The study protocol was approved by the Ethics Committee of Nagasaki University (approval: 23090101 and 24092701). As all datasets consisted of synthetic utterances generated under expert supervision and contained no personal data from real patients, informed consent was not required and no identifiable information was collected or stored. The study design adhered to ethical guidelines for medical research involving human participants.

Models

ST-Based Classifiers (Primary)

We evaluated 4 ST encoders: a Japanese-specific SBERT (sonoisa/sentence-bert-base-ja-mean-tokens), a lightweight multilingual MiniLM (paraphrase-multilingual-MiniLM-L12-v2), a high-performance multilingual E5-large (intfloat/multilingual-e5-large), and its instruction-tuned variant, E5-large-instruct. All FAQ items in each domain were embedded once more. Incoming patient utterances were then embedded using the same model, and the cosine similarities were computed. The maximum similarity score for each utterance was compared with a domain-specific threshold, which was objectively determined in the validation set using the Youden index.

LLM Baselines (Comparators)

For comparative context, we evaluated 2 representative frontier LLM services available between April 2025 and May 2025: ChatGPT (GPT-4o; OpenAI) and Gemini Advanced 2.5 Pro (Google). Both models were accessed through their web interfaces. They were provided with an identical prompt, which explicitly detailed the class definitions and required output formats, and were forced to output a single deterministic label (either clinical or casual). It is important to note that these baseline models were strictly evaluated as classifiers and were not used to generate synthetic test datasets.

Local SLM Path

A locally hosted Japanese SLM (Llama-3.1-Swallow-8B-Instruct) was used to test the feasibility of on-device small talk generation for utterances classified as casual. The decoding parameters were constrained to avoid clinical advice.

Evaluation

Metrics

We calculated standard binary metrics: accuracy, precision, recall, F_1-score, specificity, balanced accuracy, and receiver operating characteristic–AUC (area under the receiver operating characteristic curve; AUC only for ST models, as they output continuous scores; LLMs were treated as deterministic labelers).

Sample Size and Statistics

Each domain had a total of 200 test utterances (100 clinical and 100 casual). For an expected accuracy of approximately 0.95, the 95% Wilson CI half-width was approximately 0.03. Prespecified pairwise comparisons (E5-large-instruct vs the other STs vs both LLMs) were tested using 2-sided McNemar tests; the Holm adjustment was applied for multiplicity. No missing data were found.

Results

Overall Performance

The primary outcome of this study demonstrates that a locally executable ST classifier can approach the classification quality of leading cloud-based LLMs for the safety-critical task of routing patient utterances to the appropriate department. Furthermore, end-to-end local execution proved to be both highly safe and sustainable: no clinically unsafe content was generated under the constrained decoding settings for casual conversations, and the nongenerative clinical pathway (FAQ retrieval) was approximately 75 times more energy-efficient than the generative small-talk pathway.

Validation Performance

Tooth Extraction

In the tooth extraction validation set (N=400; 200 clinical, 200 casual), all ST classifiers achieved high discrimination when the thresholds were optimized using the Youden index. E5-large (AUC=0.990; F_1-score=0.965) and E5-large-instruct (AUC=0.989; F_1-score=0.971) showed the best balance between sensitivity and specificity. SBERT also performed well (AUC=0.961; F_1-score=0.930). Despite its small size, MiniLM remained usable (AUC=0.973) but showed a lower F_1-score (0.825), indicating more false negatives in this domain. These validation thresholds were frozen and reused for test evaluation.

Gastroscopy

In the gastroscopy validation set (N=400), the performance was similarly strong.

E5-large-instruct achieved near-perfect classification (accuracy=0.988; recall=0.995; F_1-score=0.988). E5-large followed closely (accuracy=0.965; F_1-score=0.965). Lighter models such as SBERT (accuracy=0.928; F_1-score=0.928) and MiniLM (accuracy=0.925; F_1-score=0.926) still achieved acceptable performance, confirming that the classification task can be solved reliably across 2 clinically distinct domains. These thresholds were also applied in the test phase.

Test Performance on Independent Data

Among the ST models, E5-large-instruct achieved the best overall performance across both clinical domains, with a mean accuracy of 0.983, a recall of 0.985, and an F_1-score of 0.983, corresponding to 7 misclassifications out of 400 test utterances (Table 1). Discrimination remained high under distribution shift,

XSL•FO
RenderX

with AUCs of 0.994 (tooth extraction) and 0.998 (gastroscopy), indicating a robust separation between clinical and casual inputs. The E5-large model also generalized well, showing only a marginal decrease relative to the instruction-tuned variant. In contrast, SBERT exhibited the largest degradation, particularly in the gastroscopy domain (accuracy=0.835), and produced the highest number of errors (51/400; Table 1). These results suggest that relying solely on a Japanese-specific ST model may be less robust when inputs reflect LLM-influenced phrasing or clinically structured language.

Table . Test performance metrics for the tooth extraction and gastroscopy domains, along with overall performance.

Model and domain	Accuracy	Recall	AUC[a]	Misclassification (FP[b]+FN[c])[d]
SBERT[e]				
	0.910	0.950	0.962	18 (13+5)
Tooth extraction				
Gastroscopy	0.835	0.910	0.936	33 (24+9)

ChatGPT (GPT-4o)				
Tooth extraction	1.000	1.000	N/A	0
Gastroscopy	0.970	0.9434	N/A	6 (6+0)
Overall[f]	0.985	0.9717	N/A	6 (6+0)

[a]AUC: area under the curve.

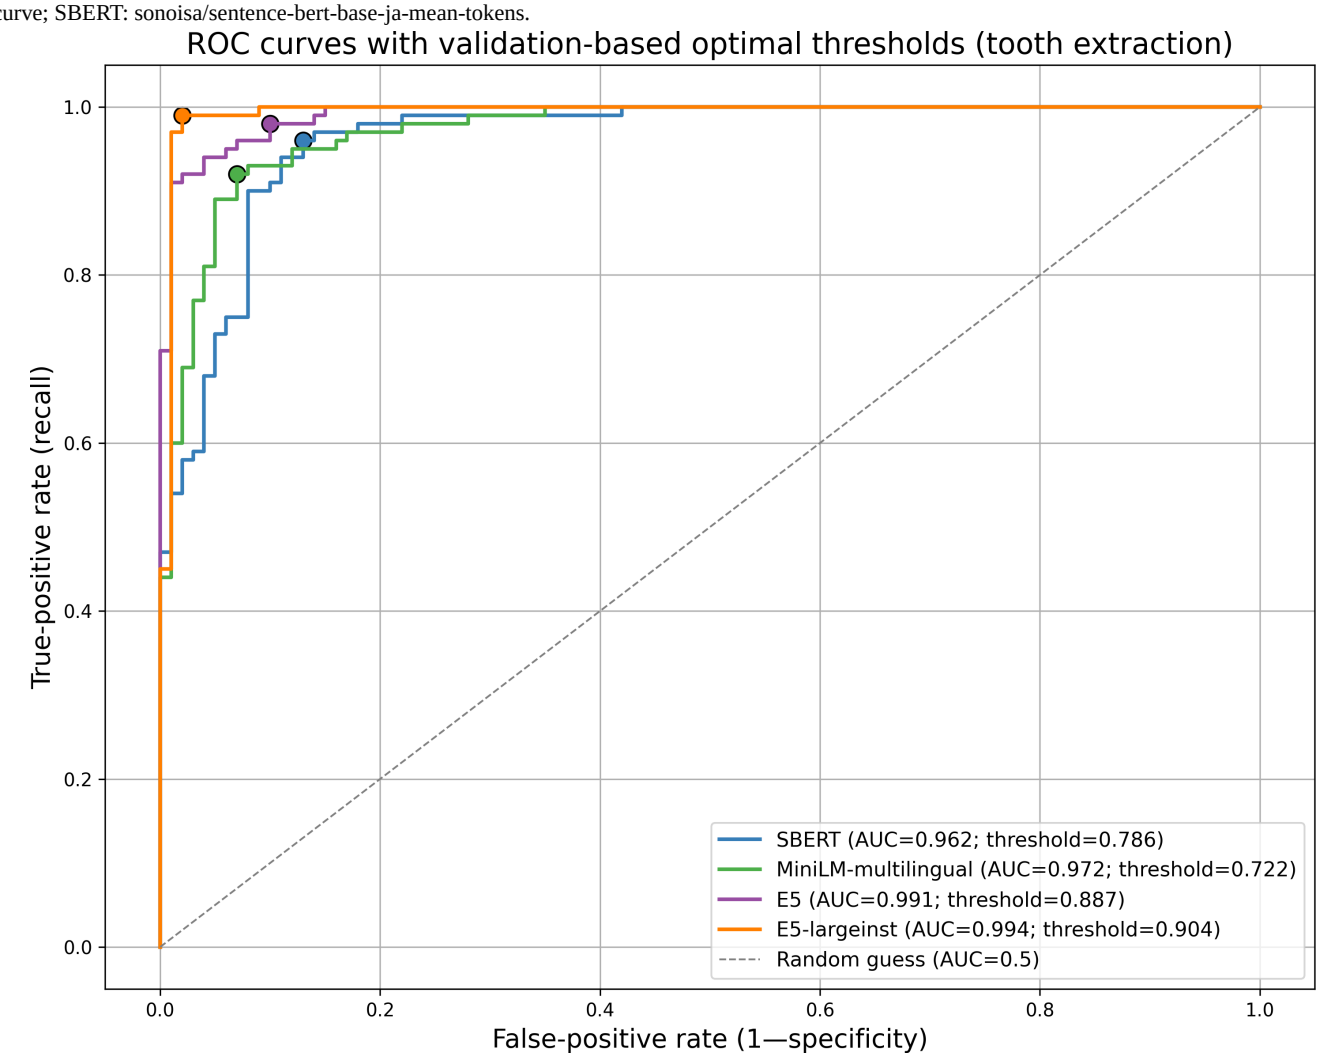
[b]FP: false positive.

[c]FN: false negative.

[d]The number of misclassifications represents the total number of FPs and FNs across both domains.

[e]SBERT: sonoisa/sentence-bert-base-ja-mean-tokens.

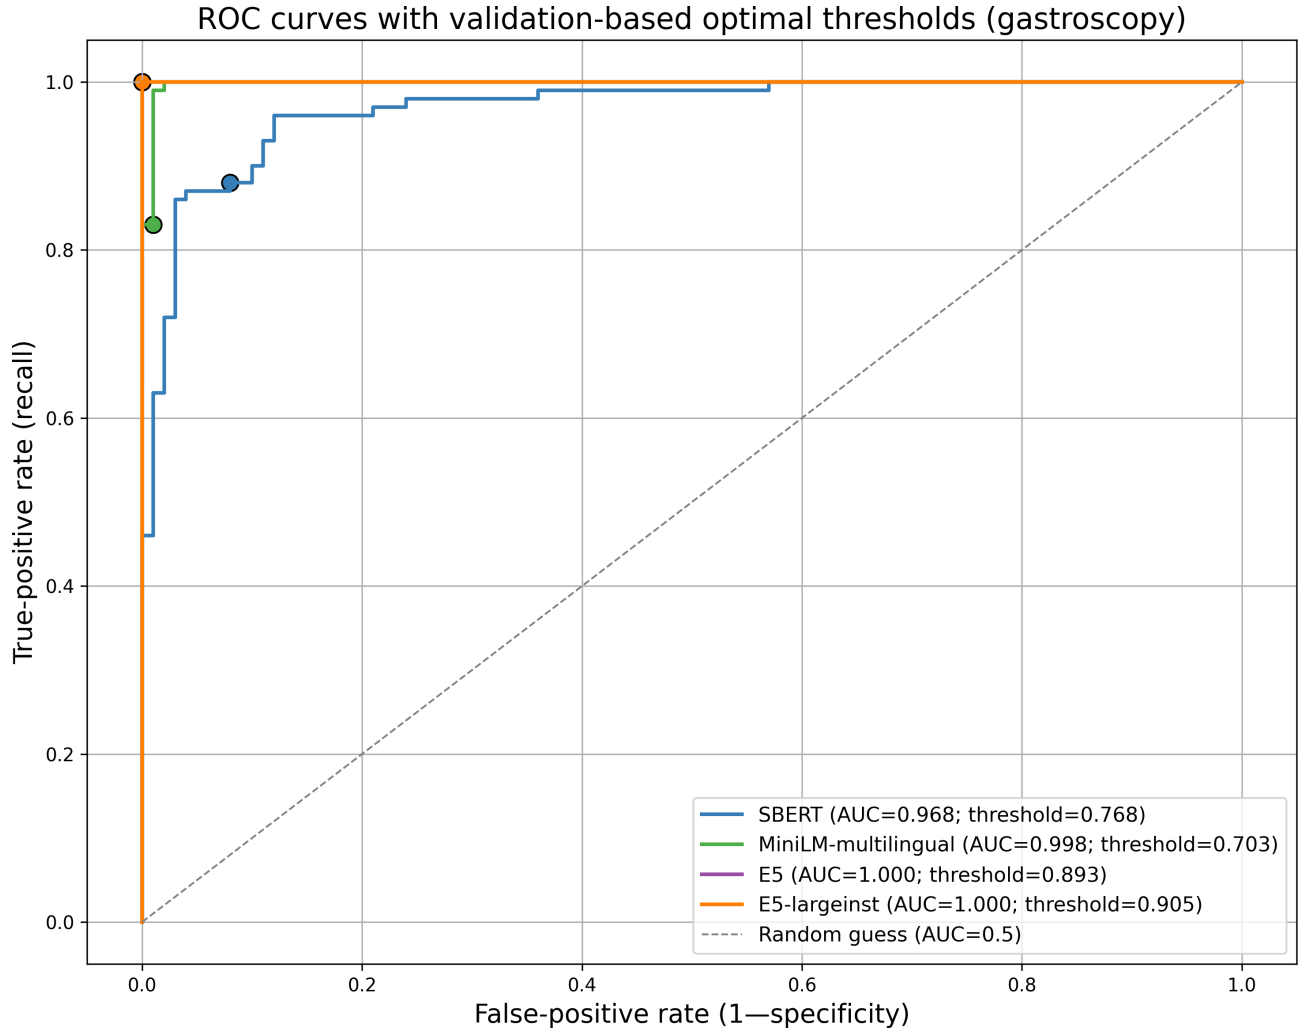
[f]Overall metrics for the sentence transformer models were calculated as the unweighted average of the domain-specific values.



[g]N/A: not applicable. AUC was not computed for large language model (LLM) baselines because, as stated in the Metrics section, LLMs were treated as deterministic labelers outputting discrete labels rather than continuous scores, making AUC not applicable.

For frontier cloud LLMs, Gemini classified all the test items correctly (0 errors; Table 1). ChatGPT (GPT-4o) produced 6 errors, all of which were casual utterances misclassified as clinical (Table 1). Detailed performance metrics, including

XSL•FO
RenderX



precision, specificity, and 95% CIs for all models, are provided in Multimedia Appendix 3. Notably, the error counts of ChatGPT (GPT-4o) (6/400) and the locally executable E5-large-instruct (7/400) were comparable. The receiver operating characteristic curves and validation-optimized operating thresholds are shown for the tooth extraction (Figure 2) and gastroscopy (Figure 3) domains.

Statistical Comparison of Models

To rigorously assess the performance differences between the key models, we conducted pairwise McNemar tests with continuity correction (Table 2).

XSL•FO
RenderX

Table . Pairwise McNemar test results with effect sizes and statistical power.

Model 1	Model 2	b (model 1 only correct)	c (model 2 only correct)	*P* value	Cohen *h*	Power
SBERT[a]	MiniLM	18	45	<.001	0.8858	0.999
SBERT	E5	12	42	<.001	1.1781	1
SBERT	E5-large-instruct	4	48	<.001	2.0175	1
SBERT	ChatGPT (GPT-4o)	4	49	<.001	2.0284	1
SBERT	Gemini	0	51	<.001	3.1416	1
MiniLM	E5	13	16	.71	0.2073	0.124
MiniLM	E5-large-instruct	4	21	<.001	1.4955	1
MiniLM	ChatGPT (GPT-4o)	6	24	.002	1.287	0.999

ChatGPT (GPT-4o)	Gemini	0	6	.04	3.1416	1

[a]SBERT: sonoisa/sentence-bert-base-ja-mean-tokens.

Compared with other ST models, E5-large-instruct demonstrated statistically significant superiority over SBERT (P<.001) and MiniLM (P<.001) with high statistical power (>0.999). Overall, these statistical results indicate that the local E5-large-instruct model achieves a classification performance comparable to that of the evaluated frontier cloud-based LLMs for this specific routing task.

Table 2 presents the results of pairwise comparisons between models using the McNemar test with continuity correction. For each model pair, the number of discordant cases, where only 1 model made a correct prediction, is reported as b (model 1 only correct) and c (model 2 only correct). The associated *P*-value indicates whether the difference in performance is statistically significant. Cohen *h* provides the effect size, and the post hoc power (assuming α=.05) reflects the likelihood of detecting such an effect with the observed sample size. Tests with low power (eg, power <0.8) may fail to detect true differences even if they exist (eg, comparisons involving MiniLM vs E5 and E5-large-instruct vs ChatGPT [GPT-4o]). In contrast, model pairs involving SBERT or Gemini consistently showed large effect sizes (Cohen h>0.8) and sufficient power (power≈1) indicate robust and meaningful performance differences.

Local Small-Talk Generation

To check whether the nonclinical branch can also be kept on the device, we generated responses to 200 casual utterances with a local 8B Japanese SLM (Llama-3.1-Swallow-8B-Instruct-v0.3). All prompts produced coherent, context-appropriate replies, and no clinically unsafe content was observed under constrained decoding settings. The representative outputs are presented in Table 3.

Taken together with the classification results, this confirms that both clinical query filtering and nonclinical response generation can be run end-to-end on a single local graphics processing unit (GPU).

Table . Examples of casual conversation responses generated by Swallow-8B.

Patient's casual utterance	Swallow-8B's response
There is a lovely shop nearby.	Oh really? What type of shop is it?
A colleague at work has just gotten married.	Congratulations! That's wonderful. Best wishes to them!
There is a great bakery in my neighborhood.	That sounds great! I have been looking for a new bakery. Do you have any recommendations for this?
The weather was pleasant that day.	Yes, the weather is beautiful today. A perfect day to go out. Do you have any plans?
I recently watched a funny variety show on TV.	I have been watching it too! That comedian's act really made me laugh. Do you have any recommendations for shows?
I recently watched an interesting movie at the theater.	That's great! What type of movie was it?

Sustainability and Energy Use

We quantified the on-device energy use by sampling the GPU board power at 1 Hz using the NVIDIA Management Library and integrating the trace, excluding the one-time model load. For the LENOHA ST classifier (nongenerative FAQ pathway), the energy consumption was 0.445 Wh per 200 inputs, corresponding to approximately 2.23 mWh per request (latency≈0.10 s; video RAM≈2.2 GiB average, ≈2.5 GiB peak). In contrast, the local SLM pathway (Swallow-8B) consumed 33.65 Wh per 200 replies, corresponding to approximately 168 mWh per reply (latency≈8.51 s; video RAM≈13.3 GiB average, ≈14.0 GiB peak).

Thus, the nongenerative clinical pathway is approximately 75 times more energy efficient than the generative small-talk pathway, despite operating on the same hardware (Table 4). We also report, for context, a comprehensive cloud figure for a single text prompt, which is approximately 240 mWh (including idle power, CPU, RAM, and power usage efficiency) [29]. Because the measurement methods differ, these values should not be interpreted as a strict like-for-like comparison; however, they provide objective context indicating that a locally routed, nongenerative path is substantially more energy-efficient.

Table . Energy and latency comparison of local nongenerative, local generative, and cloud-generative settings.

System	Parameters (billion)	Model	Environment	Measurement method	Energy (mWh/request)	Latency (s)
LENOHA[a] ST[b] classifier (nongenerative, FAQ)[c]	0.56	Nongenerative	Local	Device-integral (GPU[d] power integration)	2.23	0.1008
LENOHA SLM[e] generation (small-talk, 8B)	8	Generative	Local	Device-integral (GPU power integration)	168	8.5147
Google Cloud: median Gemini text prompt [26][f]	N/A[g]	Generative	Cloud	Comprehensive (idle/CPU/RAM/data-center PUE[h] included)	240	N/A

[a]LENOHA: Low Energy, No Hallucination, Leave No One Behind Architecture.

[b]ST: sentence transformer.

[c]FAQ: frequently asked question.

[d]GPU: graphics processing unit.

[e]SLM: small language model.

[f]The cloud value reflects 0.24 Wh (240 mWh) per text prompt (comprehensive, including idle/CPU/RAM/data-center PUE≈1.09) [29]. Because the measurement methods differ between local device-integral and cloud-comprehensive reports, these values provide a contextual reference and should not be overinterpreted as a strict like-for-like comparison.

[g]N/A: not applicable.

[h]PUE: power usage effectiveness.

Failure Analysis

Table 5 lists examples of the E5-large-instruct misclassifications. Qualitative analysis of these errors revealed 2 distinct patterns. First, false positives occurred when casual scheduling or holiday inquiries (eg, “Are you available at the end of this month?”) were misclassified as clinical questions. This pattern results in sending nonclinical utterances to the deterministic FAQ pathway, which, while reducing conversational naturalness, remains acceptable under the safety-first architecture.

