic information may improve AF detection performance in selected settings [35]. These studies provide useful context for the present findings, but direct numerical comparison should be interpreted cautiously because the underlying datasets, recording durations, input modalities, and intended use cases differ substantially. In this context, this study does not seek novelty in the network architecture itself; rather, its contribution lies in evaluating an RRI-based, 3-class, noise-aware framework in long-term garment-type wearable Holter ECG recordings, a setting in which noisy and clinically heterogeneous data are common. By converting the RRI time series into histogram images, this approach preserves AF-related irregularity patterns in a form suitable for CNN-based analysis while remaining conceptually closer to established HRV-based rhythm assessment than to raw waveform classification. As RRI-based representations use interval-derived information rather than full raw waveform input, converting an RRI time series into 2D images for CNN-based analysis may provide a conceptually simple and practical framework for AF screening in noisy wearable ECG recordings.

With a single-lead Holter or wearable ECG, reliably identifying P waves and fibrillatory waves (f waves), which are important for conventional AF diagnosis, can be challenging in the presence of noise. This problem is particularly pronounced in garment-type devices (eg, shirt- or belt-type systems), where artifacts arising from body movements and variable electrode contacts are common [8,36]. Garment-type Holter systems are expected to reduce the skin burden associated with adhesive electrodes, but they may be associated with more frequent noise contamination because of motion artifacts and variable electrode contact. Compared to curated public databases, real-world long-term Holter recordings contain a greater proportion of segments affected by noise artifacts. If such noise is not adequately identified, model performance, particularly specificity, may deteriorate, leading to an increased number of false positives [37]. RRI-based analysis offers a practical advantage in this setting; provided that R-peaks are accurately detected, it may be less dependent on raw waveform morphology than waveform-based approaches, making it attractive for handling noisy wearable ECG recordings [38].

To better handle noise-contaminated wearable ECG data, we implemented two additional strategies: (1) histogram binning of the RRI time series and (2) explicit annotation and learning of noise as a separate class. Histogram binning may provide a degree of local aggregation, thereby reducing the effects of minor timing fluctuations or isolated R-peak detection errors [39]. In addition, by formulating the task as a 3-class problem (non-AF, AF, and noise), the model was designed to distinguish uninterpretable segments from AF and non-AF rhythms without requiring a separate preprocessing step to exclude noisy data in advance. This framework may be advantageous for real-world wearable Holter ECG recordings, in which noise contamination is often unavoidable. Several previous studies have reported higher classification accuracies after rigorously excluding noisy segments from analysis [4,34,40]. However, such approaches may be less applicable to daily wearable monitoring, where preprocessing and manual cleaning are not always feasible. In this study, the AF diagnostic performance remained high despite the inclusion of noise-containing recordings, suggesting that this 3-class noise-aware framework is practical for AF screening in garment-type wearable ECG monitoring.

At the same time, noise sensitivity was substantially lower in the external validation than in the internal validation. One possible explanation is the very small proportion of noise-labeled segments in the external dataset, which makes sensitivity estimates unstable. Another possibility is a domain shift in noise characteristics: many noise segments in the institutional wearable dataset were associated with relatively prolonged signal degradation, such as electrode detachment or sustained signal loss, whereas the noise segments additionally annotated in the AFDB were retrospectively identified as visually apparent artifacts in a public dataset that did not originally include an explicit noise label. Additional review of false-negative noise windows suggested that some visually nondiagnostic ECG segments still yielded structured RRI histograms after automatic R-peak detection, while others contained mixed noisy and analyzable ECG portions within the same window. Thus, waveform-level visual noise annotation did not always correspond to degradation of the RRI-based feature representation used by the model, limiting the generalizability of noise classification across datasets. Although lower noise sensitivity should be regarded as a limitation, the

XSL•FO
RenderX

consistently high noise specificity indicates that the model rarely assigned analyzable AF or non-AF windows to the noise class. This may be relevant in clinical review workflows, where excessive exclusion of interpretable rhythm segments could also be undesirable. The noise class in the present framework should therefore be interpreted as an operational class to avoid forcing unreliable windows into AF or non-AF categories, rather than as a universal artifact detector. Future implementations may benefit from complementary signal quality assessment, wear status detection, or preprocessing procedures.

The choice of the analysis window length for AF detection must be aligned with the model performance and the clinical significance of AF episodes. Previous studies using cardiac implantable electronic devices have suggested that stroke risk may increase when atrial high-rate episodes persist for ≥6 minutes, and 6 minutes have therefore been proposed as a clinically relevant threshold [28,29]. In this study, considering this evidence, we evaluated window lengths of 1.5, 3, and 6 minutes. Both internal and external validations suggested that the 3-minute window provided a clinically reasonable balance between AF sensitivity and specificity. However, the differences across window lengths were modest, and no formal statistical comparison was performed; therefore, this interpretation should be regarded as exploratory rather than definitive. The 3-minute model showed a high patient-level correlation with the reference AF burden in the AFDB, with performance comparable to that reported in previous studies [4,41]. A plausible explanation for the slightly lower AF sensitivity of the 6-minute model is that longer windows are more likely to include mixed rhythm or transitional segments, which may dilute AF-related irregularity within a single window; however, the high patient-level AF burden correlation suggests that the practical impact of this effect on overall burden estimation was limited. These window-level classification metrics and patient-level AF burden estimates address complementary aspects of performance: the former reflects the model's ability to classify individual ECG windows, whereas the latter reflects the clinical interpretability of aggregating those predictions over an entire recording. Although small differences in AF burden estimates may not necessarily alter patient management in every clinical context, this analysis was included to show that the aggregated model outputs remained clinically meaningful beyond segment-level classification accuracy alone. From a practical monitoring perspective, a 3-minute window also allows AF status to be updated at relatively short intervals while still permitting consecutive-window aggregation to identify clinically relevant sustained episodes. Collectively, these findings indicate that a 3-minute RRI-based model may provide a practical balance for AF screening and AF burden assessment in ambulatory long-term Holter monitoring while allowing consecutive-window aggregation to support the detection of sustained AF episodes.

Future Directions

As the present model was specifically designed to detect AF on the basis of RRI irregularity, AT/AFL episodes were excluded from the primary training and validation framework. AT/AFL often exhibit relatively regular RRIs and therefore do not consistently share the irregular rhythm pattern that characterizes AF, making them difficult to detect reliably using an RRI irregularity–based approach alone [26]. In a secondary analysis, in which AFL was grouped with the AF class for broader clinical categorization, diagnostic performance decreased, further supporting the limited suitability of the present RRI-based framework for identifying AT/AFL as AF. Therefore, future studies should explore a 2-stage algorithm in which RRI-based screening is followed by a detailed waveform-based analysis to identify AT/AFL among segments classified as non-AF. Incorporating additional features, such as waveform morphology and periodicity measures, may help construct a more comprehensive framework for diagnosing supraventricular arrhythmias using wearable ECG devices [42].

As the demand for AI-based diagnosis from single-lead ECG data increases, AF detection algorithms embedded in standard smartwatches still face limitations, including "unclassifiable" recordings and suboptimal sensitivity and specificity [43,44]. Conversely, the direct application of DL to smartwatch ECG waveforms can yield a performance that markedly surpasses that of built-in algorithms, suggesting that the potential for AI applications in wearable ECG will continue to grow. Within this context, the RRI-based 2D-CNN model developed in this study appears to be a promising AF screening approach that combines noise-aware design with potential practical applicability in prolonged high noise settings, such as garment-type wearable Holter monitoring. Our findings may contribute to the future implementation of garment-type wearable diagnostic systems and the development of efficient AF screening tools in primary care and community-based health care settings.

Limitations

Although this study demonstrated the effectiveness of an RRI-based automatic AF detection model using single-lead Holter ECG recordings, it has several limitations.

First, although the CNN-based DL model achieved high classification performance, its decision-making process relied on internal latent representations and was not directly interpretable at the individual-prediction level. This inherent "black-box" nature reflects the broader challenge of explainability in medical AI and underscores the need for complementary approaches, such as model-agnostic explanation techniques, if the system is to be used for clinical decision support.

Second, because AT/AFL episodes and paced rhythms were excluded from the primary training and validation framework according to the predefined task definition, the present model was not designed or evaluated as a general classifier of supraventricular tachyarrhythmias or paced ECG recordings. In particular, pacemakers may artificially regulate RRIs and thereby alter the RRI irregularity patterns on which the present algorithm depends. Accordingly, its applicability to AT/AFL detection and to recordings containing paced rhythms remains limited and should be addressed in future studies using dedicated datasets and complementary features beyond RRI irregularity alone.

XSL•FO
RenderX

Third, although internal validation was performed using institutional data and external validation was conducted using the AFDB, the model's generalizability across different clinical settings, patient populations, recording conditions, and ECG devices remains uncertain. In particular, the institutional and external validation datasets were enriched for AF relative to a general screening population. As PPV and NPV are mathematically dependent on disease prevalence, the favorable predictive values observed in this study may not directly translate to lower-prevalence screening settings; in particular, the PPV may be lower when the algorithm is applied to populations in which the true prevalence of AF is low. Noise characteristics can also vary substantially among wearable devices and datasets, and this may partly explain the markedly lower noise sensitivity observed in the external validation. Future studies should determine whether the same model, or a suitably adapted version, can be applied across diverse hardware platforms, external noise conditions, and lower-prevalence screening populations. In addition, because windows containing both AF and non-AF labels were excluded from training to avoid ambiguous supervisory signals, the reported classification performance may be somewhat optimistic relative to more heterogeneous real-world recordings containing frequent rhythm transitions. The proportion of such excluded candidate training windows was less than 0.1% in the present dataset. Consistent with this low transition rate, the patient-level AF burden distribution was bimodal, with many patients showing either no AF or very high AF burden and relatively few patients showing intermediate AF burden. Therefore, patients with highly active PAF characterized by frequent transitions between AF and non-AF rhythms were likely underrepresented. Moreover, because window-level reference labels were assigned using a majority vote rule, short AF episodes occupying less than half of a given window could be underrepresented, particularly in longer windows such as the 6-minute setting. Thus, the present framework should be interpreted as a window-level AF screening and burden estimation approach rather than a definitive episode-level detector for very brief AF events.

Fourth, the proposed method depends on automatic R-peak detection because the model input was derived from RRI data. Potential sources of R-peak detection error include noise and artifacts in Holter or wearable ECG recordings, as well as limitations in the acquisition system. Although the device incorporated analog band limiting intended for antialiasing before 250 Hz ADC sampling, the available specifications did not indicate a sharp low-pass filter below 100 Hz; therefore, residual aliasing of high-frequency components cannot be completely excluded. To assess the practical reliability of the R-peak detection step, we performed a supplementary manual quality assessment using 300 randomly sampled 30-second ECG segments; however, this was not an exhaustive beat-level validation of all 2850 hours of institutional recordings. In the external validation, manually annotated noise segments in the AFDB may not have fully reproduced the sustained mechanical artifacts encountered in garment-type wearable ECG recordings, and waveform-level visual noise labels may not always correspond to degradation of RRI-based feature representations. These factors may have contributed to the low noise sensitivity observed in the external validation. In addition, because the RRI-derived histogram was limited to a predefined heart rate range of 30 to 400 beats per minute, RRIs longer than 2.0 seconds were not explicitly represented as prolonged-pause features. Thus, clinically significant pauses, such as those observed in tachy-brady syndrome, would require separate pause-detection logic or waveform-based review.

Fifth, although we performed a rudimentary semiquantitative review of ectopic burden in patients with 0% AF burden, this assessment was based on sampled non-AF ECG segments and was not a formal beat-by-beat adjudication of premature atrial contractions or premature ventricular contractions across the entire non-AF class. The review suggested that the non-AF recordings were not limited to exceptionally clean sinus rhythm, but the precise prevalence and distribution of ectopic beats in all non-AF windows remain unknown. As the present model relies entirely on RRI irregularity, frequent ectopy may mimic AF-like irregularity, and may affect the interpretation of the model's true specificity.

Conclusions

This study developed and evaluated an RRI-based AF screening approach in which RRI time series data extracted from single-lead garment-type Holter ECGs were transformed into 2D images for DL-based classification. A 2D-CNN model trained on these visualized RRI features demonstrated high classification accuracy in both internal and external validations, suggesting potential utility for AF screening in prolonged monitoring settings using recordings without paced rhythms; recordings containing paced rhythms should currently be considered outside the intended use of this RRI-based algorithm. The 3-class framework, which explicitly separated noise from AF and non-AF rhythms, may be useful for handling real-world garment-type recordings that contain uninterpretable segments. However, broader validation across more diverse patient populations, recording environments, and device types will be necessary before routine clinical deployment can be considered. Importantly, the real-world performance of this framework will depend on the reliability of R-peak detection and on device- and dataset-specific noise characteristics.

Future work should further evaluate real-time feasibility and explore integration with waveform-based approaches for other supraventricular arrhythmias, such as AT/AFL.

Funding

This study was conducted under a collaborative research agreement with the Mitsufuji Corporation, which provided research funding to the University of Osaka.

Data Availability

The electrocardiographic (ECG) data used in this study were obtained from patients who provided informed consent. The study protocol was approved by the Institutional Ethics Committee of the University Hospital. Due to ethical and legal restrictions related to patient privacy, raw ECG data are not publicly available. Anonymized and processed data (including derived R-R interval features and model input representations), as well as the analysis code, are available from the corresponding author upon reasonable request for research purposes and are subject to institutional approval. The in-house ECG annotation tool is available on GitHub [45].

Conflicts of Interest

TN, KO, TO, and YS reported research funding (to their institutions) from Mitsufuji Corporation related to this work. The other authors declare no competing interests.

Abstract

Background: Despite the increasing use of machine learning (ML) in clinical research, the early stages of data preparation, especially for structured clinical data, often receive limited methodological scrutiny. These datasets typically contain missing values, complex categorical variables, and imbalanced class distributions, all of which complicate downstream model development and interpretation.

Objective: This study introduces a structured preprocessing framework designed to address common challenges in medical tabular data and to assess how preprocessing choices affect the stability and portability of predictive models across settings.

Methods: We constructed a modular workflow comprising 3 components. First, preprocessing strategies included imputation for missing data, 3 types of categorical encoding (one-hot, frequency, and target), and resampling approaches for class imbalance (Synthetic Minority Over-sampling Technique [SMOTE] and Random Over Sampling Example [ROSE]). Second, 6 classification algorithms were used to evaluate performance patterns, including logistic regression (LGR), decision tree (DT), random forest, XGBoost (XGB), CatBoost (CAT), and light gradient-boosting machine (LightGBM). Third, we assessed cross-dataset portability using 2 datasets with distinct data-generating mechanisms: a registry for patients with end-stage renal disease (ESRD; n=412) and the population-based Behavioral Risk Factor Surveillance System (BRFSS) 2015 survey. For each dataset, we independently cleaned, standardized, encoded, tuned, and evaluated models using the same predefined hyperparameter search space, without cross-dataset feature matching or pooling the area under the ROC curve (AUC) calculations; the complete pipeline was then rerun on BRFSS as an external replication.

Results: One-hot encoding in combination with ROSE yielded the most consistent performance improvements in terms of AUC (0.940) and accuracy (0.932), particularly for classifiers sensitive to class distribution. Notably, ROSE enhanced sensitivity without substantially distorting the original data structure. Feature importance rankings also contributed to model interpretability, and performance trends were largely reproducible in cross-context application.

Conclusions: Our findings suggest that preprocessing decisions often treated as ancillary play a central role in shaping model outcomes, especially in high-variance clinical datasets. The proposed framework offers a reproducible and adaptable tool for aligning data preparation with the unique demands of health care prediction tasks and may serve as a foundation for future efforts to standardize preprocessing in clinical ML workflows.

Introduction

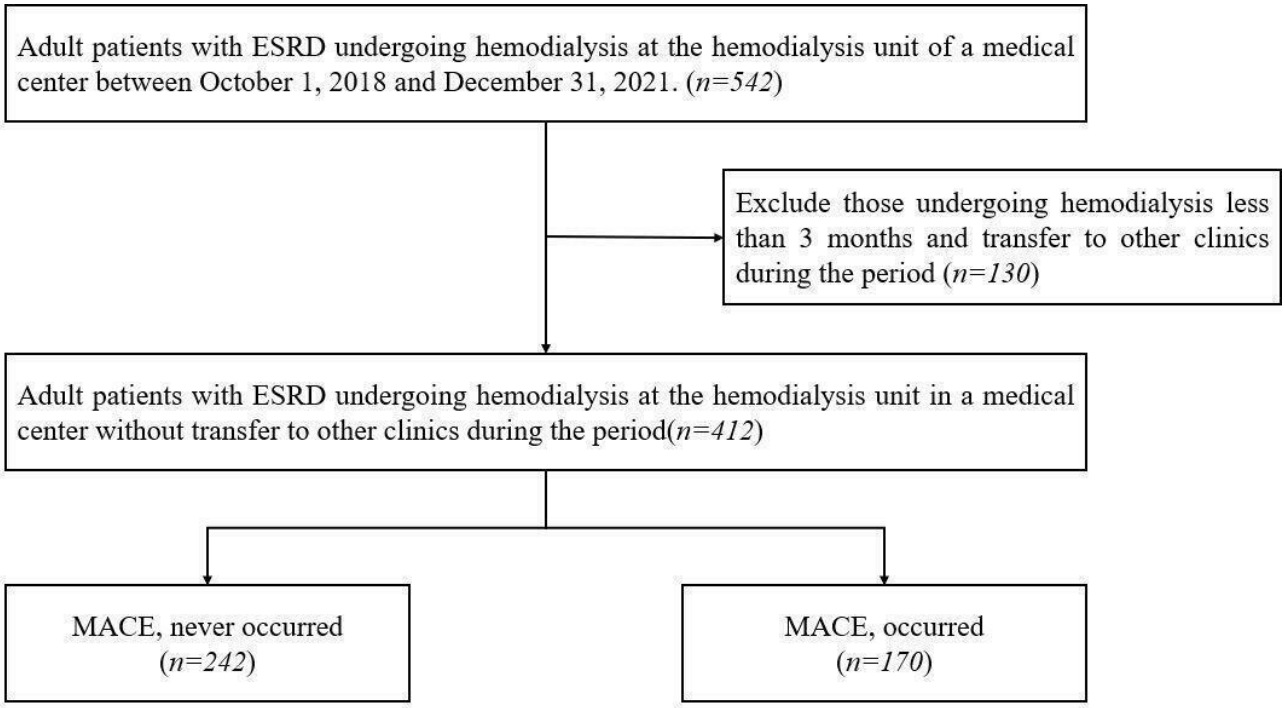
Although health care institutions generate vast volumes of health and clinical tabular data on a daily basis, these valuable resources frequently encounter significant bottlenecks when being translated into effective predictive models [1,2]. In practice, suboptimal model performance is often not attributable to the limitations of the algorithms themselves but rather to the lack of consistency and strategic planning in the data preprocessing pipeline [3,4]. Prior studies have demonstrated that various preprocessing techniques such as data imputation, normalization, and feature selection are highly sensitive in their impact on model performance [5,6], and may even introduce bias or lead to overfitting [7]. Consequently, a critical yet insufficiently addressed question arises: Can we establish a generalizable and reproducible data processing framework that assists users in selecting appropriate machine learning (ML) predictive models?

In the domain of medical informatics, ML models have been extensively used for predictive analyses of health and clinical data. However, extant literature has predominantly focused on comparing algorithmic accuracy and model performance [8,9], while offering limited systematic investigation into critical data processing steps such as data cleaning, feature encoding, and handling of class imbalance [10,11]. This oversight is particularly consequential given the inherent characteristics of medical datasets, which frequently exhibit high rates of missing values, numerous categorical variables, and severely imbalanced outcome distributions—factors that significantly influence predictive outcomes depending on the preprocessing choices made [12,13].

Despite the enormous volume of clinical and health data generated daily by health care institutions, transforming these data into effective predictive models remains challenging due to pervasive issues such as high missingness, class imbalance, and the need for robust variable encoding. Although prior studies have examined individual procedures such as comparing one-hot versus target encoding [14,15] and evaluating synthetic data augmentation techniques like the Synthetic Minority Over-sampling Technique (SMOTE) [16], systematic evaluations of the interactive effects among diverse preprocessing workflows are exceedingly scarce, particularly across heterogeneous medical datasets. Furthermore, there is a notable gap in comparative research on encoding strategies (eg, one-hot, frequency, and target encoding) and imbalance correction methods (eg, SMOTE and Random Over Sampling Example [ROSE]), which hampers the establishment of best practices in clinical ML.

This study proposes a comprehensive, reproducible framework specifically for medical tabular data. The framework is built upon three core components: (1) the Data Processing Strategy Layer, which systematically evaluates essential preprocessing techniques, including missing value imputation, variable encoding, and class imbalance correction; (2) the Model Selection and Optimization Layer, which ensures compatibility with a diverse range of supervised learning algorithms; and (3) Cross-Dataset Validation, which tests the framework's transferability and consistency on 2 highly heterogeneous real-world clinical datasets. This design not only streamlines the preprocessing pipeline but also minimizes overlap with subsequent methodological details.

The primary contribution of this work lies in developing and empirically validating an end-to-end data processing framework that transcends the limitations of single-model, single-dataset analyses. By shifting the focus from solely model-centric performance metrics to a holistic methodological architecture, our approach provides both data scientists and clinical researchers with a modular and standardized workflow. This framework is expected to bridge the gap between algorithm development and clinical application, offering robust empirical evidence and actionable guidance for advancing predictive modeling in health care.



Methods

Data Collection

Initially, we enrolled 542 adult patients with ESRD undergoing hemodialysis at the hemodialysis unit of a medical center between October 1, 2018, and December 31, 2021. Patients who had received hemodialysis for less than 3 months or who were transferred to other clinics during the study period were excluded. After these exclusions, 412 adult patients with ESRD undergoing chronic hemodialysis without transfer remained eligible for analysis. Among them, 242 patients had no occurrence of major adverse cardiovascular events (MACEs), while 170 experienced at least one MACE. The primary objective of this study was to determine the incidence of MACEs in this population. A flowchart of the study participants is presented in Figure 1. The detailed baseline demographic and clinical characteristics of the cohort are summarized in Table 1.

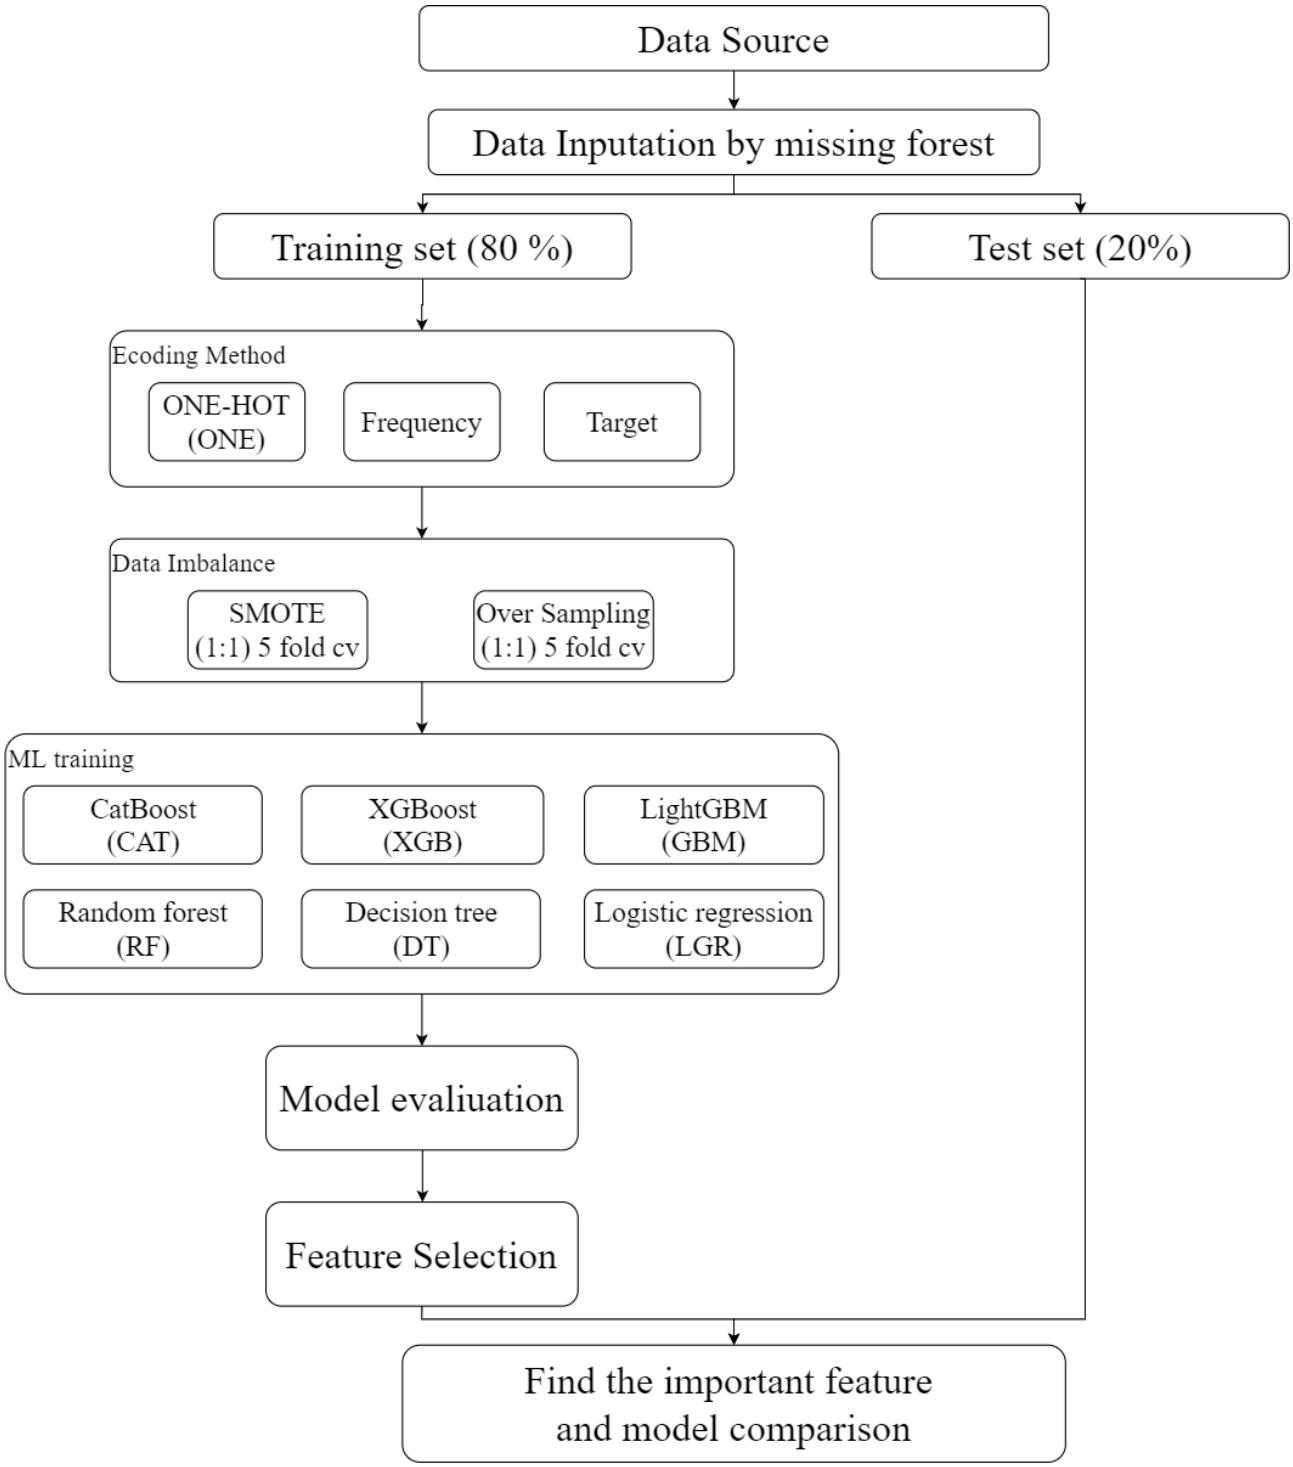
This study specifically targeted the unique clinical needs and complexities of patients with ESRD by collecting 84 variables. These variables were meticulously selected based on their significant impact on clinical outcomes in patients with ESRD. Demographic data, such as age and gender, were included, and dialysis vintage reflected the duration and history of each patient's dialysis treatment. Additionally, we detailed the anatomical and functional characteristics of the aortic and mitral valves, which are crucial for understanding cardiovascular complications in patients with ESRD. Specifically, we included parameters such as types of arteriovenous access (AVA), mitral valve calcification (MV calc), aortic regurgitation (AR), aortic stenosis (AS), mitral regurgitation (MR), and mitral stenosis (MS).

In terms of cardiovascular health, this study placed particular emphasis on the grading and types of left ventricular hypertrophy (LVH) [17] and the ejection fraction (EF) of the heart, which are critical indicators of cardiovascular health in patients with ESRD. Given the high prevalence and impact of comorbidities such as diabetes mellitus, hypertension, dyslipidemia, coronary artery disease, heart failure, chronic obstructive pulmonary disease, liver cirrhosis, malignancy, arrhythmia, and a history of amputation among patients with ESRD, we included these comorbidities in our analysis.

To better meet the clinical needs of patients with ESRD, we expanded the range of biochemical laboratory data. This included comprehensive assessments of total protein, albumin, liver enzymes (aspartate aminotransferase and alanine aminotransferase), alkaline phosphatase [18], total bilirubin, lipid profiles, glucose levels, complete blood count, iron studies, aluminum levels, postdialysis weight, uric acid, and key electrolytes. To address the specific needs of patients with ESRD, we further measured calcium and phosphate metabolism indicators, such as calcium and phosphate levels, urea kinetics (Kt/V), parathyroid hormone levels, and the calcium-phosphate product, to more effectively manage mineral and bone disorders in these patients.

The medication history was also thoroughly documented, particularly focusing on drugs commonly used in the management of ESRD, such as phosphate binders, calcitriol, and other treatments relevant to the patients' condition.



This study included 412 patients. The mean age was 69.19 years, with older patients more likely to experience MACE (70.94 years vs 67.96 years, P=.01). Females comprised 46.6% of the cohort, with a lower proportion in the MACE group, although this difference was not statistically significant (P=.08). Aortic valve calcification was more prevalent in the MACE group (72.6% vs 56.1%, P=.005), and AS as well as certain types of LVH were also associated with the occurrence of MACE. Diabetes mellitus (DM) and peripheral arterial occlusive disease (PAOD) were more common among patients who experienced MACE (DM: 58.2% vs 40.9%; P=.001; PAOD: 34.1% vs 21.9%; P=.008). In terms of medication use, a higher proportion of patients in the MACE group were on insulin (P<.001) and antiplatelet drugs (P<.001). These results provide an overview of the baseline characteristics of the patients and offer important references for improving the accuracy of predictive models.

Data Preparation

The data preprocessing methodology in this study is organized into 2 primary components: variable encoding and data balancing. The overall analytical workflow and preprocessing framework are illustrated in Figure 2. This integrated approach is designed to enhance the quality and representativeness of clinical datasets, thereby improving the robustness and generalizability of subsequent predictive models.

XSL•FO
RenderX

Figure 2. Research analysis process framework diagram. Preprocessing components are fit on training folds only and then applied to validation folds; ROSE or SMOTE are applied to training folds only to prevent leakage.

Data Imputation

Missing data are a common challenge in clinical datasets and can significantly compromise the validity of statistical inferences if not appropriately addressed. In this study, we used a nonparametric multiple imputation strategy using the *missForest* package in R (R Core Team) [19]. This method uses random forest models to iteratively predict missing values based on observed data, effectively capturing complex nonlinear associations and interactions between variables. Unlike simpler imputation techniques such as mean substitution or k-nearest neighbors, missForest has been shown to yield more accurate and less biased estimates in both continuous and categorical variables, particularly in mixed type medical data [15,20]. This approach offers a robust and flexible foundation for downstream ML analysis while preserving the integrity of the original dataset.

Compared to SMOTE, which generates new samples through linear interpolation between neighboring minority class points, ROSE applies a smoothed bootstrap technique. It estimates a kernel density around each minority instance and samples new

XSL•FO
RenderX

points from this local distribution. This approach allows ROSE to preserve the original variance and nonlinear structure of the data, making it particularly effective for clinical datasets where preserving subtle distributional patterns is important.

Imputation models were fit on the training fold only and then applied to the corresponding validation fold within each split. No statistics from the validation fold were used to fit the imputation model. This fold-wise procedure was repeated across all folds to prevent information leakage.

Variable Encoding and Expansion

In clinical datasets, categorical variables are abundant and require conversion into numerical formats to be effectively used in statistical and ML models. Three encoding methods were implemented to address this challenge, each offering a unique balance between preserving information and managing computational complexity. Although all 3 approaches aim to transform qualitative data into quantitative representations, they differ in their operational mechanisms and associated trade-offs.

One-hot encoding converts each categorical variable into a series of binary indicators, where each category is represented by an individual binary feature. This method maintains the inherent nonordinal nature of the original variable but can lead to a substantial increase in dimensionality, particularly when the variable in question has many unique categories. In contrast, target encoding substitutes each category with a statistical summary such as the mean, weighted mean, or smoothed mean of the target variable computed from the training dataset. This not only reduces dimensionality but also encapsulates the predictive relationship between the categorical feature and the outcome variable, although it necessitates careful handling to avoid target leakage [14]. A third approach, frequency encoding, assigns to each category a numerical value based on its relative frequency within the dataset. This method is highly efficient in reducing computational burden and memory usage, as it compresses categorical information into a single continuous variable without imposing any artificial order [21].

To combine the complementary strengths of these methods, a unified encoding strategy was adopted. Specifically, the one_hot function from the *mltools* package in R was applied to perform one-hot encoding, which expanded the original set of 83 variables to 113. This expansion increased the granularity of the dataset, facilitating a more detailed representation of the clinical phenomena under this research. The inclusion of target and frequency encoding provided an additional layer of comparison, enabling an evaluation of their relative performance under conditions of significant missingness and class imbalance. Prior work has demonstrated that, particularly in datasets with high proportions of missing data and imbalanced classes, preprocessing methods based on one-hot encoding can significantly enhance both accuracy and robustness in classification tasks [15].

All categorical encoders were fit on the training fold only and then applied to its validation fold. Target encoding used an out-of-fold smoothing scheme: for each fold, category means and smoothing weights were computed from the training fold and then mapped to the validation fold. No target information from the validation fold was used to compute encodings.

Data Imbalance

Clinical datasets often exhibit imbalanced class distributions, where the minority class, despite its clinical significance, is underrepresented. Such imbalance can lead to biased models that disproportionately favor the majority class. To counteract this, 2 complementary strategies, Random Over-Sampling (ROS) and the SMOTE, were incorporated, along with an evaluation of the ROSE method [22].

The ROSE method uses a bootstrap resampling framework augmented by kernel density estimation to generate synthetic samples for the minority class. This approach avoids the pitfalls associated with simply duplicating minority samples, offering a more nuanced correction of the class distribution. Menardi and Torelli [23] provide an extensive discussion of these resampling techniques, emphasizing their utility in balancing datasets for binary classification tasks. On the other hand, SMOTE, as introduced by Chawla et al [24], synthesizes new minority class instances by interpolating between existing samples. This technique enriches the minority class by generating additional, diverse examples, thereby improving the model's ability to capture the characteristics of rare events. Empirical studies have shown that SMOTE can lead to marked improvements in performance metrics, such as the area under the ROC curve (AUC), though it may overgeneralize when faced with extreme imbalance.

Comparative evaluations in the literature further underscore the respective merits of these techniques. For instance, Kamalov et al [25] found that ROSE, despite its relative simplicity, remains a stable and computationally efficient solution, especially in multi-label contexts. Similarly, investigations by Gnip et al [26] and Nguyen et al [27] have confirmed that both ROSE and SMOTE are effective in mitigating the adverse effects of class imbalance, with the optimal choice being contingent upon the specific characteristics of the dataset and the available computational resources.

Integration of Preprocessing Components

The overall preprocessing workflow was designed to integrate the 2 components variable encoding and data balancing, into a coherent sequence. Initially, missing values were imputed using the random forest approach, ensuring that the dataset was complete and reliable. This was followed by the transformation of categorical variables via the combined encoding strategy, which not only translated qualitative data into numerical features but also expanded the feature set to enhance data granularity. Finally, class imbalance was addressed through the application of ROSE and SMOTE, thereby ensuring that the resulting dataset was well-suited for the development of predictive models.

Each preprocessing step was carefully implemented so that subsequent operations built upon an increasingly refined version of the dataset. The robust imputation stage preserved the original data's distributional properties, while the encoding procedures facilitated the construction of a rich, multidimensional feature space. The balancing techniques further adjusted the dataset to

XSL•FO
RenderX

prevent bias toward the majority class, enabling the models to more effectively capture the subtleties of clinically significant, albeit rare, events.

Methodological Rationale and Literature Justification

The methodological choices articulated above are firmly grounded in this body of literature. The use of a random forest–based imputation method is well-supported by studies demonstrating its efficacy in preserving data structure and ensuring the validity of statistical inferences [15,19]. Similarly, the comparative evaluation of encoding methods draws on prior research that highlights the trade-offs between dimensionality, computational efficiency, and the risk of target leakage [14,21]. Moreover, the advantages of one-hot encoding in contexts marked by high missingness and class imbalance have been substantiated by empirical investigations [15]. The incorporation of data balancing strategies, including ROSE and SMOTE, is equally well-documented, with seminal works establishing their effectiveness in correcting class imbalances [23,24], and more recent studies further validating these methods [25-27].

The data preprocessing methodology presented herein represents a rigorous and systematic approach to overcoming the multifaceted challenges inherent in clinical datasets. By sequentially addressing missing data, encoding categorical variables into a more informative numerical format, and correcting class imbalances, the workflow transforms raw clinical data into a format that is both analytically robust and amenable to predictive modeling. This integrated preprocessing pipeline is instrumental in bridging the gap between the complexities of clinical data and the demands of advanced statistical and ML techniques, ultimately contributing to the development of models that are both reliable and clinically pertinent.

Class rebalancing was applied only to the training portion of each fold. Validation folds preserved the original class distribution. For transparency and reproducibility, we report resampling parameters in Table S4 in Multimedia Appendix 1, including SMOTE and ROSE sampling ratios and the random seed used.

Data Segmentation

k-fold cross-validation is a commonly used resampling technique for evaluating the performance of ML models. Specifically, the dataset is divided into k subsets (folds), and in each iteration, one subset is used as the validation set while the remaining k-1 subsets are used as the training set. This process is repeated k times, with a different subset used for validation each time. This method effectively prevents overfitting and provides a more robust evaluation of the model. It is particularly useful for estimating the generalization error in small datasets [28].

In this study, we used 5-fold cross-validation to obtain an accurate estimate of model performance through multiple splits and evaluations while reducing bias caused by data partitioning.

Robust Model Engineering: Tuning, Processing, and Risk Mitigation

All preprocessing and modeling steps, including cleaning, standardization, encoding, resampling, model fitting, and hyperparameter tuning, were executed separately within each dataset. No features, encoders, parameters, or statistics were transferred across datasets. For each model, hyperparameters were tuned by grid search with 5-fold cross-validation on the training set. A single predefined hyperparameter search space and evaluation criterion, detailed in Table S1 in Multimedia Appendix 1, was used for both ESRD and BRFSS. Grid search and model selection were rerun independently in each dataset so that optimal hyperparameters were learned within ESRD and BRFSS separately and were never reused across datasets.

Model Building and Validation-Phase 1

In Phase 1, we compared alternative encoding and class-imbalance handling strategies for predicting MACE. Traditional logistic regression and 6 ML models were evaluated, including decision trees [29], random forests [30,31], XGBoost [32], CatBoost [33], and LightGBM [34]. All models were trained and evaluated using 5-fold cross-validation [35] within each dataset, following the generic engineering framework described in the previous subsection, that is, grid search hyperparameter tuning with the shared search space in Table S1 in Multimedia Appendix 1 and dataset-specific model selection.

The workflow, including preprocessing, resampling, and hyperparameter tuning, was then rerun independently on the BRFSS 2015 dataset to assess cross-dataset portability of the pipeline rather than to externally validate a single ESRD-trained model. All training was executed on a workstation equipped with an Intel Core i9 10th-generation CPU (3.3 GHz) and 64 GB RAM, using the CPU only. Average runtimes for each pipeline are reported in Tables 2 and 3 to help readers gauge computational cost. In this phase, multiple performance metrics were used, including accuracy, sensitivity, specificity, precision, F_1-score, and AUC. The mean and SD of these metrics were calculated across folds to assess predictive accuracy, robustness, and consistency. The overall workflow is summarized in algorithm S1 in Multimedia Appendix 1.

Performance Estimation and Statistical Testing

Within each dataset, model performance was summarized from 5-fold cross-validation. For each metric (AUC, accuracy, and F_1-score), we calculated 95% CIs from the 5-fold–specific estimates using a 2-sided Student t interval. This procedure corresponds to applying the *t.test* function in R to the vector of fold-level values. Because these metrics are bounded between 0 and 1, upper limits were truncated at 1.0 when necessary, and models with zero variance across folds yield a point interval at the mean.

For pairwise AUC comparisons within the same dataset, we applied the nonparametric DeLong test to out-of-fold predictions pooled across the 5 validation folds, using the *roc.test* function from the *pROC* package. We report 2-sided *P* values; all tests are conducted within the dataset, and we do not compute pooled AUCs or conduct between-dataset hypothesis tests.

Model Refinement and Variable Selection-Phase 2

In the second phase, the AUC [36] was used to evaluate the models from the first phase. For the optimal data processing method and the corresponding best-performing ML model, a detailed scoring and ranking of variables was conducted based on their importance and contribution to the model's predictive performance.

XSL•FO
RenderX

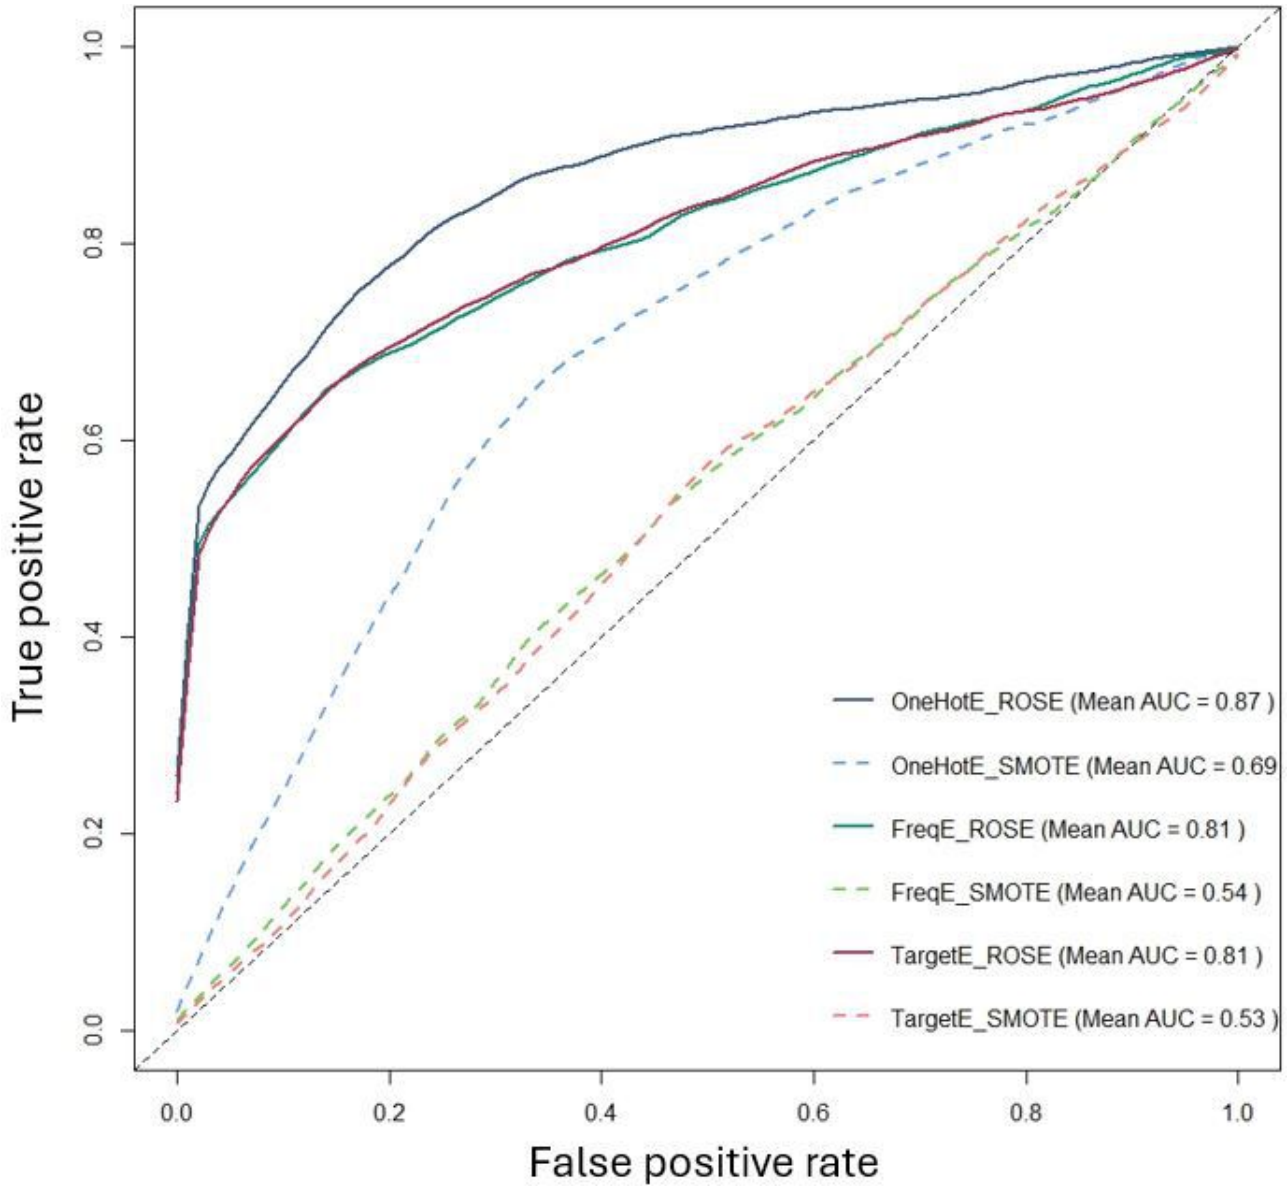
The variables were converted into percentile rankings, with the most important variable assigned a score of 100, while the least important variable was assigned a score of 0. Using the 5-fold cross-validation approach, the scores from 5 iterations were summed and ranked, with the highest possible score being 500. Based on this scoring system, the top 15 highest-ranked variables were selected for remodeling, allowing for a more focused and in-depth analysis of their impact on the outcomes.

Ethical Considerations

This study was reviewed and approved by the Institutional Review Board of Shin-Kong Wu Ho-Su Memorial Hospital (IRB No. 20231101R; approval date: December 14, 2023). The requirement for informed consent was waived by the ethics committee due to the retrospective nature of the study and the use of deidentified data. All procedures were conducted in accordance with the ethical standards of the responsible institutional and national committees on human experimentation and with the principles of the Declaration of Helsinki. The privacy and confidentiality of all participants were strictly protected throughout the study, and no personally identifiable information was disclosed. No compensation was provided to participants.

Results

Phase 1



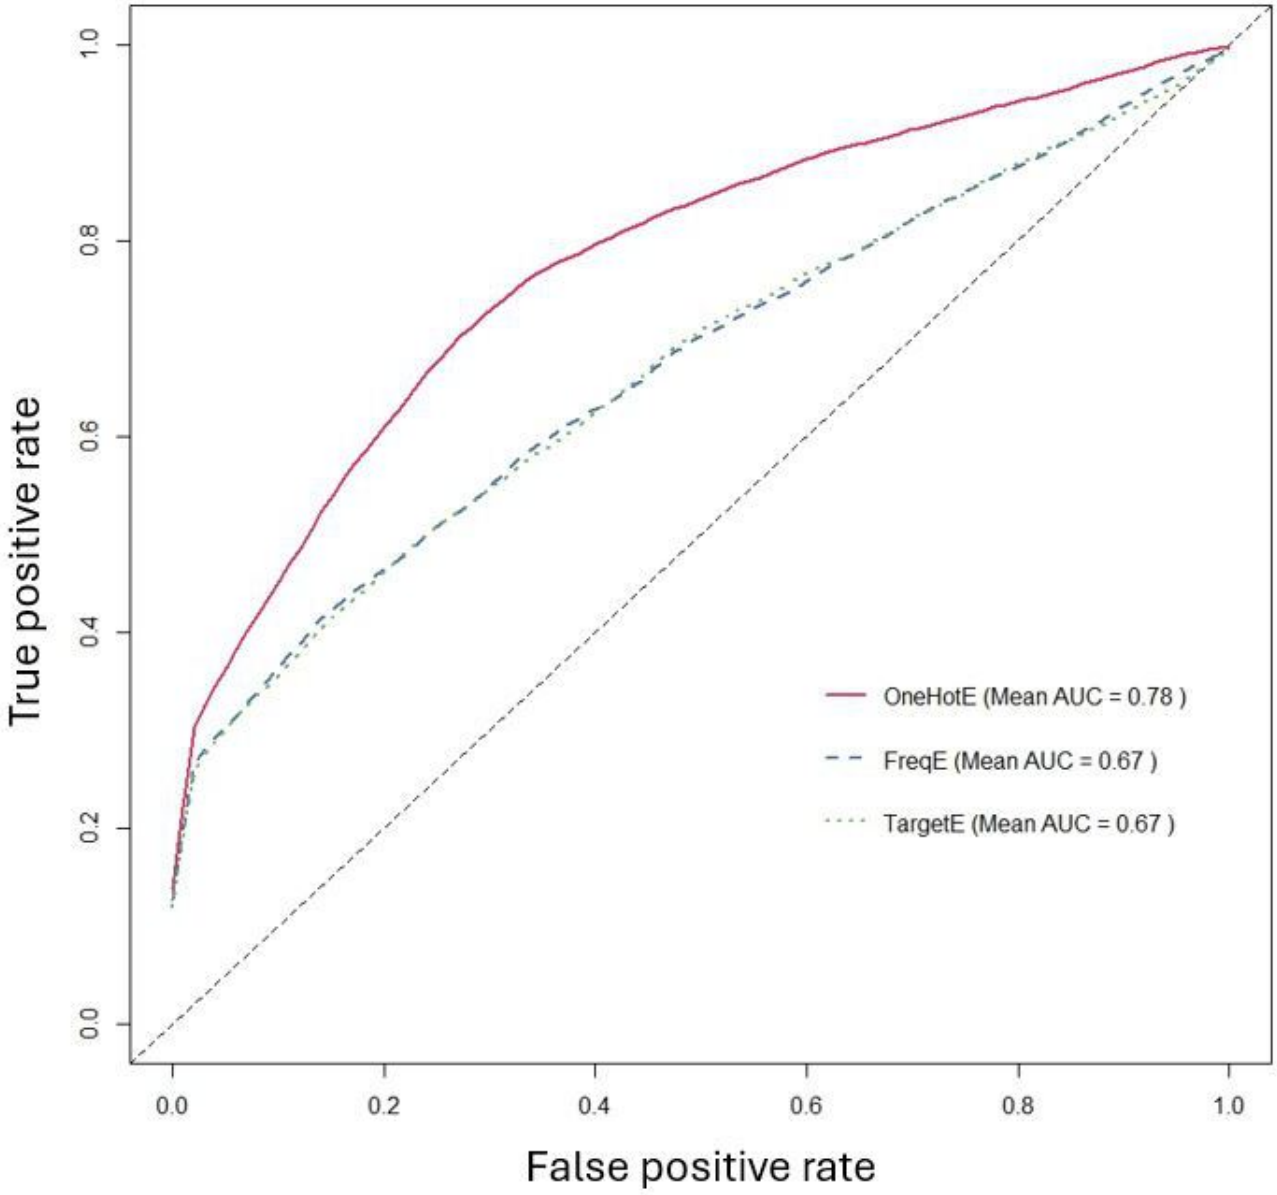
In this phase, we systematically evaluated the predictive performance of multiple ML models, including logistic regression, decision trees, random forests, XGBoost, CatBoost, and LightGBM, using 5-fold cross-validation. The primary objective was to determine the most effective combination of encoding methods (one-hot Encoding, frequency encoding, and target encoding) and data imbalance handling techniques (ROSE and SMOTE) for predicting MACE.

Models were evaluated by accuracy, F_1-score, and AUC with 5-fold cross-validation, and Table 2 reports the fold mean, SD, and t-distribution–based 95% CIs for each combination. Among all pipelines, the OneHotE_ROSE–LightGBM model achieved the best overall performance, with mean accuracy of 0.932 (SD 0.112; 95% CI 0.759 - 1.000), F_1-score of 0.918 (SD 0.137; 95% CI 0.754 - 1.000), and AUC of 0.940 (SD 0.116; 95% CI 0.794 - 1.000). Frequency and target encoding under ROSE also performed strongly (AUC 0.913 and 0.900, respectively), but at a slightly lower level than one-hot encoding in the same setting.

To formally assess differences between preprocessing strategies, we performed pairwise DeLong tests on out-of-fold AUCs, with results summarized in Table S2 in Multimedia Appendix 1. Most ROSE pipelines showed significantly higher AUC than their SMOTE counterparts (all $P \leq .002$), and OneHotE_ROSE in particular was markedly superior to OneHotE_SMOTE. Within the ROSE group, OneHotE_ROSE, FreqE_ROSE, and TargetE_ROSE did not differ significantly from each other ($P \geq .67$), indicating a top-performing cluster. Together with the averaged ROC curves in Figures 3-5, these results support selecting one-hot encoding with ROSE as the primary preprocessing strategy for Phase 2.

XSL•FO
RenderX

Figure 3. Comparison of the average area under the ROC curve (AUC) of different data models. AUC: area under the ROC curve; ROSE: Random Over Sampling Example; SMOTE: Synthetic Minority Over-sampling Technique.



A direct comparison of encoding methods in Figure 4 further confirmed that one-hot encoding was the most effective approach, achieving the highest average AUC (0.78), outperforming both frequency encoding and target encoding (both at 0.67). Meanwhile, Figure 5 illustrates that ROSE significantly outperformed SMOTE, achieving an average AUC of 0.83, compared to 0.59 for SMOTE. This result reinforces the conclusion that ROSE generates more representative synthetic samples, preserves the original data distribution more effectively, and enhances model generalization.

Our findings strongly suggest that one-hot encoding combined with ROSE is the most effective preprocessing strategy for this predictive task. This combination preserves categorical feature integrity while mitigating class imbalance, leading to the most robust and accurate predictive models. In contrast, SMOTE not only struggled to enhance model performance but, in some cases, even contributed to its degradation. These insights guided the selection of the optimal model for further feature importance analysis in Phase 2.

Phase 2

Following the identification of the optimal preprocessing strategy in Phase 1, we conducted a detailed analysis of feature importance and remodeled the dataset using the most influential variables. Table 4 presents the top 15 most important variables ranked based on their cumulative scores from 5-fold cross-validation, with antiplatelet, chest X-ray for aortic arch calcification (CXR.AoAC).0, and insulin emerging as the most significant predictors. These variables were selected to refine the models, ensuring a more efficient and interpretable predictive framework.

XSL•FO
RenderX

Table . The top 15 variables ranked by importance after 5-fold cross-validation.

Ranking	Feature	Score[a]
1	Antiplatelet	496
2	CXR.AoAC[b].0	466
3	Insulin	453
4	No.of.hypotension.episodes	435
5	CXR.AoAC.2	434
6	Dyslipid	410
7	DM[c]	392
8	AVA[d]	378
9	AR[e].0	367
10	AV.cal[f]	348
11	PAOD[g]	337
12	LVH[h].type.1	302
13	Calcitriol	299
14	AS[i].0	295
15	Statin	292

[a]The score calculation method is as follows: in the 5-fold cross-validation, the fields are sorted according to their importance, with the highest being 100 and the lowest being 0. The scores from the 5 folds are then summed to obtain the final score.

[b]CXR_AoAC: chest X-ray for aortic arch calcification.

[c]DM: diabetes mellitus.

[d]AVA: aortic valve area.

[e]AR: aortic regurgitation.

[f]AV cal: aortic valve calcification.

[g]PAOD: peripheral arterial occlusive disease.

[h]LVH: left ventricular hypertrophy.

[i]AS: aortic stenosis.

The high-performing ML models from Phase 2 identified a set of correlated features predictive of MACE in patients with ESRD, which can be grouped into 3 main clusters, including structural predictors of MACE, systemic burdens with traditional risk factors, and other indicators of disease severity. The corresponding feature importance profile for the Phase 2 LightGBM model is visualized in Figure S1 in Multimedia Appendix 1. The first group includes aortic arch calcification statuses (CXR.AoAC.0 and CXR.AoAC.2), and concentric LVH (LVH.type.1). These features reflect the model's ability to capture structural markers representative of the broader spectrum of chronic kidney disease–mineral and bone disorder pathology. Moderate AoAC and AV calcification signal cumulative metabolic and inflammatory insults from longstanding phosphate imbalance, high uremic toxin burden, and chronic inflammation [37-39], while the absence of calcification indicates a protective cardiovascular profile to MACE risk. Additionally, concentric LVH has been long recognized as an independent predictor of MACE and all-cause mortality in patients with ESRD [17,40], results from chronic pressure overload, often due to arterial stiffness secondary to vascular calcification. Collectively, these structural changes contribute to hemodynamic consequences such as heart failure and fatal arrhythmias, thereby resulting in higher MACE risk [41].

The second group of predictors comprises DM, dyslipidemia, and PAOD. DM and dyslipidemia are well-established contributors to atherosclerosis and are exacerbated in ESRD [42,43], forming a vicious cycle with both ESRD-specific and traditional risk factors. For example, hyperglycemia promotes the accumulation of advanced glycation end-products due to impaired clearance, leading to endothelial dysfunction, oxidative stress, and inflammation, thereby fueling the atherosclerosis process [44]. PAOD, a direct manifestation of exacerbated systemic atherosclerosis, also shares similar underlying pathophysiology. Despite not being an isolated predictor, PAOD's strong association to higher MACE risk [45] makes it a valuable proxy for assessing a patient's total atherosclerotic burden.

The third group includes antiplatelet, intradialytic hypotension (IDH), and valvular disease status. With a score of 496, antiplatelet use serves as a surrogate marker for clinician-identified ischemic risk and thus MACE vulnerability [46]. Furthermore, the number of IDH episodes ranked fourth, underscoring the hemodynamic stress of dialysis, with

XSL•FO
RenderX

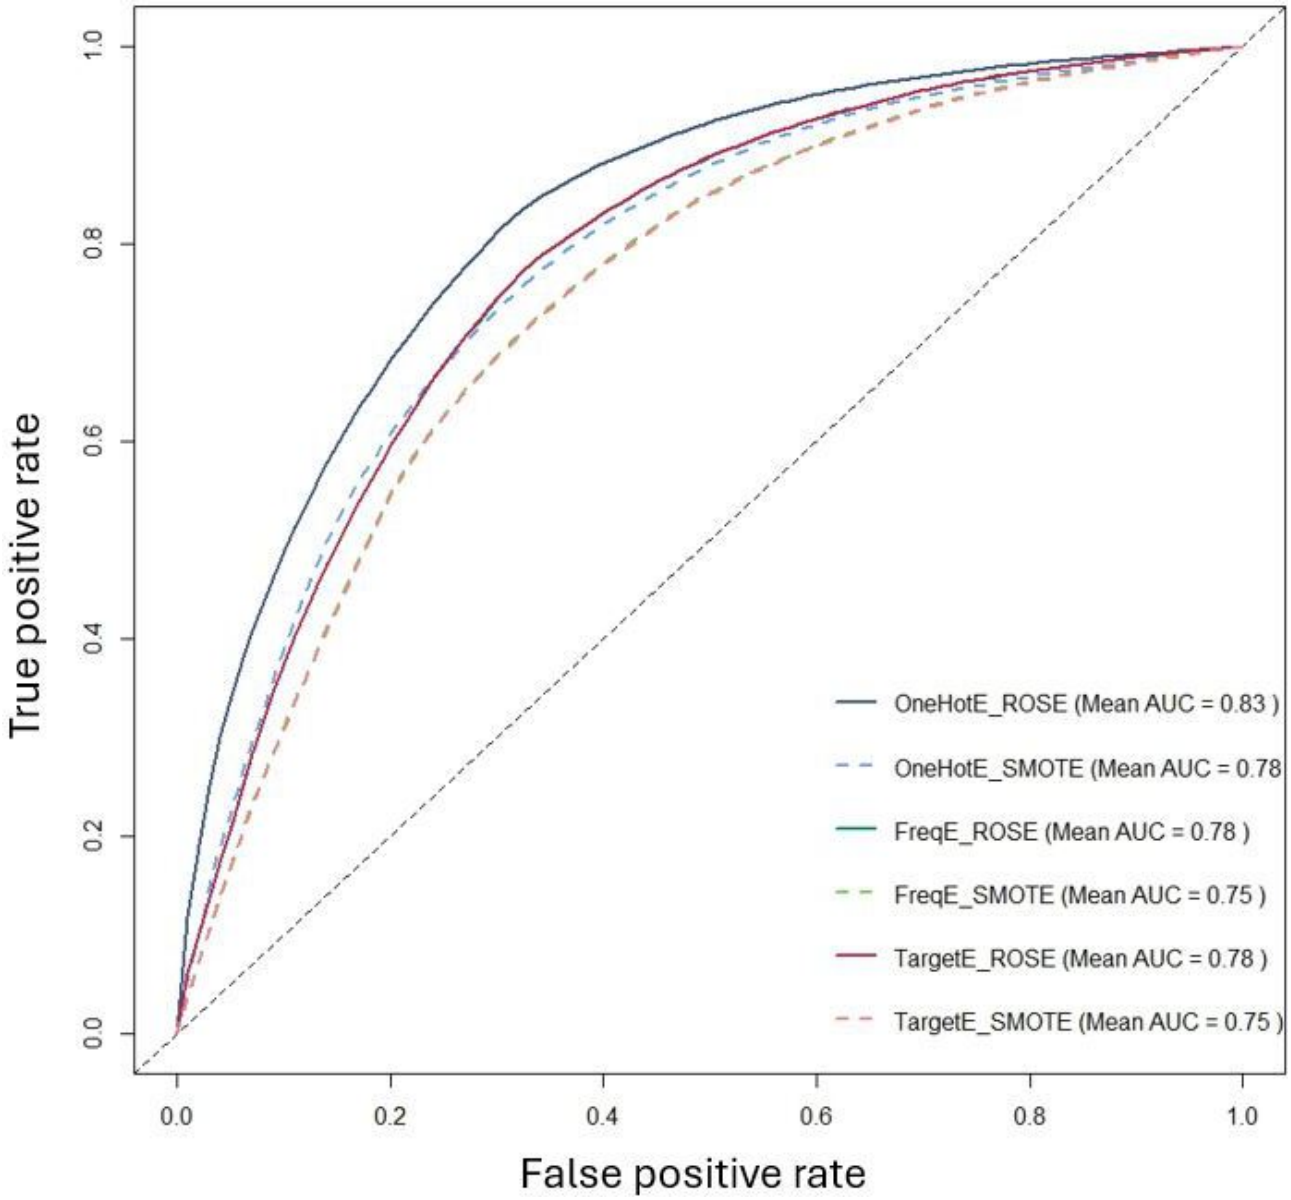
cumulative episodes contributing to myocardial stunning and ischemic damage, thus in turn linked to MACE [47]. Tracking IDH frequency could offer a more comprehensive view of cardiovascular stress rather than focusing on isolated episodes as well as the episode severity. In addition, the absence of valvular diseases such as AS or aortic regurgitation reflects a mitigated risk of LVH and atherosclerosis progression [48]. The Phase 2 model effectively learned patterns of clinical practice—such as medication use and hemodynamic instability—offering real-world applicability and insights that extend beyond static risk markers to isolated hypotensive events.

The models were then retrained with one-hot encoding combined with either ROSE or SMOTE, and their performance was evaluated by accuracy, F_1-score, and AUC with 5-fold cross-validation (Table 3). Among the ROSE-based models, LightGBM and XGBoost achieved the highest discrimination, with LightGBM reaching accuracy 0.906 (SD 0.115; 95% CI 0.763 - 1.000), F_1-score 0.892 (SD 0.119; 95% CI 0.745 - 1.000), and AUC 0.925 (SD 0.112; 95% CI 0.786 - 1.000), and XGBoost reaching accuracy 0.913 (SD 0.122; 95% CI 0.762 - 1.000), F_1-score 0.899 (SD 0.138; 95% CI 0.728 - 1.000), and AUC 0.906 (SD 0.137; 95% CI 0.736 - 1.000). Random forest under ROSE also performed well (AUC 0.915; 95% CI 0.750 - 1.000), confirming that ensemble methods benefited most from the refined feature set.

To place these gains in context, we also examined the traditional logistic regression (LGR) baseline in the same table. LGR trained in only 0.08 s for both ROSE and SMOTE variants, confirming its computational efficiency. However, its discrimination lagged behind the ML models, with AUC values of 0.755 (ROSE) and 0.728 (SMOTE). This contrast highlights a clear trade-off: while LGR offers near-instantaneous runtime, the proposed ML pipeline delivers markedly stronger predictive accuracy, justifying its added complexity for clinical applications.

To validate the statistical significance of these differences, we conducted DeLong tests for all model pairs, with detailed *P* values reported in Table S3 in Multimedia Appendix 1. ROSE-based ensembles (LightGBM, XGBoost, and random forest) achieved significantly higher AUCs than all SMOTE-based models (all $P \leq .022$), while differences among the ROSE ensembles themselves were small and often not statistically significant. In contrast, the logistic regression baseline under ROSE achieved AUC 0.755 (SD 0.050; 95% CI 0.694 - 0.817), clearly lagging behind the gradient boosting models despite its very short training time. These findings confirm that combining ROSE with gradient-boosted ensembles yields the most stable and discriminative performance in the Phase 2 setting.

These findings highlight the robustness of ROSE in preserving critical data characteristics, while the selection of the top 15 features enhanced model efficiency without compromising predictive accuracy. The combination of ROSE with XGBoost and LightGBM yielded the most reliable performance, reinforcing the effectiveness of targeted feature selection and imbalance handling in MACE prediction.



Discussion

Principal Results

To assess cross-dataset portability and reproducibility, we applied the integrated preprocessing and modeling framework to 2 datasets with distinct data-generating mechanisms: an in-house ESRD registry (n=412) and the population-based BRFSS 2015 survey. Cross-dataset comparisons of model performance, encoding strategies, and imbalance-handling methods are summarized in Figures 6-8. For each dataset, the full workflow was executed independently, including missForest imputation, one-hot, frequency, target encoding, ROSE or SMOTE resampling, model tuning, and evaluation, with no cross-dataset feature matching and no pooled AUC computations. The framework yielded improved discrimination and clinically interpretable feature-importance rankings in both settings.

Limitations

Our study has several constraints that warrant consideration. The ESRD cohort includes 412 patients, which limits the capture of rare patterns; multicenter expansion is ongoing to increase diversity. Despite 5-fold cross-validation, nested grid search, and an independent BRFSS run to assess cross-dataset portability, overfitting cannot be fully excluded, so temporal and multi-site validations are planned. Although the workflow performed well for cardiovascular and metabolic endpoints, its applicability to other disease domains remains uncertain and will be explored. By design, the BRFSS analysis did not involve feature harmonization, pooled AUCs, or between-dataset hypothesis tests. Finally, while ROSE outperformed SMOTE in our experiments, optimal resampling and encoding choices are likely dataset dependent, and hybrid strategies and embedding-based representations merit further investigation.

Comparison With Prior Work

In contrast to previous studies that tend to focus on isolated aspects of data preprocessing, our research offers a comprehensive, end-to-end framework that addresses the multifaceted challenges inherent in clinical data, namely high missingness, heterogeneity, and severe class imbalance. While earlier works typically investigated single techniques in a limited scope, our study integrates multiple advanced methods and validates the entire pipeline using cross-dataset comparisons. This holistic approach provides a stronger foundation for both improving predictive performance and facilitating clinical translation, marking a clear advancement over traditional, piecemeal methodologies.

Conclusions

This study introduces a robust, generalizable, and interpretable data preprocessing framework for predicting MACEs among patients with ESRD. Although the improvements in performance metrics are incremental, they directly address key challenges

XSL•FO
RenderX

inherent in clinical data heterogeneity and quality. The proposed pipeline enhances both predictive reliability and model transparency, offering practical value for clinical decision support and operational planning in nephrology care.

While system-level integration was not the primary focus of this work, the pipeline was deliberately designed for seamless adoption in real-world settings. By using routinely available clinical variables and lightweight computational procedures, it can be incorporated into existing analytics environments with minimal architectural adjustment. This design supports efficient deployment across diverse institutions and datasets, as evidenced by the consistent performance observed in both the ESRD registry and the BRFSS dataset. Such scalability reinforces its translational potential for broader clinical and public health applications.

Future work should prioritize cross-context application across more heterogeneous populations and evaluate the integration of deep learning architectures to further enhance predictive accuracy and extend applicability to other high-risk patient groups and chronic disease domains.

Abstract

Background: Predicting enterocutaneous fistula (ECF)–associated sepsis and mortality poses significant challenges in digital health care due to the disease's complexity and heterogeneous clinical manifestations. Current approaches that rely on single-modal data or traditional scoring systems often fail to capture the intricate immune-inflammatory dynamics and multisystem involvement in patients with ECF.

Objective: This study aims to develop an artificial intelligence (AI)–driven multimodal fusion model integrating clinical, imaging, and transcriptomic data for early prediction of ECF-associated sepsis and 28-day mortality, addressing the limitations of conventional single-dimensional models.

Methods: This study leveraged publicly available datasets (Medical Information Mart for Intensive Care III [MIMIC-III], electronic Intensive Care Unit [eICU], and The Cancer Genome Atlas) to construct a multimodal framework. Clinical parameters were processed using Extreme Gradient Boosting, abdominal imaging features were extracted via convolutional neural networks, and transcriptomic profiles were analyzed with variational autoencoders. A Transformer-based fusion network was employed for joint prediction and validated through cross-validation and external testing. Key features were identified using Shapley Additive Explanations and Local Interpretable Model-Agnostic Explanations interpretability algorithms, while immune regulatory mechanisms were explored via weighted gene co-expression network analysis.

Results: The multimodal model achieved an area under the curve (AUC) of 0.89 for predicting sepsis and 28-day mortality, outperforming unimodal models (clinical-only model, AUC 0.72, and imaging-only model, AUC 0.78). Critical predictors included Sequential Organ Failure Assessment score, lactate levels, intra-abdominal free fluid on imaging, and immunoregulatory genes (programmed death-ligand 1 [PD-L1] and indoleamine 2,3-dioxygenase 1 [IDO1]). Mechanistic analysis revealed distinct immune reprogramming in patients with sepsis, characterized by increased regulatory T cells and M2 macrophages, along with downregulated cluster of differentiation 8+ (CD8+) T cells.

Conclusions: This multimodal AI model offers an innovative digital solution in medical informatics, enabling precise early risk stratification for ECF-associated sepsis. By integrating multisource data and providing interpretable insights into

XSL•FO
RenderX

immune-inflammatory pathways, the model enhances health care quality for patients with ECF and paves the way for personalized intervention strategies.

(JMIR Med Inform 2026;14:e79985) doi:10.2196/79985

KEYWORDS

enterocutaneous fistula; sepsis; multimodal artificial intelligence; immunoregulation; radiomics; transcriptomics

Introduction

Enterocutaneous fistula (ECF) is a severe digestive system complication secondary to abdominal surgery, severe infection, or inflammatory bowel disease [1,2]. Its primary characteristic is the outflow of intestinal contents into the abdominal cavity or onto the body surface through fistulous channels [3,4]. Although uncommon in clinical practice, ECF has attracted significant attention due to its highly complex infection pathways and high mortality rates [5]. Complicated intraabdominal infection (CIAI) and secondary sepsis represent the most critical causes of death in patients with ECF, with rapid disease progression and mortality rates reaching 30%-50% [2,6]. However, current clinical practice lacks effective tools for early risk assessment and intervention in these patients, leading to delayed identification of high-risk cases and postponed interventions, which significantly compromise treatment efficacy and prognostic improvement [7,8].

From a mechanistic perspective, patients with ECF with concurrent abdominal infections exhibit complex immune dynamics involving both structural damage to the intestinal mucosal barrier and bacterial translocation [9,10], accompanied by features of immune dysregulation such as T-cell dysfunction, impaired antigen presentation, upregulation of immunosuppressive factors, and cytokine storms [11]. This immune reprogramming not only exacerbates systemic inflammatory response syndrome but also directly promotes the development of multiple organ dysfunction syndrome [12,13]. Consequently, accurately identifying immune dysregulation states and predicting infection risk in complex clinical scenarios has become a key scientific challenge in infectious diseases and critical care medicine.

Artificial intelligence (AI) and deep learning (DL) have achieved revolutionary progress in medical big data mining in recent years. These technologies demonstrate unprecedented potential, particularly in the joint modeling of multisource heterogeneous data, automated extraction of complex imaging features, and intelligent identification of potential biomarkers [14,15]. As an advanced AI approach, multimodal fusion models integrate clinical indicators, molecular features, and imaging data to construct unified representation spaces, offering novel solutions for precise prediction and exploration of pathological mechanisms in complex diseases [16,17]. This strategy has demonstrated dual advantages in the prediction and interpretation of oncology and stroke.

To further clarify the innovative aspects and methodological positioning of this study, we conducted a systematic review and comparison of recent representative AI-based sepsis prediction studies (Table 1). We summarized their data modalities, algorithmic frameworks, major strengths, and existing limitations to highlight the potential advantages and research gaps of a multimodal fusion strategy for complex infection prediction.

However, AI applications in ECF-associated complex infections and sepsis remain at an early stage. Existing studies predominantly rely on Sequential Organ Failure Assessment (SOFA) scores or single experimental indicators to construct simple classifiers for mortality prediction, lacking systematic integration of immune mechanisms, molecular characteristics, and clinical dynamics. This limitation hinders their ability to meet clinical demands for intelligent stratification of complex diseases. Therefore, there is an urgent need for an AI-based prediction system with strong generalizability, high interpretability, and clear mechanistic relevance to facilitate precise identification and intervention guidance for high-risk individuals.

The novelty of this study is reflected in several key aspects. First, we focus on the highly heterogeneous clinical scenario of ECF-associated CIAI and secondary sepsis, and develop an AI-based risk prediction framework tailored to real-world surgical decision-making rather than relying on generic models derived from unselected intensive care unit (ICU) populations. Second, within a unified modeling architecture, we systematically integrate longitudinal clinical variables, abdominal imaging phenotypes, and transcriptomic features, thereby establishing a closed-loop strategy that simultaneously optimizes predictive performance, model interpretability, and mechanistic insight. Third, the model adopts a modular and scalable multimodal design: while the full trimodal configuration enables mechanistic exploration, a dual-modal version can maintain comparable predictive accuracy in clinical settings where transcriptomic data are unavailable, thus balancing scientific depth with practical deployability. Finally, by combining explainable modeling with network-based bioinformatics analyses, we identify key candidate druggable factors, providing potential translational clues for personalized intervention and targeted therapeutic strategies.

To address these challenges, this study develops a multimodal DL prediction model integrating clinical data, RNA expression profiles, and computed tomography/magnetic resonance imaging (CT/MRI) data. The framework combines multiple submodel architectures, including Extreme Gradient Boosting (XGBoost), convolutional neural networks (CNNs), and variational autoencoders (VAEs), with a transformer-based fusion architecture for multitask learning. The model simultaneously predicts “sepsis risk” and “28-day mortality risk,” while employing interpretability algorithms such as Shapley Additive Explanations (SHAP) and Local Interpretable Model-Agnostic Explanations (LIME) to identify key predictive factors. Further

XSL•FO
RenderX

integration of weighted gene coexpression network analysis (WGCNA), differential expression analysis, and immune cell infiltration inference helps decipher immune regulatory network changes and identify core intervention targets, providing a theoretical foundation for mechanistic research and potential therapeutic strategies.

Table 1. Comparative summary of existing artificial intelligence–based sepsis prediction approaches.[a]

Study	Data modality	Core algorithm	Strengths/advantages	Limitations/weaknesses	Relevance to this study
Fleuren et al [7]	Multistudy review (intensive care unit/emergency department/inpatient, clinical data)	Systematic review and meta-analysis	Quantified diagnostic accuracy of various machine learning models for sepsis; established baseline methodology.	High heterogeneity among studies; few real-world deployments.	Serves as a methodological benchmark for AUC[b]/PR[c]-AUC metrics and reporting standards.
Wang et al [18]	Clinical and laboratory (electronic health record)	Random forest and logistic regression	Simple, interpretable, and deployable; used open datasets.	No imaging or molecular data; limited generalization.	Provides a strong single-modality clinical baseline for comparison.
Yan et al [19]	Structured and unstructured clinical text	Natural language processing and machine learning hybrid	Demonstrated that text and structured data improve early detection.	Heterogeneous methods and a lack of a standardized feature space.	Highlights potential to replace transcriptomic data with clinical text for near real-time settings.
Liu et al [20]	Time-series electronic health record (MIMIC-III[d])	XGBoost[e] and temporal feature engineering	Temporal modeling improved AUROC[f]; robust on public datasets.	Still electronic health record–only; lacks imaging/molecular integration.	Serves as a tree-based temporal modeling baseline.
Peng et al [21]	Transcriptomics	Gene signature and risk scoring	High interpretability via immune gene signatures; mortality prediction focus.	Computationally intensive; limited clinical applicability.	Provides a benchmark for molecular-level analysis and model interpretability.
Yang et al [22]	Clinical (multimodel evaluation)	Multiple machine learning algorithms	Broad performance benchmarking across models.	No multimodal integration.	Supplies a comparative reference for overall metric ranges.

[a]This table systematically compares representative artificial intelligence studies on sepsis prediction published in recent years, encompassing both single-modality (clinical, temporal, and transcriptomic data) and multimodal (structured + textual data) modeling strategies. Each study lists its data type, core algorithm, main advantages, and limitations, while the "Relevance to this study" column highlights the relationship and complementary value of each work relative to the multimodal model proposed in this study.

[b]AUC: area under the curve.

[c]PR: precision-recall.

[d]MIMIC-III: Medical Information Mart for Intensive Care III.

[e]XGBoost: Extreme Gradient Boosting.

[f]AUROC: area under the receiver operating characteristic curve.

Methods

Study Patients and Sample Collection

This retrospective study utilized publicly available databases and did not directly involve patient recruitment or intervention. The study population comprised adult patients diagnosed with CIAI, sepsis, or both from the Medical Information Mart for Intensive Care III [MIMIC-III], electronic Intensive Care Unit (eICU), and Gene Expression Omnibus (GEO) databases. Inclusion criteria were (1) confirmed ECF diagnosis; (2) complete clinical follow-up data; (3) imaging findings suggestive of abdominal infection; and (4) availability of contemporaneous laboratory parameters, clinical course documentation, or molecular-level data. Exclusion criteria were (1) incomplete records; (2) severely deidentified data preventing temporal alignment; and (3) significant confounding factors such as underlying immunodeficiency or malignancy. The collected clinical data are presented in Multimedia Appendix 1.

Gene expression data were obtained from publicly available TCGA (The Cancer Genome Atlas) and GEO datasets related to abdominal infections, sepsis, and intestinal barrier dysfunction. Selection criteria required RNA sequencing (RNA-seq) or microarray data types, a sample size of 30 or more, and availability of clinical information or survival data. Imaging data primarily originated from the MIMIC-Chest X-Ray (MIMIC-CXR) and Radiopaedia databases, including CT and MRI scans from patients with ECF or abdominal infection. All data were publicly accessible, fully deidentified, and compliant with ethical standards (see Figure S1 in Multimedia Appendix 2).

For the MIMIC-III and eICU datasets, a 2-step approach was used to identify ECF cases:

- Diagnosis code anchoring: Patients with International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) code 569.81 (intestinal fistula, excluding rectal/anal fistula) recorded during hospitalization were selected.

XSL•FO
RenderX

- Supporting evidence within the temporal window (within 72 hours before or after ICU admission; at least one of the following criteria had to be met): (1) surgical or imaging reports containing the keywords “enterocutaneous fistula,” “ECF,” “entero-cutaneous,” “肠皮瘘,” or “对外瘘”; (2) fistulography, operative notes, or bedside drainage records explicitly indicating an enteric origin of the fistula; or (3) nursing or wound care documentation describing bowel contents leaking through a skin tract.

Exclusion criteria were as follows: rectal/anal fistula (ICD-9-CM 565.1) and rectovaginal fistula (ICD-9-CM 619.1). For external cohorts using ICD-10-CM, ECF was mapped to K63.2, while K60.* (anal fistula) and N82.* (female genital tract fistula) were excluded. Postoperative ECF cases were included when K91.89 co-occurred with fistula-related keywords in clinical narratives.

Text mining was as follows: Clinical records were screened using the keyword set {“enterocutaneous fistula,” “ECF,” “entero-cutaneous,” “fistula to skin,” “bowel contents from wound,” “肠皮瘘,” “肠内容物外溢”}. Ambiguous cases were independently reviewed by 2 researchers, and discrepancies were resolved through discussion to achieve consensus. The GEO and TCGA datasets were used solely for mechanistic transcriptomic analysis and were not involved in ECF case identification.

All data used in this study were obtained from publicly accessible, fully deidentified databases (MIMIC-III, eICU, TCGA, and GEO). As this study involved a secondary analysis of anonymized data, ethical review and informed consent were exempt.

Clinical Information and Label Definition

With multidisciplinary support (critical care medicine, infectious diseases, and bioinformatics analysis), clinical labels were systematically defined and categorized for patient data. The primary labels were as follows:

- Infection classification: no infection, localized infection, CIAI, and sepsis.
- Immunophenotype: immune activation, immune dysregulation, and immune suppression.
- Outcome measures: death within 28 days, ICU discharge, and prolonged hospitalization.
- Severity scores: SOFA, quick SOFA, and Acute Physiology and Chronic Health Evaluation II (APACHE II), which were used to quantify acute physiological derangements.

All labels were automatically extracted based on clinical diagnostic criteria and predefined database fields, with manual verification to ensure consistency. The training data were uniformly converted into tensor structures to facilitate subsequent model input and multimodal integration (Figure S2 in Multimedia Appendix 2).