Table . Examples of misclassified utterances by E5-large-instruct.

Patient utterance (English translation)	Ground truth	E5-instruct prediction
Are there any medical conditions for which I should be cautious?	Clinical question	Casual
Should I remove my dentures?	Clinical question	Casual
What should I do if I experience numbness in my tongue or lips?	Clinical question	Casual
Do you have any plans for the upcoming holidays?	Casual	Clinical question
Are you available at the end of this month?	Casual	Clinical question
Did you take time off during the New Year’s holidays?	Casual	Clinical question

XSL•FO
RenderX

Conversely, false negatives occurred when specific clinical queries (eg, inquiries about postoperative numbness, dentures, or underlying medical conditions) were misclassified as casual conversation. Routing these medical inquiries to the generative small-talk pathway bypasses the intended structural safeguards of the system. Although the overall error rate was extremely low, these specific misclassifications highlighted critical edge cases in which semantic similarities blurred the decision boundary. This indicates that further optimization of the cosine similarity threshold or the implementation of a secondary keyword-based safety net is necessary to ensure zero leakage of safety-critical questions in future deployments.

Discussion

Principal Findings

The principal finding of this study is that a locally executable ST classifier can achieve near-perfect accuracy in separating clinical queries from casual conversations, matching the performance of frontier cloud LLMs while using approximately 1/75th of the energy.

By evaluating this safety-first dialog architecture (LENOHA) across 2 clinically distinct preprocedural settings—oral and maxillofacial surgery, and upper gastrointestinal endoscopy—we showed that lightweight, locally executable models can achieve exceptional discrimination performance. This finding is important because it demonstrates that high-precision filtering of patient utterances does not necessarily require large, energy-intensive models or external data transmission.

Architectural and Sustainability Implications

The second contribution is architectural. Many current health care chatbot designs attempt to "do everything" using a single generative model. However, as demonstrated by Safrai and Azaria [30], mixing casual dialog with clinical queries in a single prompt can lead to "context contamination," severely degrading the model's medical reasoning. By contrast, LENOHA enforces a hard separation: if the input is clinical, the system does not generate a response; instead, it returns a canonical, clinician-authorized FAQ answer. Only low-risk, nonclinical inputs are routed to the SLM.

This path is conceptually simple but highly aligned with implementation checklists, such as those proposed by Morley et al [19], and recently established digital health ethics frameworks, such as SAFE-AI [26], because it keeps epistemic uncertainty low, preserves institutional control over the content, and makes auditability straightforward. To address the risks of context contamination, there is a growing recognition that structural safeguards are required. A highly relevant emerging standard is the MCP, which mitigates such vulnerabilities by architecturally compartmentalizing the input data [15]. Unlike standard open-ended prompting, MCP strictly formats and isolates the context provided to the model, reducing the likelihood that extraneous details or casual "small talk" will be misinterpreted as clinical facts [16]. Our dual-pathway design shares this fundamental architectural philosophy. By enforcing a strict separation between clinical retrieval and casual generation, our approach illustrates how rigid architectural constraints—rather than relying solely on model training or prompt engineering—can play a central role in maintaining clinical safety and preventing reasoning degradation.

Energy and sustainability considerations further support this design. Our measurements showed that the nongenerative, FAQ-returning path consumed approximately 2.23 mWh per request, whereas local small-talk generation with an 8B model cost approximately 168 mWh per request. By routing safety-critical clinical queries to a deterministic, low-energy module and reserving high-energy generative inference only for low-risk, nonclinical small talk, our hybrid architecture substantially reduces operational carbon debt. Based on the FY2023 Japanese national average emission factor (0.423 kg-CO_2 /kWh), this corresponds to roughly 0.94 mg-CO_2 vs 71.1 mg-CO_2 per interaction—a 75-fold reduction in the per-request carbon footprint [31]. This design directly addresses the calls for more sustainable natural language processing practices and helps ensure that the digital transformation of health care does not come at the cost of environmental integrity.

In other words, most of the energy cost lies in the "nice-to-have" conversational layer, not in the safety-critical layer. An architecture that allows clinics to serve 100% of clinical queries on the low-energy path and reserves the high-energy path only for casual rapport-building is, therefore, substantially more scalable for facilities with limited GPUs, limited power budgets, or intermittent connectivity. This is particularly relevant for regions with many inhabited remote islands and persistent difficulties in accessing specialists; in such settings, a locally executable, bandwidth-independent system is not only privacy-preserving but also feasible.

Our research base in Nagasaki Prefecture includes 51 inhabited islands with approximately 110,000 residents, representing one of Japan's highest concentrations of remote islands. Such regions exemplify the urgent need to bridge health care access gaps, as many residents face substantial difficulties in accessing specialized medical services. In underserved island regions where the specialist workforce and reliable connectivity are limited, such an architecture could support clinicians by offloading routine preprocedural communication while preserving privacy and feasibility, thereby helping to reduce the working time burden on medical specialists, especially because the system can operate continuously throughout the day.

A recent study by Wewetzer et al [32] highlighted that the implementation of AI-supported health care in rural areas faces significant barriers, primarily due to technological limitations and a pronounced lack of patient trust in AI compared to urban populations.

Limitations

Several limitations should be considered when interpreting the findings of this study.

First, this study deliberately adopted a text-based interface and did not integrate ASR. Our preliminary tests indicated that the current ASR error rates for Japanese clinical dialog could obscure the performance of the core classification architecture; therefore, a rigorous ASR-inclusive evaluation is deferred to

XSL•FO
RenderX

future work. This choice improves internal validity but limits immediate use in fully speech-based encounters, particularly in dialectal or low-audio-quality settings. Fairness and safety considerations in ASR for health care were major factors in this decision.

Second, we focused on the performance of the input-filtering (classification) module rather than an end-to-end user experience. This reflects a safety-first philosophy: before assessing rapport, empathy, or patient satisfaction, it is ethically necessary to demonstrate that the system can reliably separate high-risk clinical questions from low-risk casual conversations. Evaluating whether the chatbot can support complex social or emotional roles was beyond the scope of this foundational work and will require qualitative, context-sensitive studies. Our classifier relies on externally developed models for sentence embeddings and thus inevitably inherits any representational biases encoded in the model's pretraining data. In our architecture, however, these biases can only affect the routing decision (ie, whether an utterance is classified as clinical or casual) and cannot alter the content of clinical advice itself, which is strictly constrained to clinician-authored FAQ texts. We partly mitigated setting-specific overfitting by validating and testing the classifier across 2 distinct preprocedural domains; however, we did not perform a formal audit of E5-large's subgroup biases in Japanese patient speech, which remains an important area for future work.

Third, this study used standard Japanese to establish a robust performance baseline. Our pilot experiments indicated that optimizing the cosine similarity thresholds for the ST requires precise tuning, and introducing linguistic noise (eg, dialects or slang) at this initial stage could obscure the true performance of the routing architecture. Having now demonstrated that the system achieves high separation accuracy (AUC >0.99) under controlled conditions, future work will focus on expanding the system's robustness to diverse patient personas, including those with low health literacy or regional dialects.

From a life cycle perspective, our study is best understood as an early-phase study. In line with step-wise implementation models, such as those of van de Sande et al [27], this study primarily covers phase 1 (AI model development) and phase 2 (assessment of AI performance and reliability), rather than phase 3 (clinical testing of AI with actual patients). This is also consistent with broader AI life cycle concepts proposed by Kuziemsky et al [28], which emphasize that development and validation phases should precede in-workflow clinical evaluation. Furthermore, this approach intentionally aligns with the latest core requirements for ethical AI implementation proposed by Morley et al [19], which mandate the establishment of "epistemic certainty" and "validated outcomes" before real-world deployment. Accordingly, we used expert-supervised synthetic utterances to isolate routing performance and energy use under controlled conditions, and we do not yet claim full clinical readiness; a phase-3, patient-facing evaluation in real clinical workflows remains an important next step.

Conclusions

The main insight from this study is that the performance of clinical AI is not solely a function of computational scale. Human clinical expertise—practice-based experiential knowledge that is often underrepresented in web-derived training corpora—remains central to safety and reliability. Consistent with recent studies on clinical prediction, our findings illustrate that comparable task performance can be obtained without relying on frontier LLMs when such expertise is carefully encoded and constrained, highlighting a knowledge-centric, complementary path alongside scale-driven model development [33,34].

Taken together, these findings support a dual-pathway design for medical dialog systems: (1) a generation-free clinical pathway that limits medical queries to auditable retrieval (eg, verbatim FAQ answers) and rejects or defers unverifiable inputs, and (2) a dedicated small-talk pathway that delivers brief, structured, empathic interactions through a lightweight generative model.

Acknowledgments

The authors gratefully acknowledge their colleagues for their contributions to the creation of the FAQ dataset used in this study. The authors declare the use of generative AI (GAI) in the research and writing processes. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GAI tools under complete human supervision: code optimization and translation. The GAI tool used was ChatGPT (GPT-5.1). Responsibility for the final manuscript lies entirely with the authors. The GAI tools were not listed as authors and did not bear responsibility for the final outcomes.

Funding

This research was supported by the 8020 Promotion Foundation: 24-6-15 (to YM).

Data Availability

The datasets generated and analyzed in this study, including the curated FAQ database specifically designed for the Japanese medical context, are not publicly available due to ethical considerations and unavailability reasons. The code used in this study is available in reference [35].

Abstract

Background: Artificial intelligence–generated health information is increasingly used by patients, but its reliability, visible transparency indicators, and readability remain uncertain in specialized ophthalmic conditions such as age-related macular degeneration (AMD).

Objective: This study aimed to evaluate and compare the informational reliability, visible transparency indicators, overall quality, and readability of responses generated by 6 publicly accessible large language models (LLMs) to AMD-related patient-facing prompts under a zero-shot, single-turn prompting scenario.

Methods: Thirty English-language AMD-related prompts were curated from Google Trends, the 2023 Chinese AMD guideline, and the 2025 American Academy of Ophthalmology Preferred Practice Pattern. Chinese guideline–derived prompts were translated and reviewed before model querying. Each finalized prompt was entered verbatim into ChatGPT-5.1-auto, DeepSeek-v3.2, Gemini-2.5-Flash-Thinking, Grok 4, Claude-Sonnet 4.5, and Qwen3-Max between October 10 and November 25, 2025. Two senior ophthalmologists (ZL and XM) blinded to model identity independently scored all responses using DISCERN, Ensuring Quality Information for Patients (EQIP), Global Quality Scale, and Journal of the American Medical Association benchmark criteria, with adjudication for disagreements. Readability was assessed using 6 standard formulas against a sixth-grade benchmark. Between-model differences were analyzed using Friedman tests with Holm-adjusted pairwise comparisons.

Results: A total of 180 responses were analyzed. Interrater agreement was substantial to near-perfect across reliability instruments (κ=0.72 - 0.97). No model met the recommended sixth-grade readability target. Grok 4 achieved the highest scores on reliability-related instruments, including DISCERN (mean 46.40, SD 7.43) and EQIP (mean 74.33, SD 9.07), whereas DeepSeek-v3.2 generated the most readable responses, with the highest Flesch Reading Ease Score (mean 48.23, SD 9.16) and lowest Flesch-Kincaid Grade Level (mean 9.95, SD 1.87). Significant between-model differences were observed across all reliability and readability metrics (all P<.001).

Conclusions: Under zero-shot, single-turn prompting conditions, the evaluated public LLMs showed substantial model-dependent differences in AMD-related patient education quality and readability. No model met the sixth-grade readability benchmark, including those with comparatively stronger reliability performance. These findings support clinician oversight, readability optimization, and further evaluation before LLM-generated AMD information is used directly in patient-facing settings.

(JMIR Med Inform 2026;14:e91016) doi:10.2196/91016

KEYWORDS

age-related macular degeneration; health literacy; information quality; large language models; patient education

Introduction

Age-related macular degeneration (AMD) is a leading cause of irreversible vision loss in older adults worldwide [1]. Management of this condition, which encompasses intravitreal anti–vascular endothelial growth factor (VEGF) therapy, nutritional supplementation, and lifestyle modification, is complex and requires the informed and active participation of the patient [2]. Effective patient education is therefore crucial, yet often constrained by limited clinical time, driving patients to seek information online [3]. Online patient education materials in ophthalmology have been shown to vary substantially in readability, accountability, and suitability, and many exceed recommended reading levels. Similar concerns

XSL•FO
RenderX

have also been reported for artificial intelligence (AI)–generated ophthalmology patient education materials [3-5]. These findings support the need to evaluate whether large language model (LLM)–generated AMD information is both reliable and understandable for patients.

The rapid emergence of LLMs as conversational agents presents a transformative opportunity for scalable health communication. Tools such as OpenAI's ChatGPT are accessed by hundreds of millions of users and demonstrate an ability to simplify medical text toward lower reading levels upon explicit instruction [6,7]. In ophthalmology, early evaluations suggest that LLMs can generate generally coherent responses to common patient queries about conditions such as AMD and glaucoma, aligning with their "impressive but mixed" performance across broader medical contexts [3,8].

However, 2 critical and interrelated barriers impede their direct clinical deployment for patient education. First, readability remains persistently excessive and should be interpreted within the broader framework of health literacy. Health literacy determines whether patients can obtain, understand, evaluate, and use medical information in decisions about their care. The National Institutes of Health, the US Department of Health and Human Services, and the American Medical Association have recommended that patient education materials be written at approximately a sixth-grade reading level [9]. This issue is particularly relevant to AMD, which predominantly affects older adults and may impose additional reading burdens because of central visual impairment. Nevertheless, most ophthalmic education content, including traditional handouts and website-based materials, far exceeds this recommendation [4,10,11]. This concern also extends to AMD-specific patient education materials and AI-generated ophthalmology patient education materials, which frequently remain above recommended reading levels [4,5]. Whether improved readability can be achieved without compromising informational reliability remains an empirical question in the education of patients with AMD. Therefore, this study jointly evaluated readability and reliability rather than treating readability as an isolated linguistic outcome.

Current evaluations in ophthalmology, while noting issues of factual omission or nuance, have not systematically quantified this trade-off using standardized, multidimensional reliability instruments (eg, DISCERN and Ensuring Quality Information for Patients [EQIP]) alongside rigorous readability metrics [4,12,13].

Crucially, the performance landscape of state-of-the-art LLMs remains unmapped in specialized clinical domains such as AMD. Existing multimodel comparisons are either generic or limited in scope, leaving a significant gap in understanding how newer, advanced models (eg, Grok 4, Claude-Sonnet 4.5, and DeepSeek-v3.2) perform relative to each other [14]. Furthermore, assessments conducted under a "zero-shot"–prompting scenario, which best simulates a naive patient's initial and unoptimized query, are essential to establish a realistic performance baseline but are seldom the focus [15,16].

Therefore, to move from generic caution toward actionable evidence, this study aims to (1) conduct a systematic, head-to-head evaluation of 6 leading LLMs on a curated set of AMD patient–facing prompts; (2) simultaneously quantify output quality using 4 established reliability tools (DISCERN, EQIP, Global Quality Scale [GQS], and Journal of the American Medical Association [JAMA] benchmark criteria) and 6 readability formulas; and (3) explicitly analyze the interplay—or trade-off—between reliability and readability under a minimalist, real-world-query simulation. By establishing this comprehensive performance atlas, we provide the empirical foundation necessary for the informed selection, targeted optimization, and safe, human-supervised integration of LLMs into ophthalmic patient care.

Methods

Prompt Development and Selection

A set of 30 English-language prompts on AMD was formulated through a multistep process (Textbox 1). First, an analysis of global Google Trends data from October 10, 2020, to October 10, 2025, was conducted based on the MeSH term "Age-Related Macular Degeneration" to identify frequently used patient search queries. This yielded 25 high-frequency search phrases. Second, 8 clinically focused prompts were extracted from the "Evidence-Based Guidelines for Diagnosis and Treatment of Age-Related Macular Degeneration in China (2023)" [17]. For these Chinese guideline–derived prompts, the initial English translation was performed by ZL immediately after extraction. The translated prompts were then reviewed and validated by XM for semantic equivalence, ophthalmic terminology, and consistency with English clinical expression. Subsequently, 10 topic prompts were extracted from the 2025 American Academy of Ophthalmology "Age-Related Macular Degeneration Preferred Practice Pattern" [18]. Finally, from these 43 initial prompts, irrelevant or duplicate entries were removed, resulting in 30 unique English-language prompts (Textbox 1). These finalized English-language prompts were entered verbatim into the 6 evaluated LLMs without modification, and the responses were collected for further analysis. The final sample size of 30 prompts was selected a priori to provide a representative cross-section of common public-search, guideline-derived, and clinically relevant AMD information needs while preserving the feasibility of manual-blinded evaluation by ophthalmologist raters.

XSL•FO
RenderX

Textbox 1. Curated prompt set for evaluating large language models in the education of patients with age-related macular degeneration (n=30).

Google Trends data of the 25 most significant keywords queried globally for age-related macular degeneration between 2020 and 2025:

1. macular degeneration icd 10
2. neovascular age-related macular degeneration
3. neovascular
4. exudative age-related macular degeneration
5. nonexudative age-related macular degeneration
6. age-related macular degeneration treatment
7. macular degeneration treatment
8. what is macular degeneration
9. age-related macular degeneration
10. exudative macular degeneration icd 10
11. nonexudative age-related macular degeneration icd 10
12. choroidal neovascularization
13. retinopathy
14. age-related macular degeneration symptoms

Evidence-based guidelines for diagnosis and treatment of age-related macular degeneration in China (2023):

15. What is the preferred diagnostic modality for neovascular AMD?
16. Should nutritional supplements be recommended for patients with early to intermediate AMD?
17. How should patients with AMD who exhibit a suboptimal initial response to anti-VEGF therapy be managed?
18. How should persistent pigment epithelial detachment after anti-VEGF therapy in AMD patients be managed?
19. How should “nonexudative” macular neovascularization (MNV) detected by OCTA in AMD patients be managed?
20. What is the appropriate follow-up protocol for patients with AMD?

Age-related macular degeneration preferred practice pattern (2025 American Academy of Ophthalmology):

21. AMD Definition and Classification
22. AMD Epidemiology and Risk Factors
23. AMD Diagnosis and Monitoring
24. Early and Intermediate AMD Management
25. Neovascular AMD Anti-VEGF Therapy
26. Geographic Atrophy in AMD
27. AMD Treatment Protocols
28. AMD Treatment Complications
29. AMD Patient Management
30. AMD Socioeconomic Considerations

Note on prompt curation: From the initial 25 Google Trends queries, 11 were excluded: “icd 10,” “exudative macular degeneration,” “exudative,” “nonexudative,” “amd,” “dry macular degeneration,” “dry age-related macular degeneration,” “wet age-related macular degeneration,” “wet macular degeneration,” “neovascularization,” and “glaucoma.” From the 8 prompts extracted from the Chinese guideline, 2 were excluded: “How should anti-VEGF agents be selected for the treatment of neovascular AMD?” and “What is the optimal anti-VEGF treatment regimen for neovascular AMD?” All 10 topic prompts from the American Academy of Ophthalmology Preferred Practice Pattern were retained, resulting in the final set of 30 prompts.

LLMs and Query Process

Six publicly available, general-purpose conversational LLMs were evaluated: ChatGPT-5.1-auto (OpenAI; August 7, 2025), DeepSeek-V3.2-Exp, displayed in the public interface as DeepSeek-v3.2 (DeepSeek; September 25, 2025), Gemini-2.5-Flash-Thinking (Google; June 17, 2025), Grok 4 (xAI; July 9, 2025), Claude Sonnet 4.5 (Anthropic; September 29, 2025), and Qwen3-Max (Alibaba Cloud; September 24, 2025). These dates were used to document the public model versions or modes available during the data collection period and do not imply access to fixed back-end model-weight snapshots. These models were selected because they were broadly accessible during the study period, represented major international and Chinese AI developers, were available as identifiable model versions or modes, and could be evaluated

XSL•FO
RenderX

under the same zero-shot, prompt-only procedure. Dedicated retrieval-augmented answer engines designed primarily around live search and source ranking, such as Perplexity, were not included. However, this exclusion did not mean that all evaluated public web interfaces functioned as pure stand-alone base models. The study evaluated each model as encountered by a typical public user under default interface settings. During review of the raw outputs, ChatGPT-5.1-auto and Qwen3-Max displayed retrieval- or citation-related artifacts in at least some default interface responses, including source links or Urchin Tracking Module (UTM)–tracked links and bracketed web citations. These features were not manually activated, disabled, standardized, or selectively removed. Therefore, the results should be interpreted as a comparison of default public interface responses rather than a controlled comparison of nonretrieval stand-alone model capabilities. All queries were conducted between October 10 and November 25, 2025, through the official publicly accessible web interfaces of the 6 evaluated models. No API calls, automated scripts, browser extensions, plug-ins, or programmatic access methods were used. Each finalized English-language prompt was manually entered by the authors into each model interface, and the corresponding response was manually extracted and recorded for analysis. All Google Trends searches and LLM queries were conducted in private or incognito browsing mode after signing out of Google and other personal accounts. Browser cache and cookies were cleared before each session to minimize local browser session effects. All prompts and model outputs included in the analysis were in English. Each prompt was entered in a separate new session, without prior conversational history, additional context, custom instructions, user-specified system prompts, repeated prompt optimization, regeneration, or selective response replacement. Default public user interface settings were used. Accordingly, API-level generation parameters, including temperature, top-p, maximum token length, and frequency or presence penalties, were not displayed to or controllable by the investigators and were not manually set. A single response from each model for each prompt was collected for analysis.