Clinical Variable Preprocessing

The clinical data were derived from diverse sources with heterogeneous variable types, requiring standardized processing. Key steps were (1) *z* score normalization of continuous variables to eliminate scale differences; (2) one-hot encoding of categorical variables to preserve classification information; (3) temporal alignment of time-series indicators (eg, inflammatory markers and organ function scores) with sliding-window feature extraction; and (4) multiple imputation by chained equations (MICEs) for missing values, excluding fields with missing data more than 30%. After standardization and filtering, 125 feature variables were retained, comprising demographic information, organ scores, biochemical indices, and medication/intervention records, collectively forming the clinical data feature space (Figure S3 in Multimedia Appendix 2).

Image Preprocessing

All original CT and MRI images were exported in DICOM (Digital Imaging and Communications in Medicine) format and converted into high-quality PNG/JPEG files (Figure S4 in Multimedia Appendix 2). The preprocessing pipeline involved (1) window width/level adjustment to enhance abdominal structure contrast; (2) Gaussian and median filtering for noise reduction and image stabilization; (3) uniform cropping to 512×512 pixels for standardized resolution; (4) intensity normalization (0-1 range) to minimize scanner-induced pixel value variations; and (5) augmentation, including rotation (+10° or −10°), horizontal flipping, scaling, and brightness perturbation, to improve model robustness (Figure S5 in Multimedia Appendix 2). These operations were implemented using Python libraries (OpenCV, SimpleITK, and Pillow; Python Foundation). All images underwent dual evaluation by radiology experts to exclude blurred, obscured, or ambiguously labeled cases.

Gene Expression Data Processing

The genomic data comprised RNA expression profiles related to intestinal immunity from the TCGA and GEO databases. Data standardization followed this pipeline: (1) expression matrix normalization and batch effect correction using DESeq2 or limma; (2) filtering of low-expression (FPKM [fragments per kilobase of transcript per million mapped reads] <1) and low-variance genes, retaining highly variable gene sets from immune-related pathways; (3) construction of patient × gene matrices for subsequent autoencoder and WGCNA modeling; and (4) dimensionality reduction of RNA expression data to 50 latent variables via an autoencoder for multimodal fusion. All data processing was implemented in R (R Foundation) and Python environments using Bioconductor and scikit-learn packages (Figure S6 in Multimedia Appendix 2).

Data Balancing and Augmentation Strategies

To address class imbalance, the following enhancement and resampling methods were applied to the training set: phenotypic data used the synthetic minority over-sampling technique for minority class augmentation; genomic data incorporated Gaussian noise injection to improve model robustness; imaging data underwent standard data augmentation (rotation/flipping) to simulate clinical complexity; and temporal data employed window slicing and mixed sampling to generate pseudo-sequences. The final unified multimodal input tensors included a clinical variable matrix (N×125), a gene expression matrix (N×50), and an image tensor (N×1×512×512), all formatted for downstream model training.

RenderX

Model Selection and Construction

This study developed specialized submodels for clinical data, gene expression data, and medical imaging to perform feature extraction and classification prediction. Based on this, a unified multimodal fusion DL framework was established to achieve risk prediction for ECF-associated CIAI and sepsis.

Lightweight tree-based algorithms, including XGBoost and random forest, were selected for clinical data. These algorithms identified key clinical variables affecting prognosis through embedded feature selection and generated stable intermediate prediction features (Figure S7A-B in Multimedia Appendix 2). XGBoost demonstrates excellent robustness and feature interpretability, making it suitable for processing structured medical record data with missing values.

For gene expression data, a VAE model was constructed to learn low-dimensional latent expression features in an unsupervised manner, followed by a t-distributed stochastic neighbor embedding dimensionality reduction algorithm for visualization and feature compression (Figure S7F in Multimedia Appendix 2). The VAE possesses strong nonlinear fitting capabilities, enabling dimensionality reduction while preserving potential distribution patterns of expression data and facilitating subsequent fusion modeling.

A deep CNN was chosen and structurally optimized for imaging data based on 2 backbone networks, residual network 50 (ResNet-50) and EfficientNet-B0, to extract complex anatomical and inflammatory sign features from abdominal CT/MRI images (Figure S7C-E in Multimedia Appendix 2). To enhance model generalizability, a squeeze-and-excitation attention mechanism module was introduced to guide the model to focus on key lesion areas.

The output features from the 3 modalities were fused into a unified feature representation through fully connected layers. A dual-branch prediction module was implemented at the top level to simultaneously accomplish 2 tasks: “sepsis risk” and “28-day mortality risk” (ie, a multitask learning structure). The entire framework was developed on the PyTorch platform, with the fusion module referencing the Transformer Encoder architecture and incorporating a dropout strategy to prevent overfitting.

Model Training Strategy

All models were trained with GPU acceleration using NVIDIA RTX A6000 graphics cards on the PyTorch 2.1 framework. The dataset was split into training, validation, and test sets at a ratio of 7:2:1 to ensure robust generalization performance. The training protocol incorporated the following:

- Optimizer selection: AdamW optimizer with an initial learning rate of 1×10^{-4} and a step learning rate scheduler decay strategy.
- Loss function design: binary cross-entropy (BCE) loss for main task training, with weighted coefficients balancing multitask loss contributions.
- Transfer learning: ImageNet-pretrained weights initialized the imaging module, significantly improving small-sample learning efficiency.
- Early stopping: training terminated when validation loss failed to decrease for 5 consecutive epochs to prevent overfitting.
- Regularization: Dropout (P=0.30) and BatchNorm layers enhanced model stability during training.

To enhance the rigor and reproducibility of the proposed method, this study formalized the multimodal fusion and multitask learning framework as follows:

Let  denote the clinical variable matrix,  denote the imaging feature tensor, and  denote the omics feature matrix.

After encoding via corresponding feature extraction modules (eg, CNN, Transformer, or VAE), we obtain their low-dimensional representations:

$$z_c=f_c(X_c),\ z_i=f_i(X_i),\ z_g=f_g(X_g)$$

The 3 latent features are integrated via a Transformer-based encoder to obtain the fused representation:

$$z_f=\text{Fusion}(z_c,z_i,z_g)=\text{Softmax}(W_c z_c+ W_i z_i+W_g z_g)$$

In the multitask learning framework, the model outputs included the risk of postoperative fistula ($\hat{y}_1$) and the 28-day mortality risk ($\hat{y}_2$), defined as follows:

The loss function was defined as a weighted BCE formulation:

$$L=\lambda_1 \cdot \text{BCE}(y_1,\hat{y}_1)+\lambda_2 \cdot \text{BCE}(y_2,\hat{y}_2)$$

where λ_1 and λ_2 are task-specific weights, dynamically adjusted according to dataset balance and validation performance.

To evaluate the computational feasibility and clinical deployment potential of the developed multimodal AI model, we analyzed key performance indicators, including the number of parameters, training time, and inference latency. The model contained approximately 3.2×10^6 parameters, with an average training time of about 45 seconds per epoch on a single NVIDIA RTX 3090 GPU, and converged within approximately 1.2 hours. The inference time per sample was 0.18 seconds, meeting the requirement for real-time clinical prediction.

From a theoretical complexity perspective, the core Transformer-based fusion module has a time complexity of $O(N \cdot d^2)$, where N is the number of features and d is the embedding dimension. As the features from each modality were dimensionally reduced before fusion, the overall computational load remained light. The model can be stably executed on a standard high-performance workstation (Intel i9 CPU, 32 GB RAM, single GPU), requiring fewer computational resources than mainstream deep imaging models (eg, ResNet-50).

In summary, the proposed model achieves high predictive accuracy while maintaining excellent computational efficiency and hardware adaptability, supporting scalable deployment in ICU clinical environments.

XSL•FO
RenderX

Model Performance Evaluation

The model's performance was evaluated on the test set using the following metrics: AUC, which measures discriminative ability; accuracy, which indicates overall classification correctness; sensitivity and specificity, which evaluate identification capability for positive and negative samples; F_1-score, which assesses performance on imbalanced datasets; and the confusion matrix, which analyzes prediction error distribution. Additionally, to enhance clinical interpretability, SHAP and LIME were employed for explainable analysis of multimodal prediction results, identifying key decision variables, critical regions, and significant genes to strengthen model credibility and application value.

In comparison with potentially similar approaches (Table 2), the trimodal model achieved the best or cobest performance across all evaluated metrics. The dual-modal model (clinical + imaging), while not relying on transcriptomic data, retained approximately 93% of the overall predictive performance, demonstrating its feasibility for clinical deployment.

Table 2. Comparative performance of the proposed approach versus potential analogues (test set).[a]

Method	Modalities	Area under the curve	Accuracy	Sensitivity	Specificity	F_1-score	Precision-recall-area under the curve
Proposed (trimodal)	Clinical + imaging + transcriptomic	0.86	0.879	0.862	0.901	0.851	0.82
Bimodal (clinical + imaging)	Clinical + imaging	0.834	0.862	0.847	0.886	0.836	0.792
Single modal (clinical only)	Clinical	0.811	0.838	0.826	0.869	0.821	0.764
Single modal (imaging only)	Imaging	0.795	0.827	0.812	0.854	0.807	0.751
Single modal (omics only)	Transcriptomic	0.805	0.836	0.82	0.864	0.815	0.758
Logistic regression (clinical feats)	Clinical	0.782	0.818	0.798	0.842	0.792	0.728
Extreme Gradient Boosting (clinical feats)	Clinical	0.803	0.832	0.818	0.86	0.813	0.756
Sequential Organ Failure Assessment score	N/A[b]	0.742	0.792	0.761	0.815	0.747	0.69
Acute Physiology and Chronic Health Evaluation II	N/A	0.721	0.777	0.742	0.807	0.733	0.671

[a]The table compares the proposed trimodal model, the dual-modal version (excluding transcriptomic data), 3 single-modality models (clinical-only, imaging-only, and transcriptomics-only), 2 classical machine learning baselines (Logistic Regression and Extreme Gradient Boosting, both using the same clinical feature set), and traditional clinical scoring systems (Sequential Organ Failure Assessment and Acute Physiology and Chronic Health Evaluation II). All metrics were calculated on an independent test set; the precision-recall area under the curve was included as a complementary measure for imbalanced data. All metrics were calculated on an independent test set. The results show that the multimodal fusion model achieved the best or cobest performance across area under the curve, accuracy, sensitivity, specificity, and F_1-score, while the dual-modal model maintained comparable overall performance with superior clinical deployability.

[b]N/A: not applicable.

Clinical Validation and Model Optimization

To ensure the applicability and generalizability of the model in real-world settings, we designed an external validation framework based on publicly available databases. The external validation data were obtained from the eICU Collaborative Research Database version 2.0 (a multicenter open ICU dataset) and integrated with transcriptomic data from the GEO database (GSE185263 and GSE176307) to construct an independent validation cohort. A total of 134 adult ICU patients were included, with inclusion and exclusion criteria, variable structures, and data modalities kept consistent with the primary training set (MIMIC-III) to ensure the objectivity and independence of the validation results.

During the validation phase, the AI model first underwent transfer inference using the eICU dataset, and its generalization performance was evaluated using metrics such as AUC, sensitivity, specificity, and F_1-score. Subsequently, multimodal feature revalidation was conducted using the GEO transcriptomic samples to confirm the consistency of key immunologic and imaging features across independent datasets. Throughout model optimization, the fusion-layer weighting and feature selection strategies were dynamically adjusted according to the external validation outcomes, thereby improving cross-platform and cross-population prediction stability.

This closed-loop validation and optimization pipeline, built upon publicly accessible databases, facilitates a transition from a purely data-driven AI system to a validation-driven, generalizable AI system, ensuring that the model maintains robust performance and clinical transferability across heterogeneous datasets and diverse clinical environments (Table 3).

Table 3. Baseline characteristics of the external validation cohort (electronic intensive care unit).[a]

Variable	Total (n=134)	Enterocutaneous fistula–related sepsis (n=50)	Nonsepsis (n=84)	*P* value
Age (years), mean (SD)	59.2 (12.9)	60.8 (12.3)	58.3 (13.1)	.31
Male, n (%)	84 (62.7)	33 (66.0)	51 (60.7)	.53
BMI (kg/m^2), mean (SD)	24.0 (3.6)	24.3 (3.9)	23.8 (3.5)	.46
Acute Physiology and Chronic Health Evaluation II score, mean (SD)	17.3 (6.1)	20.1 (5.8)	15.7 (5.9)	.003
Sequential Organ Failure Assessment score, mean (SD)	7.6 (3.2)	9.2 (3.4)	6.7 (2.9)	.001
Lactate (mmol/L), mean (SD)	2.6 (1.3)	3.1 (1.1)	2.3 (1.3)	.004
C-reactive protein (mg/L), mean (SD)	80.2 (30.9)	94.5 (28.4)	71.5 (30.1)	<.001
White blood cells (×10^9/L), mean (SD)	12.2 (4.7)	13.9 (4.9)	11.2 (4.4)	.006
Imaging data available, n (%)	116 (86.6)	46 (92.0)	70 (83.3)	.15
RNA sequencing data available, n (%)	38 (28.4)	16 (32.0)	22 (26.2)	.47
28-Day mortality, n (%)	27 (20.1)	18 (36.0)	9 (10.7)	<.001

[a]The external validation cohort was derived from the publicly available Electronic Intensive Care Unit Collaborative Research Database version 2.0, comprising 134 adult intensive care unit patients, of whom 50 (37.3%) had enterocutaneous fistula–related sepsis. The table summarizes the main demographic, clinical, and laboratory characteristics. Continuous variables are presented as mean (SD), and categorical variables as n (%). Between-group comparisons were performed using independent-sample (unpaired), 2-tailed *t* tests or chi-square tests, depending on the data distribution. *P* values indicate statistical significance at $P<.05$.

Identification of Key Immune Factors

To further investigate the potential immune mechanisms underlying ECF-associated CIAI and sepsis, this study conducted gene-level differential analysis and regulatory network mining based on CIAI- and immune-related datasets from TCGA and GEO. First, DESeq2 and edgeR were used to perform differential expression analysis on transcriptomic data from patients with ECF with infection versus noninfected controls (differentially expressed gene [DEG] screening thresholds: |log2 fold-change| > 1 and adjusted $P<.05$), obtaining a set of candidate genes showing differential expression.

Subsequently, WGCNA was employed to construct expression modules and identify coexpressed gene modules significantly associated with clinical indicators, including sepsis severity, 28-day mortality, and immune scores. Hub genes within these modules were considered core regulatory candidate genes and prioritized for subsequent functional enrichment analysis.

To ensure the robustness of the results, multiple datasets were used to cross-validate candidate gene consistency, and stable core immune factors were screened through intersection and Venn diagram analyses.

Functional Pathway Enrichment Analysis

Functional annotation and pathway enrichment analysis were performed on the DEGs and WGCNA-identified key module genes. Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) analyses were utilized to investigate biological processes (BP) and signaling pathways related to immune activation, immunosuppression, inflammatory response, cell death, and intestinal barrier function.

The enrichment analysis was implemented in R using the clusterProfiler and enrichplot packages, with visualization of hierarchical structures and significance levels to facilitate the identification of key pathways and functional clusters. These enrichment results subsequently support the interpretation of the molecular basis underlying model predictions and their potential mechanisms.

Immune Cell Infiltration Analysis

This study performed immune cell infiltration analysis using RNA-seq data to complement transcriptomic analysis at the cellular level. The CIBERSORT and xCell algorithms were employed to estimate the relative abundance of major immune cell subsets in each sample (including T cells, B cells, monocytes, macrophages, and neutrophils). This analysis helps elucidate potential relationships between different immune states and infection phenotypes.

Subsequent correlation analysis between immune cell composition and clinical labels explored whether specific immune subset distribution patterns exist for classification or prediction purposes. This strategy may also provide foundational data for identifying potential immune intervention targets.

Intervention Potential Factors and Dynamic Feature Extraction

This study further investigated molecular factors with intervention potential by integrating DEG analysis, coexpression network structure, and immune cell infiltration patterns. Protein-protein interaction (PPI) network analysis of key genes and screening against drug databases (DrugBank and Drug–Gene Interaction Database) identified molecules with known drug-target backgrounds.

XSL•FO
RenderX

Additionally, when sample data permitted temporal grouping, immune dynamic pattern mapping was performed to preliminarily characterize expression trends of key factors during disease progression. These findings may inform future early identification strategies and time-sensitive intervention approaches.

Statistical Analysis

All statistical analyses were performed in R (version 4.2.3), Python (version 3.10), and SPSS (version 26.0) environments, using 2-tailed (unpaired) tests with a significance level of $P<.05$. For clinical and grouping variables, descriptive statistics evaluated baseline characteristic distributions, with normally distributed data presented as mean (SD) and nonnormal data as median (IQR). Between-group comparisons used independent *t* tests or Mann-Whitney *U* tests for continuous variables, and chi-square or Fisher exact tests for categorical variables. Multigroup comparisons employed 1-way analysis of variance or Kruskal-Wallis tests with least significant difference or Bonferroni correction, and repeated-measures analysis of variance was used to analyze longitudinal data. For bioinformatics data, differential expression analysis used DESeq2 or edgeR (thresholds: |log2 fold-change| > 1 and adjusted *P* value <.05, used as predefined screening criteria). GO and KEGG enrichment analyses utilized clusterProfiler (significance assessed by *P* value or false discovery rate). Immune cell deconvolution applied CIBERSORT or xCell, and Pearson or Spearman correlation examined gene-immune cell-clinical label relationships. Missing data were handled using MICE. Normality was assessed using Shapiro-Wilk or Kolmogorov-Smirnov tests, with log transformation or nonparametric tests applied when assumptions were violated. Analyses used pandas, statsmodels, scipy, and ggpubr for statistical computing and visualization.

Ethical Statement

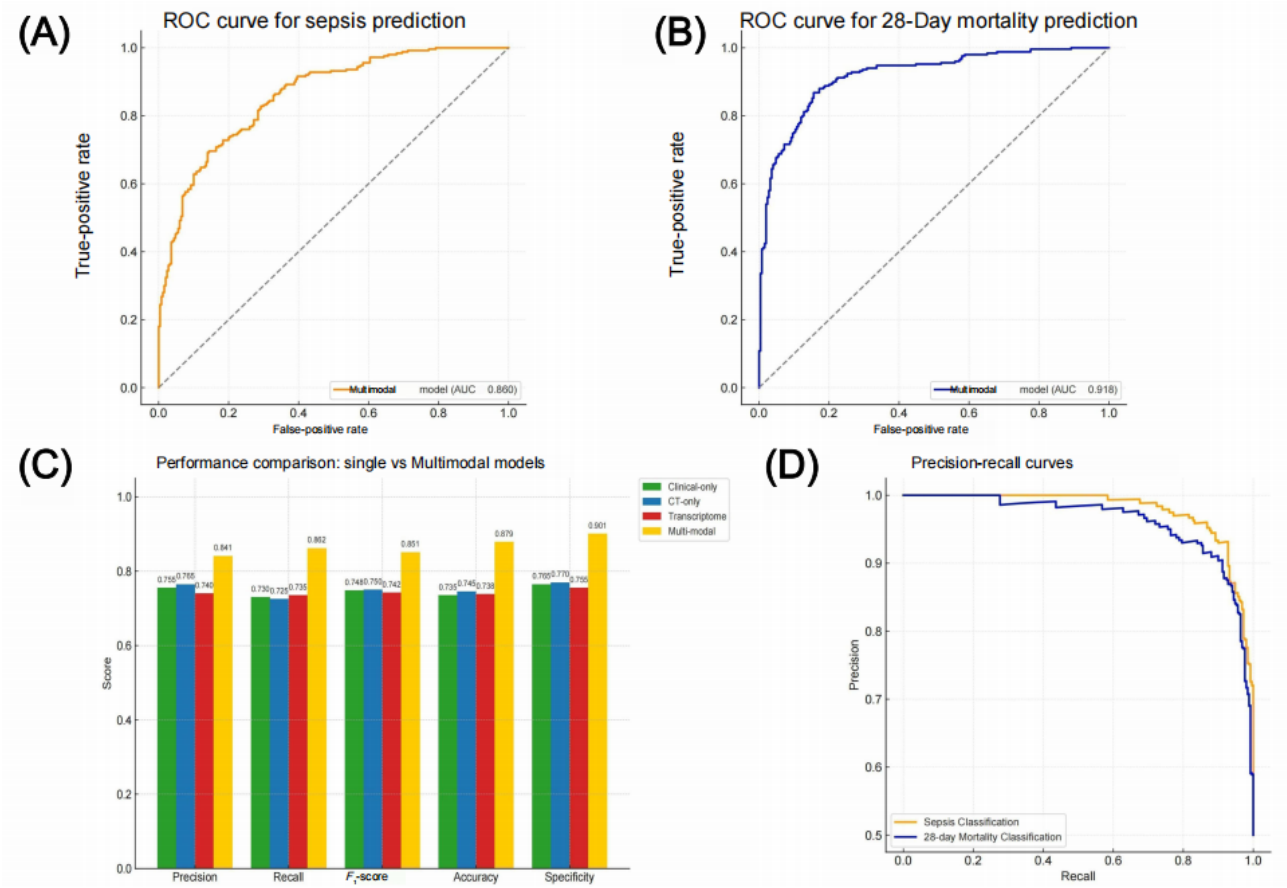
This study used publicly available, fully deidentified datasets (MIMIC-III, eICU, TCGA, and GEO). Under institutional policies and applicable regulations, analyses of such anonymized secondary data do not constitute human research. Therefore, institutional review board approval and informed consent were not required. All data were handled in accordance with applicable data protection and privacy regulations.

Results

Multimodal AI Model Significantly Enhances Prediction Performance for Sepsis and Mortality Risk

This study's multimodal AI fusion prediction model demonstrated marked advantages in identifying high-risk patients with ECF-associated CIAI and sepsis. By integrating clinical indicators, radiomic features, and transcriptomic data, the model achieved prediction performance superior to conventional unimodal models across multiple critical tasks.

In the sepsis prediction task (Figure 1A), the multimodal model generated a receiver operating characteristic curve with an AUC of 0.860, indicating robust discriminative capacity to accurately differentiate between high- and low-risk patient groups. For 28-day mortality prediction (Figure 1B), the model attained an AUC of 0.910, demonstrating equally powerful predictive capability and robustness for short-term prognosis assessment.



To further validate the practical classification performance across different tasks, we compared our multimodal model with 3 unimodal models (utilizing solely clinical, imaging, or transcriptomic data) across 5 core performance metrics (Figure 1C): precision (positive predictive value), recall (sensitivity), F_1-score, accuracy, and specificity (true-negative rate). Results showed that the multimodal model led across all metrics (precision 0.841, recall 0.862, F_1-score 0.851, accuracy 0.879, and specificity 0.901). Compared with unimodal models, the multimodal approach showed notable improvements in recall and specificity, exceeding the second-best performing model (imaging-based or clinical-based) by nearly 10% points and confirming its capacity for accurate high-risk patient identification while effectively reducing false positives.

Considering the class imbalance in clinical data (particularly for sepsis and mortality cases), we incorporated precision-recall curve analysis to more comprehensively evaluate model performance on imbalanced data (Figure 1D). Results demonstrated that the multimodal model maintained high precision and recall across both prediction tasks, with the precision-recall curve preserving good precision even in high-recall regions. This indicates the model's stability and adaptability for identifying high-risk populations.

In summary, the multimodal fusion model exhibited outstanding overall performance in predicting ECF-associated sepsis and mortality risk, demonstrating high practical utility and clinical translation potential.

XSL•FO
RenderX

Figure 1. Performance evaluation of the multimodal artificial intelligence model for predicting enterocutaneous fistula–associated complicated intraabdominal infection and sepsis. (A) Receiver operating characteristic (ROC) curve for sepsis prediction (area under the curve [AUC] 0.860), demonstrating the model's discriminative ability between positive and negative cases. (B) ROC curve for 28-day mortality prediction (AUC 0.879), indicating the model's capacity to identify high-risk patients. (C) Comparison of multimodal and single-modality models across 5 performance metrics (precision, recall, F1-score, accuracy, and specificity), showing that the multimodal model outperforms all single-modality configurations. (D) Precision-recall curve evaluating the model's robustness under class-imbalanced conditions.

Subgroup Performance Analysis

To evaluate the robustness and fairness of the model across different populations and clinical characteristics, a multidimensional subgroup analysis was conducted. The results demonstrated that the model maintained consistently high predictive performance across subgroups defined by age (<60 years vs ≥60 years), admission type (surgical vs medical patients), and immune phenotype (immune-activated vs immune-suppressed; Table 4). In the age-based analysis, the AUCs were 0.872 and 0.858, with no statistically significant difference (DeLong *P*=.41). For surgical versus medical admissions, the AUCs were 0.866 and 0.881, respectively (*P*=.37). Among immune-activated and immune-suppressed phenotypes, the AUCs were 0.885 and 0.843 (*P*=.29). Furthermore, sensitivity, specificity, and F_1-scores across all subgroups fluctuated within +0.03 or –0.03, indicating strong intergroup consistency and model stability. These findings suggest that the model demonstrates reliable discriminative capability across different age groups, clinical contexts, and immune states, thereby providing evidence for its fairness and potential for clinical generalization.

XSL•FO
RenderX

Table 4. Performance of the multimodal artificial intelligence model across patient subgroups.[a]

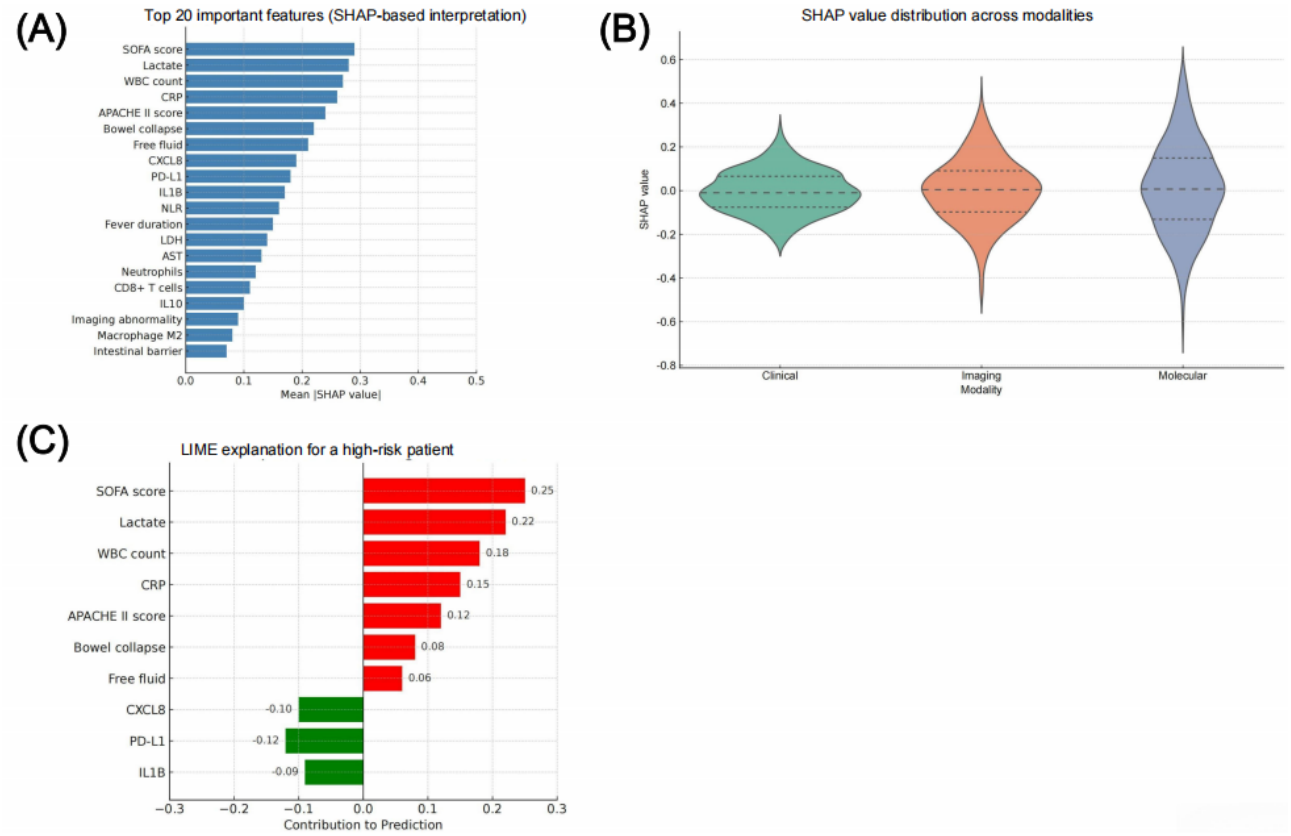
Subgroup	n	Area under the curve	Accuracy	Sensitivity	Specificity	F_1-score
Age <60 years	302	0.872	0.881	0.867	0.895	0.852
Age ≥60 years	298	0.858	0.876	0.854	0.884	0.845
Surgical admission	271	0.866	0.878	0.86	0.891	0.848
Medical admission	329	0.881	0.885	0.871	0.896	0.856
Immune-activated phenotype	262	0.885	0.888	0.875	0.902	0.857
Immune-suppressed phenotype	238	0.843	0.869	0.841	0.882	0.836

[a]The subgroup analysis included stratifications by age, admission type, and immune phenotype. All area under the curve values were calculated on the independent test set, and differences between subgroups were assessed using the DeLong test. Performance metrics are reported as mean values. The results indicate that the model maintained consistent predictive performance across different populations, with no statistically significant differences (DeLong test: age, *P*=.41; admission type, *P*=.37; immune phenotype, *P*=.29), suggesting strong fairness and robustness for clinical applications.

Interpretability Analysis Reveals Key Feature Contributions and Decision Logic of Multimodal Model

To enhance the multimodal prediction model's transparency and trustworthiness in clinical practice, this study incorporated 2 mainstream interpretability methods: SHAP and LIME. It conducted both global and local analyses of the model's decision-making logic.

First, the global feature importance ranking based on SHAP analysis (Figure 2A) showed that clinical indicators, including SOFA score, lactate level, white blood cell count, and C-reactive protein (CRP), had the highest mean SHAP values, indicating their greatest contribution to model predictions. Additionally, imaging features such as APACHE II score, intraabdominal free fluid, and intestinal structural collapse demonstrated substantial importance, reflecting the model's ability to focus on key pathophysiological indicators when integrating multimodal information.



In comparing the contribution distributions across modalities (Figure 2B), the multimodal model exhibited more concentrated and broader SHAP value distributions after fusion, demonstrating enhanced consistency and stability in decision interpretation alongside improved predictive performance. By contrast, unimodal models (clinical or imaging only) showed more dispersed feature influence and less stability.

To further validate the model's reasoning logic at the individual level, LIME analysis was performed on high-risk patient predictions (Figure 2C). Results revealed that SOFA score, lactate concentration, white blood cell count, and CRP level were positive contributing factors that substantially drove high-risk predictions, while molecular indicators such as decreased interleukin 1B (IL1B) expression and downregulated programmed death-ligand 1 (PD-L1) served as negative contributors, helping reduce false alarms. The multimodal features demonstrated complementary synergistic effects, further improving the credibility of individual-level decision-making.

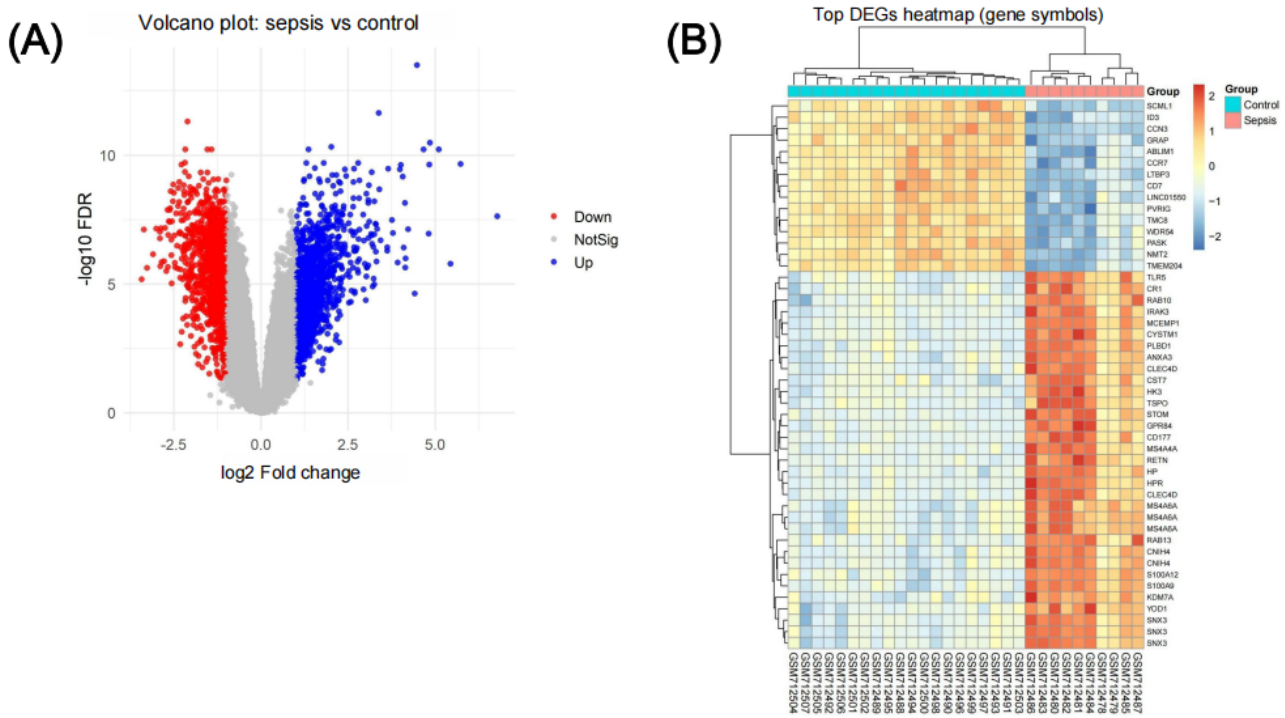
In summary, through global (SHAP) and local (LIME) interpretability mechanisms, the model successfully revealed the contribution pathways of different modal variables in the decision-making process. This enhanced the model's interpretability and provided clinicians with clear references, facilitating the transition from a "black box" to a "transparent box" clinical paradigm.

XSL•FO
RenderX

Figure 2. Global and local interpretability analysis of the multimodal artificial intelligence model. (A) Shapley Additive Explanations (SHAP)–based feature importance ranking showing the top 20 variables contributing to sepsis prediction. The Sequential Organ Failure Assessment (SOFA) score, lactate, white blood cell count (WBC), C-reactive protein (CRP), and Acute Physiology and Chronic Health Evaluation II (APACHE II) score were the major contributors, while imaging and molecular features such as bowel collapse, intraabdominal free fluid, and programmed death-ligand 1 (PD-L1) expression also showed high importance. (B) Distribution of SHAP values across clinical, imaging, and molecular modalities, illustrating the contribution and variability of features within each modality and reflecting the model's stability and consistency in multimodal fusion. (C) Local Interpretable Model-Agnostic Explanations (LIME)–based local interpretability plot for an individual high-risk patient. Red bars indicate positive contributors that increase the predicted risk, whereas green bars denote negative contributors that reduce the risk, revealing the model's decision logic at the individual-case level. AST: aspartate aminotransferase; CXCL8: C-X-C motif chemokine ligand 8; IL: interleukin; LDH: lactate dehydrogenase; NLR: neutrophil-to-lymphocyte ratio.

Differential Expression Analysis Reveals Sepsis-Associated Transcriptomic Alterations

To investigate the molecular mechanisms underlying ECF-associated CIAI and sepsis, we performed systematic bioinformatics analyses of transcriptomic data from public databases (TCGA and GEO).



Specifically, we conducted differential expression analysis between high- (sepsis) and low-risk (control) groups using DESeq2 (thresholds: |log2 fold-change| > 1, false discovery rate < 0.05), identifying 2474 significant DEGs (1294 upregulated and 1180 downregulated; Figure 3A; defined by |log2 fold-change| > 1 and false discovery rate (FDR) < 0.05). These genes potentially involve key pathological processes, including inflammation, immune regulation, apoptosis, and gut barrier function.

Hierarchical clustering heatmap analysis (Figure 3B) demonstrated clear separation of expression patterns between sepsis and control groups. In particular, it revealed enrichment of upregulated genes in sepsis samples with strong disease-state correlation. This pattern suggests that these genes may play pivotal roles in sepsis pathogenesis, providing biological insights and potential diagnostic markers.

These findings establish the molecular foundation for subsequent functional enrichment analyses (GO/KEGG) and network construction (WGCNA/PPI), while providing compelling evidence for understanding sepsis transcriptomic signatures.

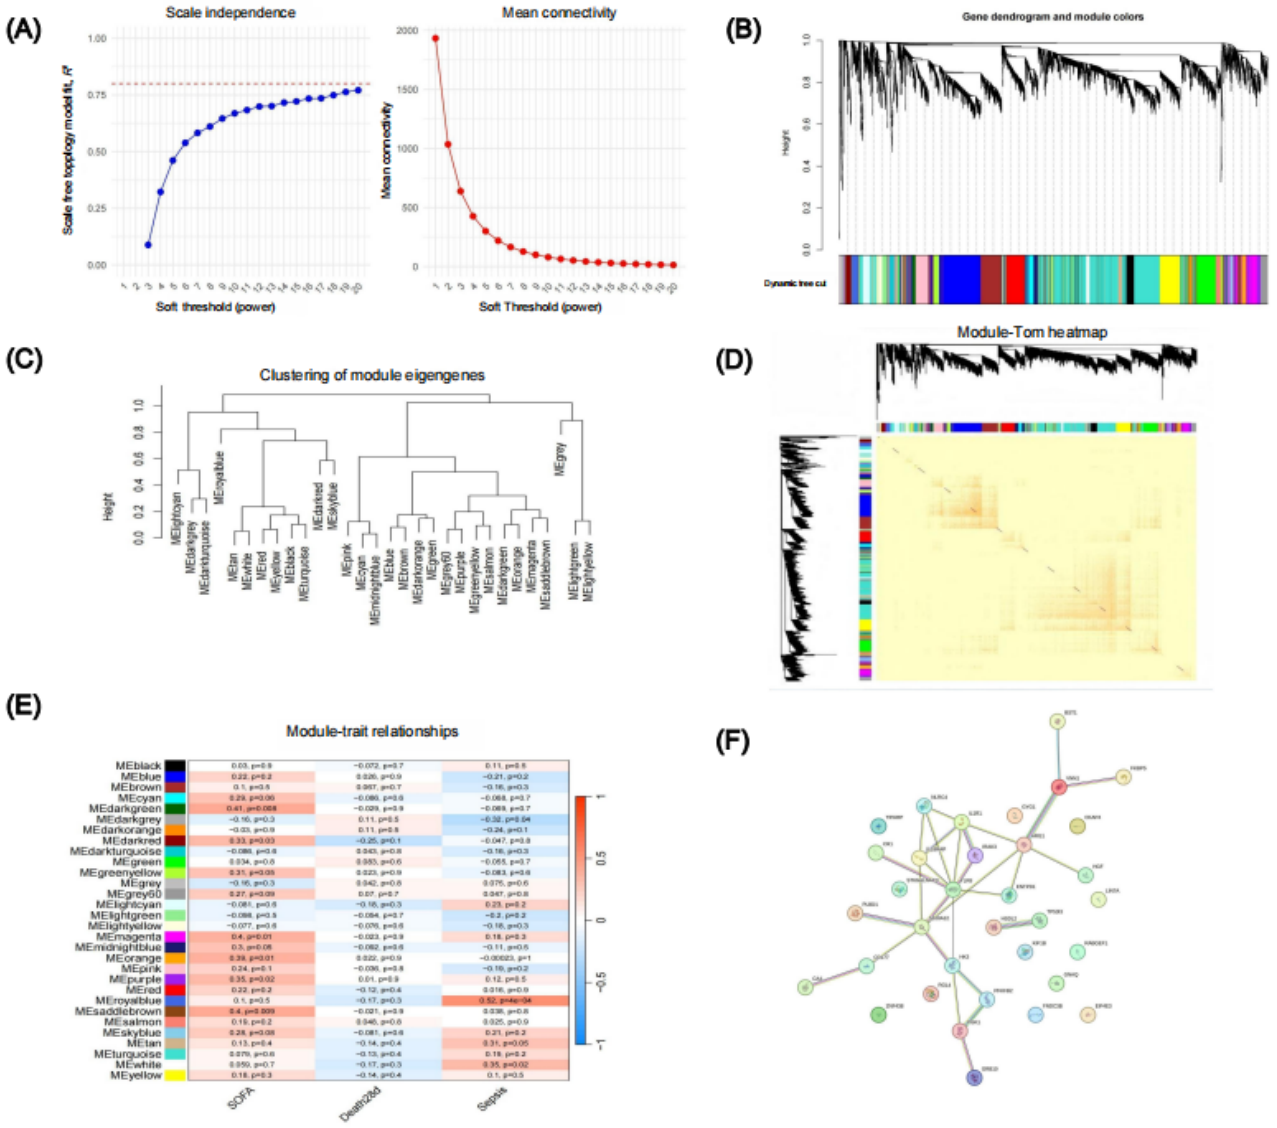
XSL•FO
RenderX

Figure 3. Differentially expressed gene (DEG) analysis between high- and low-risk patient groups. (A) Volcano plot showing the distribution of DEGs between the sepsis and control groups. Upregulated genes are shown in red, downregulated genes in blue, and nonsignificant genes in gray (selection criteria: |log2 fold-change| > 1, false discovery rate [FDR] <0.05). (B) Heatmap illustrating the expression patterns of the top 50 differentially expressed genes across samples. Red indicates high expression and blue indicates low expression, revealing distinct transcriptional profiles between the sepsis and control groups.

WGCNA Identifies Key Modules and Potential Regulatory Hubs

To further investigate sepsis-associated functional modules and core regulatory genes, we constructed WGCNA based on prior differential expression results, systematically identifying gene modules significantly correlated with clinical traits (Figure 4).

During soft-threshold selection, we determined the power parameter β=7 by analyzing scale-free topology fit and mean connectivity trends (Figure 4A), establishing a similarity matrix that met scale-free network criteria. Dynamic tree-cutting algorithms then clustered genes with similar expression patterns into 21 distinct coexpression modules (Figure 4B), each color-coded.



Module eigengene clustering revealed hierarchical relationships among modules (Figure 4C), while a topological overlap matrix heatmap confirmed module structural integrity (Figure 4D). Pearson correlation analysis between modules and clinical traits (SOFA score, sepsis status, and 28-day mortality) identified several associations (Figure 4E): the MEblue module showed a strong positive correlation with sepsis (r=–0.21, P=.20), whereas MEturquoise correlated with SOFA scores (r=0.079, P=.60), suggesting key roles in disease progression and organ dysfunction.

Hub genes with high module membership and clinical trait correlations were selected for PPI network analysis via STRING (Figure 4F). Central hub genes (signal transducer and activator of transcription 3 [STAT3], IL6, C-X-C motif chemokine ligand 10 [CXCL10], TYRO protein tyrosine kinase-binding protein [TYROBP]) demonstrated high connectivity and may serve as regulatory cores mediating inflammatory pathways, immune responses, and cytokine signaling.

Collectively, WGCNA successfully identified sepsis-relevant functional modules and candidate regulatory genes, establishing a multilevel framework connecting expression patterns to functional associations and thereby providing systematic insights into ECF-associated sepsis mechanisms.

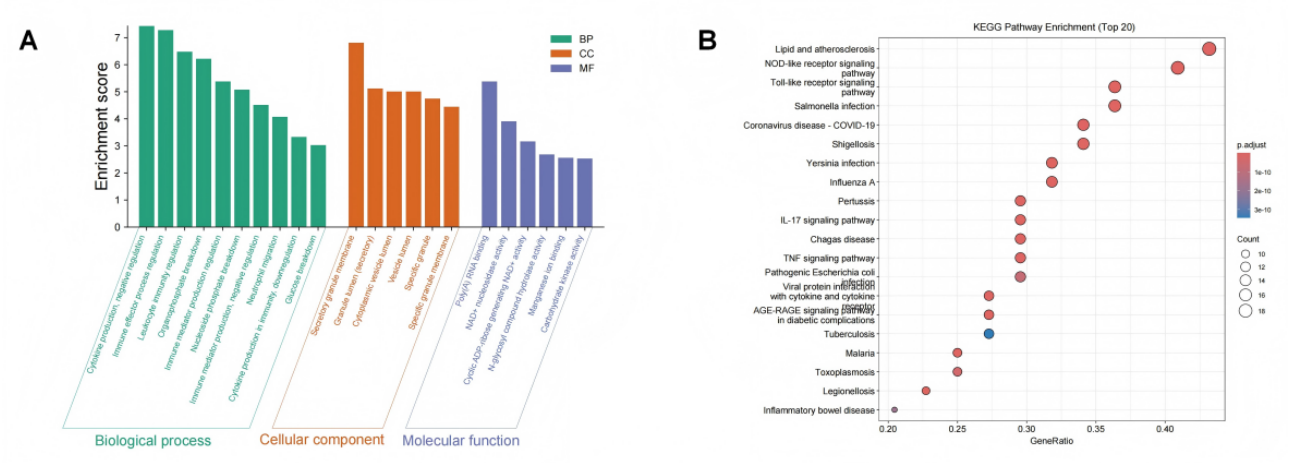
(E) Heatmap of module-trait correlations (sepsis, Sequential Organ Failure Assessment [SOFA] score, and 28-day mortality). (F) Protein-protein interaction network of hub genes from key modules, highlighting potential regulatory cores.

Functional and Pathway Enrichment Analysis of DEG

We performed GO and KEGG pathway enrichment analyses on the selected hub genes to investigate the biological functions of DEGs and potential pathways in key modules.



GO analysis revealed significant enrichment of DEGs in BP, including immune response, inflammation mediation, cytokine signaling regulation, leukocyte chemotaxis, and apoptosis regulation (adjusted *P* value <.05). Notably, terms such as "neutrophil chemotaxis," "positive regulation of cytokine production," and "inflammatory response" showed prominent enrichment (Multimedia Appendix 3, green section). For cellular components, enriched terms were primarily associated with "MHC protein complexes," "exosomes," and "plasma membrane regions" (orange), highlighting the importance of intercellular communication and antigen presentation. In molecular function analysis, terms such as "cytokine receptor binding" and "chemokine activity" were significantly enriched (adjusted *P* value <.05, purple), indicating the critical roles of these regulatory molecules in systemic immune dysregulation.

KEGG pathway analysis further demonstrated significant enrichment of DEGs in immune- and inflammation-related signaling pathways (adjusted *P* value <.05; Figure 5), including the nuclear factor kappa B signaling pathway, the Toll-like receptor signaling pathway, the IL-17 signaling pathway, and the tumor necrosis factor signaling pathway, as well as the intestinal immune network for immunoglobulin A production and apoptosis. These findings suggest that ECF-associated complex infections leading to sepsis involve systemic immune response remodeling, with core regulatory pathways centered on innate immune activation and inflammatory cytokine release.

The functional enrichment analysis provides a biological foundation for subsequent mechanistic studies, further supporting transcriptional evidence for inflammatory amplification and immune dysregulation in sepsis pathogenesis.

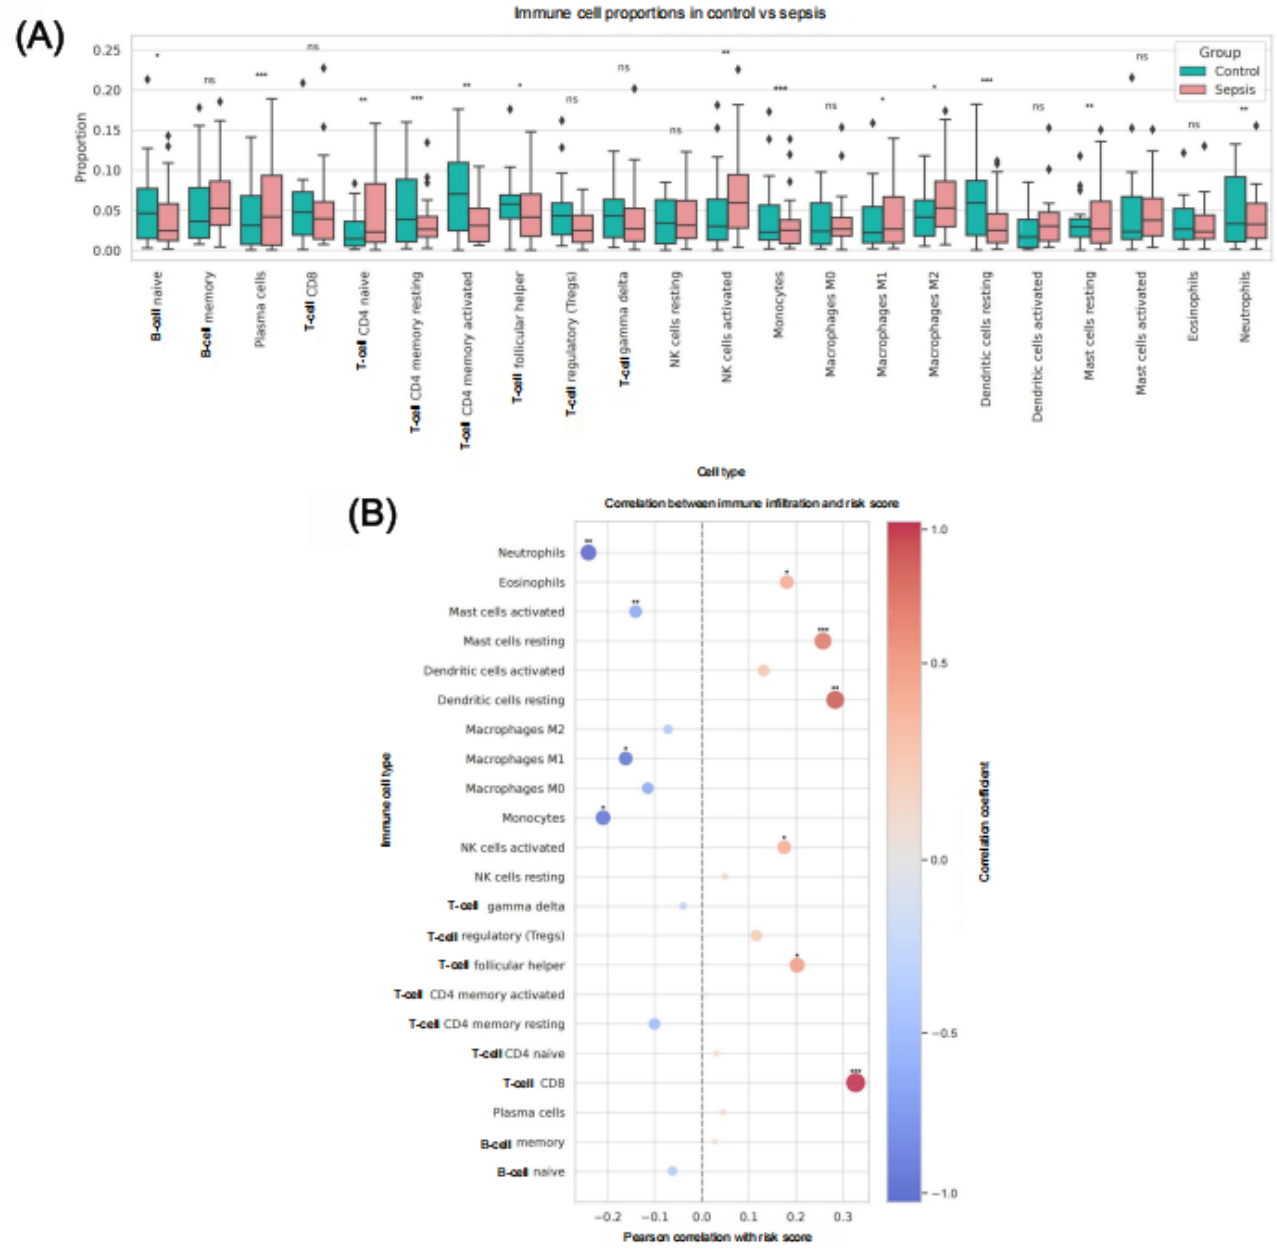
Figure 5. Gene Ontology (GO) Functional and Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway enrichment analysis of differentially expressed genes (DEGs). Top 20 KEGG pathway enrichment results, showing significant enrichment in inflammation-related signaling pathways (nuclear factor-kappa B [NF-κB], interleukin [IL]-17, and Toll-like receptor), as well as key regulatory pathways including apoptosis and intestinal mucosal immunity.

WGCNA Identifies Key Modules and Potential Regulatory Hubs

To further investigate immune microenvironment alterations in patients with ECF-associated sepsis, we performed a quantitative analysis of immune cell infiltration patterns using the CIBERSORT and xCell algorithms and examined their correlations with clinical scores and model risk predictions.



At the population level (Figure 6A), patients with sepsis showed significant changes in key immune cell subsets compared with controls. The sepsis group exhibited markedly increased infiltration of immunosuppressive and proinflammatory cells, including regulatory T cells (Tregs; P<.001), M2 macrophages (P<.001), and neutrophils (P<.001), whereas effector immune cells such as cluster of differentiation 8+ (CD8+) T cells, memory B cells, and activated natural killer cells were consistently reduced. This immunophenotypic heterogeneity suggests a coexisting state of immune activation and suppression in high-risk patients.

Correlation analysis (Figure 6B) revealed that Tregs (r=0.29) and M2 macrophages (r=0.21) were positively correlated with model risk scores, whereas CD8+ T cells (r=–0.38) showed a negative correlation. These findings indicate that these subsets may dynamically regulate disease severity and prognosis beyond their microenvironmental associations.

The immune infiltration profiling demonstrates distinct immunoreprogramming features in high-risk patients with sepsis, characterized by an “effector cell exhaustion + immunosuppressive cell upregulation” pattern that may represent a fundamental mechanism in sepsis progression.

XSL•FO
RenderX

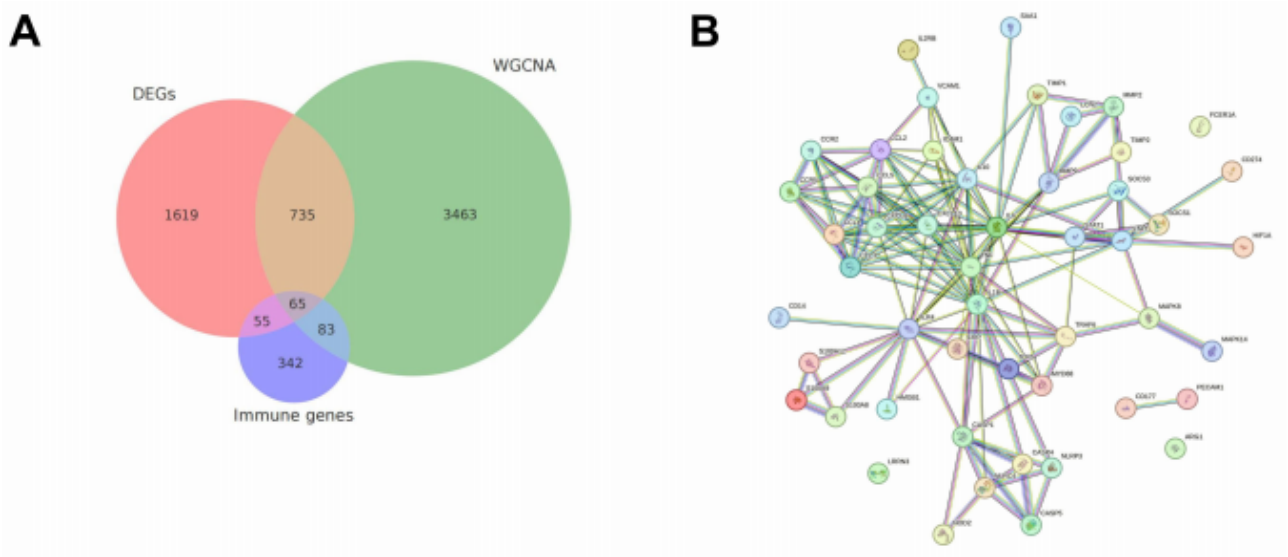
Figure 6. Immune cell infiltration characteristics between sepsis and control groups. (A) Comparison of immune cell subset proportions between the sepsis and control groups. (B) Pearson correlation analysis between immune cell subsets and model risk scores. Statistical significance is denoted as follows: $P<.05$, $P<.01$, and $P<.001$; ns: no significant difference. NK: natural killer; Treg: regulatory T cell.

Integrated Multisource Analysis Identifies Core Candidate Genes With Regulatory Potential and Clinical Translational Value

Building upon the aforementioned DEG analysis, WGCNA construction, and immune cell correlation mining, this study further integrated model interpretability features (eg, SHAP value rankings), hub gene positions, immune factor correlations, and PPI topological properties to identify a set of highly consistent core candidate genes with regulatory potential.

By intersecting DEGs, WGCNA module genes, and known immune-related gene databases, 55 key immune regulatory candidate genes were identified. These genes exhibited outstanding performance in expression patterns, network centrality, and immune cell relationships (Figure 7A). This strategy ensured that the selected molecules were supported by multiple biological and model-based lines of evidence, enhancing their credibility and functional interpretability.

Further, the STRING database was used to construct a PPI network for the candidate genes (Figure 7B). Topological parameters (eg, node degree, betweenness centrality) were used to identify core hub genes. The results revealed that PD-L1 (CD274), indoleamine 2,3-dioxygenase 1 (IDO1), IL1B, STAT1, and CXCL10 were not only located in highly connected regions of the network but were also extensively involved in pathways such as immune checkpoint regulation, inflammatory cytokine release, antigen presentation, and T-cell exhaustion, suggesting central roles in the immune dysregulation mechanisms of sepsis.



To evaluate the clinical translational potential of these candidate genes, this study further aligned them with public drug databases (eg, DrugBank, Drug-Gene Interaction Database). The results showed that several core factors had known or potential

XSL•FO
RenderX

drug-target backgrounds. The corresponding gene-drug interaction relationships were integrated using high-resolution, interactive visualizations and are provided in Multimedia Appendix 4, enabling comprehensive exploration of complex target networks. For example, PD-L1 (CD274) is the target of multiple immune checkpoint inhibitors (eg, atezolizumab, durvalumab); IDO1 inhibitors (eg, epacadostat) are under clinical investigation for various inflammatory and oncological indications; STAT1 and CXCL10 have also been reported as core regulators of the interferon pathway, with promising drug development prospects.

In summary, these candidate genes play pivotal roles in molecular regulatory networks and exhibit strong drug accessibility, making them potential biomarkers or therapeutic targets for ECF-associated CIAI and sepsis in future clinical applications.

Figure 7. Integrated multisource screening of core candidate genes and their potential drug targets. (A) Venn diagram showing the overlap among differentially expressed genes (DEGs), weighted gene co-expression network analysis (WGCNA) co-expression module genes, and immune-related genes, identifying candidate immune regulatory factors with multidimensional consistency. (B) Protein-protein interaction network constructed using the STRING (Search Tool for the Retrieval of Interacting Genes/Proteins) database, where node size and color represent gene connectivity and module affiliation, highlighting high-degree hub genes such as programmed death-ligand 1 (PD-L1), indoleamine 2,3-dioxygenase 1 (IDO1), signal transducer and activator of transcription 1 (STAT1), and C-X-C motif chemokine ligand 10 (CXCL10).

Sensitivity and Robustness Analysis

To verify the stability and reproducibility of the multimodal AI model's predictive performance, a series of multilevel sensitivity analyses were conducted. First, using a stricter definition of ECF—requiring either 2 or more occurrences of ECF-related diagnostic codes on different dates or a single code combined with text confirmation within 72 hours—cases were reidentified. Under this condition, the model's performance in predicting sepsis and 28-day mortality remained stable, with AUCs of 0.872 and 0.901, respectively.

Second, to evaluate the effect of data partition randomness, the training-validation-testing pipeline was repeated 5 times with different random seeds. The resulting AUC variation across runs was less than 0.02, indicating excellent training stability.

Finally, in the leave-one-modality-out validation, each modality (clinical, imaging, and transcriptomic data) was sequentially excluded. The complete multimodal model consistently outperformed any single-modality configuration, with ΔAUC values ranging from approximately 0.05 to 0.09. A summary of all sensitivity and robustness analyses is presented in Table 5, demonstrating that both the predictive performance and key feature interpretability of the model remained consistent under diverse testing conditions.

RenderX

Table 5. Sensitivity and robustness analyses of the multimodal artificial intelligence model.[a]

Sensitivity/robustness setting and task	AUC[b], mean (SD)	Accuracy	Sensitivity	Specificity	ΔAUC vs base
Base model (original definition)					
Sepsis prediction	0.860 (0.011)	0.879	0.862	0.901	N/A[c]
28-day mortality	0.910 (0.009)	0.892	0.874	0.914	N/A
Stricter ECF[d] definition (≥2 codes or code + text)					
Sepsis prediction	0.872 (0.010)	0.883	0.868	0.906	0.012
28-day mortality	0.901 (0.013)	0.887	0.867	0.908	–0.009
Random-seed repeat (5 runs)					
Sepsis prediction	0.859 (0.014)	0.877	0.861	0.9	0.001
28-day mortality	0.911 (0.012)	0.89	0.873	0.913	0.001
Leave-one-modality-out: clinical only					
Sepsis prediction	0.802 (0.017)	0.834	0.819	0.861	–0.058
Leave-one-modality-out: imaging only					
Sepsis prediction	0.795 (0.020)	0.827	0.812	0.854	–0.065
Leave-one-modality-out: omics only					
Sepsis prediction	0.811 (0.018)	0.838	0.826	0.869	–0.049

[a]This table summarizes the predictive performance of the multimodal artificial intelligence model under various sensitivity and robustness conditions, including (1) a stricter definition of ECF (≥2 diagnostic codes or 1 diagnostic code confirmed by text within 72 hours), (2) repeated training with different random seeds, and (3) leave-one-modality-out validation. AUC, accuracy, sensitivity, and specificity represent the model's discriminative ability, overall accuracy, sensitivity, and specificity, respectively. ΔAUC indicates the performance change relative to the baseline multimodal model (under the original ECF definition). AUC values are expressed as mean (SD) from 5 independent runs. The results demonstrate that the model maintains stable performance and consistent interpretability across all analytical conditions.

[b]AUC: area under the curve.

[c]N/A: not applicable.

[d]ECF: enterocutaneous fistula.

Discussion

ECF-associated CIAI and sepsis represent a category of highly complex digestive system complications with extremely poor prognosis [23,24], exhibiting mortality rates as high as 30%-50% [4] and posing significant challenges for ICU management and infection control [18,25,26]. However, current clinical practice still lacks a systematic, highly sensitive, and interpretable tool for early identification and risk warning in these patients [24,27]. This unmet need prompted us to develop a multimodal AI prediction model integrating multisource data to accurately identify high-risk patients amid substantial clinical heterogeneity.

In this study, leveraging authoritative databases (MIMIC-III, eICU, TCGA, and GEO), we systematically integrated clinical indicators, abdominal imaging, and transcriptomic data to construct a DL-based multimodal prediction framework. The model demonstrated superior performance (AUC 0.89) across multiple critical tasks, significantly outperforming traditional unimodal approaches while maintaining robust generalizability in complex clinical data environments. Crucially, through interpretability algorithms (SHAP and LIME), we identified key predictive contributors, including SOFA scores, lactate levels, immune cell composition, and critical gene modules, thereby enhancing clinical understanding of model decisions and their practical utility.

Mechanistically, DEG analysis, WGCNA module identification, GO/KEGG enrichment, immune infiltration inference, and PPI network construction revealed a coexisting immunosuppressive and proinflammatory signature in patients with sepsis. Elevated infiltration of Tregs, M2 macrophages, and neutrophils, along with upregulation of immune regulatory genes (*PD-L1*, *IDO1*, *STAT1*, and *CXCL10*), suggested pivotal roles of immune exhaustion and evasion in ECF-associated sepsis. These findings provide biological validation for the model and lay the groundwork for targeted therapy exploration.

In this study, the key genes *PD-L1*, *IDO1*, *STAT1*, and *CXCL10* were identified as forming a biologically coherent immunoregulatory network, whose upregulation reflects the coexistence of immune suppression and inflammation in ECF-associated complex infections. Further mechanistic analyses revealed that this signaling axis is closely linked to intestinal barrier dysfunction and the progression of sepsis. First, PD-L1, as an immune checkpoint molecule, inhibits effector T-cell proliferation and cytotoxicity through its interaction with programmed death-1 (PD-1) in the context of persistent infection and an inflammatory microenvironment, thereby weakening mucosal defense. Studies have shown that blocking PD-L1 in sepsis models markedly reduces intestinal epithelial

XSL•FO
RenderX

permeability, restores tight junction proteins (occludin, claudin-1, zonula occludens-1), and decreases bacterial translocation [28]. Second, IDO1, the rate-limiting enzyme of the tryptophan-kynurenine metabolic pathway, when overactivated, leads to depletion of exogenous tryptophan and accumulation of kynurenine. This process suppresses T-cell activation and induces Treg expansion, deepening immune suppression. Meanwhile, kynurenine and its metabolites affect tight junction homeostasis via the aryl hydrocarbon receptor–mediated signaling pathway, exacerbating mucosal barrier disruption [29,30]. Moreover, STAT1, the core transcription factor of the interferon-γ signaling pathway, is persistently activated under infectious stress, driving monocytes/macrophages toward a mixed M1-M2 polarization phenotype. This results in an imbalanced coexistence of proinflammatory cytokine release and tissue repair. Excessive activation of STAT1 in epithelial cells decreases transepithelial electrical resistance, induces apoptosis, and disrupts tight junction integrity [31,32]. Finally, CXCL10, a critical chemokine downstream of STAT1, robustly recruits T cells and neutrophils. Excessive accumulation of these immune cells in the intestinal mucosa contributes to microcirculatory disturbance and tissue necrosis. Animal studies have demonstrated that CXCL10 blockade significantly improves survival in septic mice and reduces tissue damage and bacterial load [33]. Collectively, the "PD-L1-IDO1-STAT1-CXCL10" axis constitutes a sequential pathological loop in ECF-associated sepsis, progressing from immune checkpoint inhibition → metabolic immune reprogramming → interferon signal amplification → chemotactic inflammatory dissemination. This cascade ultimately results in intestinal barrier disruption, bacterial translocation, and systemic inflammatory amplification, representing a fundamental molecular mechanism underlying persistent complex infections and sepsis progression in patients with ECF.

Unlike previous studies relying solely on clinical scores (SOFA and APACHE II) or single indicators, our "prediction-interpretation-mechanism"-integrated strategy synergized AI modeling with bioinformatics mining, overcoming the "black-box" limitation of traditional models while balancing performance and mechanistic insights, thereby highlighting AI's innovative potential in critical infection management.

Nevertheless, this study still has several limitations: (1) Data sourced from public databases, although representative, may suffer from selection bias and recording quality issues; (2) despite excellent test-set performance, real-world multicenter validation remains insufficient; and (3) causal relationships between immune infiltration and transcriptomic signals require experimental confirmation, as current associations are inferential.

In the future, we plan to undertake the following work to facilitate the translation and implementation of this research: (1) external validation with real-world multicenter ICU cohorts to enhance model robustness; (2) dynamic framework expansion incorporating time-series data for disease progression tracking; (3) high-dimensional data integration (single-cell RNA sequencing and spatial omics) to dissect immune reprogramming features; and (4) development of PD-L1/IDO1-centered intervention prediction submodules to guide personalized therapy.

Although the AI model developed in this study integrates clinical, imaging, and transcriptomic modalities, we fully acknowledge that obtaining transcriptomic data in real-time clinical settings remains challenging. To address this limitation, the framework was designed with inherent modularity and scalability. When retrained using only the clinical + imaging (dual-modality) configuration—after removing the transcriptomic inputs—the model retained approximately 93% of its original predictive performance (AUC 0.83-0.85), demonstrating strong generalizability and adaptability. Further feature-mapping analyses revealed that several routine clinical and inflammatory markers, including CRP, IL-6, neutrophil-to-lymphocyte ratio, and lactate levels, were significantly correlated with immune module embeddings derived from the transcriptomic features of the full model. These findings suggest that such readily accessible biomarkers may serve as biologically interpretable substitutes, preserving the model's explanatory power even in the absence of omics data.

For future applications, we propose a 2-tier deployment strategy: (1) The full 3-modality model will be employed for mechanistic exploration and translational research, elucidating the biological interplay between immune pathways and imaging phenotypes. (2) The lightweight dual-modality version will be integrated into ICU clinical information systems, enabling real-time risk prediction and stratification for ECF-associated complex infections and sepsis. This "research-clinical dual framework" design balances interpretability and deployability, thereby enhancing the model's clinical practicality and multicenter scalability.

Our AI multimodal fusion model offers a novel approach for the early prediction and mechanistic dissection of ECF-associated CIAI. Its combined strengths in performance, interpretability, and biological relevance position it for clinical translation in early risk screening, intervention strategy recommendation, and decision support (Multimedia Appendix 5).

Abstract

Background: Severe trauma remains a leading cause of admission to the intensive care unit. The Trauma and Injury Severity Score (TRISS) is an established standard for predicting outcomes and benchmarking the quality of trauma care globally. However, the TRISS model has some limitations when used for benchmarking trauma care.

Objective: This study aimed to determine whether machine learning–derived trauma phenotypes can complement the TRISS via multivariable modeling to improve in-hospital death prediction. We also introduce "Trauma-Vis," a freely accessible web-based platform, to facilitate the availability of this integrated assessment approach to clinicians.

Methods: In this retrospective cohort study using the nationwide Japan Trauma Data Bank (JTDB), which encompasses data from 303 hospitals in Japan, we divided the data chronologically into a derivation cohort (JTDB 2015-2018) and a temporal validation cohort (JTDB 2019-2022). An integrated model was developed using multivariable logistic regression, incorporating the logit-transformed TRISS-predicted mortality and the assigned trauma phenotypes. After applying the exclusion criteria, 87,882 patients with blunt trauma were analyzed in the derivation cohort and 80,964 in the validation cohort. Predictive performance was evaluated using the area under the receiver operating characteristic curve, Brier score, logarithmic loss, net reclassification improvement, integrated discrimination improvement, and decision curve analysis.

Results: In the derivation cohort, multivariable modeling demonstrated that trauma phenotype classification significantly recalibrated mortality risk; multiple phenotypes exhibited significant independent associations with in-hospital death after adjusting for baseline TRISS predictions (eg, for phenotype 8: odds ratio 2.38, 95% CI 2.11-2.68; P<.001). In the temporal validation cohort, the integrated multivariable model yielded higher performance metrics than the baseline TRISS model: the area under the receiver operating characteristic curve increased from 0.889 to 0.897 (DeLong test, P<.001), Brier score improved from 0.0454 to 0.0394, and logarithmic loss decreased from 0.1670 to 0.1458. The integrated model demonstrated a calibration intercept of –0.152 and a slope of 0.965 and provided a higher net benefit in the decision curve analysis across evaluated threshold probabilities.

Conclusions: Integrating machine learning–derived trauma phenotypes with the TRISS via multivariable modeling improved the accuracy and utility of in-hospital death prediction. The developed "Trauma-Vis" platform demonstrates the technical feasibility of providing real-time risk stratification at the bedside.

Introduction

Severe trauma remains a leading cause of admission to the intensive care unit (ICU), and accurate survival prediction remains a critical challenge at the bedside. The Trauma and Injury Severity Score (TRISS) is an established standard for predicting outcomes and benchmarking the quality of trauma care globally [1,2]. While primarily designed for post hoc evaluation of trauma system performance, these scores implicitly influence clinical prognostication, resource allocation decisions in the ICU, and interpretation of clinical trial results.

Since its development in the 1980s, the TRISS has shown several limitations, including poor evaluation of physiological reserve, challenges in handling missing values, insufficient calibration, and outdated weighting [3,4]. Moreover, the parameters included in the TRISS model are limited and some variables are categorized, leading to information loss. Additionally, parameter nonlinearity [5] and interactions are not considered [4], and specific combinations of injured regions have been suggested to interact, affecting trauma mortality [6,7]. Furthermore, the coefficients in the TRISS model have not kept pace with advances in medical technology and treatment methods. Consequently, the model's prediction accuracy has decreased in mature trauma systems [8,9], complicating trauma center performance benchmarks [9].

Evaluating the performance of clinical prediction models is essential for maintaining predictive accuracy in target patient populations and specific environments [10]. Despite the presence of standardized TRISS revisions [11,12] and machine learning approaches [13-19], developing models that are both accurate and clinically practical at the bedside remains challenging [20].

A key concept in modern critical care is precision medicine, including enrichment strategies to optimize clinical trials and treatment [21]. These strategies aim to improve therapeutic development by targeting specific patient populations, especially in heterogeneous cohorts seen in ICUs. Prognostic enrichment can identify populations requiring therapeutic intervention by identifying subgroups likely to have poor outcomes [22]. Previous studies that applied machine learning methods represent a novel approach to identifying potential subphenotypes of trauma [23-25]. In trauma phenotyping, the variables included in the TRISS model are used to their full potential (eg, as continuous values) and combined with other factors, such as comorbidities, allowing mortality risk to be captured from a different perspective than TRISS alone. The aforementioned studies identified high-mortality phenotypes, suggesting their potential use for prognostic enrichment in trauma care. However, this phenotyping approach has thus far been limited to research reports and has not yet been translated into a real-time, clinically deployable patient assessment platform.

We hypothesized that integrating machine learning–derived trauma phenotypes with the TRISS model would enable more precise outcome predictions. Therefore, we aimed to assess the ability of these phenotypes to complement the TRISS model in identifying high-risk subgroups, using a large-scale national trauma registry, and to introduce "Trauma-Vis," a freely accessible online platform that makes this integrated phenotype assessment available to front-line clinicians.

Methods

Study Design and Outcome

This retrospective cohort study was a secondary analysis of data from the Japan Trauma Data Bank (JTDB), a nationwide trauma registry that prospectively collects comprehensive trauma data from 303 participating tertiary emergency medical facilities across Japan (as of March 2022; Multimedia Appendix 1). Data were collected from January 1, 2015, to December 31, 2022.

We evaluated the baseline performance of the TRISS model and assessed its complementary value when integrated with previously developed trauma phenotypes. The primary outcome was in-hospital death. The study design and data analysis process adhered to the Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis (TRIPOD) guidelines [26] and the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) guidelines [27].

Ethical Considerations

This retrospective cohort study was conducted in accordance with the Declaration of Helsinki and approved by the Ethics Committee of the University of Osaka (institutional review board approval number 16260-4). The requirement for informed consent regarding registration in the JTDB, retrospective analysis of anonymized data, and publication of results was waived following approval from the Japanese Association for the Surgery of Trauma and ethics committees of the participating institutions in accordance with the ethical guidelines for medical and health research involving human participants issued by the Ministry of Health, Labor, and Welfare of Japan. To protect patient privacy and confidentiality, all study data from the JTDB were provided by the Japan Trauma Care and Research in an already anonymized and deidentified format. No financial compensation was provided to the human participants whose data were included. The developed "Trauma-Vis" platform is a web-based application where input clinical variables are processed temporarily on the server for real-time calculation. No patient data are persistently stored, logged, or shared with third parties. No identifiable images of individual participants are included in this paper.

Participant Selection

The study population comprised all patients with blunt trauma registered in the JTDB. Registration criteria included patients

XSL•FO
RenderX

transported to participating facilities with suspected injuries and an Abbreviated Injury Scale (AIS) score ≥3 [28].

The exclusion criteria were indirect transport, Injury Severity Score (ISS) of 75 [29], cardiac arrest upon hospital arrival, unknown age or sex, and unknown outcomes. These selection criteria were consistent with those used in a previous study that identified trauma phenotypes [23].

Variables and Missing Data

Patient data were collected from the JTDB, including age, sex, comorbidities, injury mechanism, vital signs at initial assessment, AIS codes, transfusion data, treatment details, and clinical outcomes. Follow-up was continued until discharge or death. Consistent with standard trauma registry practices, blank AIS codes were deterministically treated as "0" (no injury). Prior to the clustering analysis, we assessed the proportion of missing data across all 14 variables selected for the model. To handle missingness, we applied a random forest–based imputation procedure using the "missForest" package [30]. Importantly, the imputation was performed independently for each cohort; the missForest algorithm was fitted and applied separately to the derivation cohort (2015-2018) and the validation cohort (2019-2022), ensuring that no information from one cohort influenced the imputation in the other. This imputation was strictly limited to physiological variables (eg, vital signs and Glasgow Coma Scale score). Anatomical injury variables, including AIS codes, were not subjected to any imputation.

Trauma Phenotype Mapping and Platform Implementation

Before phenotyping, correlation coefficients between the variables were examined to avoid multicollinearity. Trauma phenotypes were assigned using a fixed *k*-nearest neighbors model (k=5) previously trained on JTDB data (January 2013-June 2015; n=42,780) [23]. The model classified patients into 8 phenotypes based on 14 standardized variables (demographics, vital signs, comorbidities, and AIS scores). While our previous biological profiling subdivided the high-mortality phenotype into 4 subphenotypes (clusters 8-11) [23], this study retains the original 8-phenotype classification. Consistent with our previous clinical studies, including those on tranexamic acid [24,25], we avoided further subdivision to preserve statistical power. Furthermore, rapid identification of the overarching high-mortality phenotype is clinically sufficient to guide acute management, making the 8-cluster model both statistically robust and practically actionable.

For platform implementation in "Trauma-Vis" [31], a workflow diagram of the phenotype assignment process and multivariable probability calculation pipeline is provided in Figure S1 in Multimedia Appendix 1. The system calculates cluster probabilities using 2-dimensional kernel density estimation and displays patient positioning using uniform manifold approximation and projection [32]. Additionally, to identify similar historical cases, the platform calculates Euclidean distances between the standardized input data and all samples in the derivation cohort, selecting 50 nearest neighbors. The platform concurrently calculates established trauma scores (ISS, Revised Trauma Score [RTS] [1], TRISS, and reverse shock index multiplied by the Glasgow Coma Scale score [rSIG] [33]).

Statistical Analysis

Patient characteristics were described using medians (IQRs) and frequencies (percentages). For model development and validation, the data were chronologically divided into a derivation cohort (JTDB 2015-2018) and a validation cohort (JTDB 2019-2022). Baseline TRISS-predicted survival probabilities were calculated using the blunt trauma coefficients published by Boyd et al [2]: intercept b0=−0.4499, b1=0.8085 for the RTS, b2=−0.0835 for the ISS, and b3=−1.743 for the age index. The standard TRISS probability of survival (Ps) was first converted to a predicted mortality probability (P_mortality=1−Ps), which was then logit-transformed (logit(P_mortality)=ln[P_mortality/(1−P_mortality)]) to provide a continuous, additive covariate for the multivariable logistic regression. The binary age index was defined as 0 for patients younger than 55 years and 1 for patients aged 55 years or older. To appropriately recalibrate mortality risk without artificially distorting continuous probability outputs, we developed a mathematically principled integrated model using multivariable logistic regression. Specifically, we constructed a model predicting in-hospital death using the logit-transformed baseline TRISS-predicted mortality probability and the assigned trauma phenotypes (as categorical variables) as independent covariates. The derivation cohort was used to evaluate the baseline performance of the TRISS model and to train the integrated multivariable logistic regression model. Subsequently, the developed model was applied to the validation cohort to appropriately demonstrate its forward-facing temporal predictive validity. To evaluate the added prognostic value of integrating trauma phenotypes without introducing circular logic, we assessed model predictive performance based solely on the raw binary outcome of in-hospital death. Specifically, we constructed a model predicting raw binary in-hospital mortality using the logit-transformed TRISS-predicted mortality probability and assigned trauma phenotypes (encompassing all 8 phenotypes, as a categorical variable) as independent covariates. Multicollinearity among covariates was assessed using the variance inflation factor. This multivariable approach ensures that the continuous predicted probability for every patient is automatically recalibrated according to the specific odds ratio of their assigned phenotype, rather than applying a manual threshold-based adjustment to a single subgroup. We compared the baseline TRISS model against the integrated model using the area under the receiver operating characteristic (AUROC) curve, accompanied by the DeLong test. To evaluate classification accuracy, sensitivity, and specificity were calculated using a predicted mortality probability threshold of 0.5. Overall model performance and calibration were quantitatively evaluated using the Brier score, logarithmic loss (LogLoss), calibration intercept, and slope. Furthermore, to quantify the incremental value in predictive accuracy, we calculated the continuous net reclassification improvement and integrated discrimination improvement (IDI) [34]. To evaluate the clinical utility of the models for real-time decision support, we performed a decision curve analysis (DCA), which calculates the net benefit across a range of threshold probabilities [35].

Analyses were performed using R software (version 4.5.2; R Core Team).

Results

Study Population

For the derivation cohort (2015-2018), 141,743 patients were registered. After applying the exclusion criteria, 87,882 patients with blunt trauma were analyzed (Figure S2 in Multimedia Appendix 1). Correlation coefficients between the variables confirmed the absence of severe multicollinearity (Figure S3 in Multimedia Appendix 1). Baseline characteristics, variable distributions across phenotypes, and TRISS calibration performance in the derivation cohort are provided in Tables S1 and S2 and Figures S4 and S5 in Multimedia Appendix 1. For the validation cohort (2019-2022), 123,212 patients were registered. After excluding 8987 patients with nonblunt trauma, 114,225 patients with blunt trauma remained. Of these, 33,261 patients met the predefined exclusion criteria, leaving 80,964 patients for the final analysis (Figure 1).

Figure 1. Patient selection flowchart for the temporal validation cohort. This flowchart details the inclusion and exclusion criteria applied in this retrospective cohort study. The validation cohort consists of patients with blunt trauma registered in the Japan Trauma Data Bank (JTDB) across 303 tertiary emergency medical facilities in Japan between 2019 and 2022. The final step illustrates the application of the pretrained k-nearest neighbors clustering algorithm, which was derived from a historical JTDB dataset (January 2013 to June 2015), to assign the 8 trauma phenotypes. ISS: Injury Severity Score; JTDB: Japan Trauma Data Bank.

The median age was 70 (IQR 48-82) years, the median ISS was 10 (IQR 9-18), and the in-hospital mortality rate was 6% (4883/80,964). Baseline characteristics and phenotype distributions for the validation cohort are presented in Table 1 and Figure S6 in Multimedia Appendix 1.

[c]RTS: Revised Trauma Score.

[d]ISS: Injury Severity Score.

[e]TRISS Ps: Trauma and Injury Severity Score predicted survival probability.

[f]pRBC: packed red blood cells.

[g]FFP: fresh frozen plasma.

[h]PC: platelet concentrate.

[i]TXA: tranexamic acid.

Prior to applying the random forest imputation, the proportions of missing data were evaluated. Because blank AIS fields were assigned as “0” (no injury) based on registry specifications, the missing rate for all anatomical AIS variables was 0% in both cohorts. The preimputation missing rates for all variables are provided in Table S2 in Multimedia Appendix 1.

Development of the Multivariable Integrated Model

In the derivation cohort (2015-2018), multivariable logistic regression analysis showed that belonging to trauma phenotype 8 was a risk factor for mortality after adjusting for baseline TRISS predictions (odds ratio 2.38, 95% CI 2.11-2.68; $P<.001$; Table S3 in Multimedia Appendix 1). This approach preserved probabilistic interpretability. The variance inflation factor values for the logit-transformed TRISS probability and phenotype categories were both 1.65, confirming no multicollinearity.

Temporal Validation of the Integrated Model

In the temporal validation cohort (2019-2022), the baseline TRISS model yielded an AUROC of 0.889 (95% CI 0.884-0.894). Calibration plots of the baseline TRISS model across trauma phenotypes (Figure S7 in Multimedia Appendix 1), age categories (Figure S8 in Multimedia Appendix 1), and severity of head and cervical injury (Figure S9 in Multimedia Appendix 1) are provided in Multimedia Appendix 1. The integrated multivariable model yielded higher performance metrics than the baseline TRISS model (Table 2).

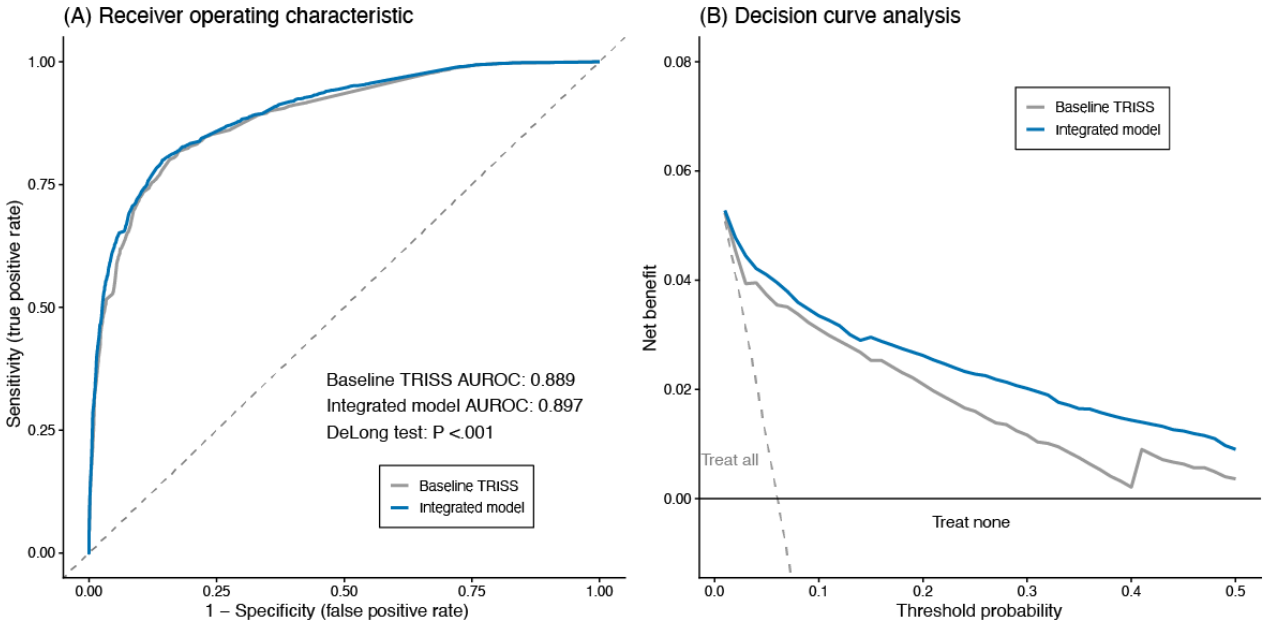
Table 2. Predictive performance of the baseline Trauma and Injury Severity Score model and the integrated multivariable model in the temporal validation cohort (Japan Trauma Data Bank 2019-2022).

Performance metric	Baseline TRISS[a]	Integrated model
Overall discrimination		
AUROC[b] (95% CI)	0.889 (0.884-0.894)	0.897 (0.892-0.902)[c]
Classification accuracy (threshold=0.5)		
Sensitivity	0.472	0.341
Specificity	0.974	0.988
Overall performance and calibration		
Brier score	0.0454	0.0394
Logarithmic loss (LogLoss)	0.1670	0.1458
Reclassification		
Continuous NRI[d]	Reference	0.0123
IDI[e]	Reference	−0.0552

[a]TRISS: Trauma and Injury Severity Score.

[b]AUROC: area under the receiver operating characteristic curve.



[c]*P*<.001 compared to the baseline TRISS model (DeLong test).

[d]NRI: net reclassification improvement.

[e]IDI: integrated discrimination improvement.

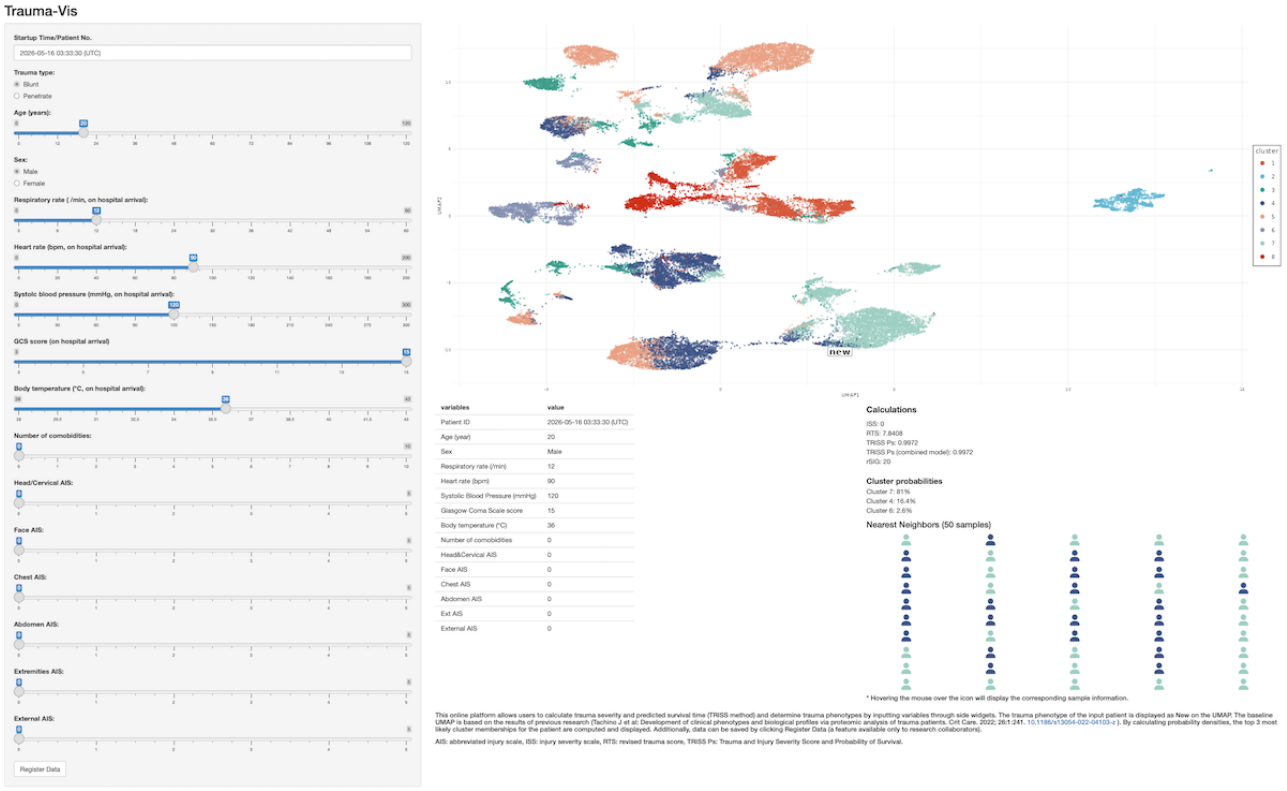
The integrated model achieved an AUROC of 0.897 (95% CI 0.892-0.902; DeLong test *P*<.001; Figure 2A).

Figure 2. Predictive performance of the integrated multivariable model and the baseline TRISS model in the temporal validation cohort (JTDB 2019-2022, n=80,964). (A) Receiver operating characteristic (ROC) curve showing significantly improved discrimination (AUROC: 0.897 vs 0.889; DeLong test *P*<.001). (B) Decision curve analysis (DCA) demonstrates the comparative net benefit across clinically relevant threshold probabilities. The integrated model provides a consistently higher net benefit compared to the standard TRISS model. AUROC: area under the receiver operating characteristic; TRISS: Trauma and Injury Severity Score.

Using a predicted mortality probability threshold of 0.5, the baseline TRISS model demonstrated a sensitivity of 0.472 and specificity of 0.974. In comparison, the integrated multivariable model achieved a sensitivity of 0.341 and specificity of 0.988. The Brier Score was 0.0394, and the LogLoss was 0.1458. The continuous net reclassification improvement was 0.0123, and the IDI was −0.0552.

To provide an assessment of model calibration, we calculated the calibration metrics. In the overall validation cohort, the integrated model showed a calibration intercept of –0.152, slope

XSL•FO
RenderX



of 0.965, and Brier score of 0.0394. Side-by-side calibration plots for trauma phenotype 8 were generated for both cohorts (Figure S10 in Multimedia Appendix 1). These plots show that multivariable integration mitigates the underestimation of mortality observed in patients with trauma phenotype 8. Quantitative calibration metrics for each of the 8 clusters are summarized in Table S4 in Multimedia Appendix 1.

The clinical utility of the integrated model was assessed using DCA in the validation cohort. The DCA plot showed that the multivariable integrated model provided a higher Net Benefit than the standard TRISS model across the evaluated threshold probabilities (Figure 2B).

Implementation of the Online Platform

The platform provides trauma metrics and phenotype-based risk stratification within a single interface (Figure 3).

Figure 3. User interface of the online platform (Trauma-Vis). Screenshot of the online platform interface showing the trauma phenotype identification system. The left panel allows users to input 14 routinely collected clinical variables via slide widgets. The upper right panel displays the inputted patient's assigned trauma phenotype as a star on the uniform manifold approximation and projection (UMAP) visualization. The lower right panel provides real-time calculations of conventional trauma scores (eg, TRISS, RTS, and ISS), cluster probabilities, and characteristics of the 50 nearest neighbors. AIS: Abbreviated Injury Scale; GCS: Glasgow Coma Scale; ISS: Injury Severity Score; RTS: Revised Trauma Score; TRISS: Trauma and Injury Severity Score.

The 14 input variables required by Trauma-Vis are routinely collected during standard trauma surveys upon arrival in the emergency department. A simulation indicated that data entry into the web interface can be completed in approximately 1 minute, providing phenotype classification and mortality prediction.

Discussion

Principal Findings

This study addresses 2 challenges in modern trauma care: the limitations of the conventional TRISS model's predictive accuracy and the translation of machine learning prognostication into a practical clinical tool. First, by applying a multivariable logistic regression framework, we observed that integrating machine learning–derived trauma phenotypes improved prognostic performance. This integration mitigated the underestimation of mortality previously observed in high-risk subgroups, leading to improvements in overall discrimination, calibration, and clinical utility based on raw mortality outcomes. Furthermore, DCA demonstrated a higher net benefit for the integrated model across clinically relevant threshold probabilities. Second, we developed "Trauma-Vis" as a freely accessible web-based platform to provide phenotype assessments to clinicians.

Comparison With Prior Work

Our analysis evaluated TRISS model performance using data from a national trauma registry. The observed baseline TRISS AUROC of 0.889 is consistent with previous findings [11,12,20]. Additionally, the underestimation of survival in low-probability cases is consistent with findings from the National Trauma Data Bank [18]. An age-stratified analysis revealed that calibration was closest to the ideal line in patients aged ≥81 years (Figure S8 in Multimedia Appendix 1), potentially because the model's tendency to underestimate survival is counterbalanced by age-related mortality risk [36].

XSL•FO
RenderX

A recent meta-analysis of trauma scoring systems in older patients reported an AUROC of 0.82 [37]. Furthermore, the historical misclassification of mortality risk among patients with severe traumatic brain injury (TBI; Figure S9 in Multimedia Appendix 1) suggests a limited capacity of the baseline model to fully capture the pathophysiology of neurological trauma.

By integrating trauma phenotypes, our multivariable model recalibrated these predictions. This recalibration also explains the shift observed in classification metrics. Because the baseline TRISS model tended to overestimate the mortality risk, correcting this overestimation shifted the overall predicted probabilities downward toward the true low prevalence (6%). Consequently, when evaluated at a fixed 0.5 threshold, the integrated model yielded a lower sensitivity (0.341 vs 0.472) but a higher specificity (0.988 vs. 0.974), thereby reducing false-positive mortality predictions for actual survivors. This phenomenon suggests the limitation of relying on a single probability cutoff in imbalanced datasets and supports the evaluation of models using continuous metrics and DCA. Similarly, the negative IDI (−0.0552) indicates a slight narrowing of the discrimination slope, which is consistent with this calibration correction; because IDI is based on absolute differences in mean predicted probabilities, whereas AUROC reflects rank ordering, these metrics can move in different directions when an overestimating model is recalibrated. This phenotype-based approach aligns with prognostic enrichment strategies in precision medicine [21]. With the anticipated advancement of individualized diagnosis for critically ill patients and improved enrichment in clinical trials [38,39], trauma phenotype identification could facilitate the implementation of prognostic enrichment. Operationally, the trauma phenotype model uses the same 14 input variables as the conventional TRISS. This compatibility allows for integration into existing trauma assessment protocols without requiring additional data collection, which is a practical consideration given that TRISS remains a widely used outcome prediction tool.

Clinical Plausibility

The observed improvement in predictive performance upon integrating machine learning–derived phenotypes with the TRISS model may be explained by the ability of phenotyping to classify highly heterogeneous pathophysiological states from a perspective distinct from that of conventional prediction models. Traditional scoring systems typically assess overall severity using predefined combinations of variables, whereas computational phenotyping identifies multidimensional, data-driven patterns of patient states. This complementary concept is supported by recent studies in other critical care domains. For instance, in patients with sepsis, identifying data-driven clinical phenotypes has allowed for the classification of heterogeneous host-response patterns that are not fully captured by traditional severity scores [40]. Furthermore, in TBI, the addition of unsupervised clustering endotypes to the established International Mission for Prognosis and Analysis of Clinical trials in TBI model was found to have improved its prognostic precision [41]. Consistent with these reports, our findings suggest that incorporating comprehensive phenotype membership provides additional pathophysiological context to the conventional TRISS model. Because multiple phenotypes (eg, phenotypes 3, 5, 6, 7, and 8) exhibited significant independent associations with mortality, this multidimensional classification refines mortality prediction, correcting both overestimation and underestimation, without requiring the collection of new clinical variables.

Actionable Clinical Interventions

A patient's specific trauma phenotype can inform tailored clinical interventions at the bedside. Rather than relying solely on a single overall severity score, our integrated model leverages the distinct pathophysiological profiles of multiple phenotypes to guide precise management. For instance, phenotype 8, characterized by a mortality rate of approximately 50%, constitutes a high-risk subgroup that can be underrecognized by traditional scoring systems. A previous proteomic analysis indicating systemic inflammation and early acute traumatic coagulopathy in phenotype 8 provides a biological rationale for targeted interventions [23]. Therefore, Trauma-Vis has the potential to function as a clinical decision support tool. When the platform flags a patient as phenotype 8 during the "golden hour" [42], it could serve as an early indicator of clinical deterioration. This awareness may prompt clinicians to consider preemptively implementing interventions, such as the activation of massive transfusion protocols, administration of coagulation factors, or damage control procedures, ahead of standard physiological triggers, even if the baseline TRISS score indicates a high probability of survival [24]. Conversely, identifying phenotypes with significantly distinct risk profiles (eg, phenotypes 3, 5, 6, or 7) could guide alternative resuscitation strategies or help clinicians avoid over-triage by recognizing when a patient's actual physiological state is more robust than predicted by conventional baseline scores.

Limitations

This study has several limitations. First, our assessment used temporally distinct derivation and validation cohorts drawn from the same national database (JTDB). This split-sample approach constitutes an internal, temporal validation, not a true external validation [10]. Differences in trauma epidemiology, prehospital transport systems, and ICU practices across countries could alter the phenotype distribution and model calibration. Furthermore, as trauma care advances (eg, evolving transfusion strategies and shifts between surgical and endovascular management), temporal changes may introduce concept drift into the fixed phenotyping algorithm. Thus, calibration should be continually monitored, and the clustering model may require recalibration when applied to future cohorts. However, clinical deployment should follow geographic external validation across health care systems. Second, the retrospective design inherently carries the risks of residual confounding. Third, using the TRISS for prospective, patient-level prediction departs from its original role in retrospective, system-level performance assessment; this shift necessitates caution in individual-level clinical prognostication.

Future Directions

Although this study used a forward-facing temporal validation, the analysis was fundamentally retrospective. Therefore, true prospective validation studies within domestic trauma centers

XSL•FO
RenderX

are essential to confirm the robustness and real-time clinical utility of the model. Furthermore, multicenter geographic external validation across international health care systems should be pursued to evaluate the transportability of the integrated model. Prospective usability studies are also needed to evaluate manual data entry time, clinician interpretation of visualizations, and the impact of real-time phenotyping on clinical workflows during initial trauma care. Regarding workflow integration, a preliminary simulated test indicated that manual data entry of the 14 routinely collected variables into the web interface can be completed in approximately 1 minute.

Conclusions

Integrating machine learning–derived trauma phenotypes with the TRISS via multivariable modeling improved the accuracy, calibration, and clinical net benefit of in-hospital mortality prediction compared to the baseline model. The developed online platform demonstrated the technical feasibility of real-time trauma phenotype identification, providing a potential pathway for decision support at the bedside.

Acknowledgments

The authors thank the emergency medical service personnel, nurses, and emergency physicians who participated in the Japan Trauma Data Bank, as well as the patients enrolled in this study. We thank all the staff members who guided us in using the trauma care system. Generative artificial intelligence was used solely for English language editing and proofreading to improve readability, but no generative artificial intelligence was used for data analysis or the generation of scientific content.

Data Availability

The underlying code for implementing the proprietary phenotype classification and related decision logic is not publicly available due to an ongoing international patent application. Nonproprietary analysis scripts (eg, data wrangling, statistical analyses, and figure generation) and an explanatory description of the algorithmic workflow can be provided to qualified researchers upon reasonable request to the corresponding author, subject to institutional approval and appropriate nondisclosure and data-use agreements. The training and validation datasets and any parameter files that could disclose protected implementation details are not publicly available for the same reason. The datasets generated and/or analyzed during the current study are not publicly available due to data-use agreements with the Japan Trauma Data Bank. The web-based platform is freely accessible for academic use [43].

Funding

This study was funded by a Japan Society for the Promotion of Science (JSPS) KAKENHI grant (number 23K15629) and the Takeda Medical Research Foundation Grant (number 2024045547). The funder played no role in study design, data collection, analysis and interpretation of data, or the drafting of this manuscript.

Abstract

Background: Health care systems face growing fiscal pressure while AI reaches clinical parity in several domains. UK National Health Service expenditure rose by 52%, while Australia's health expenditure grew by 29% between 2019 and 2023. Yet large-scale cost savings from AI remain limited, largely because implementation constraints continue to outweigh technical capability.

Objective: This study develops a Bayesian budget-impact framework to estimate AI-driven gross cost savings in radiology, workflow optimization, and workforce optimization in the United Kingdom and Australia, explicitly accounting for adoption uncertainty, effectiveness, and implementation risk.

Methods: We used a sequential Monte Carlo simulation with 1000 particles to estimate annual gross cost savings. The core savings function combined expenditure base, sector weight, adoption, effectiveness, and implementation risk. Priors were informed by a structured review of multiple studies per domain. The savings likelihood used a heteroscedastic noise specification in which the SD followed an exponential prior, with the mean set to 15% of each sector's observed savings estimate, ranging from US $12.0 million for Australian radiology to US $87.2 million for UK workforce optimization. The likelihood was also augmented with sector-specific observations that anchored effectiveness to published cost-reduction estimates and implementation risk to observed deployment failure rates. Scenario analysis applied multipliers to 1000 bootstrap posterior draws across optimistic, conservative, and pessimistic settings. Sensitivity analyses varied the σ scaling factor from 0.10 to 0.20 and perturbed prior means for adoption, effectiveness, and implementation risk by ±20%.

Results: Posterior annual savings were US $949 million (95% credible interval [CrI] US $720.6-US $1173.5 million) for the United Kingdom and US $737 million (95% CrI US $526.1-US $953.6 million) for Australia. Workforce optimization generated the largest share of savings in both countries, contributing 62.4% of UK savings (US $591.9 million, 95% CrI US $398.8-US $854.8 million) and 76.2% of Australian savings (US $561.4 million, 95% CrI US $331.9-US $815.3 million). Posterior implementation risk estimates ranged from 35.5% to 47.4%, below prior means of 49.1% to 57.2%, reflecting the empirical anchoring introduced through deployment-failure data. Across scenarios, projected savings ranged from US $357 million to US $1.845 billion in the UK and from US $267.2 million to US $1.454 billion in Australia. Baseline cumulative projections for 2024-2030 were US $10.1 billion for the United Kingdom and US $8.0 billion for Australia. The sensitivity analyses confirmed the robustness of the posterior savings estimates.

Conclusions: AI could generate substantial expenditure reductions in both health systems, but implementation risk remains the main constraint on realizing those gains. Workforce savings should be interpreted primarily as capacity gains that can be redeployed to higher-value care, not as automatic cash savings. The Bayesian framework offers probabilistic planning ranges rather than point forecasts and provides a practical basis for policy planning under uncertainty.

KEYWORDS

AI; artificial intelligence; Bayesian analysis; cost savings; health care economics; Monte Carlo simulation; sequential Monte Carlo

Introduction

Health care systems worldwide face an unusual convergence of fiscal pressure and technological opportunity. In the United Kingdom, National Health Service expenditure rose from £192.8 billion in 2019 to £292 billion in 2023, a 51% increase that substantially outpaced both inflation and economic growth [1]. In Australia, health care expenditure increased by 29% to Aus $252.5 billion over the same period, with hospital costs alone accounting for 42.4% of total health spending [2]. At the same time, AI has demonstrated clinical-grade performance across a wide range of health care applications, from diagnostic imaging to administrative workflows [3-6]. Yet despite growing AI adoption, large-scale, measurable cost savings remain elusive [7-9].

This gap between AI's technological maturity and its limited economic impact appears to stem less from algorithmic limitations than from implementation frameworks that fail to accommodate the probabilistic nature of AI effectiveness and the shifting risk profile of health care technology adoption. Traditional health economic models perform well for pharmaceuticals and medical devices, but they are less well suited to AI implementations, where efficacy is not static and scalability is rarely linear. Evidence suggests that roughly 50% to 57% of health care AI deployments fail to achieve their intended outcomes, defined here as failing to demonstrate the projected cost savings or clinical improvements within the planned implementation horizon rather than merely failing to deploy technically [8,10]. That pattern points to implementation, rather than technical capability alone, as the primary bottleneck.

The existing literature reveals a striking disconnect between theoretical promise and documented savings. Vendors and policy narratives often emphasize AI's cost-saving potential, but peer-reviewed evidence continues to show how difficult it is to realize those gains at scale [10]. This disconnect reflects both implementation challenges and weaknesses in existing economic evaluation methods. Recent reviews point to 3 main approaches to health care AI economic evaluation, each with clear limitations.

Performance analyses, exemplified by the evaluation of chest x-ray AI by Rajpurkar et al [11], provide point estimates but fail to capture uncertainty in both AI performance and implementation contexts. Markov and decision-theoretic models can represent temporal dynamics, but they depend on fixed transition probabilities, an assumption that fits poorly with the learning effects and adoption variability typical of AI deployment [12]. Monte Carlo simulations address some dimensions of uncertainty, yet conventional frequentist formulations are less effective at incorporating prior knowledge drawn from heterogeneous implementation studies [13].

Bayesian methods offer a more natural framework for this problem. In health technology assessment, Spiegelhalter et al [14] showed how Bayesian hierarchical models can synthesize evidence across heterogeneous clinical settings while preserving uncertainty. In health care AI, Chen et al [15] used Bayesian methods to evaluate diagnostic performance across multiple hospitals and found substantial between-institution variability that conventional approaches had missed. However, most existing work of this kind has focused on clinical effectiveness rather than economic outcomes, leaving a clear methodological gap in the evaluation of AI-driven cost savings.

Current health care AI economic evaluations suffer from several fundamental limitations. First, deterministic models do not adequately capture uncertainty in either AI performance or the implementation context. Fixed effectiveness assumptions, for example, overlook the substantial variation reported across health care settings, where identical AI systems may achieve effectiveness estimates ranging from 15% to 45%, depending on institutional conditions [16]. Second, many models understate implementation risk, even though recent evidence identifies it as the main constraint on realized AI savings. Studies of deployed health care AI systems found that implementaion barriers, rather than technical limitations, are the primary obstacles to achieving projected savings [17]. Third, many evaluations rely on short-run clinical trial evidence that does not reflect learning effects, gradual adoption, or workflow adaptation over time [18,19]. Fourth, few studies provide probabilistic savings estimates that policymakers can use directly for planning.

We address those gaps with 2 questions. First, what are the projected economic impacts of AI implementation across radiology, workflow optimization, and workforce optimization in the UK and Australian health care systems once uncertainty in effectiveness, adoption, and implementation risk is taken into account? Second, how do implementation risks affect the realization of projected AI cost savings, and how do those risks vary across sectors and national settings?

Methods

Study Design

We conducted a Bayesian budget-impact simulation to estimate AI-driven cost savings across 3 health care sectors in the United Kingdom and Australia. Rather than fitting a traditional hierarchical model, we used a Bayesian simulation framework that synthesizes evidence from heterogeneous implementation studies while explicitly incorporating uncertainty in effectiveness, adoption, and implementation risk. The primary time horizon was 2024 for the cross-sectional analysis and was extended to 2024-2030 using inflation-adjusted temporal projections based on annual inflation rates of 4% for the United Kingdom and 5% for Australia.

We adopted a payer/provider perspective, using the National Health Service (NHS) for the United Kingdom and the Australian Government for Australia. The primary estimand was annual gross cost savings, defined as the reduction in

XSL•FO
RenderX

expenditure attributable to AI-enabled efficiency gains rather than cost offsets or net savings after implementation costs. We therefore did not model implementation costs such as software licensing, system integration, staff training, governance, or cybersecurity. Nor did we model health outcomes, quality-adjusted life-years, or incremental cost-effectiveness ratios because our objective was a budget-impact analysis rather than a cost-effectiveness evaluation.

Data Sources and Sector Specifications

We drew health care expenditure data from official national statistics for the 2022-2023 period. For the United Kingdom, we used the Office for National Statistics (ONS) estimate of £292 billion in total health care expenditure [1]. For Australia, we used the Australian Institute of Health and Welfare estimate of Aus $252.5 billion [2]. We converted all monetary values to US dollars using International Monetary Fund (IMF) December 2023 spot exchange rates of £1=US $1.27 and the Reserve Bank of Australia (RBA) December 2023 spot rate of Aus $1=US $0.68. We used spot rates because they align with the official expenditure reports. Purchasing power parity rates could alternatively be used for welfare comparisons, but they would not materially alter either the direction or the rank ordering of our results. Full expenditure-base calculations are reported in Table S3 in Multimedia Appendix 1.

We derived sector expenditure weights from ONS, the Australian Institute of Health and Welfare (AIHW), and OECD: Organization for Economic Co-operation and Development (OECD) health accounts [1,2,20,21]. Radiology accounted for 0.83% of total health care spending in the United Kingdom and 2.8% in Australia [22-24]. Workflow optimization, defined here as health administration and clinical workflow process costs, accounted for 2% of UK expenditure (approximately £5.84 billion) and 2.77% of Australian expenditure (approximately Aus $7.0 billion) [1,2]. Workforce optimization, capturing compensation of employees, accounted for 30% of UK health care expenditure and, for Australia, was parameterized using the workforce payroll component of recurrent public hospital expenditure, equal to Aus $56.62 billion (representing 52.9% of recurrent public hospital expenditure and an effective model weight of 22.4% of total Australian health care expenditure) [20,21]. These shares imply approximate sector bases of £2.4 billion (US $3.05 billion) for UK radiology, Aus $7 billion (US $4.76 billion) for Australian radiology, £5.84 billion (US $7.42 billion) for UK workflow optimization, Aus $7.0 billion (US $4.76 billion) for Australian workflow optimization, £87.6 billion (US $111.25 billion) for UK workforce optimization, and Aus $56.62 billion (US $38.5 billion) for Australian workforce optimization [1,2,20-24].

As detailed below, our structured review yielded only 3 to 4 studies per domain, although all had sample sizes of at least 100 participants. That relatively sparse evidence base motivated the use of informative priors and underscores the need for future meta-analyses and registry-based evidence.

Bayesian Model Structure and Sampling

We modeled annual cost savings (S) for sector i in country j as:

where B_j represents base health care expenditure, $w_{i,j}$ denotes sector weight, $A_{i,j}$ is the adoption rate, $E_{i,j}$ represents AI effectiveness, and $R_{i,j}$ captures implementation risk. In practical terms, equation 1 multiplies total health care spending by the sector's share, the fraction of activity that adopts AI, the cost-reducing effect of AI, and the probability that implementation succeeds, yielding each sector's expected cost saving. The multiplicative specification treats adoption rate A and implementation risk R as statistically independent. Although higher-risk environments may exhibit slower AI adoption in practice (introducing negative correlation), the current literature does not provide joint (A, R) data sufficient to parameterize a bivariate distribution. The independence simplification is therefore a necessary modeling choice whose conservative implications—a modest upward bias in projected savings—are discussed in the Limitations section.

We assumed that observed cost savings followed a normal distribution centered on the value implied by equation 1. We treated the SD, σ, as an estimable parameter and assigned it a sector-country-specific exponential prior with a mean equal to 15% of the observed savings estimate for that sector-country pair. This heteroscedastic specification scales absolute estimation noise to the magnitude of projected savings, so sectors with larger projected savings also carry larger absolute uncertainty. The implied prior mean values for ranged from US $12.0 million for Australian radiology to US $87.2 million for UK workforce optimization, reflecting the variation in observed savings across sectors.

The savings equation links 3 sector-specific latent parameters—adoption rate (A), effectiveness (E), and implementation risk (R)—to 1 or more constructed savings observations per sector-country pair, derived from the eligible literature and converted to comparable annual monetary values. In the current implementation, radiology uses 2 constructed savings anchors per country, whereas workflow optimization and workforce optimization each use 1. To improve identification, we augmented the savings likelihood with sector-specific auxiliary observations for effectiveness and implementation failure so that the joint log-likelihood is the sum of the savings term, the effectiveness-observation term, and the implementation-failure term. The augmented log-likelihood is given by equation 2:

where y^S_{ij}, y^E_{ij}, and y^R_{ij} denote the observed savings, effectiveness, and implementation-failure anchors, respectively, with corresponding measurement uncertainties $\sigma^S_{i,j}$, $\sigma^E_{i,j}$, and $\sigma^R_{i,j}$ derived from the literature. This specification anchors E to literature-based cost-reduction estimates and R to empirical deployment-failure rates, while adoption A is estimated conditional on those anchored quantities. The corresponding observed inputs and measurement uncertainties are described in the Prior Distributions section, and Table S1 in Multimedia Appendix 2 reports the observed cost-savings values used for

XSL•FO
RenderX

the United Kingdom and Australia. We note that with 3 latent parameters (A, E, R) per sector-country pair—updated against 2 constructed savings observations for radiology and 1 each for workflow and workforce optimization—the model is formally underidentified. Equation 2 partially addresses this by anchoring E and R with independent observations, but residual sensitivity to prior specifications remains and cannot be fully eliminated without sector-specific multioutcome datasets. A prior sensitivity analysis reported in Multimedia Appendix 3 demonstrates that sector rank orderings and order-of-magnitude savings estimates are robust to ±20% perturbations in individual prior means and to alternative σ scaling factors.

We estimated posterior distributions using sequential Monte Carlo (SMC) with 1000 particles [25,26]. We chose SMC over conventional Markov chain Monte Carlo (MCMC) because it requires relatively little tuning and is well suited to analyzing multiple datasets. The SMC algorithm samples through a sequence of intermediate distributions that gradually transform the prior into the posterior by annealing the likelihood. At each iteration, we selected the next temperature so that the effective sample size remained close to 500. We then resampled to eliminate low-weight particles and replicate high-weight particles. After resampling, we applied an MCMC kernel to perturb duplicated particles and reduce particle degeneracy. The number of MCMC iterations was set adaptively using the estimated acceptance rate. Throughout the algorithm, the number of unique particles remained above 900, indicating stable sampler performance. This process is described in Table S3 in Multimedia Appendix 2.

Prior Distributions

We constructed prior distributions from a structured review of major health care AI studies with sample sizes of at least 100 participants and quantifiable effectiveness estimates. Complete parameter values are reported in Table S1 in Multimedia Appendix 1, and Table S2 in Multimedia Appendix 1 maps those values to the underlying literature.

The effectiveness parameter $E_{i,j}$ is defined domain-specifically and is not directly commensurate across sectors. In radiology, E represents the proportional reduction in reading cost per screening episode attributable to AI triage. In workflow optimization, E represents the proportional reduction in cost per treatment course or workflow episode. In workforce optimization, E represents the proportional reduction in overtime and excess scheduling costs. These cost categories are mutually exclusive by design: radiology savings affect reading cost per episode; workflow savings affect process cost per course; workforce savings affect labor allocation costs. Adoption rate (A) represents the proportion of eligible activities within the sector that are subject to AI-assisted delivery. Implementation risk (R) represents the probability that a given AI deployment fails to achieve its projected savings within the planned implementation horizon.

For effectiveness, we used truncated normal (TN) priors that reflect both the empirical literature and domain-specific constraints. In radiology, studies by Lång et al [27] and Marinovich et al [28] show that AI-assisted screening can improve diagnostic accuracy and workflow efficiency, although formal modeling of cost-effectiveness or combined deployment impact remains limited [29]. We therefore specified UK radiology effectiveness as TN(0.459, 0.128; lower=0.01, upper=0.6). Workflow optimization used TN(0.55, 0.12; lower=0.01, upper=0.8), anchored primarily to the radiation therapy economic analysis by Natesan et al [30]. Workforce optimization used TN(0.30, 0.10; lower=0.01, upper=0.6), informed by scheduling, overtime, and workforce-cost studies [31,32]. For Australia, we used TN(0.38, 0.06) for radiology, TN(0.50, 0.15) for workflow optimization, and TN(0.30, 0.12) for workforce optimization, with the same lower and upper bounds.

We modeled adoption rates with TN priors bounded between 0.01 and 0.35. UK adoption followed TN(0.12, 0.09), and Australian adoption followed TN(0.15, 0.10), informed by national digital health strategy reports and implementation statistics [33-35]. The upper bound of 35% reflects the maximum penetration we considered plausible under existing national AI strategies for 2024; exceeding that level would likely require infrastructure and workforce investments beyond current plans. We also capped effectiveness at 0.6 in radiology and workforce optimization, where human oversight remains substantial, and at 0.8 in workflow optimization, where the automation potential is greater and clinical risk thresholds are lower [33-35].

We specified implementation risk using sector-specific beta distributions. Radiology risks followed Beta(2.3, 1.7), representing a 57% mean risk; workflow optimization used Beta(2.8, 2.2), representing a 56% mean risk; and workforce optimization used Beta(3.5, 3.5), representing a 50% mean risk. These parameters were derived from a systematic review of AI implementation studies, particularly the analysis of deployment failures by Beede et al [17] and an evaluation of clinical integration challenges by Sendak et al [36]. We then further constrained these priors using direct implementation-failure observations in the augmented likelihood. For UK radiology, a study of the NHS AI chest diagnostics program by Ramsay et al [37] reported that 23 of 66 funded NHS trusts had not achieved clinical use at the time of reporting, yielding a failure-rate estimate of 0.348 with measurement uncertainty of 0.059 [37]. Because all 66 trusts had already been funded and committed to deployment, we interpret this as a conditional implementation-failure rate rather than a general market-adoption rate. The Royal College of Radiologists' 2023 Clinical Radiology Workforce Census reported that 46% of NHS trusts were not using AI tools in radiology practice, which is broadly consistent with that estimate [38]. For workflow optimization and workforce optimization in both countries, and for Australian radiology, where equivalent national deployment surveys were unavailable, we used a pooled estimate. A systematic review of 39 AI randomized controlled trials by Lam et al [39] found that 18 studies, or 46.2%, failed to demonstrate clinically meaningful outcomes. Further, a systematic review of 14 real-world AI implementations by Yin et al [40] found that 6, or 42.9%, did not improve patient outcomes. Inverse-variance pooling of those estimates yielded an implementation-failure anchor (Y_R) of 0.45 with SE (σ_R) of 0.07.

XSL•FO
RenderX

Sectors Analyzed

We analyzed 3 health care sectors chosen for their differing levels of AI maturity and potential cost impact. Radiology included diagnostic imaging services, with savings anchors derived from breast-screening studies [27-29]. Workflow optimization covered administrative and clinical workflow processes, but in the present implementation, its quantitative savings anchor is the radiation therapy course-level cost reduction reported by Natesan et al [30]. Workforce optimization covered staff scheduling, workload distribution, and broader human resource management, with prior evidence drawn from scheduling, overtime, and workforce-cost studies [31,32].

In each sector, we used country-specific parameters to reflect institutional differences between the United Kingdom's centralized NHS structure and Australia's more federated health care system.

Scenario Analysis

We examined 3 main scenarios to test the sensitivity of our results to implementation conditions, with full results reported in Table S1 in Multimedia Appendix 3. We applied scenario multipliers to 1000 bootstrap samples drawn from approximate posterior distributions, using normal approximations parameterized by posterior means and SDs. The resulting credible intervals (CrIs) therefore represent the 2.5th to 97.5th percentiles of the bootstrap distributions rather than simple transformations of posterior means. Multimedia Appendix 3 also reports a separate 6-scenario temporal analysis—baseline, high inflation, low inflation, currency volatility, technology acceleration, and regulatory constraint—applied to the multiyear projection model. Note that because the interval estimates rely on a normal approximation to the marginal posteriors rather than the raw particle set, this approximation can impose symmetry on skewed distributions and produce boundary effects at the parameter caps.

The baseline scenario used the core posterior distributions. The optimistic scenario assumed enhanced implementation success with reduced risk parameters, for example, Beta(3.3, 2.7) for radiology, representing a 55% mean risk; increased adoption rates at the 75th percentile of the baseline distributions; and effectiveness parameters at the upper quartile. The pessimistic scenario incorporated higher implementation risks, for example, Beta(1.3, 0.7) for radiology, representing a 65% mean risk; reduced adoption rates at the 25th percentile; and lower effectiveness parameters. The conservative scenario increased implementation risk by 10%, reduced adoption by 10%, and reduced effectiveness by 5% relative to baseline. Together, these scenarios span plausible implementation environments while maintaining internal consistency.

Temporal Projection Parameters and Learning Dynamics

For projections from 2024 to 2030, we defined  and extended equation 1 as:

Adoption followed a baseline-preserving logistic learning curve, capped at 35%, with faster uptake assumed in the United Kingdom than in Australia (, where ν is the maximum proportional gain in adoption above the 2024 baseline and τ denotes years since 2024 at the inflection point). Implementation risk decayed geometrically as  with δ=0.05, reflecting organizational learning. Effectiveness increased geometrically as  with γ=0.03, using caps of 0.60 for radiology and workforce optimization and 0.80 for workflow optimization. Country-specific inflation rates were set at 4% for the United Kingdom and 5% for Australia. Uncertainty was propagated using 1000 Monte Carlo/bootstrap draws from normal approximations to the SMC-derived posterior distributions, parameterized by posterior means and SDs for adoption, implementation risk, effectiveness, and baseline savings. Multimedia Appendix 3 reports the resulting annual and cumulative scenario projections.

Model Validation

External validation against independent national AI cost-savings benchmarks was not feasible because no published assessment matched the sector-level granularity of our model. In place of formal validation, we conducted face-validity checks by comparing posterior sector savings with analogous published estimates. UK workforce optimization savings of US $591.9 million represent roughly 0.53% of the UK workforce compensation base of about US $111 billion, a magnitude broadly consistent with overtime-reduction studies reporting efficiency gains of 2% to 8% in scheduling-optimization settings [31]. UK radiology savings of US $143.9 million against a radiology base of roughly £2.4 billion (about $3.1 billion) represent about 4.6% of sector spending, which is broadly consistent with the 4% to 7% cost-per-study reductions reported in AI-assisted reading studies [11,27]. These checks support the order-of-magnitude plausibility of our projections, although they do not substitute for external validation against detailed cost-accounting data. Expanding the framework to settings with administrative cost-accounting data would enable formal validation against observed cost trajectories; this is the single most important priority for strengthening these estimates.

All analyses were conducted in MATLAB R2023a using custom SMC functions. A complete summary of Bayesian parameter estimates comparing prior and posterior distributions is provided in Table S2 in Multimedia Appendix 2. The complete MATLAB scripts and SMC implementation code are publicly available (see Data Availability section). All data sources are fully cited and traceable to public repositories (ONS, AIHW, and OECD).

Ethical Considerations

This study used only publicly available, aggregated health care expenditure data, published peer-reviewed literature, and national health statistics. We did not use patient-level data, personally identifiable information, or clinical records at any stage. Accordingly, no institutional ethics board or Human Research Ethics Committee review was needed. In the United Kingdom, this study falls outside the scope of the UK Policy Framework for Health and Social Care Research [41], which restricts oversight to research involving NHS patients, their

XSL•FO
RenderX

tissue, or their identifiable data; computational modeling based on publicly available national statistics does not constitute such research. In Australia, the study was conducted in accordance with the *National Statement on Ethical Conduct in Human Research* [42], which exempts from Human Research Ethics Committee review research that relies solely on publicly available information with no potential for harm to individuals. No human participants were recruited, no clinical interventions were administered, and no informed consent was required.

Results

Primary Cost Savings Projections

Our Bayesian analysis revealed substantial potential for AI-driven gross cost savings across both health care systems, with total projected annual gross cost savings of US $948.8 million for the United Kingdom and US $737.1 million for Australia. Table 1 presents the comprehensive posterior estimates for all sectors and countries. The prior-to-posterior evolution of each component for each sector and country is shown in Multimedia Appendix 4.

In the United Kingdom, workforce optimization generated the largest projected savings at US $591.9 million annually (95% CrI US $398.8-US $854.8 million), accounting for 62.4% of total projected UK savings. This result reflects the considerable potential for AI-driven efficiency gains in staff scheduling, workload distribution, and human resource management within the NHS. Workflow optimization contributed US $213.1 million (95% CrI US $133.1-US $300.6 million), representing savings from administrative and clinical process improvement. Radiology contributed US $143.9 million (95% CrI US $111.4-US $169.3 million), despite accounting for a smaller share of total health care expenditure.

Australia showed the same sector ordering but lower absolute savings overall. Workforce optimization generated US $561.4 million annually (95% CrI US $331.9-US $815.3 million), accounting for 76.2% of total projected Australian savings. Workflow optimization contributed US $95.2 million (95% CrI US $62.4-US $135.8 million), and radiology contributed US $80.4 million (95% CrI US $65.3-US $94.9 million). The shared ranking—workforce, workflow, then radiology—suggests that the main cross-country difference lies in scale rather than in the location of savings. At the same time, the CrIs overlap across several sector estimates, so those differences should still be interpreted probabilistically rather than definitively.

Table 1. Annual AI cost savings projections by sector and country (2023 US $, millions).

Country	Sector	Mean savings[a] (95% CrI)[b]	CV[c] (%)
United Kingdom	Radiology[d]	143.9 (111.4-169.3)	9.4
United Kingdom	Workflow optimization[e]	213.1 (133.1-300.6)	18.2
United Kingdom	Workforce optimization[f]	591.9 (398.8-854.8)	18.2
Australia	Radiology	80.4 (65.3-94.9)	8.8

Total: Australia	All sectors	737.1 (526.1-953.6)	—

[a]Posterior estimates of annual AI-driven gross cost savings for the United Kingdom and Australia across 3 health care sectors. Values are reported in 2023 US $, using the International Monetary Fund December 2023 exchange rate for the United Kingdom (£1=US $1.27) and the Reserve Bank of Australia December 2023 exchange rate for Australia (Aus $1=US $0.68).

[b]The 95% credible intervals (CrIs) are the 2.5th to 97.5th percentiles of the raw sequential Monte Carlo (SMC) posterior. The corresponding baseline 95% CrIs in the next table were derived from 1000 bootstrap samples drawn from normal approximations to the SMC-derived posterior and therefore differ slightly (United Kingdom: 718.5-1177.7; Australia: 525.3-950.2). Both representations are internally consistent with their respective sampling procedures.

[c]CV: coefficient of variation of the posterior distribution.

[d]Radiology: diagnostic imaging reading and triage enhancements.

[e]Workflow optimization: administrative and clinical workflow process improvements (evidence base: radiation therapy treatment planning).

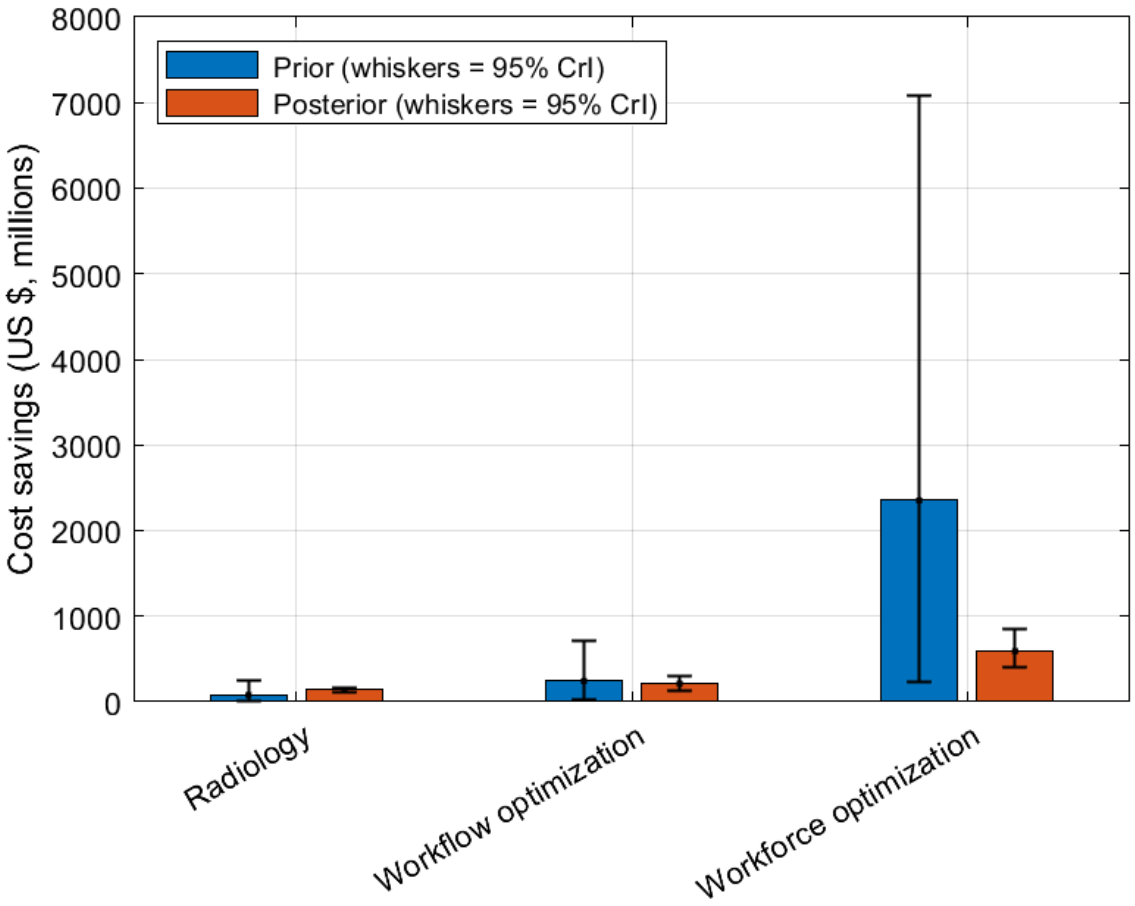
[f]Workforce optimization: staff scheduling and human resource management efficiencies.

[g]Not applicable.

Prior vs Posterior Distribution Evolution

Bayesian updating shifted several parameters in meaningful ways relative to their literature-based priors. Figures 1 and 2 illustrate the movement from prior to posterior distributions for the United Kingdom and Australia, respectively, and Table S2 in Multimedia Appendix 2 reports the corresponding numerical estimates.

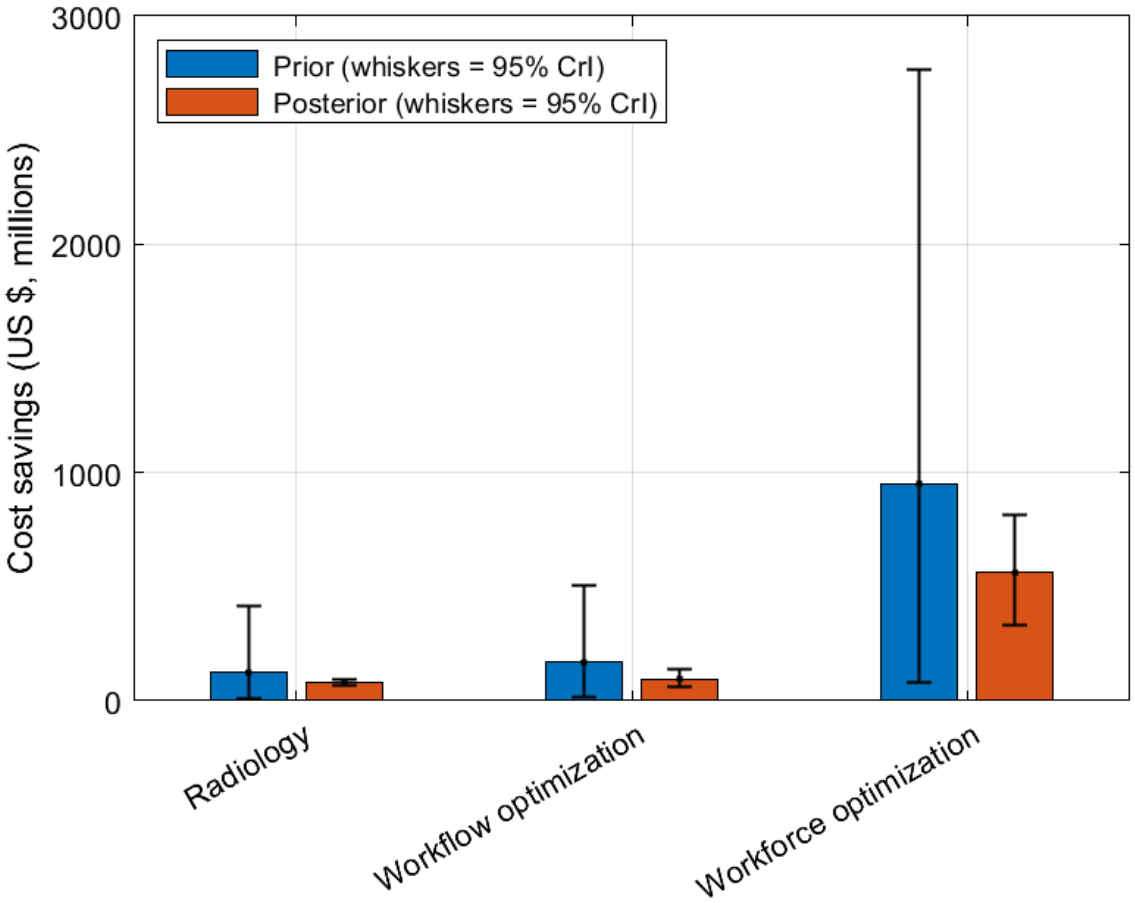
The clearest change appears in implementation risk. Posterior implementation risk fell below the prior mean in every sector-country pair, indicating that the external failure-rate anchors were more favorable than the literature-derived beta priors. In UK radiology, implementation risk dropped from a prior mean of 57.1% to a posterior mean of 35.5% (95% CrI 24.5%-46.5%), pulled strongly toward the NHS



XSL•FO
RenderX

deployment-failure anchor of 0.348 [37]. The remaining 5 sector-country pairs also moved downward, though more modestly: UK workflow fell from 54.5% to 46.8%, UK workforce from 49.8% to 46.4%, Australian radiology from 57.2% to 47.3%, Australian workflow from 55.8% to 47.4%, and Australian workforce from 49.1% to 46.7%. In those cases, the posterior was pulled toward the pooled failure-rate estimate of 0.45 [39,40]. Overall, posterior implementation-risk estimates ranged from 35.5% to 47.4%, uniformly below the prior range of 49.1% to 57.2%. This pattern suggests that the empirical deployment evidence was somewhat more favorable than our conservative prior assumptions, even though implementation risk remained substantial in all sectors and continued to constrain realized savings.

Adoption followed a different pattern. UK radiology adoption rose modestly from 13.6% to 17.0%, consistent with growing uptake of AI tools in chest imaging and mammography. In every other sector-country pair, however, posterior adoption fell below its prior mean. The declines were especially pronounced in workforce optimization, where posterior adoption fell from 13.8% to 3.9% in the United Kingdom and from 16.1% to 10.7% in Australia. These low estimates suggest that organizational barriers to implementation in human resource management are much stronger than national strategy documents alone would imply.



Effectiveness estimates also moved, mainly through shrinkage toward the auxiliary observation values. UK radiology effectiveness was anchored at 43% relative to a prior mean of 43.1%, workflow optimization at 52% relative to 55%, and workforce optimization at 26.8% relative to 30.1%. Australian radiology shifted upward from 36.8% to 42.6%, reflecting the influence of a randomized controlled trial-derived effectiveness anchor. Posterior SDs for effectiveness were also much narrower than prior SDs—for example, in radiology, the SD fell from 10.3% to 2%—showing that the augmented likelihood sharpened those parameter estimates as intended.

Scenario Analysis Results

Annual scenario analysis showed that projected savings are highly sensitive to implementation conditions. Across scenarios, total projected savings ranged from $356.6 million to $1.845 billion in the UK and from $267.2 million to $1.454 billion in Australia. Table 2 summarizes the sector-by-sector results. Under the optimistic scenario, projected annual savings rose to $1.845 billion in the UK, a 95% increase over the baseline estimate of about $0.949 billion. Australia reached $1.454 billion, a 97% increase over its baseline estimate of about $0.737 billion. These outcomes assumed lower implementation risk, stronger adoption, and effectiveness at the upper quartile of the posterior distributions. In both countries, workforce optimization remained the dominant contributor under these favorable conditions. The optimistic case also makes clear that gains are driven less by any single technology than by system-level conditions—especially adoption and implementation success—that lift all sectors simultaneously.

Under the pessimistic scenario, projected savings fell sharply to US $356.6 million in the United Kingdom and US $267.2 million in Australia. This case assumed implementation risk above 65% across sectors, adoption below 8%, and effectiveness at the lower quartile. The contrast between optimistic and pessimistic scenarios highlights the importance of organizational readiness and implementation success. In both the centralized UK system and the federated Australian system, higher risk and weaker adoption compress projected savings dramatically.

The conservative scenario yielded US $744.5 million for the United Kingdom and US $574.6 million for Australia. These estimates may offer the most plausible short-run planning values because they reflect moderate implementation friction rather than best-case or worst-case assumptions. Even so, the corresponding 95% CrIs remained wide, so they are better treated as planning ranges than as precise forecasts—particularly when comparing United Kingdom and Australian totals. Figure 3 illustrates the resulting sectoral distributions, and Tables S1 and S2 in Multimedia Appendix 3 report the annual scenario results together with the separate 2024-2030 temporal scenario analysis.

Cross-Sector Analysis and Total System Impact

Emerging studies suggest that integrating AI across multiple domains—such as radiology, administrative workflows, and workforce planning—may generate meaningful synergies [18,19]. Although our savings function could accommodate such cross-sector effects, we were unable to quantify them because the empirical evidence remains too limited. Even so, the sectoral pattern offers a clear strategic signal. Workforce optimization dominates projected cost savings across scenarios in both countries, contributing 62.4% of UK total cost savings and 76.2% of Australian total cost savings in the baseline case. That pattern suggests that human resource management may be the highest-value target for early AI investment, even though current policy and research attention remain more heavily concentrated on clinical AI applications.

XSL•FO
RenderX

Radiology remains strategically important despite its smaller aggregate savings. In the United Kingdom, it showed the largest prior-to-posterior decline in implementation risk because we were able to anchor the model to direct NHS deployment evidence [37,38]. It may therefore serve as a practical entry point for implementation learning and provide institutional experience that can support later expansion. Workflow optimization also remained economically important in both countries, ranking second in projected savings despite the organizational complexity of administrative and clinical process redesign.

Discussion

Principal Findings

Our analysis reveals that AI implementation in the United Kingdom and Australian health care systems has substantial economic potential, with projected annual gross cost savings of US $949 million and US $737 million, respectively. However, 3 critical findings challenge conventional wisdom about health care AI economics. First, workforce optimization dominates potential cost savings across both countries, contributing 62.4% (United Kingdom) and 76.2% (Australia) of total projected benefits despite receiving less attention in AI implementation literature compared to clinical applications. Second, posterior implementation risk falls below prior expectations in every sector (posterior range 35.5%-47.4% vs prior means 49.1%-57.2%) because empirical deployment failure rates are more favorable than the conservative literature-derived beta priors; nevertheless, implementation risk remains the binding constraint on realizing these savings. Third, the substantial variation between pessimistic (US $0.357 and US $0.267 billion for the United Kingdom and Australia, respectively) and optimistic (US $1.845 and US $1.454 billion for the United Kingdom and Australia, respectively) scenarios demonstrates that organizational and implementation factors, rather than technological capabilities, primarily determine AI's economic impact.

Comparison With Prior Work

The dominance of workforce optimization cost savings challenges the prevailing focus on clinical AI applications in health care technology assessment. While diagnostic AI in radiology has received extensive research attention and regulatory development, our findings suggest that administrative and human resource applications may offer superior return on investment. This pattern likely reflects substantial inefficiencies in current health care workforce management, where manual scheduling, suboptimal workload distribution, and reactive staffing decisions create opportunities for AI-driven optimization that exceed the efficiency gains available in already streamlined clinical processes.

Limitations

Several limitations shape how these findings should be interpreted. First, although we defined sector cost categories to be mutually exclusive in order to minimize double counting, some residual overlap cannot be ruled out without more detailed cost-accounting data from individual health systems. Savings estimates should therefore be interpreted as upper bounds on nonoverlapping achievable gains. Second, the sector expenditure weights and observed savings values are constructed from heterogeneous published studies rather than direct measurements of national AI-attributable cost reductions. They represent informed approximations and should not be treated as empirical observations in the classical sense. A deeper consequence of this construction is that 3 latent parameters (A, E, R) are updated from a limited number of constructed savings anchors per sector-country pair—2 in radiology and 1 in workflow and workforce—so the model remains only partially identified and posterior distributions retain sensitivity to prior specifications. A prior sensitivity analysis (Tables S3 and S4 in Multimedia Appendix 3) demonstrates that sector rank orderings and order-of-magnitude estimates are robust to ±20% perturbations of individual prior means and to alternative σ scaling factors, but the fundamental identifiability constraint cannot be resolved without larger, sector-specific implementation datasets.

Third, we excluded implementation costs such as software licensing, integration, training, governance, change management, and cybersecurity. Health systems should deduct these costs when translating our projections into business cases. Fourth, most model parameters were derived from published studies conducted in academic medical centers and large hospital networks, which may not represent community hospitals, rural facilities, or lower-resourced settings; transferability across institutions and geographies therefore remains uncertain. Fifth, the model treats adoption rate and implementation risk as statistically independent multiplicative factors. In practice, higher-risk organizations may also adopt AI more slowly, creating a negative correlation that would further reduce savings in high-risk settings. This independence assumption likely introduces a modest upward bias into projected savings. Sixth, several data quality caveats apply collectively: sector expenditure shares are derived from aggregate national health accounts and remain subject to classification uncertainty; cross-country US $ comparisons depend on spot exchange rates; and estimation noise is modeled via sector-specific heteroscedastic priors. Table S3 in Multimedia Appendix 3 reports the sensitivity of posterior savings to the σ scaling factor. Seventh, the model does not capture downstream clinical costs that AI deployment may trigger. For example, AI-assisted radiology screening may increase recall rates or biopsy referrals before sensitivity and specificity stabilize in operational settings, generating downstream costs not reflected in our savings estimates. Likewise, workflow AI that accelerates throughput may shift costs to downstream services. Quantifying such second-order effects will require health system-level cost-accounting data linked to AI deployment records.

Future Directions

Future work could strengthen the framework in several ways. Longitudinal implementation datasets would allow better calibration of adoption curves and risk decay. Natural experiments and richer cost-accounting data could help quantify cross-sector synergies and validate realized savings. The Bayesian framework can be adapted as a decision-support tool for health system planners by parameterizing priors from organization-specific readiness assessments (eg, AI maturity

XSL•FO
RenderX

scores, existing digital infrastructure, and workforce capacity) and updating with local deployment data as they accumulate. This would allow progressive narrowing of CrIs over time, transforming the current national-level projections into institution-specific investment guidance. Finally, linking economic outcomes to patient outcomes would provide a fuller assessment of value.

Conclusion

AI could generate substantial expenditure reductions in both the United Kingdom and Australian health care systems, with projected annual gross cost savings of US $949 million and US $737 million, respectively. In both countries, workforce optimization offers the largest potential gains, while implementation risk remains the main obstacle to realizing them. These findings suggest that policymakers should place as much weight on implementation science, governance, and organizational change as on technology acquisition itself. Health systems may also need to rebalance attention toward workforce optimization, develop stronger implementation-risk assessment frameworks, and create mechanisms for shared learning across centralized and federated systems. The Bayesian framework we present is best understood as a decision-support tool that provides probabilistic planning ranges under uncertainty rather than deterministic forecasts.

Acknowledgments

During the preparation of this work, we used the generative AI tools Elicit (Ought, Inc.) for assistance in literature searches, Microsoft Copilot (Microsoft Corporation) for rewriting the original draft for conciseness, and Perplexity (Perplexity AI) for assistance with coding. After using these applications, we reviewed and edited the content as needed and take full responsibility for the content of the published article.

The authors declared no financial support was received for this work.

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information files. The complete MATLAB R2023a scripts and sequential Monte Carlo (SMC) implementation code supporting this study are provided in Multimedia Appendix 5. The package includes (1) BayesianAIHealthcare_Analysis.m—the primary analysis script generating Tables 1 and 2 and Tables S1-S4 in Multimedia Appendix 3; (2) BayesianAIHealthcare_SMCSector.m—the sector-level SMC simulation with augmented log-likelihood; (3) 6 helper files for sensitivity analyses; and (4) a ReadMe file containing instructions to run the simulation code. All prior data included in Multimedia Appendices 1 and 3 are hard coded in the MATLAB scripts. No individual patient data were used or generated.

Authors' Contributions

SR contributed to conceptualization, project administration, supervision, and review and editing of the original draft. JS contributed to conceptualization, data curation, investigation, methodology, validation, visualization, writing, and review and editing of the original and revised manuscripts. CD contributed to data curation, formal analysis, investigation, methodology, validation, visualization, writing, and review and editing.

Abstract

Background: Personalized follow-up for type 2 diabetes may improve the alignment between monitoring intensity and patient needs, but operational approaches that jointly consider follow-up timing, modality, expected health benefits, and resource use remain limited.

Objective: This study develops a Markov decision process (MDP) framework for personalized follow-up planning, externally validates complementary risk-prediction models, and estimates the projected 12-month cost-effectiveness of model-generated follow-up strategies.

Methods: We retrospectively analyzed longitudinal data from 41,398 patients with type 2 diabetes managed in 10 community health centers in Nanjing, China, over the 2015-2024 calendar period. An independent Shanghai cohort included 25,506 patients from 10 communities. We developed least absolute shrinkage and selection operator (LASSO)-Cox models to predict 1-year incident complication and mortality risk and evaluated discrimination in Shanghai. Separately, a 12-cycle finite-horizon MDP used observed action-conditional state transitions with prespecified utility, cost, access, and willingness-to-pay parameters to generate personalized follow-up policies.

Results: For an example patient initially without recorded complications (S0), the personalized policy increased annual effectiveness by 0.48 quality-adjusted life days (QALDs; 0.0013 quality-adjusted life years [QALYs]) and cost by 33.46 CNY (1 CNY=US $0.15), yielding an incremental cost-effectiveness ratio (ICER) of 25,499 CNY/QALY. In a heterogeneous simulated cohort of 1000 patients initialized in S0, mean annual effectiveness increased from 313.52 to 314.05 QALDs (0.85896 to 0.86041 QALYs), and mean annual cost increased by 24.67 CNY, yielding an ICER of 17,016 CNY/QALY. External C-indices were 0.778 for incident complications and 0.812 for mortality. Deterministic sensitivity analyses did not materially alter the cost-effectiveness conclusion.

Conclusions: The MDP framework generated individualized 12-month follow-up policies with small projected QALY gains at modest incremental program cost, while the complementary risk models demonstrated external discrimination in an independent cohort. As action-conditional transitions were estimated from observational records and several economic parameters were prespecified, the modeled differences represent projections rather than causal treatment effects and require prospective implementation and economic validation before clinical adoption.

Introduction

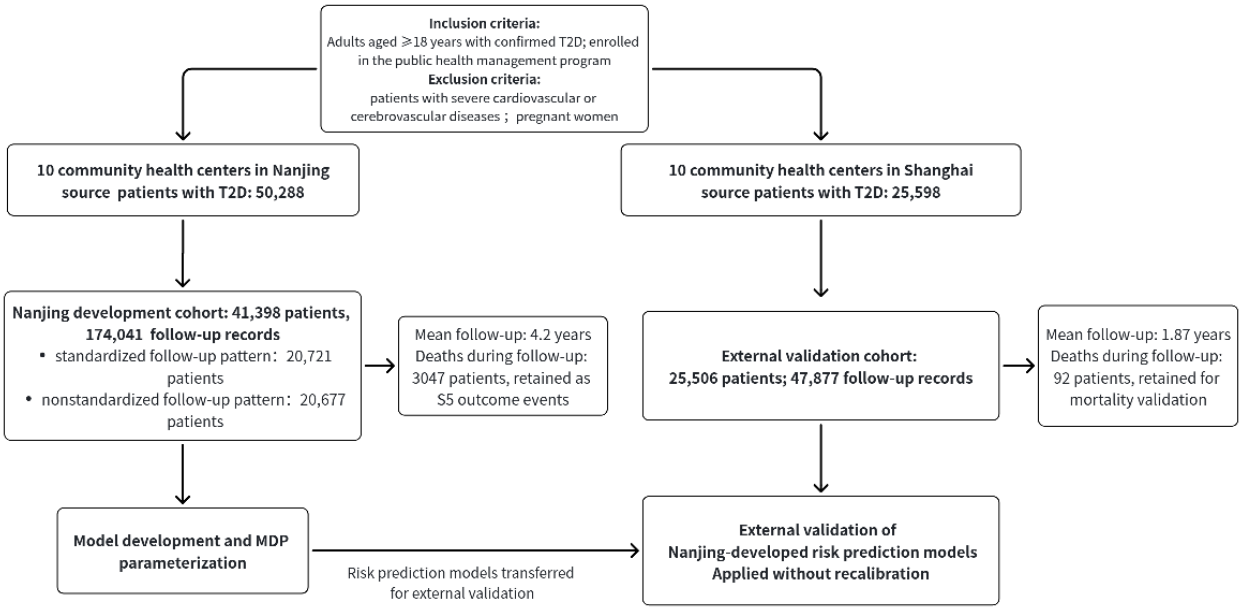
Diabetes is one of the most common chronic diseases globally [1]. In China, a combination of population growth [2], aging [3], rising obesity rates [4], and an increasingly sedentary lifestyle [5] has led to a substantial increase in the number of people with diabetes.

Diabetes management guidelines emphasize follow-up care as a critical nonpharmacological component of long-term disease management. This approach is important for monitoring glycemic control, identifying complications, improving quality of life, and supporting sustained self-management [6,7]. For instance, the American Diabetes Association recommends more frequent follow-up visits for newly diagnosed or poorly controlled patients, with individualized schedules for those at high risk of complications [8]. European guidelines also emphasize patient-centered care and individualized management according to patient characteristics, risk profiles, preferences, and treatment burden [9-11]. The Chinese guidelines recommend that primary health care providers conduct 4 evenly spaced face-to-face follow-up visits each year for patients diagnosed with type 2 diabetes [12].

Beyond guideline-scheduled visits, prior studies have examined follow-up frequency and regularity, telemedicine-assisted follow-up, and risk-stratified encounter schedules for diabetes and other chronic diseases [13-18]. These studies indicate that follow-up involves not only whether contact occurs, but also how often, when, and through which modality. However, only a few approaches provide an operational decision model that jointly determines follow-up timing and modality while accounting for projected health benefit, access burden, and resource use in primary care.

Implementing personalized follow-up in primary care is challenging because relevant longitudinal data are fragmented, planning often depends on manual judgment, and growing chronic-disease caseloads constrain clinical capacity. These constraints create a need for decision support that can translate routinely collected data into explicit follow-up policies while preserving clinical interpretability and resource awareness.

This study aimed to develop a Markov decision process (MDP)–based personalized follow-up planning framework for patients with type 2 diabetes, externally evaluate the discrimination of complementary risk-prediction models, and estimate the projected 12-month cost-effectiveness of model-generated personalized follow-up strategies compared with standardized follow-up.



Methods

Study Design

This study retrospectively analyzed real-world longitudinal data from 10 community health centers in Nanjing, China. The Nanjing source database covered the period 2015-2024, whereas individual patients had variable follow-up durations (Figure 1). Eligible patients were adults aged over 18 years with confirmed type 2 diabetes according to International Classification of Diseases, 10th Revision (ICD-10) codes and enrollment in the public health management program. Patients with severe cardiovascular or cerebrovascular diseases and pregnant women were excluded. A total of 50,288 individuals with type 2 diabetes were identified in the source database. After excluding individuals without analyzable longitudinal follow-up because of relocation, transfer out of the local public health management system, or incomplete or invalid records, 41,398 patients were included in the analytic cohort. Deaths observed after cohort entry were retained as outcome events and modeled as the absorbing state S5 rather than treated as loss to follow-up. The analytic cohort had a mean follow-up duration of 4.2 years and comprised 224 source data fields and 174,041 longitudinal follow-up records after analytic restructuring. Before risk-model development, identifiers, dates, per-measurement metadata, administrative and follow-up-process variables, outcome and survival-time variables, and fields used solely to construct MDP states and transitions were excluded from candidate prediction features. Eligible variables were subsequently encoded into 124 candidate design predictors as described below.

Figure 1. Flowchart of the Nanjing development cohort and Shanghai external validation cohort for Markov decision process (MDP)–based personalized follow-up planning in type 2 diabetes (T2D).

Patients were categorized into standardized and nonstandardized follow-up groups based on their observed follow-up patterns. Standardized follow-up was defined as 4 annual in-person visits, 1 per quarter, as stipulated by Chinese public health regulations. Nonstandardized follow-up was defined as any observed pattern that deviated from this guideline-based schedule, including fewer or more than 4 annual follow-ups, uneven follow-up intervals, or the use of telephone or community-based follow-up modalities instead of the scheduled in-person visits. The standardized follow-up group included 20,721 patients and the nonstandardized follow-up group included 20,677 patients. Because of the large sample size, several baseline variables showed statistically significant differences between the 2 groups; therefore, standardized mean differences were used as the primary criterion for assessing baseline comparability. Most measured baseline characteristics showed small between-group differences. No additional propensity score matching or weighting was performed because MDP transition-probability estimation required preserving the full observed state-action transition structure and avoiding sparse transition cells. The nonstandardized follow-up group was not a randomized intervention arm but an observational category derived from routine follow-up records. The comparison between standardized and nonstandardized follow-up patterns was treated as a descriptive assessment of observed follow-up patterns rather than as a causal estimate of treatment effect (Table 1).

[a]SMD: standardized mean difference.

[b]SMD was used to assess between-group differences in baseline characteristics, with an SMD<0.10 indicating small differences between groups. Multicategory SMDs were calculated using the multivariate formula of Yang and Dalton [19] and refer to the categories as displayed in this table. Most SMDs were below 0.10. No additional propensity score matching or weighting was performed, because estimation of the Markov decision process state-action transition probabilities required preserving the full observed transition structure and avoiding sparse transition cells.

[c]N/A: not applicable.

External evaluation of the complementary risk-prediction models used an independent cohort of 25,506 patients from 10 communities in Shanghai, with a mean follow-up duration of 1.87 years (data collected in 2023-2024). Variables required for the primary risk models were harmonized in definition and coding across the Nanjing and Shanghai cohorts. The Shanghai cohort was used only to evaluate the external discrimination of the Nanjing-developed risk models and was not used to validate the MDP policy or cost-effectiveness projections.

Ethical Considerations

This study was approved by the Ethics Board of Nanjing University, Nanjing, China (approval number OAP20240930001), and the approval covered the retrospective analysis of both the Nanjing development cohort and the Shanghai external validation cohort. The requirement for informed consent was waived because all data were deidentified and collected during routine clinical practice and public health management. No compensation was provided to participants, and no identifiable individual information is presented in this paper or its multimedia appendix.

Model Development

We formulated personalized follow-up planning as a finite-horizon MDP with 12 monthly decision cycles. The model consisted of health states, follow-up actions, action-specific transition probabilities, and an immediate monthly net health benefit reward [20,21]. Table 2 summarizes the notation, state definitions, decision variables, health utility parameters, cost parameters, willingness-to-pay thresholds, and travel-related disutility parameters used in the model.

XSL•FO
RenderX

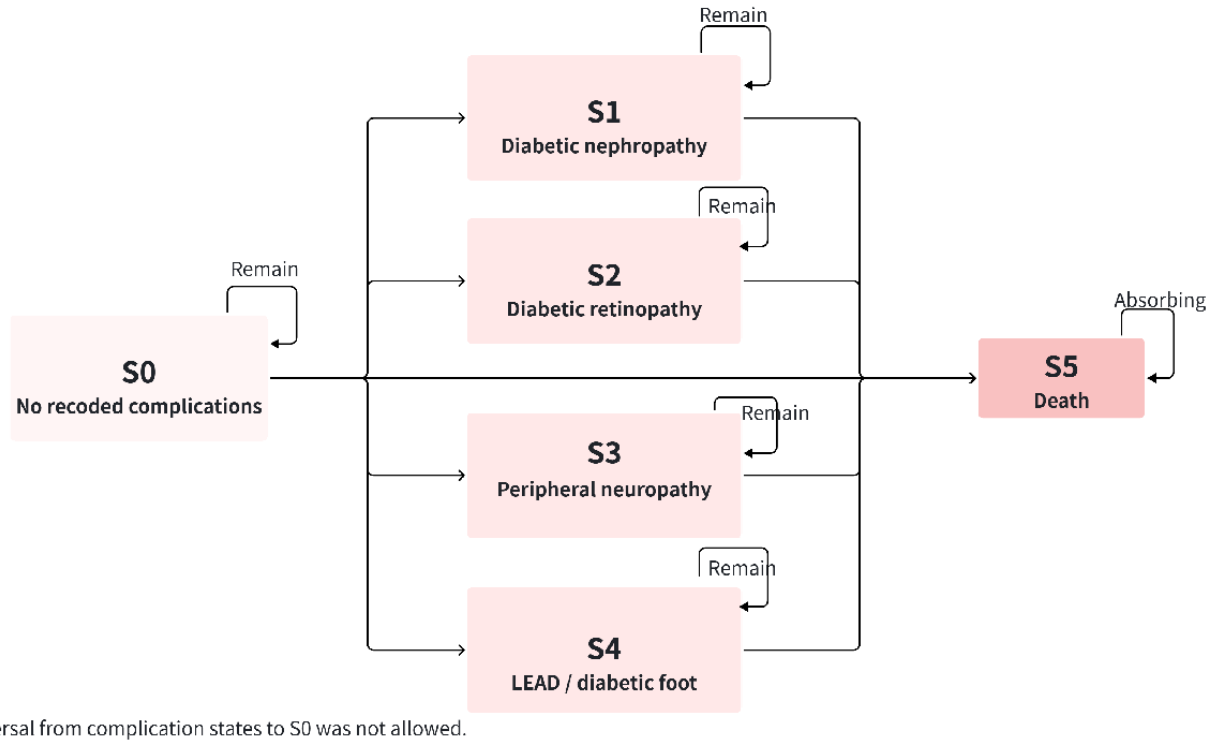
Table 2. Notation used in the 12-month Markov decision process model for personalized follow-up planning in type 2 diabetes.

Variables	Meaning statement
Fundamental variables	
i	Patient, i=1, ..., N
t	Period, t=1, ..., 12
$s_{i,t}$	Health state of patient i in month t, $s_{i,t} \in$ {S0, S1, S2, S3, S4, S5}
S0	No recorded diabetes-related complication
S1	Diabetic nephropathy
S2	Diabetic retinopathy
S3	Diabetic peripheral neuropathy
S4	Lower-extremity arterial disease and diabetic foot
S5	Death
$d_{i,t}$	Patient i without complications at t, with 1 indicating yes and 0 indicating no.
$c_{\text{any},\ i,t}$	Patient i has any recorded diabetes-related complication at t, with 1 indicating yes and 0 indicating no.
$C_{\text{neph},\ i,t}$	Patient i has diabetic nephropathy at t, with 1 indicating yes and 0 indicating no.
$c_{\text{ret},\ i,t}$	Patient i has diabetic retinopathy at t, with 1 indicating yes and 0 indicating no.
$c_{\text{neuro},\ i,t}$	Patient i has diabetic peripheral neuropathy at t, with 1 indicating yes and 0 indicating no.
$c_{\text{lead},\ i,t}$	Patient i has lower-extremity arterial disease and diabetic foot at t, with 1 indicating yes and 0 indicating no.
	Action-specific transition probability of moving from health state s in month t to health state s' in month t+1 under follow-up action a.
Δt	Length of each monthly cycle, fixed at 365/12 days in the base-case analysis.
u_s	Health utility value of state s, where s=0, 1, 2, 3, 4, 5 corresponds to S0, S1, S2, S3, S4, and S5, respectively.
$c_{\text{comp},\ s}$	Annual complication-related cost for health state s, where s=0, 1, 2, 3, 4, 5; the value is 0 for both S0 and S5.
$c_{\text{base},\ i}$	Annual baseline diabetes management cost for patient i, applied only while the patient is not in the death state and converted to monthly cost by dividing by 12.
$c^0{}_t$	Cumulative number of outpatient follow-up visits used before month t.
$F_{i,t}(a_t, c^0{}_t)$	Monthly modeled modality-specific follow-up cost for patient i in month t.
f_1	Additional outpatient follow-up charge applied from the fifth outpatient visit onward.
f_2	Modeled telephone follow-up charge per call.
f_3	Modeled community follow-up charge per visit.
$c^{\text{base}}{}_{i,t}$	Monthly baseline diabetes management cost for patient i in month t.
$c^{\text{comp}}{}_{i,t}$	Monthly complication-related cost for patient i in month t.
$c^{\text{follow}}{}_{i,t}$	Monthly modeled follow-up charge for patient i in month t.
$c^{\text{total}}{}_{i,t}$	Monthly cost for patient i in month t, including monthly baseline cost, monthly complication-related cost, and the modeled follow-up-charge component.
$c^{\pi}{}_i$	Annual cost for patient i under policy π, obtained by summing the 12 monthly total costs.
	Travel distance of patient i to outpatient follow-up, measured in kilometers.
H	Travel-related disutility coefficient applied to outpatient follow-up, defined as 0.00032 utility loss per kilometer in the base-case model.
λ_D	WTP[a] threshold expressed as CNY[b]/QALD[c].

XSL•FO
RenderX

Variables	Meaning statement
λ_Y	WTP threshold expressed as CNY/QALY[d].
$V_t(s,c^O_t;\lambda_D)$	Maximum expected cumulative net health benefit from month t onward.
Decision variables	
a_t	Follow-up action selected in month t, where 0 denotes no follow-up, 1 outpatient follow-up, 2 telephone follow-up, and 3 community follow-up; the action set is A={0, 1, 2, 3}.

[a]WTP: willingness-to-pay.



[b]1 CNY=US $0.15.

[c]QALD: quality-adjusted life day.

[d]QALY: quality-adjusted life year.

Health states were operationally defined using structured diagnosis records coded according to the ICD-10 Healthcare Security Version [22] issued by the National Healthcare Security Administration of China. Diabetes-related complication states were identified using ICD-10 code categories corresponding to type 2 diabetes with renal complications, ophthalmic complications, neurological complications, peripheral circulatory complications, and diabetic foot. The health state space consisted of 6 mutually exclusive states: no recorded diabetes-related complication (S0), diabetic nephropathy (S1), diabetic retinopathy (S2), diabetic peripheral neuropathy (S3), lower-extremity arterial disease and diabetic foot (S4), and death (S5; Figure 2). Baseline prevalent complications were defined as relevant ICD-10–coded diagnoses recorded before or at model entry, whereas incident complications were defined as the first newly recorded ICD-10–coded diagnosis of a complication category during follow-up among patients without that complication category at baseline. Death was identified from mortality records and modeled as the absorbing state. Once a patient entered a complication state, reversal to S0 was not allowed in the model. The detailed ICD-10 Healthcare Security Version coding algorithm and state-assignment rules are provided in Tables S19 and S21-S23 in Multimedia Appendix 1.

Figure 2. Health-state transition structure of the 12-month Markov decision process model for personalized follow-up planning in patients with type 2 diabetes. LEAD: lower-extremity arterial disease.

Actions were the decisions or measures that could be taken in each state and that influenced state transitions within the model. In the model constructed in this study, decisions involved determining the number of follow-ups, intervals, and methods for a patient over the course of a year. Periods were defined as t=1, 2, ..., 12, corresponding to the months of the year. Clinical events and follow-up records with irregular dates were assigned to the corresponding monthly cycle according to their recorded dates. Monthly state-action transitions were then constructed from the patient's recorded health state and follow-up action within each monthly cycle.

XSL•FO
RenderX

Let a_t denote the follow-up action selected in month t, where a_t=0 represents no follow-up, a_t=1 represents outpatient follow-up, a_t=2 represents telephone follow-up, and a_t=3 represents community follow-up. Let c^0_t denote the cumulative number of outpatient follow-up visits completed before month t.

Rewards were defined as immediate monthly net health benefits rather than as ratios of health benefits to costs. The MDP objective was to maximize the expected cumulative net health benefit over the 12-month horizon. Monthly health benefits were measured in quality-adjusted life days (QALDs), and monthly costs were converted into QALD-equivalent losses using the willingness-to-pay threshold.