Response Preprocessing and Blinding

Before scoring, all model responses were transferred from the original model-specific files into a standardized scoring template and assigned anonymized response codes. Model names, file names, interface labels, logos, time stamps, ordering information, and any explicit self-identifying boilerplate text indicating the model name or developer were manually removed or redacted before rater review. This redaction was limited strictly to model-identifying information and did not alter any substantive clinical content, wording, recommendations, references, uncertainty statements, or safety-related statements in the responses. However, URL-level tracking parameters embedded within reference links, including UTM parameters, were not systematically scrubbed before scoring because references were otherwise preserved to avoid altering attribution-related content. Therefore, although explicit model names, interface labels, and self-identifying boilerplate were removed, some reference URLs may have retained model-identifying tracking strings. The 2 ophthalmologist raters received only anonymized prompt response pairs and were not informed of the model source. When discrepancies occurred, a third ophthalmologist (CM) adjudicated the score using the same anonymized materials.

Outcome Measures

Reliability Assessment

Two board-certified ophthalmologists (ZL and X.M) with over 10 years of clinical experience independently evaluated the anonymized and preprocessed responses using 4 established tools while remaining blinded to the model sources. In case of disagreement between the 2 raters, a third ophthalmologist of equivalent qualification served as the final adjudicator.

DISCERN

DISCERN was used to assess the quality of information regarding “treatment choices” in patient education materials [19]. It consists of 16 items divided into 3 sections: reliability of information (items 1 - 8), specific quality of information on treatment choices (items 9 - 15), and an overall rating (item 16). Each item is scored from 1 to 5, with a total score range of 16 - 80. Higher scores indicate better overall quality. For this study, scores were defined as follows: 16 - 26: “very poor,” 27 - 38: “poor,” 39 - 50: “fair,” 51 - 62: “good,” and 63 - 80: “excellent.” [20]

Ensuring Quality Information for Patients

EQIP was used to assess the overall quality of health education materials regarding information sources, accuracy, comprehensibility, and presentation format [21]. It consists of 20 items. Each item is answered “Yes/No,” with “Yes” scoring 1 point and “No” scoring 0 points. The final score is the percentage of “Yes” items out of the total (ie, proportion of “Yes” × 100). Higher scores indicate better material quality [22].

Global Quality Scale

GQS is a single-item, 5-point Likert scale for subjective overall evaluation of health education materials: 1 point for “Very poor,” 2 for “Poor,” 3 for “Fair,” 4 for “Good,” and 5 for “Excellent.”

JAMA Benchmark Criteria

JAMA criteria focus on the standardization and transparency of online health information, including 4 items: authorship, attribution of sources and references, disclosure of conflicts of interest (or sponsorship or advertising), and currency. Each item is scored “Yes/No,” with “Yes” scoring 1 point and “No” scoring 0 points, for a total score of 0 - 4. Higher scores indicate better performance in information transparency and standardization [23]. In this study, the JAMA benchmark was applied uniformly across all model outputs as a structured proxy for visible transparency and verifiability features within the response text, rather than as a direct measure of factual accuracy, clinical safety, true human authorship, or actual financial conflicts of interest. Because citation display may be an interface-level feature rather than an intrinsic property of the underlying model, JAMA benchmark scores in this study should be interpreted as visible transparency under default public interface conditions.

XSL•FO
RenderX

Hallucination Assessment Scope

For transparency, hallucination was operationally defined as fabricated clinical facts, guideline-inconsistent recommendations, unsupported certainty regarding diagnosis or treatment, or nonverifiable references presented as evidence. However, hallucination was not prespecified as a stand-alone analytic end point in this study. During clinical evaluation, raters assessed the informational reliability, transparency indicators, overall quality, and readability of model responses using DISCERN, EQIP, GQS, JAMA benchmark criteria, and readability formulas. Although unsupported or misleading content could influence these quality scores, the raters did not perform claim-level fact checking, assign binary hallucination labels, or record model-level hallucination frequencies. Therefore, hallucination frequency was not reported as an independent outcome.

Readability Assessment

Because all prompts and model outputs analyzed in this study were in English, English-language readability formulas were used. No Chinese-language prompts, untranslated Chinese-language prompts, or Chinese-language model outputs were included in the readability assessment.

Responses were analyzed using six standard readability formulas calculated via an online tool (readabilityformulas.com):

1. Automated Readability Index (ARI) [24]:

$$4.71(\text{CharactersWords})+0.5(\text{WordsSentences})-21.43$$

2. Flesch Reading Ease Score (FRES) [25]:

$$206.835-1.015(\text{WordsSentences})-84.6(\text{SyllablesWords})$$

3. Gunning Fog Index (GFI) [25]:

$$0.4[(\text{WordsSentences})+100(\text{Complex wordsWords})]$$

4. Flesch-Kincaid Grade Level (FKGL) [25]:

$$0.39(\text{WordsSentences})+11.8(\text{SyllablesWords})-15.59$$

5. Coleman-Liau Index (CL) [25]:

$$5.89(\text{CharactersWords})-0.3(\text{SentencesWords})-15.8$$

6. Simple Measure of Gobbledygook (SMOG) [25]:

$$14.430\times\text{Polysyllables}\times 30\text{sentences}+3.1291$$

The readability scores were compared and analyzed with the sixth-grade level of readability recommended by the American Medical Association and the National Institutes of Health [26]. This threshold was considered appropriate for the education of patients with AMD because it has been used in prior studies of AMD-specific and geriatric patient education materials, and because AMD predominantly affects older adults, for whom central visual impairment may further increase the practical burden of reading and processing complex written health information [5,27]. Following prior readability studies, including the referenced *PeerJ* article, the accepted readability level was defined as ≥80.0 for the FRES and ≤6 for the other 5 grade-level formulas. For interpretation, lower FRES values indicate more difficult reading, whereas higher ARI, GFI, FKGL, CL, and SMOG values indicate greater reading difficulty; therefore, FRES values below 80.0 or grade-level formula scores above 6 were interpreted as exceeding the recommended sixth-grade readability level.

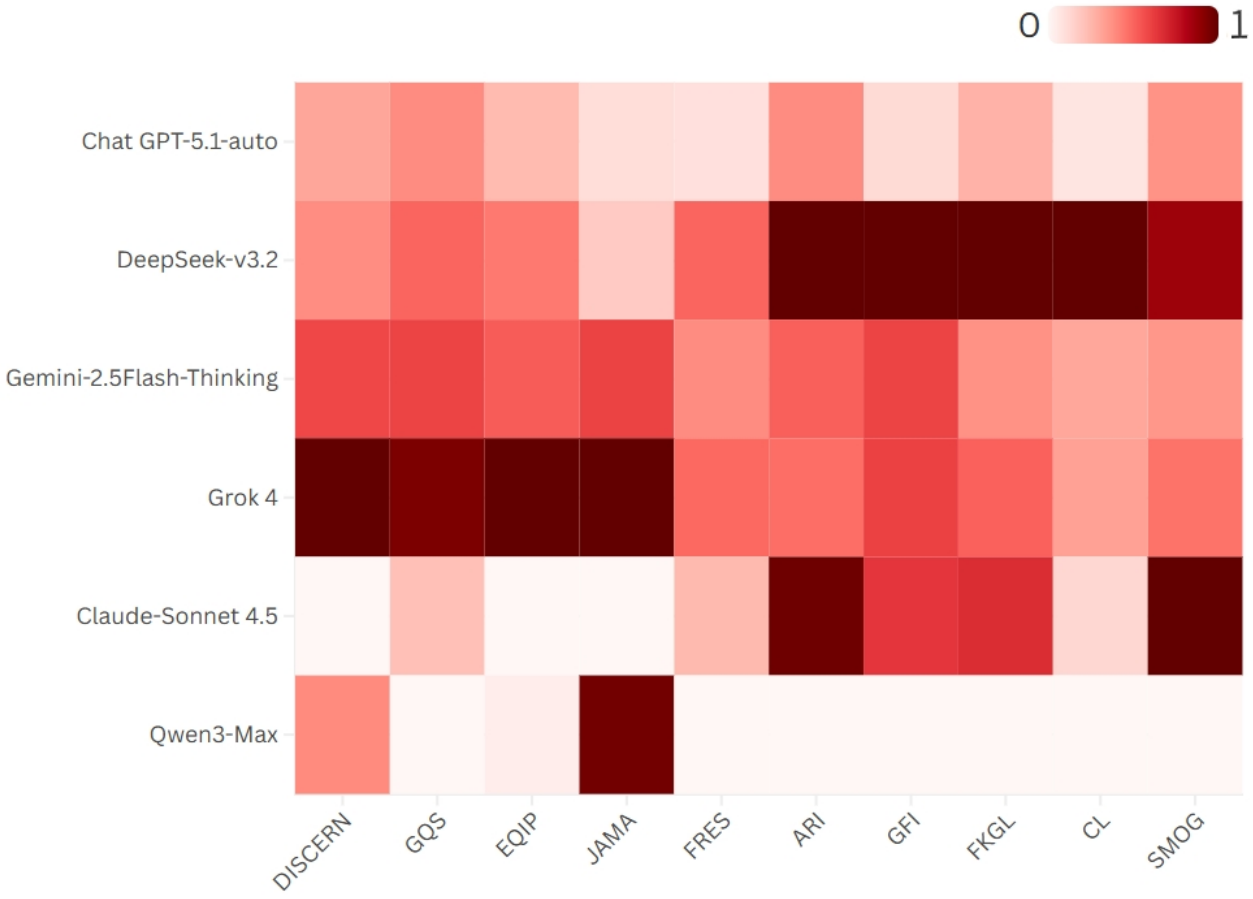
Statistical Analysis

Overview

All statistical analyses were performed using IBM SPSS Statistics (version 29.0; IBM Corp) and R (version 4.3.2; R Core Team). First, the mean and standard deviation for each of the 6 models across all 30 prompts were calculated. Interrater agreement between the 2 independent assessors on the 4 reliability measures (DISCERN, EQIP, GQS, and JAMA benchmark criteria) was calculated using Cohen κ. Cohen κ values and corresponding 95% CIs were calculated from the paired preadjudication ratings of the 2 independent assessors. Agreement was categorized as follows: κ≤0, no agreement; 0.01 - 0.20, slight; 0.21 - 0.40, fair; 0.41 - 0.60, moderate; 0.61 - 0.80, substantial; and 0.81 - 1.00, almost perfect agreement.

Reliability Analysis

Cohen κ was used to assess interrater agreement for the 4 reliability tools. Descriptive statistics (mean, SD) were calculated for each model across all 30 prompts for each measure. The Friedman test was used to examine overall differences among the 6 models for each measure, followed by post hoc pairwise comparisons with Holm-Bonferroni adjustment for multiple comparisons when significant. A P value of <.05 was set as the threshold for statistical significance. Composite reliability and readability z scores were calculated as described in the Statistical Analysis subsection and were used to generate the composite visualization.



Readability Analysis

Readability scores were calculated for each model's responses using the established readability metrics. Given the repeated-measures design, in which each of the 30 standardized AMD prompts was answered by all 6 models, the Friedman test was used to compare differences in readability scores among the 6 models. When the overall Friedman test was significant, post hoc pairwise comparisons were performed with Holm-Bonferroni adjustment. To assess whether the generated text met the sixth-grade reading level, the Wilcoxon signed-rank test was used to compare readability scores against the standardized sixth-grade threshold. P values were calculated for all tests, with P<.05 considered statistically significant.

Regarding Figure 1, average scores for each model were normalized by indicator using minimum-maximum normalization, resulting in scores ranging from 0 to 1.

XSL•FO
RenderX

Figure 1. Normalized performance heatmap of 6 large language models across reliability (DISCERN, EQIP, GQS, and JAMA benchmark criteria) and readability (ARI, FRES, GFI, FKGL, CL, and SMOG) metrics. Darker shades indicate better relative performance per metric (columns normalized independently). ARI: Automated Readability Index; CL: Coleman-Liau Index; EQIP: Ensuring Quality Information for Patients; FKGL: Flesch-Kincaid Grade Level; FRES: Flesch Reading Ease Score; GFI: Gunning Fog Index; GQS: Global Quality Scale; JAMA: Journal of the American Medical Association benchmark criteria; SMOG: Simple Measure of Gobbledygook.

For "higher-is-better" indicators, the following equation was used:

$$S_{m,k} = \frac{\bar{x}_{m,k} - \min_k}{\max_k - \min_k}$$

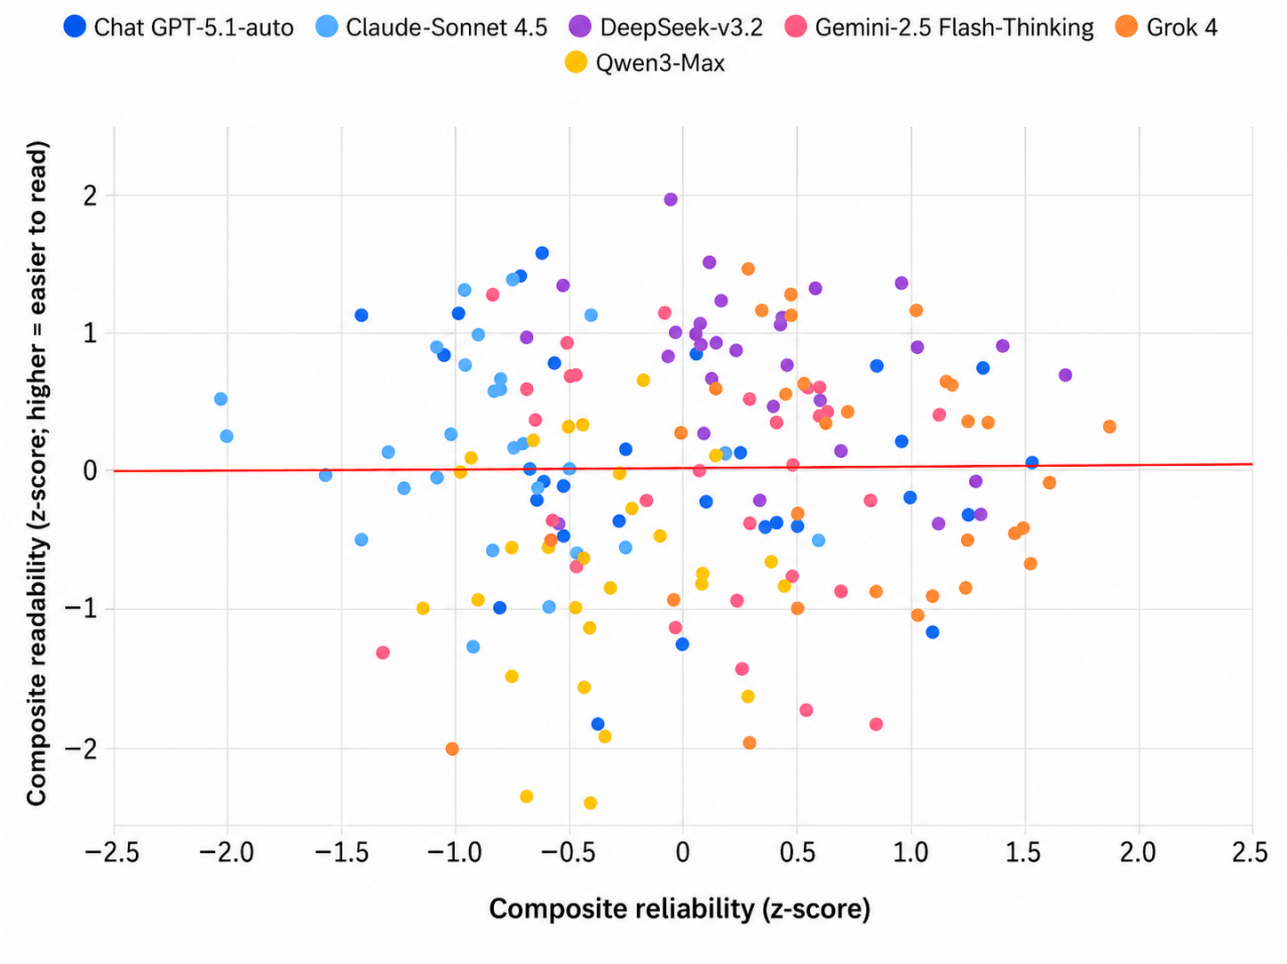
For "lower-is-better" readability grade-level indicators, the following equation was used:

$$S_{m,k} = \frac{\max_k - \bar{x}_{m,k}}{\max_k - \min_k}$$

Regarding Figure 2, all 180 observations were Z-standardized:

$$Z_{i,k} = \frac{x_{i,k} - \mu_k}{\sigma_k}$$

For "lower-is-better" readability grade-level indicators, the sign was inverted:



$$Z_{i,k*} = -Z_{i,k}$$

Composite reliability and readability were calculated as unweighted averages:

$$R_i = \frac{1}{4}\sum Z_{i,k*},\ Q_i = \frac{1}{6}\sum Z_{i,k*}$$

XSL•FO
RenderX

Figure 2. Scatterplot of composite reliability *z* scores versus composite readability *z* scores for each model response (N=180). The red line indicates the overall trend across all responses.

Regarding Figure 3, the Friedman test was used to compare overall differences among the 6 models for each indicator:

$$XF2=12nk(k+1)\sum Rj2-3n(k+1)$$

If significant, pairwise comparisons were conducted. The standardized test statistic was:

$$Z=|ra^{-}-rb^{-}|k(k+1)6n$$

The Holm-Bonferroni correction was applied. The heatmap displays −log10 (pHolm).

Ethical Considerations

This study did not involve human participants, direct interaction with individuals, identifiable private information, or individual-level patient data. The analysis was based on publicly available search-trend information, published clinical guidelines and recommendations, and textual responses generated by publicly accessible LLMs. Therefore, formal ethics review was not required, informed consent was not applicable, and no ethics approval number was assigned. No personal identifiers, private user information, or patient records were collected or analyzed. No compensation was provided because no participants were recruited. The manuscript and supplementary materials do not contain images, screenshots, or other content that could identify individual participants or users.

Results

Overview

A total of 180 responses (30 prompts × 6 models) were analyzed. Interrater agreement for all 4 reliability instruments was substantial to almost perfect, with κ values of 0.72 for DISCERN (95% CI 0.635 - 0.802), 0.80 for EQIP (95% CI 0.717 - 0.875), 0.92 for GQS (95% CI 0.864 - 0.959), and 0.97 for JAMA benchmark criteria (95% CI 0.942 - 0.988). These findings indicated substantial to almost perfect preadjudication agreement between the 2 independent ophthalmologist assessors (ZL and XM); all scoring discrepancies were subsequently resolved by a third ophthalmologist (CM) of equivalent qualification, who served as the final adjudicator using the same anonymized materials.

Reliability Scores

Substantial between-model variation was observed across all reliability-related metrics. As shown in Table 1, Grok 4 achieved the highest mean DISCERN score (mean 46.40, SD 7.43), followed by DeepSeek-v3.2 (mean 43.33, SD 8.20). A similar pattern was observed for EQIP, where Grok 4 (mean 74.33, SD 9.07) and DeepSeek-v3.2 (mean 71.50, SD 9.11) outperformed the remaining models. For the JAMA benchmark criteria, Grok 4 generated the highest mean score (mean 1.97, SD 0.67), but Qwen3-Max showed a similarly high JAMA score (mean 1.90, SD 0.40), indicating comparatively strong visible transparency despite lower scores on DISCERN, GQS, and EQIP. Claude-Sonnet 4.5 showed the lowest overall reliability-related profile across the evaluated metrics, whereas Qwen3-Max showed lower non-JAMA reliability scores but relatively strong JAMA benchmark performance. These distributional differences are illustrated by the violin plots in Figure 4A-D, which present DISCERN, EQIP, GQS, and JAMA benchmark score distributions, respectively.

Table . Reliability scores (N=30 prompts).

	DISCERN	GQS[a]	EQIP[b]	JAMA[c]

Readability Scores

Readability assessments demonstrated that all models produced text considerably exceeding the recommended sixth-grade reading level (Table 2). This interpretation was based on the predefined cutoffs: all mean FRES values were below the accepted threshold of 80.0, and all mean grade-level formula scores were above 6, indicating text harder than the recommended sixth-grade level.

Table . Readability metrics (N=30 prompts).

	ARI[a]	FRES[b]	GFI[c]	FKGL[d]	CL[e]	SMOG[f]
ChatGPT-5.1-auto, mean (SD)	13.16 (3.95)	27.50 (14.29)	14.87 (3.25)	12.47 (3.49)	15.20 (2.62)	10.49 (3.24)
DeepSeek-v3.2, mean (SD)	11.90 (2.14)	48.23 (9.16)	12.26 (1.81)	9.95 (1.87)	11.91 (1.75)	9.98 (1.50)
Gemini-2.5 Flash-Thinking, mean (SD)	14.67 (3.20)	32.60 (13.78)	13.62 (2.84)	13.34 (2.85)	14.59 (1.85)	12.07 (2.38)
Grok 4, mean (SD)	14.89 (3.38)	35.17 (17.21)	13.59 (2.37)	12.61 (3.28)	14.53 (2.61)	11.63 (2.45)

[a]ARI: Automated Readability Index.

[b]FRES: Flesch Reading Ease Score.

[c]GFI: Gunning Fog Index.

[d]FKGL: Flesch-Kincaid Grade Level.

[e]CL: Coleman-Liau Index.

[f]SMOG: Simple Measure of Gobbledygook.

DeepSeek-v3.2 showed the most favorable overall readability profile, yielding the highest FRES score (mean 48.23, SD 9.16) and the lowest scores for ARI (mean 11.90, SD 2.14), GFI (mean 12.26, SD 1.81), FKGL (mean 9.95, SD 1.87), and CL (mean 11.91, SD 1.75). However, Claude-Sonnet 4.5 achieved the lowest SMOG score (mean 9.40, SD 1.59), followed by DeepSeek-v3.2 (mean 9.98, SD 1.50). In contrast, Gemini-2.5 Flash-Thinking, Grok 4, and Qwen3-Max produced text requiring substantially higher reading proficiency, with Qwen3-Max reaching the highest FKGL (mean 15.37, SD 2.85) and SMOG (mean 13.57, SD 2.49) levels. Violin plots in Figure 5 further demonstrate clear intermodel divergence in readability distributions. Wilcoxon signed-rank tests comparing readability scores with the prespecified sixth-grade thresholds confirmed that none of the 6 models met the recommended readability level. For ARI, GFI, FKGL, CL, and SMOG, values were significantly above the threshold of 6.0 across all models, whereas FRES values were significantly below the threshold of 80.0.

Integrated Performance Visualization

After standardization, the cross-metric performance heatmap (Figure 1) revealed distinct model profiles. Grok 4 performed strongly across reliability-related metrics, particularly DISCERN, EQIP, and JAMA benchmark criteria, but this reliability advantage was not accompanied by favorable readability. Its responses showed mixed and generally less favorable readability than those of DeepSeek-v3.2. DeepSeek-v3.2 showed the most balanced performance profile, combining comparatively strong reliability with the most favorable overall readability. Consistent with Table 2, the composite *z* score scatterplots (Figure 2) showed that Grok 4 responses were distributed toward the high-reliability side but extended substantially into lower-readability regions, whereas DeepSeek-v3.2 occupied the more favorable reliability-readability region. Other models showed less favorable profiles across either reliability or readability dimensions.

Overall Between-Model Differences

Friedman tests confirmed significant between-model differences across all reliability and readability metrics (χ^2_5 range, 43.859 - 93.887; Kendall W range, 0.292 - 0.626; all P<.001) (Table 3). Reliability indices showed the strongest effect sizes, particularly for GQS (χ^2_5=93.887; W=0.626) and EQIP (χ^2_5=82.132; W=0.548). Readability metrics also demonstrated robust intermodel variability, with the largest differences seen in SMOG (χ^2_5=73.105; W=0.487) and FKGL (χ^2_5=70.367; W=0.469).

Table . Overall between-model differences (Friedman test; within-prompt paired, N=30; k=6).

	Friedman χ^2 (*df*)	Kendall W	*P* value (raw)	*P* value (Holm)
DISCERN	69.845 (5)	0.466	<.001	<.001

Pairwise Comparisons

Holm-adjusted post hoc pairwise comparisons for reliability metrics are reported in Table 4, whereas corresponding pairwise comparisons for readability metrics are reported in Table 5. For reliability metrics, Grok 4 significantly outperformed Claude-Sonnet 4.5 across all 4 reliability-related metrics and outperformed Qwen3-Max on DISCERN, GQS, and EQIP but not on JAMA benchmark criteria. DeepSeek-v3.2 also showed significantly higher EQIP scores than several comparator models. For readability metrics, DeepSeek-v3.2 generated significantly easier-to-read responses than Gemini-2.5 Flash-Thinking, Grok 4, and Qwen3-Max across multiple readability indices, including ARI, FRES, FKGL, CL, and SMOG. These pairwise differences are visualized in Figure 3A for reliability metrics and Figure 3B for readability metrics. The corresponding Wilcoxon signed-rank statistics and exact 2-sided *P* values are reported in Table 6.

[a]For ARI, GFI, FKGL, CL, and SMOG, the sixth-grade threshold was defined as ≤6; values above 6 indicate text harder than the recommended level. For FRES, the threshold was defined as ≥80; values below 80 indicate text harder than the recommended level. Exact 2-sided *P* values are reported. No zero differences occurred in these signed-rank comparisons; therefore, the full sample of 30 prompt-level observations was retained for each model-metric comparison.

Discussion

Principal Findings

In this comparative evaluation of 6 publicly accessible LLMs for the education of patients with AMD, we found substantial model-dependent differences in informational reliability, transparency indicators, overall quality, and readability. No model met the recommended sixth-grade readability benchmark under zero-shot, single-turn prompting conditions [26]. These findings suggest a persistent reliability-readability gap in current LLM-generated education materials of patients with AMD. This gap is clinically relevant because the education of patients with AMD requires information that is not only reliable and transparent but also understandable for older adults who may face visual and health literacy barriers.

Comparison With Prior Work

Building on prior studies reporting that AI-generated patient education materials often remain above-recommended readability levels despite apparent coherence and informativeness, our findings show that higher informational reliability does not necessarily correspond to better readability [4,28]. This pattern is substantiated by the distinct model profiles shown in Figures 1, 4A-D, and 5A-F, and Tables 1 and 2. This divergence appears rooted in underlying design philosophies. Grok 4, which achieved the highest mean scores in DISCERN (mean 46.40, SD 7.43) and EQIP (mean 74.33, SD 9.07) (Table 1), concurrently produced text with among the highest grade–level indices (eg, ARI: mean 14.89, SD 3.38) (Table 2). In Figure 2, Grok 4 was positioned toward the high-reliability side but was also dispersed into lower-readability regions, consistent with a “precise expert” archetype: informationally robust yet linguistically dense. In contrast, DeepSeek-v3.2 occupied a unique and practically significant niche. It attained near-top-tier reliability while consistently generating the most readable text (highest FRES: mean 48.23, SD 9.16; lowest FKGL: mean 9.95, SD 1.87) (Table 2), presenting a more balanced profile in the Figure 1 heatmap. This observation serves as a critical proof-of-concept: the reliability-readability trade-off is not an immutable law but rather a mitigable and measurable engineering challenge. The profound and consistent intermodel differences, confirmed by highly significant Friedman tests (Table 3; all $P<.001$) and detailed in the pairwise comparison heatmap (Figure 3), underscore that these performance characteristics are inherent to model architecture and training, not artifacts of query phrasing. The persistence of these performance gaps under our “zero-shot” prompting protocol is a key methodological insight. By forgoing system prompts or complex instructions to mimic a naive user’s interaction, as described in the LLMs and Query Process subsection of the Methods, we reveal the “out-of-the-box” capability landscape that patients actually face. The failure of all models to approach the readability target under these conditions indicates that intrinsic model propensity, not superficial user instruction, is the primary governor of output complexity. This finding challenges the notion that simple prompt engineering alone will suffice for clinical adoption and shifts the onus for improvement decisively onto model developers and tailored fine-tuning protocols. This reframes readability not as a downstream formatting issue but as a core design constraint that must be addressed at the model or fine-tuning level.

Clinical Implications and Future Directions

These findings have practical implications for clinician-supervised use of LLMs in the education of patients with AMD. Patients’ understanding of AMD causes,

XSL•FO
RenderX

pathophysiology, chronic progression, treatment options, and follow-up requirements can influence treatment expectations, adherence, timely care-seeking, and shared decision-making. Because LLM outputs may increasingly shape patients' knowledge before or between clinical visits, their reliability and readability have practical implications for the education of patients with AMD. However, incomplete, overly complex, or unreliable explanations may mislead patients or delay appropriate care. Therefore, evaluating the reliability and readability of AI-generated AMD education is directly relevant to treatment-related decision-making outcomes. Direct, unsupervised provision of current LLM outputs to patients with AMD risks disseminating information that is inaccurate, incomprehensible, or both. Therefore, a pragmatic, 3-stage pathway for translation is warranted. In the context of AMD, such misalignment may concretely translate into misunderstandings regarding anti-VEGF treatment expectations, disease chronicity, or the distinction between neovascular and atrophic pathways.

The initial step involves evidence-based model selection for clinical settings exploring AI-drafted materials. Our data provide clear guidance: if the priority is reliability for subsequent expert editing, Grok 4 may be a suitable starting point. If the goal is a better-balanced starting point for communication, DeepSeek-v3.2 may be considered, although human simplification and clinical review would still be required [29].

Selection alone, however, is insufficient. Future research should move from passive benchmarking toward active intervention. Our study design provides the ideal framework for this: the curated 30-prompt AMD set (Textbox 1) and the comprehensive baseline performance data (Tables 1 and 2) can be used to rigorously test specific interventions. These include advanced prompt engineering strategies, such as chain-of-thought prompting for simplification, or fine-tuning protocols explicitly designed to close the quantified "readability gap," for instance, by reducing the average FKGL of DeepSeek-v3.2 from 9.95 toward the target of 6, while vigilantly preserving reliability.

Ultimately, the most viable and safest near-term application is a synergistic human-AI workflow [30]. In this model, LLMs such as DeepSeek-v3.2 or Grok 4 act as powerful first-draft engines, significantly reducing clinician time spent on initial content creation [31]. This draft must then undergo mandatory review and literacy-sensitive simplification by a health care professional. This integrated workflow leverages AI's scalability for efficiency while retaining irreplaceable human clinical judgment for safety, accuracy, and ultimate patient comprehension.

Strengths and Limitations

Strengths

This study has several strengths. First, it provides a head-to-head comparison of 6 publicly accessible state-of-the-art conversational LLMs within a clinically specific ophthalmic context, rather than evaluating a single model or a general medical prompt set. Second, the 30-prompt benchmark was developed from both real-world patient search behavior and authoritative AMD clinical guidance, thereby improving the clinical relevance and patient-facing applicability of the evaluation. Third, the study jointly assessed informational reliability and linguistic readability using 4 established quality instruments and 6 readability formulas, allowing the reliability-readability gap to be quantified rather than described qualitatively. Fourth, all responses were independently evaluated by 2 senior ophthalmologists blinded to model identity, with adjudication of disagreements, strengthening the rigor and reproducibility of the scoring process. Finally, the zero-shot design reflects the initial, unoptimized interaction that a naïve patient may have with a publicly available LLM, providing a realistic baseline for future model selection, prompt optimization, and clinician-supervised deployment.

Limitations

This study has several limitations. First, this study evaluated 6 selected public web interface LLM responses and used a limited set of 30 AMD-related prompts. Therefore, the findings should not be generalized to all AMD-related patient information needs, retrieval-augmented answer engines, locally deployed open-source models, API-only systems, or medical-specialized models. This limitation was partly mitigated by selecting broadly accessible models from major international and Chinese developers and by deriving the prompt set from both real-world search behavior and authoritative AMD guidance.

Second, only 1 response was collected for each model-prompt pair under a zero-shot, single-turn design. Although this approach was intended to reflect the first answer a naïve patient might receive, it does not capture within-model stochastic variability, repeated regenerations, or multiturn patient-LLM interactions. Public web interfaces may also include hidden system prompts, interface-level settings, dynamic context handling, dynamic safety filters, and back-end updates that were not controllable by the investigators. Therefore, the findings should be interpreted as version- and interface-dependent snapshots rather than fixed estimates of model performance. Future studies should incorporate repeated regenerations, API-based controlled sampling where available, and multiturn dialogue designs to better quantify response variability, ecological validity, and reproducibility. An additional limitation concerns default interface-level retrieval behavior. Although dedicated retrieval-augmented answer engines were excluded, several raw outputs indicated that some evaluated public interfaces, particularly ChatGPT-5.1-auto and Qwen3-Max, displayed source links, tracking links, or bracketed web citations under default settings. This weakens any interpretation of the study as a comparison of strictly stand-alone model knowledge. Such interface-level retrieval or citation behavior may have influenced response breadth, apparent currency, attribution, and JAMA benchmark scores. Accordingly, our findings should be interpreted as default public interface performance snapshots rather than fixed estimates of base-model capability. Future studies should separately evaluate browsing-enabled and browsing-disabled modes, where available, and explicitly record whether web retrieval or citation display was enabled, reporting retrieval or citation display status for each model and, ideally, for each response. Although explicit model names, interface labels, and self-identifying boilerplate were removed before scoring, complete blinding cannot be guaranteed. Some

XSL•FO
RenderX

reference URLs retained in the scoring materials may have contained model-identifying tracking parameters, such as UTM tags, which could have compromised complete blinding for responses from models whose interfaces generated such links. In addition, different LLMs may have recognizable stylistic patterns, response structures, or residual boilerplate language. Therefore, residual rater unblinding remains possible despite anonymization and standardized scoring procedures.

Third, all prompts and model outputs analyzed in this study were in English, and the readability formulas used here are primarily validated for English-language text. Although Chinese guideline–derived prompts were translated and reviewed before model querying, the findings may not directly apply to Chinese-language or other non-English patient education settings. In addition, readability scores were calculated using a single online calculator, which may introduce calculator-specific variation despite consistent application across all outputs.

Fourth, the prompt set was not composed exclusively of layperson-style patient education prompts. Several prompts were derived from clinical guidelines or included specialized AMD-related terminology, including prompts related to diagnostic coding or optical coherence tomography angiography–based management of nonexudative macular neovascularization. These clinician-adjacent prompts may have induced more technical responses and contributed to the high reading-grade levels observed. Readability estimates for responses containing alphanumeric diagnostic codes or list-based *ICD-10* (*International Classification of Diseases, Tenth Revision*) outputs may be mechanically distorted because such content can affect syllable counts, word counts, and sentence segmentation. Consequently, the findings should be interpreted as reflecting a mixed AMD information-seeking scenario rather than a pure layperson FAQ setting.

Fifth, hallucination was not prespecified as an independent analytic end point. In this study, hallucination was operationally understood as fabricated clinical facts, guideline-inconsistent recommendations, unsupported certainty regarding diagnosis or treatment, or nonverifiable references presented as evidence. Although the clinical raters evaluated reliability, transparency indicators, overall quality, and readability using DISCERN, EQIP, GQS, and JAMA criteria, they did not formally record hallucination frequency, perform claim-level fact checking, or assign binary hallucination labels to each response. Therefore, the present findings should not be interpreted as a direct estimate of hallucination risk, guideline concordance, or clinical safety. This limitation is clinically important because hallucinated AMD-related information could mislead patients about disease prognosis, urgency of anti-VEGF therapy, monitoring intervals, nutritional supplementation, or the distinction between neovascular and nonexudative disease. Future studies should incorporate prespecified hallucination detection, claim-level verification against current clinical guidelines, interrater agreement for hallucination labels, and model-level hallucination frequency reporting. In addition, the JAMA benchmark was originally developed for online health information rather than conversational AI. Because unprompted LLMs do not have conventional human authorship or financial disclosure structures, low JAMA scores should be interpreted as reflecting limited visible transparency and verifiability within model outputs rather than as direct evidence of poor factual accuracy or clinical unsafety.

Conclusions

In this comparative evaluation of 6 publicly accessible LLMs, AMD-related patient-facing responses showed substantial model-dependent differences in informational reliability, transparency indicators, overall quality, and readability. No model met the recommended sixth-grade readability benchmark under zero-shot, single-turn prompting conditions, indicating that current LLM outputs remain insufficient as directly deployable education materials for patients with AMD. These findings support the need for clinician oversight, readability optimization, and further evaluation using repeated sampling, multiturn interactions, and claim-level accuracy assessment before LLM-generated AMD information is used in patient-facing settings.

Acknowledgments

The authors thank all members of the study team for their contributions to prompt development, response evaluation, and manuscript revision. In this study, publicly accessible large language models were used as the objects of evaluation; their responses to standardized prompts were assessed and scored by the investigators according to the prespecified evaluation framework. During manuscript revision, generative artificial intelligence (AI)–assisted tools were used only for language polishing, wording refinement, and organizational editing under full author supervision. Generative AI tools were not used to generate study data, perform statistical analyses, interpret the results, or create tables or figures. All intellectual content, study design, data interpretation, manuscript review, and final decisions were completed, critically verified, and approved by the authors.

Funding

This research was funded by financial support from the National Natural Science Foundation of China, awarded to XM, under grant 81271022.

Data Availability

The summarized evaluation data are provided in the main manuscript tables. The finalized prompt set, query and collection protocol, and representative raw model outputs are provided in Multimedia Appendix 1. Additional raw model outputs are available from the corresponding author on reasonable request.

Abstract

Background: Pneumonia is a common infectious disease, and antibiotic treatment in hospitalized patients must balance efficacy, safety, and resistance risk. However, antibiotic selection and dose adjustment still rely heavily on clinician experience. Although large language models (LLMs) are promising for clinical reasoning, their direct use for antibiotic selection and dose recommendation is limited by hallucinations and weak adherence to clinical constraints.

Objective: This study aimed to develop and externally validate a constrained LLM-based clinical decision support pipeline for antibiotic selection and dose recommendation in hospitalized patients with pneumonia.

Methods: We conducted a multicenter retrospective study using electronic health record narratives, antibiotic orders, and laboratory indicators of hepatic and renal function from 331 hospitalized patients with pneumonia from 2 hospitals in China. The development cohort included 233 patients, and the external validation cohort included 98 patients. The pipeline integrated dual-branch retrieval (similar-case vector retrieval plus guideline-based knowledge graph retrieval), clinician-defined rule constraints, and hybrid-context reasoning. DeepSeek-V3, GLM-4.6, and GPT-4o were evaluated using F_1-score and Jaccard accuracy.

Results: On the internal test set, the full pipeline using DeepSeek-V3 achieved the best performance, with an F_1-score of 0.8110 (95% CI 0.7371-0.8762) and Jaccard accuracy of 0.7624 (95% CI 0.6810-0.8386) for antibiotic selection and an F_1-score of 0.7538 (95% CI 0.6671-0.8329) and Jaccard accuracy of 0.7076 (95% CI 0.6145-0.7938) for joint antibiotic selection plus dosing recommendation. On the external validation set, performance remained high, with an F_1-score of 0.8605 (95% CI 0.7891-0.9252) and Jaccard accuracy of 0.8571 (95% CI 0.7857-0.9184) for antibiotic selection, and an F_1-score of 0.8503 (95% CI 0.7789-0.9150) and Jaccard accuracy of 0.8469 (95% CI 0.7755-0.9133) for antibiotic selection plus dosing recommendation. The system also provided traceable evidence and rule trigger information to support clinician review.

Conclusions: A constrained, retrieval-augmented LLM pipeline improved the consistency and interpretability of antibiotic selection and dose recommendation for hospitalized patients with pneumonia and provided preliminary evidence of cross-site generalizability.

Introduction

Pneumonia is a major infectious disease worldwide and remains a leading cause of morbidity and mortality. Accordingly, standardized diagnosis, treatment, and antimicrobial management are essential components of modern health care. In China, the burden of community-acquired and hospital-acquired pneumonia remains substantial, driven in part by rapid population aging and increasing numbers of immunosuppressed patients and patients with multimorbidity [1]. At the same time, the evolution of bacterial resistance continues to outpace the development and clinical availability of new antimicrobials, making inappropriate antibiotic use a major global public health challenge [2]. In real-world practice, inappropriate antimicrobial prescribing remains common and may compromise treatment efficacy, increase the risk of adverse drug events, accelerate the spread of antimicrobial resistance, and raise health care costs [3]. For hospitalized patients with pneumonia, antibiotic selection often requires early empirical treatment before definitive microbiological results become available. At the same time, patient-specific factors such as hepatic or renal impairment, older age, and multimorbidity can substantially influence antibiotic selection and dose recommendation. These challenges highlight the need for clinical decision support (CDS) tools that can assist individualized antimicrobial therapy while remaining aligned with guideline constraints.

Before the advent of large language models (LLMs), biomedical informatics had long explored CDS approaches. Early rule-based and knowledge-based expert systems [4,5] encoded medical knowledge as "if-then" rules with strong interpretability but relied heavily on manual maintenance and were difficult to update in response to evolving guidelines, emerging evidence, and complex clinical contexts. Subsequently, traditional natural language processing and machine learning methods were applied to tasks such as clinical text structuring, risk prediction, and adverse event detection [6-8]. Deep learning models, including recurrent neural networks and bidirectional encoder representations from transformers, further improved clinical text representations [9-13]. However, prediction or classification remained the dominant paradigm at this stage, often without providing an auditable chain of clinical reasoning [10,14,15]. In the area of medication recommendation and individualized prescribing, previous studies have mainly focused on medication information extraction, prescription review alerts, or medication prediction [6,16,17], with limited ability to jointly incorporate guideline constraints, patient-specific variation, and cross-modal clinical evidence. In addition, limited interpretability and traceability have remained major barriers to clinical adoption in high-risk medication decisions.