For patient i in month t, current state s, action a, and prior follow-up count c^0_t, the adjusted health utility was defined as follows:

where u_s is the health utility of state s, $I(a=1)$ is an indicator for outpatient follow-up,  is the travel distance for outpatient follow-up, and η is the travel-related disutility coefficient. The death state S5 was assigned a utility of 0.

Monthly QALDs were calculated as follows:

where Δt=365/12 denotes the fixed length, in days, of each monthly cycle. Therefore, a patient who remains living throughout a complete cycle accrues the state-specific utility multiplied by 30.4167 days. Patients in the absorbing death state accrue 0 QALDs.

The costing analysis adopted a restricted public health program perspective rather than a full health-system or societal perspective. The annual baseline diabetes-management cost represented routine program expenditures, while modality-specific follow-up costs reflected additional charges in the model. The first 4 outpatient follow-up visits were assigned no additional charge because they are considered routine services under the public health program. This does not imply zero resource use or that all provider costs are fully captured by the baseline cost.

Monthly cost comprised a baseline management component, a complication-related component, and a follow-up component. The monthly follow-up cost for patient i in month t, denoted as $F_{i,t}(a_t, c^O_t)$, was defined as follows:

$$F_{i,t}(a_t, c^O_t) = I(a_t=1)I(c^O_t \geq 4)f_1 + I(a_t=2)f_2 + I(a_t=3)f_3$$

where $I(\cdot)$ is an indicator function, f_1 is the additional outpatient follow-up charge applied from the fifth outpatient visit onward, f_2 is the modeled telephone follow-up charge per call, and f_3 is the modeled community follow-up charge per visit. Under the specified accounting convention, the first 4 outpatient follow-up visits were assigned no additional modality-specific charge. This assignment represents a charging rule within the model and should not be interpreted as indicating zero provider resource use. Modality-specific charges were accrued only in the month in which the corresponding follow-up action occurred.

The monthly cost components, monthly total cost, and annual cost over the 12-month horizon were then calculated as follows:

The annual baseline diabetes management cost for patient i, denoted by $c_{base,i}$, was calculated using the following prespecified age-adjustment function:

$$c_{base,i} = c_{max}/[1 + \exp(-Age_i/k)]$$

where c_{max}=15,000 CNY/year (1 CNY=US $0.15) was the annual baseline-management cost ceiling and k=10 was the age-scale parameter. Over the modeled age range of 40-80 years, this function generated annual baseline management costs of approximately 14,730-14,995 CNY. It therefore represented an approximately constant annual baseline diabetes-management cost with limited age adjustment and was treated as a prespecified modeling assumption rather than a cost function estimated directly from individual-level expenditure data. The baseline management cost was accrued in all living states S0-S4. Patients in states S1-S4 additionally accrued the corresponding annual complication-related cost $c_{comp,s}$. As the MDP used monthly cycles, both annual cost components were divided by 12 before monthly accrual. No baseline management, complication-related, or follow-up cost was accrued after entry into S5. Thus, all annual costs reported in the cost-effectiveness analyses were obtained as the sum of the 12 monthly costs.

The willingness-to-pay threshold was expressed internally as CNY per QALD:

$$\lambda_D=(\lambda_Y/365)$$

where λ_Y is the willingness-to-pay threshold expressed as CNY per quality-adjusted life year (QALY) and λ_D is the corresponding threshold expressed as CNY per QALD.

The immediate reward used in the MDP was the monthly net health benefit:

$$ri,t(st,at,cOt; \lambda D) = QALDi,t(st,at) - (Ctotali,t/\lambda D)$$

Thus, the willingness-to-pay threshold entered the MDP optimization through the net health benefit reward function. Incremental cost-effectiveness ratios (ICERs) were calculated after policy optimization and were not maximized directly in the Bellman recursion. Transition probabilities were estimated from observed monthly transitions in the longitudinal data. To reduce instability arising from sparse state-action cells, we applied Laplace smoothing to the transition probability estimates. For month t, current state s, action a, and admissible next state s', the smoothed transition probability was calculated as follows:

where $n_t(s, a, s')$ is the observed number of transitions from s to s' under action a in month t, $N_t(s, a)$ is the total number of observed transitions starting from state s under action a in month

XSL•FO
RenderX

t, and K_s is the number of clinically admissible next states under the no-reversal constraint. The main analysis used α=1. Sensitivity analyses were conducted using alternative Laplace smoothing parameters. The transition structure comprised 288 month-by-action-by-state cells. Four cells had no observed transitions; all 4 were in the absorbing death state S5 in month 12, where only 1 next state was admissible, so the smoothed probability remained 1 and the absorbing structure was preserved. Among the 240 cells starting from a living state, the smallest observed denominator was 28 and the median was 1453; only 1 of these cells had a denominator below 30, and 24 had a denominator below 100. Telephone follow-up was the sparsest action, with a median denominator of 131.5. Across all 288 cells, including those starting from the absorbing death state, 17 cells had a denominator below 30 and 55 had a denominator below 100.

We further conducted deterministic 1-way sensitivity analyses to assess uncertainty in key cost-effectiveness parameters. Health utility values, complication-related medical costs, the annual baseline-management cost ceiling c_{max}, outpatient follow-up cost, telephone follow-up cost, community follow-up cost, and travel-related disutility were varied by +20% or –20% from their base-case values. Specifically, c_{max} was evaluated at 12,000, 15,000, and 18,000 CNY/year; the base-case value remained 15,000 CNY/year. For these scenarios, the MDP was re-solved, and group-level QALYs, costs, ICERs, and incremental net monetary benefits were recalculated while holding all other parameters at their base-case values. As the willingness-to-pay threshold entered the MDP objective through the net health benefit reward function, analyses varying the willingness-to-pay threshold were interpreted as willingness-to-pay–dependent policy reoptimization scenarios rather than fixed-policy acceptance-threshold analyses. Specifically, the MDP was re-solved under willingness-to-pay thresholds corresponding to 1× and 3× China's 2024 per capita gross domestic product per QALY. Therefore, changes in incremental QALYs, incremental costs, and ICERs across willingness-to-pay scenarios reflect changes in the optimized policy, not a recalculation of the ICER for a fixed policy.

As the follow-up planning problem had a fixed 12-month horizon, the optimal policy was solved using backward induction. Let $V_{T+1}(s, C_{T+1}; \lambda_D)$ denote the value function at month t, where the horizon is t=12 and c^O_t records the cumulative number of outpatient follow-up visits used before month t for cost accounting. The value function gives the maximum expected cumulative net health benefit from month t onward for a patient in state s, and the terminal value was set as follows:

$$V_{T+1}(s, C^O_{T+1}; \lambda_D) = 0$$

For each month, state, and follow-up count, the value function was recursively updated as follows:

where A={0, 1, 2, 3} denotes the action set consisting of no follow-up, outpatient follow-up, telephone follow-up, and community follow-up; $r_t(s, a, C^O_t; \lambda_D)$ is the immediate monthly net health benefit; C^O_{t+1} is the updated follow-up count after action a;  is the smoothed transition probability; and γ is the discount factor. The base-case MDP used an algorithmic discount factor of γ=0.98 for the expected future value in the Bellman recursion, whereas annual QALDs and costs were reported as undiscounted sums of the 12 monthly outcomes. The discount factor was varied in deterministic sensitivity analyses, including γ=1.000 and γ=0.9959. At each monthly cycle, at most one action could be selected. Patients alive at the start of a monthly cycle accrued full monthly QALDs and costs, with transitions applied at the end of the cycle. The terminal value of zero closes the analysis at the 12-month horizon, so no health benefit accruing after month 12 is credited to any policy.

A monthly factor of 0.98 corresponds to an annual factor of 0.98^{12}=0.785, that is, an effective annual discount rate of approximately 27%. This value was applied as an algorithmic parameter within the Bellman recursion and does not enter the reporting of effectiveness or costs: annual QALDs and costs are reported as undiscounted sums of the 12 monthly values. The monthly factor of 0.9959, corresponding to the annual rate of 5% recommended by the China Guidelines for Pharmacoeconomic Evaluations [23], and the undiscounted case of 1.000 were both examined in deterministic sensitivity analysis.

Clinical variables such as fasting blood glucose, blood pressure, BMI, urine microalbumin, complication indicators, and other electronic health record features were treated as candidate inputs for state identification and risk prediction. The least absolute shrinkage and selection operator (LASSO)-Cox models identified routinely collected variables that discriminate complication and mortality risk.

For the example-patient analysis, we first specified the patient's baseline characteristics (Table 1) and assigned the patient to an initial health state according to baseline complication status. The MDP then generated a 12-month personalized follow-up policy for each possible initial state from S0 to S4. The primary analysis used exact expected-value propagation over the smoothed transition probabilities to calculate annual QALDs, annual costs, and ICERs. Under policy π, the annual expected QALDs for patient i were calculated by summing the expected monthly QALDs across all 12 cycles. Annual QALYs were obtained by dividing annual QALDs by 365.

To check the simulation algorithm, we additionally performed a Monte Carlo simulation with 10,000 trajectories. The Monte Carlo analysis was used as an algorithmic check rather than as the primary estimator of QALDs and costs. The group-level simulation used a cohort of 1000 heterogeneous patients initialized in S0, with variation in age and travel distance. The simulated S0 cohort used a fixed random seed of 12; age was sampled as an integer from 40 to 80 years, and travel distance was sampled uniformly from 0.5 to 10.0 km. The state-specific base utility of S0 was fixed at 0.868 for all patients. Individual variation in adjusted utility arose from action-specific travel

XSL•FO
RenderX

disutility and subsequent differences in expected health-state occupancy. A worked month-by-month expected-value trace for 1 selected simulated patient and direct reconciliation of monthly and annual QALDs and costs for selected patient-strategy examples are provided in Tables S8 and S9 in Multimedia Appendix 1.

For the economic evaluation, QALDs were retained as the model's health-effect unit because the MDP used monthly cycles over a 12-month horizon. To align with standard health economic reporting, QALDs were converted to QALYs by dividing QALDs by 365, and ICERs were reported primarily as CNY per QALY in accordance with conventional cost-utility analysis and pharmacoeconomic evaluation practice [23-25]. CNY per QALD was provided only as a supplementary equivalent where applicable.

Model Parameterization

Transition-Probability Parameterization

Empirical monthly state-action transition counts were constructed from observed longitudinal follow-up records. For the primary analysis, all eligible chronologically continuous month-to-month transitions were retained, including transitions crossing calendar-year boundaries, provided that the records represented consecutive monthly observations for the same patient. Clinical events and follow-up actions were assigned to their corresponding monthly cycles according to their recorded dates, and transitions were summarized by cycle month, current health state, follow-up action, and next health state. Laplace smoothing was then applied to these aggregated transition counts.

The aggregated transition table contained the observed transition count nt, a, s, s', denominator Nt, a, s; number of clinically admissible next states Kt, a, s; admissible-transition indicator; and smoothed transition probability. The smoothed probabilities in this file were used to construct the transition tensor $P[t, a, s, s']$ for all primary analyses. The observation unit underlying these counts is the patient-month within an eligible patient-year, so that a patient contributing several eligible years contributes several monthly transitions; the denominators reported for each cell are therefore counts of patient-months rather than counts of distinct patients.

Missing Data and Imputation

We quantified missingness for selected core variables used in risk prediction, state identification, transition-probability estimation, and MDP parameterization; these summaries are reported in Table S18 in Multimedia Appendix 1. Records with missing outcome information, survival time, event indicators, or MDP-defining information such as health state or transition action were excluded from the corresponding analysis because these quantities define the analytic outcome or transition structure. Predictor imputation was performed only after the Nanjing development cohort and the independent Shanghai external validation cohort had been defined and kept separate. The preprocessing workflow is shown in Figure S1 in Multimedia Appendix 1.

For predictor variables retained in the modeling pipeline, missing values were handled using random-forest–based imputation. The imputation procedure for the Nanjing cohort was fitted within the development data. The Shanghai external validation cohort was processed separately without using outcome information or observations from the Nanjing model-fitting process, thereby reducing the risk of information leakage between development and external validation.

We considered the missing-data mechanism most consistent with missing at random, conditional on observed demographic characteristics, clinical measurements, visit patterns, and disease history. This assumption was considered more plausible than missing completely at random because missingness in real-world electronic health records is often related to clinical workflow and observed patient characteristics. However, missing not at random could not be fully excluded, particularly for laboratory tests or examinations that may have been selectively ordered for patients with higher clinical risk. As random-forest–based imputation does not fully propagate imputation uncertainty in the same way as multiple imputation, inferential statistics from imputed predictors were interpreted cautiously, and the prediction models were treated as risk-stratification tools rather than causal explanatory models.

Risk Prediction Model Development and Validation

The framework has 2 components with distinct roles. The risk prediction component, described in this subsection, evaluates whether routinely collected primary-care variables discriminate incident complications and mortality, and it is the component for which validation in an independent external cohort was possible. The decision component requires action-conditional transition probabilities, that is, the probability of each next health state given the current state and the follow-up action selected in that cycle. These cannot be obtained from the Cox models, which estimate 1-year risk from eligible person-year records and were not conditioned on the follow-up action; they were therefore estimated nonparametrically from the observed month-by-state-by-action transition counts, as described above. The 2 components are accordingly reported together but were not coupled numerically: no quantity produced by the risk prediction models enters the transition tensor, adjusted health utility, cost function, immediate reward, or Bellman recursion. Within the MDP, a policy is individualized by the current health state, travel distance, and age.

To predict the time from a patient's current health state to subsequent complications or death, we developed 2 risk prediction models: an incident complication model and a mortality model. Both models were fitted on a person-year data structure: each patient contributed 1 record per eligible follow-up year, and the time variable within each record was the number of days of exposure during that year, censored at 365 days. The 2 models therefore estimate 1-year risk on the same timescale as the 12-month horizon of the MDP. For the incident complication model, the event indicator was a first newly recorded complication diagnosis within the year; patients whose first eligible year already carried a complication diagnosis were excluded as prevalent cases, and person-years occurring after a first complication were removed from the risk set, so

XSL•FO
RenderX

that each patient contributed at most 1 incident event. For the mortality model, the event indicator was death within the year. As each patient contributed several person-years, all inference accounted for within-patient clustering: cross-validation folds were assigned at the patient level, the optimism bootstrap resampled patients rather than person-years and refitted the Cox model conditional on the LASSO-selected predictor set, and the refitted Cox models used cluster-robust SEs with the patient as the clustering unit. All candidate predictors were first entered into a LASSO-penalized Cox proportional hazards model for feature selection. The penalty parameter was tuned using 10-fold cross-validation based on partial-likelihood deviance. The lambda.1se rule was prespecified before model fitting as the primary tuning rule to obtain a parsimonious and stable prediction model, and the lambda.min rule was prespecified as a secondary analysis reported in Table S24 in Multimedia Appendix 1. Models were not selected on the basis of external validation performance. After predictors with nonzero LASSO coefficients were selected, these variables were refitted in multivariable Cox models to estimate coefficients, hazard ratios, and 95% CIs. As variable selection was performed before Cox refitting, *P* values from the refitted Cox models were interpreted as exploratory results only. The purpose of these models was prediction and risk stratification rather than causal inference. Model discrimination was assessed using the apparent C-index, the patient-level bootstrap optimism–corrected C-index conditional on the LASSO-selected predictor set, and the external C-index in the Shanghai validation cohort. The Cox proportional hazards assumption was assessed using scaled Schoenfeld residuals.

To assess whether departures from the proportional hazards assumption materially affected discrimination, particularly for the mortality model, we conducted an additional sensitivity analysis using random survival forest models, which are nonparametric ensemble methods for right-censored survival data and do not require the proportional hazards assumption [26]. For each outcome, the random survival forest model was trained using the same LASSO-selected predictors as the primary Cox model. Each forest used 500 trees, a minimum node size of 15, the log-rank splitting rule, and mtry=floor(sqrt[*p*]), where *p* was the number of LASSO-selected predictors. The same Nanjing development cohort and Shanghai external validation cohort were used, and discrimination was evaluated using the Harrell C-index. This sensitivity analysis examined whether relaxing the proportional hazards assumption materially changed model discrimination rather than replacing the LASSO-Cox models used for parsimonious risk stratification and interpretability.

The health utility values for patient *i* at time *t* are shown in Table 3. Published utility evidence for type 2 diabetes and diabetes-related complications indicates that the health utility values used in the model were 0.868 for S0 (no recorded diabetes-related complication), 0.753 for S1 (diabetic nephropathy), 0.830 for S2 (diabetic retinopathy), 0.769 for S3 (diabetic peripheral neuropathy), and 0.692 for S4 (lower-extremity arterial disease and diabetic foot); the utility value for S5 (death) was set to 0 [27,28].

Table 3. Health utility values used for type 2 diabetes and diabetes-related complication states in the Markov decision process model[a].

Markov decision process state	Health state	Utility parameter	Health utility value
S0	No recorded diabetes-related complication	u_0	0.868
S1	Diabetic nephropathy	u_1	0.753
S2	Diabetic retinopathy	u_2	0.830
S3	Diabetic peripheral neuropathy	u_3	0.769
S4	Lower-extremity arterial disease and diabetic foot	u_4	0.692
S5	Death	u_5	0.000

[a]The state indices used in this table are identical to the Markov decision process health-state definitions and the analysis code: S1 denotes diabetic nephropathy, S2 diabetic retinopathy, S3 diabetic peripheral neuropathy, S4 lower-extremity arterial disease and diabetic foot, and S5 death.

Travel distance was included to represent the accessibility burden of outpatient follow-up. Prior evidence suggests that longer driving distance to primary care is associated with poorer glycemic control among patients with diabetes [29]. In the MDP, this burden was represented as a travel-related utility decrement applied only to outpatient follow-up. The base-case coefficient was 0.00032 utility loss per kilometer; it was treated as a model parameter rather than an exact causal estimate and was varied by +20% or –20% (range 0.000256-0.000384) in deterministic sensitivity analysis. No travel-related disutility was applied to nonoutpatient actions, and S5 (death) had a utility of 0.

Annual medical cost parameters are presented in Table 4. These annual costs were used as input parameters for the economic evaluation but were converted to monthly state costs before being applied in the 12-month MDP model.

XSL•FO
RenderX

Table 4. Annual medical cost parameters used for type 2 diabetes and diabetes-related complication states[a].

MDP[b] state	Health state	Cost parameter	Annual cost, CNY[c]/year
S0-S4 while alive	Baseline diabetes management	$c_{base,i}$	15,000/(1+exp[–Age$_i$/10])
S0	No complication-related cost	$c_{comp,0}$	0
S1	Diabetic nephropathy	$c_{comp,1}$	12,000
S2	Diabetic retinopathy	$c_{comp,2}$	4500
S3	Diabetic peripheral neuropathy	$c_{comp,3}$	5500
S4	Lower-extremity arterial disease and diabetic foot	$c_{comp,4}$	8000
S5	Death	N/A[d]	0

[a]$c_{base,i}$ denotes the annual baseline diabetes management cost accrued while patient *i* remained alive and was calculated as 15,000/(1+exp[–Age$_i$/10]) CNY/year. The baseline management cost was accrued in all living states S0-S4 and was distinct from the state-specific annual complication-related cost $c_{comp,s}$. Patients in S1-S4 therefore accrued both the baseline management cost and the corresponding complication-related cost. Annual costs were divided by 12 before entering the monthly MDP cycles. No cost was accrued after entry into S5.

[b]MDP: Markov decision process.

[c]1 CNY=US $0.15.

[d]N/A: not applicable.

To avoid ambiguity in state-to-parameter mapping, all utility and cost parameters were indexed according to the same state definitions used in the MDP health-state space. Specifically, S1 corresponded to diabetic nephropathy, S2 to diabetic retinopathy, S3 to diabetic peripheral neuropathy, S4 to lower-extremity arterial disease and diabetic foot, and S5 to death. The same mapping was used in the analysis code, parameter tables, sensitivity analyses, and ICD-10 state-assignment appendix. The complete state-to-parameter mapping is provided in Table S20 in Multimedia Appendix 1.

According to the Chinese National Basic Public Health Service Standards [30], patients with type 2 diabetes are entitled to 4 free outpatient clinic follow-up visits annually [12,31,32]. Under the model's accounting convention, these first 4 outpatient visits were therefore assigned no additional modality-specific charge. Outpatient visits beyond the first 4 were assigned a charge of 12 CNY per visit, based on a registration fee of 2 CNY and a blood glucose test fee of 10 CNY. Telephone and community follow-up were assigned modeled charges of 13.8 CNY per call and 40 CNY per visit, respectively. These amounts should be interpreted as charge-based model inputs rather than estimates of the full economic opportunity cost of provider time, facilities, consumables, or administrative support. As the MDP used monthly decision cycles, these charges were accrued only in the month in which the corresponding follow-up action occurred.

Results

Risk Prediction Model Performance

For the incident-complication model, after excluding 669 patients with prevalent complications, removing 19,144 postevent person-years, and applying the prespecified outcome-time eligibility criteria, 152,415 eligible patient-year observations from 40,729 patients were included, with 7050 first incident complication events. After prespecified exclusions and one-hot encoding, 124 candidate design predictors entered the LASSO-Cox model; the lambda.1se rule retained only duration of diabetes. The apparent, optimism-corrected, and Shanghai external C-indices were 0.777, 0.777, and 0.778, respectively. The mortality model included 174,041 eligible patient-year observations from 41,398 patients and 3047 deaths. Of the same 124 candidate design predictors, 7 were retained by lambda.1se; the corresponding apparent, optimism-corrected, and external C-indices were 0.768, 0.767, and 0.812. Selected predictors are shown in Table 5.

XSL•FO
RenderX

Table 5. Penalized Cox model predictors for complication and mortality risk in the Nanjing development cohort[a].

Risk factors	Coefficient	Hazard ratio (95% CI)	*P* value
Outcome : complications			
Duration of diabetes	0.084	1.087 (1.084-1.090)	<.001
Outcome : death			
Splenomegaly (abnormal)	0.468	1.597 (1.446-1.764)	<.001
Lips (abnormal)	0.431	1.539 (1.393-1.699)	<.001
Lower limb edema	0.395	1.484 (1.348-1.635)	<.001
Mass	0.383	1.466 (1.325-1.622)	<.001
Hepatomegaly	0.347	1.415 (1.271-1.575)	<.001
Mobile dullness	0.274	1.315 (1.185-1.460)	<.001
Age	0.070	1.072 (1.068-1.076)	<.001

[a]CIs and *P* values were obtained using cluster-robust SEs with the patient as the clustering unit. As predictor selection preceded Cox refitting, *P* values are exploratory and were not used for model selection.

In the prespecified lambda.min secondary analysis, 65 predictors were retained for incident complications and 95 for mortality. External C-indices were 0.752 and 0.833, respectively, compared with 0.778 and 0.812 for the primary lambda.1se models. Four selected categorical variables (occupation, marital status, medical payment type, and blood group) were structurally unavailable in Shanghai and, for the lambda.min external-discrimination analyses only, were fixed at their development-cohort reference levels. Predictor imputation was completed separately within the Nanjing development cohort and the Shanghai external-validation cohort before model fitting, and no additional imputation was performed during model fitting or external scoring. Neither primary lambda.1se model included these variables, so primary external validation was unaffected. In single-year cross-sectional analyses, duration of diabetes alone yielded C-indices of 0.790 in the second follow-up year (32,923 patients; 1194 events) and 0.768 in the third follow-up year (25,564 patients; 1383 events). These secondary analyses are reported in Table S24 in Multimedia Appendix 1.

Scaled Schoenfeld residual tests showed no evidence of violation of the proportional hazards assumption for the incident-complication model (global P=.93), whereas significant deviations were detected for the mortality model (global P<.001). Therefore, we used the LASSO-Cox models primarily as prediction and risk-stratification tools rather than as causal explanatory models. To examine whether relaxing the proportional hazards assumption materially affected model discrimination, we conducted a sensitivity analysis using random survival forest models that do not rely on the proportional hazards assumption. For the incident-complication model, the 500-tree random survival forest achieved a development C-index of 0.781 and an external C-index of 0.776, compared with 0.777 and 0.778 for the LASSO-Cox model, respectively. For the mortality model, the random survival forest achieved a development C-index of 0.791 and an external C-index of 0.814, compared with 0.768 and 0.812 for the LASSO-Cox model, respectively. The corresponding external C-index differences relative to LASSO-Cox were −0.002 for incident complications and +0.002 for mortality. These differences were negligible in magnitude, indicating that the random survival forest did not materially improve external discrimination. For mortality, the detected proportional-hazards deviations did not materially weaken discrimination; for incident complications, the random survival forest served as a nonparametric sensitivity check despite no detected proportional-hazards violation. We retained the LASSO-Cox models as the primary risk models because they provide a parsimonious and interpretable set of predictors. Detailed results of the random survival forest sensitivity analysis are provided in Table S17 in Multimedia Appendix 1.

Development of Personalized Follow-Up Planning

The MDP model generated a 12-month personalized follow-up policy for each example patient according to the patient's initial health state, age, and travel distance. Clinical variables from electronic health records were used for state identification and in the risk prediction models. The MDP itself used the current health state, age, monthly health utility, travel distance, and smoothed transition probability matrices to determine the optimal follow-up schedule and modality.

Table 6 summarizes the MDP-generated personalized follow-up strategies for example patients entering the model from different initial health states. The table reports the annual number of follow-ups and the distribution of follow-up modalities; the complete month-by-month schedules are provided in Table S1 in Multimedia Appendix 1. Patients in S5 were assigned no follow-up because death was modeled as an absorbing state. If a patient's complication status changed during follow-up, the subsequent strategy would be updated according to the new health state. The illustrative S0 patient was aged 60 years and had a travel distance of 2.0 km. Group-level expected follow-up counts are reported separately in Table S11 in Multimedia Appendix 1.

XSL•FO
RenderX

Table 6. Summary of MDP[a]-generated personalized follow-up strategies by initial health states[b].

Initial state	State definition	Total follow-ups per year, n	Outpatient, n	Telephone, n	Community, n	Follow-up pattern
S0	No complication	5	4	1	0	4 outpatient follow-ups and 1 telephone follow-up
S1	Diabetic nephropathy	8	8	0	0	8 outpatient follow-ups
S2	Diabetic retinopathy	6	6	0	0	6 outpatient follow-ups
S3	Diabetic peripheral neuropathy	6	6	0	0	6 outpatient follow-ups
S4	Lower-extremity arterial disease and diabetic foot	6	5	0	1	5 outpatient follow-ups and 1 community follow-up

[a]MDP: Markov decision process.

[b]The table summarizes the 12-month MDP-generated follow-up plans for example patients by initial health state. The complete month-by-month follow-up schedules are provided in Table S1 in Multimedia Appendix 1. Death was modeled as the absorbing state S5 and was therefore not assigned follow-up.

Effectiveness at the Individual Level

At the individual level, the personalized follow-up strategy improved expected health outcomes for the example patient. For the example patient initially in S0, the personalized strategy increased annual QALDs from 313.64 to 314.12, corresponding to an increase of 0.48 QALDs per year. A Monte Carlo algorithmic check with 10,000 simulated trajectories produced similar results: the personalized strategy yielded 314.26 QALDs compared with 313.75 QALDs under standardized follow-up. In this check, the final complication-state probability was 5.19% under the personalized strategy and 5.09% under the standardized strategy, and the corresponding final death probabilities were 1.28% and 1.61%. These Monte Carlo estimates are reported in Table S4 in Multimedia Appendix 1. Complete expected-value effectiveness results across all initial states are provided in Table S2 in Multimedia Appendix 1.

Cost-Effectiveness Analysis at the Individual Level

Annual costs were obtained by accumulating monthly state and follow-up costs over the 12-month horizon. For the example patient initially in S0, the personalized strategy increased effectiveness by 0.48 QALDs and increased annual cost by 33.46 CNY. The resulting ICER was 25,499 CNY/QALY, or 69.86 CNY/QALD. The Monte Carlo algorithmic check produced broadly consistent cost-effectiveness results for the S0 example patient. The willingness-to-pay threshold, set at 3 times China's 2024 per-capita gross domestic product, was 287,248 CNY/QALY. The ICER was substantially below this threshold, indicating that the personalized follow-up strategy was cost-effective for the example patient under the model assumptions, although it was not cost-saving under the base-case program-costing assumptions. The complete individual-level cost-effectiveness results across initial health states are provided in Table S3 in Multimedia Appendix 1.

Effectiveness at the Group Level

At the group level, we evaluated the MDP-based personalized follow-up strategy in a heterogeneous simulated cohort of 1000 patients initialized in S0. The analysis used a fixed cycle duration of 365/12 days for each of the 12 monthly cycles. The personalized strategy produced a mean annual effectiveness of 314.05 QALDs (0.86041 QALYs), compared with 313.52 QALDs (0.85896 QALYs) under the standardized strategy. The mean incremental effectiveness was 0.529 QALDs (0.00145 QALYs) per patient-year. The cohort-mean month-by-month accumulation of QALDs and costs under both strategies is reported in Table S10 in Multimedia Appendix 1; the 12 monthly values sum exactly to the annual cohort means reported in Tables S5 and S6 in Multimedia Appendix 1. The corresponding annual reconciliation based on patient-level and monthly sums is provided in Table S7 in Multimedia Appendix 1.

The cohort-level QALDs were consistent with the model's state utilities and end-of-horizon state distributions. For reference, a patient remaining in S0 throughout the full year without outpatient travel disutility would accrue $365 \times 0.868 = 316.82$ QALDs. The slightly lower cohort means reflected transitions to lower-utility complication states, mortality, and outpatient travel disutility.

We also compared monthly expected state distributions under the 2 strategies, including complication-state occupancy and cumulative mortality, as reported in Tables S12 and S13 in Multimedia Appendix 1. By the end of the 12-month horizon, the expected proportion of patients occupying complication states S1-S4 was 5.114% under the personalized strategy and 5.115% under the standardized strategy, corresponding to 51.14 and 51.15 expected patients per 1000 patients, respectively. The corresponding expected cumulative mortality proportions were 1.437% and 1.610%, corresponding to 14.37 and 16.10 expected deaths, respectively. The 2 strategies therefore produced broadly comparable end-of-horizon state distributions, and the group-level advantage of the personalized strategy lay in improved QALDs and cost-effectiveness rather than in a large reduction in end-of-horizon complication or death probabilities. The personalized strategy nevertheless resulted in slightly lower cumulative mortality and 0.0126 additional expected living patient-months per patient over the 12-month horizon.

In the present group-level simulation, patients were initialized in S0 to evaluate personalized follow-up planning among

XSL•FO
RenderX

patients without baseline complications. The base utility of S0 was fixed at 0.868 for all patients, whereas age, travel distance, and action-specific travel disutility contributed to heterogeneity in simulated outcomes. The personalized strategy generated a mean of 2.72 follow-ups per patient-year, including 1.74 outpatient follow-ups, 0.96 telephone follow-ups, and 0.01 community follow-ups; the standardized strategy generated 3.98 outpatient follow-ups per patient-year. The corresponding group-level strategy summary is provided in Table S11 in Multimedia Appendix 1.

Cost-Effectiveness Analysis at the Group Level

Under the specified program-costing assumptions, the personalized strategy increased mean annual cost by 24.67 CNY and mean annual effectiveness by 0.00145 QALYs compared with standardized follow-up. The resulting ICER was 17,016 CNY/QALY, which was substantially below the willingness-to-pay threshold of 287,248 CNY/QALY. The complete group-level cost-effectiveness results are provided in Table S5 in Multimedia Appendix 1.

The incremental total cost was decomposed into baseline diabetes-management expenditure, complication-related cost, and additional modality-specific follow-up charges. Compared with standardized follow-up, the personalized strategy increased mean baseline diabetes-management expenditure by 15.64 CNY and mean additional follow-up charges by 14.94 CNY, while reducing mean complication-related cost by 5.91 CNY. These components reconciled exactly with the total incremental cost of 24.67 CNY. The higher baseline diabetes-management expenditure was consistent with the additional 0.0126 expected living patient-months under the personalized strategy. The additional follow-up charge reflected the expected distribution of outpatient, telephone, and community follow-up actions across patients and health-state trajectories.

Sensitivity Analysis

To examine whether the MDP results were sensitive to the smoothing assumptions used in transition probability estimation, we repeated the group-level MDP analysis using alternative Laplace smoothing parameters of α=.1, .5, 1.0, and 2.0; detailed results are provided in Table S14 in Multimedia Appendix 1. Across these smoothing parameters, the personalized strategy increased mean annual effectiveness by 0.00136-0.00178 QALYs and increased mean annual cost by 19.95-53.67 CNY compared with standardized follow-up. The corresponding ICERs ranged from 14,716 to 31,151 CNY/QALY. All ICERs remained substantially below the willingness-to-pay threshold of 287,248 CNY/QALY, indicating that the projected cost-effectiveness results remained consistent across the examined transition-probability smoothing parameters.

We also performed deterministic 1-way sensitivity analyses for health utility values, complication-related medical costs, the annual baseline-management cost ceiling c_{max}, follow-up costs, the algorithmic discount factor, and travel-related disutility. The parameter ranges are reported in Table S15 in Multimedia Appendix 1, and the corresponding results are presented in Table S16 in Multimedia Appendix 1. Across these deterministic scenarios, the personalized strategy increased annual effectiveness by 0.00124-0.00160 QALYs and increased annual cost by 21.74-55.68 CNY compared with standardized follow-up. The corresponding ICERs ranged from 14,987 to 35,613 CNY/QALY. The ICER for the personalized strategy remained below the willingness-to-pay threshold of 287,248 CNY/QALY across all examined deterministic scenarios. Varying the algorithmic discount factor only had a little effect on the conclusion: with no discounting, the personalized strategy increased annual effectiveness by 0.00145 QALYs and annual cost by 25.42 CNY, resulting in an ICER of 17,494 CNY/QALY. With a monthly factor of 0.9959, corresponding to an annual discount rate of 5%, the corresponding values were 0.00145 QALYs, 25.29 CNY, and 17,408 CNY/QALY. Both ICERs remained far below the willingness-to-pay threshold. In the willingness-to-pay–dependent policy re-optimization analyses, the MDP was re-solved using willingness-to-pay objectives corresponding to 1 and 3 times China's 2024 per capita gross domestic product. Under the 1× gross domestic product objective, the personalized strategy increased effectiveness by 0.00140 QALYs and cost by 18.65 CNY, resulting in an ICER of 13,295 CNY/QALY. Under the 3× gross domestic product objective, the personalized strategy increased effectiveness by 0.00145 QALYs and cost by 24.67 CNY, resulting in an ICER of 17,016 CNY/QALY. Both ICERs were below their corresponding willingness-to-pay thresholds. Varying the annual baseline-management cost ceiling c_{max} to 12,000, 15,000, and 18,000 CNY/year produced ICERs of 14,987, 17,016, and 19,018 CNY/QALY, respectively; the 15,000 CNY/year scenario reproduced the base-case result.

External Validation of Risk Prediction Models in the Shanghai Cohort

The final risk-prediction models developed in Nanjing were applied without reestimating model parameters in the independent Shanghai cohort of 25,506 patients from 10 communities (mean follow-up 1.87 years). The eligible incident-complication validation set contained 25,499 observations with 1742 events and yielded an external C-index of 0.778. Mortality validation used all 25,506 observations, including 125 deaths, and yielded an external C-index of 0.812. As the Shanghai cohort had a shorter follow-up duration than the Nanjing development cohort, these analyses validate discrimination rather than the MDP policy, cost-effectiveness projections, or long-term clinical effectiveness.

Discussion

Principal Findings

Using longitudinal primary-care data, we developed a 12-month finite-horizon MDP that selected follow-up timing and modality by maximizing expected net health benefit under prespecified utility, cost, access, and willingness-to-pay parameters. In both the example-patient and simulated-cohort analyses, the personalized policy produced small projected QALY gains at modest incremental program cost. In the 1000-patient S0 cohort, the ICER was 17,016 CNY/QALY, below the modeled willingness-to-pay threshold of 287,248 CNY/QALY.

XSL•FO
RenderX

End-of-horizon complication-state occupancy was nearly identical between strategies, whereas modeled mortality was slightly lower under the personalized policy. As action-conditional transitions were estimated from observational records and may reflect confounding by indication, these differences are model-based projections and should not be interpreted as causal effects of follow-up modality.

Deterministic sensitivity analyses preserved the overall cost-effectiveness conclusion across the examined transition-smoothing, utility, cost, travel-disutility, willingness-to-pay, cycle-convention, and discount-factor scenarios. These analyses support structural robustness within the specified model but do not quantify sampling or joint parameter uncertainty; accordingly, they do not provide a probability that the personalized strategy is cost-effective. The higher modeled cost arose from both additional modality-specific follow-up charges and greater accrual of baseline management costs over the slightly larger number of expected living patient-months.

Comparison With Prior Work

Prior diabetes follow-up research has examined encounter frequency, guideline adherence, telemedicine, personalized care systems, and self-management support [15-17,33-36]. Risk-based follow-up has also been evaluated in other chronic-disease settings [18,37,38]. These studies inform who may need more intensive care or how follow-up can be delivered, but fewer provide an explicit sequential decision framework that jointly selects timing and modality while incorporating expected health benefit, accessibility, and resource use. Related methodological work has applied machine-learning methods to predict follow-up intervals and has used MDP or approximate dynamic programming formulations to schedule health care encounters and allocate resources in other service settings [20,21,39].

Our study extends this literature by formulating follow-up planning as a sequential decision problem and incorporating QALDs and program costs directly into the MDP reward structure. The model did not project short-term cost savings; instead, it generated a small additional expected health benefit at an incremental modeled cost. This distinction is important in primary care, where decision support should make the trade-off between expected benefit and resource use explicit rather than equating personalization with lower expenditure.

The framework should be viewed as a candidate decision-support approach rather than a ready-to-deploy scheduling system. After prospective validation, it could support structured planning of follow-up frequency and modality using routinely collected clinical information together with prespecified utility, cost, and accessibility parameters. Its effects on clinician workload, patient adherence, service substitution, and implementation feasibility were not evaluated here and should be established before the model is used to modify mandated or routine follow-up schedules.

The incident-complication model was highly parsimonious: lambda.1se retained duration of diabetes alone, with apparent, optimism-corrected, and external C-indices of 0.777, 0.777, and 0.778, respectively. The lambda.min model retained 65 predictors but had lower external discrimination, and the single-year analyses yielded similar discrimination with duration of diabetes alone. Several conventional metabolic markers, including fasting blood glucose, blood pressure, and BMI, provided little incremental 1-year discrimination beyond duration of diabetes in this analysis. This parsimony reflects both the 1-year prediction horizon and the prespecified lambda.1se tuning rule, under which duration of diabetes alone achieved discrimination comparable to that of the larger lambda.min model. These findings are specific to 1-year risk discrimination in the available data and do not imply that these or other established clinical risk factors are clinically unimportant. For mortality, lambda.1se retained 7 predictors; although lambda.min yielded a higher external C-index (0.833 vs 0.812), the prespecified parsimonious model remained primary rather than selecting a model based on external performance. The 500-tree random survival forest sensitivity analysis changed external C-indices by only −0.002 for incident complications and +0.002 for mortality. Thus, the detected proportional-hazards deviations in the mortality model did not materially impair discrimination. These risk models were complementary validation analyses and supplied no numerical input to the MDP.

Limitations

This study has several limitations. First, action-specific transition probabilities were estimated from observational follow-up records rather than randomized or prospectively assigned interventions. They may therefore reflect care-seeking behavior, clinician decision-making, access, adherence, residual baseline imbalance, and unmeasured confounding; Laplace smoothing addresses sparse cells but not confounding by indication. Most baseline differences were small, although exercise frequency and blood type had standardized mean differences of .199. Transition-cell denominators represent patient-month transitions rather than distinct independent patients, and sampling uncertainty in these probabilities was not modeled. The incremental effectiveness estimate was also small relative to its variation across smoothing scenarios. The MDP results should therefore be interpreted as projected decision-support outputs under the estimated transition structure, rather than as causal evidence for reducing guideline-based follow-up requirements. Individualization was limited to health state, travel distance, and age because the LASSO-Cox risk estimates did not condition the action-specific transitions.

Second, random-forest–based predictor imputation does not propagate imputation uncertainty in the same way as multiple imputation. In addition, the Cox models were fitted to person-year records, so patients with longer follow-up contributed more records, although cross-validation, bootstrap resampling, and robust SEs were handled at the patient level. The models were therefore used for prediction and risk stratification rather than coefficient-level causal inference. The reported bootstrap optimism correction was conditional on the LASSO-selected predictor set and therefore quantified optimism in the Cox refitting step rather than uncertainty from repeating the complete variable-selection procedure. External calibration

XSL•FO
RenderX

was not assessed, so the reported C-indices establish discrimination but not calibration of absolute risk.

Third, routine public health records did not capture medication costs, productivity losses, or the full opportunity cost of provider time, facilities, consumables, and administrative support. The analysis therefore used a restricted public health program perspective. The absence of an additional charge for the first 4 outpatient visits is a program accounting convention, not evidence of zero resource use. Adding omitted resource components could change the absolute costs and ICER in either direction, depending on differential resource use. As a substantial component of the incremental cost arises from baseline-management expenditure accruing over additional living patient-months, the cost-effectiveness ratio implied by this survival channel alone is close to the baseline-management cost divided by the utility of S0; its magnitude is therefore largely determined by this prespecified cost parameter. The baseline-management cost function was also prespecified rather than estimated from individual-level expenditure data; varying its annual ceiling, c_{max}, from 12,000 to 18,000 CNY/year assessed structural sensitivity but did not substitute for empirical cost validation.

Fourth, travel distance was represented as a linear accessibility-related disutility. This simplification may not capture nonlinear relationships or nontravel-related barriers and may favor lower-burden modalities for patients living farther from primary care. Part of the projected QALY gain therefore reflects modeled access burden rather than biomedical disease control alone.

Fifth, the MDP states were mutually exclusive and did not explicitly represent concurrent diabetes-related complications, which may underestimate the burden of multimorbidity. The 12-month horizon also captures short-term projected cost-effectiveness rather than lifetime value, as major diabetes-related complications often develop over multiple years.

Finally, the Shanghai cohort had shorter follow-up than the Nanjing development cohort and was used only to validate risk-model discrimination; neither external calibration nor the MDP policy or economic projections were validated in Shanghai. Prospective studies should evaluate implementation effectiveness, workload, adherence, modality-specific outcomes, calibration, and generalizability, while considering risk-adjusted or causal methods for estimating action-conditional transitions.

Conclusions

This study developed a 12-month MDP framework that uses observed action-conditional transition patterns together with prespecified utility, cost, access, and willingness-to-pay parameters to generate personalized follow-up policies for patients with type 2 diabetes. In the modeled analyses, the personalized strategy produced small projected QALY gains at modest incremental program cost, and independent Shanghai data supported the discrimination of the complementary risk-prediction models. As the decision model relied on observational transition data and partly prespecified economic parameters, these results should be regarded as model-based projections requiring prospective implementation, calibration, and economic validation rather than as causal evidence for changing guideline-mandated follow-up schedules.

Abstract

Background: Adverse drug reactions pose a serious threat to health care, leading to patient harm and substantial economic burden. Dashboards for drug safety surveillance are a valuable tool to tackle it.

Objective: This qualitative study aims to develop a dashboard for drug safety tracking with active and iterative involvement of end users. To support dashboard development, we formulate and iteratively refine design principles (DPs) for drug safety dashboards using the affordance theory.

Methods: Following a design science research approach, we conducted 3 cycles of iterative design and evaluation involving the end users. Four professional end users (with expertise in drug screening, drug discovery, and data science) and 6 nonprofessional end users (drug consumers) were engaged in the requirements gathering sessions through co-design workshops, usability testing through think-aloud sessions, and heuristic evaluation.

Results: The analysis resulted in a set of 8 DPs refined using the prototype's affordances (ie, actionable properties of the dashboard that guide user interaction and interpretation of data). Following themes emerged in the formulation and refinement of DPs: addressing the bootstrap problem through designing for immediate use (DP1a), allowing identification of patterns through visualizing causality while signalizing uncertainty (DP1b), tracking trends for relevant variables (DP1c), implementing user-controlled views (DP2a) and customizable levels of data granularity (DP2b), guiding user's visual attention through spatial layouts (DP2c), designing for higher public value (DP3a) and providing features to support decision-making for varied stakeholders' groups (DP3b). A high-fidelity dashboard prototype for drug safety surveillance was proposed as a result of applying the final set of DPs. Heuristic evaluation of the prototype revealed an overall usability score of 84%.

Conclusions: Applying DPs rooted in affordance theory led to a purposeful and user-relevant artifact that can improve understanding of drug safety data and potentially guide decision-making processes for professional users. Our theoretical contribution lies in providing refined DPs, while also demonstrating how affordances can aid dashboard development in pharmacovigilance. Our findings may be applicable to similar health information systems in related domains.

Introduction

Overview

Adverse drug reactions (ADRs) pose a serious risk, leading to hospitalization of millions of patients every year, and the incidence of ADRs resulting in hospitalization has been consistently increasing in recent years [1-5]. ADRs are not only a major health concern, but also a tremendous economic burden, generating costs of several billion dollars each year [6,7]. Monitoring side effects associated with medicinal products is critical for regulatory bodies, health care providers, pharmacists, and, most importantly, drug consumers.

The rapid spread of health misinformation through online channels poses significant risks to public health [8,9]. Evidence suggests that many individuals, including physicians and medical students, resort to online searches for clinical information (ie, general web and social media queries rather than official pharmacovigilance portals). These channels frequently present user-generated or commercially sponsored content (eg, and influencer posts) that lacks expert review. Only a fraction of users consult credible resources (eg, specialized academic databases) [10,11]. Importantly, more than half of the online searches by health care professionals focus on drug safety and ADRs [12]. Relying on unverified sources for health information can be a major threat to public health, erode public trust, and can lead to severe consequences, including harm or

XSL•FO
RenderX

death [13]. Specialized platforms, such as interactive visualization dashboards for drug safety information at-a-glance, offer drug safety information in a trusted and concise way. Such platforms could be intended for professional users (ie, health care professionals, pharmacists, researchers, pharmaceutical companies, and regulatory agencies concerned with pharmacovigilance), as well as nonprofessional users (ie, patients, medical journalists, or lawyers protecting patient rights).

Dashboards in pharmacovigilance (DiPs), however, are scarce and often have complex interfaces resembling decision support systems rather than accessible designs. Additionally, most of the DiPs are not available online as open-source platforms, but are offered as proprietary software under license [14-17]. As a result, they have a limited audience and lack widespread availability. Moreover, DiP often lacks salient usability features, is poorly designed due to the absence of a structured design approach, or has functional deficiencies [17,18]. Several data mining techniques have been proposed as a valuable tool for early detection of potential safety signals (ie, indications or evidence that suggest a possible new ADR) in pharmacovigilance [19,20]. However, existing DiP rarely integrates data mining methods to enhance raw drug safety information and therefore offers limited insight [21-23]. Given the shortcomings of current platforms for drug safety surveillance and the scarcity of prescriptive knowledge regarding their design, we investigate the idea of finding more fitting designs for handling such data. In search of suitable design principles (DPs) that should lead the development of similar platforms, this study relies on the design science research (DSR) strategy and is guided by the following research question: what are the appropriate DPs for interactive dashboards in drug safety surveillance?

To address this question, we set out to develop and evaluate DPs for a class of dashboards in pharmacovigilance, following the DSR approach. We show that engaging in prototype creation reveals general DPs applicable to similar systems. Consequently, besides the artifact being developed, emergent DPs are proposed as transferable concepts for similar systems within the boundary conditions studied. To this end, we use the notion of affordances—properties of physical things or relationships between actors and these things—to support our research. Affordances help in exploring different designs in this study, since different physical features of the prototype can afford (ie, provide and bring about) the same functionality.

This study consists of the following steps. First, we identify general DPs for visual dashboards of drug safety data. Second, following the DSR methodology, we perform the requirements gathering session with a group of experts in drug screening, bioinformatics, and data science. Third, we create a prototype of an interactive dashboard, where we present drug safety data in a visually friendly manner, with the purpose of improving its general understandability. To this end, we also focus on finding suitable data mining techniques for knowledge extraction from publicly available data in pharmacovigilance. Fourth, we assess the prototype in demonstration and evaluation sessions with users to detect potential usability issues and receive feedback on possible improvements to the design. Altogether, we carry out 3 iterations of the DSR phases.

The aim of this research is thus to enhance the understanding of drug safety data and improve the potential for decision-making among intended users. Specifically, our objectives are to (1) formulate DPs, (2) re-evaluate these in 3 iterations of alternating phases of prototype development, demonstration, and evaluation, and (3) gain insight on how the notion of affordances and DPs can support the development of visualization tools in drug safety surveillance. It is important to mention that, in this study, by “professional users” we refer specifically to researchers in drug screening, bioinformatics, and data science; clinicians and pharmacists were not recruited in our sample. Accordingly, the DPs and evaluation results reported here are grounded in researcher workflows. While some principles are likely cross-cutting across stakeholder groups, we do not evaluate their applicability to clinician- or pharmacist-facing workflows in this study.

Current State of Drug Safety Surveillance Systems and Data Mining Standards

Three major global databases monitor drug safety: Food and Drug Administration (FDA) Adverse Events Reporting System (FAERS) database, VigiBase maintained by the Uppsala Monitoring Center (UMC) and World Health Organization (WHO), and EudraVigilance managed by the European Medicines Agency (EMA). FAERS, the world’s largest repository with more than 24 million reports as of March 2022, serves as a key postmarketing pharmacovigilance tool. EudraVigilance and VigiBase similarly collect ADR reports from the European Economic Area. These reports, submitted by manufacturers (mandatory) and health care professionals or consumers (voluntary), document suspected side effects from one or more drugs per patient case [20,24,25].

Although crucial for surveillance, these reports cannot establish direct causality because of factors such as comorbidities or concurrent medication [25]. To address this, database curators apply data mining to detect safety signals for expert review. The FDA encourages signal detection in drug development, as it positively impacts the process, while the WHO and UMC offer similar services to industry partners [20,26].

Several digital platforms exist for drug safety surveillance, but many, including FAERS, rely solely on reporting frequencies rather than integrated data mining [21]. According to Kumar [17], the FAERS dashboard is affected by limited awareness, unclear purpose, unintuitive navigation, and challenges in interpreting its data. Most reviewed platforms pose accessibility challenges, as they rely on proprietary databases, restricting access, reproducibility, and public transparency [16]. Many are outdated or limited in scope, relying on small datasets or alternative data sources instead of major repositories [14-16,27,28], while others focus only on ADR reporting rather than analysis and visualization [29-31].

Moreover, most platforms were not developed using the DSR process or participatory design methods and lack usability testing. Therefore, their complex interfaces often resemble expert decision support systems rather than accessible designs

XSL•FO
RenderX

[14-16], which can impact usability, hinder tool adoption, and compromise their practical impact [18,32]. These factors emphasize the need for open-source, user-centered drug safety tools that enhance accessibility and stakeholder engagement.

Data mining techniques are routinely used in pharmacovigilance to enhance the understanding of drug and vaccine safety profiles [33-36]. While no universal standard exists, guidelines provide statistical support for interpreting detected signals [37]. Disproportionality analysis (DPA) is currently the most common technique recommended by the FDA, UMC (WHO), and EMA, although the organizations deploy different statistical approaches [38]. Despite its importance, DPA results are seldom integrated into public dashboards, which continue to rely mainly on reporting frequencies [21-23]. This limitation may hinder a thorough understanding of the drug safety profiles and potentially lead to overlooking important trends, which further emphasizes the importance of incorporating safety signal assessments in public dashboards in pharmacovigilance.

New platforms have been developed in recent years primarily leveraging artificial intelligence (AI), machine learning, and real-world data integration for ADR detection in clinical practice. Specific new platforms include the PVClinical system using OMOP-CDM and Observational Health Data Sciences and Informatics (OHDSI) software stack for electronic health record integration [39] and established platforms such as Oracle Argus Safety, repClinical, PvNET, and ArisG for ADR administration and reporting [40]. AI-powered approaches show particular promise, with systematic reviews demonstrating effective natural language processing application across 16 studies for user-generated content analysis [41] and 12 studies showing deep learning models outperforming traditional machine learning for adverse event extraction [42]. However, challenges remain, including data quality, regulatory compliance, and the need for clinical validation of these emerging platforms [43].

Recent research on human-computer interaction (HCI) and user-centered design in pharmacovigilance dashboards is limited but emerging, with only a few directly relevant studies identified in the past few years. The strongest evidence comes from Yu et al [44] who developed a visualization platform for FDA adverse event data with usability demonstration through case studies and validated accuracy against manually processed data. In a study on integrating human-centered design of a public health data dashboard for sexually transmitted infections in the state of New York, Ansari and Martin [45] found that dashboards must reflect actual workflow needs, address data limitations transparently, and use design elements, such as clear notes and estimated data displays, to build user trust and handle common data quality issues. This process resulted in a highly functional design template. Malkani et al [46] identified and ranked key health care dashboard design attributes such as clarity, simplicity, visual hierarchy, responsiveness, and intuitive navigation as most critical for improving usability and user-centered decision-making. Gavriilidis et al [47] applied user-centered DPs to create the PVClinical platform for ADR investigation, identifying “actionability” as a key adoption factor and emphasizing needs for explainable, human-interpretable results. Broader context comes from patient safety dashboard research, where Murphy et al [48] found that among 33 studies, only 4 incorporated informatics or human factors principles in development or evaluation, highlighting a significant gap in rigorous HCI application.

The evidence base remains thin, with most pharmacovigilance visualization research focusing on technical implementation rather than systematic user-centered design evaluation. More rigorous HCI research is needed in this specialized domain [44,47,48]. Table 1 summarizes the limitations of available dashboards and shows the prototype features we explore in response to the identified gaps.

XSL•FO
RenderX

Table . Research gaps were identified through limitations to available dashboards for pharmacovigilance and prototype features were intended to address them.

Platform category (examples)	Key limitations noted in the literature	Intended prototype features
Regulatory public dashboards (FAERS[a]; EudraVigilance; VigiLyze)	Emphasize reporting frequencies; statistical signal detection (eg, DPA)[b] typically not available in the public UI[c]; access and reproducibility constraints (open access but not open source; VigiLyze requires membership). The FAERS public dashboard shows issues with awareness, navigation, and interpretability for nonspecialists [17,21-23]	Integrates DPA outputs in the UI; offers guided interactions; co-designed and usability-tested; open data and code with an open-access dashboard
Enterprise pharmacovigilance dashboards (Oracle Argus Safety; ArisG; repClinical; PvNET)	Proprietary, case-management and regulatory-reporting focus; limited public documentation of integrated analytics, no participatory design or formal usability evaluation; constrained transparency and reproducibility [40]	Offers exploratory analysis; transparent metrics (downloadable DPA files); hybrid-open model enabling inspection, reuse, and migration to a fully open-source stack
Clinical and EHR analytics on OMOP-CDM (PVClinical)	Integrates EHRs[d] via the OHDSI[e] stack and reports user-centered design; scope differs from spontaneous report dashboards; platform availability varies; continued need for clinical validation and regulatory alignment [39,43,47]	Complements PVClinical by focusing on FAERS spontaneous reports; reports outcomes of co-design, think-aloud usability (and its quantitative outcomes), and heuristic evaluation as a result of systematic user involvement in multicycle evaluation process
Academic or research visualization platforms	Often older or limited-scope implementations with small or alternative datasets; few report systematic user-centered design [14-16,28,44]	Built on open FAERS data—the largest, regularly updated public repository with API[f] access; applies recent visualization techniques via implementation of domain-informed design principles
Patient-facing ADR[g] reporting and medication information apps	Designed primarily for ADR submission or mobile information; not intended for exploratory signal analytics or integrated DPA visualization [27,29-31]	Analytic dashboard for exploring suspected drug-event patterns, supporting stakeholder decision contexts

Affordance as a Lens to Study DPs

Affordances are the action possibilities an artifact enables through its material features [49-51]. We use this lens operationally: each DP states (1) the intended user activity (affordance), (2) the dashboard features that enable it (material properties), and (3) the boundary conditions in which the principle applies. In this study, the artifact does not itself cause understanding or decisions; it supports them insofar as its features enable the specified affordances [52].

Formulating the DPs

DPs provide prescriptive guidance for constructing an artifact to meet stated objectives [50,53-55]. Drawing on literature on pharmacovigilance data literacy and dashboard design, we formulated DPs using the structure by Chandra et al [53] that ties (1) intended user activity (affordance), (2) enabling features (material properties), and (3) boundary conditions. We use the following template for DPs formulation:

Provide the system with (material property—in terms of form and function) in order for users to (activity of user or group of users—in terms of action) given that (boundary conditions—user group's characteristics or implementation settings) [53].

We consider drug safety surveillance as the boundary condition and analyze 2 user groups for this DSR prototype: (1) nonprofessionals (drug consumers) and (2) professional users as operationalized in this study (researchers in drug screening, bioinformatics, and data science). While health care professionals and pharmacists are central stakeholders for pharmacovigilance dashboards, they were not recruited in the present sample; consequently, findings and DPs are grounded in these boundary conditions.

We categorize the DPs into three classes: (1) DPs related to functionality that address the question of how well the dashboard serves its purpose, (2) DPs related to the mode of display that refer to the specific visualization techniques, and (3) DPs related to added value, which focus on the benefits the artifact provides to the public or end users.

We selected and refined DPs by applying an affordance alignment test: a principle was retained only when a target user

XSL•FO
RenderX

goal could be mapped to a concrete dashboard feature expected to enable the activity in the drug safety context [52,53]. Subsequent evaluation rounds confirmed and sharpened their scope.

DPs Related to Functionality

The value of new information infrastructures (IIs) lies in the users' community. However, since this community is initially small, the benefits of using the system may not be immediately apparent. Several authors emphasized the bootstrap problem that arises when the benefits of new IIs are perceived as indirect, delayed, or uncertain, which can lead to resistance in the system's adoption [56,57]. To address this issue, Hanseth and Lyytinen [57] recommend designing IIs for direct usefulness, that is, prioritizing immediate practical benefits for the users. This approach may enhance the perceived value of the system and help expand the user community. It may also create a positive feedback loop, where the use of the system leads to its further improvements, which in turn increase its usefulness and value. Consequently, we formulated the following DP: DP1a: it provides features to address the bootstrap problem, so that the system affords immediate use of the dashboard in drug safety surveillance.

Recker [58] investigates public dashboards related to the coronavirus pandemic, concluding that many present data through simple attributes (eg, number of cases, number of deaths, and number of recovered). Integrating state-tracking features that enable monitoring changes in states and events that trigger them (such as fluctuations in infection rates, or timelines of lockdowns and restrictions) could be a significant improvement, and the information presented in dashboards should answer the question how, instead of just how many. We formulated two DPs: (1) DP1b: it provides features to describe possible causality between variables, so that the system affords identification of patterns and trends in drug safety surveillance. (2) DP1c: it provides features to track changes in variables, so that the system affords tracking of the progression of relevant states in drug safety surveillance.

DPs Related to the Mode of Display

Matheus et al [59] suggest incorporating customizable views into decision-making dashboards, as this design strategy may help bypass the interpretation bias—"a single view might result in a limited picture of the situation." Expanding views to more than one view may lead to better understanding of the problem. Customized views help users to focus on relevant information and reduce the cognitive load associated with processing large volumes of data. We formulated the following DP: DP2a: it provides features to support customized views, so that the system affords examining various dimensions of data in drug safety surveillance.

Matheus et al [59] also suggest incorporating customizable features into decision-making dashboards, including the ability to toggle between detailed and high-level data visualizations. As these dashboards often contain a large volume of data, such features can help users understand the problem at hand by providing varying levels of detail. We formulated the following DP: DP2b: it provides overview and details, so that the system affords exploring data of different granularity levels in drug safety surveillance.

Toreini et al [60] follow a set of experiments to find ways to decrease task resumption failures. Tracking the real-time eye movements of the participants, they conclude that users start from and focus their attention on the upper left corner of the dashboard. Several authors suggest incorporating attention-augmenting features into dashboard elements (such as varied color, size, shape, and orientation) and visual cues (buttons and dials) to direct attention toward objects of higher importance [60,61] Consequently, DP2c: it provides features that stimulate attention and place important elements on the top-left area of the dashboard, so that the system affords improved attention management while using the dashboard in drug safety surveillance.

DPs Related to Added Value

Matheus et al [59] claim that creating dashboards should go beyond simply visualizing data. Creating public value should be embedded in the design process, as the data on its own is of little use. This way of thinking of the design process—through the prism of public value—transgresses the initial idea of merely finding the ways to present data in the best visual way. Data visualization should be the means, not the goal, and asking the question "what is the added value?" during the design process is necessary. Designers should prioritize generating public values such as engagement, transparency, and accountability, while also upholding public values such as privacy. Consequently: DP3a: it provides features to create public values, so that the system affords users' engagement in dashboard use in drug safety surveillance.

Embedding features that support decision-making is a crucial aspect of dashboard development [59]. Such features can be valuable for professional users, including health care professionals, pharmacists, researchers, and regulatory bodies in pharmacovigilance. We also expect the users would gain greater understanding and take up higher responsibility toward their own health, which would equip them better for decision-making. We formulated the following DP: DP3b: it provides features to support decision-making, so that the system affords users to evaluate what-if scenarios and consider different alternatives in drug safety surveillance. Initial DPs are shown in Table 2.

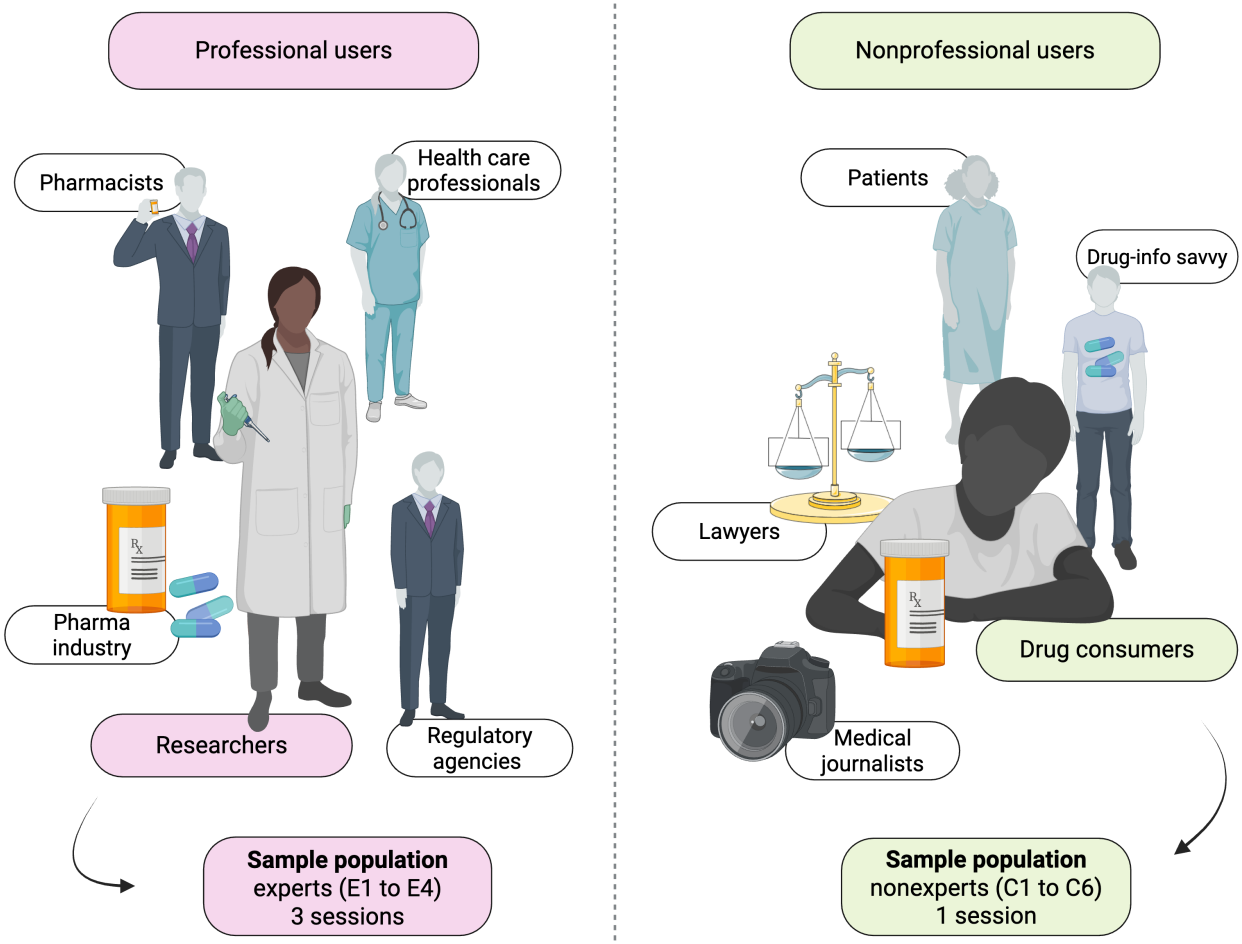
XSL•FO
RenderX

Table . Overview of initial design principles.

Design principle	Affordance	Material properties
DP1a	Obtaining immediate practical benefits while using the dashboard [56]	Features that respond to users' requirements, features that address actual user problems and offer solutions
DP1b	Identification of patterns and trends through exploration of DPA[a] analysis [58]	Features that enable identification and examination of patterns and trends in drug-ADR[b] evaluations
DP1c	Monitoring the progression of relevant states (how variables change over time) [58]	Features that allow tracking changes in relevant variables
DP2a	Exploring, analyzing, and interpreting data from different angles [59]	Features that enable analysis of data from multiple perspectives
DP2b	Exploring data from a broad and narrow perspective by switching between levels of granularity [59]	Features to adjust the level of detail depending on users' needs and the context of analysis
DP2c	Improved attention management while using the dashboard [60,61]	Features that stimulate attention, visual cues that direct attention toward important elements
DP3a	Active involvement in exploring the data, potentially increasing users' satisfaction [59]	Features with a potential to create public value (engagement, transparency, accountability, and adherence to privacy)
DP3b	Evaluating alternatives of actions, exploring what-if scenarios [59]	Features that support decision-making

[a]DPA: disproportionality analysis.

[b]ADR: adverse drug reaction.



Methods

Data Collection and Target Groups

We have considered 2 target groups for this work: professional users and nonprofessional users. We define professional users as those whose professional activities are concerned with drug safety surveillance and thus have extensive knowledge in the domain. For clarity, throughout the paper, "professional users" refers to this researcher group; the implications for clinician- and pharmacist-facing workflows lie outside this study's boundary conditions. In contrast, nonprofessional users are not professionally concerned by drug safety surveillance and in that sense are laymen in the domain of pharmacovigilance. Figure 1 depicts the user groups.

XSL•FO
RenderX

Figure 1. Professional (left) and nonprofessional (right) user groups. The broader professional stakeholder landscape includes health care professionals, pharmacists, researchers, regulatory agencies, and industry. In this study, the professional participants recruited were researchers in drug screening or drug development (E1-E4). Nonprofessional participants were drug consumers (C1-C6).

We have recruited a group of 4 expert users (referred to as experts, with participant IDs of E1 to E4) for this study. All experts were scientists of different academic degrees and expertise levels and were working on drug development and screening projects. Three out of 4 experts had extensive experience in data science and bioinformatics. In addition, all experts had many years of experience in data visualization and communication to the general and scientific community. Experts participated in the co-design workshop, pilot evaluation, and heuristic evaluation sessions.

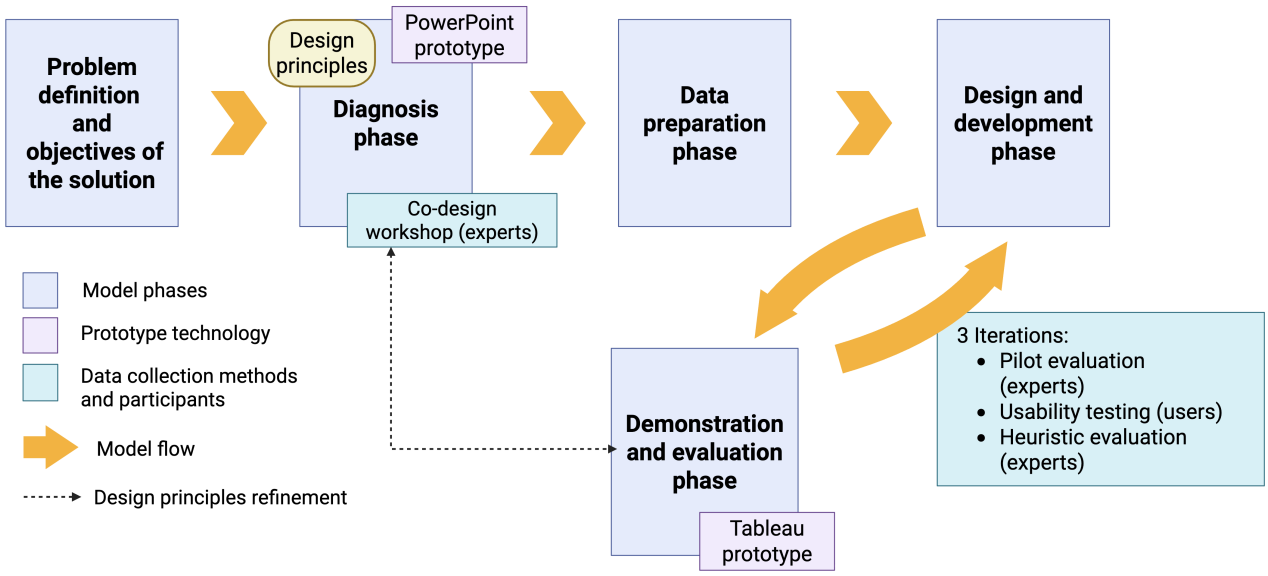
For usability testing (think-aloud session), we have recruited a group of 6 nonexpert users (referred to as nonexperts, with participant ID of C1 to C6). All nonexperts were drug consumers and had a history of continuous medication therapy of at least 7 days at least once in the previous year. We assumed these users were potentially also drug safety information-savvy and might provide meaningful insights into which complex analyses are possible. Importantly, nonexperts were novices in the sense that they had no prior exposure to the tool in question or any other similar dashboards [62]. Although some nonexperts shared parts of professional experience with experts (eg, C4 and C5 had expertise in biomedical engineering and data science), they were not working on drug screening and discovery projects.

By design, think-aloud usability testing was conducted solely with nonprofessional "novice" users to evaluate first-time learnability and immediate practical use (DP1a) without prior-exposure effects from experts who had already interacted with the prototype during co-design and/or the pilot evaluation [62].

Overall, all participants were between 28 and 44 years old and were based in Germany, Sweden, France, Finland, and Portugal. A detailed description of participants recruited for this study is shown in Table S1 in Multimedia Appendix 1. Given the age range and the presence of multiple participants with advanced technical or professional backgrounds, this sample likely exhibits above-average digital and data literacy; while valuable for investigating complex interaction issues in early iterations, this may inflate task performance relative to older adults and users with lower digital health literacy.

DSR Approach

We followed a framework proposed by Sauro and Lewis [63] to quantitatively analyze the user experience. Furthermore, in heuristic evaluation, we quantitatively collected and analyzed data in line with the framework proposed by Dowding and Merrill [64]. Additionally, we qualitatively collected and analyzed data in all experimental sessions in this study.



We modified a staged DSR model, initially proposed by Peffers et al [65]. Thus, the DSR framework applied in this study consisted of the following stages: (1) problem definition and

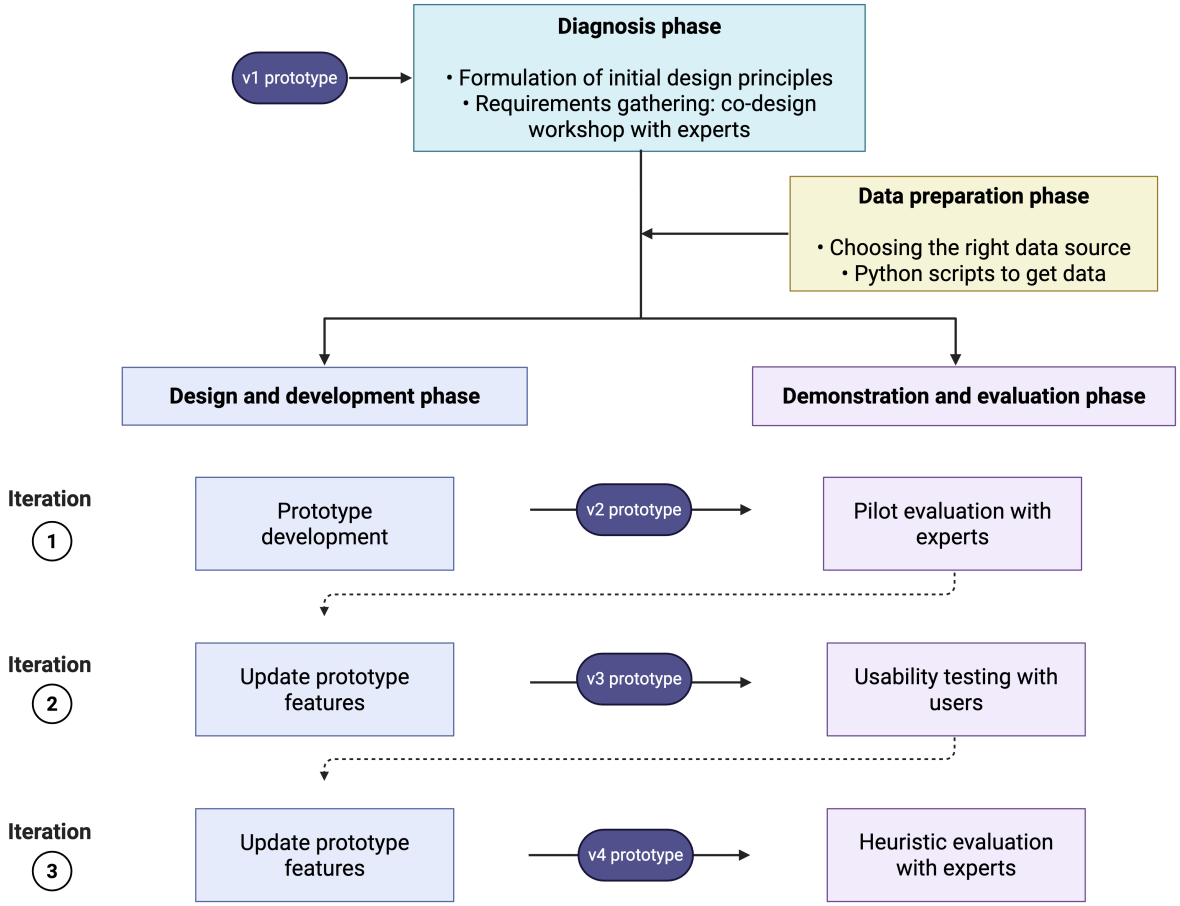
XSL•FO
RenderX

objectives of the solution, (2) diagnosis phase, (3) data preparation phase, (4) design and development phase, and (5) demonstration and evaluation phase. Detailed descriptions of each phase are found in Multimedia Appendix 2.

A depiction of the DSR process is shown in Figure 2. v1-PowerPoint and v2-v4-Tableau prototypes were used in diagnosis and demonstration and evaluation phases, respectively. Blue boxes show individual phases and the order in which they occurred in DSR (yellow arrows). DPs emerged in the diagnosis phase and were then iteratively refined in the demonstration and evaluation phases.

Figure 2. Applied design science research model.

Data Collection in DSR Cycle



We have performed 3 iterations of the DSR cycle. That is, we started with the diagnosis phase, in which we first identified initial DPs by gathering secondary data available in the literature. Then, we proceeded with one requirement gathering session, in the form of a co-design workshop with experts. Next, we have engaged in the data preparation phase, where—after selecting a suitable drug safety data source—we have written Python scripts to get and process the data.

We then performed 3 iterations of alternating design and development and demonstration and evaluation phases. In the first iteration, we developed a prototype in Tableau software (v2; Tableau Software LLC) [66], and tested it in the pilot evaluation session with experts. The results obtained in this way fed the second DSR iteration. We have updated prototype features (v3) and proceeded with usability testing (in a think-aloud session) with nonexperts. Finally, in the last iteration, upon updating prototype features (v4), we performed heuristic evaluation with experts. A flowchart of research activities is shown in Figure 3.

Further details about the design and development phase are provided in Multimedia Appendix 2. In that appendix, we describe the diagnosis phase, including the development of DPs and requirements gathering. We also provide information on how we used Statista [67] and participant requests to inform the selection process of 5 drugs used for prototype development: ibuprofen, acetaminophen (paracetamol), prednisone, quetiapine, and morphine.

XSL•FO
RenderX

Figure 3. Overview of data collection activities.

Demonstration and Evaluation Phase

Iteration 1: Pilot Evaluation

The researcher was moving through the dashboard by performing a set of predefined activities, while the participants controlled the navigation process by suggesting improvements whenever necessary. The session lasted 1 hour and was recorded with Otter.ai (Otter.ai, Inc) [68].

Iteration 2: Usability Testing

We have performed 6 usability tests with nonexpert users in think-aloud sessions. These included live meetings with 4 participants (C1, C2, C3, and C4) and virtual meetings with 2 participants (C5 and C6). Before the session, we have provided the users with a detailed protocol including introduction of the study, explanation on usability testing in the think-aloud session and a list with predefined tasks. These tasks required participants to do activities on the interface without the researchers' guidance. For the most part, researchers remained silent during users' task performance. Users were encouraged to express their thoughts while conducting the tasks. Additionally, 2 participants (C2 and C3) shared their thoughts on the usefulness of the dashboard and their interest in the tool in general. These short and unstructured discussions unfolded at the end of the sessions and were incorporated into findings. Each session lasted between 1.5 hours and 2.5 hours and was recorded with the same software, Otter.ai [68].

Experts were intentionally not included at this think-aloud stage to avoid learning effects from earlier sessions; their structured feedback was captured in the expert-focused co-design phase, pilot evaluation, and in the subsequent heuristic evaluation with 4 and 3 experts, respectively, which is within the 3 - 5 evaluator range known to uncover the majority of usability problems [69,70].

Iteration 3: Heuristic Evaluation

As originally suggested by Nielsen [71] and confirmed by other authors [62,69,72,73], 85% of usability violations can be detected by 3 to 5 evaluators in heuristic evaluation. We have performed heuristic evaluation with 3 experts (E1, E2, and E3).

Data Analysis

Overview

We used the framework method by Gale et al [74] to qualitatively analyze data in search of codes and themes. Importantly, and due to the specificity of DSR as a methodology (ie, when data are collected in iterations to repeatedly improve an artifact), codes and themes in this work refer to identified usability issues, dashboard features or elements undergoing evaluation and refinement, or any concept related to these (ie, the motivation behind the revision of DPs). Additionally, to prioritize the issues detected in usability testing and select appropriate solutions, we applied a method by Sauro and Lewis [63]. Finally, we analyzed the data from the heuristic evaluation through the assessment of 10 usability factors. These concepts

XSL•FO
RenderX

are discussed further below. Overall, we detected 33 themes (entities) in the co-design workshop session and 20 themes in the pilot evaluation session.

Usability Testing

For detecting usability issues, we applied a quantitative method by Sauro and Lewis [63]. We prioritized the usability issues according to their severity, considering the following factors: how much the issue has impacted the user trying to achieve the task, how critical the task was, and what was the frequency of the issue. Thus, the severity of issues was calculated by multiplying task criticality, impact, and frequency of occurrence. Overall, we detected 69 usability issues.

Each issue was then assigned one or more solutions. To choose the optimal solution to each usability issue, we considered 2 factors: complexity and effectiveness. Finally, a cost-benefit ratio (return on investment [ROI]) was calculated by dividing the effectiveness by the complexity. We decided which solutions to implement based on the following criteria: the solution had an ROI of 5 or more, was technically feasible, and was not solving the issue already covered by another solution with higher ROI. Overall, out of 56 conceptualized solutions, we arrived at 22 final solutions to be implemented. For a detailed description of the applied method, refer to Sauro and Lewis [63] and Rosemberg [75].

Heuristic Evaluation

Applying Dowding and Merrill's [64] heuristic evaluation, we assessed 10 usability factors using 49 close-ended questions. Usability factors had varying question counts; the maximum score per factor was calculated by summing questions assigned to it. Scores obtained per expert were calculated by summing the questions answered yes by each expert, per factor. A mean score was calculated by summing individual expert scores and dividing by the number of experts. The final result was the mean score divided by the maximum score (per factor and cumulatively). Next, overall severity rankings per usability factor were assigned, ranging from 0 (no usability problem) to 5 (usability catastrophe). Finally, qualitative analysis of comments per factor informed suggestions on future implementations. For a detailed description of the applied method, refer to Dowding and Merrill [64] and Nielsen [71].

Ethical Considerations

Informed consent was obtained from all participants prior to inclusion. Participation was voluntary, and participants were informed that they could opt out at any time. They were provided with information on how their data would be processed and that study data would be retained for no longer than 2 years from study start. No ethics or institutional review board approval was required for this work.

According to the Swedish Ethical Review Act (2003:460) [76], this study did not require formal ethical approval because it did not involve sensitive personal data, biological material, or any physical or psychological intervention. Only non-sensitive demographic information (country of residence, age, gender, profession) was collected. All participants were adults and data were pseudonymised using participant ID codes prior to analysis. Participants also provided consent for publication of the study results.

Results

Diagnosis Phase: DPs and Low-Fidelity Prototype

We have implemented DPs into a v1-low-fidelity prototype in PowerPoint. One dashboard element could be assigned to multiple DPs, but each assignment involved different functionalities of the element. Some DPs were action-oriented (DP1a and DP3a), and all material properties were assigned to them. We show how DPs shaped the v1-low-fidelity PowerPoint prototype in Table 3.

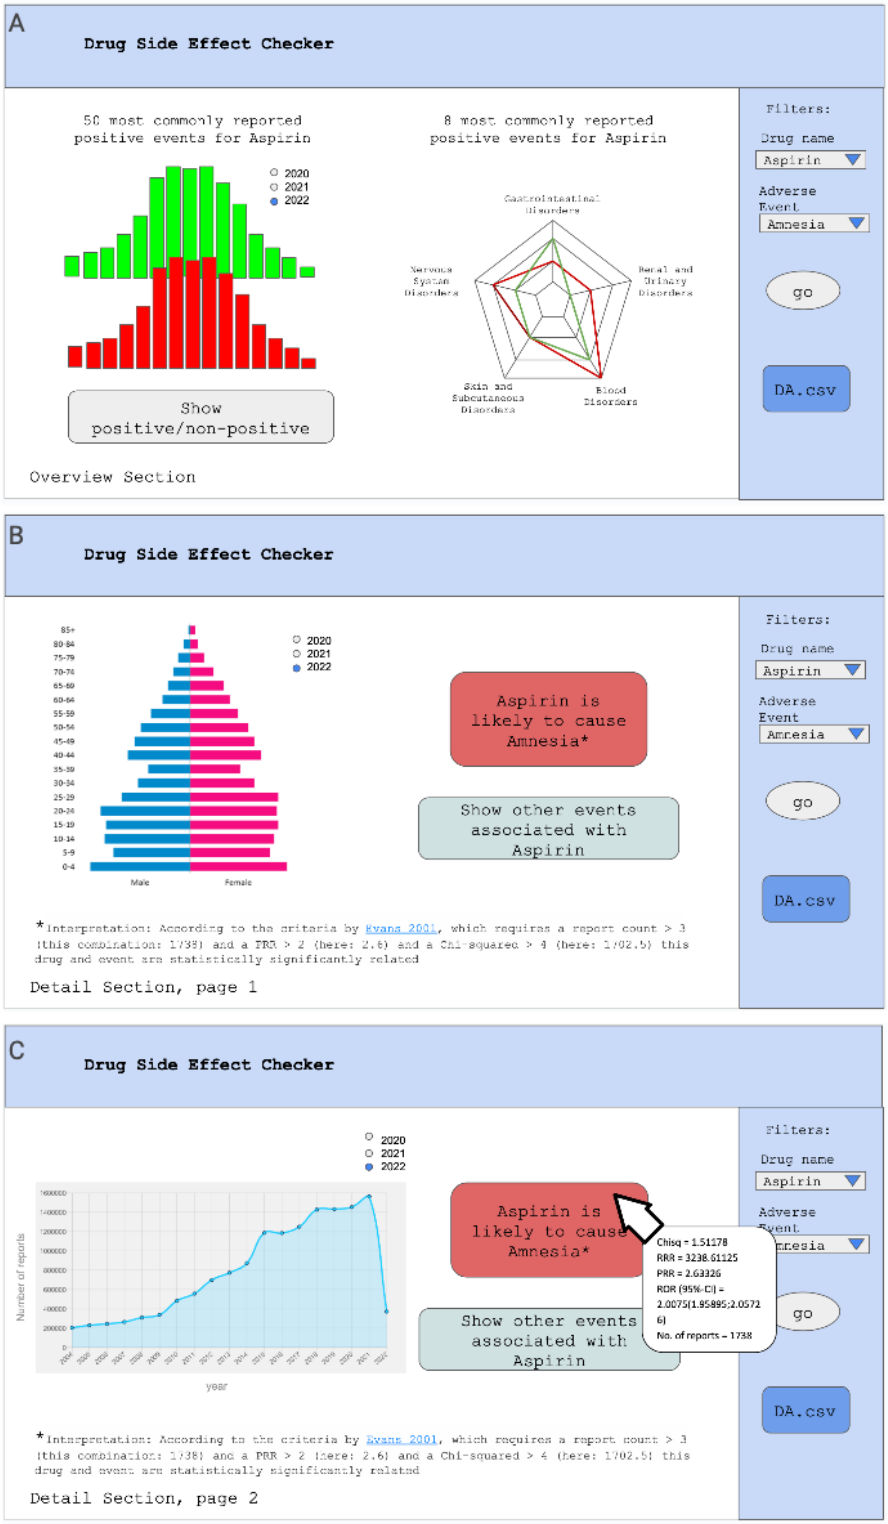
To afford exploration of data of varied granularity (DP2b), we created two dashboard sections: (1) an overview of common side effects for the chosen drug (the overview section) and (2) a detailed analysis of specific drug-side effect pairs (the detail section), split in separate pages where different visualization techniques were used (eg, a graph with age-gender distribution of affected populations). Additionally, we added drug and side effect search fields (Figure 4A–C).

To afford identification of patterns and trends (DP1b), the overview section displays a histogram of commonly reported side effects for a queried drug. Users could toggle between positive and negative side effects using buttons (Figure 4A). To afford monitoring the progression of relevant states (DP1c), a line graph with a year filter tracked reports for drug-side effect pairs over time (Figure 4C). Additionally, to afford improved attention management (DP2c), key graphs were positioned top-left, and warning messages were color-coded.

The system provided downloadable evaluation files containing detailed drug safety metrics (DA.csv, Figure 4A–C) to afford evaluating alternatives of actions (DP3b). Warning messages indicated whether an event was statistically significantly related to queried side effects and provided DPA information on mouse hover (Figure 4C). Two affordances, obtaining immediate practical benefits while using the dashboard (DP1a) and active involvement in exploring the data (DP3a) were expected to be enacted across all prototype features, as they aligned with the prototype's purpose.

XSL•FO
RenderX

Table . Instantiation of material properties.



Design principle	Instantiation of prototype features
DP1a	Initiated by all features and iteratively refined in response to users' input
DP1b	Graphs belonging to the overview section, warning messages with DPA[a] metrics on hover
DP1c	Line graph with the number of reports per drug-ADR[b] pairs, with year filters
DP2a	Interactivity of the graphs (eg, buttons to toggle between positive and negative ADRs), with year filters
DP2b	Splitting the dashboard into the overview and detail sections, with year filters
DP2c	Placing the graphs on the top-left, color-coded warning messages
DP3a	Initiated by all features expected to elicit values related to the transparency of drug safety data or the user engagement in health information tracking
DP3b	DPA metrics as downloadable files (DA.csv), warning messages with DPA information on hover

[a]DPA: disproportionality analysis.

[b]ADR: adverse drug reaction.

Figure 4. An excerpt from the v1-low-fidelity PowerPoint prototype. (A) The overview section. (B-C) The detail section.

Diagnosis Phase: Requirements Gathering

Through a collaboration with a group of experts in a co-design workshop, we gathered the requirements for the prototype development. The v1-low-fidelity PowerPoint prototype was used in this session to visualize content of the dashboard, serving as a canvas for design activities. We summarize the principal findings in Table 4.

XSL•FO
RenderX

Table . Principal findings from the co-design workshop.

Feature or element	Related DPs[a]	Feedback
Indication graph	• DP2b (overview and details) • DP3b (decision-making support)	Offers details on common prescriptions for a queried drug, adding an extra variable to the displayed dataset.
Scrolling	• DP2c (attention stimulation)	Use scrolling instead of pagination, it is a preferred way for users to interact with the dashboards.
Drug and event search fields	• DP2b (overview and details)	Users seek information on potential side effects both before and after drug administration. Separate search fields allow users to look up a drug only (before an event occurs) or a drug and ADR[b] (after an event occurs).
DPA[c] metrics files	• DP3b (decision-making support) • DP2b (overview and details)	To influence decision-making of professional users, DPA files should include formulas and information on statistical models used for calculations, as well as the interpretation of calculated indicators.
Removing DPA info from the warning message's hover	• DP2b (overview and details)	While beneficial for researchers, high-level granularity data may confuse nonprofessional users. Access to DPA metrics is provided through downloadable files.
Age-gender distribution graph with modified age ranges, positioned top-left	• DP2b (overview and details) • DP3b (decision-making support) • DP2c (attention stimulation)	The graph provides information on common demographic attributes (age and gender). Using 10-year ranges provides optimal data granularity.
Histogram of most commonly reported side effects, positioned top-left	• DP2b (overview and details) • DP2c (attention stimulation) • DP2a (customized views) • DP1b (causality between variables)	The graph provides an overview of the most commonly reported ADRs, with the option to customize the display using a histogram filter (Related, Unrelated, All events). Limiting the bars to 20 provides optimal data granularity.
Per drug, there is a line graph showing the sum of side effects reported over time (the first line graph) and a second line graph illustrating specific side effects reported over time	• DP1c (state-tracking) • DP2a (customized views)	For researchers, viewing time series of drug-ADR report numbers is crucial. The second line graph helps identify, for example, specific events contributing to sudden increases in ADRs in selected years. The histogram filter is linked with line graphs, enhancing customization options.

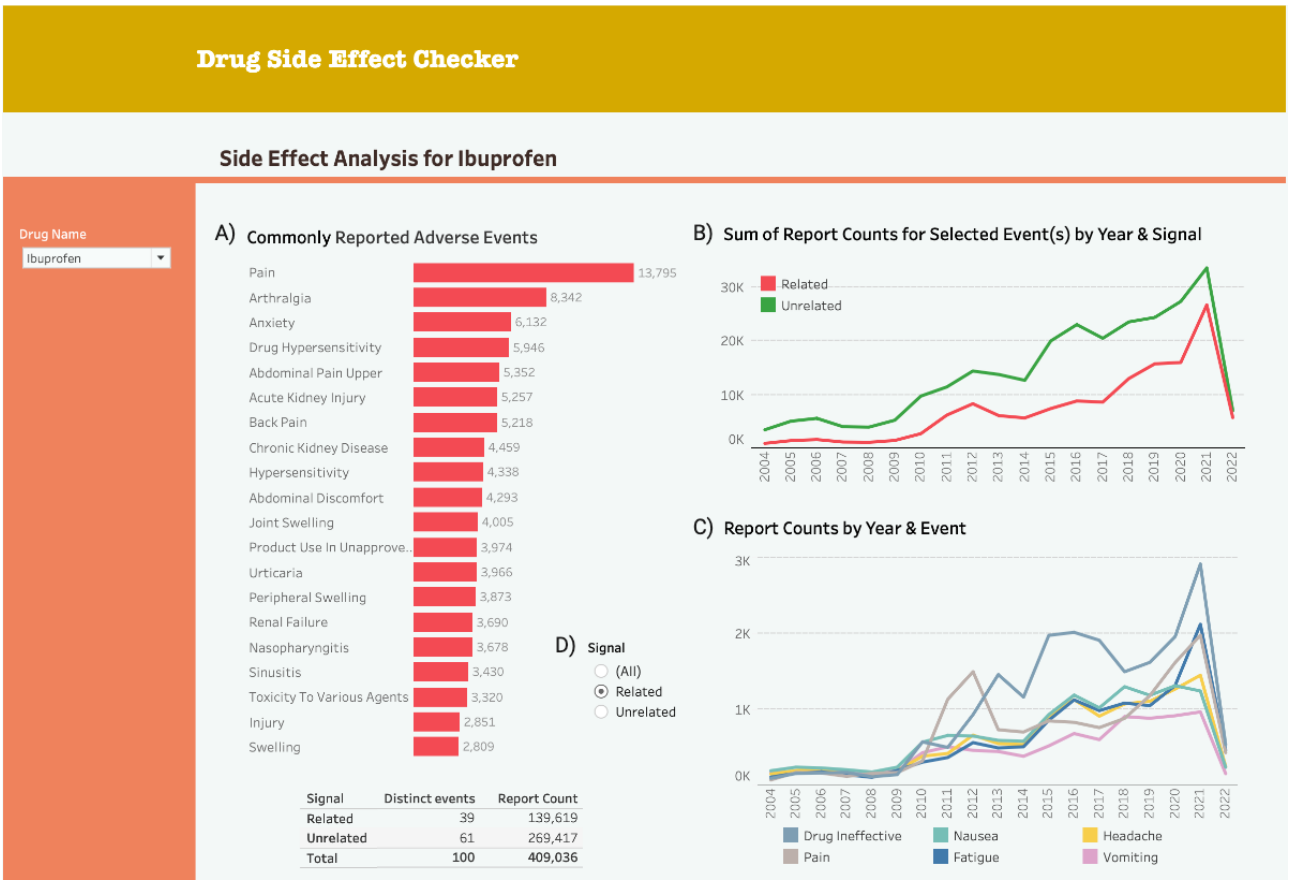
[a]DP: design principle.

[b]ADR: adverse drug reaction.

[c]DPA: disproportionality analysis.

Adjusting Data Granularity

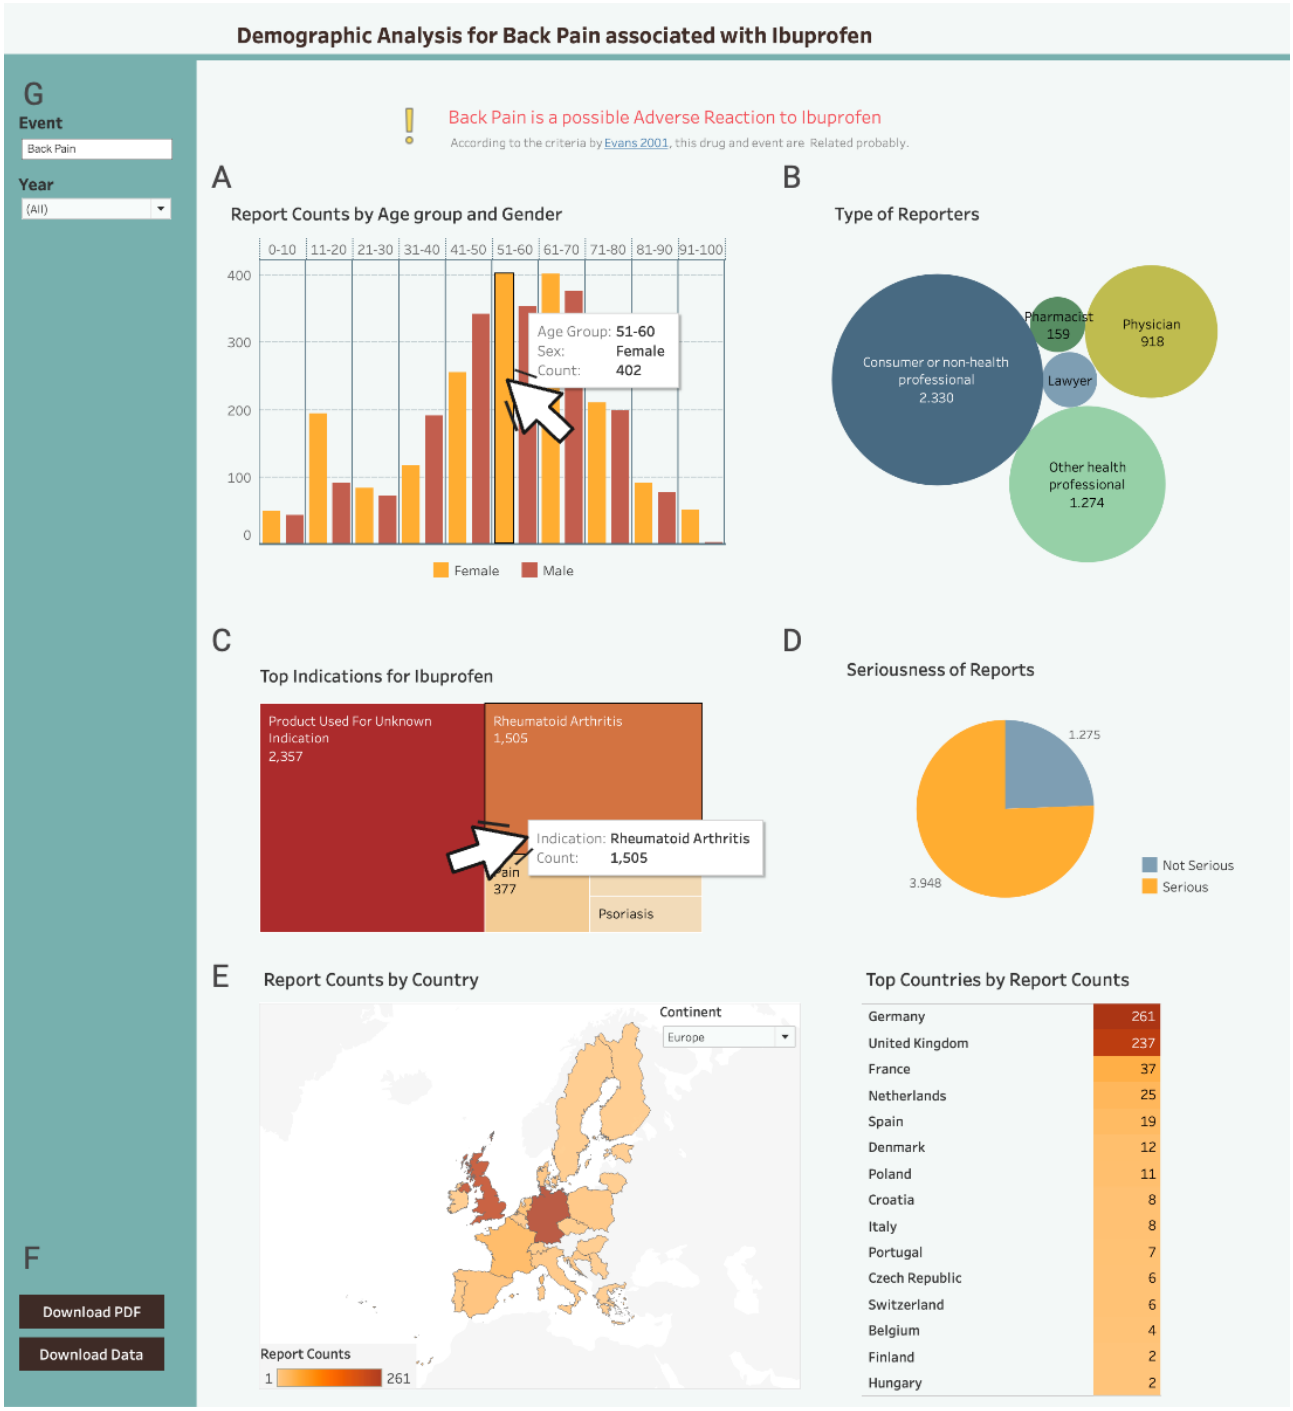
We found evidence that the dashboard supported the exploration of data of varied granularity (DP2b). Feedback from experts suggested adjusting the detail level on display. Some elements were considered too detailed, resulting in information overload, especially on the histogram and the age-gender distribution graph. Recommendations included fixing the histogram's displayed bars at 20 and setting age intervals on the age-gender distribution graph to 10 years (Figures 5A and 6A, respectively). Additionally, it was suggested that displaying detailed DPA metrics while hovering the warning message might confuse users unfamiliar with similar statistical methods, as per E1: this proportional reporting ratio and all that (...) Not super easy to interpret, right? This is greater than 2, but like, what is the upper bound? What is the lower bound? Like, how low can it go? (...) These values are not so easy to understand if you're not the professional who uses them.



Thus, the DPA information was removed from the warning message and added to downloadable DPA files, together with formulas for score calculation and interpretation of indicators. This was also in line with the suggested increase of data granularity on some occasions. Likewise, it has been proposed to implement a functionality to view the data by the condition for which a drug was prescribed. Finally, while initially considered, the BMI variable was ultimately excluded from the age-gender distribution graph. Although useful for analysis, BMI is rarely provided in the reports. Therefore, it was necessary to adjust the intended data granularity to what was available in the datasets. Considering all the above, we revised the following DP: DP2b: It provides an overview and details, while controlling overview-to-detail ratio, so that the system affords exploring data of different granularity levels in drug safety surveillance.

Accounting for different data granularity interest among various user groups, and considering that customizable level of detail

XSL•FO
RenderX



in displayed data can reduce distraction and potentially influence decision-making, we revised another DP: DP3b: It provides features to support decision-making and cluster them by the needs of distinct user groups, so that the system affords users to evaluate what-if scenarios and consider different alternatives in drug safety surveillance.

Figure 5. The first Tableau (v2-high-fidelity) prototype with analysis for ibuprofen (the overview section). (A) Modified histogram. (B) The first line graph. (C) The second line graph. (D) The histogram's filter.

(B) The reporter's type of occupation. (C) The indication graph. (D) The seriousness of the outcome. (E) The map with number of reports per country and the associated table. (F) Download buttons. (G) The event search field.

Scrolling Over Pagination

Feedback suggested changing from pagination to scrolling, as users often prefer to scroll, rather than having to navigate through multiple pages. Pagination is also considered more expensive in terms of browsing and might significantly slow the system down. Thus, we revised the DP: DP2c: it provides features that stimulate attention, place important elements on the top-left area of the dashboard, and promote scrolling over pagination, so that the system affords improved attention management while using the dashboard in drug safety surveillance.

Iteration 1

Design and Development: First Tableau Prototype

We transformed the v1-low-fidelity PowerPoint prototype into a v2-high-fidelity dashboard in Tableau, incorporating refined DPs based on the guidance from the co-design workshop. Figures 5 and 6 show the prototype after the first iteration.

After requirements analysis, to better afford monitoring the progression of relevant states (DP1c), we introduced 2 graphs: a line graph showing all side effect reports per drug per year

XSL•FO
RenderX

(Figure 5B) and a line graph showing specific side effect reports per drug per year (Figure 5C).

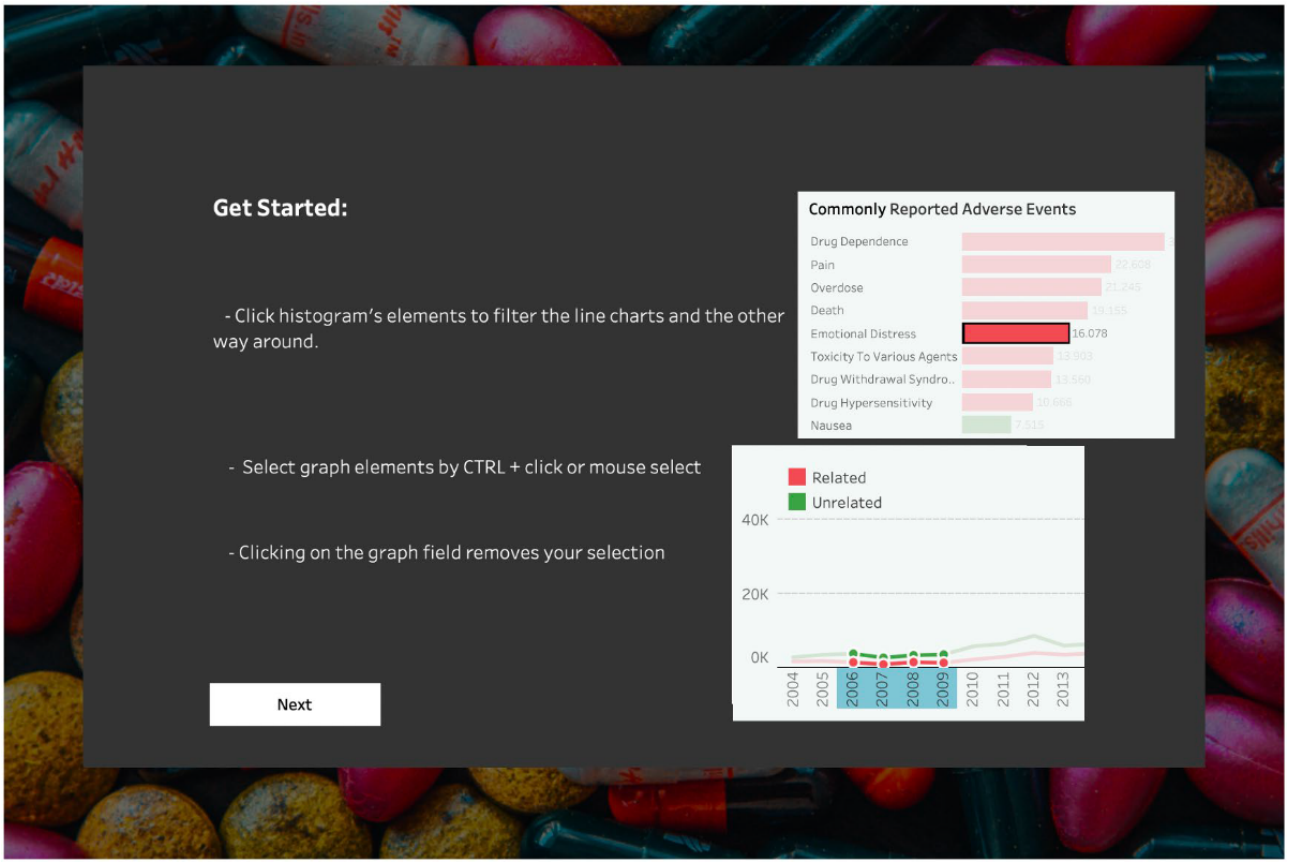
For exploration of data of varied granularity (DP2b), we added an indication graph showing the conditions for which the queried drug was prescribed when a side effect occurred (Figure 6C). In line with revised DP2b, we modified the age-gender distribution graph (Figure 6A). We also modified the histogram by reducing the number of bars to better afford identification of patterns and trends (DP1b). A map displayed side effect distribution per country with interactive continent selection and year filtering (Figure 6E).

With regard to improved attention management (DP2c), we positioned the histogram and the age-gender distribution graph on the top-left overview and detail sections, respectively. We replaced pagination with scrolling, aligning with DP2c. To better afford evaluating alternatives of actions (DP3b), we introduced safety signal reports with DPA information, displayed upon clicking the download data button (Figure S1 in Multimedia Appendix 3). To better afford exploring data from different angles (DP2a), all graphs in the overview section were made interactive: for example, selecting up to 6 histogram bars was reflected in the second line chart, where up to 6 individual events were displayed. It was also possible to limit the dataset by year ranges (Figure S2 in Multimedia Appendix 3).

Demonstration and Evaluation: Pilot Evaluation

While conducting a pilot evaluation, we were looking for suggestions on possible improvements to the prototype before embarking on usability testing. Overall, we received advice to implement a getting started tutorial containing screenshots of the dashboard elements with a short explanation on salient functionalities (eg, how to remove the selection and how to select using keyboard or mouse).

Importantly, expert E3 suggested implementing a feature related to selection-keeping—when the user chooses one or more side effects by clicking on the histogram bars, and then changes their drug selection, the dashboard should keep the selection of side effects. This feature can be useful to quickly compare drugs from the same drug classes (eg, ibuprofen and aspirin). According to E3: if you want to compare that one drug to another drug, to see if it (selected side effect) also occurs really often, then this makes sense (...) And you can see it (selected side effect) directly in the ranking.



This feature was in line with DP3b, potentially enhancing the decision-making of professional users.

Iteration 2

Design and Development: Updating Prototype Features

We updated the system by implementing selected findings from the pilot evaluation session. Thus, we introduced a getting started tutorial with informative screenshots that guided users through the dashboard functionalities (Figure 7).

Figure 7. An exemplary page from the getting started tutorial in the v3-updated prototype.

XSL•FO
RenderX

To better afford evaluating alternatives of actions (DP3b), we introduced the selection-keeping feature. For a detailed explanation, refer to Figure S3 in Multimedia Appendix 3, where we present a real-world scenario demonstrating the comparison of 2 commonly used pain-relieving drugs: ibuprofen and acetaminophen (also known as paracetamol).

Demonstration and Evaluation: Usability Testing

We conducted usability tests with nonprofessional users (refer to Multimedia Appendix 4 for details). We found several usability issues that could hinder obtaining immediate practical benefits while using the dashboard (DP1a). We grouped the issues according to the affected dashboard features or elements, and we discussed them in the corresponding order.

The getting started tutorial was hard to follow and long. Users struggled to grasp how the individual screenshots relate to the dashboard concepts. This confusion arose because the screenshots presented isolated dashboard elements instead of the dashboard as a whole. The inability to skip or revisit the tutorial was also a major issue. Regarding the histogram and associated filter**,** users had trouble understanding how to select bars by clicking or by dragging sections. Finding the histogram's filter (Figure 5D) took more than 15 seconds, which could hinder identification of patterns and trends (DP1b), as failing to use the filter could impede the thorough exploration of data.

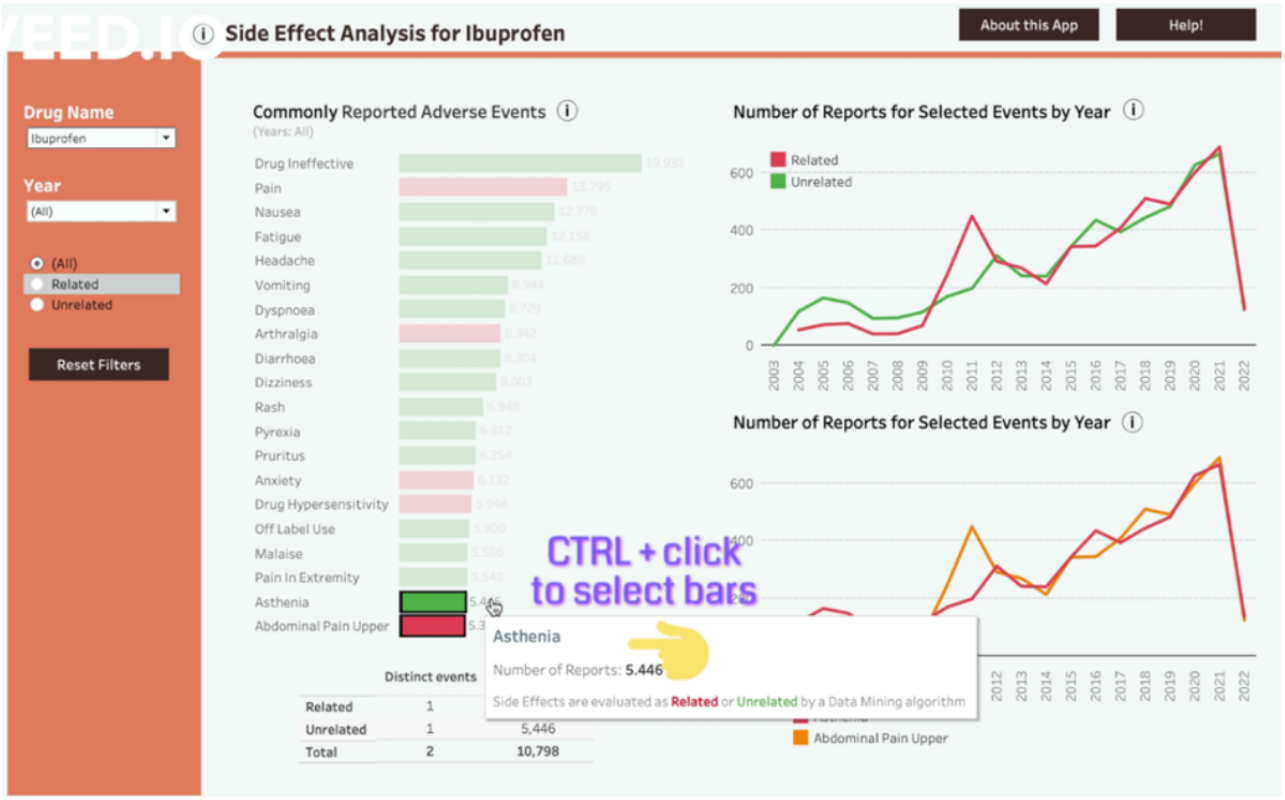
Usability problems also arose for year selection across different dashboard sections. Users didn't fully explore year selection options and found deselecting elements challenging (Multimedia Appendix 4). The absence of a year selection field in the overview section could impede exploration of data of varied granularity (DP2b) and, in consequence, interfere with monitoring the progression of relevant states (DP1c).

Some dashboard elements lacked visibility and clear explanations of their utility. For example, the event search field was not visible enough (Figure 6G) and the utility of the second line graph was not clear to the users. Additionally, the dashboard language was too technical. We also found issues with download buttons, DPA metrics files, and safety signal reports. Multiple download buttons and files made downloads difficult. Moreover, the download dialog box was located beyond eye reach and the system failed to inform about the download status. Finally, safety signal reports were too detailed and specific. According to C2, the report provided "unnecessary information overload" in which the participant was not interested.

End questions revealed users' confusion about the data source and the meaning behind the evaluation of side effects as related or unrelated to a drug by data mining algorithms. This lack of understanding could constrain evaluating alternatives of actions (DP3b). However, users found the system attractive for exploring drug safety information (DP3b). They were often encouraged by its interactivity to explore data from different angles (DP2a) and expressed their interest in using the system as an auxiliary drug information source. C4 suggested that people generally search online for drug safety information, seeking medical advice on websites of compromised quality. The participant considered the dashboard a suitable information source even for users with no pharmacovigilance background, as long as it is supplementary to professional medical advice. Similarly, C3 suggested the system could be useful for direct comparison of drugs with the same active substance produced by different manufacturers. C3 often asks for a cheaper drug alternative at the pharmacy and could use the system to compare the safety information of equivalent drugs.

Iteration 3

Design and Development: Updating Prototype Features



Introducing the Video Tutorial

To better afford obtaining immediate practical benefits while using the dashboard (DP1a), we modified the tutorial. Usability testing revealed that users learn best by doing, but they require basic knowledge to get started. Well-designed tutorials allow users to uncover the true potential of the app and understand the associated benefits [77]. Following the idea that undiscovered features practically do not exist, we replaced the tutorial with the animated walkthrough video.

We recorded key features in a brief video (more than 1 minute) with subtitles explaining dashboard actions. We used icons (eg, pointing finger and large mouse cursor) to guide users and added a skip video button for more experienced users (Figure S5 in Multimedia Appendix 3). Finally, we included a help button allowing users to rewatch the tutorial (Figure 8).

XSL•FO
RenderX

Figure 8. A frame from the getting started video tutorial of the v4-updated prototype.

Emphasizing the Utility of Dashboard Elements

We addressed many usability issues by adding short labels to dashboard elements (Figures 9 and 10).

To better afford monitoring the progression of relevant states (DP1c), we included an info icon next to graphs and section headers. Users could see information about graph functionality and displayed data, as well as the explanation of complex terms. We also included information on the content of the overview and detail sections and explained how graphs interacted with each other.

Similarly, we expected the issue of insufficient visibility and unclear utility of some elements (eg, the event search field and the second line graph) would be addressed by including additional information in the tutorial (Figures S6 and S7 in Multimedia Appendix 3). Finally, we implemented the "About this App" section (Figure 11), where users could find information about the data source, safety signal evaluation, possible limitations to the tool, and external links.

Considering all the above, we refined the DPs: (1) DP1a: it provides features to address the bootstrap problem, add walkthrough videos, and explain dashboard elements**,** so that the system affords immediate use of the dashboard in drug safety surveillance. (2) DP1c: it provides features to track changes in the variables and highlight their utility, so that the system affords tracking of the progression of relevant states in drug safety surveillance.

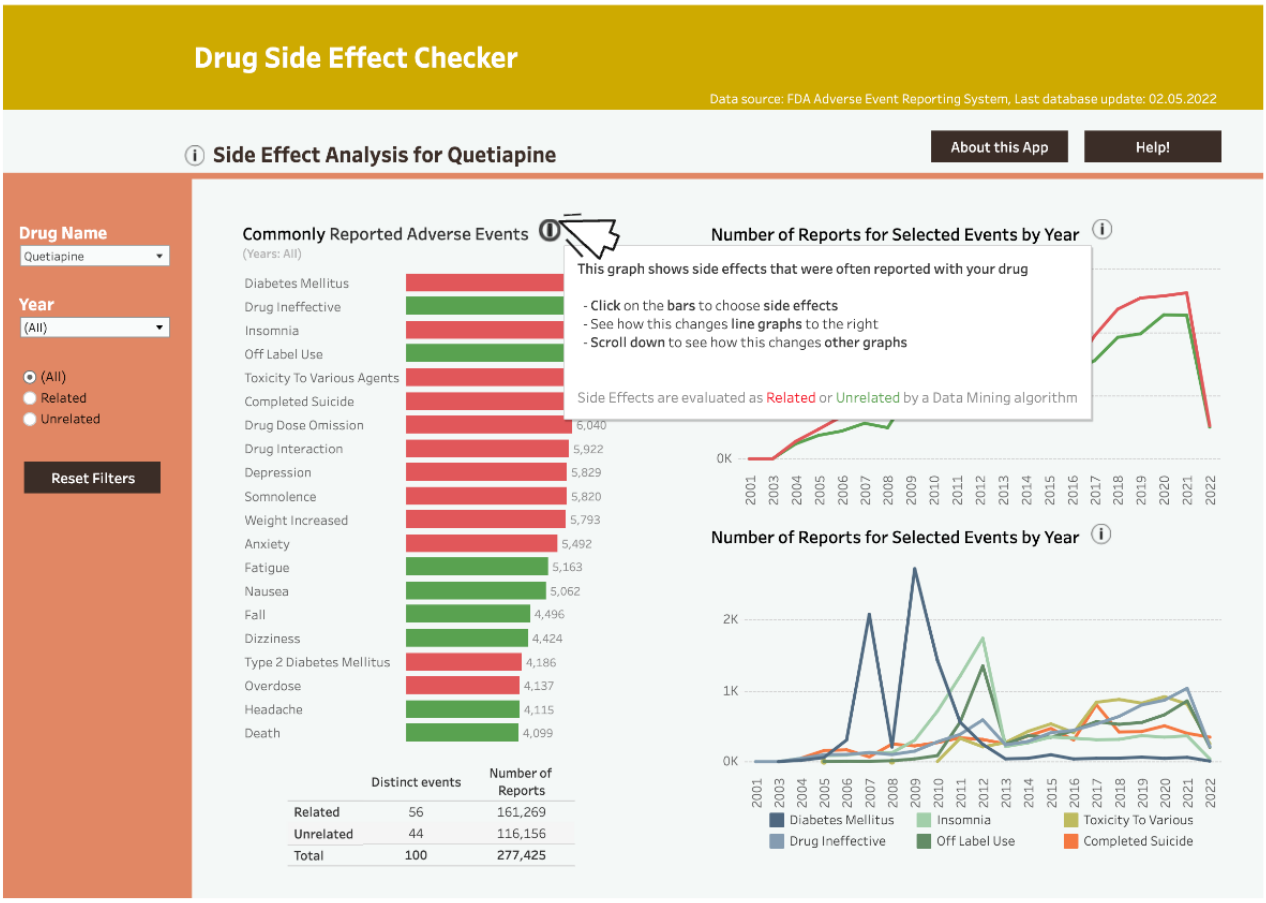
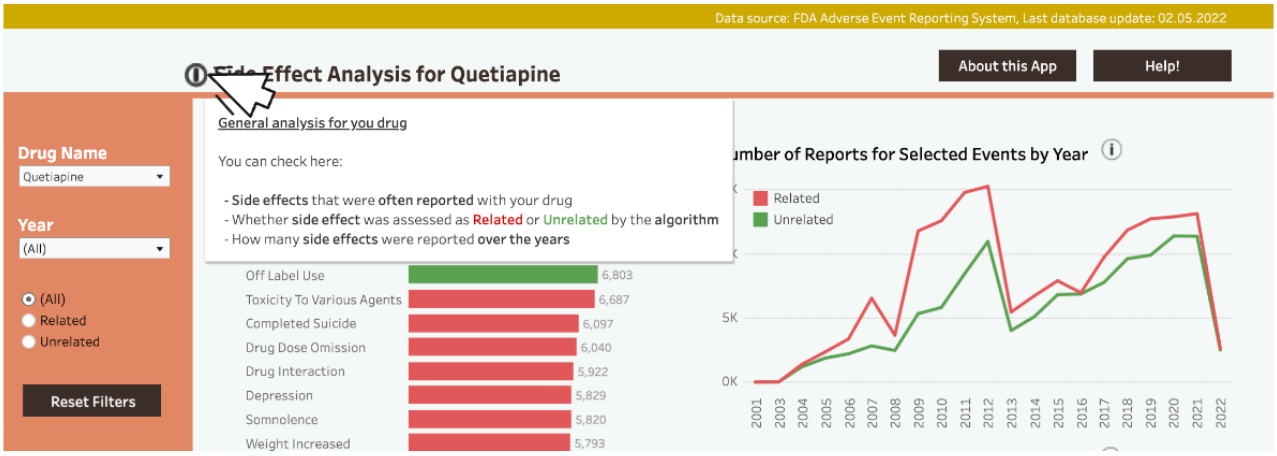
RenderX

Figure 9. Histogram with the info icon. Prototype v4.





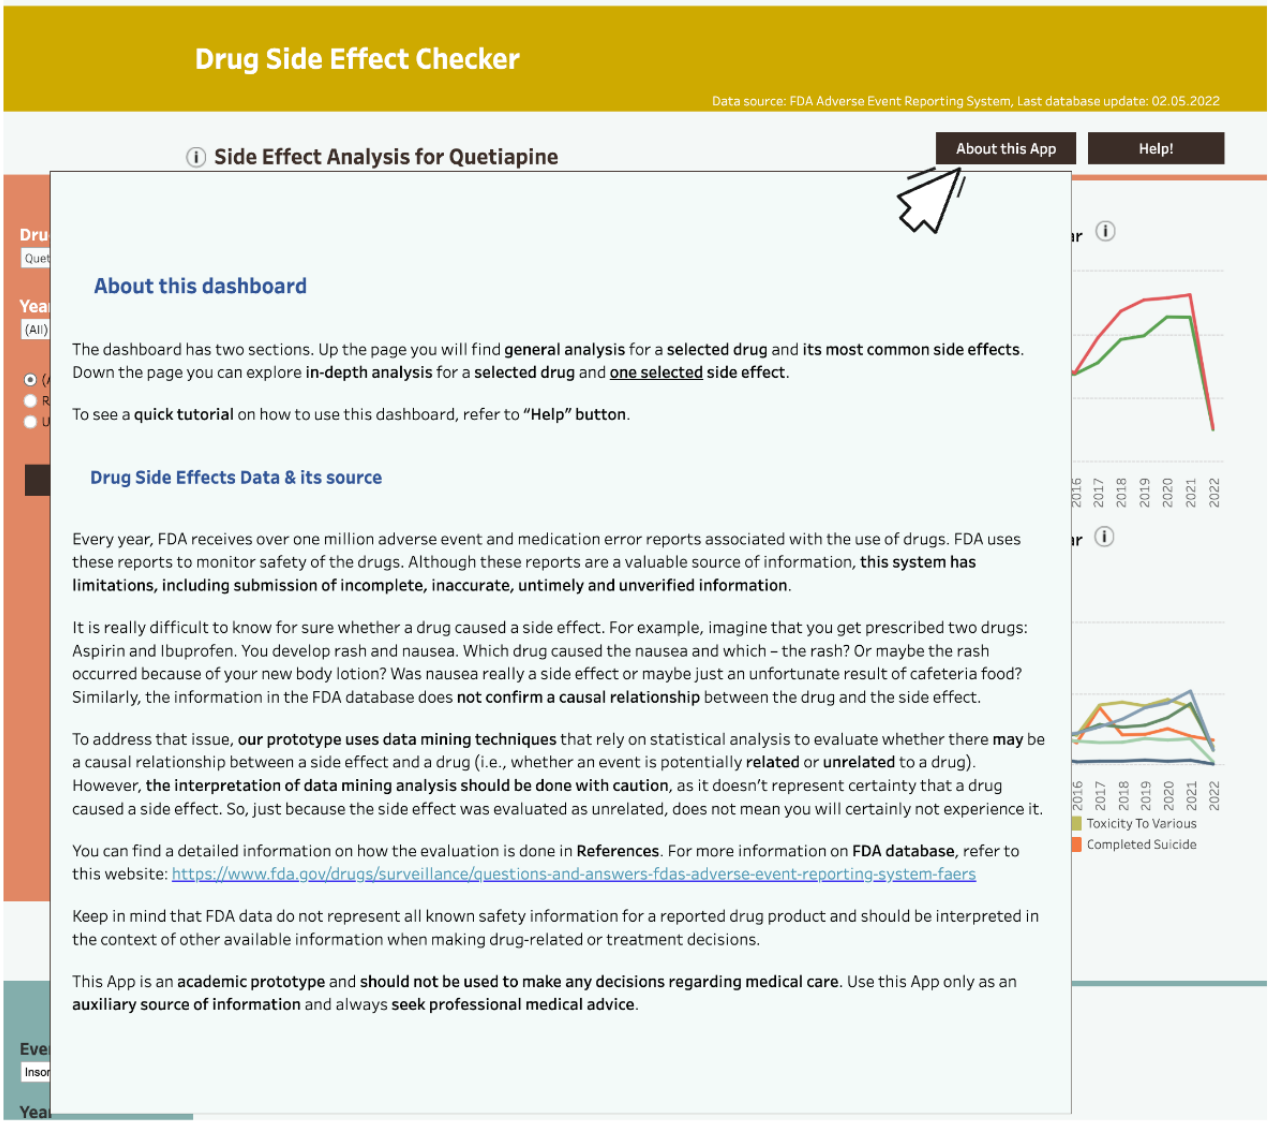


Figure 10. The overview section with the info icon. Prototype v4.

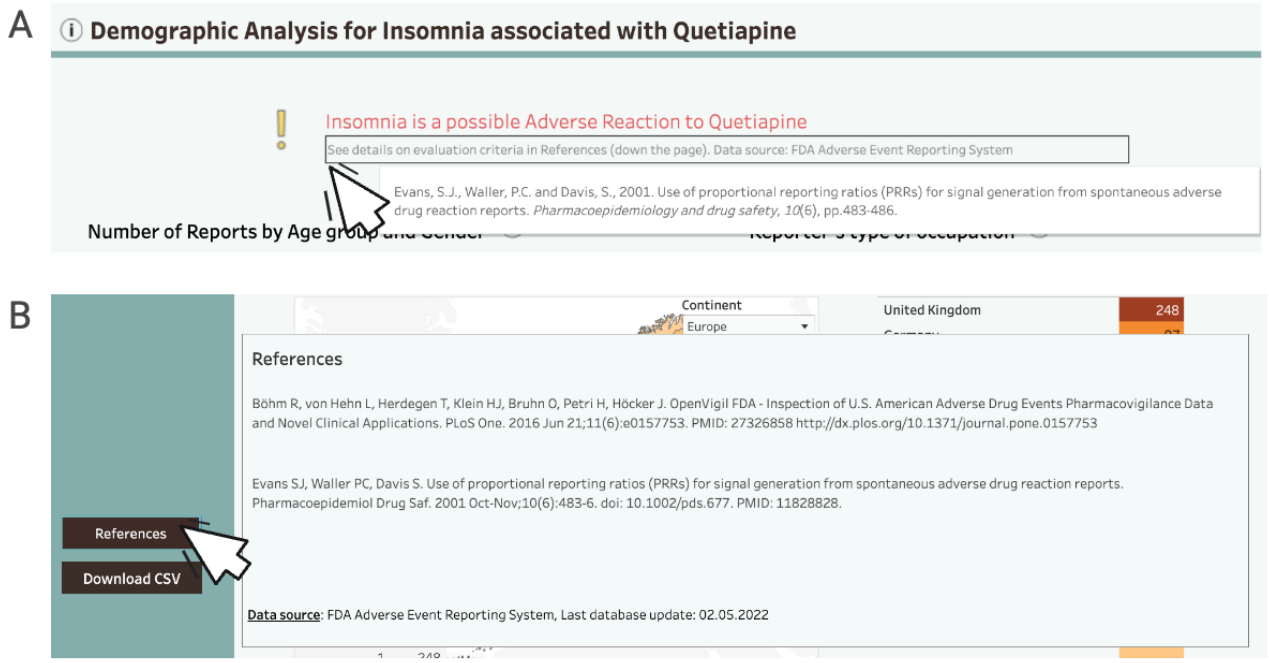
XSL•FO
RenderX

Figure 11. The About this App dashboard section. Prototype v4.

Signalizing the Uncertainty of Data Mining Results



To better afford identification of patterns and trends (DP1b), we added the information on the uncertainty behind DPA evaluation and advised caution when interpreting the results. Since safety signal detection can be used for hypothesis building, but not testing, we found it crucial to highlight these concepts. Safety signal detection is a starting point for further investigations, not a conclusion. Considering ethical and safety concerns, appropriate warnings are necessary.

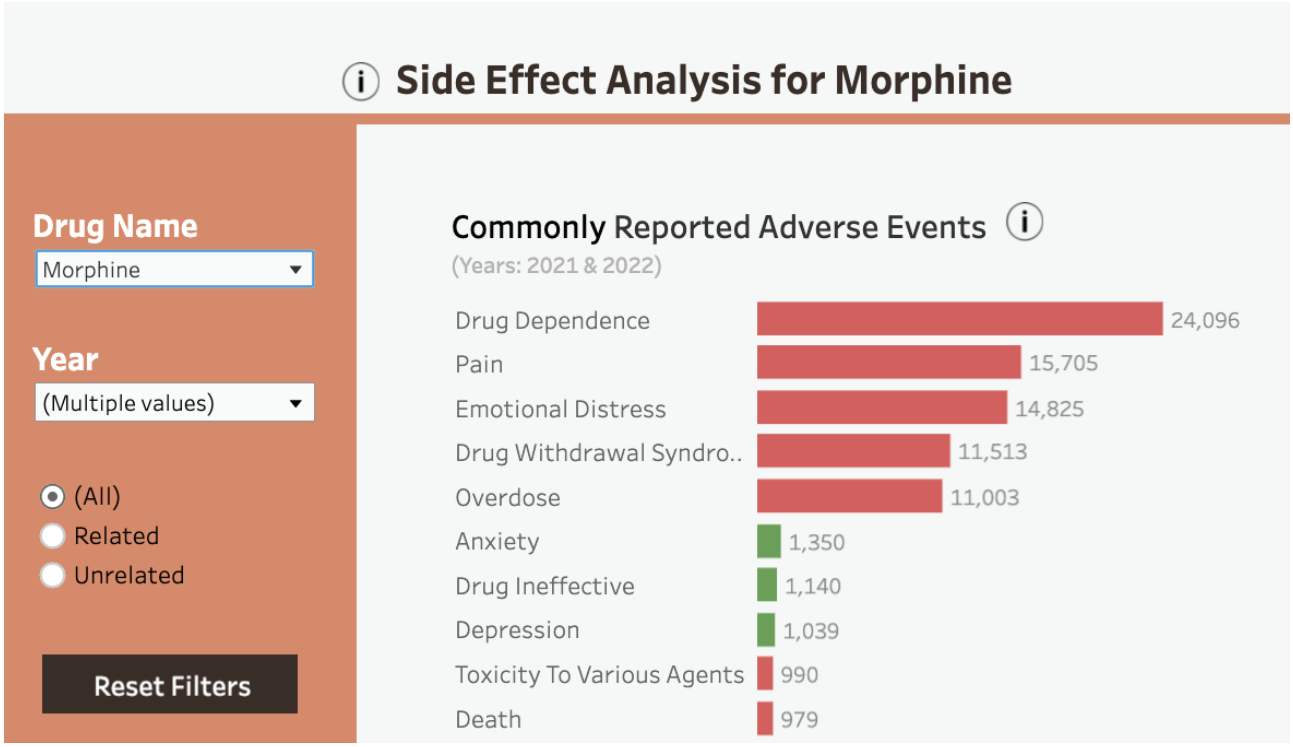
We addressed all the above in several ways. First, we provided the explanation on the interpretation of DPA in a disclaimer (not shown) and in the About this App section. Accounting for users less familiar with the topic, we provided an illustrative real-world case scenario to explain the concepts. We also implemented the References button, providing the links to evaluation criteria and including similar information in the warning message (Figure 12). Finally, we added links to external resources on many occasions and further enriched DPA files in explanation. In line with the above, we refined the following DP: DP1b: it provides features to describe possible causality between variables and signalize uncertainty behind DPA results in different ways, so that the system affords identification of patterns and trends in drug safety surveillance.

Together, these changes replace specialist terminology with plain-language labels and confine full statistical detail to downloadable files, reducing cognitive load for lay users while preserving transparency for professional review.

XSL•FO
RenderX

Figure 12. (A) The warning message with the information on hover. (B) The References button with the information on hover. Prototype v4.

Improving the Usability of Other Elements



To address the usability issues related to the histogram, and to improve attention management while using the dashboard (DP2c), we relocated the histogram's filter to the upper-left corner, removed the confusing filter's name, and added a histogram's year filter with the information about the current year selection. We also implemented a Reset Filters button to unselect elements in the overview section (Figure 13).

To facilitate obtaining immediate practical benefits while using the dashboard (DP1a), we simplified the language and modified download options, removing redundant download buttons and files. With regard to evaluating alternatives of actions (DP3b), and considering different data granularity needs of users (DP2b), we removed safety signal reports from the background of the download page and simplified the view. Finally, we moved the download dialog box to the eye reach (Figure S8 in Multimedia Appendix 3).

The summary of all solutions implemented after usability testing is shown in Table S2 in Multimedia Appendix 4. The final version (v4) of the prototype was made available online [78]. We recommend using Google Chrome as a browser for a better experience.

XSL•FO
RenderX

Figure 13. Histogram with the side effect filter (All, Related, Unrelated), year filter, the Reset Filters button (bottom left), and information on current year selection (in fine print, gray). Prototype v4.

Demonstration and Evaluation: Heuristic Evaluation

We concluded the DSR cycle by performing heuristic evaluation (Figure 14). We identified 4 out of 10 usability factors with the lowest usability score: flexibility and efficiency of use (52%), user control and freedom (67%), visibility of system status (83%), and consistency and standards (83%). Two usability factors had the usability scores above 90%: recognition rather than recall (92%) and match between system and real world (93%), while 4 usability factors had the usability scores of 100%: aesthetic and minimalist design, orientation, spatial organization, and information coding, where the last 3 factors were related to dashboard visualization. The overall usability score was 84% (Table 5).

XSL•FO
RenderX

Figure 14. Usability scores per usability factor. Total is the overall usability score.

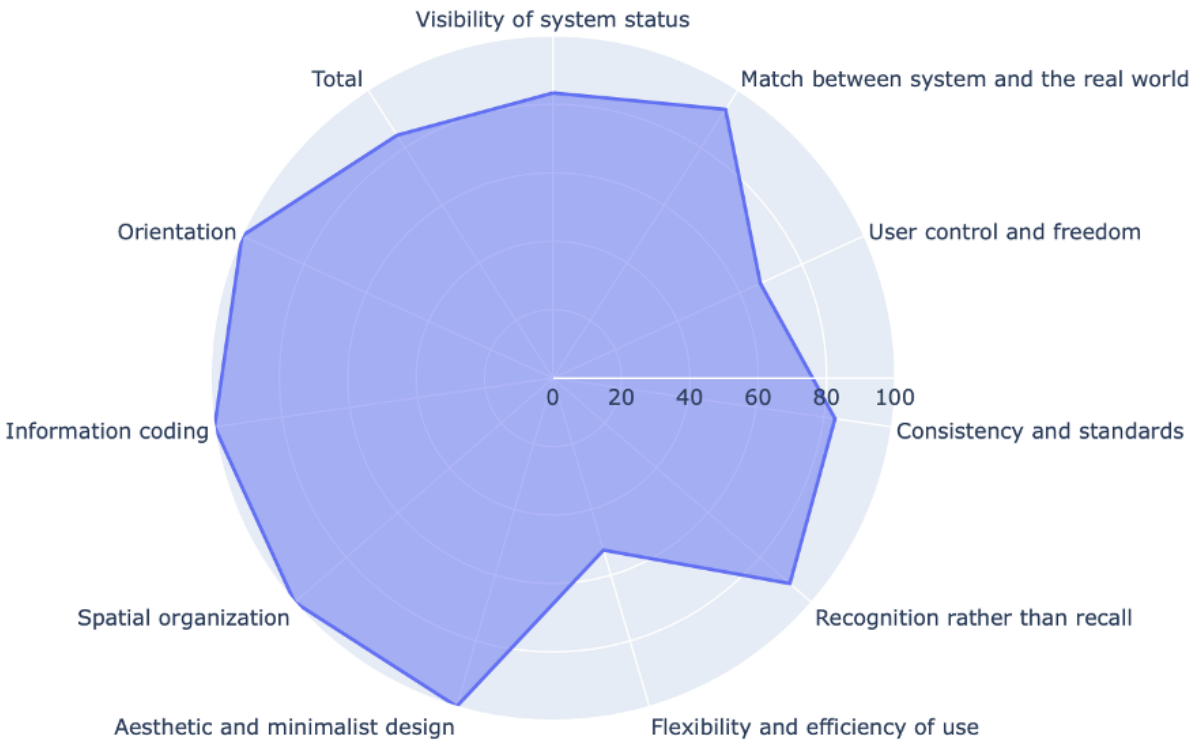


Table . A summary of usability factors with corresponding usability scores. Maximum score is a sum of close-ended questions per usability factor (eg, usability factor #9 had 2 questions, thus its maximum score was 2). E1, E2, and E3 are the scores assigned to each usability factor by each expert (ie, the sum of questions answered as yes by E1, E2, and E3). The result is the mean score divided by the maximum score, displayed as a percentage. Total is the overall usability score.

ID	Usability factor	Maximum score	E1	E2	E3	Mean score	Result (%)
1	Visibility of system status	6	5	5	5	5	83
2	Match between system and the real world	5	5	5	4	4.7	93
3	User control and freedom	5	4	3	3	3.3	67
4	Consistency and standards	6	5	4	6	5	83
5	Recognition rather than recall	4	4	3	4	3.7	92
6	Flexibility and efficiency of use	7	4	4	3	3.7	52
7	Aesthetic and minimalist design	7	7	7	7	7	100
8	Spatial organization	3	3	3	3	3	100
9	Information coding	2	2	2	2	2	100
10	Orientation	4	4	4	4	4	100
	Total	49	43	40	41	41	84

XSL•FO
RenderX

The overall severity ratings (Table 6) were in line with the obtained usability scores in most cases. Usability factor #3—user control and freedom was assigned the severity rating of 2 (minor usability problem), while the usability factor #1—visibility of system status was assigned the severity rating of 1 (cosmetic problem only) by all experts. Surprisingly, the usability factor #6—flexibility and efficiency of use, although it obtained the lowest overall usability score, was assigned the severity rating of 0 (no usability problem) by all experts. Several other usability factors were assigned the severity rating of 1 by some experts: usability factor #2—match between system and the real world (E3), usability factor #4—consistency and standards (E1), and usability factor #5—recognition rather than recall (E2). All remaining usability factors were evaluated as 0 (no usability problem).

The majority of usability issues referred to the flexibility and efficiency of use. We found evidence that the system lacked the ability to control display configurations and to hide unnecessary displays. Interestingly, although all participants noticed the lack of the option to hide unnecessary displays, it was not considered essential. According to E1: no buttons to hide or unhide panels, but not sure if the button is necessary. Information is well spread.

This could explain why this usability factor—although it obtained a relatively low usability score—was assigned an overall severity rating of 0 (no usability problem). Yet, as we saw a clear consensus regarding insufficient control of display configurations, we refined the following DP: DP2a: it provides features to support customized views and to control display configurations, so that the system affords examining different aspects of data in drug safety surveillance.

Table . Overall severity ratings assigned by experts (E1, E2, and E3) in heuristic evaluation.[a]

ID	Usability factor	Overall severity rating		
		E1	E2	E3
1	Visibility of system status	1	1	1
2	Match between system and the real world	0	0	1
3	User control and freedom	2	2	2
4	Consistency and standards	1	0	0
5	Recognition rather than recall	0	1	0
6	Flexibility and efficiency of use	0	0	0
7	Aesthetic and minimalist design	0	0	0
8	Spatial organization	0	0	0
9	Information coding	0	0	0
10	Orientation	0	0	0

[a] A score of 2: minor usability problem, 1: cosmetic problem only, 0: no usability problem.

Feedback also suggested that the system lacked clear exit options and a universal undo function, hindering user control and freedom. We also found support for the utility of the reset button; however, some participants noted that it did not deselect all elements when clicked. Regarding the visibility of system status**,** participants pointed out insufficient system feedback on its status. E3 identified a lack of visual feedback when selecting elements on some graphs. Although this action affected histograms, it was not communicated to the user. Similarly, E2 identified missing information on year selection in the detail section. Finally, concerning the consistency and standards**,** participants noted the absence of visual cues to identify active screens. E2 struggled to identify active screens when navigating between the main and download pages.

As a future agenda, we recommend implementing enhanced user control over display configurations, options to hide unnecessary displays, and adding a back or undo button. The functionality of the reset filters button should be improved to uniformly remove selections. Better feedback on the system status, like displaying selected years in the detail section, is crucial. Prompts and visual cues (eg, the event search box) should be placed where the eye is likely to be looking. Finally, all interactive elements (eg, the histogram and the first line graph) should provide feedback upon selection.

Discussion

DPs and the Value of Affordance Theory in This Study

Following the DSR methodology, we were able to empirically test and refine the initial, theory-driven DPs, by iteratively juxtaposing the results of experimental prototyping with theory-grounded, conceptual design recommendations. Consequently, we prove that the iterative translation of evaluation outcomes into prototype features results in refined design guidelines that could lead other practitioners in similar domains.

XSL•FO
RenderX

Throughout the study, we applied the affordance lens pragmatically: target affordances remained stable while prototype features were iteratively refined to instantiate them, which is in line with the view of Iivari [79] and Chandra et al [53]. Table 7 summarizes each principle in terms of user activity (affordance), enabling features (material properties), and the boundary conditions.

Table . The final list of refined design principles.

Design principle	Revised content
DP1a	Provide features to address the bootstrap problem, add walkthrough videos and explain dashboard elements, so that the system affords immediate use of the dashboard in drug safety surveillance
DP1b	Provide features to describe possible causality between variables and signalize uncertainty behind DPA[a] results in different ways, so that the system affords identification of patterns and trends in drug safety surveillance
DP1c	Provide features to track changes in the variables and highlight their utility, so that the system affords tracking of the progression of relevant states in drug safety surveillance
DP2a	Provide features to support customized views and to control display configurations, so that the system affords examining different aspects of data in drug safety surveillance
DP2b	Provide overview and details, while controlling overview-to-detail ratio, so that the system affords exploring data of different granularity levels in drug safety surveillance
DP2c	Provide features that stimulate attention, place important elements on the top-left area of the dashboard, and promote scrolling over pagination, so that the system affords improved attention management while using the dashboard in drug safety surveillance
DP3a	Provide features to create public values, so that the system affords users' engagement in dashboard use in drug safety surveillance
DP3b	Provide features to support decision-making and cluster them by the needs of distinct user groups, so that the system affords users to evaluate what-if scenarios and consider different alternatives in drug safety surveillance

[a]DPA: disproportionality analysis.

Addressing Existing Research Gaps

Our literature review identified pharmacovigilance systems that did not sufficiently incorporate user requirements, with resulting usability shortcomings [17,18,32]. We respond to this by using the DSR as a methodology. Additionally, this research gap was closely related to the bootstrap problem and DP1a (designing for direct use). We tackled the bootstrap problem in 2 ways: first, by including the requirements gathering phase in the design cycle, we increased the probability of addressing the real needs of users and therefore solving the right problem; second, by giving the users the opportunity to engage with the prototype in the initial stages of development, we initiated its use from the early versions. This positively affects the quality of the prototype and increases the chances of its successful adoption in the future. By iteratively responding to users' needs and targeting usability issues, we built a high-fidelity prototype that is usable for the evaluated tasks and user groups (overall usability score: 84%) and is designed to support sustained use; broader deployment remains future work.

We previously identified the lack of data mining techniques as a limitation of some of the systems for pharmacovigilance [17,21-23]. We suggested this was an important research gap to address, related directly to DP1b (causality between variables). We implemented DPA evaluation in the dashboard by including the information on potential safety signals [80]. We emphasized the uncertainty behind these results in multiple ways to make sure users were aware of their interpretation. Finally, the advantage of our prototype comes with improved visualization techniques. To that end, we followed the guidelines for visual dashboards by Bremser and Wagner [61] when deciding on visualization elements and features.

Consistent with DP3b ("cluster features by the needs of distinct user groups"), we view clinicians and pharmacists, researchers, and public users as distinct personas requiring layered functionality and language; our present DSR cycles cover the latter 2 groups (public users and research professionals), and clinician-facing tailoring should be undertaken in subsequent evaluations by others. In addition, regulatory decision-makers, policy analysts, and global health agencies represent further personas aligned with DP3b; though not evaluated here, they are recognized within our stakeholder scope and remain outside this study's boundary conditions.

Creating Public Value

Here, we articulate how the DPs and their instantiation can create public value when scaled and deployed in appropriate contexts; in this study, we assess feasibility and task-level usability rather than population-level impact.

XSL•FO
RenderX

We previously reviewed systems for pharmacovigilance that use proprietary databases or other data sources limited in diversity of stored information, volume, and availability [14-16,27,28]. To respond to this gap, related directly to DP3a (public value), we based the prototype on rich, open-access datasets with safety reports registered worldwide. In addition, both the code and the prototype are open-source and made available online, potentially contributing to the pharmacovigilance community. Moreover, through improved visualizations, we aim to enhance understanding and encourage users' active participation in interpreting the information.

To counter the misinformation during the COVID-19 pandemic, Murthy [81] recommends addressing information deficits where there is a high public interest but limited quality information available. Additionally, the author advocates for the modernization of public health communications by developing new, credible, and evidence-based online tools to effectively convey information to communities. By providing transparent and accurate drug safety data from reliable sources, our system may contribute to fighting misleading information and negative attitudes toward medication.

Our system is also a step forward in a higher degree of patient empowerment (the restoration of patients' access to public health data) and patient participation (the ability of patients to receive drug safety information and act upon it). In line with our findings, drug consumers could use the prototype for direct comparison of drugs with the same active compound, but produced by different manufacturers. Generic drugs (drug equivalents), although chemically the same as brand-name drugs (drugs produced by the pharmaceutical company that discovered them, protected by the patent), are often negatively perceived by drug consumers [82-84]. This is due to misbeliefs about brand-name drugs being better medicines per se.

There is strong evidence that, through a variety of incentives, medical doctors are influenced by pharmaceutical companies on which drugs to prescribe [85-88]. Physicians often enter contractual relationships with vendors, the latter being mostly representatives of brand-name drug companies, rather than cheaper generic drugs [89]. We suggest that by having a tool to directly compare primary safety profiles of drugs and their alternatives at hand, doctors may be encouraged to make more ethical decisions on their choice of collaboration with pharmaceutical companies.

Enhancing the Decision-Making

We integrated exportable DPA files into the prototype, considering them the main enabler of decision-making. When combined with data visualizations, this feature can significantly benefit pharmacovigilance professionals, including those affiliated with pharmaceutical industry or research institutes. These same affordances are pertinent to policy analysts and global health agencies, who require transparent, auditable summaries and cross-jurisdictional trend overviews. Detecting unusual or previously unknown drug-ADR associations is a first step in drug safety investigations [23,90]. Identified signals prompt further research, influencing actions such as product labelingchanges or potential drug withdrawal [91].

Regulatory bodies such as FDA, WHO, and EMA systematically monitor drug safety signals. Unusual associations undergo thorough scrutiny, involving literature reviews, clinical study revisions, and exploration of biochemical mechanisms. Results are compared with product information, and pharmaceutical companies are asked to provide relevant data, promoting higher industry accountability [91,92].

Contributions

Theoretical Contribution

Our work contributes to the prescriptive knowledge [93] by providing a list of refined, empirically-driven DPs. We suggest that, by delineating DPs, our work puts forward general design recommendations in similar solution domains. These can be extrapolated to a class of similar problems concerned with data visualization in pharmacovigilance. We do not claim the DPs are completely generalizable to other settings. Instead, they are put forward with the ambition to lead research on similar problems in wider contexts.

To our knowledge, there is no previous research that uses DSR methodology in designing dashboards for pharmacovigilance. By engaging in the DSR cycle, we were able to define affordances for similar systems, contributing to better understanding of the problem domain. These were (1) prompting users to engage with the dashboard (enabled by improved usability and attention management), (2) aiding analysis of what-if scenarios to support decision-making processes, (3) presenting data from different angles and at multiple granularity levels to examine its different facets, (4) showing changes in relevant variables over time, and (5) creating public value through generated insights.

Finally, we contribute to DSR by providing insights into how different requirements gathering and evaluation methods can support the development of visualization dashboards. While no claims can be made about the validity of these findings to other systems, we hope the techniques proposed here can be a useful instrument for identifying design issues early in the prototype development.

Practical Contribution

The practical contribution of our study lies in the developed artifact, publicly available online. Our system can be used by researchers and practitioners in pharmacovigilance, upon refinements. The code is open-source [94] and others can repurpose or reuse the scripts as partial solutions or inspiration for their projects. Though we confined our prototype to 5 drugs and 500 secondary events, the code can be adapted to an infinite number of drugs or secondary events to suit others' needs. For larger multisource deployments, the ETL and DPA steps can be executed in batches without altering the front end. Because the user interface consumes flat exports, the prototype can be reproduced in fully open-source dashboards or a custom front end.

The prototype is intended to demonstrate and operationalize the DPs. While usable for the studied tasks, broader public deployment requires the scale-up steps outlined in the next section. Any public-facing release by adopters would also

XSL•FO
RenderX

require clear plain-language disclaimers and risk communication for lay users, basic accessibility compliance, and a documented support pathway; these deployment activities are outside the scope of this study.

Our project however can be considered a hybrid open-source considering our reliance on the Tableau, which is a proprietary software. Table 8 provides an accurate description of the hybrid nature of our project with its respective components.

Finally, we do not claim full generalizability. The DPs are intended as reusable, prescriptive heuristics for similar dashboards within the stated boundary conditions; adaptation to clinician and pharmacist-facing workflows and additional user groups should be iteratively refined in those settings.

Table . Open-source status of project components.

Component	Status	Implication
Data	Open source	Fully accessible and usable by anyone
Code	Open source	All transformation and analysis code (eg, Python or R scripts) is on GitHub under an Open Source Initiative–approved license, allowing others to reuse and modify it
Dashboard prototype	Proprietary/Open access	The dashboard itself is viewable and accessible to anyone via Tableau Public (making it "open access"), but its dependency on proprietary Tableau software means others cannot easily reproduce, fork, or host a modified version without their own Tableau software or an equivalent proprietary viewer

Limitations and Future Research Agenda

This study has some limitations. First, drug safety surveillance can be viewed differently, leading to different affordances than those outlined here. Second, the DSR cycle could be extended to yet another phase. Iivari et al [95] proposes a framework for DPs evaluation in terms of their reusability: through the criteria of accessibility, importance, novelty, actability and effectiveness. Similarly, empirical testing of how revised DPs apply to other settings could be done through their repeated application in different boundary conditions [52]. Future research could address these issues to test the quality of the outcomes of this DSR project. Third, to support broader use, the prototype should be expanded to all FDA drugs and events via direct application programming interface calls [21].

Establishing readiness for broad public deployment of the prototype will require expanded datasets and multisite evaluations beyond the scope of this study. Moreover, including data from other databases (eg, EudraVigilance and VigiBase) would improve DPA evaluation, but requires (1) source-specific mapping into the common schema, (2) robust cross-repository deduplication, and (3) compliance with licensing and governance constraints. If further deployments are undertaken, evaluation can focus on user engagement, operational reliability, and decision support alignment with expert assessments, as these activities are beyond this study.

Relatedly, in the final prototype version, we keep shortcuts and advanced controls to a minimum to maintain clarity for nonprofessional users. This design choice explains the lower expert scores on flexibility, efficiency of use, and user control and freedom, which were nevertheless judged as low-severity issues. For expert-only deployments, future implementers can add more controls and configuration.

Importantly, our participant sample represented young and digitally proficient (late 20s to mid 40s), and several nonexpert participants held technical or professional roles (eg, data science, biomedical engineering, and humanitarian logistics). This sampling may limit generalizability to older adults and individuals with lower digital health literacy [96]. Older adults are more likely to experience polypharmacy [97] and may have distinct interaction needs (eg, larger text, higher contrast, simplified and error-tolerant interactions) [98], which we did not assess in this study. Future independent evaluations should specifically include older adults and lower-literacy users and consider accessibility guidance (eg, larger typographic scales, high-contrast palettes, and keyboard navigability) when adapting the dashboard for these groups.

Relatedly, some nonprofessional users found data mining terms challenging even when aided by tooltips and tutorials. The present prototype mitigates this by using plain-language labels, info icons, an "About this App" section, and by keeping advanced formulas in downloadable files; however, residual risk of misinterpretation remains. We therefore reiterate that DPA supports hypothesis generation rather than confirmation and should be interpreted cautiously by lay audiences. To reduce potential user anxiety, we emphasize this uncertainty in plain language and signpost users to seek professional advice for individual decisions. However, we did not evaluate affective outcomes (eg, worry and decisional conflict) among lay users; given the potential for spontaneous report dashboards to provoke anxiety, such outcomes should be assessed in independent evaluations by others.

Furthermore, it would be beneficial to implement a higher variety of data sources: scientific literature, clinical studies or data from text mining [20]. Also, the prototype would benefit from comprehensive benchmarking, such as head-to-head comparisons with existing pharmacovigilance tools on performance, cost, or user satisfaction. Future work could also

XSL•FO
RenderX

expand DPA methods to improve the validity of detected safety signals. Integrating and systematically evaluating additional machine learning approaches for ADR signal detection could enhance analytical breadth and validate performance across settings.

Finally, integration into health care IIs (eg, electronic health records) was outside the scope of this DSR prototype. The artifact targets public FDA data and does not process identifiable patient records. Any operational deployment by adopters would require institutional governance (eg, data use agreements, access control, auditability, and security increase) and, where applicable, compliance with jurisdictional regulations. The use of standard terminologies, decoupled Python scripts, and portability to open source (Multimedia Appendix 2) is intended to ease such translation, but we do not evaluate these deployment aspects here.

Conclusion

In this study, we applied the DSR cycle to investigate the design of visual dashboards to support activities within pharmacovigilance. To that end, we identified required affordances, developed corresponding DPs that satisfied them, and demonstrated their implementation, showing that they brought about expected outcomes. The developed DPs are anticipated to be applicable in various pharmacovigilance settings. Finally, we hope our research will be a catalyst of further research in similar domains.

Abstract

Background: In the evolving landscape of health care, data use plays an ever-increasing role in health care IT. However, data are often siloed and uncoded free text distributed across several IT systems. This paper introduces a health knowledge management platform, designed to integrate, harmonize, and enable reuse of health care and medical research data. The platform aims to bridge the gap between research and patient care, showcased through real-world scenarios, emphasizing data harmonization and knowledge management within a health care institution. The study is based at the University Hospital Schleswig-Holstein.

Objective: The main objective of this project is to design, implement, and evaluate a knowledge management platform that integrates health care and biomedical research to support use cases in both domains.

Methods: The study describes the “health knowledge management platform” designed to access and gain knowledge from health care and medical research data. We performed several rounds of focus groups with stakeholders to elicit the platform requirements. In the process, we identified key aspects of the platform. From the functional requirements, we designed an architectural concept. The platform evaluation follows the Framework for Evaluation in Design Science Research and International Organization for Standardization/International Electrotechnical Commission (ISO/IEC) 25010 standard with a focus on key aspects identified and real-world scenarios. Two application scenarios, cardiology and radiology, are selected for a requirement-based, qualitative evaluation.

Results: We show that our health knowledge management platform is capable of integrating diverse data formats like Health Level 7 Version 2 messages, CSV exports, and Digital Imaging and Communications in Medicine. It currently integrates over 46 million admit, discharge, transfer messages, 38 million imaging studies, and structured clinical data for approximately 1.5 million patients. The platform supports different scenarios based on its 5-layer architecture, including a clinical data repository and services like Master Patient Index and Consent Management. The evaluation against 39 predefined functional requirements showed our platform’s capability in certain real-world scenarios of cardiology and radiology. Our evaluation demonstrates that the platform covers the majority of the identified requirements to support knowledge management in health care institutions.

Conclusions: Our requirement-based evaluation of the health knowledge management platform at University Hospital Schleswig-Holstein reveals its capabilities, which is possibly leading to better knowledge transfer between patient care and research. The platform’s architecture and standardized data improve the quality of data and facilitate access to knowledge. Ongoing development and potential quantitative measures will further enhance its applicability in dynamic health care landscapes.

Introduction

In modern health care, data play a crucial role in supporting clinical decisions, improving treatment strategies, and enabling clinical research. Clinicians and researchers require access to reliable, structured, and machine-readable data for applications such as clinical decision support systems (CDSS), artificial intelligence (AI), and federated learning models [1-4]. However, in many hospitals, data remain siloed and poorly coded and exist often in free-text formats within the hospital information systems. These silos limit data reuse, complicate integration, and limit the deployment of intelligent systems that depend on structured and consistent inputs [5-7]. Additionally, the coexistence of multiple interoperability standards adds to the complexity of data integration and management [8,9].

However, instead of focusing only on technical interoperability between systems, hospitals need platforms that structure, harmonize, standardize, and make data usable across various scenarios [10]. Structured and centrally available data are a central prerequisite for building learning health care systems [11], which aim to improve patient care and research at the same time. Such systems rely on data from diverse sources, such as clinical information systems (CIS), picture archiving and communication systems (PACS), and laboratory information systems (LIS), or data from medical devices, wearable sensors, and mobile apps [12,13]. It is not sufficient to exchange data between systems. Data must be transformed into usable knowledge. This highlights the importance of knowledge management in health care. It shifts the focus from isolated data handling toward creating value from data by organizing, linking, and making it accessible for different stakeholders via an integrated platform. “Knowledge Management is therefore a conscious strategy of getting the right knowledge to the right people at the right time and helping people share and put information into action in ways that strive to improve organizational performance” [14]. This definition shows that the value of data lies not only in its availability but also in its structured, contextualized, and accessible form. There are different kinds of knowledge, but for now, we mainly focus on empirical knowledge. To implement knowledge management in health care settings, a technical infrastructure is needed that ensures interoperability, data harmonization, and support for various applications on a consistent data basis.

The Medical Informatics Initiative funded by the German Federal Ministry of Research, Technology and Space aims toward reliable and fast access to data-centric platforms for biomedical research by setting up (medical) data integration centers (Medical Data Integration Center or Data Integration Center) at the German university hospitals [15,16]. Our approach goes beyond pure secondary use of data by aiming to support both research and immediate patient care. To achieve this, we iteratively develop a health knowledge management platform architecture that not only facilitates structured data integration but also provides interfaces and functionalities, which allow the reuse of data for, for example, clinical decision support and cohort exploration. In doing so, it contributes to a future-ready infrastructure for emerging applications such as AI-driven analytics, personalized medicine, or federated learning.

The main objective of this project is to design, implement, and evaluate a knowledge management platform that integrates health care and biomedical research to support use cases in both domains. Therefore, the three subobjectives are (1) to identify the requirements of such a knowledge management platform, (2) to design an architectural concept for the knowledge management platform based on the requirements, and (3) to implement and qualitatively evaluate the platform against the requirements.

Methods

Ethical Considerations

The referenced studies were carried out in adherence with the Declaration of Helsinki and approved by the local medical ethics committees of Kiel University (approval B279/18 and D596/22). Informed consent was obtained from all of the participants in the studies.

Overview

Our methodology is based on the Framework for Evaluation in Design Science Research (FEDS) by Venable et al [17], which describes the process from defining the problem, through deriving a solution based on requirement engineering (RE), evaluating the platform, and communicating the outcomes.

Framework for Evaluation in Design Science Research

The FEDS consists of 4 components: problem, solution, evaluation, and communication.

Problem

The first step involves identifying and understanding the challenges related to siloed and insufficiently structured and coded health care data in a university hospital setting. Much of the clinical information is documented in unstructured formats such as free text or PDF documents. These are often embedded in hospital information systems, which limits accessibility and reuse [17]. Additionally, relevant data are distributed across various primary source systems, complicating semantic interoperability and secondary (research) use. Moreover, structured and centrally accessible data are essential prerequisites to enable future applications such as AI-based decision support or federated learning approaches [18].

Solution (via RE)

Overview

The second step of the FEDS focuses on designing and developing an effective artifact to address the identified problems. In the FEDS context, an artifact can refer to a tangible or intangible entity—such as software applications, system architectures, databases, protocols, guidelines, or frameworks—created or modified as part of the solution development process [17]. In this study, the solution is our health knowledge management platform, designed to integrate structured and unstructured, alphanumeric, and multimedia health care data while harmonizing them. The platform is further designed to improve interoperability, thereby creating a unified data management environment for both health care and research-related applications. Therefore, the development was

XSL•FO
RenderX

preceded by a systematic RE process to capture and formalize the platforms' functional needs.

RE Process

We used a structured RE approach to define the platform architecture [19,20]. From 2019 to 2024, we conducted multiple focus groups with a total of 27 stakeholders, covering a broad spectrum of roles and expertise:

- Strategic and technical leadership: including the chief digital officer and the heads of the Medical Data Integration Center.
- Technical and domain experts: such as specialists in metadata management, data integration, interoperability standards (eg, Health Level 7 [HL7] Fast Healthcare Interoperability Resources [FHIR], openEHR, and Digital Imaging and Communications in Medicine [DICOM]), and terminologies (eg, Systematized Nomenclature of Medicine—Clinical Terms, *International Classification of Diseases and Related Health Problems, 10th Revision, German Modification* [*ICD-10-GM*], Anatomical-Therapeutic-Chemical, and Logical Observation Identifiers Names and Codes [LOINC]).
- User representatives: including pharmacologists, an anesthesiologist, biobank directors, and data privacy specialists.
- Scenario-specific stakeholders: such as cardiologists, radiologists, a neurologist, a nephrologist, and a sleep medicine specialist who acted as product owners for the real-world evaluation.

The interdisciplinary composition of the focus groups ensured alignment with strategic goals and operational needs. Iterative discussions and repeated validation reasonably support the assumption that thematic saturation is achieved, in line with the approach described by Vasileiou et al [21].

The discussions were guided by the central question: "Which functions should the knowledge management platform provide to support health care and biomedical research?" [22,23]. Session results were summarized in a mind map (Multimedia Appendix 1) and clustered into thematic areas: data management and persistence, architecture, Findable, Accessible, Interoperable, Reusable principles [24], AI, data and information extraction, health telematics and regional integration, integration of research and patient care data, general knowledge integration, and integrated frontends.

Using this structure, we mapped each of the identified key aspects to functional requirements, which we derived from a previously created requirements catalog [25]. Additional requirements were specified using International Organization for Standardization (ISO) 29148 syntax ([Subject] [Action] [Constraint of Action]) [19], for example, "The platform must integrate data." Possible functionalities or solutions are annotated in the respective requirements notes (Multimedia Appendix 1). Disagreements during the requirements elicitation process were resolved through moderated discussions with the RE expert.

Subsequently, we mapped these requirements to the HiGHmed architecture [15] and extended the existing layer model to define our five-layer architecture: (1) source layer, (2) staging layer, (3) normalization layer, (4) data access layer, and (5) application layer, in line with the principle of separation of concerns [26].

Evaluation

The evaluation component involves a requirement-based artifact evaluation of the platform against the identified requirements. The primary focus lies on evaluating the functional aspects identified in the RE process. While detailed benchmarking of nonfunctional qualities (eg, performance or scalability) is beyond the current scope, quantitative insights (eg, volume of integrated laboratory data) are included. We use a technical artifact evaluation strategy guided by the quality model defined in International Organization for Standardization/International Electrotechnical Commission (ISO/IEC) 25010 [27], part of the ISO/IEC 25000 SQuaRE framework. This allows us to focus on relevant quality attributes such as interoperability, reusability, data consistency, and usability (see Key Aspects of the Platform section). The evaluation is accompanied by 2 real-world scenario-based assessments, each chosen for its distinct technical requirements:

- Cardiology: This scenario evaluates the platform's ability to integrate and harmonize structured and unstructured clinical routine data from hospital IT systems (eg, CIS, PACS, LIS, Electronic Prescribing and Medicine Administration [ePMA], and patient-generated health data [PGHD] from mobile apps and wearables for patients with heart failure patients, with a focus on technical integration, interoperability, and traceable data reuse).
- Radiology: This scenario evaluates the platform's functionality in processing imaging metadata and integrating demographic data to enable consent-compliant cohort identification and follow-up planning, focusing on system-level integration and traceability.