In recent years, advances in LLMs for medical context understanding and text generation have expanded biomedical informatics from "structuring and prediction" toward "clinical text reasoning and explainable generation" [18,19]. These models have shown promise in tasks such as medical record information extraction and clinical question answering [20-22]. For medication recommendation, LLMs can integrate illness descriptions, prior medications, and test results to generate candidate regimens and rationales [23-26]. With retrieval-augmented generation, external sources such as guideline statements, drug labels, and local clinical pathways can be incorporated into the reasoning process, thereby improving knowledge coverage and output consistency [27-29]. However, in high-risk settings such as antibiotic selection and dose recommendation, important safety challenges remain. Adherence to fine-grained constraints, including dose limits, contraindications, and hepatic or renal dose adjustment, is often unstable [26]. Model conclusions may also vary according to input phrasing and context organization [23], and hallucinations may produce potentially unsafe recommendations [30]. To support safe antimicrobial decision-making, LLM outputs should be grounded in traceable evidence, guided by explicit clinical constraints, and accompanied by reasoning that can be reviewed and verified by clinicians. These limitations highlight the need for constrained, traceable, and auditable LLM-based frameworks that can systematically incorporate external evidence and explicit clinical rules into the reasoning process.

Against this background, we developed and validated an LLM-based CDS pipeline for antibiotic selection and dose recommendation in hospitalized patients with pneumonia. Designed as an assistive tool for antimicrobial stewardship and medication review rather than a replacement for clinician judgment, the proposed framework is conceptually aligned with the information-gathering process of infectious disease consultation, in which clinicians integrate patient characteristics, laboratory findings, prior experience, and guideline recommendations to support empirical antimicrobial decisions. To support this process, the framework combines two key strategies to improve the safety and consistency of LLM-based recommendations: (1) a dual-branch retrieval mechanism that integrates similar-case vector retrieval with guideline-based knowledge graph retrieval to connect patient-specific information with external evidence and (2) clinician-defined rule constraints that explicitly encode dose adjustment, contraindications, and hepatic or renal function considerations. We further evaluated this framework on multicenter real-world data through internal testing and external validation, with comparisons across multiple LLMs (DeepSeek-V3, GLM-4.6 [Z.ai], and GPT-4o [OpenAI]). By generating recommendations together with traceable evidence and rule trigger information, the proposed system aimed to support rapid clinician verification and final decision-making while improving the interpretability, robustness, and clinical applicability of LLM-assisted antimicrobial management.

Methods

Study Design and Datasets

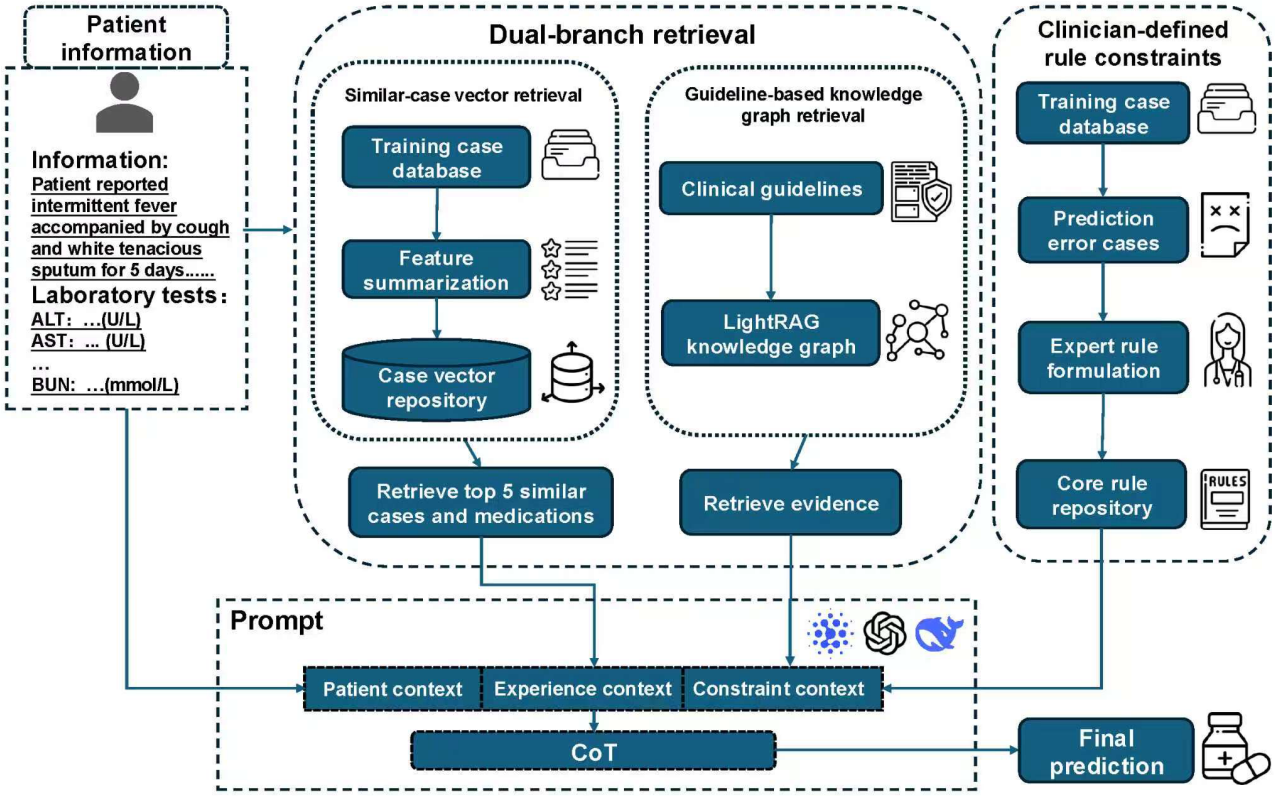
We conducted a multicenter retrospective study using electronic health record narratives, antibiotic orders (including prescription elements such as dose and route), and biochemical laboratory reports from hospitalized patients with pneumonia at 2 hospitals in China. Beijing Tsinghua Changgung Hospital served as the development cohort (n=233; January 2020-January 2024) and was split into training and internal test sets using a 7:3 ratio.

XSL•FO
RenderX

Beijing Friendship Hospital served as the external validation cohort (n=98; April 2019-September 2019).

Inclusion criteria were as follows: (1) an admission diagnosis of community-acquired or hospital-acquired pneumonia, (2) complete clinical records, and (3) at least one antibiotic order during hospitalization. The exclusion criterion was confirmed COVID-19 pneumonia.

We constructed the dataset for model input and evaluation using three data domains: (1) patient context, including admission narratives such as the chief concern, history of present illness, physical examination, and initial diagnosis; (2) medication orders, including antibiotic prescriptions and related elements such as drug name, dose, route, and dosing frequency where available; and (3) laboratory indicators, including 7 routinely used hepatic and renal function indicators closely related to antimicrobial safety (Table S1 in Multimedia Appendix 1), which were used to support dose recommendation and safety assessment.



For evaluation, raw antibiotic orders were not directly used as the gold standard but served as source information for reference label construction. Two experienced respiratory physicians reviewed the admission records and laboratory results to determine the final reference regimens. Therefore, model performance was evaluated against expert-adjudicated reference regimens rather than unreviewed raw electronic health record antibiotic orders.

Model

Overview

This study aimed to develop and validate a retrieval-augmented medication decision pipeline for antibiotic selection and dose recommendation. The pipeline takes admission notes and 7 hepatic and renal function indicators as inputs and consists of three core components: (1) a dual-branch retrieval framework, which integrates similar-case vector retrieval with guideline-based knowledge graph retrieval; (2) clinician-defined rule constraints, in which clinician-curated rules are injected as explicit constraints; and (3) a hybrid-context reasoning module, which integrates patient-specific information, retrieved evidence, and rule constraints to generate antibiotic and dose recommendations with traceable supporting evidence for clinician review. The systematic architecture and workflow of the framework are illustrated in Figure 1.

Figure 1. Systematic architecture of the proposed retrieval-augmented medication decision pipeline. ALT: alanine aminotransferase; AST: aspartate aminotransferase; BUN: blood urea nitrogen; CoT: chain of thought.

Dual-Branch Retrieval Framework

Similar-Case Vector Retrieval

To enable robust retrieval from noisy clinical narratives, we adopted a summarize-embed-retrieve workflow. For each historical case, an LLM first generated a structured clinical summary from the admission note and laboratory report covering (1) baseline characteristics, such as demographics, symptoms, and vital signs; (2) examinations and tests, such as imaging findings, infection-related markers, and hepatic and renal function, with laboratory abnormalities discretized into 4 levels (normal, mild, moderate, and severe); and (3) medical history, such as comorbidities, allergies, and prior medications. These summaries were then encoded into dense vectors using the pretrained embedding model bge-m3 to construct a case memory. For a new patient, cosine similarity was calculated

XSL•FO
RenderX

against the case memory, and the top 5 most similar cases together with their antibiotic regimens were retrieved as experience-based context for downstream reasoning. The top-5 setting was chosen empirically to balance similar-case coverage with contextual noise and prompt length constraints. The similar-case retrieval configuration and the prompt template used for similar-case summarization are provided in Multimedia Appendix 1.

Guideline-Based Knowledge Graph Retrieval

To incorporate evidence-based knowledge and explicit clinical constraints, we used authoritative clinical guidelines, including the Chinese Guidelines for the Diagnosis and Treatment of Community-Acquired Pneumonia in Adults (2016 edition) [31]. Using the LightRAG framework, we performed structured extraction of guideline text to construct a decision-oriented knowledge graph containing 1637 entities and 2077 semantic relations. The detailed parameters are provided in Multimedia Appendix 1.

The workflow included 3 steps. First, key medical concepts were extracted and normalized, including clinical symptoms, disease classification and severity, pathogen risk, drugs and administration routes, hepatic and renal function status, contraindications and precautions, and dose adjustment criteria. Second, core relationships among these entities were extracted to support constrained reasoning; relation types included "recommended_for," "contraindicated_in," "dose_adjustment_for," "not_recommended_with," "covers_pathogen," and other clinical-supporting relations. Third, the extracted information was organized into head-relation-tail triples, with guideline paragraphs or clauses retained as source metadata to enable evidence traceability.

During inference, the system retrieved knowledge snippets or subgraphs relevant to antibiotic selection, contraindications, and hepatic or renal dose adjustment based on the patient context and key laboratory indicators. These retrieved results were then provided to the downstream reasoning module as supporting evidence.

Clinician-Defined Rule Constraints

To improve the safety and clinical compliance of the recommendations, we incorporated clinician-defined rule constraints curated by physicians. These rules covered care setting and severity stratification, pathogen risk and coverage strategies, restrictions and contraindications for combination therapy, and key boundary conditions related to hepatic and renal function. The rules were injected into the structured prompt as explicit constraint context to guide antibiotic selection and dose recommendation. The representative rules are provided in Table S2 in Multimedia Appendix 1.

Hybrid-Context Reasoning

We integrated three sources of information into a unified hybrid context: (1) patient context, including admission narratives and key laboratory indicators; (2) experience context, including the top 5 similar cases and their antibiotic regimens; and (3) constraint context, including clinician-defined rule constraints and guideline or knowledge graph evidence retrieved using LightRAG.

During inference, the hybrid context was organized into a structured prompt and submitted to LightRAG in hybrid mode. All model inference was conducted in Chinese. The comprehensive prompt template, including the detailed instructions for context integration and reasoning steps, is provided in Multimedia Appendix 1. Guided by key entities and cues in the patient context, the system retrieved local entity-level details and global relational summaries related to antibiotic selection, contraindications, and hepatic or renal dose adjustment. These retrieved results were then combined with the patient context and rule constraints for downstream reasoning. On the basis of this integrated context, the model generated antibiotic and dose recommendations through a stepwise reasoning process. The final JSON array was extracted from each model response and parsed using Python's json.loads() function (Python Software Foundation). If parsing failed or the output was empty, generation was repeated up to 5 times. No manual correction was performed.

Model Implementation and Evaluation Metrics

We implemented the proposed pipeline using DeepSeek-V3, GLM-4.6, and GPT-4o. Detailed model implementation settings are provided in Multimedia Appendix 1. To examine the contribution of each module, we evaluated four categories of experimental settings: (1) a *base model* without retrieval augmentation or clinician-defined rule constraints; (2) *single-module variants*, in which only one component was added; (3) *dual-module variants*, in which 2 components were combined; and (4) the *full pipeline*, which integrated similar-case vector retrieval, guideline-based knowledge graph retrieval, and clinician-defined rule constraints.

The framework was evaluated on both the internal test set and the external validation cohort. Two tasks were assessed: *antibiotic selection* and *joint antibiotic selection plus dosing recommendation*. For the antibiotic selection task, only the standardized medication name was considered during matching. For the antibiotic selection plus dosing task, medication items were matched after standardizing drug name, dose, dosing frequency, and route of administration. Dose values were unit normalized when possible, and a 5% numeric tolerance was allowed to avoid penalizing minor unit conversion or formatting differences. Performance was measured using Jaccard accuracy, precision, recall, and F_1-score. All metrics were calculated at the patient level based on true-positive, false-positive, and false-negative medication items and then averaged across cases. We used patient-level bootstrap resampling with 10,000 iterations to calculate 95% CIs for the performance metrics. To further assess robustness and clinical applicability, we conducted subgroup analyses in high-risk populations, including older patients and patients with hepatic or renal impairment. The detailed subgroup classification criteria are provided in Table S3 in Multimedia Appendix 1. Cross-site generalizability was examined using the external validation cohort.

Ethical Considerations

This multicenter retrospective study was approved by the institutional ethics committees of Beijing Tsinghua Changgung Hospital (approval 23694-4-01) and Beijing Friendship Hospital (approval 2023-P2-031-01). The requirement for additional

XSL•FO
RenderX

informed consent was waived by the ethics committees because this study used retrospective, deidentified clinical data and involved no direct patient contact or intervention. All extracted records were deidentified before analysis, and direct identifiers such as names, medical record numbers, phone numbers, and addresses were removed. The analytic data were stored in a secure research environment accessible only to authorized study personnel. No participants received compensation because this was a retrospective secondary analysis. No identifiable patient information appears in the manuscript figures, tables, or supplementary materials.

Results

Patient Characteristics and Study Cohorts

A total of 331 hospitalized patients with pneumonia were included in this study divided into a development cohort (n=233, 70.4% from Beijing Tsinghua Changgung Hospital) and an external validation cohort (n=98, 29.6% from Beijing Friendship Hospital). Baseline demographic characteristics, hepatic or renal impairment, and antibiotic class distributions are shown in Table 1. Compared with the external validation cohort, the development cohort included older patients and a higher proportion of male patients and patients with hepatic or renal impairment. The internal test set was broadly comparable to the overall development cohort in demographic and clinical characteristics, particularly in age and the prevalence of hepatic or renal dysfunction, although some variation was observed in antibiotic class distributions. Quinolones were the most commonly used antibiotic class in the development cohort, internal test set, and external validation cohort.

Table . Baseline demographic and clinical characteristics of patients in the development set, internal test set, and external validation set[a].

Variable	Development set (n=233)	Internal test set (n=70)	External validation set (n=98)
Demographic characteristics			
Gender (man), n/N (%)	148/233 (63.5)	38/70 (54.3)	39/98 (39.8)
Age (y), median (IQR)	68.00 (59.00-75.00)	67.50 (60.00-74.00)	62.50 (54.25-73.00)
Advanced age (≥65 y), n/N (%)	149/233 (63.9)	47/70 (67.1)	43/98 (43.9)
Medical history, n/N (%)			
Hepatic or renal dysfunction	90/233 (38.6)	27/70 (38.6)	22/98 (22.4)
Antibiotic categories, n/N (%)			
Quinolones	147/368 (39.9)	52/98 (53.1)	79/110 (71.8)
β-lactamase inhibitor combinations	101/368 (27.4)	22/98 (22.4)	8/110 (7.3)
Antifungals	34/368 (9.2)	1/98 (1)	2/110 (1.8)
Cephalosporins	26/368 (7.1)	2/98 (2)	9/110 (8.2)
Carbapenems	15/368 (4.1)	4/98 (4.1)	7/110 (6.4)
Antivirals	13/368 (3.5)	4/98 (4.1)	0 (0)
Aminoglycosides	8/368 (2.2)	7/98 (7.1)	0 (0)
Tetracyclines	8/368 (2.2)	4/98 (4.1)	0 (0)
Sulfonamides	5/368 (1.4)	0 (0)	0 (0)
Glycopeptides and polypeptides	4/368 (1.1)	0 (0)	2/110 (1.8)
Macrolides	3/368 (0.8)	0 (0)	3/110 (2.7)
Oxazolidinones	4/368 (1.1)	2/98 (2)	0 (0)

[a]Percentages for antibiotic categories were calculated as the number of occurrences of each category divided by the total antibiotic category occurrences in each cohort (development cohort: n=368; internal test set: n=98; external validation cohort: n=110), reflecting prescription and category occurrence–level statistics.

Performance for Antibiotic Selection and Joint Antibiotic Selection Plus Dosing Recommendation

We compared different LLMs and integration strategies across 2 tasks: antibiotic selection and joint antibiotic selection plus dosing recommendation (Table 2). On the internal test set, the full pipeline with DeepSeek-V3 achieved the best performance among all evaluated LLM-based methods, with an F_1-score of 0.8110 (95% CI 0.7371-0.8762) and a Jaccard accuracy of 0.7624 (95% CI 0.6810-0.8386) for antibiotic selection and an F_1-score of 0.7538 (95% CI 0.6671-0.8329) and a Jaccard accuracy of 0.7076 (95% CI 0.6145-0.7938) for joint antibiotic selection plus dosing recommendation. The full pipeline with GLM-4.6 and GPT-4o also outperformed their corresponding base models but remained inferior to the DeepSeek-V3–based implementation.

Ablation Study

To assess the contribution of individual modules, we performed an ablation study using the full pipeline as the reference configuration. The configurations of all ablation variants are summarized in Table 4, and the corresponding performance results are presented in Table 5. In the antibiotic selection task, the full model achieved an F_1-score of 0.8110. Removing clinician-defined rule constraints reduced the F_1-score to 0.7429, removing similar-case vector retrieval reduced it to 0.7156, and removing guideline-based knowledge graph retrieval reduced it to 0.7843. A similar pattern was observed for joint antibiotic selection plus dosing recommendation, where the full model achieved an F_1-score of 0.7538 compared with 0.6474 after removing rule constraints, 0.5946 after removing vector

XSL•FO
RenderX

retrieval, and 0.7119 after removing guideline-based knowledge graph retrieval.

Performance declined further when multiple components were removed simultaneously. For example, the variant without guideline-based knowledge graph retrieval plus rule constraints achieved an F_1-score of 0.6253 (95% CI 0.5458-0.7012) for antibiotic selection and 0.5663 (95% CI 0.4829-0.6486) for joint antibiotic selection plus dosing recommendation, whereas the variant without vector retrieval plus rule constraints achieved F_1-scores of 0.6447 (95% CI 0.5589-0.7267) and 0.5641 (95% CI 0.4770-0.6529), respectively. The base model without retrieval augmentation or rule constraints showed the lowest overall performance.

Subgroup Analyses by Hepatic or Renal Function and Age

We further evaluated model robustness for the joint antibiotic selection plus dosing recommendation task in clinically important subgroups defined by hepatic or renal function and age using the internal test set (n=70; Figure 2). In the hepatic or renal function subgroups, the full pipeline using DeepSeek-V3 achieved mean F_1-scores of 0.7062 (95% CI 0.5823-0.8198) in patients with impairment and 0.7939 (95% CI 0.6798-0.8991) in those without impairment. In the age-based subgroups, the corresponding mean F_1-scores were 0.7291 (95% CI 0.6177-0.8326) in patients aged 65 years or older and 0.8043 (95% CI 0.6884-0.9058) in those younger than 65 years. Overall, the integration strategy maintained relatively stable performance across all subgroups, whereas the base LLM approach consistently underperformed across the board.

Figure 2. Subgroup analysis of model performance for the joint antibiotic selection plus dosing recommendation task on the internal test set by (A) hepatic and renal function and (B) age. Error bars represent 95% CIs.

Error Analysis and Expert Evaluation

To further assess recommendation safety and reasoning quality, respiratory physicians reviewed 45 error cases and a random sample of 50 generated recommendations. Error cases were categorized as safe but suboptimal or potentially unsafe. Of the 45 reviewed error cases, 43 (95.6%) were classified as safe but suboptimal recommendations, whereas only 2 (4.4%) were considered potentially unsafe. Both unsafe cases were related

XSL•FO
RenderX

to insufficient consideration of hepatic or renal function during antibiotic selection or dose recommendation.