To operationalize the qualitative scenario evaluation, we applied different evaluation activities depending on the nature of the requirement and its implementation status. These activities were selected to provide traceable evidence for requirement fulfillment, in line with the ISO/IEC 25000 standard framework. Specifically, the following evaluation activities were used:

- Scenario walkthroughs: used to evaluate end-to-end functionality under real-world conditions.
- System and architecture inspections: used to verify data flows, persistence architecture, and interoperability aspects.
- Log inspections and data audits: applied to confirm the integration of structured and unstructured data (eg, Health Level 7 Version 2 [HL7 V2] and DICOM).
- Conceptual design reviews: used for requirements that have been specified, modeled, or architecturally prepared but are not yet in operational use.

These activities support a systematic evaluation of how well the platform meets the functional requirements derived from the RE process. All evaluation activities were conducted by the institution's Data Integration Unit, a dedicated team of medical informatics experts, data engineers, and platform architects. An additional evaluation scenario is provided in Multimedia Appendix 2.

XSL•FO
RenderX

Communication

The final step involves disseminating results to relevant stakeholders. In our case, we communicate findings through this study and use them internally to inform researchers and clinicians to promote the platform and its functionalities.

Following these structured phases ensures that the platform's development and evaluation align with its goal of enabling interoperability and the effective health care data use across multiple domains by leveraging data integration as a central strategy.

Results

Problem Statement

With more than 500,000 encounters (approximately 100,000 inpatients and approximately 400,000 outpatients) annually and about 17,000 employees, University Hospital Schleswig-Holstein (UKSH) is one of the largest university hospitals in Germany and the only hospital providing maximum medical care in the state of Schleswig-Holstein (Northern Germany) [28]. It operates across 2 locations, Kiel and Lübeck, in partnership with the Medical Faculty of Kiel University and the Medical Section of the Universität zu Lübeck, forming a central hub for academic medicine in Northern Germany.

The current IT system landscape at UKSH consists of different types of information systems. The CIS builds the core of the IT system landscape, provides a general overview of the patient's history, and serves as a basis for documentation and communication across health care domains. In addition, there are specialized department-specific systems, such as radiology information systems (RIS) or echocardiography systems in cardiology. Finally, there are the function-specific specialized systems like LIS and ePMA that support specific workflows or tasks independent of the respective department. The existence of these various systems challenges data integration, harmonization, and coding and requires careful attention to ensure that all necessary information is captured and managed appropriately. The IT system landscape and its limited semantic interoperability between the different systems often result in patient data spreading across multiple systems, sometimes even redundantly. This fragmentation complicates timely access to required information and poses challenges for researchers who require timely access to relevant data, ultimately hindering effective data use and analysis.

Moreover, there is a client separation in health care, with patient care and research operating independently from an IT and data perspective. Typically, clinicians are responsible for treating patients and have access to patient-level data for that purpose only. The processes and IT systems used in patient care are often disjoint from those used for clinical and biomedical research. Accordingly, it is inherent in the nature of these IT systems that they are primarily designed for patient care purposes rather than research, that is, supporting patient-level data access, but not cohort-level access. The organizational separation between patient care and research is partly also mandated by regulation, requiring researchers to obtain patient consent and adhere to additional processes to access the necessary data. As a result, clinicians researching on patient data either request a data export from the clinical IT service provider or manually extract the data via the applications' user interfaces (ie, redundant data entry). Both are time-consuming, highly inefficient, and prone to transmission errors, leading to potential inaccuracies in the data and generating irreproducible research findings. Data exports are often raw CSV files per IT system, which requires manual data linkage and transformations to ensure consistency in units of measurement, as well as annotations with appropriate terminologies before allowing effective data analysis. In addition to the client separation, there is also a significant lack of automatic knowledge transfer between patient care and research. However, there is a demand in patient care for access to the latest scientific discoveries and insights to inform and improve clinical decision-making.

Solution

Key Aspects of the Platform

The focus groups conducted during the requirements elicitation process identified key aspects mandatory for a knowledge management platform. The first set of key aspects relates to the scenarios the knowledge management platform needs to support, which span 3 domains: health care, research enablement, and research or secondary use. For health care, participants emphasized the need to visualize heterogeneous data types (eg, laboratory data, medication data, vital parameters, reports, images, and biosignals). Requested features included patient trajectories and the comparison of patients with similar characteristics. The integration of CDSS and AI, in general, for functionalities like smart alerting was also considered essential. A further requirement, for both scenarios, health care and research, was the inclusion of PGHD, patient-reported outcome measures, and patient-reported experience measures, with patients also having access to their own health data.

For research enablement, three key aspects were mentioned: (1) self-service feasibility analysis based on cohort definitions, (2) prescreening support for clinical trial recruitment, and (3) cohort exploration tools.

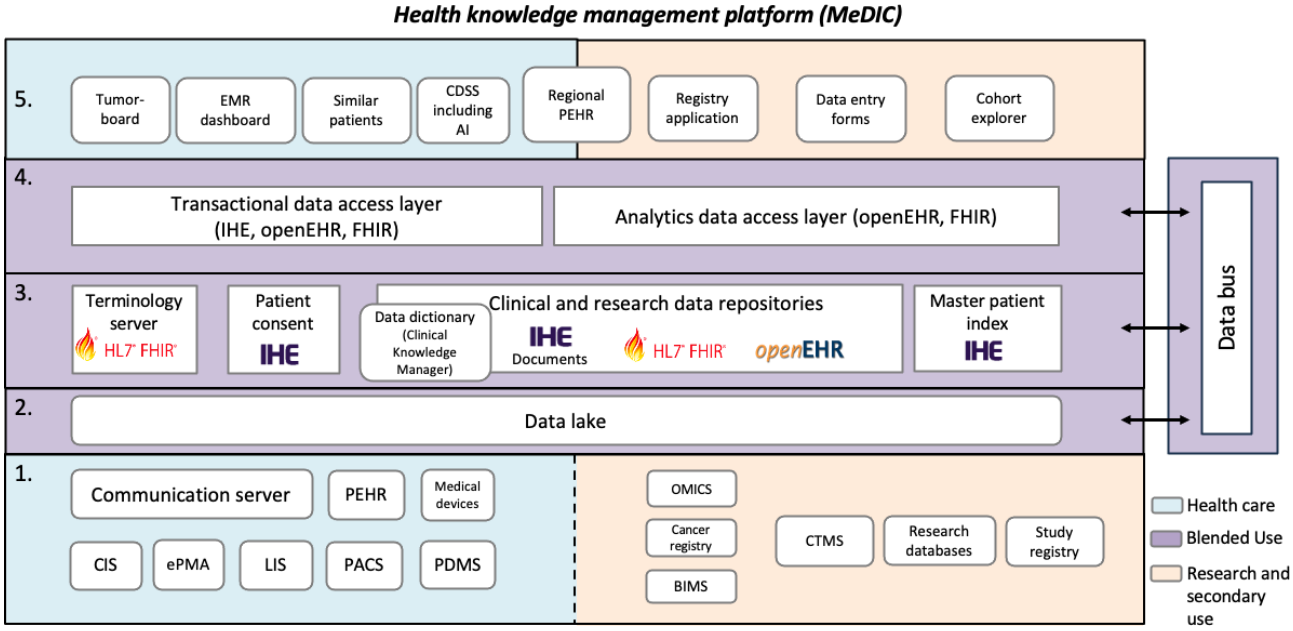
In terms of secondary use, the platform should enable care-connected research, such as research registries, by reducing redundant documentation and enabling seamless reuse of health care data. Researchers should be able to access data directly for analysis purposes or receive data exports.

After defining scenario-based needs, the view of the focus groups shifted to the data perspective. The platform needs to support various data types including structured and unstructured text, streaming data, omics data, and multimedia objects (DICOM and non-DICOM). In addition to clinical IT systems, other data sources must be integrated, including electronic health records, biomaterial information, and research data (eg, Clinical Trial Management System [CTMS]). Prefilling electronic case report forms in the CTMS with care data and integrating research data back into care are desirable. Furthermore, access to data from public sources (eg, literature databases) is requested. The platform should persist raw data on premises to serve as a single point of truth, equipped with a searchable index for data usability from the beginning.

XSL•FO
RenderX

Finally, the security and functional optimization were discussed. A clear separation of concerns is required—distinguishing between fully identifiable data, pseudonymized data, and restricted-use datasets. Raw data must be securely stored and accessible only to a small administrative group. Semantically enriched and pseudonymized datasets free from direct identifiers should be made available for health care applications and research queries. Exported data should be pseudonymized or, if possible, anonymized per project or cohort, enabling external access, for example, via national portals like the German Portal for Medical Research Data [29].

Finally, focus group participants emphasized that end users, for example, health care professionals, researchers, and lecturers, would not prefer to access data directly, but through scenario-specific applications that provide tailored visualizations and functionalities.



Requirements

A total of 39 requirements were organized into 5 distinct layers for the envisioned platform architecture to ensure a structured and modular approach. Specifically, 9 (23%) requirements were assigned to the source layer, 4 (10%) to the staging layer, 15 (39%) to the normalization layer, 2 (5%) to the data access layer, and 9 (23%) newly identified requirements to the application layer. A detailed overview of all 39 requirements and their assignment to the architectural layers is provided in Multimedia Appendix 2.

Description of the Knowledge Management Platform

The knowledge management platform consists of 5 layers and a data bus: source, staging, normalization, data access, and application layer (Figure 1).

Figure 1. Architecture of the health knowledge management platform of UKSH MeDIC with its five layers: (1) source layer, (2) staging layer, (3) normalization layer, (4) data access layer, and (5) application layer. BIMS: Biomaterial Information Management System; CIS: clinical information system; CTMS: Clinical Trial Management System; EMR: electronic medical record; ePMA: Electronic Prescribing and Medicine Administration; FHIR: Fast Healthcare Interoperability Resources; HL7: Health Level 7; IHE: Integrating the Healthcare Enterprise; LIS: laboratory information system; MeDIC: Medical Data Integration Center; PACS: picture archiving and communication system; PDMS: patient data management system; PEHR: personal cross-enterprise health record; UKSH: University Hospital Schleswig-Holstein.

Source Layer

The source layer contains all health care and research IT systems from which data are integrated (DA-01; see Key Aspects of the Platform section). Health care systems include CIS, LIS, ePMA, PACS (including multimedia data from radiology, cardiology, neurology, and gynecology; DA-03), patient data management system, personal cross-enterprise health record (PEHR; DA-07 and DA-08-3), and medical devices. Research systems include a clinical cancer registry and tumor documentation system, a Biomaterial Information Management System, a CTMS, systems for generating and analyzing OMICS data, research databases, and a local study registry. The CTMS supports the data entry process in clinical trials, but also the management of study appointments, participants, and electronic case report forms. The local study registry contains all studies running at USKH including eligibility criteria to support the prescreening for clinical trials in the future. These studies can be integrated from national and international study registries like ClinicalTrials.gov or drks.de (DA-27) [30]. Data are transferred via interfaces (eg, HL7 V2) and a communication server to the data lake (see Staging Layer section; DA-02) or exported and stored consistently into the data lake (DA-01-4). Data types range from structured (eg, laboratory reports; DA-01-4) to semistructured and free-text (eg, discharge letters; DA-01-3) and multimedia data (eg, computed tomography [CT] images; DA-03).

Staging Layer

The staging layer consists of a central data lake with analytical processing capabilities (DP-02) [31], supporting both batch and message-based (streaming) data (DP-07). Data flows are orchestrated using Apache NiFi. Incoming data are first persisted in S3 buckets (DS-03) to ensure reliability and data provenance (DS-02-2). A Master Patient Index Identifier is requested from

XSL•FO
RenderX

the Master Patient Index (MPI) in the normalization layer and replaces the hospital's patient identifier in all processed records or data (DP-20-3, DP-20-5, and DP-21). Subsequently, data are indexed in Elasticsearch to enable searchability and discovery (DS-13) and forwarded via the data bus. Unlike the source layer, the staging layer processes both health care and research domains (blended use).

Data Bus

The data bus is built on Apache Kafka and enables scalable, topic-based data distribution for both health care and research data [32]. Topics may contain either full data records or references (eg, images or electrocardiography [ECG] paths) for downstream retrieval.

Normalization Layer

The normalization layer provides harmonization and standardization of data from internal (eg, CIS) and external sources (eg, PEHR; DP-19). It includes the MPI, Patient Consent Manager (PCM), clinical and research data repositories, and a terminology server, based on interoperability standards, including HL7 FHIR, openEHR, DICOM (DP-23), and Integrating the Healthcare Enterprise (IHE). Patient identity management is handled via the MPI (DP-20-3 and DP-20-5) compliant with IHE Patient Identifier Cross-Referencing [33] and IHE Patient Demographics Query (DSC-04) [34]. The PCM manages and distributes versioned broad consents to authorized downstream systems (DAS-13) [35]. Patient-referenced metadata (DP-21) are stored in an openEHR-based clinical data repository (DS-02-2, DS-05, DS-08, and DP-33-1), while nonpatient-referenced data, such as study metadata or data about drugs, are maintained in a FHIR-based repository (DS-02-2, DS-05, DP-06, and DP-33-1). OpenEHR compositions may additionally be persisted as IHE Cross-Enterprise Document Sharing (XDS) documents (DP-33-1). The CDR is queried via openEHR Archetype Query Language (AQL), and its data models are openly accessible and managed in a clinical knowledge management tool (MDM-01) [36], while FHIR models are provided via Simplifier [37].

The terminology server supports mapping of local codes to standardized terminologies such as LOINC (eg, for laboratory data), *ICD-10-GM*, and Systematized Nomenclature of Medicine—Clinical Terms (DP-01). It provides versioned terminologies and FHIR ConceptMaps to ensure semantic interoperability across systems (DP-01) [38].

Data Access Layer

The data access layer includes transactional and analytical interfaces. The transactional data access layer supports persistence and retrieval via openEHR, FHIR, and IHE-based application programming interfaces, while the analytical data access layer supports cohort-based queries and research-driven analysis (DAS-03). Data exchange between the data lake, CDR, and project-specific data marts is handled via the data bus (DAS-12).

Application Layer

The application layer provides end-user applications that access clinical and research data via the data access layers. In the health care domain, this includes a Molecular Tumor Board (MTB) application that supports preparation for MTB sessions by providing access to patient-level data including imaging, clinical, and OMICS data (DR-01 and DR-03-3) [39]. An Electronic Medical Record Dashboard offering unified patient-level views (DR-01, DR-03, and DR-04) and a "Patients like mine" similarity application (DR-03-1, DR-03-2, and DR-03-3) [40,41] are planned, as well as various CDSS including AI-based tools. A regional PEHR application (DA-07) to integrate PGHD from smartphones, wearables, body sensors, and self-reported data via FHIR (DA-18) was tested and evaluated in a proof-of-concept. Research-oriented applications include structured data entry forms (DR-01), registry integration (DR-01) [42], and cohort explorer for feasibility analysis (DR-02) and data requests (DR-01 and DR-05). Access to data based on use requests is governed via consent management (DAS-13 and DSC-04). A centralized user management system is integrated with the hospital identity management system (DSC-12).

Evaluation

Overview

The evaluation assesses the platform against the previously identified functional requirements. We conducted scenario-based evaluations in 2 distinct medical domains to cover a broad range of technical and research-related requirements. The primary results from the cardiology and radiology scenarios are presented below, with an additional neurology scenario provided in Multimedia Appendix 2.

Clinical Routine Data in a Cardiology Scenario

The cardiology scenario evaluates the platform's technical integration, traceability, and reuse of structured clinical data for patients with heart failure, integrating routine care data [15]. The evaluation focuses on system-level interoperability and requirements fulfillment rather than on clinical effectiveness, patient outcomes, or therapeutic impact.

Patient data were processed under a study-specific consent, covering electronic medical record reuse (ethics approval obtained at Kiel University B279/18). Clinical data from CIS, LIS, and ePMA were integrated (DA-01). Demographic, laboratory, and anamnesis data (DA-01-2 and DA-01-3) were ingested as HL7 V2 admit, discharge, transfer (ADT) and observation result unsolicited (ORU) messages from the hospital's communication server (DA-01 and DA-02), while medication data were imported via CSV exports. Data were persisted in the staging layer (DS-13) and semantically harmonized using standardized terminologies such as LOINC, Anatomical-Therapeutic-Chemical, and *ICD-10-GM* (DP-01). Follow-up and echocardiography data were captured via openEHR-based data entry forms (DR-01) [43,44]. Cross-system record linkage and separation of identifying and medical data were ensured via the MPI (DP-20-3, DP-20-5, and DSC-04), with metadata stored for traceability in the openEHR-based CDR (DS-02-2 and DS-03), including the technically implemented ingestion of PEHR-derived structured data (DA-08-3) as a proof-of-concept. In addition, sensor-derived PGHD, including heart rate and activity measurements recorded via wearable devices, were transmitted as FHIR resources from

XSL•FO
RenderX

a mobile app to the PEHR and ingested into the platform (DA-18, DA-07, and DA-08 - 3) and linked via the MPI (DP-21 and DP-19) as a technical proof-of-concept.

Finally, structured data corresponding to metadata from 710 patients were transformed into validated openEHR templates (DP-06, DP-23, and DP-33-1) and persisted in the openEHR-based CDR (DA-01-4, DS-05, DS-08, and DP-21) [43-47], derived from more than 38,000 HL7 messages (DA-01, DA-02, and DP-07). All openEHR templates were validated with clinicians and published (DP-23) [36]. The resulting dataset was queried using AQL and exported as a CSV file for analysis (DAS-12 and DR-05).

Thus, the scenario meets 26 of 39 (67%) platform requirements. The evaluation activities and corresponding evidence at the requirements level are detailed in Table 1. A consolidated assessment of the resulting quality attributes according to ISO/IEC 25010 across both scenarios is summarized in Table 2.

XSL•FO
RenderX

Table . Alignment of platform requirements with scenarios.

Requirement ID	Layer	Description	Implemented in platform	Evaluation activity	Evidence or outcome
DA-01	SrcL[a]	The platform must acquire data from different heterogeneous source systems.	✓[b]	Scenario walkthrough (cardiology, radiology)	Successful ingestion of HL7 V2[c] (ADT[d]/ORU[e]) DICOM[f], and CSV data from CIS[g], LIS[h], and PACS[i] persisted as records in the data lake
DA-01 - 2	SrcL	The platform must acquire structured alphanumeric EHR[j] data.	✓	Log inspection (cardiology)	2902 laboratory reports acquired from HL7 V2
DA-01 - 3	SrcL	The platform must acquire unstructured alphanumeric EHR data.	✓	Cardiology scenario	1016 anamnesis forms acquired
DA-01 - 4	SrcL	The platform must acquire data from heterogeneous sources in a consistent manner.	✓	Technical architecture inspection	HL7 V2, CSV, FHIR[k], and DICOM processed through standardized ETL[l] pipelines and stored in uniform data structures within the data lake and CDR[m] (verified via ETL configuration and storage inspection)
DA-02	SrcL	The platform must acquire structured data based on interoperability standards from the IT and health care domains.	✓	Scenario walkthrough	Incoming data received via HL7 V2 (ADT, ORU, BAR[n]) messages from, eg, CIS and LIS
DA-03	SrcL	The platform must acquire multimedia data from various domains.	✓	Radiology scenario; ingestion test	CT[o] DICOM successfully retrieved from PACS (including data from, eg, radiology, cardiology, neurology, and gynecology) and stored in the platform [48]
DA-07	SrcL	The platform must acquire data from cross-institutional sources.	✓	Cardiology PGHD[p] ingestion in PEHR[q] (technically implemented)	FHIR-based PGHD integration pipeline from external medPower to PEHR to the platform, verified by successful ETL execution and persisted openEHR compositions in proof-of-concept
DA-08 - 3	SrcL	The platform must acquire data from personal health records with all of the following nature: * structured * unstructured.	✓	Cardiology PGHD workflow	Structured FHIR resources generated from Apple HealthKit; transmitted via PEHR, transformed into openEHR compositions, and stored in CDR (verified by stored compositions in proof-of-concept)

XSL•FO
RenderX

Requirement ID	Layer	Description	Implemented in platform	Evaluation activity	Evidence or outcome
DA-18	AppL[r]	The platform must acquire data from (FHIR-based) apps.	✓	Cardiology scenario	Successful ingestion of FHIR data from HealthKit (Apple Watch) via medPower and PEHR; ETL implemented to map to openEHR in proof-of-concept
DA-27	SrcL	The platform must integrate data from public sources.	TBD[s]	Conceptual design review	Functionality not yet implemented due to regulatory prerequisites
DP-07	SL[t]	The platform must process data from data streams.	✓	Cardiology scenario	HL7 V2 data streams (ORU, ADT, and BAR) processed weekly
DS-02 - 2	SL	The platform must store both data and metadata from multiple sources in a single storage.	✓	System inspection	HL7[u], DICOM, and CSV data including metadata, persisted in S3 storage and indexed via Elasticsearch (verified by storage inspection)
DS-03	SL	The platform must store the original data.	✓	System inspection	Original HL7 and CSV files stored in S3 buckets for traceability (verified by storage inspection)
DS-05	NL[v]	The platform must store data in a data repository.	✓	System inspection	Structured data stored in openEHR-based CDR; ~1.5 million patient records integrated (verified by storage inspection)
DS-08	NL	The platform must store the data in a way that it is available in a clinical data repository.	✓	Scenario execution (all)	AQL[w] queries executed on CDR returned structured longitudinal patient data, enabling cohort identification in both scenarios (verified via query results)
DS-13	SL	The platform must store data in all of the following ways: * full-text indexed * searchable.	✓	Technical inspection	Full-text indexing via Elasticsearch; supports full-text search (verified via query results)
DP-01	NL	The platform must process data by mapping it to multiple terminology standards.	✓	Cardiology scenario	LOINC[x], ATC[y], and ICD-10-GM[z] applied during ETL for laboratory, medication, and diagnosis data (verified via query results)
DP-02	NL	The platform must process unstructured data by using natural language processing (NLP) methods.	TBD	Conceptual design review	NLP functionality conceptually designed but not implemented

XSL•FO
RenderX

Requirement ID	Layer	Description	Implemented in platform	Evaluation activity	Evidence or outcome
DP-06	NL	The platform must process all of the following: * data * metadata.	✓	System design inspection	Metadata extraction from HL7, DICOM, CSV; structured storage of both in openEHR CDR (verified via query results)
MDM-01	NL	The platform must provide metadata management (tools).	✓	Scenario execution (radiology)	Imaging metadata stored, searchable via DICOM tag filters (verified via query results)
DP-19	NL	The platform must link external data with local data.	(✓)[aa]	Conceptual design review	PGHD from patients linked via MPI to clinical data in proof-of-concept
DP-20 - 3	NL	The platform must process data by linking it to at least 1 of the following Master Patient Indexes: * institutional * cross-institutional.	✓	Scenario execution (all)	MPI links data across systems; contains 2.3 million patient identities
DP-20 - 5	NL	The platform must process data by using at least 1 of the following IDs: * locally unique record ID * locally unique case IDs.	✓	Scenario execution (all)	Local patient IDs used in MPI, mapped to MPI-ID for further identification
DP-21	NL	The platform must process data to link records from various source systems.	✓	Scenario execution (all)	For example, record linkage across CIS, PACS, LIS, ePMA[ab]
DP-23	NL	The platform must process data according to a specified semantic data model.	✓	Technical inspection	Structured data instances validated against openEHR archetypes and templates; conformance verified through successful persistence in the CDR without schema violations
DP-33 - 1	NL	The platform must process data by transforming it into an open standardized format.	✓	Scenario execution (all)	HL7, CSV, and FHIR inputs transformed into openEHR compositions and stored in CDR; successful transformation confirmed by absence of processing errors and validated template bindings
DSC-04	NL	The platform must provide a pseudonymization ID (PID) to disconnect medical data from identifying data.	✓	Scenario execution (all)	PID service integrated; separates identifying (MPI) from clinical data (CDR)
DAS-03	AL[ac]	The platform must provide various data analysis techniques.	TBD	Conceptual design review	Framework supports integration of external analysis tools; not yet implemented

XSL•FO
RenderX

Requirement ID	Layer	Description	Implemented in platform	Evaluation activity	Evidence or outcome
DAS-12	AL	The platform must extract datamarts for research-related analysis.	✓	Scenario execution (all)	Structured data exports to CSV; used for analytics in cardiology and radiology scenarios
DAS-13	NL	The platform must only analyze (patient-) data for which consent has been obtained.	✓	Scenario execution (radiology)	Consent status checked in PCM[ad] before recontact; enforced before analysis
DR-01	AppL	The platform must provide user group–specific interfaces.	✓	Scenario execution (cardiology)	Data entry tool tailored for study nurses
DR-02	AppL	The platform must provide a user interface for cohort exploration.	✓	Scenario execution (cardiology)	Cohort builder enables data transfer unit to search by, eg, diagnosis, laboratory, procedure, and consent data
DR-03	AppL	The platform must provide enhanced visualization for holistic multimodal care information.	TBD	Conceptual design review	Not implemented
DR-03 - 1	AppL	The platform must provide user group–specific interfaces for predictive data analysis.	TBD	Conceptual design review	Not implemented; planned for future artificial intelligence module integration
DR-03 - 2	AppL	The platform must provide a user interface for the comparison of patients with similar medical histories.	TBD	Conceptual design review	Not implemented; AQL queries for patient grouping prepared
DR-03 - 3	AppL	The platform must provide trajectory data representation.	✓	Conceptual design review	Longitudinal patient trajectories rendered in the Molecular Tumor Board application, displaying multimodal data on timeline (verified via system demonstration)
DR-04	AppL	The platform must provide an interface for context-related external calls from the clinical information system (CIS/EMR[ae]).	TBD	Conceptual design review	Not implemented
DR-05	AppL	The platform must allow querying qualified search results.	✓	Scenario execution (cardiology)	AQL used for structured queries across CDR; results exported for analysis

Table . Consolidated quality attribute evaluation.

Quality attribute	Cardiology scenario findings	Radiology scenario findings
Interoperability	Demonstrated integration of structured and unstructured data from 4 source systems (HL7 V2[a] and FHIR[b]).	Integrated demographic and imaging metadata from PACS[c] and CIS[d] via CSV-based ETL[e] processes and MPI[f] linkage.
Data accuracy and consistency	Achieved through the use of standardized terminologies (*ICD-10-GM*[g] and LOINC[h]) and validation of templates by clinical experts.	Ensured by automated metadata extraction from radiological systems and consistent use of patient IDs via MPI ensured reliable linkage and cohort formation.
Reusability	Extraction logic and openEHR templates were reused from more than 38,000 HL7[i] messages (anamnesis forms: n=1016, echocardiography entries: n=616, laboratory reports: n=2902, and medication entries: n=6231).	The cohort identification process (unique patients: n=1744 and unique CT[j] studies: n=4146) and corresponding query logic can be reused for other imaging-based follow-up studies with similar criteria.
Traceability	Enabled by storing metadata and source system information alongside clinical data, ensuring transparent data provenance.	Full provenance tracking of imaging data was achieved by retaining source system identifiers and metadata (eg, modality and scan date).
User or acceptance or usability	Manual data entry interfaces (eg, echocardiography) were cocreated with clinicians and study nurses, and the final dataset was validated with domain experts from external study sites (eg, other HiGHmed sites).	Automated generation and delivery of final patient lists to the radiology department replaced manual chart review and simplified recruitment workflows.

[a]HL7 V2: Health Level 7 Version 2.

[b]FHIR: Fast Healthcare Interoperability Resources.

[h]LOINC: Logical Observation Identifiers Names and Codes.

[i]HL7: Health Level 7.

[j]CT: computed tomography.

Recontacting Patients in a Radiology Scenario

The radiology scenario evaluates the platform's technical integration, traceability, and reuse of CT imaging metadata for cohort identification of patients who underwent hip or spine CT examinations (ethics approval obtained at Kiel University [D596/22]). The evaluation focuses on data integration, metadata processing, and consent-compliant record linkage (DAS-13), while diagnostic accuracy or clinical effectiveness are out of scope [49]. The platform supported cohort preparation by combining pseudonymized CT imaging data from PACS (DA-03) with demographic data from the CIS (DA-02 and DP-21) using record linkage. Eligibility criteria (age, broad consent permitting data use and recontact, CT scan type, and CT scan age) were applied via structured queries (DP-21 and DR-05). Imaging metadata (DP-06) stored in the data lake were processed within the platform (MDM-01, DS-05, and DS-02 - 2) [48]. Imaging metadata and radiological reports were ingested as daily CSV reports into the S3 bucket in the staging layer (DA-01, DA-01-2, DA-01-4, DS-03, and DP-07), persisted in the data lake, and linked via the MPI (DP-20-3 and DP-20-5) [48]. Patient demographics were accessed via the MPI, and consent information was verified through the PCM prior to analysis (DAS-13, DP-20-3, and DSC-04). The CDR provided structured *ICD-10-GM* diagnoses (DS-08, DP-01, DP-23, and DP-33 - 1) for eligibility filtering and querying (DR-05 and DS-13). Query results were exported as CSV datasets (MPI Identifiers, patient addresses, and vital status; DAS-12), containing 1744 unique eligible patients for follow-up processing. Subsequent patient communication was outside the platform's scope.

The structured integration of imaging metadata and patient demographics enabled automated cohort identification and facilitated follow-up planning. Beyond the immediate gains for recruitment and research workflows, the setup also provides long-term efficiency: once implemented, additional cohorts can now be identified based on the continuously updated data within the platform. Thus, the radiology scenario fulfills 23 of 39 (59%) identified platform requirements. The evaluation activities and corresponding evidence at the requirements level are detailed in Table 1. A consolidated assessment of the resulting quality attributes according to ISO/IEC 25010 across both scenarios is summarized in Table 2.

Operational Assessment

In addition to the scenario-based requirement evaluation, we collected operational data metrics to provide quantitative

XSL•FO
RenderX

evidence of the platform's real-world data handling capabilities. The platform is currently connected to 10 heterogeneous clinical source systems, including ORBIS (CIS with RIS module), OPUS-L (LIS), MEONA (medication documentation), MUSE (ECG), Deep Unity (PACS), Viewpoint (gynecology and obstetrics), ODSEasy (clinical cancer registry and tumor documentation system), NEXUS (pathology information system), COPRA (patient data management system), and CentraXX (CTMS).

On a weekly basis, the platform processes approximately 180,000 HL7 ADT, 120,000 HL7 ORU, and 120,000 HL7 billing account record messages, in addition to around 30,000 DICOM studies, 12,000 RIS reports, 2500 ECG datasets, and 7000 discharge letters. The total alphanumeric data volume amounts to approximately 1 to 1.5 GB per week. As of early 2026, the platform has processed approximately 46.5 million ADT, 39.8 million ORU, 28.1 million billing account record messages, 38.3 million DICOM studies, 144,000 ECG datasets, and 4.1 million discharge letters. The MPI contains demographic records for over 2.3 million patients (since 2000), and the openEHR-based CDR stores structured data from approximately 1.5 million patients in more than 85 million compositions (including ~12 million diagnoses, ~13 million procedures, ~10 million medication requests, ~2.8 million scores from intensive care units, ~340,000 UKSH broad consents, and information on ~58,000 biospecimens). This data volume results from the platform's integration strategy: when specific data elements are requested, they are not only integrated for the selected cohort but also systematically incorporated for all patients across legacy and ongoing data. For example, a request for anesthetics data in a specific intensive care unit in 2020 leads to the integration of anesthetic data from the introduction of the respective IT system to the present, including future records.

Discussion

Principal Findings

This study presents the implementation and requirement-based evaluation of a health knowledge management platform at UKSH, assessed against 39 functional requirements and 2 real-world scenarios. To overcome the traditional separation between patient care and biomedical research, the platform integrates heterogeneous clinical data (eg, CIS, PACS, and LIS) into a structured, interoperable environment [50]. Requirements were derived through stakeholder focus groups, building upon the developed requirements catalog by Kinast et al (30/39, 77%) [25]. The catalog provided a comprehensive and systematically defined foundation for key interoperability and data integration requirements, enabling efficient requirements formalization and traceable coverage. In total, 9 of 39 (23%) additional requirements were specified using ISO 29148-compliant syntax to address context-specific needs. Overall, 30 of 39 (77%) requirements are fully implemented, while the cardiology scenario fulfills 26 of 39 (67%) and the radiology scenario fulfills 23 of 39 (59%).

However, its functional scope extends well beyond the functionalities necessary to support the selected scenarios. For example, the platform integrates radiological images (eg, x-ray, CT, and magnetic resonance imaging) together with corresponding free-text reports (DA-01-3) [48], although structured extraction and storage of report content in the CDR are not yet implemented. Two requirements stay partially or not yet fulfilled: single sign-on, which is currently limited to selected applications (eg, MTB; DSC-12), and linkage of external public data sources (DP-19). The latter, including integration of regional death registries, is on hold due to legal and organizational constraints.

The integration of patient profile-based information from public sources (DP-19), for example, to support advanced decision support use cases, remains conceptually defined but not yet operational due to legal and technical constraints. Together with the incomplete single-sign-on integration (DSC-12), these gaps reflect the current implementation status rather than architectural limitations.

Our platform supports a range of data-driven applications via the data access layer, although user group-specific interfaces for predictive data analysis (DR-03-1) have yet to be developed. A key challenge is the prevalence of unstructured clinical documentation, which limits structured reuse and data quality [51]. To address this, the normalization layer is being extended with natural language processing capabilities, and an initial pipeline for allergy information extraction from discharge letters (DP-02) has been implemented [31].

An MTB application has been deployed, enabling visualization of oncological histories, patient comparison and cohort identification, and analytical functionalities (DAS-03, DR-03, and DR-03-3) [39,52]. It is also in active use to support patient care as part of the MTB meetings. Additional functionalities include end-user cohort exploration (DR-01) and data entry (DR-05) that are planned but currently restricted to specific user groups, that is, system administrators or study nurses, respectively. Our platform shares its openEHR-based foundation with the system described by Biermann et al [53], whose work on patient trajectory analysis and predictive interfaces illustrates the extensibility of this architecture. However, some applications envisioned remain on the roadmap (eg, patients like mine and end user–enabled cohort exploration). The identified gaps highlight the need for further iterative development to realize the platform's full potential. Its design was guided by defined key aspects (see Key Aspects of the Platform section), aiming to ensure relevant quality attributes such as interoperability, reusability, data consistency, and usability aligned with the specific requirements of the UKSH environment.

A key architectural decision was the adoption of an openEHR-based CDR instead of a FHIR-based repository. While FHIR primarily supports real-time data exchange, openEHR provides a semantically rich, longitudinal data model suitable for persistent storage and consistent querying across both patient and cohort levels, posing an essential requirement for secondary use and advanced analytics [54]. Its archetype-based approach enables explicit clinical content modeling, ensuring semantic consistency and modular reuse across use cases and front ends while maintaining interoperability via FHIR interfaces. This decision is supported by the growing adoption of openEHR across European health care systems, including countries such

XSL•FO
RenderX

as Slovenia [55], Sweden [56], Norway, and Finland [57] as well as major academic hospitals such as Karolinska University Hospital and University Hospital Basel [58], and the region of Catalonia [59]. The approach also aligns with the open platform principles defined by the Aperta Foundation [60], which promote openness, semantic interoperability, and modularity.

To complement this foundation, FHIR-based applications could be integrated into the application layer, enabling patients to contribute personal health data (PGHD). Conceptually, such applications could also be considered part of the PEHR within the source layer, with data integrated bottom-up via the data lake. The platform architecture and interfaces are designed to support both integration options, allowing source systems either to maintain independent persistence or to rely on the platform's normalization layer as a shared persistence layer. We did not consider integrating the knowledge management platform directly into the CIS, as CIS platforms are primarily designed for billing, individual patient-level care, and documentation rather than cohort-level analysis or research data export. Establishing a separate platform increases architectural flexibility, without interfering with clinical workflows or billing-related functionality constraints. This also ensures that patient care remains uncompromised, as CIS and corresponding systems are not burdened with additional loads from research-related queries. Furthermore, it aligns with Findable, Accessible, Interoperable, Reusable principles by enhancing data accessibility and promoting reuse in research contexts [24].

In the platform's initial architectural design, IHE profiles played a significant role [15]. Currently, Patient Identifier Cross-Referencing [33] and Patient Demographics Query [34] are used within the MPI, along with Advanced Patient Privacy Consents [61] for consent management. Many openEHR compositions are additionally persisted as IHE XDS-compliant documents. However, as XDS-based access retrieval is not required for current scenarios, data retrieval is performed via openEHR AQL. The architectural separation of patient identifiers, consent data, and medical content supports data protection and enables modular governance. In alignment with IHE principles, our platform manages an MPI, a consent repository, and a CDR to persist the respective data types. This modular structure enables precise permission management via fine-grained consent enforcement [35]. Currently, the platform supports consents for the research-related use of patient care data, leftover biomaterial, recontact in case of incidental findings, and recontact for future research projects (ie, recruitment and follow-up) [35]. Because the platform processes both consented and nonconsented patient data, it can also support legally authorized research models beyond informed consent, such as opt-out–based research based on a specific regulation.

Limitations

One limitation concerns the stakeholder selection in the requirements elicitation process, which primarily emphasized functional requirements. Nonfunctional aspects such as scalability, security, performance, and usability were considered at the architectural level but not systematically elicited as explicit requirements. The platform's modular and layered architecture follows separation of concerns principles, allowing nonfunctional requirements to be addressed within specific components. However, these aspects were not formally evaluated in this study.

Although the requirements catalog by Kinast et al [25] facilitated the formalization and data integration requirements, it did not address user interface aspects. Consequently, 9 additional requirements had to be specified separately, expanding the scope of the RE process. The RE process did not include a dedicated study-specific stakeholder analysis. However, participation in the HiGHmed consortium ensured broad clinical domain representation across multiple use cases [15]. Additional requirements were elicited through engagement with clinicians involved in the evaluated scenarios.

The platform builds on an openEHR CDR, a technology traditionally applied to electronic health records in institutional or regional infrastructures [62-64]. Our application as a knowledge management platform integrating both research and patient care contexts represents an extended use of this technology.

Structured data are a prerequisite not only for research scenarios and applications but also for decision support. However, clinical documentation still heavily relies on unstructured free-text, either entered directly into the CIS or recorded through dictation and transcription. As a result, requirements such as DR-03-1 to DR-03-3 remain a challenge, as the respective functionalities depend on structured data. This highlights the need to establish structured data as a foundation before enabling advanced care functionalities. To address this, we plan to expand the platform's normalization layer to further include natural language processing and information extraction features, enabling the processing and structuring of the large volume of free-text reports from the CIS and its subsystems [31].

Finally, the evaluation has primarily focused on research-oriented scenarios. Broader deployment in routine care, especially for real-time decision support, remains to be assessed. Although the platform provides the necessary technical interfaces, additional application development is required to evaluate clinical integration at scale, fully demonstrating the platform's potential in both biomedical research and patient care settings.

Risk Assessment

Every modification of an IT system poses risks to data consistency, availability, and quality, particularly when integrating heterogeneous source systems via different interfaces [65]. Each data transformation step introduces the potential for errors, and repeated transformation increases the risk of inconsistencies between datasets. Our approach of acquiring raw data and transforming them centrally only once reduces repeated transformations but still introduces transformation risks. To mitigate these, we use automated processing, code reviews, and structured testing procedures [66]. Nevertheless, occasional errors occur. Once identified, the corresponding extract-transform-load process is corrected, and the affected data are reintegrated from the original S3 storage. Although

XSL•FO
RenderX

issues in the source data itself cannot be resolved, detected anomalies can be flagged within the integrated data view.

Data reliability varies by type and depends on the original purpose of documentation. For example, laboratory measurements are typically generated through standardized processes, whereas billing-related data such as diagnoses or procedures follow regulatory and reimbursement-driven documentation logic. Platform transparency regarding data provenance and quality is therefore essential. Each newly integrated data source typically includes the complete dataset of the corresponding system, including live and legacy data, rather than cohort-specific subsets. This "integrate once, use many" strategy promotes long-term sustainability and data reuse.

Beyond technical risks, governance and long-term maintenance represent additional challenges. Sustainable operation depends on strong organizational support and compliance with data privacy regulations. At UKSH, the platform is institutionally anchored through a board resolution and supported by internal funding as well as national initiatives (Network University Medicine), which adds to its long-term stability.

Comparison With Prior Work

Our health knowledge management platform integrates both health care and research functionalities within a unified architecture. This contrasts with many existing initiatives that focus either on specific use cases or predominantly on research-oriented data integration [67-69].

In Germany, initiatives such as the Medical Informatics Initiative and Network University Medicine [16] have significantly advanced health care data integration. As part of the HiGHmed consortium, we set the foundation for our platform by introducing open platforms and interoperability principles to enhance health care and research across institutional boundaries [15]. Building on this foundation, our platform extends these concepts by integrating both research and health care functionalities within a single integrated platform. Similarly, MIRACUM and DIFUTURE focus on cross-institutional data integration and secondary analyses to inform clinical practice and medical innovation [70,71]. While these initiatives emphasize research data use, our platform bridges the gap by unifying research and health care workflows, enabling bidirectional data reuse.

Internationally, comparable efforts exist. For instance, the Mayo Clinic Platform facilitates secure access to deidentified clinical data for research and innovation [72]. Unlike Mayo's Enterprise Data Trust, which primarily functions as a nontransactional analytics repository, our platform additionally supports real-time clinical workflows (eg, MTB) and research data capture directly from patient care processes, enabling immediate translational use within UKSH. Similarly, the World Health Organization's Integrated Data Platform supports large-scale population health monitoring [73] but does not integrate institutional patient care and research workflows within a unified platform.

Overall, while prior initiatives have significantly contributed to secondary use of health care data, our platform emphasizes the operational integration of health care and research through centralized consent management and a layered architecture based on separation of concerns principles.

Conclusions

This study describes and evaluates the UKSH health knowledge management platform, demonstrating how its multistandards approach effectively addresses interoperability challenges while ensuring data consistency. The scenario-based evaluation illustrates the platform's capability to support research based on real-world health care data. Its layered architecture and harmonization processes provide a structured data access layer that enables both clinical and research applications.

Future developments will focus on (1) expanding the application layer with cohort exploration tools and AI-supported data analysis tools [18] and (2) developing user-specific interfaces to enhance clinical usability. Hereby, we expect benefits through a reduction of manual data preparation for cohort identification, enabling more efficient study planning and data-driven health care. These applications will be developed to create a direct impact on patient care based on the partially and unfulfilled requirements, which will undergo further evaluation. Inspired by the "Ten Topics to Get Started in Medical Informatics Research" [74], our platform has the potential to improve several key areas in medical informatics, pushing the boundaries of both clinical practice and research capabilities.

Authors' Contributions

BK selected the method for the requirements elicitation and evaluation, chose the scenarios, conducted the evaluation, and led the drafting of the manuscript, including the initial and final versions. BS derived the initial architecture based on the requirements. BK provided expertise on the cardiology scenario, organized and moderated the expert discussions, and incorporated their results into the manuscript draft. HU conducted the radiology and neurology scenarios and contributed to expert insights. TB conceptualized the integration of patient-generated health data into the platform. BS and BB refined the platform's architecture, actively participated in expert discussions, and provided critical input to the manuscript. AKK-S contributed to the requirements for biomaterial information and study registry. All authors reviewed and approved the final manuscript.

Abstract

Background: Patients with cirrhosis may have acute kidney injury (AKI) after receiving endoscopic retrograde cholangiopancreatography (ERCP).

Objective: This study aimed to identify determinants of AKI that require dialysis following ERCP in patients with cirrhosis.

Methods: Data from the US Nationwide Inpatient Sample from 2016 to 2020 were retrospectively reviewed. Patients aged ≥20 years with liver cirrhosis who underwent ERCP were identified. The primary outcome was AKI requiring dialysis. Logistic regression with stepwise selection was used to identify factors associated with dialysis-requiring AKI among demographic variables, comorbidities, and hospital characteristics.

Results: Data from 6748 patients with liver cirrhosis who underwent ERCP were analyzed, and 2.2% (n=148) developed AKI that required dialysis. After adjustment, the results showed that decompensated liver cirrhosis (adjusted odds ratio [aOR] 4.73, 95% CI 3.12-7.15; *P*<.001), chronic kidney disease (aOR 5.93, 95% CI 4.00-8.79; *P*<.001), obesity (aOR 1.65, 95% CI 1.05-2.59; *P*=.03), and sepsis (aOR 3.57, 95% CI 2.44-5.23; *P*<.001) were significant factors associated with AKI that required dialysis. The developed model demonstrated good calibration and discrimination (c-index: 0.826 for derivation cohort, 0.824 for validation cohort).

Conclusions: Decompensated liver cirrhosis, preexisting chronic kidney disease, obesity, and sepsis are significant factors associated with AKI that require dialysis following ERCP in patients with liver cirrhosis. These findings can inform risk stratification and management strategies to improve outcomes in this high-risk population.

KEYWORDS

acute kidney injury; AKI; endoscopic retrograde cholangiopancreatography; ERCP; liver cirrhosis; nationwide inpatient sample; NIS

Introduction

Liver cirrhosis is a major cause of morbidity and mortality among individuals with chronic liver disease, and in 2019, it accounted for 2.4% of global deaths [1]. Patients with liver cirrhosis have a 15% to 50% incidence of acute kidney injury (AKI), and for hospitalized patients, the 30-day mortality rate ranges from 30% to 70%, depending on the AKI stage and patient comorbidities [2-4]. Liver disease and renal dysfunction can both result from systemic conditions affecting these organs, but it is more common for primary liver disorders to lead to renal complications [5]. The intricate relations between liver and kidney dysfunction pose a significant clinical challenge, requiring a detailed understanding of the risk factors and predictors to enhance patient outcomes.

Endoscopic retrograde cholangiopancreatography (ERCP) is an advanced endoscopic method used for diagnosing and treating

XSL•FO
RenderX

conditions of the biliary and pancreatic systems [6]. The annual number of ERCP procedures has grown consistently, now surpassing 350,000 annually in the United States [7]. ERCP is one of the most technically challenging endoscopic procedures and requires a high degree of knowledge of biliopancreatic anatomy and physiology [8]. Despite decades of improvements, the complication rate of ERCP is still high, with post-ERCP pancreatitis being the most common complication [9]. A recent study has shown that AKI is an important complication after ERCP and is associated with prolonged hospital stays and poor outcomes [10].

Chronic kidney disease (CKD) and end-stage renal disease are known risk factors for complications and in-hospital mortality after ERCP [11,12]. However, data on AKI, particularly dialysis-requiring AKI, following ERCP in patients with liver cirrhosis are limited. This gap in knowledge underscores the need for comprehensive studies to identify specific determinants of AKI that require dialysis in this patient population. Therefore, this study aimed to identify the risk factors for AKI that require dialysis following ERCP in patients with liver cirrhosis using a large-scale, nationally representative dataset.

Methods

Study Design and Patient Selection

This retrospective study used data from the US Nationwide Inpatient Sample (NIS) database, managed by the Healthcare Cost and Utilization Project (HCUP) under the US National Institutes of Health. The NIS database collects comprehensive data on approximately 8 million hospital admissions each year, including patient demographics, diagnostic and treatment details, admission and discharge timings, length of stay, and hospital characteristics. Further information about the NIS database is available on the HCUP Agency for Healthcare Research and Quality website.

This study included patients aged ≥20 years who were diagnosed with liver cirrhosis and underwent ERCP between 2016 and 2020. These patients were identified in the NIS database using the *International Classification of Diseases, 10th Edition* (*ICD-10*) codes, and all variables were defined as binary indicators based on physician-diagnosed conditions. Patients with incomplete data on sex and study end points were excluded, as were those with a history of kidney transplantation or those on chronic hemodialysis (with dialysis codes but no AKI code). The ICD codes used for identifying these conditions are listed in Multimedia Appendix 1.

Ethical Considerations

Data for this research were obtained from the Online HCUP Central Distributor website following the NIS data use agreement through HCUP. This study was a secondary analysis of the NIS database and did not involve direct interaction with patients or the public. As the database contains no patient-identifiable information, ethics approval from our institutional review board and informed consent from participants were not required in accordance with institutional guidelines.

Study Outcomes

The primary outcome was dialysis-requiring AKI, defined using *ICD-10* diagnostic codes for AKI (N17.x) together with dialysis-related procedure codes (Z49, 5A1D70Z, 5A1D80Z, 5A1D90Z, and 3E1M39Z) recorded during the same hospitalization. As the NIS database does not contain laboratory data (eg, serum creatinine levels), AKI could not be defined using standard clinical criteria and was therefore identified based on diagnostic and procedure codes.

Study Variables

Data were collected on patient demographics, including age, sex, race or ethnicity, type of admission, weekend admission, insurance status, and decompensated cirrhosis. Decompensated cirrhosis was defined by the presence of *ICD-10* codes indicating major complications of cirrhosis, including hepatic encephalopathy, portal hypertension, hepatorenal syndrome (HRS), and esophageal varices with or without bleeding. Major comorbidities were recorded, including CKD, obesity, diabetes, alcohol or drug abuse, coronary artery disease, atrial fibrillation, congestive heart failure, chronic pulmonary disease, and rheumatic disease. These conditions were treated as binary variables and defined by the presence or absence of the corresponding *ICD-10* diagnostic codes recorded during the index hospitalization. With regard to obesity, it was defined as a binary variable based on *ICD-10* diagnostic codes indicating obesity (eg, E66.x) or documentation consistent with a BMI ≥30 kg/m^2. The overall burden of comorbidities was assessed using the Charlson Comorbidity Index.

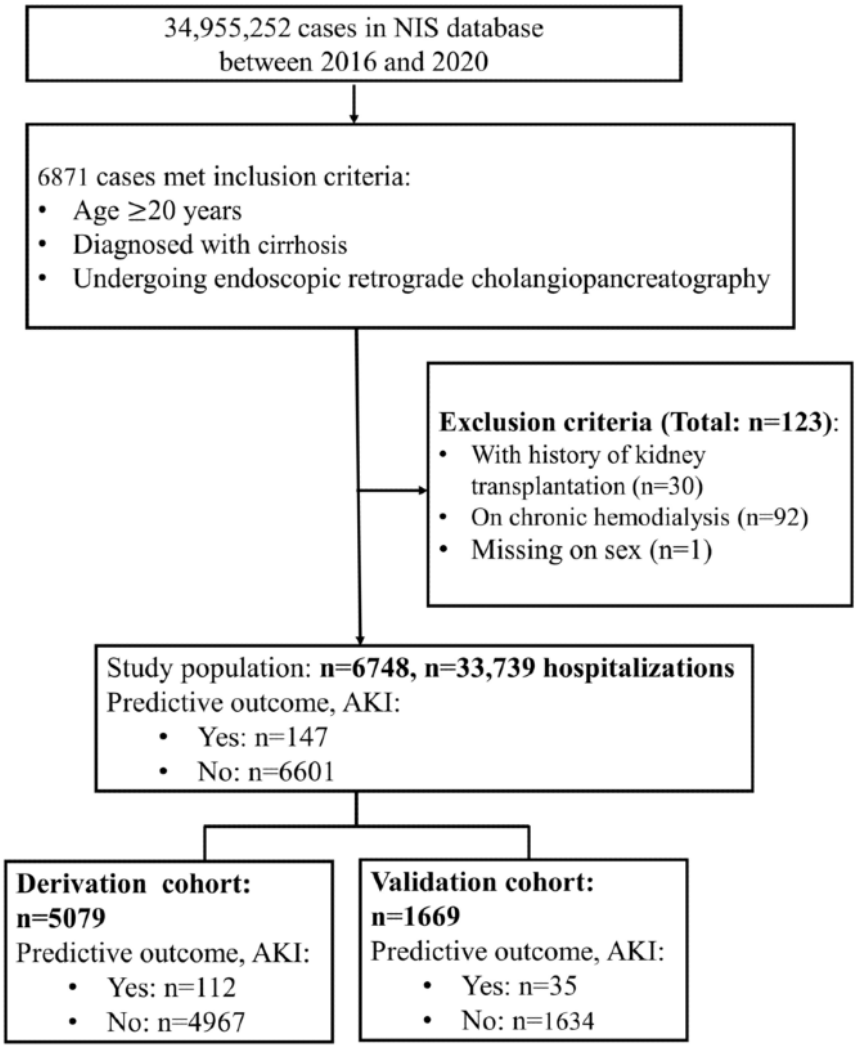
In addition, post-ERCP complications, including sepsis, infection, pancreatitis, hemorrhage, and perforation, were identified. Hospital characteristics such as bed size and hospital location were also collected. Demographic and hospital characteristics were obtained from the NIS database variables. The ICD codes used to define comorbidities and complications are provided in Multimedia Appendix 1.

Statistical Analysis

The NIS database includes a 20% sample of annual inpatient admissions in the United States; thus, the SURVEY procedure in SAS software (SAS Institute) was used. Descriptive statistics were presented as number (n) and weighted percentage (%), or as mean (SE). We randomly partitioned the study cohort into a derivation cohort (5079/6748, 75%) and a validation cohort (1669/6748, 25%). The derivation cohort was used to develop a multivariable logistic regression model, while the validation cohort was used for model evaluation.

Univariate logistic regression analysis was used to determine associations between the study variables and the occurrence of AKI that required dialysis after ERCP. The final model was determined using backward selection. All variables examined in the univariate analysis were initially entered into the multivariable logistic regression model, except for rheumatic disease and post-ERCP hemorrhage, which were not included because no AKI events occurred. Backward stepwise selection was then applied to sequentially remove variables until all remaining variables met the prespecified significance level (P<.05). A forest plot for the multivariable logistic regression

XSL•FO
RenderX



model was generated for model visualization. Model discrimination was assessed using area under the curve (AUC), and calibration was evaluated by comparing predicted and observed probabilities using calibration plots in the derivation cohort and the validation cohort. All *P* values were 2-sided, and *P*<.05 was considered statistically significant. All analyses accounted for the NIS's complex survey design to ensure accurate national estimates. All statistical analyses were performed using SAS software (version 9.4; SAS Institute). Forest plots were generated using R (version 4.4.1; R Foundation for Statistical Computing; R project website) with the grid, checkmate, abind, forestplot, and dplyr packages.

Results

Study Population Selection

The process of selecting the study population is illustrated in Figure 1. A total of 6871 patients aged ≥20 years with liver cirrhosis and who underwent ERCP from 2016 to 2020 were identified in the NIS database. Patients who had a history of kidney transplantation (n=30), were on chronic hemodialysis (n=30), and had missing sex information (n=1) were excluded. Thus, the final study sample included 6748 patients, of whom 147 developed dialysis-requiring AKI. After applying discharge weights from the NIS database, this corresponded to a national estimate of 33,739 hospitalizations.

Figure 1. Flowchart of study population selection and allocation. AKI: acute kidney injury; NIS: Nationwide Inpatient Sample.

Characteristics of the Study Population

The characteristics of the patients are described in Table 1. The mean age of the patients was 62.5 (SD 0.18) years, and 2702 (40%) were female. Most of the patients were White (4314/6748; 65.9%), and 2517 (37%) of the patients had decompensated cirrhosis. The patients were randomly divided into the derivation cohort (n=5079) and the validation cohort (n=1669). The data distributions of the 2 groups were similar. In the derivation and validation cohorts, 112 and 35 patients, respectively, developed dialysis-requiring AKI.

[e]ERCP: endoscopic retrograde cholangiopancreatography.

Associations Between the Study Variables and the Outcomes

The results of the univariate analysis of the associations between the demographic and clinical characteristics and AKI requiring dialysis are summarized in Table 2. The results showed that insurance status, decompensated cirrhosis, CKD, obesity, congestive heart failure, and post-ERCP complications such as sepsis, infection, and pancreatitis, were associated with AKI that required dialysis. The top 3 conditions with the highest risk for AKI that required dialysis were CKD (odds ratio [OR] 5.5, 95% CI 3.76-8.04), decompensated cirrhosis (OR 4.07, 95% CI 2.74-6.05), and sepsis (OR 3.39, 95% CI 2.35-4.90).

Factors Associated With AKI Requiring Dialysis After ERCP

Factors associated with AKI requiring dialysis after ERCP, after adjustment for confounders in the multivariable model, are presented in the forest plot shown in Figure 2. Independent factors associated with AKI that requires dialysis after ERCP were decompensated cirrhosis (adjusted OR [aOR] 4.73, 95% CI 3.12-7.15), CKD (aOR 5.93, 95% CI 4.00-8.79), obesity (aOR 1.65, 95% CI 1.05-2.59), and sepsis (aOR 3.57, 95% CI 2.44-5.23). Notably, insurance status (private including Health Maintenance Organization vs Medicare or Medicaid) was also independently associated with AKI that required dialysis after ERCP (aOR 1.77, 95% CI 1.15-2.71).

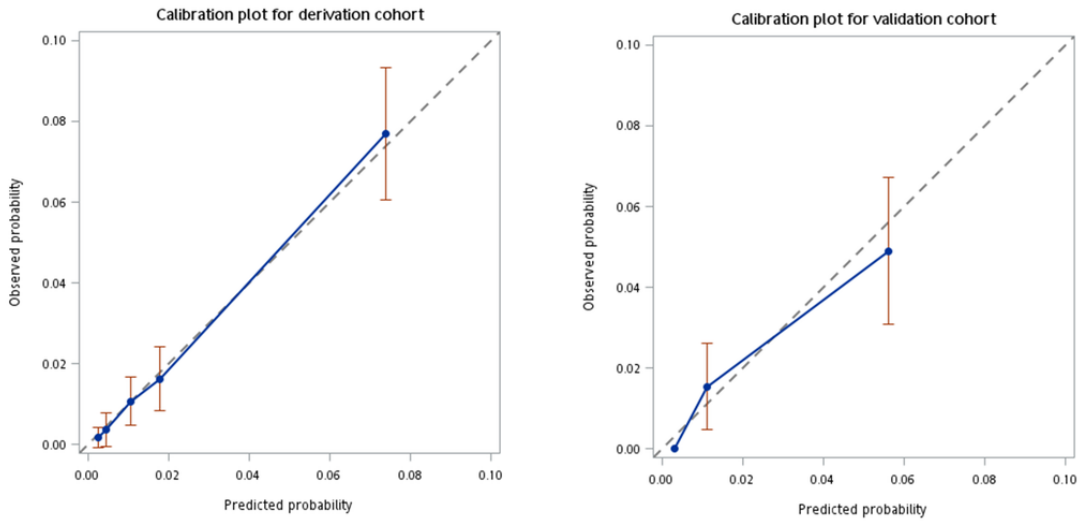

Figure 2. Associations between demographic and clinical characteristics and the risk of acute kidney injury requiring dialysis. aOR: adjusted odds ratio; CKD: chronic kidney disease; HMO: health maintenance organization.

XSL•FO
RenderX

The model fit was shown to be good in the derivation cohort (AUC=0.825) and in the validation cohort (AUC=0.824). The calibration plots are shown in Figure 3.

Figure 3. Calibration plots of the model for the derivation cohort and validation cohort. Patients were grouped into 5 and 3 risk groups in the derivation and validation cohorts, respectively, based on predicted probabilities. Points represent observed event rates within each group, with error bars indicating 95% CIs. The dashed line represents perfect calibration.

Discussion

Principal Findings

This study identified significant factors associated with AKI that requires dialysis in patients with liver cirrhosis after ERCP. The model performed well in both the derivation and validation cohorts. Accordingly, the key risk factors were decompensated cirrhosis, CKD, obesity, and sepsis. CKD and decompensated cirrhosis had the highest ORs, indicating strong associations with AKI that requires dialysis. These findings can inform clinical decisions and risk stratification to improve patient outcomes following ERCP in patients with liver cirrhosis.

Liver cirrhosis is a chronic and serious health condition and can progress to the point where the liver is no longer functional [13]. In compensated liver cirrhosis, damage to the liver is less severe and the liver is able to compensate for the damage and continue to function normally but with a reduced level of function [13]. In decompensated liver cirrhosis, the organ is no longer able to perform its normal functions because of severe damage and is characterized by the development of ascites, variceal hemorrhage, and hepatic encephalopathy. The only definitive treatment for decompensated cirrhosis is liver transplantation [13]. Damage to the kidneys is usually present in the natural progression of liver cirrhosis, and HRS is the kidney dysfunction that occurs during the progression of cirrhosis and is characterized by marked impairment of kidney function due to circulatory and hemodynamic alteration that occur with cirrhosis and a heightened systemic inflammatory response [14].

ERCP is a minimally invasive and generally safe procedure when performed by an experienced operator. As with all procedures that use iodinated contrast media, there is a risk that the medium may result in AKI in a small fraction of the patients [9]. Liver cirrhosis, especially decompensated cirrhosis, is associated with increased complications with almost all medical and surgical procedures, and many studies have compared outcomes of ERCP in patients with and without cirrhosis, and the risk of complications in patients with cirrhosis is up to 3-fold greater than that in those without cirrhosis [15,16]. The study by Eyyupkoca et al [17] reported that, compared with patients without liver cirrhosis, those with liver cirrhosis had an increased risk of pancreatitis and cholangitis and that elevated total bilirubin and a higher Child-Pugh class were risk factors for these complications. The study by Bernshteyn et al [18] also reported that Child-Pugh class C was associated with a significantly higher risk of complications after ERCP compared to class A or class B. Recent meta-analyses [19,20] have also shown that compared to patients without liver cirrhosis, those with liver cirrhosis have a significantly higher risk of adverse events including hemorrhage, pancreatitis, and cholangitis.

The study by Solanki et al [21] also reported that in patients with liver cirrhosis, therapeutic ERCP was associated with increased risk of pancreatitis and hemorrhage, whereas diagnostic ERCP was associated with increased risk of pancreatitis and cholecystitis. The authors also noted that comorbidities in patients with liver cirrhosis may increase the risk of post-ERCP complications and mortality. A matched-cohort multicenter study of patients with liver cirrhosis undergoing ERCP reported that liver cirrhosis was associated

XSL•FO
RenderX

with an overall increased risk of adverse events, and most notably an increased risk of acute-on-chronic liver failure [22].

As previously noted, kidney dysfunction is part of the natural course of liver cirrhosis, and approximately 20% of patients with cirrhosis experience AKI during the course of the disease [3]. AKI in patients with liver cirrhosis is generally categorized as HRS-associated AKI and non-HRS AKI, and studies have shown that they are distinct clinical conditions with different pathophysiology [2,23]. A recent report by Gadalean et al [10] found that the rate of AKI after ERCP in general (noncirrhotic) patients was 26% and was significantly associated with longer hospital stay and increased in-hospital mortality. Most notably, moderate to severe AKI was associated with a more than 6-fold increased risk of mortality.

Few studies have evaluated the incidence of AKI in patients with liver cirrhosis undergoing ERCP, and none to our knowledge have examined risk factors for AKI that require dialysis.

Nevertheless, a recent study examined the incidence and risk factors of AKI in patients with liver cirrhosis by analyzing the data of over 5 million outpatients, inpatients, and patients admitted to an intensive care unit [24]. The results showed that in hospitalized patients who experienced any decompensation, the rate of AKI was 29% and in stable outpatients it was 28% during a 1-year follow-up period. Infection or sepsis, hepatic encephalopathy, and intensive care unit admission were associated with AKI rates>40%.

The study by Jagtap et al [25] investigated the outcomes of ERCP in patients with decompensated cirrhosis and found higher overall adverse event rates, with cholangitis being significantly associated with an increased risk of mortality. Our results showed that patients with liver cirrhosis and obesity were at increased risk of AKI after ERCP. While we did not identify any studies focusing on obesity and liver cirrhosis in patients undergoing ERCP, the study by Abdelfatah et al [26] reported that neither obesity nor low body weight was associated with pancreatitis following ERCP. The study, however, did not examine AKI. Our results showed that sepsis was a risk factor for post-ERCP AKI in patients with liver cirrhosis. This finding is not unexpected as studies have shown that sepsis is one of the main causative factors of AKI in patients with liver cirrhosis [27,28].

Taken together, patients with liver cirrhosis undergoing ERCP are at a markedly increased risk of complications, and in particular decompensated cirrhosis, CKD, obesity, and sepsis are associated with an increased risk of AKI that requires dialysis. Knowledge of these risk factors can be incorporated into perioperative management and may improve patient outcomes.

Strengths and Limitations

One strength of our study is the use of a large, nationally representative dataset, which enhances the generalizability of our findings. Additionally, the study's robust methodology, including multivariable logistic regression and model validation, ensures the reliability of the results. However, there are several limitations to consider. The retrospective design may introduce selection bias, as the data were collected from past records, and only patients with complete information were included. The reliance on *ICD-10* codes for identifying conditions and procedures could lead to misclassification or coding errors, potentially affecting the accuracy of our findings. The NIS database lacks detailed clinical information, such as the exact severity of liver cirrhosis or kidney dysfunction, medication use, and procedural specifics, which might limit our ability to account for all potential confounders. Moreover, the database does not provide information on the exact time points of AKI onset or dialysis initiation, which precludes time-to-event analyses and limits temporal interpretation. Additionally, unmeasured variables such as socioeconomic status, lifestyle factors, and detailed laboratory parameters were not available, which could have influenced the outcomes. Finally, while the NIS provides a broad view of inpatient admissions, it does not capture outpatient data, limiting our understanding of long-term outcomes after discharge.

Conclusions

The results of this study showed that factors independently associated with AKI that requires dialysis following ERCP in patients with liver cirrhosis were decompensated cirrhosis, CKD, obesity, and sepsis. Knowledge of these factors can help enhance ERCP planning and risk stratification and improve patient outcomes in this vulnerable population. Moreover, incorporating detailed information from other databases could enable accurate evaluation and prediction of outcomes in future research.

Abstract

Background: Electronic health records offer vast clinical data for health care research, but interoperability challenges often hinder comprehensive analysis. The Health Level Seven Fast Healthcare Interoperability Resources (FHIR) standard addresses these challenges, although its nested and interconnected resource format can be complex for analytics. Several tools have emerged to facilitate analytical access, either by querying FHIR servers via representational state transfer (REST) APIs or encoding resources in relational formats. However, the performance implications of these methods remain largely unexplored.

Objective: This study aimed to benchmark the performance characteristics of different FHIR-based analytical approaches comparing REST API queries against SQL- and Spark-based big data frameworks operating on FHIR-encoded data.

Methods: We benchmarked the FHIR-PYrate library, which interfaces with a FHIR server's REST API, against Pathling, a library built for analytics based on Apache Spark, and Trino, a general-purpose SQL query engine. We defined and implemented multiple queries in each engine using 3 common analytics scenarios—data aggregation, counting, and extraction. Execution times were measured across Synthea-generated datasets of increasing size.

Results: On the largest dataset, containing 71,285,064 FHIR resources, Trino completed the aggregate query more than 12,000 times faster, and Pathling did so approximately 500 times faster than FHIR-PYrate. On average across all queries, Trino outperformed FHIR-PYrate, executing extraction queries 33 times faster and count queries 1.8 times faster. Pathling achieved a 2.6-time speedup for extraction queries, but FHIR-PYrate was approximately 13 times faster for count queries.

Conclusions: While the REST-based FHIR search API is useful for standard queries and retrieving specific patient records and can outperform alternatives for some count queries, it generally lacks the performance and expressiveness needed for complex analytics. In contrast, alternative engines such as Trino and Pathling demonstrated substantial performance advantages for these scenarios.

Fast Healthcare Interoperability Resources; FHIR; benchmark; performance; big data

Introduction

Electronic health records provide digital means to store and retrieve clinical data for millions of patients. Leveraging these real-world data provides an exciting opportunity for health care research [1]. However, the heterogeneity of electronic health record systems often results in interoperability challenges, hindering comprehensive analysis—especially across institutional boundaries [2,3]. This is where the Health Level Seven Fast Healthcare Interoperability Resources (FHIR) can help by providing a standardized framework for modeling and exchanging health care data [4]. The standard describes a data model consisting of resources that represent concepts in the health care domain. These resources are connected via references and form a graph. For example, a FHIR "Condition" resource representing a medical diagnosis may reference a "Patient" resource to which it applies and a "Practitioner" resource identifying the person recording the diagnosis. The FHIR standard also defines an HTTP representational state transfer (REST) interface and its semantics. This interface is implemented by FHIR servers to support the creation, reading, updating, and deletion of resources. Additionally, FHIR Search provides a comprehensive framework for filtering and retrieving relevant resources [5].

The increased adoption of FHIR is driving its use for analytic use cases, including decision support, feasibility research, and epidemiological research [6,7]. When conducting analytical research on FHIR data, familiarity with the graphlike structure, conventions, data types, and search semantics is required. From a purely syntactic perspective, data science and machine learning are usually conducted on tabular data, whereas FHIR resources are nested and interconnected—often encoded as JSON or XML file formats. Due to this gap, several projects aim to convert FHIR resources to a structure more suitable for analytical use cases. These approaches either interact with FHIR servers in a combination of FHIR Search and local postprocessing [8-11] or encode and store resources in a relational or columnar format first [12-15]. Nevertheless, the performance implications of these methods remain largely unexplored.

In this work, we compared analytical approaches that operate on Health Level Seven FHIR as the underlying data representation but differ in how the data are accessed and processed, ranging from REST-based querying of FHIR servers to SQL- and Spark-based querying of tabular-encoded FHIR datasets.

Methods

Engines and Queries

We compared the performance of 3 different approaches for conducting analytics on persisted FHIR resources:

- FHIR-PYrate (version 0.2.3) [9]: a Python library that interacts with a FHIR server's REST API to filter and download resources and with FHIRPath [16] to extract individual attributes
- Pathling (version 7.2.0) [12]: a Python, Scala, Java, and R library used to query FHIR data previously encoded as Apache Spark [17,18] datasets; like FHIR-PYrate, it allows for the use of FHIRPath to describe the tabular data to be extracted from the resources
- Trino (version 478) [19]: a distributed American National Standards Institute (ANSI) SQL-compliant federated query engine

The above-mentioned engines were chosen to allow for comparison between accessing resources directly via a FHIR server's search features, via a more FHIR-native way using FHIRPath expressions, and via SQL—often considered the lingua franca of data analytics [20]. Comparing Pathling and Trino additionally allowed us to benchmark 2 frameworks based on the same Delta Lake table format [21] but using different query engines. This storage-compute decoupling approach is increasingly adopted in modern data warehouse designs [22,23].

We compared the performance of each framework in 3 common analytics scenarios:

- Aggregation: summarizing data to provide statistics such as mean, median, minimum, maximum, sum, and count of values
- Counting: counting the number of resources that satisfy given criteria (eg, this is a common use in feasibility studies to assess the number of potentially eligible patients)
- Extraction: retrieving a subset of relevant data in a tabular format filtered to answer a research question

For the aggregation scenario, we counted the number of FHIR "Observation" resources grouped by their code (eg, the total number of hemoglobin level observations across all patients). This is a common query for inventorying and presenting total available data, such as in a dashboard. As FHIR Search lacks built-in aggregation capabilities, the implementation using FHIR-PYrate first had to download all "Observation" resources into an in-memory pandas DataFrame and execute the aggregation using the pandas "groupby" function. Therefore, this query represents a fundamentally challenging scenario for standard-based FHIR Search interfaces as the FHIR Search specification does not define native server-side aggregation operations. The performance characteristics are determined by the need for client-side retrieval and processing of all available resources.

For both counting and extracting, we implemented 3 queries to retrieve data. The queries were chosen to be close to real-world use cases while at the same time being compatible with the synthetic data against which they were executed. Further, the queries were increasingly complex, integrating multiple resource types and adding multiple filter conditions. The queries were

XSL•FO
RenderX

also created in a way that would allow them to be represented as a single FHIR Search request. This made comparison between the engines easier as no additional postprocessing had to take place inside the benchmarking code.

The descriptions of the 3 queries are provided in Table 1. For the count scenario, only the number of patients satisfying the filter criteria was returned, whereas for the extraction and aggregation scenarios, a projection of resource elements in tabular form was written to a CSV file.

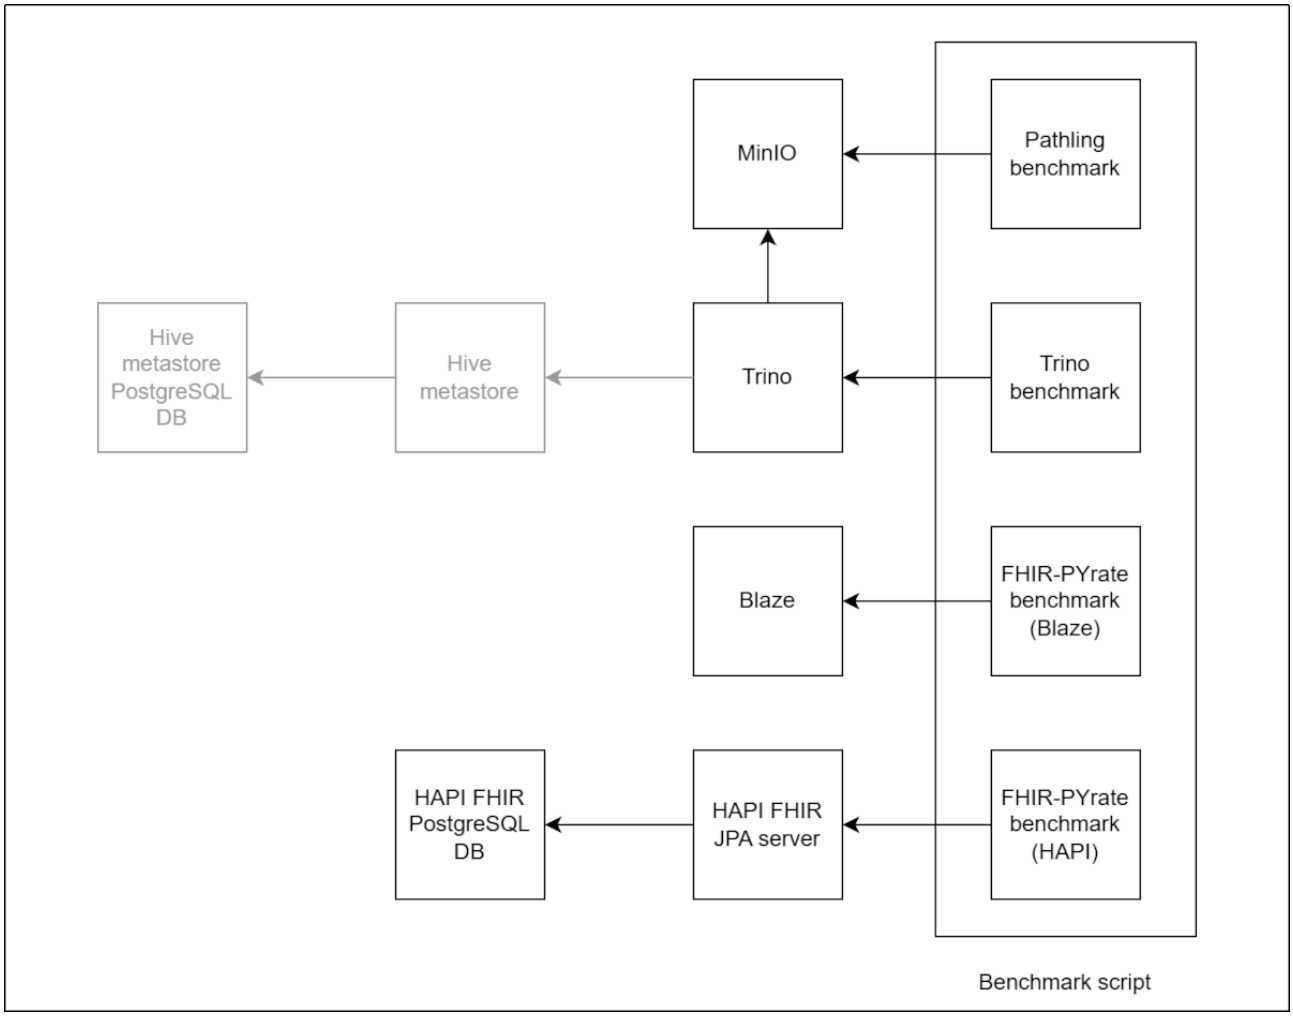
Table 1. Description of the 3 queries used to benchmark the engines for the count and extraction scenarios.

Query name	Description
Gender-age	All patients whose gender was set to "female" and whose birth date was on or after January 1, 1970
Diabetes	All patients born after January 1, 1970, with a diagnosis of diabetes documented for an encounter taking place on or after January 1, 2020
Hemoglobin	All patients with a hemoglobin laboratory value given either in mass per volume format that was higher than 25 g/dL or as a relative percentage of HbA_{1c}[a] compared to total blood hemoglobin that was higher than 5%

[a]HbA_{1c}: hemoglobin A_{1c}.

The main difference between the count queries and the aggregation and extraction ones is that the former only returns a single scalar result value to the caller, so the impact of large data transfers between the benchmark client and the query implementation is significantly reduced.

To compare the scalability of the different engines across all scenarios, we executed the aggregate, count, and extract queries on progressively larger FHIR datasets generated using Synthea [24]. The Synthea command-line tool was used to generate a reproducible dataset of 1000, 5000, 10,000, 50,000, and 100,000 records. These resources were stored as JSON-encoded files in the local file system. For each record count, the scripted benchmarking workflow was as follows:



- Start all the required software components.
- Encode the FHIR resources as Delta Lake tables using the Pathling server's bulk import operation.
- Run Delta Lake–specific OPTIMIZE and VACUUM commands to optimize the file layout.
- Load the synthetic data into the Blaze FHIR server followed by the HAPI FHIR server.
- Run PostgreSQL's VACUUM FULL and ANALYZE commands against the largest HAPI FHIR PostgreSQL tables.
- Stop the Pathling server as it is only used for encoding and persisting the resources in MinIO object storage as tabular data.
- For each query type (count, extract, and aggregate), repeat the following process 10 times: (1) record the total time taken per engine and query from the moment the query is submitted until the CSV file is fully written to disk; (2) execute the SQL queries against Trino consecutively, download all results, and save them as a CSV file; (3) restart the Trino container and MinIO and wait 30 seconds for start-up to complete to ensure that the system stabilizes and background tasks are complete before measurements begin; (4) execute the queries using Pathling and save them as a CSV file; (5) reset the cache, force garbage collection, reinitialize Spark, and wait 30 seconds; (6) execute the queries using FHIR-PYrate, saving the results as CSV files; and (7) restart the FHIR server container and wait 30 seconds.

Restarting the FHIR server and Trino clears in-memory caches and frees up unused memory for the operating system. Each benchmark run started with a different query in a round-robin fashion, ensuring that no query consistently preceded others and minimizing potential order effects. The workflow was implemented using Python (version 3.12; Python Software Foundation), and runtimes were measured using a monotonic performance counter. The benchmarks were executed on a single virtual machine (type CCX53) hosted on Hetzner Cloud running Ubuntu (version 24.04; Canonical Ltd). The machine was equipped with 32 dedicated AMD EPYC (Milan) virtual central processing units (CPUs), 128 GB of RAM, and a 600-GB Non-Volatile Memory Express solid-state drive.

Figure 1 shows the application setup on the virtual machine. For the Trino benchmark, a Hive metastore (The Apache Software Foundation) was used to register the resource tables and their location in the MinIO object storage. However, the metastore was not part of the critical path for the benchmark and was only used by Trino to determine the physical location of the Delta Lake tables.

XSL•FO
RenderX

Figure 1. Application configuration of the benchmarking virtual machine. Both the Hive metastore and the Hive metastore PostgreSQL DB were not on the critical benchmark data path and are drawn in lighter gray. FHIR: Fast Healthcare Interoperability Resources.

The individual application container images and versions are listed in Table 2. The table also includes the memory limit set for each application: for Trino, Blaze, and the HAPI FHIR JPA server, the memory limits were set via the "-Xmx64g" Java Virtual Machine option. For the remaining applications, the memory limits were set using group memory limits on the containers [25].

Table 2. Applications and their respective container image, version, and memory limit used for the benchmark.

Application	Container image	Version	Memory limit
Trino	docker.io/trinodb/trino	478	64 GB
Blaze	docker.io/samply/blaze	1.2.0	64 GB
Pathling server	docker.io/aehrc/pathling	7.2.0	56 GB
MinIO	docker.io/minio/minio	RELEASE.2025-09-07T16-13-09Z	8 GB
Hive metastore	docker.io/apache/hive	4.0.0	2 GB
Hive metastore Database	docker.io/library/postgres	18.1	1 GB
HAPI FHIR[a] server	docker.io/hapiproject/hapi	8.6.0-1	48 GB
HAPI FHIR server Database	docker.io/library/postgres	18.1	16 GB

[a]FHIR: Fast Healthcare Interoperability Resources.

The Blaze server was tuned following the production configuration guide [26], and the HAPI FHIR server PostgreSQL database was configured using the PGTune online tool [27] for data warehouse workloads. For Pathling, we deviated from the default configuration by setting the Parquet compression codec to Zstandard level 9 and the serializer to KryoSerializer. The complete benchmark configuration is available in the public source code repository.

XSL•FO
RenderX

Measuring Resource Use for Data Loading

As a first step, the FHIR resources generated by the Synthea command-line interface had to be loaded into the FHIR servers (for HAPI and Blaze) or encoded as Delta Lake tables (for Pathling and Trino). To load the resources into the servers, we used blazectl (version 1.2.0) with client concurrency set to 32; for Delta Lake, we used the Pathling server's FHIR bulk import API. The former tool reports the import duration after completion; for the latter, we used the Unix time binary to measure the duration of the synchronous import triggered via curl.

We used cAdvisor (version 0.53.0) to record the container's CPU and memory use during the data loading. The metrics were stored in a Prometheus time-series database (version 3.7.3), retrieved when the imports finished, and stored in a CSV file for later visualization. Prometheus was configured to scrape cAdvisor metrics every 5 seconds.

Per-container disk use was measured after the import was completed using the Docker command-line interface.

Comparing FHIR Server Performance

A separate benchmark was conducted to compare the performance of the 2 FHIR server implementations: Blaze and the HAPI FHIR server. The original hemoglobin query, which included multiple OR-combined composite code-value-quantity filters, could not be executed on the HAPI FHIR server due to time-out errors starting on the smallest record count. Therefore, a simplified hemoglobin query variant was used for the server-to-server benchmark that only contained one of the OR-combined filters. As the HAPI FHIR server's PostgreSQL database volume size exceeded the available disk space for the record count of 100,000, we excluded it from those benchmarks. The runs were repeated 10 times for the record counts, but only 3 times for the final 50,000 records due to the excessive runtime.

Measuring Cache Impact

The benchmarks so far were constructed to measure worst-case cold-start performance by repeatedly restarting the services between runs. To assess the impact of caching, we repeated the count and extracted workload benchmarks for the largest record count without restarting the services. The runs were repeated 5 times following 1 warm-up run.