For reasoning quality evaluation, physicians assessed 50 cases across 4 dimensions: evidence relevance, rule applicability, reasoning consistency, and hallucination risk. For evidence relevance, 88% (n=44) of the cases received the highest score, and 12% (n=6) of the cases received a partial relevance score, with no cases rated as irrelevant. All reviewed cases received acceptable ratings for rule applicability, reasoning consistency, and hallucination risk, with no cases judged to contain incorrect rule application, inconsistent reasoning, or clinically significant hallucinations.

Discussion

Principal Findings

In this multicenter retrospective study, we developed and validated a constrained LLM-based CDS pipeline for antibiotic selection and dose recommendation in hospitalized patients with pneumonia. The proposed framework, which integrates dual-branch retrieval, clinician-defined rule constraints, and hybrid-context reasoning, consistently outperformed the corresponding base LLMs across both the internal test set and the external validation cohort. It also maintained a relatively stable performance in clinically important high-risk subgroups, including older patients and patients with hepatic or renal impairment. Notably, the higher performance in the external validation cohort may be partly related to differences in patient characteristics and prescribing patterns between the 2 hospitals. The external validation cohort had a more concentrated antibiotic distribution and relatively simpler medication combinations, whereas the development cohort included a broader range of antibiotic categories and more complex regimens, which may have made the recommendation task more challenging. Together, these findings suggest that combining external evidence retrieval with explicit clinical constraints can improve the consistency and robustness and provide preliminary evidence of cross-site generalizability of LLM-assisted antimicrobial decision support.

The performance gains were attributable to the complementary contributions of multiple components rather than any single module. Ablation analyses showed consistent performance declines after removal of clinician-defined rule constraints, similar-case vector retrieval, or guideline-based knowledge graph retrieval, with larger reductions observed when multiple components were removed simultaneously (Table 5). These findings indicate that the 3 information sources served distinct but complementary functions: similar-case retrieval provided patient-aligned experience-based references; guideline-based knowledge graph retrieval contributed structured evidence-based knowledge; and clinician-defined rule constraints encoded explicit boundary conditions for dose adjustment, contraindications, and hepatic or renal function. In inpatient pneumonia management, where antibiotic decisions are both time sensitive and high risk, parametric LLM knowledge alone may be insufficient. By integrating patient-specific context, external evidence, and explicit clinical constraints within a unified reasoning framework, the proposed framework improved the consistency and safety of antibiotic recommendations. This design is also conceptually aligned with the early empirical decision-making process typically performed during infectious disease consultation while remaining intended as a clinician support tool rather than a replacement for specialist consultation or clinician judgment.

Comparison to Prior Work

Compared with traditional black-box prediction models, the proposed framework emphasizes a more interpretable, traceable, and auditable form of CDS. The system is not intended to replace clinician judgment but to function as an assistive tool for antimicrobial stewardship and medication review in hospitalized patients with pneumonia. Its practical value lies in its ability to rapidly integrate admission narratives, key hepatic and renal function indicators, similar-case experience, and guideline-based evidence to generate candidate recommendations for antibiotic selection and dose recommendation. At the same time, the system provides traceable evidence and rule trigger information, which may facilitate rapid clinician verification and improve the transparency of the decision-making process. Given that the external validation cohort differed from the development cohort in age, sex distribution, hepatic or renal impairment, and antibiotic class distribution, whereas the full pipeline still maintained strong performance, the findings further support the potential applicability of this approach in heterogeneous real-world settings.

This study has several limitations. First, the sample size was relatively limited, and the data were derived from only 2 hospitals. In particular, the external validation cohort included only 98 patients, and the distribution of antibiotic categories was imbalanced. This limits the strength of conclusions regarding cross-site generalizability. Therefore, further validation in larger, multi-regional, multilevel, and more category-balanced health care settings is needed. Second, although the reference labels were adjudicated by experienced physicians, the source information included real-world antibiotic orders, which are influenced by clinician experience, local prescribing preferences, and institutional antimicrobial stewardship policies. Accordingly, these labels should not be interpreted as an absolute gold standard, and such label-level heterogeneity may affect model generalizability. In addition, the drug library in the prompt was sorted by common clinical use, which may have introduced positional or frequency-related bias; future evaluations should test alternative drug list orderings. Third, stable structured body weight and BMI information was not available in the retrospective dataset. Consequently, the framework could not fully evaluate individualized weight-based dosing strategies for antimicrobial agents that require body weight adjustment. Future studies should incorporate structured body weight information to support more precise dose recommendation. Fourth, antibiotic options, resistance patterns, and clinical guidelines continue to evolve over time, so the knowledge graph, rule base, and retrieval resources will require ongoing maintenance and updating. In addition, the guideline-based knowledge graph was constructed from publicly available guidelines; therefore, we cannot fully exclude the possibility that some guideline

XSL•FO
RenderX

knowledge was already present in the evaluated LLMs' parametric memory. Future work should further evaluate the framework using recently updated guidelines or institution-specific antimicrobial stewardship pathways to better isolate the contribution of retrieval augmentation. Fifth, there was a temporal mismatch between the development and external validation cohorts. Although patients with confirmed COVID-19 pneumonia were excluded, residual differences in pneumonia etiology and antimicrobial prescribing behavior across time may still affect cross-cohort comparability. Finally, this study was retrospective and did not include prospective evaluation in real clinical workflows. Future work should assess the framework in human-in-the-loop practice settings and further examine its effects on prescribing quality, antimicrobial stewardship, and clinical outcomes.

Conclusions

In conclusion, we developed and externally validated a constrained LLM-based CDS pipeline for antibiotic selection and dose recommendation in hospitalized patients with pneumonia. By integrating dual-branch retrieval, clinician-defined rule constraints, and hybrid-context reasoning, the proposed framework improved the consistency and interpretability of LLM-assisted antimicrobial decision support and provided preliminary evidence of cross-site generalizability. The system also provided traceable evidence and rule trigger information to support clinician verification, highlighting its potential value for antimicrobial stewardship and medication review. Further prospective evaluation is needed to assess its performance and utility in real-world clinical workflows.

Abstract

Background: A persistent discrepancy exists between patient-reported information and physician documentation. While conversational agents have been developed to collect medical histories prior to consultations, existing evaluations have largely focused on diagnostic accuracy or user satisfaction rather than on the completeness and clinical relevance of the information collected. There remains a need to assess the extent to which clinically relevant information is captured through chatbot-based interviews, and to understand how model configurations and instructional strategies influence this coverage.

Objective: This study aimed to evaluate the extent to which a chatbot can obtain clinically useful patient history information, and to examine how prompt detail and internal reasoning influence information coverage during chatbot-based medical interviews.

Methods: We developed a medical history-taking chatbot using the Qwen3-14B-Instruct model and evaluated 4 configurations in a 2×2 factorial design: detailed and thinking mode, detailed and nonthinking mode, minimal and thinking mode, and minimal and nonthinking mode. These configurations were compared against a rule-based system baseline (choice mode) using 66 standardized primary care clinical cases, with simulated patients interacting with the chatbot according to predefined case scripts. Information coverage (%) was assessed using a checklist inspired by Objective Structured Clinical Examination (OSCE) frameworks. Three physicians independently evaluated transcript coverage, with interrater agreement assessed using full agreement rates and Fleiss κ. For the 4 LLM configurations, coverage was analyzed using 2-way repeated-measures ANOVA to examine the effects of prompt detail, internal reasoning, and their interaction. All 5 configurations, including the rule-based baseline, were additionally compared using 1-way repeated-measures ANOVA with post hoc 2-tailed paired *t* tests.

Results: Interrater agreement was substantial (Fleiss κ=0.75). Across all 66 simulated cases, information coverage differed significantly among configurations ($P<.001$), with the detailed prompt with thinking (detailed and thinking) mode achieving the highest mean coverage (72.3%, SD 14.3%), compared with moderate coverage in configurations using either thinking or detailed prompts alone (approximately 60%) and lower coverage in minimal nonthinking and rule-based configurations (approximately 51% - 54%). In the factorial analysis of the 4 LLM configurations, both prompt detail and internal reasoning were significantly associated with improved information coverage, with a significant interaction between prompt detail and internal reasoning interaction. Mode-related differences were most pronounced for past medical and family history domains. Symptom-level analyses revealed substantial variability, with higher coverage for symptoms associated with well-defined diagnostic frameworks and lower coverage for multisystem presentations.

Conclusions: In this controlled, simulated setting, the detailed prompt with a thinking mode achieved the highest overall checklist-based information coverage. The findings suggest that combining structured clinical prompts with internal reasoning may improve the completeness of chatbot-collected patient histories. Further research is needed to evaluate its impact on clinical documentation, workflow integration, and real-world usefulness.

Introduction

Information about medical history and personal perceptions provided by patients is essential for effective clinical care [1-4]. However, studies have consistently demonstrated a persistent discrepancy between what patients report and what physicians document during clinical encounters [5-8]. This discrepancy often arises from time constraints, selective note-taking, and different communication styles [8]. The absence of this information can potentially hinder accurate diagnoses, continuity of care, and patient-centered decision-making.

To bridge these informational gaps, various digital tools have been developed to collect patient data before consultation [9]. These systems aim to improve the completeness and efficiency of clinical documentation. Studies have shown that computerized history-taking enhances data quality and consistency compared to physician-recorded histories alone [10-13]. More recently, conversational agents or chatbots have emerged as promising tools in health care [14,15]. Evidence suggests that chatbots can capture clinically relevant information while maintaining patient engagement and satisfaction, offering continuous and automated data collection that has the potential to improve the completeness and accessibility of medical history-taking [16].

Despite the growing accessibility of these technologies, physicians' acceptance of AI tools remains limited due to concerns about transparency, interpretability, and accountability [17,18]. These concerns underscore the importance of evaluating AI-based tools using clinically interpretable outcome measures, rather than relying solely on technical performance metrics.

Existing preconsultation or history-taking tools are usually choice-based and structured [9,19,20]. Although these systems are interpretable and support standardized documentation, their predefined options may constrain the capture of individualized or nuanced patient information. These limitations highlight the need for more flexible and adaptive approaches that maintain interpretability while capturing richer patient narratives.

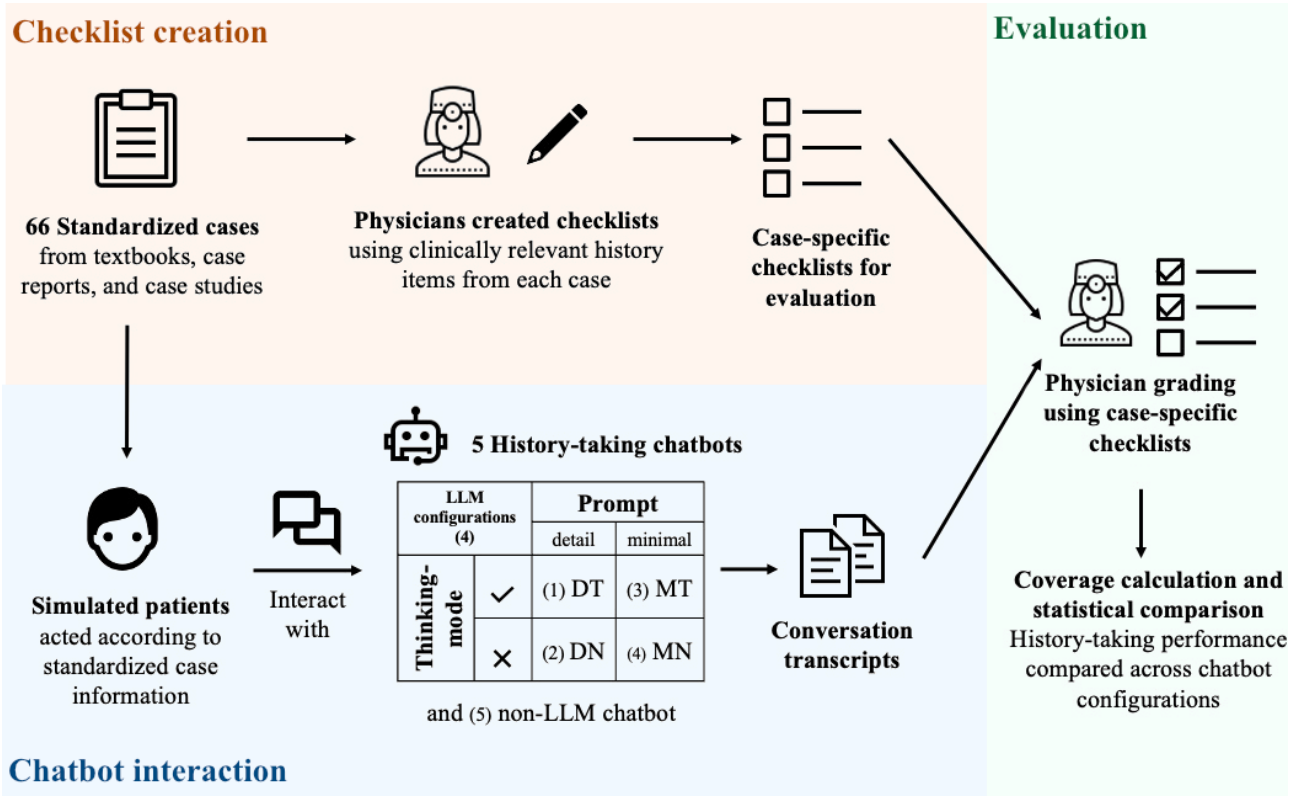
Recent advances in large language models (LLMs) have significantly enhanced their contextual understanding and multistep reasoning capabilities, facilitating more coherent and clinically relevant patient interactions. Modern LLMs can now use an internal reasoning process, frequently termed "thinking," to decompose complex clinical prompts into a sequence of intermediate logical steps before generating a final response. This deliberative process has been shown to improve performance on multifaceted tasks, leading to the generation of more structured and clinically aligned medical inquiries [21,22]. However, their outputs depend on prompt design, which is critical for guiding model behavior and reasoning structure [23-25]. Carefully constructing prompts to follow clinical reasoning frameworks can improve history coverage, mitigate premature diagnostic closure, and make the model's underlying logic more transparent.

Evaluations of AI-based conversational agents remain limited and have primarily focused on diagnostic accuracy, report quality, and user experience rather than on the completeness or clinical relevance of the information collected [26].

Detailed patient histories contribute to accurate diagnoses, treatment plans, and follow-ups by enabling physicians to systematically reason through symptom onset, progression, and contextual factors [27]. When AI-assisted systems gather more complete information, they provide richer data for clinical decision-making and are less likely to prematurely close or jump to conclusions without sufficient information. Evaluating AI tools based on detail and reasoning coverage provides additional clinically useful aspects beyond diagnosis or satisfaction alone.

To address this need, we adopted an evaluation inspired by the Objective Structured Clinical Examination (OSCE) framework, which is widely used and trusted by physicians to assess clinical competence [28]. OSCEs use checklist-based assessments to measure specific skills, ensuring interpretability and transparency. Our study applies a similar, checklist-driven approach, developed from representative clinical cases, to evaluate the coverage and completeness of AI-assisted history taking in a structured and clinically interpretable manner. This study aims (1) to assess the extent to which the chatbot can obtain clinically useful information, as measured by coverage of a case-based history-taking checklist, and (2) to determine the effects of internal reasoning and prompt detail on the chatbot's performance in achieving comprehensive history coverage.

Methods



Chatbot

Chatbot Creation

An overview of the study workflow is presented in Figure 1. The chatbot prototype was developed with the primary aim of collecting patient medical histories prior to physician encounters, to support subsequent clinical documentation and decision-making.

RenderX

Figure 1. Experimental flow: standardized clinical cases (n=66) were compiled from medical textbooks, case reports, and case studies. Physicians extracted clinically relevant history items from each case to create case-specific evaluation checklists. Simulated patients reviewed the case scenarios and interacted with 5 history-taking chatbots. The chatbot configurations included 4 large language model (LLM) conditions in a 2×2 factorial design: detailed prompt with thinking mode (DT), detailed prompt with nonthinking mode (DN), minimal prompt with thinking mode (MT), and minimal prompt with nonthinking mode (MN), as well as a non-LLM chatbot baseline. Conversation transcripts were independently evaluated by physicians using a case-specific checklist. Information coverage was calculated and statistically compared across chatbot configurations.

The chatbot prototype was developed in Python (Python Software Foundation) using the Qwen3-14B-Instruct model as the core LLM. Qwen3-14B is an open-source, transformer-based model that demonstrates competitive reasoning and instruction-following capabilities while remaining computationally efficient for local deployment [29]. The model integrates "thinking" and "nonthinking" modes within a single framework, allowing flexible switching to examine how reasoning effort affects the completeness and interpretability of conversational outputs.

The system was implemented using Python 3.13.3, Streamlit 1.44.1 (Snowflake Inc), LangChain Core 0.3.51 (LangChain Inc), and LangChain Ollama 0.3.1 (LangChain Inc), with the Ollama backend managing model inference for the Qwen3-14B. Inference was conducted locally via Ollama, which handled model loading and execution without relying on external API calls. The conversational workflow was orchestrated through LangChain, which managed modular prompt structures and response generation. The Streamlit framework was used to build the graphical user interface, enabling real-time interaction with simulated patients (SPs) and structured data logging for subsequent analysis. Model inference used the following hyperparameters: temperature=0.6, top_*P*=.95, top_k=20, repeat_penalty=1, and num_predict=128.

Types of Comparison

We evaluated 4 LLM conditions in a 2×2 factorial design and compared them with an existing choice-based, rule-driven chatbot as a non-LLM baseline.

The arms were defined as follows: detailed prompt with thinking mode (DT), detailed prompt with nonthinking mode (DN), minimal prompt with thinking mode (MT), and minimal prompt with nonthinking mode (MN); choice, the baseline condition represented a conventional rule-based chatbot using predefined options without generative language modeling.

Operational Definitions

Prompt Design (Detailed vs Minimal)

The chatbot was guided by a detailed prompt, adapted from standard medical history-taking frameworks described in clinical textbooks [3,30], instructing it to act as a virtual medical assistant conducting comprehensive patient interviews. The prompt instructed the chatbot to generate only 1 question per response, avoid repeated questions, and maintain a smooth and natural conversation flow. It specified a structured interview sequence beginning with clarification of the reason for the visit and the main symptom, followed by symptom characterization, including onset, location, quality, severity, duration, triggers, relieving factors, recurrence, and prior treatments when clinically applicable. The chatbot was then instructed to ask about associated symptoms (ASs) across organ systems, to consider multiple differential diagnoses, to ask follow-up

XSL•FO
RenderX

questions to support or rule out diagnostic possibilities, and to explore relevant external causes and risk factors. After sufficient information about the present illness had been gathered, the prompt instructed the chatbot to proceed in a fixed order to past medical history (PH), treatment and compliance, family history (FH), smoking and alcohol use, and conversation closure.

The minimal prompt instructed the chatbot to act as an AI-powered virtual medical assistant conducting a patient interview in English, generate 1 question per response, and to end the conversation when appropriate. It did not include explicit instructions regarding diagnostic reasoning, symptom characterization, AS, history-taking sequence, risk factors, or domain transitions.

The full text of both prompts is provided in Multimedia Appendix 1.

Internal Reasoning Configuration (Thinking vs Nonthinking)

In this study, "internal reasoning" refers to the generation of intermediate reasoning steps during response generation and was operationalized using the model's built-in "thinking mode." In this mode, complex, multistep deliberation occurred as intermediate reasoning steps before the model produced the final response, which were intended to guide response generation [29]. In practical terms, this configuration was expected to influence how the model selected follow-up questions and organized the next conversational step during the interview. The model's internal reasoning process was configured in one of the two ways: (1) in the thinking mode, the model internally generated intermediate reasoning steps, while the user interface displayed only the final questions or responses; or (2) in the nonthinking mode, in which internal reasoning was disabled via a prompt instruction (/no_think), and questions were generated directly without intermediate deliberation.

Baseline Description

Choice baseline is a commercially available symptom checker operating in Japan (Ubie, Inc) that guides users through fixed, multiple-choice questions based on branching clinical logic. This system is representative of current rule-based history-taking tools. Ubie was accessed in its English version through the publicly available web interface at the time of the study (which was operating in August 2025) [31].

End-of-Conversation Determination

Each LLM chatbot interaction was designed to terminate under specific conditions reflecting the intended prompt structure and conversation control strategy. The termination criteria differed across configurations to reflect the varying degrees of reasoning autonomy and prompt guidance.

Detailed Prompt (End When Sufficient Information Is Obtained)

For chatbots provided with detailed prompts, conversation termination was guided by an instruction to conclude the interview after sufficient information had been collected. Specifically, the prompt instructed the chatbot to politely inform the patient that all necessary information had been collected, thank them for their cooperation, let them know they would see the physician next, and ask about their expectations or any other questions they wanted to ask the physician. This instruction was intended to guide the chatbot to end the information-gathering phase after completing the structured history-taking sequence.

Minimal Prompt (End When Appropriate)

In this mode, the chatbot autonomously decided when sufficient information had been gathered. The conversation ended once the system determined that the patient's responses provided adequate information without explicit external cues.

Force-End Condition

Regardless of the configuration, all conversations were capped at 30 total messages (15 turns). This limit was selected to approximate a feasible preconsultation history-taking interaction while balancing information completeness with interaction burden for SPs. It also served to prevent excessively long or repetitive conversations. The same turn limit was applied to all LLM configurations to ensure comparability across modes. If this limit was reached before a natural conclusion, the conversation was automatically terminated, and the final message was recorded as the endpoint. The chatbot was not explicitly informed of this turn limit in the prompt; rather, the limit was implemented externally by the system.

This setup incorporated both prompt-guided and model-driven termination strategies to accommodate different levels of conversational control and ensure consistent stopping conditions across configurations.

Case and Checklist

Case Selection

Symptom selection was guided by 3 reference sources covering primary care curricula from different countries, which were chosen to capture common clinical presentations encountered in general practice: the Royal College of General Practitioners curriculum [32], the Japanese Primary Care curriculum [33], and the symptom list is from the textbook *Primary Care: A Case-Based Office Evaluation* [34].

Two distinct clinical cases were created or selected for each symptom, each corresponding to a different final diagnosis. This resulted in a total of 66 standardized cases. Case selection prioritized clinical variety while maintaining presentation patterns representative of outpatient encounters.

The cases were primarily adapted from 4 core textbooks emphasizing case-based reasoning in general and family medicine: *100 Cases in Clinical Medicine* [35], *Bates' Guide to Physical Examination and History Taking: Case Studies* [36], *The Patient History: An Evidence-Based Approach* [30], and *Case Files: Family Medicine* [37]

When suitable examples were insufficient in the selected textbooks, supplementary cases were adapted from journal case reports or published case studies, yielding a total of 9 cases [38-46]. All cases were reviewed by physicians to ensure that they contained the key elements of history-taking typically expected of a clinician when making a diagnosis. See Multimedia Appendix 1 for the complete list of 33 target symptoms and 2 representative diagnoses for each symptom.

XSL•FO
RenderX

Each case was further summarized into a structured checklist for the evaluation of chatbot outputs.

Checklist Creation

A structured checklist was developed to assess whether the chatbot asked clinically relevant questions for each SP case. The checklist was designed to capture the completeness and clinical appropriateness of the chatbot's biomedical inquiry, based on typical history-taking expectations in primary care.

Each checklist was organized into six domains as follows:

1. History of presenting complaint (HPC): onset, location, duration, character or quality, severity, progression, aggravating and relieving factors, treatments and their effectiveness, and any related trauma or accidents.
2. ASs: other symptoms mentioned in the case, whether present or specifically denied.
3. PH: existing conditions, comorbidities, and ongoing treatments.
4. FH: familial diseases or hereditary risks.
5. Social history (SH): history of smoking, alcohol consumption, lifestyle, and occupation
6. Other contextual information: additional relevant findings or case-specific details, including elaboration on AS when applicable.

Two physicians (a general practitioner and a family medicine resident) independently extracted checklist components from each reference case following a written protocol. The protocol specified that items were to be marked only if explicitly or implicitly mentioned in the case description, ensuring per case standardization rather than reliance on general expectations of history-taking. Discrepancies were reviewed, and final decisions were reached by consensus. An example of the created checklists is provided in Multimedia Appendix 1.

Settings

The study was conducted in a controlled simulation environment using 6 SPs.

Six Thai nonmedical SPs with advanced proficiency in conversational English participated in the simulations. Each SP was assigned a fixed subset of 11 clinical cases, and each assigned case was portrayed by the same SP across all chatbot configurations. This approach was used to maintain consistent case portrayal across configurations while distributing the workload among SPs. Before data collection, SPs received standardized written instructions and a short orientation session. They were instructed to read the assigned case scenarios carefully, respond strictly in accordance with the provided case information, and avoid adding information not included in the scenario. For questions not explicitly addressed in the case script, SPs were instructed to avoid unsupported improvisation and to use "unknown/not specified" as the default response. If an "unknown/not specified" response seemed clinically implausible or inconsistent with the assigned case scenario, SPs were instructed to consult the researcher before responding. In such cases, the researcher confirmed whether the SP should use the default "unknown/not specified" response or provide a brief answer consistent with the general clinical features of the assigned case, without adding new case-specific information.

To reduce order effects, the order of chatbot configurations was randomized using a balanced rotation scheme generated by the researcher. The rotation was designed so that each configuration appeared in different ordinal positions across cases. SPs were not informed of the chatbot configuration labels during the simulations.

All simulations were performed locally on a MacBook Pro (Apple M4 Max, 128 GB of unified memory) to ensure consistent performance across all chatbot configurations.

Each clinical case was run once for each chatbot configuration, resulting in one transcript per case-configuration pair.

Evaluation

Primary Evaluation

All chatbot-SP conversations were exported as structured text logs for independent physician evaluation. For the choice baseline, each fixed multiple-choice interaction was converted into a chronological text transcript containing the system questions, available response options, and the SP-selected option. The selected response was explicitly marked, and the resulting transcript was evaluated using the same case-specific checklist used for the LLM transcripts.

Before physician evaluation, each transcript was saved using a randomly assigned 6-digit transcript ID. The correspondence among the transcript ID, chatbot configuration, and case number was stored separately and not provided to physician raters. Therefore, physician raters were blinded to the LLM configuration labels during transcript review. However, the choice baseline could not be fully blinded because its fixed multiple-choice interaction format differed visibly from the open-ended LLM transcripts. This limitation was considered when interpreting comparisons involving the choice baseline.

Three physicians with prior OSCE evaluation experience independently reviewed the transcripts to assess coverage completeness, defined as the proportion of items on from the reference checklist that were appropriately elicited by the chatbot.

Each checklist item was marked as covered or not covered. When disagreements occurred, the final score for each item was determined by majority consensus (2 of the 3 raters). Coverage percentage for each case was then calculated as:

$$\text{Coverage (\%)} = \frac{\text{Number of covered items}}{\text{Total items in checklist}} \times 100$$

For each chatbot configuration, coverage percentages were macroaveraged across the 66 cases.

Subgroup Analysis by Question Type

Coverage was further examined by question type, corresponding to the checklist domains of HPC, ASs, PH, FH, and SH.

For the subgroup analysis by question type, each domain-specific analysis included only cases containing at least one checklist item in that domain. Therefore, the number of

XSL•FO
RenderX

cases differed across domains because not all reference cases included PH, FH, SH, or AS items. Domain-specific coverage was calculated as the number of covered items divided by the total number of checklist items within that domain for each eligible case. The mean and SD of these case-level coverage percentages were then calculated for each chatbot mode within each domain.

Symptom-Based Analysis

To explore variation across clinical presentations, coverage results were further summarized by symptom. We identified the highest and lowest macroaverage coverage percentages per symptom across all modes, and the largest advantage (Δ coverage) of the DT mode compared with the average of the other 3 LLM configurations (DN, MT, and MN).

This approach allowed the examination of symptom-level performance patterns and the identification of clinical scenarios in which the combination of detailed prompting and the thinking mode had the greatest impact.

Repetitive Questioning Analysis

To further characterize chatbot behavior beyond checklist coverage, 1 researcher conducted an exploratory descriptive review of repetitive questioning in the 4 open-ended LLM configurations. Repetitive questioning was defined as asking the same or substantially similar questions more than once despite a clear prior answer from the SP. Repeated questioning was not counted when the SP had not clearly answered the previous question, such as when a multipart question was only partially answered. This analysis was descriptive and exploratory.

Interrater Agreement

Agreement among the three physician evaluators on item-level coverage was assessed using 2 complementary metrics: (1) the proportion of items with full agreement across all raters and (2) Fleiss κ, calculated with the *statsmodels* library in Python (version 3.13.3).

Statistical Analysis

To formally examine the factorial effects among the 4 LLM configurations, a 2-way repeated-measures ANOVA was conducted with prompt detail and internal reasoning as within-case factors. The choice chatbot was excluded from this factorial analysis. To compare all evaluated configurations, including the choice baseline, a 1-way repeated-measures ANOVA was additionally conducted across the 5 configurations, followed by post hoc 2-tailed paired *t* tests with Bonferroni correction. Sphericity was assessed using the Mauchly test, and for repeated-measures ANOVA with more than 2 levels, Greenhouse–Geisser-corrected *P*-values were used when the sphericity assumption was violated. Effect sizes reported for the factorial 2-way repeated-measures ANOVA and the overall 1-way repeated-measures ANOVA were expressed as generalized eta squared (η^2_G), and pairwise effect sizes were reported as Hedge *g*.

All analyses were conducted in a Jupyter Notebook (Project Jupyter) using Python 3.13.3 and *Pingouin* package, with statistical significance set at $P<.05$.

Ethical Considerations

This study was considered exempt from formal ethics review under the Ethical Guidelines for Medical and Biological Research Involving Human Subjects in Japan [47] because it used standardized fictional or publicly available case scenarios that did not contain information relating to identifiable individuals and because it involved SPs who were nonmedical volunteers recruited outside clinical care settings and who role-played predefined cases without providing personal health information. All SPs were informed of the study's purpose and procedures before participating and agreed to participate voluntarily. Transcript data were labeled using randomly assigned study IDs, and no personally identifiable information was included in the evaluation files, figures, or supplementary materials. SPs received a small honorarium for their participation. No identifiable participant images or personal information is included in the manuscript or supplementary materials.

Results

Interrater Agreement

To assess the reliability of grading across evaluators, interrater agreement was calculated based on all checklist items. The evaluators achieved an overall full agreement rate of 81.90%, indicating a high level of consistency in their assessments. The Fleiss κ value was 0.753, representing substantial agreement according to the Landis and Koch Benchmark Scale [48]. These results suggest that the evaluation criteria were well-defined and consistently applied among raters.

Comparison of Coverage Across Chatbot Modes

Across all 66 SP cases, coverage rates varied substantially among the 5 chatbot configurations (Table 1). The DT mode achieved the highest mean coverage (72.3%, SD 14.3%), followed by the MT mode (60.5%, SD 15.0%), the DN mode (59.8%, SD 13.6%), the MN mode (54.0%, SD 15.3%), and the choice chatbot (51.1%, SD 13.3%).

To formally examine the factorial effects among the 4 LLM configurations, a 2-way repeated-measures ANOVA was conducted with prompt detail and internal reasoning as within-case factors. This analysis showed significant main effects of prompt detail ($F_{1, 65}=56.74$; $P<.001$; $\eta^2_G=0.085$) and internal reasoning ($F_{1, 65}=47.45$; $P<.001$; $\eta^2_G=0.096$). A significant interaction between prompt detail and internal reasoning was also observed ($F_{1, 65}=6.32$; $P=.01$; $\eta^2_G=0.011$), indicating that the effect of internal reasoning differed according to prompt detail. The DT configuration achieved the highest overall coverage among the 4 LLM configurations.

To compare all evaluated configurations, including the choice baseline, a 1-way repeated-measures ANOVA was additionally conducted across the 5 configurations. Sphericity was assessed using Mauchly test and was not violated. Therefore, uncorrected results are reported. This analysis revealed a significant effect

XSL•FO
RenderX

of chatbot mode on coverage ($F_{4, 260}$=36.88; P<.001; η^2_G=0.21), indicating that the completeness of gathered information differed significantly across chatbot modes.

Post hoc pairwise *t* tests with Bonferroni correction (Table 2) showed that the DT mode significantly outperformed all other configurations. Among the remaining configurations, DN and MT did not differ significantly (P>.99). However, both DN and MT achieved higher coverage than MN and choice. The MN and choice modes did not differ significantly (P>.99).

Overall, these findings demonstrate that both prompt detail and internal reasoning are associated with improved information completeness, with their combination in the DT mode producing the greatest coverage.

Table . Mean coverage percentages (SD) across 5 chatbot configurations in 66 simulated patient interviews. Each configuration represents a combination of prompt detail (detailed vs minimal) and internal reasoning (thinking vs nonthinking).

Chatbot mode	Prompt type	Reasoning mode	Average coverage (%), mean (SD)
DT[a]	Detailed	Thinking	72.3 (14.3)
DN[b]	Detailed	Nonthinking	59.8 (13.6)
MT[c]	Minimal	Thinking	60.5 (15.0)
MN[d]	Minimal	Nonthinking	54.0 (15.3)
Choice			51.1 (13.3)

[a]DT: detailed prompt with thinking mode.

[b]DN: detailed prompt with nonthinking mode.

[c]MT: minimal prompt with thinking mode.

[d]MN: minimal prompt with nonthinking mode.

Table . Post hoc pairwise *t* test comparisons between chatbot configurations using a repeated-measures design. Bonferroni correction was applied for multiple comparisons.

Comparison (A)	Comparison (B)	*2-tailed t* test (*df*)	*P* (Bonferroni-corrected)	Hedge *g*
DT[a]	DN[b]	7.20 (65)	<.001	0.88
DT	MT[c]	7.05 (65)	<.001	0.80
DT	MN[d]	9.40 (65)	<.001	1.22
DT	Choice	9.71 (65)	<.001	1.53
DN	MT	−0.39 (65)	>.99	−0.05
DN	MN	3.50 (65)	.008	0.40
DN	Choice	4.52 (65)	<.001	0.65
MT	MN	3.41 (65)	.01	0.42
MT	Choice	4.31 (65)	<.001	0.66
MN	Choice	1.48 (65)	>.99	0.21

[a]DT: detailed prompt with thinking mode.

[b]DN: detailed prompt with nonthinking mode.

[c]MT: minimal prompt with thinking mode.

[d]MN: minimal prompt with nonthinking mode.

Subgroup Analysis by Question Type

Coverage was further examined across 5 question types based on mean coverage: HPC, ASs, PH, FH, and SH (Table 3). The DT mode achieved the highest coverage in most question categories, including HPC, AS, FH, and SH; however, the choice baseline showed slightly higher coverage for PH. The DN and MT modes showed intermediate performance, while MN and the choice chatbot demonstrated the lowest coverage overall, except for the high PH coverage observed in the choice baseline.

Marked variation was observed across question types: HPC and AS achieved relatively high coverage in most modes, whereas PH, FH, and SH showed greater discrepancies among configurations.

A series of 1-way repeated-measures ANOVAs revealed significant differences in coverage among chatbot modes for all question types. Sphericity was assessed using Mauchly test, and Greenhouse-Geisser-corrected *P*-values were used when sphericity was violated. Significant differences were observed for all question types: HPC (n=66; $F_{4, 260}$=12.06; P<.001), AS (n=64; $F_{4, 252}$=7.69; P<.001), PH (n=57; $F_{4, 224}$=34.39; P<.001),

XSL•FO
RenderX

FH (n=28; $F_{4, 108}$=50.12; P<.001), and SH (n=57; $F_{4, 224}$=13.47; P<.001).

Significant mode-related differences were consistent across all question types, with the largest effects observed for FH and PH.

Table . Mean coverage percentages (SD) for each chatbot configuration by question type[a].

Question type	Cases, n	DT (%), mean (SD)[b]	DN (%), mean (SD)[c]	MT (%), mean (SD)[d]	MN (%), mean (SD)[e]	Choice (%), mean (SD)
HPC[f]	66	79.0 (19.7)	77.3 (20.2)	69.5 (26.0)	60.4 (28.7)	62.6 (22.0)
AS[g]	64	80.1 (22.9)	76.0 (22.5)	78.7 (25.0)	75.8 (23.2)	64.7 (26.2)
PH[h]	57	93.0 (19.9)	36.0 (48.0)	53.5 (48.1)	45.6 (46.6)	94.7 (15.5)
FH[i]	28	98.2 (9.4)	7.1 (26.2)	58.9 (49.2)	21.4 (41.8)	3.6 (18.9)
SH[j]	57	45.3 (38.4)	12.0 (25.7)	19.3 (31.8)	21.1 (35.1)	11.4 (27.3)

[a]Sample sizes differ because the analyses were restricted to cases containing at least one checklist item in each domain.

[b]DT: detailed prompt with thinking mode.

[c]DN: detailed prompt with nonthinking mode.

[d]MT: minimal prompt with thinking mode.

[e]MN: minimal prompt with nonthinking mode.

[f]HPC: history of presenting complaint.

[g]AS: associated symptom.

[h]PH: past medical history.

[i]FH: family history.

[j]SH: social history.

Symptom-Based Analysis

The highest and lowest macroaveraged coverage percentages per symptom across all modes were examined. To explore variation across clinical presentations, coverage was further summarized by symptoms (Table 4).

Table . Top 3 and bottom 3 symptoms ranked by mean macroaverage coverage across all chatbot modes (n=33 symptoms).

Rank	Symptom	Average coverage (%), mean (SD)
Highest coverage		
1	Palpitations	77.60 (14.50)
2	Joint pain	75.23 (6.77)
3	Abdominal pain	72.83 (8.78)
Lowest coverage		
31	Fever	47.79 (9.13)
32	Impaired vision	46.11 (5.76)
33	Nausea and vomiting	46.07 (6.34)

Across all chatbot modes, the symptoms with the highest average coverage were palpitations (77.60%, SD 14.50%), joint pain (75.23%, SD 6.77%), and abdominal pain (72.83%, SD 8.78%).

In contrast, the lowest-coverage symptoms were nausea and vomiting (46.07%, SD 6.34%), impaired vision (46.11%, SD 5.76%), and fever (47.79%, SD 9.13%).

These results highlight substantial variation in information completeness across presenting complaints.

The full list of 33 symptoms is provided in Multimedia Appendix 1

We then identified the largest advantage (Δ coverage) of the DT mode over the average of the other 3 LLM configurations (DN, MT, and MN).

To identify the symptom types with the greatest improvement under the DT configuration, we calculated the difference in mean coverage between DT and the average of the other 3 LLM modes (DN, MT, and MN).

The 5 symptoms showing the largest relative advantage of DT were weakness, headache, dysphagia, palpitations, and dizziness. Among these 5 symptoms with the largest DT advantage, coverage improvements ranged from approximately 22.4%-30.6% points compared with the average of the other

XSL•FO
RenderX

LLM configurations. Pairwise differences between DT and individual LLM configurations are shown in Table 5.

Table . Top 5 symptoms showing the largest relative advantage of the detailed prompt with the thinking mode (DT) configuration in coverage percentage compared with other large language model (LLM) configurations.

Symptom	Δ coverage (DT[a] - Mean of DN, MT, and MN) (%)	DT-DN[b] (%)	DT-MT[c] (%)	DT-MN[d] (%)
Weakness	30.6	30.3	21.2	40.4
Headache	30.0	30.0	35.0	25.0
Dysphagia	28.2	25.8	14.6	44.2
Palpitations	26.8	33.2	15.4	31.7
Dizziness	22.4	22.6	17.9	26.8

[a]DT: detailed prompt with thinking mode.

[b]DN: detailed prompt with nonthinking mode.

[c]MT: minimal prompt with thinking mode.

[d]MN: minimal prompt with nonthinking mode.

Repetitive Questioning Analysis

In an exploratory review of repetitive questioning, repeated questions were observed in 4 of 66 (6.1%) DT transcripts, 7 of 66 (10.6%) DN transcripts, 3 of 66 (4.5%) MT transcripts, and 10 of 66 (15.2%) MN transcripts. Repetitive questioning was uncommon overall but occurred more often in nonthinking configurations than in thinking configurations, most frequently in the MN configuration.

Discussion

Principal Findings

This study demonstrates that LLM-based chatbot interviews are capable of collecting patient-reported medical history across multiple clinical areas in a controlled, simulated setting. Across the evaluated settings, LLM-based chatbots achieved overall information coverage comparable to or exceeding that of the existing choice-based system, supporting their feasibility as flexible tools for collecting baseline patient history. Notably, the MN configuration performed at a level comparable to the choice-based baseline. This indicates that the use of an LLM alone, without structured prompting or reasoning support, does not inherently provide an advantage. Instead, the completeness and clinical relevance of the collected information, as reflected by case-based checklist coverage, were strongly influenced by prompt design and the presence of internal reasoning mechanisms.

Among the evaluated configurations, the DT mode achieved the highest overall coverage. Compared with other LLM configurations and the choice-based baseline, DT achieved an absolute improvement in information coverage of approximately 12 - 21 percentage points at a fixed interaction length. The factorial analysis showed additional significant main effects of prompt detail and internal reasoning, as well as a significant interaction between prompt detail and internal reasoning. These findings suggest that detailed prompting and internal reasoning each contributed to improved coverage, and that their combination was associated with the greatest information capture in this controlled simulated setting.

Prompt detail appeared to play an important role in establishing a clinically coherent interview structure. While the underlying language model could collect relevant patient information, detailed prompts improved the consistency and depth of history taking. Configurations lacking sufficient prompt structure tended to produce less detailed information in several history components, resulting in an overall reduction in coverage. These findings suggest that prompt detail functions as a clinical framework, aligning the model's flexible behavior with established medical interviewing frameworks and supporting more reliable information collection.