Measuring Data Skew Impact

To evaluate robustness to realistic data skew, we ran another benchmark using three new count queries based on the distribution of "Observation" codes in the Synthea dataset for the largest record count: (1) skewed-hot codes, which filter on 5 high-frequency "Observation" codes selected from the 10 most common codes; (2) skewed-rare codes, which filter on 5 low-frequency "Observation" codes selected from the 10 rarest codes; and (3) skewed-mixed codes, which combine both the hot and rare codes using the logical OR operator.

These workloads stress low-selectivity scans vs highly selective filters without modifying the dataset. Each query was executed 5 times, and we measured the mean of the execution time.

Results

Overview

Tables 3 and 4 detail the number of resources corresponding to the Synthea record counts, the size of the raw JSON files, the time taken to import the resources to the FHIR servers and Delta Lake, and the size of the volumes used to store the imported resources.

Table 3. Fast Healthcare Interoperability Resources (FHIR) resource counts, file size, import duration, and volume sizes corresponding to the Synthea record counts. The HAPI FHIR server was excluded from the largest record count benchmarks as the required disk space would exceed the available resources.

Records, n	FHIR resources by type, n					Synthea JSON file size	
	Patient	Condition	Observation	Encounter	Total	Bulk	Transaction
1000	1144	38,516	515,968	62,476	618,104	653 MB	1018 MB
5000	5760	202,166	2,963,729	339,867	3,511,522	3.6 GB	5.6 GB
10,000	11,481	402,577	5,915,941	683,151	7,013,150	7.2 GB	12 GB
50,000	57,538	2,047,676	30,371,746	3,475,991	35,952,951	37 GB	57 GB
100,000	115,153	4,075,593	60,168,356	6,925,962	71,285,064	73 GB	113 GB

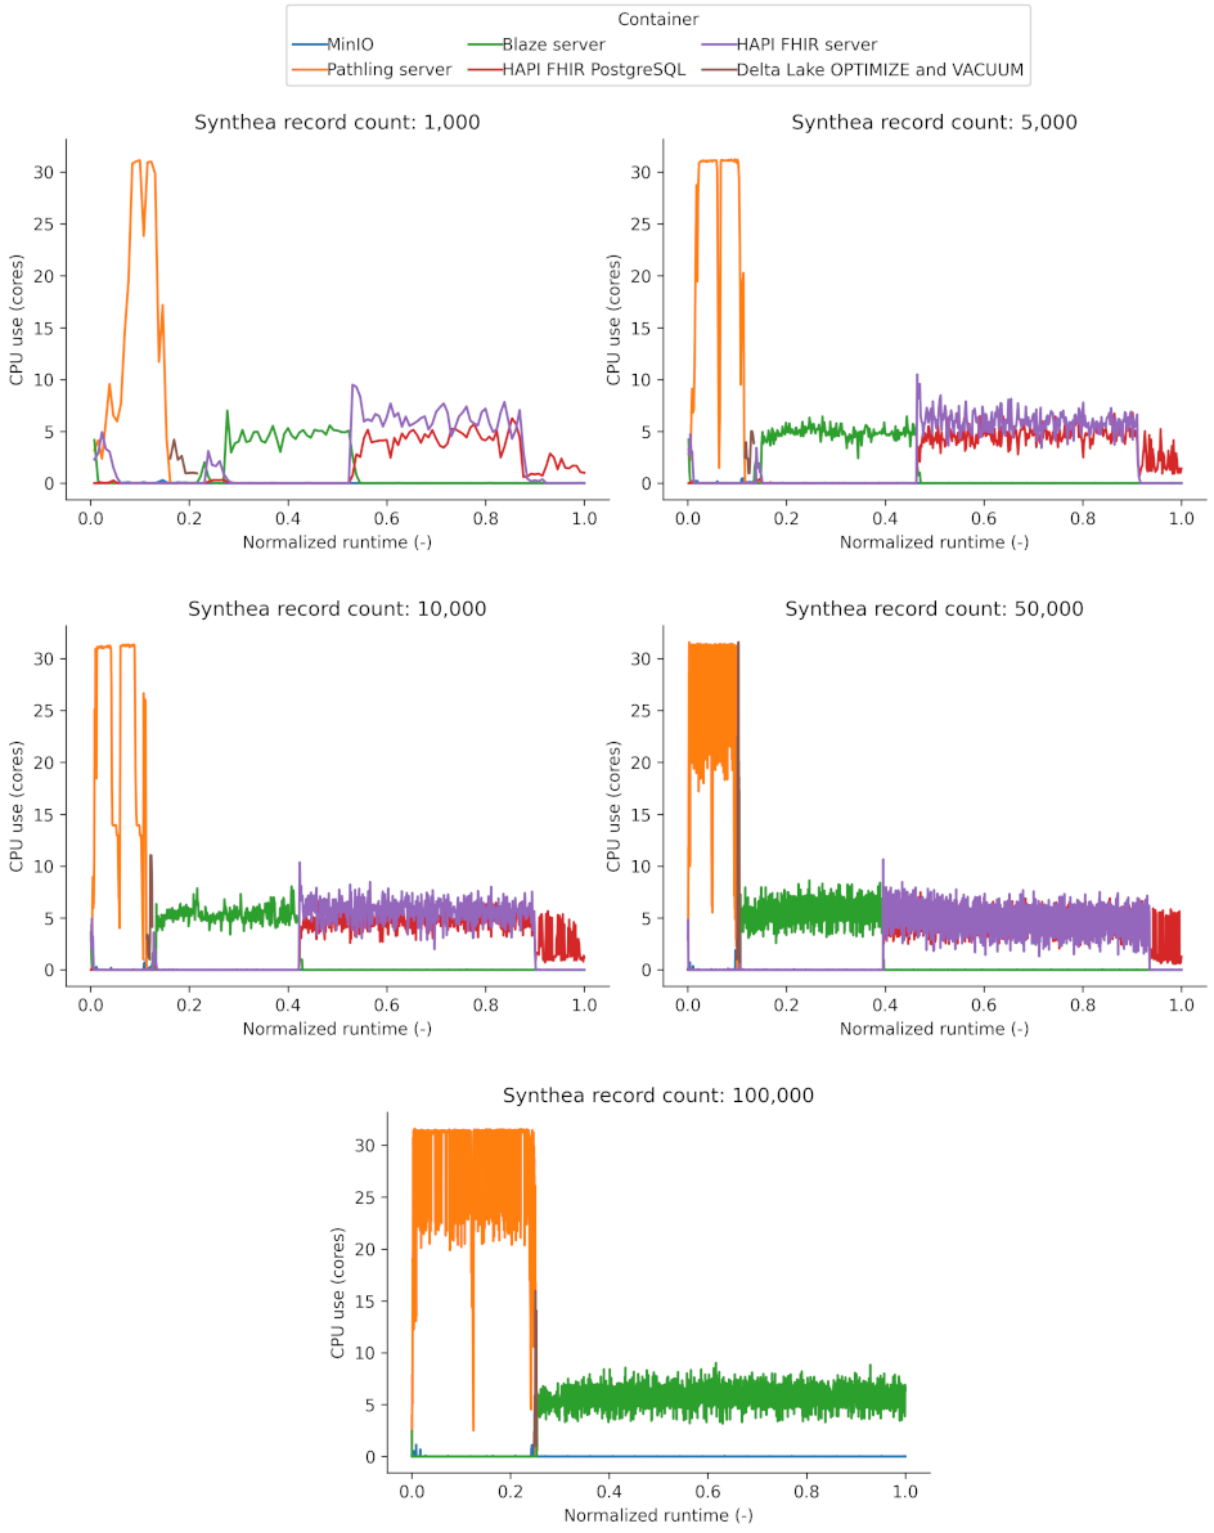
Table 4. Import duration and volume sizes corresponding to the Synthea record counts. The HAPI Fast Healthcare Interoperability Resources (FHIR) server was excluded from the largest record count benchmarks as the required disk space would exceed available resources.

Records, n	Import duration			Volume size		
	Pathling	Blaze server	HAPI server	MinIO (Pathling and Trino)	Blaze	HAPI PostgreSQL database
1000	1 min 26 s	2 min 56 s	5 min 12 s	103.5 MB	3.924 GB	19.3 GB
5000	5 min 52 s	14 min 52 s	25 min 25 s	584.1 MB	7.729 GB	47.91 GB
10,000	10 min 50 s	26 min 16 s	52 min 23 s	1.177 GB	11.33 GB	78.53 GB
50,000	47 min 44 s	2 h 12 min 49 s	4 h 37 min 53 s	6.386 GB	44.19 GB	379.2 GB
100,000	1 h 26 min 27 s	4 h 22 min 49 s	N/A[a] (excluded)	11.35 GB	84.05 GB	N/A (excluded)

[a]N/A: not applicable.



Because of the way Synthea was implemented, specifying a record count did not exactly return the same number of "Patient" resources. In the following graphs, we refer to the dataset size as "record count," corresponding to the individual resource counts in Tables 3 and 4.

Figures 2 and 3 show the memory and CPU use during data loading across the evaluated systems. During the bulk import into the Pathling server, memory consumption rapidly reached the configured limits, and CPU use became saturated, particularly for larger record counts. After completion of the import, the execution of the Delta Lake OPTIMIZE and VACUUM commands resulted in a brief peak in both CPU and memory use due to the deletion of expired files from object storage.

In contrast, the Blaze server exhibited lower CPU and memory use during transactional ingestion of FHIR resources. For the HAPI FHIR setup, CPU use was split between the PostgreSQL database and the server application, whereas memory consumption was dominated by the server. Following import, the execution of VACUUM and ANALYZE statements led to increased CPU and memory use on the PostgreSQL database, which was visible toward the end of the runtime.

FHIR Server Performance

Figure 4 shows the duration of the count queries comparing Blaze and the HAPI FHIR server. For smaller record counts and the 2 simpler gender-age and diabetes queries, performance was similar. At the largest record counts, and across all queries, Blaze completed the requests faster. For the data extraction scenario shown in Figure 5, results varied depending on the query: Blaze exhibited lower execution time for gender-age extraction but performed worse for the diabetes query. Both servers demonstrated similar performance for the hemoglobin query. Figure 6 shows the results of data aggregation queries. Across all record counts and queries, execution times were lower for Blaze than for HAPI FHIR.

RenderX

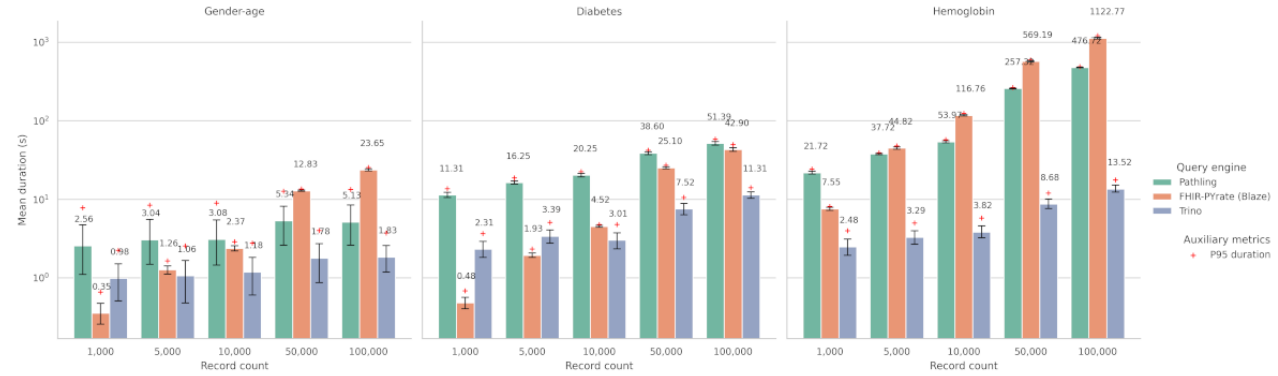
Cross-Framework Performance Comparison



For count workloads, Blaze exhibited subsecond execution times for the gender-age and diabetes queries across all record counts (Figure 7), outperforming both Trino and Pathling. For the complex hemoglobin query, Trino performed best for the largest record counts.

Figure 7. Mean execution times (log-scale; lower is better) by query and record count comparing Pathling, Blaze, and Trino for count queries. Error bars indicate the 95% CIs of the mean. All runs were repeated 10 times.

For extraction workloads (Figure 8), Trino maintained the lowest mean latency for the largest record counts across all queries. FHIR-PYrate exhibited linear growth and substantially higher absolute latency at larger record counts, exceeding 1000 seconds at 100,000 records. At smaller sizes, it outperformed both Pathling and Trino. Pathling showed similar linear growth to that of FHIR-PYrate.

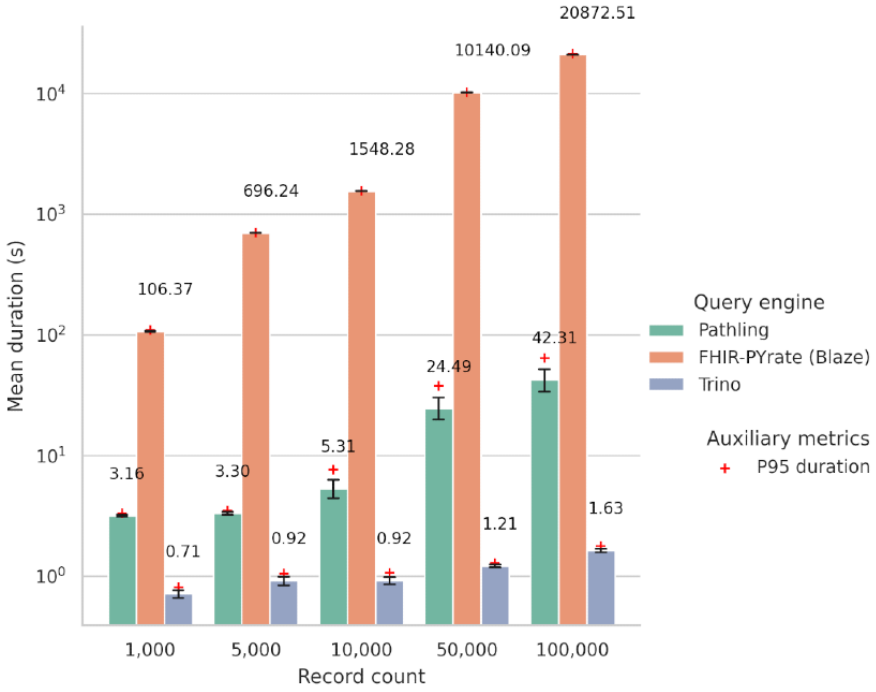


Figure 8. Mean execution times (log-scale; lower is better) by query and record count comparing Pathling, Blaze, and Trino for extraction queries. Error bars indicate the 95% CIs of the mean. All runs were repeated 10 times.

Finally, the aggregate workload (Figure 9) amplified the performance differences observed in extraction queries. Trino again showed the lowest latency and the most stable scaling behavior across record counts. Pathling scaled linearly but with higher absolute runtimes than Trino. FHIR-PYrate showed the steepest performance degradation, with aggregate queries reaching multi-hour execution times at the largest record count.

XSL•FO
RenderX

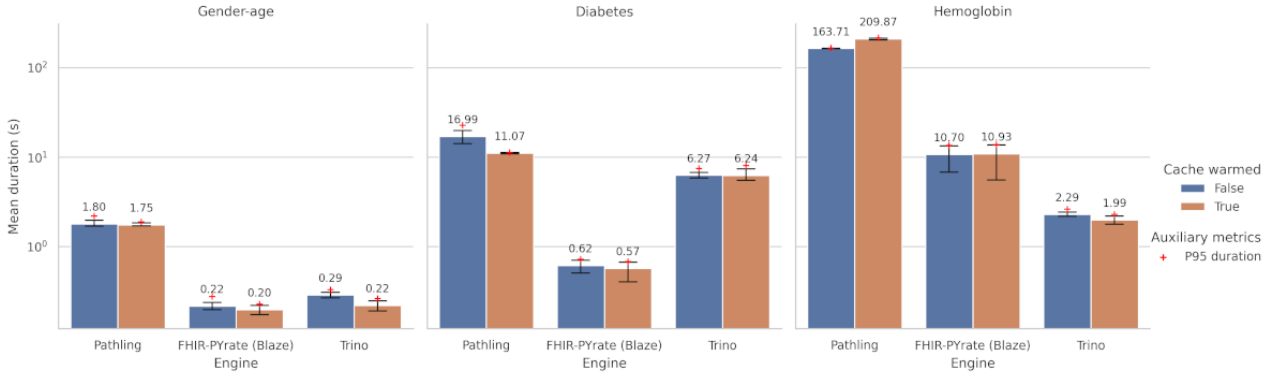

Figure 9. Mean execution times (log-scale; lower is better) by query and record count comparing Pathling, Blaze, and Trino for aggregation queries. Error bars indicate the 95% CIs of the mean. All runs were repeated 10 times.

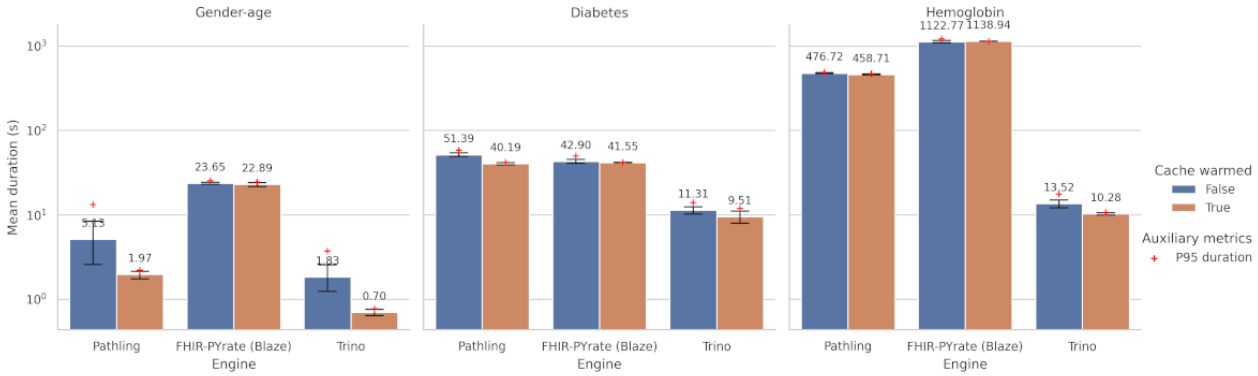
Cache Impact



Figures 10 and 11 show the impact of keeping services running for both the count (Figure 10) and extraction (Figure 11) query types. Cache warming had a small effect on count-based queries across all engines, whereas extraction workloads showed lower runtimes under warm-cache conditions for Pathling and Trino. The FHIR back end showed smaller differences between cold and warm execution.

Figure 10. Log-scaled mean execution time for the count queries of 5 consecutive runs (lower is better) comparing warm-cache to cold-cache runtimes. Error bars indicate the 95% CIs of the mean.

XSL•FO
RenderX

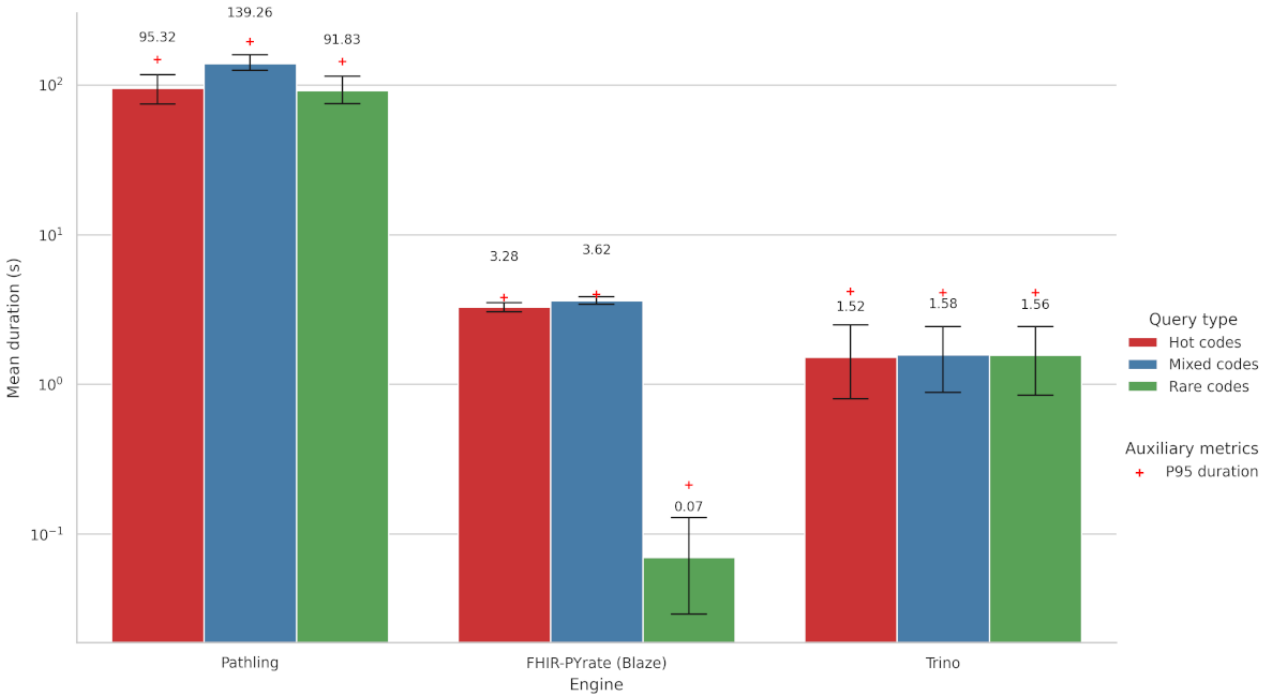


Figure 11. Log-scaled mean execution time for the extraction queries of 5 consecutive runs (lower is better) comparing warm-cache to cold-cache runtimes. Error bars indicate the 95% CIs of the mean.

Data Skew

Figure 12 shows execution times for count queries over hot, rare, and mixed "Observation" codes. The selected rare codes accounted for 0.0006% (394/60,168,356) of the total observations, and the hot codes accounted for 15.3% (9,188,358/60,168,356). Pathling showed little sensitivity to code frequency. Hot- and rare-code workloads exhibited comparable runtimes, indicating similar end-to-end execution costs across skew levels, with mixed-code queries taking the longest. Blaze showed strong sensitivity to skew. Rare-code queries were completed substantially faster than hot- and mixed-code workloads. Mixed-code performance was close to hot-code performance. Trino exhibited no sensitivity to skew, with all workloads performing nearly identically.

Figure 12. Log-scaled mean execution time (lower is better) for counting "Observation" resources with common, rare, and either codes. Error bars indicate the 95% CIs of the mean.

Discussion

There are at least 5 programming libraries that aim to implement analytical features using the FHIR Search API to retrieve data [8-11]. This is indicative not only of the increased use of FHIR as a format for conducting clinical research but also of an attempt at leveraging well-standardized interfaces: an FHIR server's RESTful interface. However, the results of this benchmark show that frameworks purpose-built for analytics can execute common queries significantly faster. A key factor in this performance gap lies in the design differences between online transaction processing and online analytical processing systems. FHIR servers, typically designed for transactional workloads or accessing individual patient records, are not optimized for computationally intensive operations such as aggregations or large-scale data filtering and extraction. In contrast, Trino and Pathling leverage modern distributed data processing paradigms. These systems enable efficient execution plans by integrating data retrieval, computation, and caching mechanisms directly within their frameworks. Still, for the count workload, we found Blaze to outperform the tested alternatives for simpler queries and lower record counts.

XSL•FO
RenderX

For the aggregation and extraction scenario, one performance-limiting factor was the need to fetch the results from the FHIR server sequentially using pagination, as the FHIR Search specification does not define native aggregation operations. The FHIR-PYrate implementation, therefore, was required to retrieve all matching "Observation" resources and perform grouping client side in pandas. In contrast, both Trino and Pathling executed the aggregation directly within the query engine using optimized query planning. The FHIR-PYrate library does allow for parallel fetching of search results, but this requires specifying an expected beginning and end date based on which to partition the search queries. For these scenarios, using the FHIR bulk export standard may be a higher-performing alternative [28].

We limited the selection of queries to only those that could be implemented as a single FHIR Search query. This avoids adding too much postprocessing logic to the total execution time. However, this also revealed challenges in the FHIR Search expressiveness and implementation in the server [5]. For example, the diabetes query in the count scenario was initially supposed to count the number of distinct patients satisfying the criteria. This would require a count on the "Patient" resource type filtered using reverse chaining ("_has") to only include those patients who were referenced in a diabetes "Condition" *and* in an "Encounter" in the specific date range within which the diagnosis was recorded. However, multiple "_has" parameters are processed independently, which would cause "Patient" resources with diabetes "Conditions" recorded as part of any "Encounter" to be counted as well. Furthermore, FHIR Search requires explicitly defining search parameters for nonstandard resource elements (such as for searching within extensions). Depending on the implementation, this also requires reindexing all resources before searches can be executed using custom parameters. Even the availability of standard search parameters varies between servers. Compared to FHIR Search, Trino is not as limiting in its expressiveness, as it is an American National Standards Institute SQL-compliant query engine. Similarly, Pathling is based on Apache Spark, where both SQL queries and a DataFrame API can be used to query the data.

Both Pathling and Trino access the same data source—FHIR resources encoded as Delta Lake tables—but use different implementations to query them. This is an example of storage-compute decoupling, where storage and computation engines can be scaled and replaced independently. This also allows for querying the data using any other framework that supports reading Delta Lake tables and makes it easier for users to use tools they are already familiar with. Despite these advantages, the transition from FHIR-native data structures to tabular formats introduces challenges: encoding FHIR resources in Delta Lake tables requires additional infrastructure and processing steps. This process not only incurs extract, transform, and load overhead but also necessitates standardization efforts as the schema of these tables is not standardized and currently bound to the implementation of the Pathling encoders. Standardizing the encoding of FHIR resources as "Open" table formats might, therefore, be a useful future endeavor to ensure interoperability for analytics [29]. Systematic performance benchmarking of alternative encodings of FHIR resources would be valuable future work as schema design choices can affect query performance across analytics engines.

The resource use measured when loading the Synthea resources from the disk to the FHIR servers and Delta Lake tables differed across the tested system. Using Pathling, the FHIR JSON files were encoded faster and ended up using less disk space than both the HAPI and Blaze FHIR servers. However, Pathling also used more CPU and memory during loading. The 2 FHIR servers were loaded using 1 transaction bundle per Synthea patient record, and even though the blazectl client concurrency was set to 32, the servers did not fully saturate the available CPUs. This could be a result of the transaction processing implementation limiting the maximum concurrency. In comparison, the Pathling server used bulk import functionality, which was likely less affected by database locks and similar bottlenecks necessary to ensure atomic transaction processing. If it were implemented in all evaluated systems, consistently using bulk import would make the results more comparable.

The limited cache sensitivity observed for count workloads suggests that these queries were dominated by full-table scans rather than metadata or plan reuse. In contrast, extraction workloads benefited from cache reuse in Pathling and Trino, likely reflecting reuse of Parquet or Delta Lake metadata, execution plans, and file system caches in Spark and MinIO. While Trino caches Delta Lake metadata by default (for 30 minutes), we did not enable file system caching, which might have shown a more significant impact on cache-warmed performance.

The HAPI FHIR server was unable to complete the hemoglobin query beginning with the lowest record counts. When attempting to run the count variant of the query, we observed a single PostgreSQL CPU max out until eventually the query was aborted with an "out of disk space" error. We believe this may be caused by the way in which multiple OR-combined code-value-quantity searches are translated to SQL queries in the server.

The observed differences in the impact of data skew on the count performance highlight how engines respond differently to skew in predicate selectivity and result cardinality. Pathling's and Trino's insensitivity to code frequency suggests that performance is dominated by full-table scans, with limited benefit from selective predicates in the current execution model. In contrast, Blaze benefited substantially from highly selective predicates. Mixed-code queries remained dominated by high-frequency codes, explaining why their performance resembled hot-code workloads. These results demonstrate that realistic long-tail code distributions can affect engine performance and that benchmarks assuming uniform code distributions may overstate the performance of scan-dominated pipelines. The present experiment isolated skew in single-table predicate selectivity; join-key skew and shuffle skew in multi-table and multi-worker cohort queries remain important directions for future work.

All benchmarks were run on a single virtual machine, which means that both the benchmarked components and the code used to observe them were not isolated from each other. Additionally, all network communication occurred on the same local loop-back network interface, making the results less

XSL•FO
RenderX

realistic as the impact of network latency was not measured. As modern data processing frameworks are capable of—and even optimized for—running analytical queries distributed across multiple compute nodes, how these findings generalize to such setups necessitates further exploration.

Future research should aim to establish a common set of benchmark scenarios tailored to health care analytics on FHIR. Drawing inspiration from benchmarks such as TPC-H [30], such a framework could provide a standardized methodology for evaluating diverse analytics engines and facilitate comparison across tools and architectures. This is particularly relevant with the new SQL-on-FHIR standard [7].

While our results show that FHIR Search performs poorly for analytical workloads dominated by large scans and aggregations, FHIR servers in general provide strengths that are critical in production environments: fine-grained access control; provenance and audit logging; transactional guarantees; and standardized functionality for searching, creating, updating, patching, and deletion. In many deployments, these features outweigh analytical throughput and justify the use of FHIR Search for patient-level queries and standardizable workflows [31]. Our findings, therefore, do not argue against FHIR servers as a primary clinical data interface but, rather, highlight their unsuitability as a sole back end for large-scale cohort analytics and population-level queries, where columnar analytics engines can provide substantial performance advantages.

The FHIR standard is primarily designed for interoperability and the exchange of health care data. In particular, while the REST-based FHIR Search API is useful for standard queries and retrieving specific patient records, it is generally not suitable for high-performance, complex analytics, making it necessary to move the data to a more robust analytical environment. Engines such as Trino and Pathling demonstrated substantial performance advantages for analytics scenarios.

Acknowledgments

The present work was performed in (partial) fulfillment of the requirements for obtaining the degree “Dr. rer. biol. hum.” from the Friedrich-Alexander-Universität Erlangen-Nürnberg (JZ). During the preparation of this work, the authors used GPT-5.2 (OpenAI) to improve the readability and language of parts of the manuscript. Abstract

Background: Accurate diagnosis of middle ear diseases remains challenging due to the specialized nature of otoscopic interpretation and the global shortage of otolaryngologists.

Objective: We aimed to evaluate the impact of a deep learning–based AI support system on the diagnostic performance of clinicians with varying levels of expertise, specifically focusing on its ability to bridge the gap between trainees and experts.

Methods: In this retrospective reader study, a deep learning model (EfficientNet-B4) was developed using a large-scale dataset of 7335 endoscopic images. The model was designed for multi-class classification, simultaneously identifying primary categories (chronic otitis media, otitis media with effusion, or none [indicating the absence of the first two]) and secondary features (attic retraction, myringitis, otomycosis, and ventilation tube). To assess clinical impact, diagnostic performance was compared among 3 otology professors, 5 senior residents, and 5 junior residents using an independent clinical assessment set of 100 images. Participants performed diagnoses both with and without AI-generated predictions, with a time constraint of 1 minute per image to simulate real-world clinical pressure.

Results: In 5-fold cross-validation, the deep learning model achieved 94.8% accuracy for the primary classification. The stand-alone AI achieved diagnostic accuracies ranging from 94.0% to 99.0% in the clinical assessment set. AI support significantly enhanced diagnostic accuracy across all groups for primary classification, with improvements of 11.0% for otology professors, 28.8% for senior residents, and 32.2% for junior residents (P<.001). Accuracy increased from 78.7% to 89.7% for otology professors, from 65.0% to 93.8% for senior residents, and from 54.4% to 86.6% for junior residents. The accuracy gap between the most experienced (otology professors) and least experienced (junior residents) groups was reduced from 24.3% to 3.1%. For secondary categories, significant improvements were observed in diagnosing attic retraction and myringitis among residents. AI-supported accuracy for attic retraction was higher in senior residents than that of the stand-alone AI, although the 95% CIs overlapped substantially, so the difference was not statistically significant.

Conclusions: Our findings demonstrate that deep learning–based AI support substantially improves the diagnostic accuracy of middle ear diseases, particularly for less experienced clinicians. By narrowing the performance gap between trainees and experts, this system shows high potential as a valuable adjunct for clinical decision-making and medical education in otology.

Introduction

Middle ear diseases, including chronic otitis media (COM) and otitis media with effusion (OME), are prevalent worldwide [1]. For example, OME is extremely common, with a prevalence of 80% to 90% in children, and early diagnosis is crucial due to the potential impact on speech and language development associated with hearing loss [2,3]. However, many countries face difficulties due to a shortage of otolaryngologists. In 64% of African countries, there is less than 1 otolaryngologist per million people [4]. Otoscopy, essential for diagnosing middle ear diseases [5], can present challenges even for specialists in achieving accurate interpretation. Due to the shortage of specialists, nonspecialists often diagnose middle ear diseases [4,6,7], which can lead to misdiagnoses and, consequently, inadequate treatment.

To address the challenge of diagnosing middle ear diseases, machine learning (ML) approaches for the diagnosis of middle ear diseases have been proposed for decades [8-10]. ML models can be used to accurately predict the presence or absence of middle ear effusions in pediatric patients and achieve significantly higher diagnostic accuracy than traditional otoscopy performed by experts [8]. A convolutional neural network was developed to automatically detect tympanic membrane (TM) and middle ear infections from endoscopic images, showing high accuracy and potential for clinical application [9]. The diagnostic performance of the ML models was comparable to that of experienced otolaryngologists and demonstrated that the imbalance problem due to disease prevalence could be mitigated through data augmentation [11]. Recent reviews and a meta-analysis have also reported the growing use of image-based AI for diagnosing middle ear diseases, with generally high diagnostic performance [12-14]. Recent studies have further evaluated the generalizability of these models and compared their performance with that of clinicians [15,16].

In a previous study [10], we developed a deep learning model capable of simultaneously diagnosing 2 or more diseases using a database of 6630 endoscopy images that included various diseases. Our deep learning model could predict 2 noncoexisting diseases (OME and COM) along with 4 concurrently detectable diseases (attic retraction, myringitis, otomycosis, and ventilation tube). The diagnostic accuracy ranged from 95.3% to 99.4%.

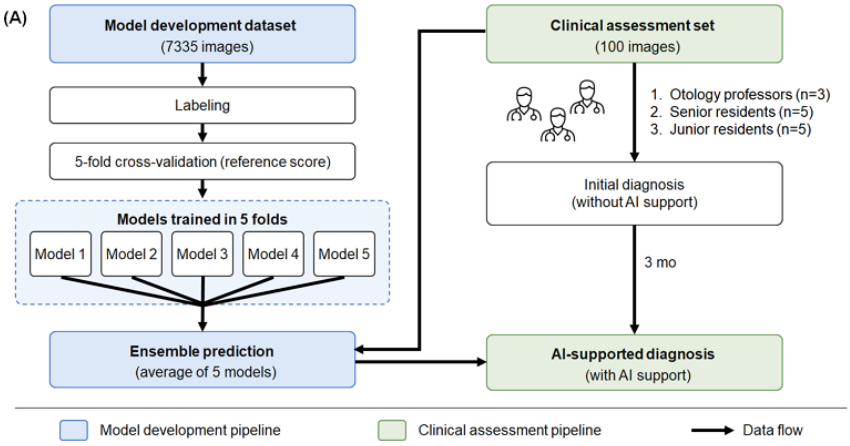
Although deep learning models have demonstrated high diagnostic performance, their accuracy can fluctuate based on training data and model architecture [11,17]. There is also a risk of misdiagnosis in cases with apparent characteristics. Consequently, there is growing interest in how ML models can enhance diagnostic performance by supporting clinical decisions. Recent studies have also examined human-AI collaboration in clinical diagnosis, including how AI recommendations influence physician decision-making and diagnostic performance [18,19]. In dermatology, for instance, decision support from deep learning systems improved diagnostic accuracy by 33% for both specialists and general practitioners [17]. However, in the field of endoscopic diagnosis for middle ear diseases, the impact of deep learning models on clinical decisions remains unexplored.

This study makes 3 contributions. We quantify the effect of AI support on middle ear diagnosis across different levels of clinical experience; assess whether AI support narrows the diagnostic performance gap between trainees and experts; and characterize how clinicians respond to AI recommendations, including changes in diagnostic decisions after AI support.

Methods

Data Description

Endoscopic images were retrospectively collected at Asan Medical Center from January 2018 to December 2020 (Figure 1A). The final dataset comprised 7435 images, including 7335 images for model development and a separate clinical assessment set of 100 images. Each patient contributed 1 image to the dataset. Endoscopic examinations were performed for diagnostic purposes, and the captured images were stored in the hospital server without patient identification information.



Two experienced otologists independently and blindly annotated each collected image (Figure 1B). Only images with complete agreement between the 2 otologists were included in either the model development dataset or the clinical assessment set, and images with any discordant annotation were excluded. The excluded images were not retained, and their number was not recorded. No additional objective reference standard was used for the clinical assessment set. In the primary class, the collected images were annotated as one of the following: “COM,” “OME,” and “None” (indicating the absence of COM or OME). COM was defined as visible perforation of the TM. OME was defined as the presence of effusion in the middle ear cavity, which was characterized by the color change of the TM, such as amber, or the air fluid level in the middle ear cavity. In the secondary classes, the collected images were annotated as presence or absence of “attic retraction,” “myringitis,” “otomycosis,” and “ventilation tube.” Attic retraction was defined as the retracted TM or bony destruction in the attic. Myringitis was defined as any inflammation of the TM, including acute otitis media. Otomycosis was defined as the whitish debris or visible pores of fungus in the TM or external auditory canal. Ventilation tube was defined as a tube inserted through the TM. A myringotomy containing a ventilation tube was not considered a perforation in the annotation of COM. We expanded our database with more cases of attic retraction and otomycosis, which had shown relatively lower diagnostic performance in our previous study [10]. The distribution of cases across the primary and secondary classes is summarized in Figure 1B.

The clinical assessment set did not overlap with the model development dataset. None of the 100 images in the clinical assessment set were included in the training, validation, or test folds used to develop the 5 models comprising the ensemble. For this set, cases with a primary class of “None” and negative findings for all secondary classes were excluded to avoid overrepresentation of normal cases. The number of cases for each disease category was determined based on the class distribution used in our previous study [10], and images were randomly selected within these categories. No images were excluded based on image quality assessment for either model

XSL•FO
RenderX

training or clinician evaluation. The clinical assessment set size was determined pragmatically by considering reader burden and the need to evaluate multiple clinician groups both before and after AI support.

Figure 1. (A) Schematic diagram for comparison of initial and AI-supported diagnoses, (B) distribution of otoendoscopic images across primary and secondary classes in the model development dataset (top) and the clinical assessment set (bottom), (C) deep learning network for multi-class classification, and (D) user interface for clinical assessment. "None" indicates the absence of chronic otitis media (COM) and otitis media with effusion (OME).

Sum		51	22	27	100

Construction of AI Support Using Deep Learning

The deep learning network architecture in this study was based on our previous work [10]. EfficientNet-B4 [20] was customized to incorporate both shared and task-specific layers, enabling precise predictions of concurrently existing diseases in the TM (Figure 1C). The deep learning model classified an endoscopic image into one of the primary classes: OME, COM, and "None." Simultaneously, it determined the presence or absence of 4 secondary classes: attic retraction, myringitis, otomycosis, and ventilation tube (Figure 1).

RGB images reformatted to 256 × 256 × 3 with circular cropping were fed to the deep networks as inputs. Circular cropping removed only the noninformative dark periphery outside the otoendoscopic field of view while retaining the TM and the surrounding external auditory canal. The pretrained weights from ImageNet were applied for transfer learning. Categorical cross-entropy loss was used for the mutually exclusive primary classes, whereas binary cross-entropy loss was used for each of the 4 secondary classes because the secondary classes were not mutually exclusive. To prevent overfitting, data augmentation methods were used: random rotation (−90° to 90°), shift (0% - 20% of the image size in the horizontal and vertical axes), magnification (0% - 20%), horizontal flip, brightness modification (0% - 20%), and resolution reduction (0% - 50%). The models were trained for 200 epochs with a differential learning rate, which was initially set as 10^{-3} and decreased by half when the validation loss stagnated for 50 epochs. To assess the model performance more objectively and robustly, 5-fold cross-validation was performed using 7335 images (Figure 1A). Five-fold cross-validation was performed with each patient's single image assigned to only 1 fold, thereby preventing patient overlap across folds. For 5-fold cross-validation, 3 folds were used for training, 1 fold was used for validation, and 1 fold was used for testing. The validation and test folds were permutatively changed across the 5 folds. The reported cross-validation performance metrics were calculated using the test set, not the training or validation data.

The evaluation metrics for each label were precision, sensitivity (recall), specificity, and Dice similarity coefficient (DSC), which were defined as precision = true positives [TPs]/(TPs + false positives [FPs]), sensitivity = TPs/(TPs + false negatives [FNs]), specificity = true negatives [TNs]/(FPs + TNs), and DSC = 2 × precision × recall/(precision + recall). The per-class accuracy was calculated by dividing the sum of TPs and TNs by the total number of images in a fold.

Impact of AI Support on Diagnostic Decision

To analyze the impact of deep learning predictions on diagnostic decisions, we compared diagnoses made without AI support ("initial diagnosis") to those made after referring to deep learning predictions ("AI-supported diagnosis"). The

XSL•FO
RenderX

AI-supported diagnosis was conducted 3 months after the initial diagnosis. The order of the 100 images was randomized during the second reading session to reduce recall bias. For the AI-supported diagnosis, clinicians were provided with predictions generated using a soft-voting ensemble of 5 deep learning models trained during the cross-validation. The predicted probabilities were averaged across the 5 models to generate the final AI predictions. During the AI-supported assessment, clinicians reviewed the AI predictions before making their final diagnostic decisions. The AI predictions were presented as categorical outputs for the primary and secondary classes. No confidence scores or probabilities, heat maps, saliency maps, or other explanatory visualizations were provided to the clinicians. We compared the diagnostic performance across 3 groups: otology professors (n=3), senior residents (n=5), and junior residents (n=5). For each clinician group, sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) were additionally calculated for the primary and secondary classes. Diagnoses for the clinical assessment set were made using still images identical to the input of deep learning model, with participants given 1 minute per image.

To characterize clinician responses to AI recommendations, we additionally analyzed cases in which the initial diagnosis differed from the AI prediction for the primary class. An AI recommendation was considered accepted when the AI-supported diagnosis matched the AI prediction and rejected when the AI-supported diagnosis did not match the AI prediction. We also categorized each diagnosis according to the change in correctness from the initial to the AI-supported assessment as incorrect to correct, correct to incorrect, correct to correct, or incorrect to incorrect.

Statistical Analysis

All statistical analyses were performed using SAS software (version 9.4; SAS Institute). Assessment times for the initial and AI-supported diagnoses were summarized using the median and IQR. The 95% CIs for accuracy, DSC, sensitivity, specificity, PPV, and NPV were estimated using the percentile bootstrap method with 2000 replicates. For each replicate, images were sampled with replacement to generate a bootstrap sample of the same size as the original dataset, and the performance metrics were recalculated. Because the resampling unit was the image, these CIs do not account for between-clinician variability. *P* values for accuracy were calculated using generalized estimating equations with image as the clustering unit to model repeated diagnostic assessments of the same image across clinicians and reading sessions. “Clinician” was not included as a clustering factor. $P<.05$ was considered statistically significant.

Ethical Considerations

This study was approved by the institutional review board of Asan Medical Center (2021 - 0837), and the requirement for informed consent for the retrospective use of otoendoscopic images was waived. All study images were deidentified before analysis, and the investigators had no access to personal identifying information. Written informed consent was obtained from all clinician readers before participation. No compensation was provided to the clinician readers. No images included in the manuscript contain identifiable facial features or personal information. The study was conducted in accordance with the Declaration of Helsinki.

Results

Diagnostic Performance of Deep Learning Models in Cross-Validation

Table 1 shows the diagnostic performance of deep learning models in the 5-fold cross-validation using 7335 images. In predicting the primary class, both accuracy and DSC were 94.8%. Among the secondary classes, ventilation tube was the most accurately diagnosed (99.5%), followed by otomycosis and attic retraction. Myringitis had a relatively lower predictive accuracy of 95.0%.

Table . Diagnostic performance of deep learning models in 5-fold cross-validation (“reference score” in Figure 1A).

Class	Accuracy (%; 95% CI)	DSC[a] (%; 95% CI)	Sensitivity (%; 95% CI)	Specificity (%; 95% CI)
Primary class	94.8 (94.3 - 95.3)	94.8 (94.3 - 95.3)	94.8 (94.3 - 95.3)	95.6 (95.0 - 96.0)
Attic retraction	97.0 (96.6 - 97.3)	91.4 (90.3 - 92.5)	88.6 (87.0 - 90.3)	98.8 (98.5 - 99.1)
Myringitis	95.0 (94.5 - 95.5)	84.1 (82.4 - 85.7)	83.7 (81.4 - 85.8)	97.1 (96.7 - 97.6)

Diagnostic Performance of AI Support for the Clinical Assessment Set

AI support suggested diagnoses with accuracy ranging from 94.0% (myringitis) to 99.0% (ventilation tube), as shown in Table 2. When compared to cross-validation, the accuracies for individual disease identification varied by 0.2% to 1.7%.

Initial Diagnosis of Clinicians for the Clinical Assessment Set

The diagnostic accuracy for the primary class demonstrated a positive correlation with clinical experience (*P*<.001 for otology professors vs senior residents, otology professors vs junior residents, and senior vs junior residents; Table 3). The junior resident group showed a significantly lower accuracy of 54.4%. For all secondary classes, no significant differences were found between the otology professor and senior resident groups. On the other hand, in the diagnosis of myringitis, the junior resident group showed an accuracy difference of more than 11.6% compared to both the otology professor and senior resident groups (*P*<.001).

AI-Supported Diagnosis of Clinicians for the Clinical Assessment Set

AI support significantly improved the diagnostic accuracy of the primary class by 11.0%, 28.8%, and 32.2% for the otology professor, senior resident, and junior resident groups, respectively (P<.001; Table 2). The senior resident group achieved the highest accuracy (P=.03 for otology professors vs senior residents; Table 3), whereas the difference between the otology professor and junior resident groups was reduced to 3.1% (P=.17; Table 3). Among the secondary classes, both the senior and junior resident groups demonstrated significant performance improvements in diagnosing attic retraction and myringitis (Table 2). For attic retraction, AI-supported accuracy was higher in the senior resident group than that of stand-alone AI (99.0%, 95% CI 97.8% - 99.8% vs 98.0%, 95% CI 95.0% - 100%), although the 95% CIs overlapped substantially. Regarding otomycosis and ventilation tube diagnoses, accuracy differences among the 3 groups ranged from –0.8% to 2%, but these changes were not statistically significant. Sensitivity, specificity, PPV, and NPV for each clinician group can be found in Multimedia Appendix 1. The median assessment time was 3 seconds in both the initial (IQR 2 - 5 seconds) and AI-supported (IQR 2 - 6 seconds) sessions.

Clinician Responses to AI Recommendations

Among 1300 clinician image assessments for the primary class, the initial diagnosis differed from the AI recommendation in 499 cases (Table 4). Clinicians accepted the AI recommendation in 79.2% (395/499) of cases and rejected it in 20.8% (104/499) of cases. The acceptance rate was 65.8% (50/76) for otology professors, 84.0% (157/187) for senior residents, and 79.7% (188/236) for junior residents. Final diagnoses were correct in 95.9% (379/395) of accepted cases and 31.7% (33/104) of rejected cases. Among rejected recommendations, clinicians retained their initial diagnosis in 90 cases and selected a diagnosis different from both the initial diagnosis and the AI recommendation in 14 cases. Across all 1300 assessments, 384 initial errors were corrected after AI support, whereas 46 initially correct diagnoses became incorrect. Of these 46 cases, 13 occurred when the initial diagnosis differed from the AI recommendation and 33 occurred when it matched the AI prediction.

Acceptance of AI recommendations differed across experience groups. When the initial diagnosis differed from the AI prediction, otology professors accepted the AI recommendation in 65.8% (50/76) of cases compared with 84.0% (157/187) for senior residents and 79.7% (188/236) for junior residents. When clinicians rejected the AI recommendation, the final diagnosis was correct in 42.3% (11/26) of cases for otology professors and 46.7% (14/30) for senior residents, whereas it was correct in only 16.7% (8/48) of cases for junior residents.

Table . Clinician responses to AI recommendations for the primary class.

Clinician response	OPs[a]	SRs[b]	JRs[c]	Overall

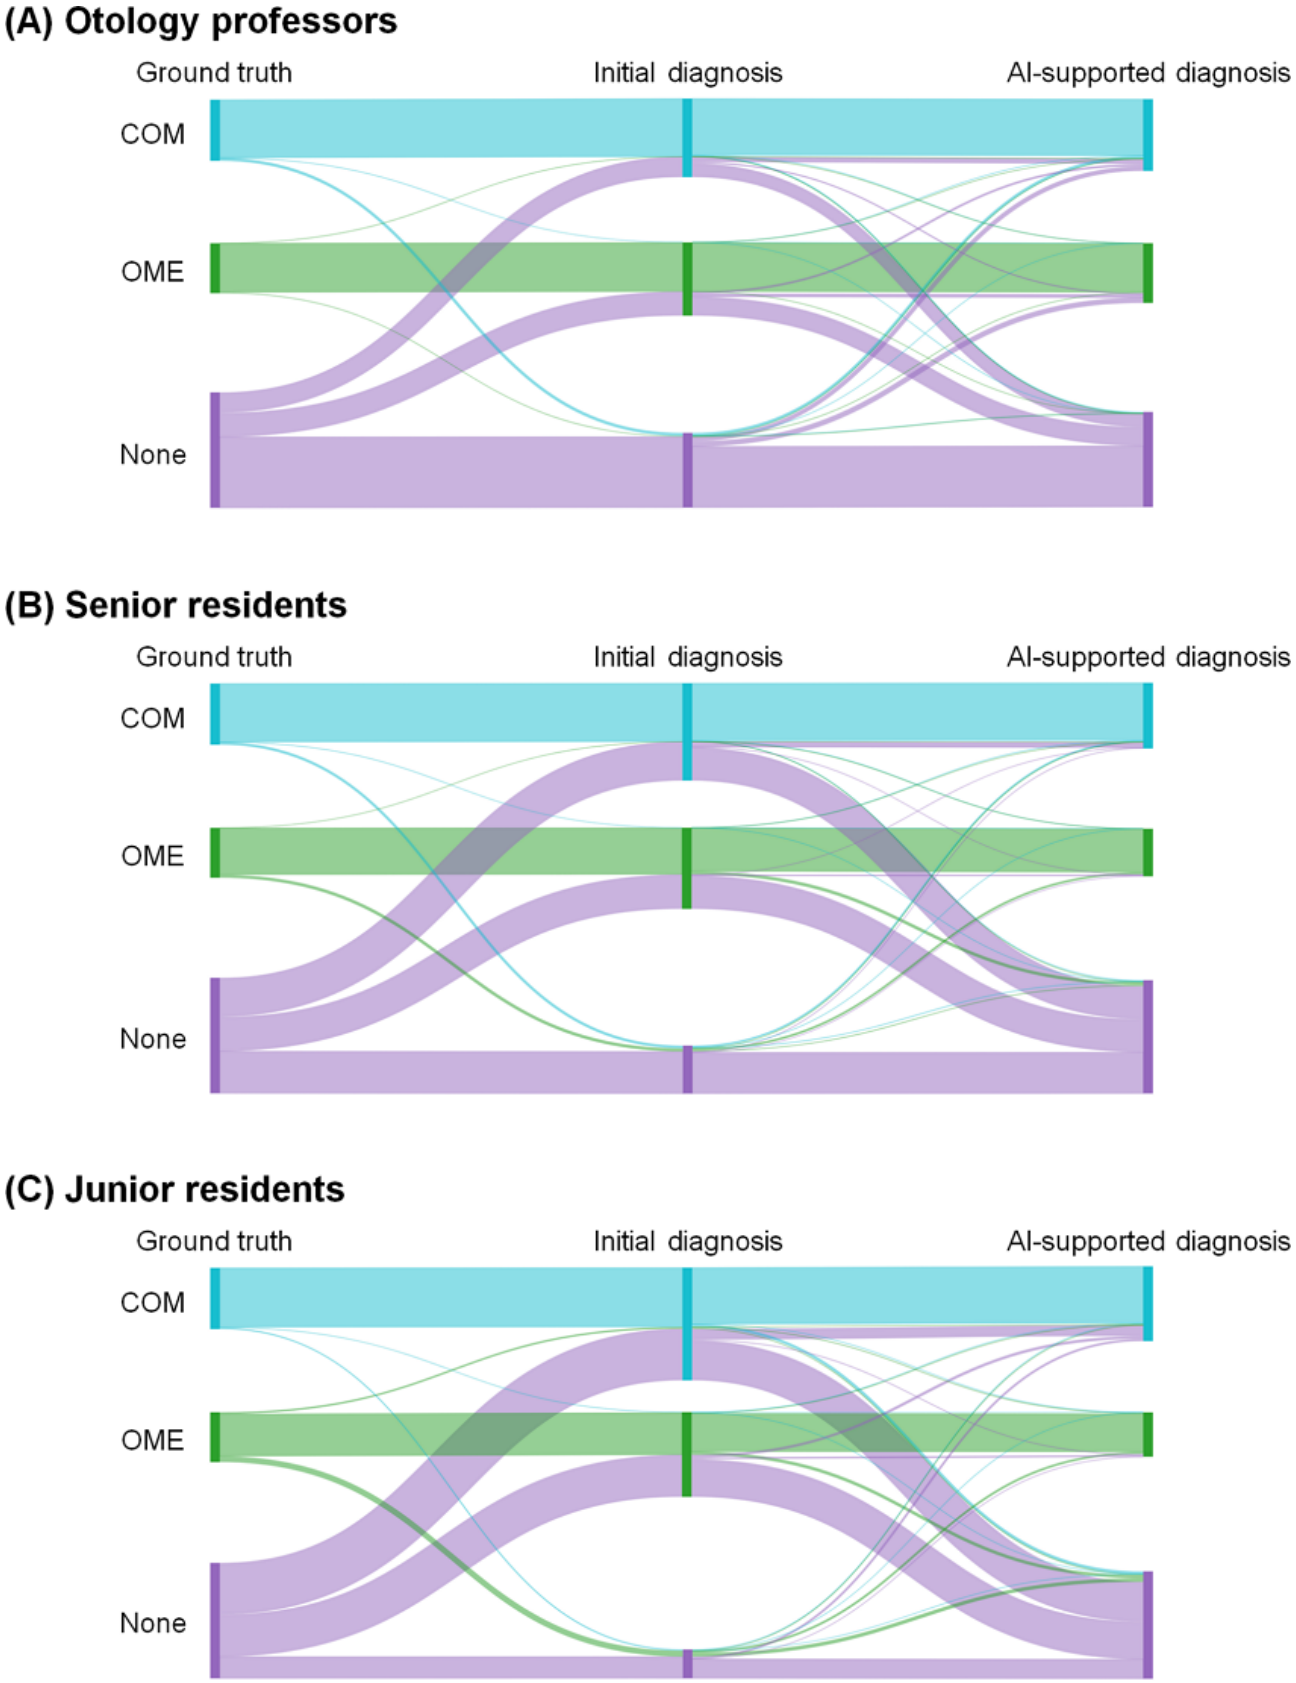
Discussion

Major Findings

In this study, we developed AI support for the diagnosis of middle ear diseases using a deep learning model trained on a large-scale database of 7335 endoscopic images. The data imbalance issue arising from different prevalence rates was mitigated by using our expanded database. The trained models effectively reduced the disparity in diagnostic performance across individual diseases, consequently enhancing the quality of our AI support. For a separate clinical assessment set of 100

XSL•FO
RenderX



images, AI support improved diagnostic performance across 3 groups—otology professors, senior residents, and junior residents—while also reducing the disparity in diagnostic accuracy due to different levels of clinical expertise. In the diagnosis of attic retraction, referring to AI predictions enabled senior residents to achieve higher accuracy than that of stand-alone AI, although the 95% CIs overlapped substantially.

Clinical Impact of AI Support

The diagnostic accuracy of clinicians in this study ranged from 54.4% to 78.7% for the primary class, which is comparable to the performance reported in our previous study [10]. By referring to the AI support, the diagnostic accuracy of clinicians improved to between 86.6% and 93.8%. Recent studies have also shown that AI can outperform clinicians in middle ear disease diagnosis [16]. AI assistance has also been shown to reduce workload in medical image interpretation [21]. The junior resident group, which had the lowest diagnostic accuracy in the initial diagnosis, showed the highest propensity to alter decisions after referring to AI support (Figure 2). The additional analysis showed that improvement after AI support was primarily associated with correction of initially incorrect diagnoses, although some initially correct diagnoses became incorrect after AI support. The 33 correct-to-incorrect changes that occurred when the initial diagnosis matched the AI prediction likely reflect intrareader variability over the interval rather than an effect of AI support. Clinician responses to AI recommendations also differed according to clinical experience. Senior and junior residents were more likely than otology professors to accept AI recommendations, whereas junior residents were less likely to make a correct final diagnosis when they rejected the AI recommendation. These findings suggest that the role of AI support may differ according to the clinician's level of experience. Considering the characteristics of middle ear diagnosis, where multiple diseases are concurrently detectable, this finding demonstrates the potential of AI support in augmenting clinical decision-making, particularly in cases that pose diagnostic challenges for less experienced clinicians, including nonotologists.

XSL•FO
RenderX

Figure 2. Changes in diagnostic performance of the primary class through referencing AI support. “None” indicates the absence of chronic otitis media (COM) and otitis media with effusion (OME).

Use of AI Support in Medical Education

The deep learning models and evaluation methods used in this study can also be applied to educational simulations. Previous research has demonstrated that otoscope simulation enhances confidence in diagnosing otological diseases compared to conventional training methods [5]. With the evaluation system used in this study, trainees can be exposed to a diverse array of

XSL•FO
RenderX

endoscopic images in a short period. Furthermore, the integration of deep learning predictions in constructing simulation data offers a novel approach to medical education in otology, potentially accelerating the learning curve and improving diagnostic skills across various levels of expertise.

Diagnostic Errors With AI Support

Diagnostic errors in the primary class predominantly manifested as misclassifications of "None" (absence of COM or OME) as disease positive, whereas the opposite scenario was exceedingly rare (Figure 2). This pattern likely stemmed from the exclusion of cases in the clinical assessment set where the primary class was "None" and all secondary classes were negative, which represented cases without COM, OME, or any secondary finding (Figure 1B). Intriguingly, within the otology professor group, there were instances in which images initially correctly diagnosed as "None" were reclassified as COM or OME after referring to AI support. This suggested the possibility that diagnostic capabilities may be blurred by AI support. Consequently, the otology professor group exhibited a higher rate of FPs for OME than the senior and junior resident groups. This finding is consistent with growing concerns that AI support may improve diagnostic performance while also creating risks of automation bias [22]. In our study, the increased false-positive diagnoses of OME among otology professors after AI support suggest that even experienced clinicians may be influenced by AI suggestions in selected cases. This finding also suggests that AI support should not be assumed to provide uniform benefits across levels of clinical expertise. Therefore, clinicians should interpret AI outputs in the context of their own assessment and consider them as supportive information.

AI assistance also carries potential risks. Beyond the automation bias discussed above, reliance on AI may lead clinicians to defer to the model even when their independent judgment would be correct. Habitual use of diagnostic AI during training may also affect the development of independent diagnostic skills. These effects could not be evaluated with the current study design and warrant prospective and longitudinal investigation.

Limitations

First, our deep learning models for AI support were trained on a database from a single medical center, potentially limiting their generalizability. Because the dataset was fully anonymized before analysis, demographic information such as age and sex was unavailable, and the demographic representativeness of the dataset could not be evaluated. In addition, exclusion of images with discordant annotations may have removed diagnostically challenging cases and led to overestimation of both model and clinician performance. Future studies should incorporate multicenter data encompassing diverse patient demographics and a variety of imaging devices.

Second, the coverage of AI support needs to expand to include additional middle ear diseases such as congenital cholesteatoma and tympanosclerosis plaque. Furthermore, our results indicated relatively lower diagnostic accuracy for myringitis and otomycosis. The input images were resized to 256 × 256 × 3 rather than using the original high-resolution images to support efficient model training and potential real-time application. Although the model showed high overall classification performance, this downsampling may have reduced fine-grained visual details used for diagnosis. These limitations may reduce the applicability of the system across a broader range of middle ear diseases. EfficientNet-B4 also operates as a black-box model, and the image features underlying its predictions are not directly interpretable.

Third, the clinical assessment set was disease enriched because cases with a primary class of "None" and negative findings for all secondary classes were excluded. Therefore, it did not reflect the prevalence of normal ears in routine clinical practice, which may have affected performance estimates and contributed to the observed false-positive rate. The clinical assessment was based on 100 images. A set of this size limits the precision with which the diagnostic improvements are estimated and increases sampling variability, particularly for secondary categories with few positive cases. Although AI support improved primary-class accuracy across all 3 experience groups, the magnitude of the observed improvements should be interpreted with caution and confirmed in a larger assessment set. The clinical assessment involved a small and unbalanced clinician sample (3 otology professors, 5 senior residents, and 5 junior residents). These small group sizes, particularly for the otology professor group, limit the statistical reliability of the between-group comparisons. Because the bootstrap resampled images only, the resulting CIs do not reflect between-clinician variability. The generalized estimating equations models accounted for repeated assessments of the same image. Correlation among readings by the same clinician was not modeled. Therefore, uncertainty in the between-group comparisons may be underestimated, particularly given the small and unbalanced reader sample.

Fourth, the clinical assessment used single static images, which may not fully reflect real-world otoendoscopic evaluation based on dynamic examination and clinical context. The AI support was evaluated using selected static otoendoscopic images, which may introduce frame selection bias. In real practice, diagnostic performance may also depend on how well the clinician captures the image, which could influence AI-assisted diagnosis. Image quality in real-time use may also vary because of differences in illumination, focus, artifacts, and anatomical variations. The robustness of the model under conditions not represented in the study data was not specifically evaluated. The 1-minute time limit was reached in only 3 AI-supported readings and was therefore unlikely to have materially affected the comparison between the 2 sessions.

Fifth, all clinicians performed the initial diagnosis first and the AI-supported diagnosis 3 months later. This fixed order means that the AI support effect cannot be fully separated from a learning effect over the interval or a residual memory effect for the same images. This interval may also explain the correct-to-incorrect changes that occurred when the initial diagnosis matched the AI prediction. The magnitude of the observed improvement, particularly in the resident groups, should therefore be interpreted with caution. Future studies should counterbalance the reading order across clinicians to better isolate the effect of AI support.

XSL•FO
RenderX

Sixth, this study assessed changes in diagnostic decisions before and after exposure to AI predictions but did not directly evaluate how clinicians interpreted or weighted the AI recommendations. Therefore, the specific human-AI decision-making processes underlying these changes remain unclear, including whether providing confidence or uncertainty information would alter clinicians' decision patterns, particularly for borderline cases.

Seventh, AI support's utility for nonotologists remains unexplored. This limits the generalizability of our findings beyond otologists. Given that primary care physicians often encounter middle ear diseases, validating the AI support's effectiveness in these broader clinical contexts would be valuable.

Conclusions

We developed an AI support system for middle ear disease diagnosis using an expanded database of 7335 endoscopic images, demonstrating potential to enhance diagnostic performance across different levels of clinical expertise. With AI support, the primary class accuracy gap between otology professors and junior residents narrowed from 24.3% to 3.1%, and junior residents' sensitivity increased from 66.8% to 87.2% for the primary class and from 21.4% to 60.0% for myringitis. The diagnostic improvements were most evident among junior residents, who showed the highest tendency to modify their initial diagnoses based on AI support, reaching a level of diagnostic performance comparable to that of otology professors. These results were obtained at a single center with a specific endoscope type and patient population. Although AI support narrowed the trainee-expert performance gap in this setting, its generalizability to the lower-resource environments in which such support is most needed remains to be established, and multicenter validation across diverse hardware and patient populations is required before broad policy implications are drawn.

Abstract

Background: Therapeutic drug monitoring (TDM) aims to optimize clinical outcomes but is hindered by logistical delays and susceptibility to data errors. Integrating model-informed precision dosing with point-of-care testing, fortified by rule-based validation and alerts, forms a transformative clinical decision support system (CDSS) essential for securing this complex workflow.

Objective: This study evaluates, *in silico*, the effectiveness of a rule-based CDSS for imatinib in detecting data-quality issues and optimizing therapeutic dosing, compared with a human TDM expert.

Methods: We simulated a set of 60 virtual patients using a previously developed population pharmacokinetic model and deliberately enriched it with data-quality errors (eg, timing inaccuracies and reporting errors) to stress-test system resilience. We compared CDSS and TDM expert performances based on their error-detection capabilities and the clinical impact on therapeutic target attainment and safety.

Results: The CDSS and the expert demonstrated comparable error-detection capabilities. The CDSS showed numerically higher sensitivity (53%, 95% CI 35% - 70% vs 45%, 95% CI 30% - 61%) and lower specificity (83%, 95% CI 63% - 95% vs 100%, 95% CI 81% - 100%). Clinically, the CDSS demonstrated significantly higher rates of target attainment than the expert (33/60, 55% vs 22/60, 37%; *P*=.046). However, the CDSS resulted in 5 detrimental outcomes against 1 for the TDM expert, in which patients initially within the target range fell outside it.

Conclusions: The CDSS demonstrated high efficacy in optimizing imatinib exposure while serving as a robust digital gatekeeper. While active optimization drives higher efficacy, a few observed detrimental cases highlight that algorithmic safety remains contingent on data integrity. This proof-of-concept study validates the CDSS architecture as a prerequisite for future prospective clinical trials.

Introduction

Deeply rooted in the philosophy of precision medicine, therapeutic drug monitoring (TDM) offers a systematic framework for optimizing pharmacotherapy at the individual patient level, by tailoring drug dosing to ensure maximum therapeutic efficacy while minimizing the risk of toxicity [1-3]. This process relies on the precise quantification of drug concentrations in biological fluids, typically blood or plasma, where the timing of sampling is critical to accurately estimate drug exposure [1-3]. By interpreting timely sampled (traditionally at trough and steady state) drug concentrations in biological fluids within the context of established pharmacokinetic-pharmacodynamic relationships, clinicians can propose informed dosing adjustments that align with the patient's specific pharmacokinetic profile and ensure optimal outcomes [1-3]. This strategy has been recommended for various drugs across oncology, infectious diseases, immunology, psychiatry, and other specialties, aiming to deliver at the right dose and time for each patient [1]. Despite these advantages, traditional TDM remains limited by its reliance on centralized laboratories, slow analytical turnaround, need to wait for steady state before sampling, simplistic "rule-of-three" dosing adaptations poorly adapted to drugs with nonlinear pharmacokinetics, and heterogeneous clinician awareness and guideline availability, all of which delay or hinder truly individualized dosage optimization [1,3]. The operational burden of this process is substantial, requiring extensive collaboration among diverse health care stakeholders [2,4]. The fragmentation of tasks across preanalytical, analytical, and postanalytical stages creates numerous vulnerabilities, rendering the entire workflow prone to systemic errors [2,4]. A recent review reported that preanalytical factors (including steps prior to sample preparation for analysis) account for the majority of laboratory errors, ranging from 46% to 68% of total testing errors, with approximately 26% of these failures exerting a detrimental effect on patient care [4]. These errors are predominantly driven by timing inaccuracies, where studies have shown that up to 60% of specimens may be collected at inappropriate sampling times for traditional TDM, and 22% to 31% are drawn before steady state, rendering the results invalid for interpretation [4]. Furthermore, the omission of essential data, such as the time of the last dose intake or the current dosage regimen, frequently compromises the ability to interpret results accurately, a challenge that persists even with the implementation of computerized provider order entry systems [4].

Integrating model-informed precision dosing (MIPD) with point-of-care (POC) diagnostics creates a powerful synergy for personalized drug therapy [5-7]. Leveraging population pharmacokinetic (popPK) models and Bayesian forecasting, this method provides the best prediction of individual exposure from available medical data and drug measurements [5]. Crucially, MIPD software surpasses the limitations of standard TDM by accurately handling unconventional sampling times, where traditional TDM is unfeasible [5]. While performance depends on the validity of the popPK models in the targeted population, MIPD facilitates flexible monitoring through optimized sampling strategies, allowing for dose adjustments independent of steady-state achievement [5]. When coupled with bedside POC, this flexibility is fully realized, enabling rapid, decentralized sampling that significantly shortens the decision-making loop and minimizes process-related errors [6,8]. Though current MIPD platforms already mitigate many limitations of classical TDM, their clinical impact remains constrained by suboptimal workflow integration and the lack of embedded safeguards against erroneous inputs or implausible measurements [2,4,5].

Adding rule-based validation, alerts, and workflow features on top of an MIPD engine yields a clinical decision support system (CDSS) that outperforms individualized dosing strategies [9-11]. By checking data plausibility, flagging potential reporting errors, standardizing the interpretation of exposure against therapeutic targets, and delivering concise recommendations within the routine workflow, a CDSS stands as the closest substitute for a TDM expert [9-11]. Although MIPD could, by definition, be regarded already as a form of CDSS, since it transforms patient data into dosing recommendations, the term CDSS is reserved here for the combination of an MIPD core with an integrated validation system delivering actionable recommendations [9-11]. Well-designed CDSS seamlessly integrated into electronic health records can reduce preventable medication errors, shorten the interval between measurement and decision, and manage alert thresholds to detect true problems without causing alert fatigue and loss of trust [10,11].

Imatinib, the first small-molecule targeted anticancer agent to demonstrate unprecedented efficacy against specific malignancies, is characterized by marked interindividual pharmacokinetic variability. As a result, it has been confirmed that precise dosing is required to maintain steady-state trough concentrations within well-established therapeutic windows: specifically, >1000 ng/mL for chronic myeloid leukemia and >1100 ng/mL for gastrointestinal stromal tumors, while avoiding concentrations above 2000 to 3000 ng/mL associated with toxicity [12-14]. Imatinib TDM-guided dosing is associated with significantly improved clinical outcomes compared to standard care, including higher rates of major molecular and cytogenetic responses at 12 months (63% in the TDM-guided group vs 37% in the control group) [13,15,16]. Furthermore, cost-effectiveness analyses demonstrate that TDM yields improved quality-adjusted life years and lower overall costs [13,17,18]. As a result, imatinib TDM practice for patients with chronic myeloid leukemia and gastrointestinal stromal tumor is formally endorsed by the IATDM-CT (International Association of Therapeutic Drug Monitoring and Clinical Toxicology) [19]. New targeted anticancer drugs tending to replace imatinib may also require TDM and dosage adjustment; however, there is still a lack of supporting evidence in this regard [13]. Furthermore, as these new drugs are more expensive than imatinib, now available in generic form, the latter remains recommended as first-line treatment, and its TDM is likely to delay drug rotation due to ineffectiveness or toxicity issues [20]. While imatinib TDM by POC measurement has been explored, its integration with MIPD, and particularly its embedding within a CDSS framework, remains novel, offering a unique opportunity for real-time, decentralized dose optimization in the outpatient setting.

RenderX

This study aims to rigorously determine whether the proposed imatinib CDSS is suitable for subsequent clinical prospective evaluation by (1) quantifying its ability to detect data-quality issues and (2) characterizing its clinical performance in recommending effective and safe dosing adaptations. As such, it provides a proof of concept that underpins future real-life prospective trials and large-scale implementation.

Methods

popPK Model and Virtual Patients

We simulated virtual patients (N=60) using a validated structural one-compartment popPK model (Table 1), developed on real patients receiving imatinib followed at our institution, using MonolixSuite (version 2024R1; Simulations Plus) [21,22].

Table . Parameters of the imatinib population pharmacokinetic model.

Parameter	Value
CL[a] (L/h)	11
ω^{b}_{Cl} (CV%[c])	33
V_d[d] (L)	365
ω_{Vd} (CV%)	58
k_a[e] (h^{-1})	1.28
σ_{prop}[f] (CV%)	34

[a]CL: typical clearance.

[b]ω: interindividual variability parameter.

[c]CV: coefficient of variation.

[d]V_d: typical central volume of distribution.

[e]k_a: typical first-order absorption rate constant.

[f]σ_{prop}: proportional residual error.

We used specific dosing regimens of 100 mg, 300 mg, 200 mg, 400 mg, 600 mg, or 800 mg once daily, and 200 mg, 400 mg, 600 mg, or 800 mg twice daily. To ensure clinically relevant pharmacokinetic profiles, individual pharmacokinetic parameters were sampled from their original distributions, corresponding to elimination half-lives between 3 and 48 hours, and were used to simulate *true* concentrations (C_{true}) from treatment initiation up to steady state by day 11 of treatment. We added a proportional individual-dependent residual error (residual unexplained variability [RUV]) to simulate *observed* concentrations (C_{obs}). We stratified the population into 3 equal groups of 20, based on steady-state *observed* trough concentrations ($C_{min,obs}$), to ensure necessary intervention: underexposed (<500 ng/mL), within target (1100 - 2000 ng/mL), and overexposed (>3000 ng/mL), excluding ambiguous cases close to therapeutic boundaries (500 - 1100 ng/mL and 2000 - 3000 ng/mL). To assess the robustness of TDM interventions, we imputed single data-quality issues reflecting clinical routine into 45 of the cases (Table 2 and Table S1 in Multimedia Appendix 1), leaving 15 as valid steady-state samples. These data-quality scenarios were categorized into 6 distinct groups (Table 2 Table S1 in Multimedia Appendix 1). The first 2 groups defined the scope of data considered valid for the TDM expert, for whom interpretability was strictly limited to samples drawn at the trough or within a window permitting acceptable extrapolation (up to 6 h before the steady-state trough). These included (1) valid data and (2) extrapolation valid for TDM expert and CDSS. In contrast, the CDSS demonstrated a broader scope of technical validity due to its MIPD-based architecture, enabling the processing of (3) extrapolation valid for CDSS (EC). This category comprised samples drawn during the absorption phase or explicitly declared as not at steady state. While technically processable by the CDSS, provided these conditions were correctly declared, they were classified as invalid for standard interpretation by the TDM expert. The remaining categories included the following: (4) blocking issues (BIs), involving critical data conflicts such as chronological timestamp inversion or date-format transposition that technically preclude any analysis; (5) extrapolation issues (EIs), where non–steady-state samples were incorrectly classified as steady-state; and (6) miscellaneous issues (MIs), a heterogeneous group encompassing treatment initiation date shift, sampling-time rounding, sample mislabeling, dosage transcription error, and concentrations below the lower limit of quantification set at 100 ng/mL. We compiled the 60 simulated cases in a Microsoft Excel spreadsheet, each one contributing a single $C_{min,obs}$.

RenderX

Table . Classification, description, and distribution of virtual patients and errors.

Category and coding	Short description	Number of patients (N=60)
Valid		
VTC	Valid steady-state trough sample	15
Extrapolation valid for TDM[a] expert and CDSS[b]		
ETC	Pretrough sample requiring extrapolation (up to 6 h before trough)	3
Extrapolation valid for CDSS		
EC1	Absorption phase sample requiring extrapolation (1 h to 3 h postdose)	3
EC2	Non–steady-state sample (explicitly declared)	3
Blocking issue		
BI1	Chronological inversion of timestamps (initiation, dose, or sampling)	6
BI2	Date format transposition (day/month swap) in timestamps	3
Extrapolation issue		
EI	Non–steady-state sample (misclassified as steady-state)	3
Miscellaneous issue		
MI1	Shift in treatment initiation date (+6 d to 9 d)	3
MI2	Sampling time rounding discrepancy (15 min to 60 min before trough)	6
MI3	Absorption phase sample (1 h to 3 h postdose) mislabeled as trough	3
MI4	Trough sample mislabeled as absorption phase (1 h to 3 h postdose)	3
MI5	Dosage regimen transcription error	6
MI6	Concentration below the lower limit of quantification (virtually fixed at 100 ng/mL)	3

[a]TDM: therapeutic drug monitoring.

[b]CDSS: clinical decision support system.

Ethical Considerations

This validation study was conducted entirely *in silico* using simulated virtual patient profiles generated from a popPK model. The underlying clinical data used to develop the popPK model were collected in accordance with institutional guidelines at Lausanne University Hospital and approved by the Ethics Committee of the Canton of Vaud (project number: 2024 - 01723). Informed consent for research participation was systematically obtained from all patients prior to data extraction through the institution's general consent framework.

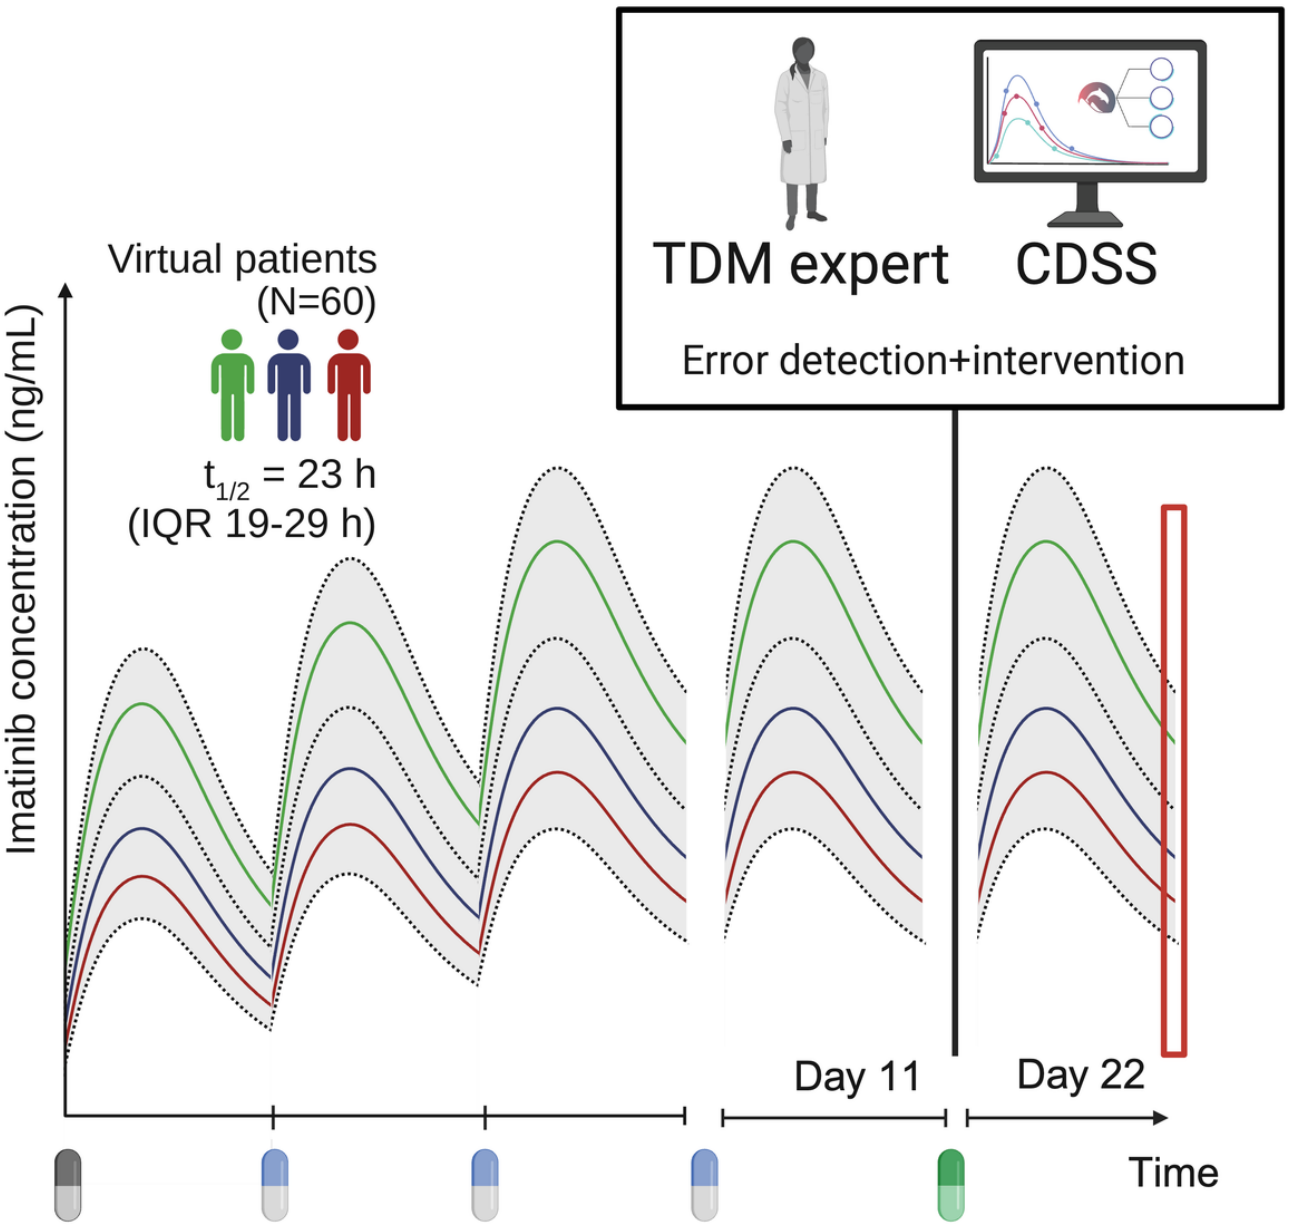
CDSS Development

We adopted as CDSS the software developed in the context of the TuberXpert project [23] under an open-source license (AGPLv3 [GNU Affero General Public License version 3]) as part of the sotalya ecosystem [24]. Though originally targeted to rifampicin, the software is very generic and, given a suitable drug popPK model (defined in an XML file), can be applied to a vast spectrum of drugs. The drug model file embeds all the mathematical information a popPK model offers to compute drug circulating concentrations: model type, typical pharmacokinetic parameter values along with their interindividual variability, influence of specific covariates on these parameters, and residual error model. It allows the computation of dosage adjustments, specifically targeting a C_{min} of 1500 ng/mL (within the established 1100 - 2000 ng/mL therapeutic range) in the cases of this study, but also the automatic detection of potential anomalies in the sampling data. The computational core used by this CDSS system is Tucuxi [25], another open-source software [24] that specifically handles all numerical aspects of the modeling.

The CDSS software requires, as input, among other optional data, the dosage history; dosing and sampling times; and covariate information for each patient. We therefore parsed the spreadsheet prepared for the TDM expert with a Python script and generated the input files required by Tucuxi. A first set of checks was applied at this stage, discarding patients for whom either the concentration measurement date or the last dose date

XSL•FO
RenderX

preceded the treatment start date, issues corresponding to data entry errors. We then fed the generated input files to the CDSS and automatically parsed the generated reports to either detect further errors or extract useful data: (1) the suggested dosing scheme; (2) the (optional) discontinuation interval; (3) any warnings due to either statistical inconsistencies with respect to the population model described in the drug file or inefficacy/toxicity alerts. In particular, the measurement result was checked to be within the 10th to 90th expected percentile range for each dosage regimen, and the dates were further controlled to ensure that the sample was meaningful (ie, not too far in time with respect to the last dose intake).



Internally, Tucuxi-CDSS is organized in three processing layers: (1) data validation and preprocessing, which performs consistency checks and flags preanalytical errors; (2) model-based computation, which queries the Tucuxi-Core engine to derive percentile-based plausibility assessments and Bayesian a posteriori parameter estimates; and (3) decision logic and reporting, which compares predicted exposure metrics to configurable therapeutic targets and assembles a structured clinical recommendation. The system is highly configurable through XML files that define not only the drug models but also covariate boundaries with soft and hard thresholds, language settings, and institution-specific reporting templates, enabling deployment across diverse clinical environments. A detailed description of the system architecture, operational workflow, and verification strategy is provided on readthedocs [26] and in reference [27].

Resolution of the Virtual Cases by a TDM Expert or a CDSS

The same 60 virtual cases were independently assessed by both the CDSS and a TDM expert (PT), a pharmacist holding a PhD in clinical pharmacology and head of the TDM unit at the Service of Clinical Pharmacology of the University Hospital of Lausanne. While informed of the possible presence of data-quality errors, both evaluators remained blinded to the specific nature and frequency of these issues. Error detection was assessed by requiring evaluators to explicitly specify any suspected data issue, using methodology-specific tools and, notably, the 10th to 90th percentile popPK curves for each imatinib dosing regimen as a common reference range for both the expert and the CDSS. These curves represent the likelihood of having a concentration within this range given the variability in the population. Figure 1 schematically summarizes the study methodology.

XSL•FO
RenderX

Figure 1. Schematic representation of the *in silico* study methodology. A virtual cohort (N=60) was simulated using a population pharmacokinetic (popPK) model, incorporating metabolic diversity with a median half-life ($t_{1/2}$) of 23 (IQR 19 - 29) hours. The cohort was stratified into 3 subsets: cases valid for both the clinical decision support system (CDSS) and the therapeutic drug monitoring (TDM) expert (n=18), cases valid only for the CDSS (n=6), and invalid cases (n=36). Following the initiation of imatinib therapy (gray pill), a primary TDM evaluation was performed on day 11 (steady state), where a head-to-head comparison was conducted between the human expert and the CDSS to assess error detection and formulate dosing adjustments (green pill). Subsequent simulations were performed based on these interventions to evaluate their impact on steady-state concentrations at day 22 (red box), where final target attainment was compared between both arms. The shaded area represents the population prediction interval derived from the underlying popPK model. The different curve colors (green, blue, and red) represent examples of patients' imatinib pharmacokinetic profiles.

Error-Detection Performance

To evaluate the accuracy of error detection of the TDM expert and the CDSS in identifying data-quality issues, sensitivity (equation 1), specificity (equation 2), precision (positive predictive value, equation 3), and the F_1-score (harmonic mean of precision and sensitivity, equation 4) were calculated based on the classification of cases as either valid or erroneous [28]. Corresponding 95% CIs were computed using the Clopper-Pearson exact method for sensitivity, specificity, and precision, and statistical comparability was assessed by examining the overlap of these intervals [29]. These metrics were defined as follows:

(1)Sensitivity= TPTP+FN

(2)Specificity= TNTN+FP

(3)Precision= TPTP+FP

(4)F1=2× Precision ×SensitivityPrecision+Sensitivity

where TP represents true positives (correctly identified issues), TN represents true negatives (correctly identified valid cases), FP represents false positives (valid cases incorrectly flagged as issues), and FN represents false negatives (missed issues).

XSL•FO
RenderX

Clinical Outcomes After TDM Expert or CDSS Intervention Analysis

Following this validation step, both evaluators aimed to achieve a steady-state trough target of 1100ng/mL to 2000 ng/mL by proposing dosing adjustments. Following their respective dosing interventions, the resulting true steady-state trough concentrations ($C_{min,true}$), assumed to be reached 22 days after treatment initiation, were simulated using the individuals' true pharmacokinetic parameters. In instances where no dosing adjustment or treatment discontinuation was proposed, the simulation assumed the continuation of the initial dosing regimen. Clinical outcomes were assessed at baseline (day 11 posttreatment initiation) and compared to the postintervention outcomes observed at day 22 posttreatment initiation. Cases were then classified into 6 mutually exclusive categories based on baseline and day 22 therapeutic target attainment (1100 - 2000 ng/mL) [14]: "effective" when a patient off-target at baseline achieved the target following a dosing adjustment; "unnecessary" when a patient already within target received a dosing adjustment and remained within target; "critical" when an underexposed patient became overexposed following a dosing adjustment; "ineffective" when a patient remained underexposed or overexposed, or shifted from overexposure to underexposure after a dosing adjustment; "detrimental" when a patient initially within target fell outside the target at day 22 regardless of whether a dosing adjustment had been made (ie, patients who moved outside the target because of pharmacological drift despite no adjustment belong to this category); and "no intervention" when no dosing adjustment was proposed and the patient did not meet the definition of the "detrimental" category. Statistical discordances between the TDM expert and CDSS interventions were evaluated using the McNemar test [30].

Subset Analyses

To accurately evaluate the system's ability to flag data-quality issues, error-detection performance was assessed on 2 distinct sets. The primary analysis was conducted on the full set (N=60), encompassing all simulated scenarios. A secondary, stratified analysis was performed on a restricted subset (n=54), specifically excluding the 6 EC cases. This exclusion was necessary to neutralize the validation disparity between the 2 methods, as these specific cases represented samples that were correctly identified as valid by the CDSS logic but were inherently considered erroneous or unusable by the TDM expert due to the limitation introduced previously.

Further detailed assessments of clinical interventions were performed across 3 subpopulations to isolate different performance drivers. Beyond the full dataset (N=60), an initial exclusion set (exclusion 1, n=51) was established by removing all BI (BI1 and BI2), which represented timestamp errors that technically precluded any dosing intervention by either method. To facilitate a rigorous head-to-head comparison, a second, refined set (exclusion 2, n=39) was created by further excluding cases that introduced methodological asymmetry. This included the removal of ECs, as well as EIs and mislabeled absorption-phase samples (MI3), thereby isolating a subset of clinical scenarios in which both the expert and the CDSS had a theoretically equal opportunity to propose valid dosing adjustments.

Results

Error Detection

Overall, the TDM expert and the CDSS demonstrated comparable error-detection capabilities, with widely overlapping CIs suggesting no substantial difference in performance (Table 3 and Table S2 in Multimedia Appendix 1). In the standard set (N=60), the human TDM expert demonstrated perfect specificity (100%, 95% CI 81% - 100%) and precision (100%, 95% CI 82% - 100%), detecting no false positives. However, the expert achieved a lower sensitivity (45%, 95% CI 30% - 61%) compared to the CDSS (53%, 95% CI 35% - 70%; Table 3). Consequently, the CDSS exhibited a slightly higher F_1-score (64% vs 62%), despite a lower specificity (83%, 95% CI 63% - 95%), resulting from a higher false-positive rate than that of the TDM expert. When excluding the 6 ECs (n=54), the expert's sensitivity improved to 50% (95% CI 33% - 67%), while the CDSS's specificity increased to 89% (95% CI 65% - 99%). In this refined analysis, both methods achieved an identical F_1-score of 67% (Table S2 and Figure S1 in Multimedia Appendix 1). Figure S2 in Multimedia Appendix 1 offers a detailed count of the true positive and false negative rates stratified by error types.

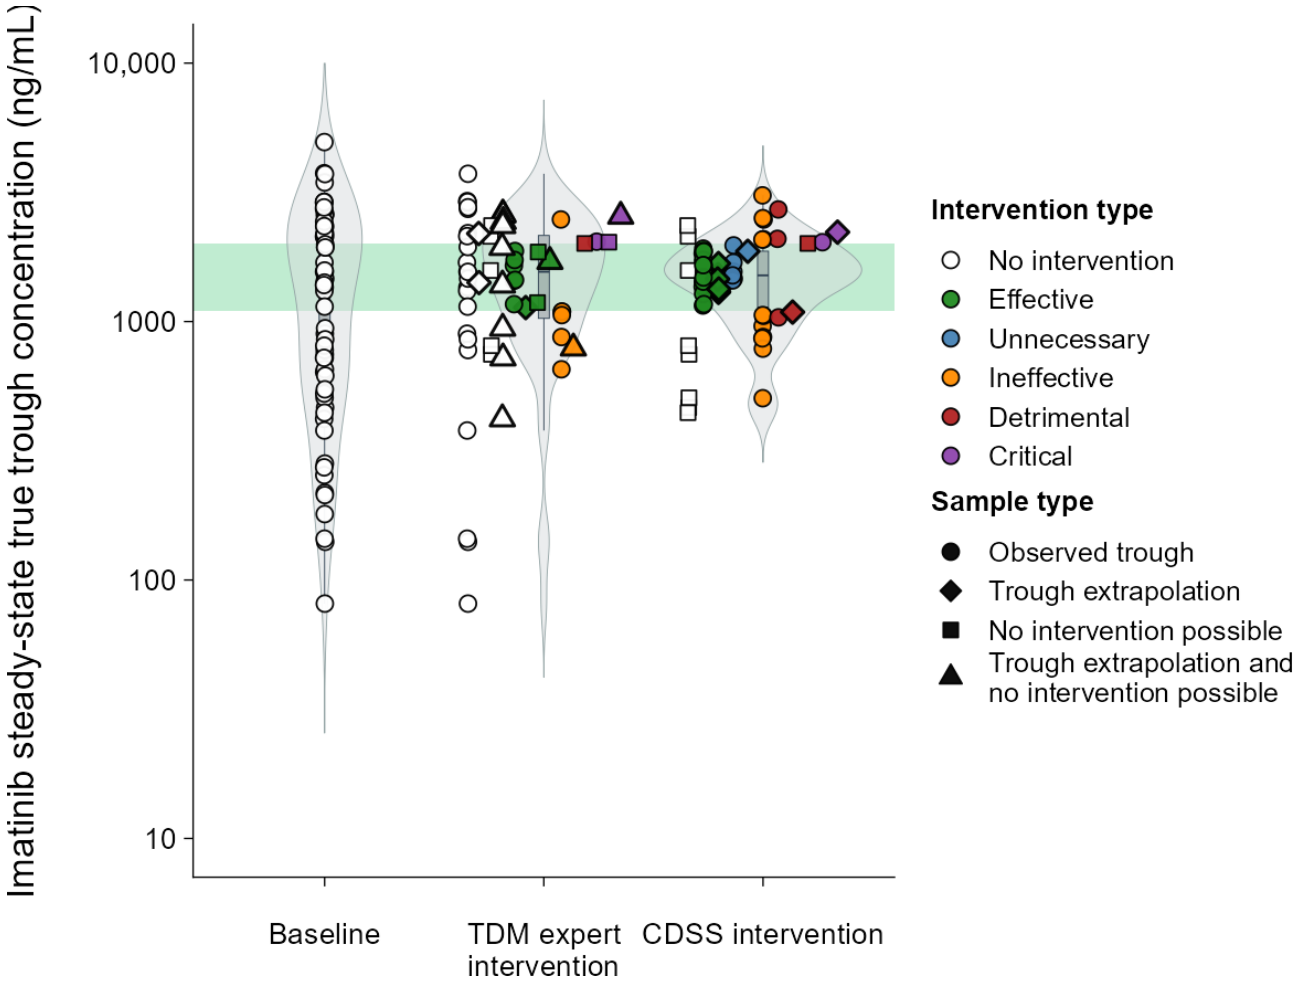
Table . Comparative analysis of error-detection performances (N=60).

Metric	TDM[a] expert, % (95% CI)	CDSS[b], % (95% CI)
Sensitivity	45 (30 - 61)	53 (35 - 70)
Specificity	100 (81 - 100)	83 (63 - 95)
Precision	100 (82 - 100)	83 (61 - 95)
F_1-score[c]	62	64

[a]TDM: therapeutic drug monitoring.

[b]CDSS: clinical decision support system.

[c]As the F_1-score is a composite metric that does not follow a binomial distribution, no exact Clopper-Pearson CI is available, and it is reported as a point estimate only.



XSL•FO
RenderX

Clinical Outcomes After TDM Intervention

In the full standard set (N=60), both the TDM expert and the CDSS significantly improved the proportion of patients reaching the therapeutic target compared to baseline, from 22% (n=13) to 37% (n=22, *P*=.02) and 55% (n=33; *P*<.001), respectively (Figures 2 and 3, Table 4, and Table S4 in Multimedia Appendix 1). The CDSS achieved a statistically significantly higher proportion of target attainment compared to the expert (*P*=.046).

In the exclusion 1 set excluding BIs (n=51), the CDSS maintained a higher success rate (n=32, 63%) compared to the expert (n=19, 37%; *P*=.01; Table S4 and Figure S3 in Multimedia Appendix 1). In the exclusion 2 set (n=39) designed to most fairly compare head-to-head TDM experts and the CDSS, the latter still outperformed the TDM expert, with 69% (n=27) of patients reaching the target vs 41% (n=16) for the expert (*P*=.01; Table S4 and Figure S3 in Multimedia Appendix 1).

Figure 2. Distribution of steady-state true trough concentrations of imatinib at baseline and after therapeutic drug monitoring (TDM) expert or clinical decision support system (CDSS) intervention (N=60). The green band depicts the therapeutic target (1100 - 2000 ng/mL) for the steady-state trough concentration [14]. Colors indicate the intervention outcome: green indicates effective interventions where patients initially underexposed or overexposed attained the target; blue represents unnecessary interventions for patients within target at baseline who received a dosing adjustment and remained within target; orange denotes ineffective interventions where patients remained underexposed or overexposed or shifted from overexposure to underexposure despite dosing adjustment; purple represents critical intervention where patients were underexposed but turned overexposed after dosing adjustment; red signifies detrimental interventions where patients initially within target fell outside the target regardless of dosing adjustment; and white stipulates no intervention (absence of dosing adjustment, unless classified as detrimental). Shapes represent the sample type: circles indicate observed troughs at steady state; diamonds concentrations requiring extrapolation to the trough; squares cases where no intervention was possible; and triangles cases requiring extrapolation precluding intervention.

Analysis of intervention types revealed 5 detrimental cases in the CDSS (Table 5, Tables S5 and S3 in Multimedia Appendix 1, Figures 2 and 4, and Figures S4 and S5 in Multimedia Appendix 1): 1 patient each in the EC1, EI (misclassified steady-state), MI2 (sampling time rounding), and MI4 (sample mislabeling) categories, and a specific pharmacological deviation was observed in a BI case (BI2) common to the TDM expert intervention (Table 5 and Table S5 and Figure S5 in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 3. Distribution of patients across clinical outcomes after therapeutic drug monitoring (TDM) expert or clinical decision support system (CDSS) intervention (N=60). The asterisk (*) and empty circle (°) indicate statistical significance (*P*<.05) of the difference between CDSS and either TDM expert or baseline, respectively [30].

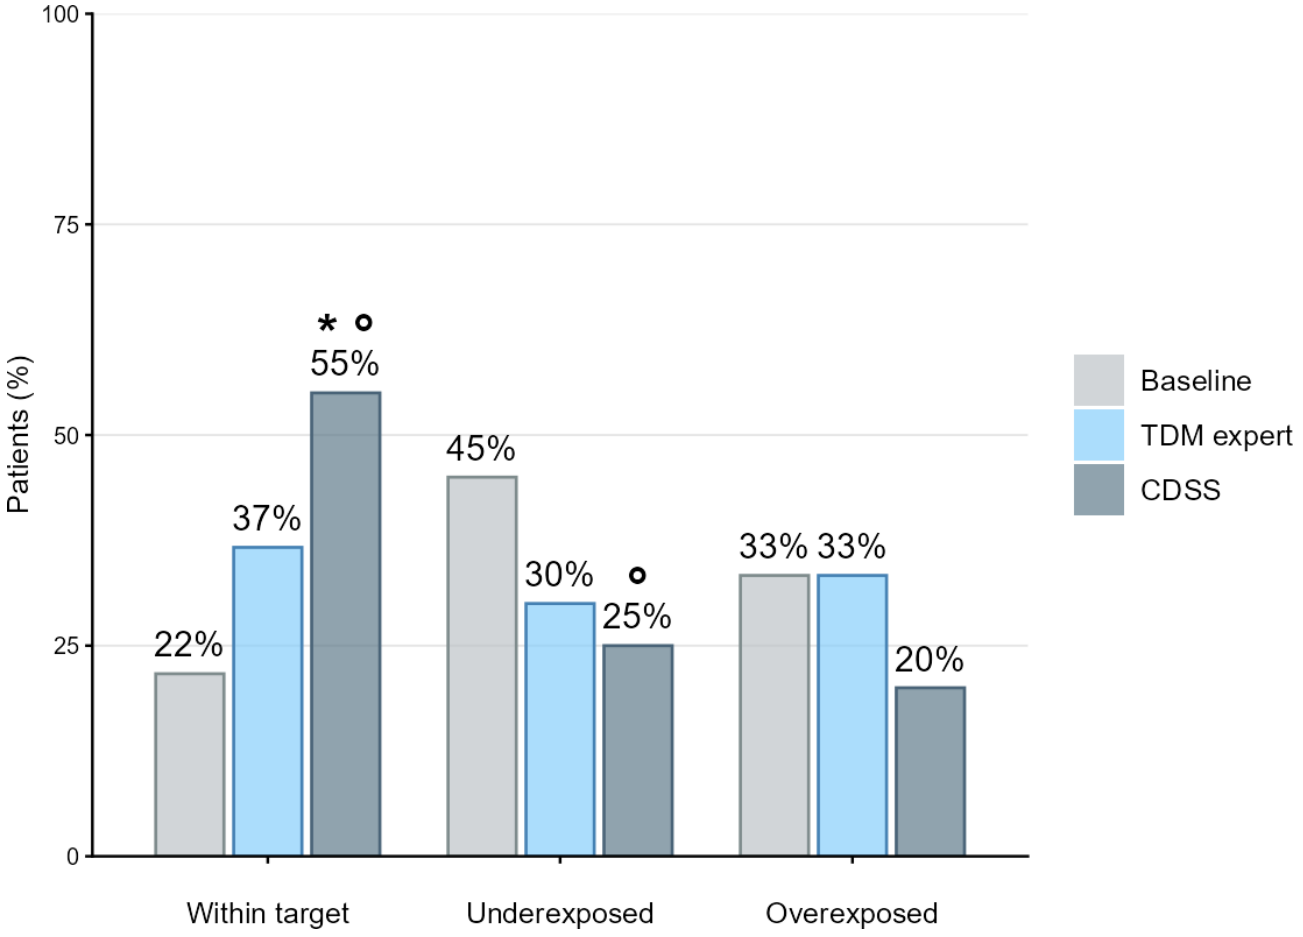


Table . Comparative analysis of clinical outcomes after the intervention (N=60).

Clinical outcome	Baseline, n (%)	TDM[a] expert intervention, n (%)	CDSS[b] intervention, n (%)	*P* value (expert vs baseline)	*P* value (CDSS vs baseline)	*P* value (CDSS vs expert)
Within target	13 (22)	22 (37)	33 (55)	.02	<.001	.046
Underexposed	27 (45)	18 (30)	15 (25)	.02	.01	.61
Overexposed	20 (33)	20 (33)	12 (20)	>.99	.10	.06

[a]TDM: therapeutic drug monitoring.

[b]CDSS: clinical decision support system.

Conversely, the CDSS demonstrated a statistically significantly higher rate of "effective" interventions (25 cases vs 10 cases; *P*=.002), whereas the expert more frequently proposed "no intervention" strategies (39 cases vs 8 cases; *P*<.001; Figures 2 and 4, Table 5, Tables S3 and S5 in Multimedia Appendix 1). As shown in Figure 2 and Table 5 and Tables S3 and S5 in Multimedia Appendix 1, the CDSS significantly proposed unnecessary dose adjustments in 7 cases, whereas the TDM expert correctly avoided these entirely (*P*=.02). The frequency of ineffective interventions was statistically comparable between the 2 methods, with 7 instances for the expert vs 13 for the CDSS (*P*=.11), and similar results were obtained when exclusions were applied.

Critical	3	2	>.99

[a]TDM: therapeutic drug monitoring.

[b]CDSS: clinical decision support system.

Figure 4. Representation of clinical outcomes after intervention of clinical decision support system (CDSS) or therapeutic drug monitoring (TDM) expert (N=60). Within therapeutic target (W) was defined as 1100 ng/mL to 2000 ng/mL for a trough steady-state concentration, and underexposed (U) and overexposed (O) were defined as below and above these thresholds, respectively [14].

Discussion

Principal Findings

This *in silico* study compared the performance of a rule-based CDSS and a human TDM-expert in optimizing therapeutic target attainment using imatinib as a case study and showed enhanced performance of the CDSS over the TDM expert. The CDSS consistently outperformed the expert across a variety of settings, representative of "real-life" scenarios, allowing a refined head-to-head comparison designed to ensure that both the software and the expert could actively intervene. Regarding safety, although the global reduction of off-target exposure suggests a net benefit, it is important to note that 5 patients who were initially within the therapeutic window drifted off-target following CDSS recommendations. This highlights that, while the algorithm effectively reduces the total number of patients outside the therapeutic window compared to the expert, its safety remains fairly contingent on data integrity.

This work provides several novel contributions to the field of digital precision medicine. Specifically, it offers the first validation of a "nonexpert" CDSS architecture integrating MIPD with a rule-based validation layer designed for decentralized,

XSL•FO
RenderX

POC settings specifically for imatinib. Furthermore, it establishes a necessary technical benchmark by providing the first head-to-head performance evaluation between such an automated system and a human TDM expert, specifically focusing on system resilience by simulating a "chaotic" environment with a 75% error prevalence, allowing for a rigorous assessment of the CDSS as a digital gatekeeper for data integrity. Ultimately, by demonstrating that an automated system can achieve comparable or superior performance to an expert baseline, this study provides the essential proof-of-concept required to transition toward prospective, real-life clinical trials of automated precision dosing.

A key driver of differences in target attainment between the CDSS and the TDM expert was the contrasting intervention strategies. As clinical outcomes were evaluated based on the steady-state $C_{min,true}$, the high RUV (34%) makes the estimation of this true exposure from a single observed concentration, $C_{min,obs}$ difficult for a human expert without computational aid. In contrast, the CDSS uses Bayesian forecasting to estimate the steady-state trough, effectively "seeing through" the measurement noise. In addition, the TDM expert frequently adopted a more conservative approach, choosing "no intervention" when facing slightly off-target exposure, while the study relied on a rigid therapeutic threshold (1100 - 2000 ng/mL). In clinical reality, experts do not infrequently incorporate a wider "margin of tolerability," accepting marginally out-of-range concentrations to avoid disrupting a stable patient by iterative dosing adaptations. By strictly penalizing deviations outside this narrow window, our evaluation metric may inherently favor the CDSS's mathematical precision over the expert's pragmatic, clinically anchored approach. Consequently, the dosing adjustments proposed by the CDSS globally bring patients closer to the targeted steady-state trough of 1500 ng/mL, despite rare instances of detrimental adjustments. While the CDSS's active optimization strategy appears able to drive higher efficacy, its translation into routine practice must account for clinical inertia, where clinicians may be appropriately reluctant to change established regimens, as previously reported [31]. Additionally, the expert's active dosing adjustments in 2 chronological inversion cases (BI1) likely reflect either routine clinical pragmatism or an overlooked documentation error during manual review, contrasting with the CDSS's strict, rule-based execution blocks.

The relatively low sensitivity observed for both the TDM expert (45%, 95% CI 30%-61%) and the CDSS (53%, 95% CI 35%-70%) highlights a critical dependency on the statistical thresholds used for error detection. Both methods rely on popPK percentile curves to assess the biological plausibility of a sample (computed for the CDSS and plotted for the TDM expert); in this study, the 10th and 90th percentiles were used as boundaries for expected concentrations. While this broad interval maximizes specificity (100%, 95% CI 81%-100% and 83%, 95% CI 63%-95% for the TDM expert and the CDSS, respectively) by reducing false alarms, it inherently limits the ability to flag subtler deviations, such as certain EIs or MIs that may still fall within those wide confidence bands. There is a direct, adjustable trade-off between sensitivity and specificity governed by these thresholds. Adopting more stringent boundaries, for instance, narrowing the acceptance range to the 20th and 80th percentiles, would increase the sensitivity, ensuring that fewer errors go undetected. Given that the CDSS should prioritize safety, maximizing sensitivity is often the priority to "rule out" potential data-quality issues [28]. However, this shift would come at the cost of reduced specificity, potentially generating more false positives and increasing the risk of "alert fatigue" for clinicians, and further hindering proper adherence toward dosing recommendations [10,32]. The calibration of error-detection sensitivity necessitates a critical balance between clinical safety and therapeutic effectiveness. On one hand, adopting more stringent detection boundaries enhances safety by effectively flagging errors, thereby preventing the CDSS from proposing harmful, detrimental dosing adaptations based on flawed data and predictions. On the other hand, such hyper-vigilance may disproportionately penalize "physiologically extreme" but valid patients whose pharmacokinetic profiles naturally reside within the tails of the population distribution. By incorrectly categorizing these biological outliers as data errors, the system may lead to a conservative "no intervention" approach from the end-user, thus withholding necessary dose optimizations and leaving the patient outside the therapeutic target. Consequently, maximizing the clinical utility of the tool requires an optimized threshold that serves as a rigorous digital gatekeeper against noise without compromising the active optimization required to accommodate inherent biological diversity. Future implementations of the CDSS should therefore explore adjustable sensitivity settings, allowing institutions to calibrate this balance according to their specific tolerance for risk versus workflow interruption. Finding the optimal balance will require formal usability studies involving end-users to determine the threshold where the safety benefit of error detection remains acceptable relative to the clinical burden of alert fatigue.

Regarding the 4 of the 5 detrimental cases that arose from active interventions observed exclusively with the CDSS, the limited sample size stratified by error type precludes the identification of a systematic failure mode. These cases were not concentrated within a specific error category, but were distributed singly across the EC1, EI, MI2, and MI4 subgroups. Furthermore, in each instance, the remaining replicates within the same error category (2 or 5 cases) were not detrimental. This suggests that these isolated failures are likely attributable to probabilistic factors inherent to individual concentrations predicted by the CDSS, rather than a structural inability of the CDSS to handle specific error types, although the scarcity of data precludes definitive conclusions. Overall, further studies using substantially larger datasets are required to determine whether specific patterns underlie these detrimental outcomes. At this stage, the error-detection logic relies on a relatively rudimentary approach using population percentile curves to flag biological implausibility. While this method is precisely the one currently used in clinical routine, it lacks the resolution to consistently distinguish measurement noise from true physiological shifts when relying on a single data point. Consequently, the development of a dedicated module specifically engineered for error detection, beyond simple percentile boundaries, will be a primary focus for future iterations of the CDSS to further mitigate these safety risks. In addition, a single instance of a

XSL•FO
RenderX

detrimental outcome was identified in a BI case (BI2), where the nature of the error technically precluded any dosing adaptation by either the expert or the CDSS. In this scenario, the patient drifted out of the therapeutic target independently of any intervention. This deviation highlights a discrepancy between clinical conventions and pharmacokinetic reality regarding the definition of steady-state. While clinical practice typically assumes steady state to be reached at 97% after 5 half-lives, slight accumulation continues beyond this point. In this specific case, the patient's $C_{min,true}$ was borderline at the upper therapeutic limit after 11 days of treatment. Consequently, the slight additional accumulation that occurred after the 22 days of treatment was sufficient to push the concentration above the threshold. Thus, this artifact underscores the limitations of enforcing stringent, binary therapeutic target limits without accounting for the natural pharmacological drift inherent to borderline cases. Moreover, in the real world, biological fluctuations further complicate the picture.

Clinical Implications

By demonstrating that a CDSS can match or exceed expert performance in detecting errors and optimizing doses, we provide a pathway for decentralizing expert-level TDM. Currently, high-quality TDM is often restricted to specialized centers with on-site TDM experts. A reliable CDSS acts as a supportive device, allowing nonspecialized clinicians in smaller clinics or resource-limited settings to provide the same level of precision dosing as a dedicated expert while ensuring safe use by enabling the detection of errors. Furthermore, the system's resilience to data-entry errors suggests it can serve as a critical safety buffer in high-pressure clinical environments where human cognitive fatigue may occur.

Limitations

Several limitations of this study must be acknowledged. First, the investigation was purely *in silico*, which inherently simplifies the complexities of clinical practice. The popPK model used is intrinsically a coarse representation of reality. Furthermore, evaluating cases via a structured spreadsheet may not fully replicate the cognitive environment of routine TDM practice. While this format minimizes clinical "noise" by providing only the strict minimum data required for TDM (eg, dosing history, sampling time, and concentration), it lacks the visual safety guardrails and patient history available in modern electronic health records systems. The repetitive nature of assessing 60 complex cases in this manner may have introduced a further cognitive load or fatigue not typically present during isolated clinical interventions, potentially impacting the expert's detection performance. Moreover, the investigation used the same popPK model for both virtual patient generation and CDSS evaluation. This form of circular modeling bias has nevertheless the merit of evaluating purely the intrinsic potential for dosage adjustment, while getting rid of model validity issues. While the substantial RUV (34%) mimics real-world measurement noise, true external validity would require evaluation against independent datasets. Second, unlike prospective real-life scenarios, the evaluators did not have access to patient history or prior dosing patterns, and the simulation assumed a single isolated data-quality error per individual. Consequently, the system was not fully tested against the chaotic data integrity issues not infrequently encountered in routine clinical practice, where compounded vulnerabilities, such as the simultaneous occurrence of timing inaccuracies and transcription errors, are plausible. Confronting the system with such overlapping errors could lead to unpredictable performance, where errors might either mask one another or, conversely, create extreme statistical outliers that are more easily detected. While the current study provides a necessary baseline characterization of system sensitivity to specific error types, future research must incorporate multifaceted error scenarios to better reflect real-world clinical complexity. Third, the study design introduced a potential bias by assuming automatic implementation of the CDSS's recommendations. In a clinical setting, a physician would act as a gatekeeper: by bypassing this validation step, we could not assess "recommendation adherence" or the safety impact of a clinician potentially overriding the software. Fourth, statistical power was constrained by the sample size, particularly when stratified by specific error subtypes. With some error categories containing as few as 3 to 6 cases, robust statistical comparisons regarding the detection of specific error types or their associated outcomes were limited by low statistical power, increasing the risk of type II errors. Furthermore, the set was intentionally imbalanced to "stress-test" error detection, resulting in a high prevalence of errors or extrapolation (75%), however not much higher than some real-life estimations [4]. This left a small control group of valid cases for both the CDSS and the TDM expert (n=18), rendering the specificity estimate particularly imprecise: in such a limited sample, even a minimal number of false positives can disproportionately lower the calculated specificity. Fifth, informing the human evaluator beforehand about the potential presence of data-quality errors likely introduced a Hawthorne effect [33]. By priming the expert to be hyper-vigilant, the study may have measured an artificially heightened state of alert rather than a standard clinical cognitive baseline. However, this design choice probably induces a conservative bias; comparing the CDSS against a hyper-vigilant expert baseline demonstrates that the system's detection capabilities remain comparable even to a clinician performing at peak alertness. In routine practice, where cognitive fatigue and lack of priming might lead to lower human vigilance, the relative advantage of an automated gatekeeper would likely be even more pronounced. Finally, the comparison relied on a single TDM expert, whose decision-making may not represent a generalized consensus; further trials involving more TDM experts will be necessary to implement the tool into clinical practice. However, while certain extrapolation scenarios inherently favored the CDSS's mathematical flexibility over the expert's conventional "rule of 3" constraints, it is notable that the CDSS retained its superior performance even in the restricted exclusion 2 subset where these technical biases were minimized.

Conclusions

This *in silico* study validates the proposed CDSS as a robust tool for precision dosing, demonstrating error-detection performances globally comparable to those of a human TDM expert, while significantly outperforming the expert in therapeutic target attainment. While the CDSS's active

XSL•FO
RenderX

optimization strategy yielded superior overall efficacy, resulting in fewer patients outside the therapeutic window, safety remains a concern as detrimental interventions can sometimes be observed with the CDSS. Despite limitations inherent to the simulation design, these findings establish solid proof-of-concept for CDSS TDM. Consequently, this work lays the necessary groundwork for future prospective clinical trials, which remain a prerequisite for the routine implementation of such a CDSS.

Abstract

Background: Despite advances in understanding and treating non–ST-elevation acute coronary syndrome (NSTE-ACS), patients continue to experience high rates of adverse outcomes, particularly those with non–ST-segment elevation myocardial infarction, which remains a leading cause of cardiovascular mortality. Existing risk models may not fully reflect contemporary patient populations due to substantial changes in clinical profiles. Developing new machine learning (ML)–based risk calculators may improve the prediction of in-hospital mortality (IHM) at different stages of the diagnostic process, and ultimately improve patient outcomes.

Objective: This study aimed to develop predictive models for IHM in patients with NSTE-ACS using ML methods and predictor sets obtained during the diagnostic process.

Methods: This retrospective observational study included 1144 patients with NSTE-ACS admitted between 2019 and 2021. IHM occurred in 94 (8.1%) of 1144 patients. Predictive models were developed using multivariable logistic regression, Random Forest, XGBoost (Extreme Gradient Boosting), and CatBoost algorithms. Model performance was evaluated using the area under the receiver operating characteristic curve (ROC-AUC), area under the precision-recall curve, calibration metrics, and decision curve analysis.

Results: A key feature of the developed models was their applicability at different stages of the diagnostic process, using predictors available at each specific stage. At admission, ML models achieved ROC-AUC values up to 0.93. After incorporating laboratory and echocardiographic data, predictive performance increased to ROC-AUC values of 0.94 to 0.95. The best-performing model demonstrated an ROC-AUC of 0.951 (95% CI 0.946 - 0.956), a sensitivity of 0.902 (95% CI 0.889 - 0.916), and a specificity of 0.891 (95% CI 0.886 - 0.896). The area under the precision-recall curve reached 0.685, and the Brier score was 0.0331, indicating good calibration. Random Forest models demonstrated greater clinical utility than the Global Registry of Acute Coronary Events score (P<.001). Shapley Additive Explanations analysis identified the most significant predictors of mortality risk, including Killip class of acute heart failure, age, Charlson comorbidity index, creatinine level, and hematocrit level.

Conclusions: ML-based models enabled accurate prediction of IHM in patients with NSTE-ACS at different stages of the diagnostic process and may improve risk stratification and clinical decision-making in real-world practice.

Introduction

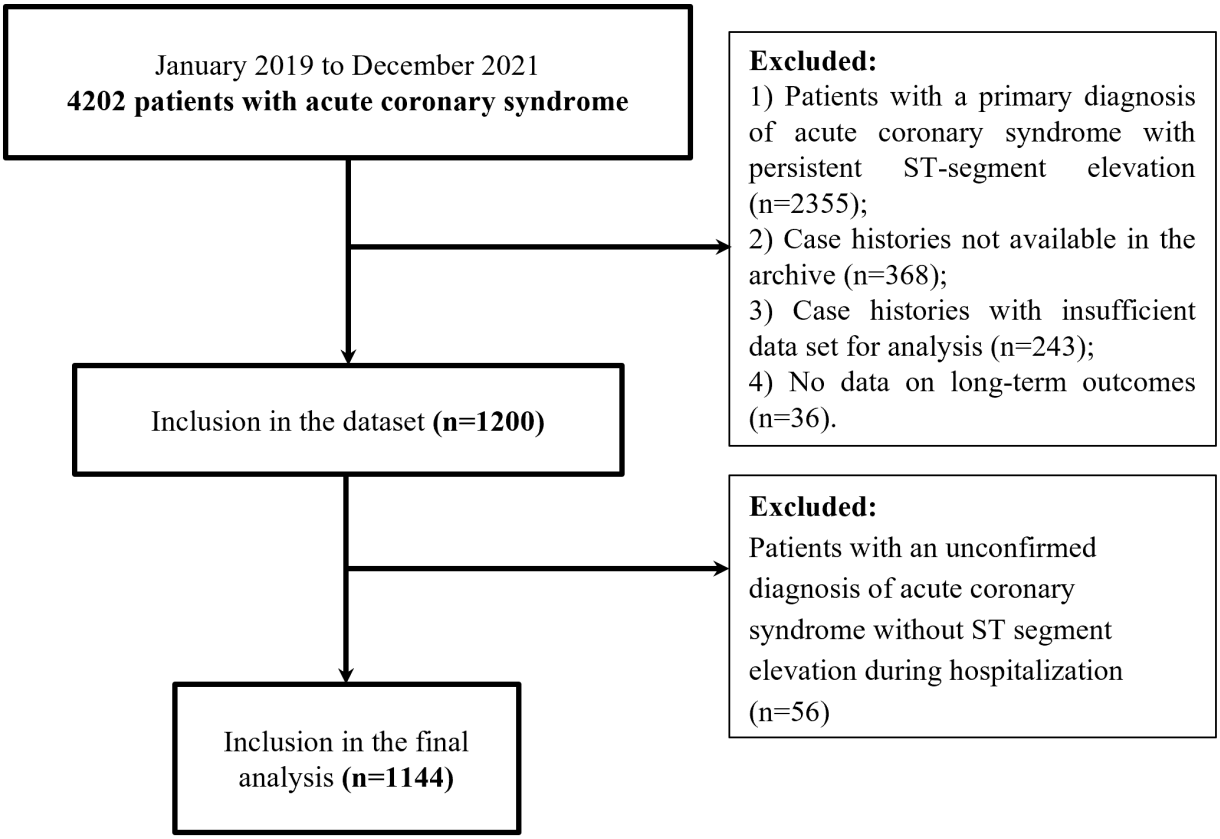
Despite modern advances in understanding the pathophysiology of non–ST-segment elevation acute coronary syndrome (NSTE-ACS) and the continuous refinement of pharmacological and invasive treatment strategies, registry studies continue to report a high incidence of adverse outcomes in the aforementioned patient population, with no discernible trend toward reduction in recent years [1,2]. The well-known heterogeneity of the population of patients with NSTE-ACS presents a major challenge in making optimal clinical decisions [3,4]. Furthermore, non–ST-segment elevation myocardial infarction (NSTEMI), which is a primary nosological entity within NSTE-ACS, remains a leading cause of morbidity and mortality among cardiovascular diseases (CVDs) worldwide [5]. The insufficient improvement in both short- and long-term outcomes for patients with NSTEMI compared to those with ST-segment elevation myocardial infarction (STEMI) is likely attributable to the more complex clinical phenotype of the former group [6].

Given the marked heterogeneity of the clinical profiles of patients with NSTE-ACS, the refinement of risk stratification for predicting adverse cardiovascular events, including in-hospital mortality (IHM), is an integral component of optimizing diagnostic and treatment strategies to improve prognosis [7,8]. To date, the Global Registry of Acute Coronary Events (GRACE) risk calculator remains the only guideline-recommended scoring system for assessing the risk of adverse outcomes in patients with NSTE-ACS [9-12]. However, GRACE was developed and validated in the early 2000s and is therefore based on clinical and demographic data that may not fully reflect the contemporary patient population [13,14]. Over the past decade, the clinical profile of patients with NSTE-ACS has evolved substantially due to population aging and the increasing prevalence of comorbidities. This likely affects the applicability of existing risk calculators both in specific subgroups, such as female and older patients [15], and in the contemporary NSTE-ACS population overall [16].

Moreover, traditional statistical models used in most risk scores, including logistic regression, may have limitations when handling a large number of predictors and complex nonlinear relationships between variables and outcomes. In this context, machine learning (ML) approaches have attracted increasing attention because of their ability to model complex interactions and potentially improve predictive performance [17].

Recent studies have demonstrated the potential of ML methods for predicting IHM in patients with NSTEMI or NSTE-ACS. Algorithms such as Random Forest (RF), XGBoost (Extreme Gradient Boosting), LightGBM, support vector machines, and deep learning have shown improved discrimination compared with traditional risk scores. However, existing studies remain heterogeneous with respect to patient populations, data sources, and clinical settings, including intensive care unit–based datasets [18], NSTEMI-only cohorts [19], or NSTE-ACS populations restricted to patients undergoing percutaneous coronary intervention [20]. Importantly, relatively few studies have evaluated ML-based risk prediction models designed for use at different stages of the diagnostic process in a contemporary, real-world NSTE-ACS population.

This study was designed to address these limitations. We developed ML models to predict IHM in a contemporary real-world cohort of patients with NSTE-ACS. Unlike many previous studies, the proposed models were designed for application at different stages of the diagnostic process, including the stage before laboratory data become available. The performance of several ML algorithms was compared with traditional approaches, including logistic regression and the GRACE-based strategy, with the aim of developing clinically applicable risk prediction tools for NSTE-ACS management.



Methods

Overview

This study used data acquired at the Research Institute of Cardiology, a branch of the Federal State Budgetary Scientific Institution “Tomsk National Research Medical Center of the Russian Academy of Sciences.” The anonymized dataset included information on 1144 patients with NSTE-ACS (men: n=657, 57.4%; and women: n=487, 42.6%), aged 30 to 98 (median 67, IQR 59.7-75) years, who were admitted to the facility between 2019 and 2021. All patients included in the study signed written informed consent for the processing of personal data. The final cohort consisted of 512 patients with a clinical diagnosis of unstable angina and 632 patients with primary or recurrent NSTEMI. The patient enrollment flowchart is presented in Figure 1.

Figure 1. Flowchart of patients enrolled.

Eligibility Criteria

Inclusion Criteria

The inclusion criteria were as follows:

- Diagnosis at admission: NSTE-ACS, defined as the presence of acute clinical signs or symptoms of myocardial ischemia, with electrocardiography (ECG) showing no persistent ST-segment elevation in at least two adjacent leads and no new-onset left bundle branch block
- Patients of any gender aged ≥18 years
- Consent to the processing of personal data signed by the patient or their legal representative upon admission

Exclusion Criteria

The exclusion criteria were as follows:

- Patients with an initial diagnosis of acute coronary syndrome with persistent ST-segment elevation
- Lack of clinical and diagnostic data necessary to make a meaningful assessment of the condition and to study disease outcomes
- No consent for the processing of personal data, signed by the patient or their legal representative

Data Collection

For each patient, data on 149 parameters were retrospectively collected, encompassing anamnestic, anthropometric, clinical, and laboratory characteristics (Table S1 in Multimedia Appendix 1). Data were stored in a personalized electronic database using Microsoft Excel 2010 (Certificate of State Registration 2023622190 dated July 3, 2023) [21]. Demographic and anthropometric data included age, sex, and BMI. The anamnestic information analyzed as predictors of adverse events included the functional class of chronic heart failure (CHF), prior decompensation of CHF, and a history of conditions such as anemia or bleeding, uncontrolled arterial hypertension, essential arterial hypertension, hypotensive episodes (blood pressure <90/60 mm Hg), pulmonary embolism, peritonitis, coronary artery disease (CAD), atrial fibrillation, acute cerebrovascular events, and type 2 diabetes mellitus. Additional variables included were the presence and stage of chronic kidney disease (CKD), the presence of malignant neoplasm, peripheral arterial disease, a family history of CVD, duration of CAD, the number of prior myocardial infarctions, the number of previously implanted intracoronary stents, and the Charlson comorbidity index (CCI). Furthermore, the dataset captured prior procedures, such as history of invasive coronary angiography (ICA), percutaneous coronary intervention, and coronary artery bypass grafting. Indicators characterizing the patients' condition at admission were also assessed, such as the presence of community-acquired pneumonia (CAP), class of acute heart failure (AHF) by T. Killip (Killip class), anginal pain at admission, positive response to short-acting nitrates, pain radiation, dyspnea on admission, palpitations, symptoms of weakness, dizziness, systolic blood pressure (SBP), diastolic blood pressure (DBP), heart rate (HR), pulse, pulmonary rales and dry rales, signs of ongoing myocardial ischemia on admission, CRUSADE (Can Rapid risk Stratification of Unstable Angina Patients Suppress Adverse Outcomes with Early Implementation) score, cardiac arrhythmias, and oxygen saturation level.

XSL•FO
RenderX

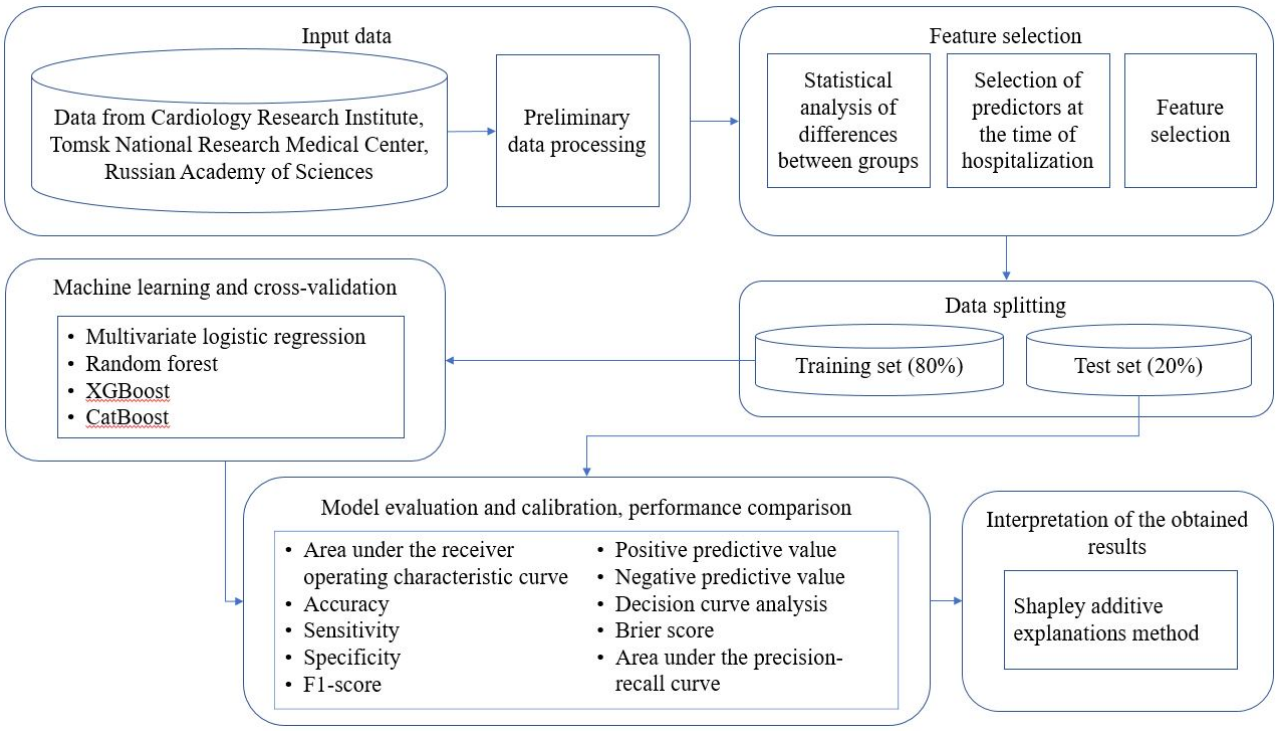
Within the first hours of hospitalization, a standard set of laboratory tests was performed, assessing the following parameters: white blood cell count, hemoglobin level, red blood cell count, hematocrit, platelet count, glucose, creatinine, total bilirubin, alanine aminotransferase, aspartate aminotransferase, creatine phosphokinase, creatine phosphokinase-MB, total cholesterol, triglycerides, fibrinogen levels, as well as the international normalized ratio.

Data collection spanned a 3-year period (2019-2021). During this time, 2 different immunoassay analyzers (with different reference intervals) were used in the hospital to determine troponin I levels: “Access2” (upper limit of normal [99th percentile] of 0.04 ng/mL) and “AQT90 FLEX” (upper limit of normal [99th percentile] of 0.023 ng/mL). Consequently, quantitative data for this marker were not included in the subsequent analysis; instead, the fact of troponin I elevation above the 99th percentile was used.

Within the first hours of hospitalization, the following instrumental studies were performed: ECG was used to assess the QRS duration, QT and corrected QT (QTc) intervals, and the presence of pathological Q waves. Echocardiography (EchoCG) was performed to measure the longitudinal dimensions of the left atrium and right ventricle, thickness of the interventricular septum and posterior wall of the left ventricle, myocardial mass and mass index, end-diastolic and end-systolic dimensions and volumes, stroke volume (SV), the peak early (E) to late (A) ventricular filling velocity ratio (E/A), and left ventricular ejection fraction (LVEF) using both M-mode and B-mode.

For each patient, the glomerular filtration rate was calculated during the hospital stay, along with the GRACE risk score. Among the indicators describing the dynamics of the patient’s condition, the development of hospital-acquired pneumonia (HAP) was additionally considered. All clinical characteristics and factors assessed during hospitalization occurred prior to the IHM and were considered predictors rather than perimortem events.

Additionally, data obtained during ICA were analyzed. ICA was performed during the index hospitalization in 900 (78.7%) of 1144 patients. The presence of multivessel atherosclerotic CAD (defined as ≥2 major epicardial arteries with a diameter of >2.5 mm affected) and angiographic evidence of slow coronary flow were used as potential prognostic factors.



All binary indicators, describing the presence or absence of a characteristic, were coded as 1 (present) or 0 (absent). Variables with multiple levels, such as Killip class of AHF, New York Heart Association functional class, and CKD stage, were transformed into several variables. The first variable was modeled as a continuous measure (values 0 - 4), the second as a dichotomous variable indicating the presence or absence of the condition (AHF, CKD, or CHF), while several additional variables were constructed to contrast mild versus severe disease stages (CKD stages 3 - 5 coded as “1,” otherwise “0”; Killip classes III and IV of AHF coded as “1,” otherwise “0”).

The primary end point of the study was the occurrence of IHM or death within 30 days of the acute coronary event. Hereafter, this composite end point is referred to as IHM and is coded as “1.” A code of “0” was assigned to survivors, defined as patients who were alive at discharge and at 30 days after the onset of NSTE-ACS.

It should be noted that the data obtained on the frequency of IHM do not fully reflect the institution’s overall mortality rates due to the flow-based processing of information and the exclusion of a number of patients from this study for the reasons mentioned earlier (Figure 1). The study included 6 main stages (Figure 2).

XSL•FO
RenderX

Figure 2. Study design flowchart.

At stage 1, data were cleaned to remove manual entry errors, while categorical features were encoded. Missing data were not imputed. If the missingness of a variable exceeded 10%, such variables were excluded from further analysis (Table S2 in Multimedia Appendix 1). The missing data were mainly attributable to the heterogeneity of patients' medical history at the time of hospital admission, as well as to differences in the clinical indication for assessing certain laboratory parameters depending on the patient's clinical status (eg, presence or absence of anemia or diabetes mellitus) and during follow-up measurements (eg, hemoglobin and creatinine levels). Variables that demonstrated statistically significant differences but were not included in the final prognostic models contained missing values ranging from 0% to 10%, which were not imputed. Continuous variables were presented as median and IQR (Q1; Q3), while categorical variables were presented as counts and percentages.

At the second stage, statistical analysis of the data was performed, comprising an intergroup comparison of 149 continuous and categorical features.

At the third stage, using the data normalized in the previous stage by z-score standardization (mean 0, SD 1), univariate logistic regression (ULR) was applied to calculate weight coefficients and area under the receiver operating characteristic curve (ROC-AUC) with 95% CIs for a preliminary assessment of potential predictors. The ULR model was trained on 80% of the data randomly selected from the dataset. The ROC-AUC estimate was obtained by testing the predictive ability of the ULR model on the final test set, which contained the remaining 20% of the data. The procedure of splitting the data into 80% and 20% subsets was repeated 100 times with the computation of the ULR model, weight coefficients, and ROC-AUC; the results were averaged, and the 95% CI was estimated.

During the fourth phase of the study, predictive models for IHM were developed using the following ML algorithms: multivariate logistic regression (MLR), RF, Stochastic Gradient Boosting (XGBoost), and CatBoost (CB).

The models were designed to reflect several distinct stages of the diagnostic workflow for patients with NSTE-ACS. The first scenario used data available at initial presentation, including demographic, anthropometric, and anamnestic data, as well as findings from the physical examination. CAP was modeled separately, as its diagnosis requires additional confirmatory testing.

The second diagnostic scenario incorporated laboratory results. The third scenario added findings from instrumental investigations, specifically EchoCG. The final, fourth scenario accounted for the potential development of HAP during hospitalization.

For baseline comparison, a ULR model was also calculated based on a single predictor—the GRACE risk score.

At the fifth stage, the Shapley Additive Explanations (SHAP) method [22] was used to interpret the output of the best-performing model. Furthermore, the clinical utility of the models was evaluated using decision curve analysis (DCA) [23].

The normality of continuous variables was assessed using the Kolmogorov-Smirnov test. As none of the variables followed a normal distribution, the Mann-Whitney *U* test was used for intergroup comparisons. Differences in the frequency of categorical variables were analyzed using the chi-square test. A *P* value of less than .05 was considered statistically significant. For dichotomous variables, the Fisher exact test was additionally used to calculate odds ratios (ORs) with 95% CI.

XSL•FO
RenderX

Potential predictors for the prognostic model were identified through forward sequential feature selection using both ULR and MLR algorithms. Model performance was evaluated using stratified 10-fold cross-validation. The optimization metric for hyperparameter tuning was the maximization of the ROC-AUC.

ML Algorithms

For training, cross-validation, and final testing of all multivariable prognostic models, the dataset was randomly split as follows: 80% of the data were used for training and cross-validation, performed using stratified 10-fold cross-validation, and 20% were reserved for final testing.

Model parameter and hyperparameter tuning were performed to maximize the ROC-AUC during cross-validation. The final model quality was assessed on the test set using the ROC-AUC and additional metrics, including accuracy, sensitivity, specificity, and the F_1-score. To calculate these latter metrics, an optimal probability threshold was determined by identifying the point that maximized the average of sensitivity and specificity across the cross-validation folds. Given the class imbalance (with an IHM prevalence of 8.1%), the Brier score was calculated for all models [24].

The selection of predictors for the multivariate models was guided by the ROC-AUC values from the ULR models. A feature was included in the pool of potential predictors for IHM if it increased the cross-validated ROC-AUC of the multivariate model. Predictors selected by MLR were subsequently used to train the RF, XGBoost, and CB models. For these ensemble methods, the possibility of including other potential predictors was also evaluated.

Hyperparameter tuning was performed at the same stage. To estimate the 95% CIs of the model performance metrics, the random data-splitting procedure (80% training and cross-validation, 20% testing) was repeated 100 times; the results were averaged, and 95% CIs were calculated. This approach minimized the risk of an “optimistic” test set selection. To compare the predictive performance of the models, a bootstrap procedure with 1000 resamples, identical for the compared models, was applied, and *P* values were estimated.

For the best-performing models, area under the precision-recall curve (PR-AUC) and model calibration were assessed. PR-AUC was calculated using average precision, defined as the weighted mean of precision at each threshold, with the increase in recall serving as the weight. Calibration analysis was conducted for 3 models corresponding to different stages of the diagnostic process. Models were trained on 80% of the data, while calibration curves were evaluated on the remaining 20% test dataset. For the best-performing model, the relationship between positive predictive value (PPV) and negative predictive value (NPV) across classification thresholds was also analyzed.

Predictor importance for the best-performing model was assessed using SHAP values. Finally, all models, including the GRACE score baseline model, were compared for their clinical utility using DCA. Data analysis was performed using the Python programming language and the following libraries: NumPy, SciPy, Pandas, CB, XGBoost, Sklearn, DCA, and SHAP.

Ethical Considerations

This study was conducted in accordance with the principles of the Declaration of Helsinki and was approved by the Human Research Ethics Committee of the Research Institute of Cardiology, Tomsk National Research Medical Center (protocol No. 235, November 23, 2022). The study was based on retrospectively collected clinical data obtained during routine medical care. Upon hospital admission, patients provided written consent for the processing of their personal data in accordance with institutional policy and applicable legislation. Before analysis, all data were deidentified to protect participants' privacy and confidentiality. No additional interventions or direct contact with participants were performed as part of this study. As this was a retrospective observational study, prospective registration was not required under the International Committee of Medical Journal Editors recommendations.

Results

Overview

Of the 1144 patients with NSTE-ACS included in the study, IHM was recorded in 94 (8.1%) of 1144 patients. The group with fatal outcomes demonstrated a significantly higher prevalence of specific clinical and laboratory characteristics (Table S1 in Multimedia Appendix 1).

Patients in the IHM group were significantly older, with a median age of 80.5 (IQR 72 - 85) years compared to 66 (IQR 60 - 75) years in the survivor group (*P*<.001), while the absence of a family history of CVD was significantly more common (78/94, 83% vs 611/1050, 58.2%; *P*<.001). BMI was significantly higher in survivors than in nonsurvivors (median 28.6, IQR 25.5-32.4 vs 26, IQR 22.9-29.2; *P*<.001).

Significant differences were observed in clinical presentation at admission. Weakness was reported by 37 (39%) of 94 patients in the IHM group versus 172 (16.4%) of 1050 patients in the survivor group (OR 3.3, 95% CI 2.1 - 5.2; *P*<.001). Loss of consciousness was recorded in 14 (15%) of 94 patients in the IHM group compared to 20 (2%) of 1050 patients among survivors (OR 9.0, 95% CI 4.4 - 18.5; *P*<.001).

SBP was significantly lower in the IHM group, with a median of 110.5 mm Hg (IQR 99.3 - 135.8) versus 139.5 mm Hg (IQR 123 - 155) in survivors (*P*<.001). Similar differences were recorded for HR (median 90, IQR 75 - 109 bpm vs 75, IQR 65 - 88 bpm; *P*<.001). The presence of auscultative phenomena was strongly associated with mortality. Both dry (11/94, 12% vs 42/1050, 4%; *P*=.002) and pulmonary (36/94, 38% vs 110/1050, 10.5%; *P*<.001) rales were significantly more frequent in the IHM group.

Overall, the CCI was significantly higher in the mortality group (median 8, IQR 6-10 vs 5, IQR 3-7; *P*<.001). Conversely, an inverse association was observed for certain traditional risk factors. The proportion of active smokers was lower in the IHM group (24/94, 26%) compared to survivors (446/1050, 42.5%; *P*<.001), as was the prevalence of a family history of CVD (16/94, 17% vs 439/1050, 41.8%; *P*<.001). Comorbidities and complications during hospitalization also played a crucial role. CAP was present in 17 (18%) of 94 patients in the IHM group

XSL•FO
RenderX

compared to 25 (2%) of 1050 patients among survivors (OR 9.1, 95% CI 4.7 - 17.5; *P*<.001). Cardiogenic shock was observed more frequently in the nonsurvivor group than in the survivor group (41/94, 44% vs 13/1050, 1%; OR 61.7, 95% CI 31.2 - 122.1; *P*<.001). Similarly, AHF Killip classes II and III were more common among nonsurvivors (63/94, 67%) than among survivors (112/1050, 10.7%; OR 29.8, 95% CI 18.2 - 49.0; *P*<.001).

Laboratory findings also revealed significant disparities between the groups. Hemoglobin levels were markedly lower in the nonsurvivor group, with a median of 113 (IQR 99 - 132) g/L compared to 136 (IQR 123 - 148) g/L in survivors (*P*<.001). Hematocrit levels were similarly reduced, measuring 34% (IQR 30 - 39) versus 39.9% (IQR 36 - 43) in the survivor group (*P*<.001). Conversely, creatinine levels were significantly elevated in patients with fatal outcomes, registering a median of 129 (IQR 101 - 189) µmol/L against 94 (IQR 81 - 115) µmol/L in survivors (*P*<.001).

A number of instrumental findings from ECG and EchoCG also demonstrated statistically significant differences between the groups. The most substantial disparities were observed for the following parameters. LVEF was significantly lower in nonsurvivors (median 44%, IQR 35 - 59) than in survivors (median 60%, IQR 52 - 64*;* *P*<.001). Furthermore, left ventricular systolic dysfunction (LVSD; LVEF <49%) was observed in 44 (47%) of 94 patients in the IHM group compared to 171 (16.3%) of 1050 patients in the survivor group (*P*<.001). SV was substantially reduced in nonsurvivors: 45.5 (IQR 36.6 - 55) mL versus 60 (IQR 51 - 69) mL in the survivor group (*P*<.001). Multivessel CAD was associated with a significantly higher incidence of fatal outcomes (42/94, 45% vs 303/1050, 28.9%; *P*<.001). The median QTc interval in the fatal outcome group was 433 (IQR 413 - 461) ms compared to 419 (IQR 402 - 439) ms in survivors (*P*=.001). The QRS duration was also longer: 108 (IQR 94 - 130) ms versus 98 (IQR 88 - 110) ms (*P*<.001).

The results of the ULR analysis, performed on features with statistically significant intergroup differences, demonstrate significant associations between various patient characteristics and IHM and allow for the ranking of these features by their level of importance (Table S3 in Multimedia Appendix 1). On the basis of the ULR analysis, the presence of AHF demonstrated the highest prognostic significance for IHM (ROC-AUC=0.805; β=4.6). It was closely followed by the glomerular filtration rate (ROC-AUC=0.799; β=−4.95), age (ROC-AUC=0.793; β=4.52), LVSD (ROC-AUC=0.786; β=3.1), SV (ROC-AUC=0.774; β=−3.6), and oxygen saturation level (ROC-AUC=0.774; β=−4.03). Several other variables also showed high prognostic potential (ROC-AUC>0.7), including the CCI, SBP, DBP, LVEF, troponin-I, CRP levels, hemoglobin and hematocrit levels, the presence of multivessel CAD, and signs of ongoing myocardial ischemia.

Model Development

At the third stage, prognostic models for IHM were developed corresponding to the following diagnostic scenarios:

1. At hospital admission, prior to the availability of laboratory results and the ability to calculate the GRACE risk score, which requires creatinine and troponin I levels (models 1 and 2)
2. After obtaining laboratory results
3. After obtaining EchoCG results
4. During hospitalization

The validation and testing results of the MLR prognostic models across these different stages of the diagnostic and treatment process are presented in Table 1.

Treatment stage and model	Predictors	ROC-AUC[a] during cross-validation	ROC-AUC during final testing
9	GRACE, hematocrit, BMI, community-acquired pneumonia, symptoms of weakness, Charlson comorbidity index, family history of cardiovascular diseases, dry rales, loss of consciousness, left ventricular systolic dysfunction, hospital-acquired pneumonia, cardiogenic shock	0.940 (0.939, 0.942)	0.947 (0.942, 0.953)

[a]ROC-AUC:area under the receiver operating characteristic curve.

[b]GRACE: Global Registry of Acute Coronary Events.

Models 1 and 2 differ by the inclusion of the CAP feature in the latter. The performance evaluation of models 1 and 2 during cross-validation and final testing shows their minor differences, with the latter demonstrating superior metrics.

Following the assessment of laboratory results, models 3 to 6 can be computed. The baseline model based on the GRACE risk score showed higher prognostic accuracy than a model using its component predictors in a continuous form (ROC-AUC=0.907 vs 0.889).

The inclusion of additional predictors—such as anthropometric data (BMI), anamnestic data (CCI and family history of CVD), assessment of the patient's condition at admission (weakness, dry rales, and loss of consciousness), clinical data, and hematocrit level—improved prognostic accuracy compared to the GRACE score alone, achieving an ROC-AUC of 0.928. Using the LVSD predictor further increased performance to an ROC-AUC of 0.935. Finally, accounting for the development of HAP and cardiogenic shock during treatment yielded the highest accuracy, with an ROC-AUC of 0.947.

Using various ML methods, prognostic models for IHM in patients with NSTE-ACS were developed (Table 2).

The analysis of the developed predictive models revealed that all of them exhibited high forecasting accuracy, which ranged from an ROC-AUC of 0.889 (for the first model that used isolated predictors from the GRACE scale) to 0.951 (for the model that included, in addition to the GRACE predictors, features assessed at each stage of the diagnostic and therapeutic process). Models developed using various ML methods demonstrated a consistent increase in predictive value with the inclusion of predictors selected at subsequent stages of the diagnostic process (Figure 3). The best models at each stage were created using RF (Figure 4).

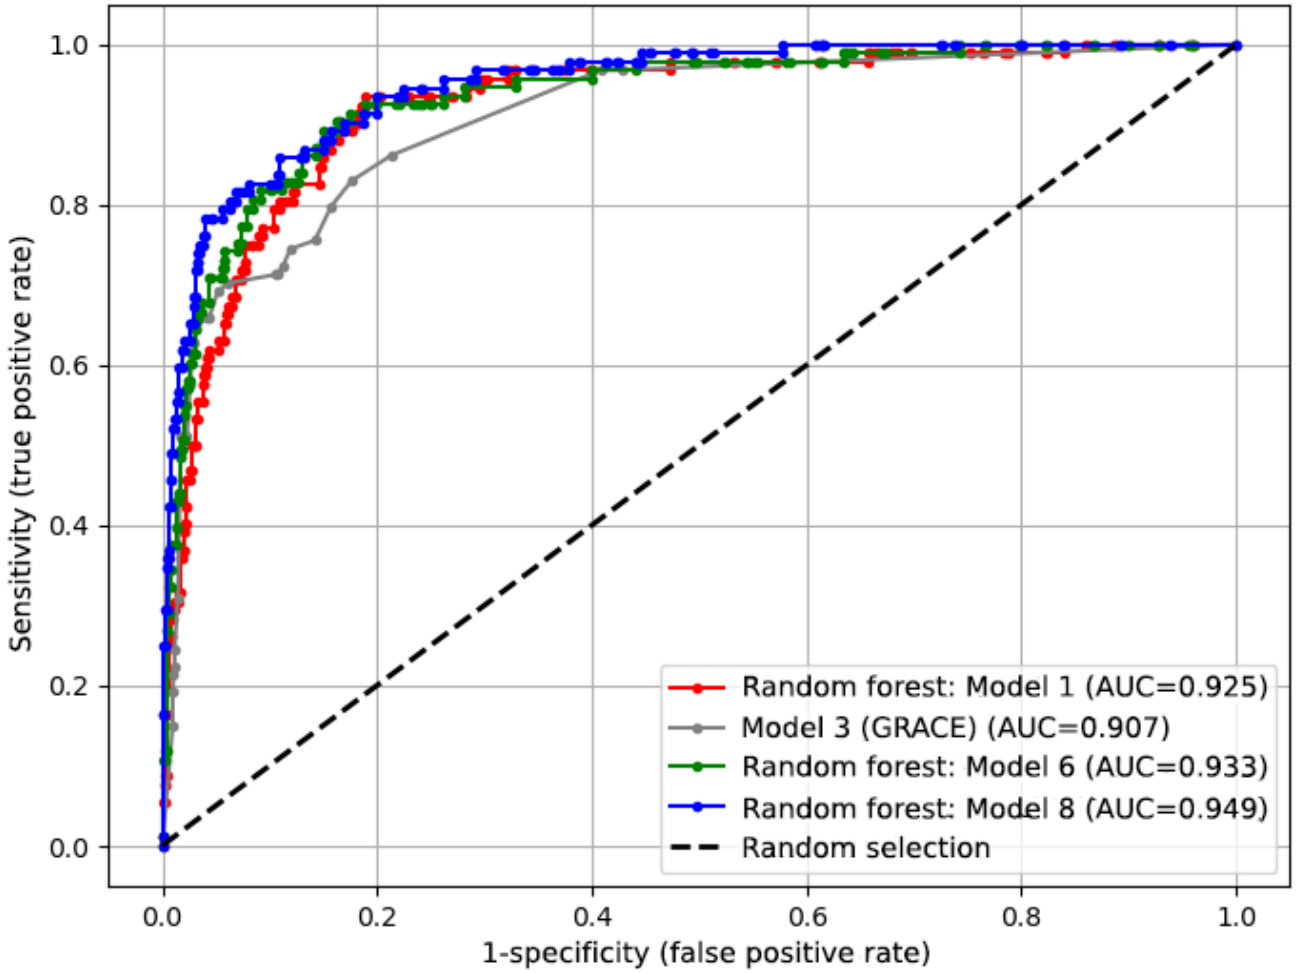
[a]AUC: area under the curve.

[b]MLR: multivariate logistic regression.

[c]The model uses isolated predictors instead of the GRACE scale: age, heart rate, systolic blood pressure, Killip class of acute heart failure, and creatinine.

The developed models demonstrated high discriminative performance (Table 2). However, due to the pronounced class imbalance in the dataset—reflected in the expectedly low F_1-score values (0.421 - 0.555)—additional model calibration was performed.

PR-AUC analysis accounting for class imbalance (IHM prevalence of 8.1%) demonstrated good predictive performance of the developed models. Model 1, predicting IHM at hospital admission, achieved a PR-AUC of 0.620 (95% CI 0.613 - 0.627). Model 6, developed for mortality prediction



XSL•FO
RenderX

when laboratory data were available, achieved a PR-AUC of 0.641 (95% CI 0.634 - 0.647). Model 7, incorporating echocardiographic parameters, showed a PR-AUC of 0.647 (95% CI 0.640 - 0.653). Model 9, predicting IHM in the postoperative period, demonstrated the highest PR-AUC of 0.685 (95% CI 0.679 - 0.690).

Calibration curves were constructed for models 1, 6, and 9, which were trained on 70% of the data and evaluated on the remaining 30% test dataset (Figures 5-7). Analysis of the calibration curves demonstrated a high level of agreement between predicted and observed outcomes. The predicted outcome points were located close to the line of ideal calibration. The Brier scores were 0.0378, 0.0375, and 0.033, indicating excellent model calibration, given the prevalence of IHM of approximately 8.1%. Figures 5-7 also present the distribution of predicted probabilities for the groups of deceased and surviving patients.

Analysis of the PPV and NPV curves showed that PPV increased as the classification threshold increased (Figure 8). At a classification threshold of 0.1, the PPV for IHM was approximately 37%, whereas at thresholds above 0.3, it exceeded 85%.

Furthermore, DCA was used to compare the clinical utility of the models against the GRACE score (Figure 9). The analysis showed that all developed models provided greater clinical utility than the GRACE score, with the RF models demonstrating the highest net benefit.

The importance of predictors used in the models was analyzed using the SHAP method. The results for the RF model are presented in Figure 10 (for model 8) and Figure 11 (for model 9).

Higher SHAP values, indicating an increased risk of IHM, were associated with pulmonary edema and cardiogenic shock at admission (Killip classes III and IV), older age, and greater comorbidity burden. Additional confirmed predictors included hematocrit and BMI, with lower values associated with a higher risk of IHM. During the treatment stage, predictors identified at earlier diagnostic stages remained important, while cardiogenic shock and HAP also emerged as significant contributors to mortality risk (Figure 11).

Discussion

Principal Findings

In this study, we proposed a stage-specific approach to predicting IHM in NSTE-ACS using ML algorithms that account for data availability at different phases of the diagnostic process. The developed models demonstrated high predictive performance, which consistently increased with the inclusion of additional clinical, laboratory, and instrumental predictors, achieving a maximum ROC-AUC of 0.951. RF-based models provided the best discrimination and clinical utility compared with traditional GRACE-based risk assessment.

Currently, NSTE-ACS remains the leading cause of emergency hospitalization in cardiology departments. Recently, due to the progressive aging of the population, the proportion of NSTE-ACS within the structure of acute coronary events has increased significantly. In 2020, the number of NSTE-ACS cases nearly doubled that of STEMI [25]. Despite improvements in the management of patients with NSTE-ACS, updated clinical guidelines, and high rates of invasive treatment application, real-world clinical practice acknowledges a lack of positive dynamics indicating further improvement in treatment outcomes for the main conditions within this syndrome [26]. For instance, according to data from the annual Swedish SWEDEHEART registry [1], a general trend of decreasing mortality from NSTEMI was observed between 1995 and 2008: IHM dropped from 12% to 4%, and long-term mortality from 27% to 16%. However, over the last 17 years (2008 - 2024), the rates of in-hospital and 30-day mortality for NSTEMI have remained largely unchanged, reaching 3.6% and 4.5%, respectively, in 2023, despite an increased frequency of invasive treatment use [27]. In a large 3-year ACS registry presented by Toušek et al [28], IHM was 6.2% for NSTEMI and 1.2% for unstable angina.

Given the significant heterogeneity within the cohort of patients with NSTE-ACS, risk stratification for adverse cardiovascular events is essential, as this approach determines not only treatment strategy but also disease prognosis. It has been demonstrated that the use of risk stratification tools helps to avoid subjectivity in clinical decision-making for patients with NSTE-ACS [5,29].

Risk assessment and the subsequent determination of patient management strategy ensure the application of the necessary scope of established diagnostic and therapeutic methods in a hospital setting. According to a number of studies, this leads to improved short- and long-term clinical outcomes [30-32]. Furthermore, the quantitative calculation of the risk of adverse ischemic events surpasses subjective clinical assessment. Among existing calculators, the GRACE risk score remains the primary tool for objective risk stratification, both at admission and at discharge [33]. However, it is important to note several limitations of using this score with the cohort of contemporary patients with NSTE-ACS.

XSL•FO
RenderX

Primarily, 2 studies [13,14] that largely formed the basis for the original clinical guideline recommendations to implement and use the GRACE score in routine practice involved a patient population with a clinical profile significantly different from that of patients with contemporary NSTE-ACS. The modern profile is characterized by a significant comorbid status [6,34]. This feature logically reflects a global trend associated with the progressive aging of the population [25]. Furthermore, a recent large international multicenter study [16], which included a contemporary population of patients with NSTE-ACS, demonstrated that using GRACE score versions different from the original calculator leads to substantial variations in the classification of estimated risk, even when applying the same threshold values (ie, ≤108 and >140 points). This study also showed that the diagnostic performance of the 0/1-hour algorithm (using high-sensitivity cardiac troponin I) for identifying patients with myocardial infarction significantly surpasses that of any GRACE risk assessment used alone.

Thus, these limitations of the GRACE score, coupled with the persistent need to improve outcomes in NSTE-ACS—particularly long-term outcomes—necessitate the development of new risk calculators for adverse ischemic events, tailored to the modern clinical patient profile.

The results of our study not only confirmed several known facts but also revealed new insights. Within this research, multiple ML models were developed and compared for predicting IHM in a contemporary cohort of patients with NSTE-ACS. We confirmed the high prognostic value of the GRACE risk score (ROC-AUC=0.911, 95% CI 0.910 - 0.913) and demonstrated that categorizing the continuous predictors of the GRACE score can improve predictive accuracy. Model 4, based on the continuous-form GRACE predictors, showed an ROC-AUC of 0.888 (95% CI 0.886 - 0.890). The comparison of these models revealed a statistically significant difference (P<.001). Multilevel categorization of continuous predictors may enhance the predictive accuracy of prognostic models by incorporating additional knowledge that refines the relationships between predictors and the outcome [35]. Our experiments demonstrated that when a large number of additional predictors were included in the models, the difference between the model based on the GRACE score and the model incorporating the 5 individual predictors (age, HR, SBP, Killip class, and creatinine) became statistically nonsignificant.

Simultaneously, our study revealed that using additional anamnestic data and physical examination findings allows for the development of models with significantly superior predictive performance. This includes models for the first scenario, which do not incorporate laboratory results and can be applied at the very early stages of the diagnostic process (ROC-AUC=0.930, 95% CI 0.925 - 0.935; sensitivity=0.843, 95% CI 0.828 - 0.859; and specificity=0.852, 95% CI 0.847 - 0.857). Expanding the predictor set with laboratory findings and subsequently with instrumental investigation results significantly enhanced the quality of IHM prediction in patients with NSTE-ACS, with the best model achieving an ROC-AUC of 0.942 (95% CI 0.937 - 0.947), a sensitivity of 0.871 (95% CI 0.856 - 0.887), and a specificity of 0.868 (95% CI 0.863 - 0.873). The accuracy of IHM prediction during inpatient treatment reached an ROC-AUC of 0.951 (95% CI 0.946 - 0.956), a sensitivity of 0.902 (95% CI 0.889 - 0.916), and a specificity of 0.891 (95% CI 0.886 - 0.896). High ROC-AUC, sensitivity, and specificity values indicate the strong discriminative performance of the developed models.

The best performance was demonstrated by models developed using RF, with ROC-AUC values ranging from 0.925 to 0.951 depending on the predictors used, indicating high predictive capability. The logistic regression model showed slightly lower performance, with ROC-AUC values ranging from 0.916 to 0.947 but remained a reliable predictive tool. The XGBoost and CB models demonstrated comparable performance, with ROC-AUC values ranging from 0.919 to 0.947. At the final diagnostic stage, model 7 demonstrated high predictive performance (ROC-AUC 0.942), although this was slightly lower than that of model 9, which incorporated treatment-period variables (ROC-AUC=0.951).

Given the substantial class imbalance in the analyzed dataset (IHM prevalence of 8.1%), additional evaluation metrics were applied, including the Brier score and PR-AUC, along with calibration analysis of the best-performing models and assessment of the relationship between PPV and NPV across classification thresholds. The analysis yielded the following findings. Model 1 demonstrated good discriminative performance (PR-AUC=0.62), low prediction error (Brier score=0.0378), minimal systematic bias (intercept −0.08), and a slight tendency to overestimate risk (slope 0.92). Model 6 showed improved discriminative ability (PR-AUC=0.641) and comparable prediction error (Brier score=0.0375) relative to model 1, with similarly minimal systematic bias (intercept=0.08) and a comparable tendency toward risk overestimation (slope 0.90). Model 9 demonstrated the best discriminative performance (PR-AUC=0.685) and the lowest prediction error (Brier score=0.0331), with no evidence of substantial miscalibration (slope 1.02), although a small intercept shift was observed (intercept=0.12). Overall, all models showed a favorable balance between discrimination and calibration and provided a wide range of predicted probabilities (approximately 80%), enabling effective risk stratification of patients at very high risk of IHM. On the basis of these findings, the developed models appear suitable for potential use in clinical practice.

To identify the model with the best predictive performance, DCA and SHAP analyses were additionally used. DCA showed that the RF model provided greater net benefit than all other models (Figure 9). Moreover, across all threshold probabilities, the net benefit of the RF model remained positive, indicating its potential clinical utility. SHAP analysis confirmed the importance of the GRACE score predictors for forecasting IHM in patients with NSTE-ACS (Figures 10 and 11). The highest feature importance was associated with the Killip class for AHF. At early stages, the most critical risk factors were elevated creatinine levels, advanced age, and high HR, while low SBP could be considered a marker for IHM. Concurrently, we demonstrated that low hematocrit levels, high CCI, and low BMI increase the risk of IHM. Interestingly, patients with a family history of CVD tolerated NSTE-ACS better than those without this factor. During the treatment phase, important risk factors were cardiogenic shock and HAP, while findings from

XSL•FO
RenderX

the physical examination and SBP at admission, as well as LVSD and CAP, lost significance (Figure 11).

The SHAP analysis provides additional insight into the clinical mechanisms underlying the identified predictors of IHM. Factors such as cardiogenic shock and pulmonary edema (Killip classes III and IV) reflect severe acute hemodynamic compromise and are well-established markers of high short-term mortality risk in NSTE-ACS. Older age and a higher comorbidity burden likely reflect reduced physiological reserve and a higher prevalence of chronic organ dysfunction. Lower hematocrit and lower BMI may indicate anemia, frailty, or chronic disease states, which are associated with poorer tolerance of acute ischemic events.

From a clinical perspective, models developed for different stages of the diagnostic process may support early risk stratification and guide clinical decision-making. At the admission stage, early identification of high-risk patients may facilitate more intensive monitoring and earlier invasive evaluation. At later stages of hospitalization, identification of complications, such as cardiogenic shock or HAP, may guide escalation of supportive therapy and help prevent further clinical deterioration.

Recent studies have demonstrated the efficacy of ML algorithms, such as Support Vector Machine, XGBoost, and RF [36]. The ROC-AUC metric of the developed models ranged from 0.73 to 0.883. Similar accuracy results (ROC-AUC=0.87) for patients with NSTEMI were achieved using a multilayer perceptron, outperforming the GRACE score [37]. The RF method enabled the development of an IHM prognostic model for patients with NSTEMI with a ROC-AUC of 0.889 [17]. The RF method also provided the best IHM prediction results for patients with NSTEMI, with an ROC-AUC of 0.890 [19].

Our study demonstrated superior predictive accuracy, with ROC-AUCs of 0.942 during diagnosis and 0.951 during the treatment stage. Table 3 summarizes data reflecting the accuracy of various IHM prognostic models in patients with NSTE-ACS. For cross-study comparison, we limited the analysis to area under the curve, sensitivity, and specificity, as these metrics were the most consistently reported in previously published studies.

On the basis of the developed models, a web service—a calculator for assessing IHM risk in patients with NSTE-ACS—has been created and is available for clinical testing (the electronic link is provided in the supplementary materials in Multimedia Appendix 1).

Conclusions

The use of ML methods allowed the development of several prognostic models for IHM in patients with NSTE-ACS at various stages of the diagnostic process. Models based on the RF algorithm demonstrated the best predictive performance. We showed that incorporating additional anamnestic data and physical examination findings at hospital admission enables the development of a model surpassing the accuracy of the GRACE score (ROC-AUC=0.92 vs 0.911). The inclusion of laboratory data (creatinine and hematocrit) and instrumental findings (LVSD) further enhanced predictive accuracy (ROC-AUC=0.942). Risk factors recorded during inpatient treatment (HAP and cardiogenic shock) provided the highest prognostic accuracy, with an ROC-AUC of 0.951. The performance of the models and their potential clinical applicability were supported by calibration curve analysis as well as by the Brier score, PR-AUC, slope, and intercept metrics. The data obtained during this study were summarized in the form of model 9 and became the basis for the presented risk calculator. The application of this developed model in clinical practice could facilitate a personalized treatment approach and contribute to reducing IHM in patients with NSTE-ACS.

Limitations

To confirm the efficacy of the developed models, further research is required, including prospective and multicenter trials. Future work should also explore the integration of these models into clinical decision support systems for automated data analysis and improved quality of care.

Data processing was carried out with the financial support of the State Task of the Far Eastern Federal University, project FZNS-2023-0010.

Authors' Contributions

VR contributed to the conceptualization and design of the study, recruited patients, developed the study database, edited the manuscript, and gave final approval of the manuscript. AN contributed to the study concept and design, recruited patients, developed the study database, and wrote and edited the manuscript. AV performed the statistical analysis and wrote the manuscript. KS contributed to the conceptualization and design of the study, performed the statistical analysis, and wrote and edited the manuscript. BG contributed to the conceptualization and design of the study, edited the manuscript, and gave final approval of the manuscript.

Conflicts of Interest

None declared.

Multimedia Appendix 1

Supplementary tables presenting baseline clinical characteristics, variables excluded because of missing data, and the predictive performance (coefficients and ROC-AUC values) of individual variables included in the machine learning analysis.