Internal reasoning mechanisms may have further contributed by enabling prioritization and adaptive follow-up questioning. When internal reasoning was absent, chatbots tended to remain within the same history domain that was emphasized early in the prompt, resulting in limited progression to subsequent components. In contrast, reasoning-enabled configurations appeared better able to identify clinically relevant information and pursue follow-up questions that extended beyond the initial domain, such as PH, FH, and SH. These findings suggest that internal reasoning may support dynamic decision-making within the interview, complementing structured prompts by guiding when and how to transition between history components. In the exploratory review of repetitive questioning, repeated questions were observed slightly more often in nonthinking configurations than in thinking configurations. This pattern may suggest that internal reasoning helped the chatbot make more consistent use of prior conversational context in some cases. However, because the internal reasoning process itself was not directly analyzed, this interpretation should be considered a possible explanation rather than a confirmed mechanism. Further qualitative error analysis of transcript-level behavior would be needed to better examine how reasoning-mode configurations influence question selection, domain transitions, and use of prior conversational context.

The low coverage observed in SH, even in the DT configuration, should be interpreted in relation to the alignment between the prompt's scope and the checklist criteria. To prevent the chatbot from drifting into overly broad or nonclinical lifestyle discussions, social history questioning was limited to key

XSL•FO
RenderX

clinically relevant risk factors, specifically smoking and alcohol consumption. Consequently, lower SH coverage may partly reflect a mismatch between the prompt's scope and the grading checklist, rather than a general inability of the chatbot to collect social history. While this design choice supported a focused interview, it resulted in limited coverage of other SH subcategories included in the grading checklist that were not explicitly prompted. This limitation reflects broader challenges in capturing social history information, as SH sections can contain a wide range of social, behavioral, and environmental determinants, yet they are variably documented in practice [49]. In real-world use, the scope of social history questioning may need to be adapted according to the clinical scenario, specialty, or intended use of the chatbot in clinical care.

Performance varied across clinical scenarios. Symptoms linked to specific organ systems and common diagnostic pathways, such as palpitations, joint pain, and abdominal pain, were associated with higher coverage, whereas systemic or nonspecific presentations, such as fever and nausea and vomiting, were more challenging because they may require broader and less linear exploration across multiple organ systems. This suggests that a single static interviewing strategy is unlikely to perform optimally across all contexts and that adaptation to the presenting complaint may be required. The largest gains with the DT mode were observed in cases containing distinctive diagnostic cues (eg, transient visual loss in suspected transient ischemic attack or thunderclap onset in subarachnoid hemorrhage). In these scenarios, the combination of detailed prompting and internal reasoning may have helped the chatbot ask more targeted follow-up questions, although this mechanism was not directly tested.

Taken together, these results suggest that chatbot-based systems may be capable of collecting clinically relevant patient history information in controlled, simulated settings, supporting their potential role in preconsultation data gathering. The findings further suggest that the reliability and completeness of this information depend on the integration of multiple design elements, including sufficiently detailed prompts to provide clinical structure and internal reasoning mechanisms to support prioritization and progression through the interview. In practice, such systems are best positioned as supportive tools that augment baseline information collection alongside clinician-led interviews.

Comparison With Prior Work

Consistent with previous studies [16,26], our results support the feasibility of using chatbots to collect patient medical histories prior to physician encounters. Beyond demonstrating feasibility, this study extends prior work by quantitatively evaluating information coverage across multiple clinical domains and symptom types. The findings further suggest that structured prompt design and the inclusion of internal reasoning mechanisms, as explored in earlier studies [22,25], can support clinically oriented questioning, leading to more comprehensive and diagnostically relevant information collection.

Limitations

This study has several limitations. First, the fixed 15-turn limit may have truncated deeper questioning, potentially underestimating the full capabilities of the chatbot configurations, particularly for later history domains such as PH, FH, and social history. Because this limit was implemented externally and was not explicitly stated in the chatbot prompts, the models could not anticipate the remaining number of turns when prioritizing questions. Lower coverage in these later domains may therefore partly reflect the predefined conversation-length limit rather than the model's full potential capabilities. In addition, this study did not formally analyze how conversation length or stopping point affected performance.

Second, the results are based solely on the Qwen3-14B-Instruct model. While this model has demonstrated strong reasoning capabilities, the findings regarding "thinking mode" may vary across different model architectures or larger-scale models.

Third, only a single detailed prompt design was evaluated, and the results may not generalize to other prompt styles or instructional formulations.

Fourth, the symptom-level analyses were based on a limited number of simulated cases (2 cases per symptom), which may not fully capture the heterogeneity of real-world clinical presentations.

Fifth, the evaluation was conducted using SP cases in a controlled setting, and chatbot performance may differ in real-world clinical environments.

Sixth, the low SH coverage should be interpreted as a limitation in prompt-rubric alignment. It may partly reflect the evaluation design rather than an inherent inability of the model to collect social history information.

Seventh, the choice chatbot differed from the LLM configurations in its design objectives, interface format, branching logic, and stopping rules. Therefore, it should be interpreted as a pragmatic baseline reference rather than a fully equivalent comparator. In addition, although physician raters were blinded to LLM configuration labels, the choice baseline could not be fully blinded during evaluation because its fixed multiple-choice format was visibly different from the open-ended format of the LLM transcripts.

Finally, the outcome in this study was checklist-based information coverage, which remains a surrogate measure. Because the checklists were derived from standardized case information, the coverage score primarily reflected whether the chatbot elicited expected case-specific information, rather than whether it performed an optimal or fully individualized clinical interview. Higher coverage does not necessarily indicate better diagnostic accuracy, clinical safety, patient experience, conversational efficiency, or real-world usefulness.

Future Directions

Future work should evaluate chatbot performance in real clinical settings, where patient perceptions, communication styles, and time constraints vary more widely. Integrating chatbot-collected histories with clinician documentation workflows and examining

XSL•FO
RenderX

the impact of this integration on documentation quality and patient-physician information alignment will be important next steps. Future studies should also examine how chatbot-collected histories can be summarized and presented to clinicians, whether findings generalize to other LLMs, including larger frontier models, and how conversation length, adaptive stopping strategies, and transcript-level error patterns, such as repetitive questioning, missed transitions, and irrelevant follow-up questions, influence information coverage and conversational quality. Future simulation-based studies should also consider analytical approaches that account for simulated-patient-level variability, as well as clinical safety outcomes, such as hallucination-related errors and potentially unsafe responses.

Conclusions

This study evaluated the effects of prompt detail and internal reasoning on checklist-based information coverage in LLM-based chatbot medical history taking using standardized primary care cases. In this controlled simulated setting, the LLM chatbot was able to collect patient history information across multiple clinical domains, with the detailed prompt and thinking mode achieving the highest overall coverage among the evaluated configurations. The results indicate that both structured clinical prompt design and internal reasoning configuration influence the completeness of chatbot-collected patient history information, with performance varying across symptom types. These findings support the feasibility of LLM-based chatbots for preconsultation history collection within the scope of checklist-based evaluation in a controlled simulated setting.

Acknowledgments

During manuscript preparation, ChatGPT (OpenAI) was used to assist with language editing and to improve the readability of the author-drafted text. The authors have reviewed, edited, and verified all AI-assisted text and take full responsibility for the manuscript's final content.

Funding

This work was supported by the Cross-Ministerial Strategic Innovation Promotion Program (SIP) on "Integrated Health Care System" Grant Number JPJ012425.

Data Availability

The chatbot implementation code used at the time of the study is available at the GitHub repository [50]. The analysis-ready aggregate dataset generated and analyzed during this study is available from the corresponding author upon reasonable request. Full chatbot-SP transcripts, case scripts, and the complete set of detailed checklist items are not publicly available because they may contain participant-generated wording and case-specific details derived from copyrighted or licensed source materials.

Privacy Leakage in Federated Learning in Radiology Reports: Comparative Evaluation of Tokenizer and Batch-Size Privacy Risks

Abstract

Background: Federated learning (FL) enables multi-institutional model training on clinical text without sharing raw data; however, gradient inversion methods can reconstruct sensitive information from shared model updates. The extent of such privacy leakage in FL applied to radiology reports, and the role of tokenizer design, remains unclear.

Objective: This study aimed to quantify gradient-based reconstruction of radiology report text in an FL setting and to compare privacy risk across 3 transformer tokenization strategies in a controlled, tokenizer-aware evaluation.

Methods: Six FL clients trained a GPT-2–style transformer (sequence length 32) on 2 public clinical-text corpora comprising 368,751 diagnostic reports, 98,206 discharge summaries, and 1500 MIMIC-CXR (Medical Information Mart for Intensive Care Chest X-Ray) radiology reports. Models were trained using 3 tokenizers (GPT-2, RadBERT, and LLaMA-2) with batch sizes of 64, 128, and 256. An active malicious-server threat model was assumed, and analytic gradient inversion was applied to recover text. Reconstruction fidelity was measured over 5 runs using exact sentence accuracy, sentence-level bilingual evaluation understudy (S-BLEU), and recall-oriented understudy for gisting evaluation (ROUGE-L).

Results: Exact sentence reconstruction ranged from 27% to 75% across tokenizers, datasets, and batch sizes. At batch size 64 on the discharge dataset, accuracy was 64.7% (GPT-2), 70% (RadBERT), and 67.5% (LLaMA-2), decreasing to 27.3%, 28.5%, and 27.5% at batch size 256. S-BLEU declined with increasing batch size (eg, discharge reports from 0.69 to 0.31). Reconstruction fidelity did not differ significantly across tokenizers (all but one of 27 comparisons nonsignificant; none significant after Holm correction), and approximately 75% of clinical concepts were represented in the reconstructed text (a corpus-level upper bound), regardless of tokenizer. Batch size was the dominant factor governing leakage.

Conclusions: Under a worst-case malicious server that tampers with the shared model and observes unprotected per-client gradients (no secure aggregation or differential privacy), substantial portions of radiology-report text can be reconstructed, with up to approximately 75% of reconstructed 32-token sequences and 75% of clinical concepts (not direct patient identifiers) recovered from FL gradients. In a controlled ablation holding model architecture fixed, tokenizer choice, including domain-specific tokenizers, did not significantly affect leakage under the evaluated conditions, whereas batch size was the primary determinant, and no tokenizer significantly reduced the risk. Tokenizer selection should therefore not be treated as a privacy safeguard in this setting. Safeguards such as secure aggregation and differential privacy should therefore be evaluated as candidate protections for FL deployments that must satisfy Health Insurance Portability and Accountability Act (HIPAA) and General Data Protection Regulation (GDPR) requirements in radiology natural language processing (NLP); legal compliance additionally depends on organizational safeguards, risk assessment, and governance beyond the scope of this study.

Introduction

Background

Radiology reports serve as an indispensable tool in medical diagnostics, providing critical insights [1] that complement imaging data. These textual data contain rich clinical information, including patient history, diagnostic impressions, and recommended follow-ups, often bridging gaps left by imaging alone. In recent years, advancements in AI, particularly transformer-based large language models (LLMs) [2], have revolutionized natural language processing (NLP), making it possible to analyze unstructured textual data at scale. LLMs such as the GPT family [3] are now being explored for their potential in radiology to assist in generating summaries [4], extracting relevant clinical insights, and identifying patterns across large datasets [5-7]. A recent systematic review of LLM evaluations in clinical medicine highlights the rapid growth of these models and underscores the need for robust evaluation frameworks to ensure their safety, reliability, and ethical alignment in health care applications [8].

Radiology LLMs can be collaboratively developed across multiple institutions, leveraging diverse clinical reports to enhance model robustness and improve generalizability across unseen health care settings. Nevertheless, health care data, such as radiological data sharing, faces significant challenges due to stringent data protection laws such as the Health Insurance Portability and Accountability Act (HIPAA) [9] in the United States and the General Data Protection Regulation (GDPR) [10] in the European Union, which mandate strict safeguards for the privacy of sensitive patient data. Federated learning (FL) [11], a decentralized machine learning approach where models are trained across multiple institutions without exchanging raw data, has emerged as a promising solution to address these challenges by ensuring that sensitive data remain within each participating institution while still enabling collaborative model development. Multicentric FL clinical collaborations [12-15] are transforming medical research by enabling privacy-preserving data sharing, fostering innovation, and addressing critical concerns around data ownership and security.

Nevertheless, FL's decentralized nature introduces inherent vulnerabilities that may compromise patient confidentiality [16,17]. While they eliminate direct data sharing, FL systems rely on the exchange of model parameters between institutions and a central server. An active malicious server—one that not only observes gradients but also modifies the shared model architecture before distribution—can exploit these parameters to reconstruct sensitive data, exposing significant vulnerabilities. Existing research has shown that gradient-inversion attacks [18-20] can reconstruct private text from models trained on generic language datasets, but such risks remain largely unexplored in the domain of radiology [21].

Recent advances in NLP have demonstrated that leveraging domain-specific tokenizers [18] and training LLMs on domain-adapted corpora significantly enhances performance in specialized fields such as medicine and genomics. For instance, studies such as Gu et al [22] introduced PubMedBERT, showing that pretraining on biomedical literature yields superior results on downstream clinical tasks compared to generalist models. Similarly, prior studies such as Zhang et al [23] demonstrate that fine-tuning LLMs such as BioBERT and MedAlpaca with domain-specific data and tailored tokenization strategies substantially enhances performance in medical tasks. These adaptations enable the models to capture nuanced, domain-relevant semantics that general-purpose LLMs typically overlook.

To specifically investigate the role of tokenization in privacy leakage within FL, we isolate tokenizer design as the primary variable while keeping the underlying model architecture constant. While most prior work compares entire language models [8], we argue that vocabulary segmentation alone can influence the susceptibility of models to gradient-inversion attacks. Tokenizers trained on domain-specific corpora (eg, RadBERT) are more likely to encode medical terms as single tokens, increasing their semantic coherence; we hypothesized that this would also make such terms easier to reconstruct—a prediction our controlled experiments ultimately did not support (see the "Results" section). In contrast, general-purpose tokenizers tend to fragment clinical phrases into multiple subwords, which may reduce both interpretability and recoverability. This design choice not only impacts downstream clinical utility [22] but might, we hypothesized, also alter the reidentifiability of sensitive entities during model inversion—a prediction our controlled experiments did not support. By decoupling the tokenizer from the model architecture, our approach provides a targeted evaluation of how vocabulary structure relates to the balance between semantic fidelity and patient privacy.

In our controlled evaluation, the radiology-specific RadBERT [24] tokenizer did not yield significantly higher reconstruction fidelity under attack than general-purpose tokenizers such as GPT-2 [25] and LLaMA-2 [26]. This indicates that the advantages of domain-adapted pretraining for capturing clinical semantics do not come at the cost of measurably greater gradient-inversion leakage; the vulnerability is intrinsic to the attack and is governed primarily by batch size—though under this imprint-probe construction the batch-size effect operates proximately through increased bin-collision burden rather than as a general law of federated training. This observation aligns with evidence that tokenizer and model design choices can influence performance in domain-specific applications, raising the question of whether they likewise affect privacy risk under gradient inversion. Building on this insight, we investigate the extent to which radiology report data can be reconstructed from transformer-based models trained in a simulated FL environment. By orchestrating targeted attacks in a multiclient setup using publicly available radiological datasets, we expose critical vulnerabilities in current FL frameworks. Our study deliberately focuses on the attack surface and does not evaluate defense mechanisms or privacy-preserving strategies. Rather, it aims to characterize worst-case risks and motivate future work toward robust, domain-aware privacy protections for safe deployment of clinical foundation models.

XSL•FO
RenderX

Scope and Contributions

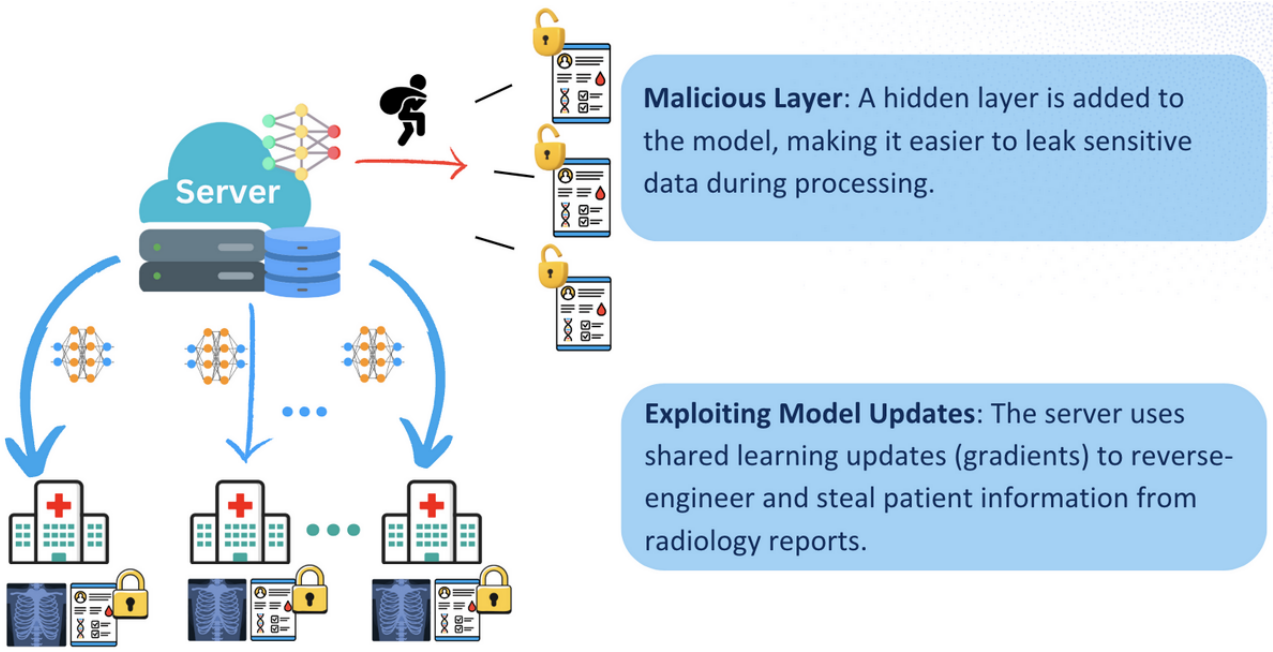
This work establishes a foundational analysis of the privacy vulnerabilities inherent in applying transformer-based FL to radiology reports. We focus on characterizing the attack surface by quantifying the reconstruction risk under a worst-case gradient-inversion scenario. To this end, we provide a systematic comparison of information leakage across major tokenizers, namely, GPT-2, RadBERT, and LLaMA-2. Our central contribution is a controlled demonstration that, with model architecture held fixed, tokenizer choice—including domain-specific tokenizers like RadBERT—does not significantly change the risk of leaking sensitive patient data, whereas batch size does; practitioners therefore should not, in this setting, rely on tokenizer selection as a privacy safeguard. These findings provide a necessary benchmark and guidepost for developing effective privacy-preserving defenses in medical FL systems. Clinical utility is not directly evaluated in this study and is inferred from prior work establishing improved downstream performance with domain-specific clinical tokenizers.

Methods

Ethical Considerations

This study is a secondary computational analysis of 2 publicly available, previously deidentified clinical text corpora: the dischargesum dataset [27] and the MIMIC-CXR (Medical Information Mart for Intensive Care Chest X-Ray) free-text radiology reports accessed via PhysioNet [28] under the standard PhysioNet credentialed-access Data Use Agreement. No new data from human participants were collected as part of this work. No identifiable individuals appear in any figure, table, or supplementary material. No participants were recruited, and no compensation was provided. Per institutional policy at the German Cancer Research Center (DKFZ) and consistent with PhysioNet's terms of use, secondary computational analysis of these deidentified public corpora qualifies for ethics board exemption; the original institutional review board approvals covering the primary collection of MIMIC-CXR (Beth Israel Deaconess Medical Center) and Dischargesum extend to secondary research use without additional consent. All experiments were performed on local DKFZ compute infrastructure and no patient data were transmitted to external services.

FL and Transformer Models



FL [11] is a decentralized machine learning paradigm that allows multiple institutions to collaboratively train a common model without exchanging raw data. Each client trains locally and sends only gradient updates to a central server for aggregation. In our implementation, we simulated this multi-institutional setup using a GPT-2–style transformer (instantiated as a compact 3-layer encoder with token-embedding dimension m=96, 8 attention heads, feed-forward hidden size 1536, and approximately 13.4 M trainable parameters, following the field guide to FL baseline architecture [29]) combined with 3 different tokenizers. The overall attack pathway is illustrated in Figure 1.

- GPT-2 tokenizer: 50,257 tokens
- StanfordAIMI/RadBERT tokenizer: 30,522 tokens
- LLaMA-2-7B tokenizer: 32,000 tokens

All tokenizers operated with a fixed sequence length of 32 tokens, so any observed privacy differences are attributable to vocabulary segmentation rather than to input shape or representational scale. Holding the foundation-model architecture fixed at this small, well-characterized baseline allows the tokenizer to serve as the sole independent variable across our GPT-2, RadBERT, and LLaMA-2 comparisons. The 32-token sequence length follows the field guide to FL baseline configuration [29] and is consistent with prior gradient-inversion experiments on text models [30]; it provides a controlled, computationally tractable regime in which the imprint construction's bin disentanglement is well-characterized. To emulate real multi-institutional training, we randomly partitioned 2 radiology text datasets across 6 cloud - based clients: the public Dischargesum corpus (98,206 discharge summaries; 368,751 diagnostic reports) and a locally curated sample of 1500 free-text reports from MIMIC-CXR. Training was repeated with batch sizes of 64, 128, and 256 sequences to measure how aggregation granularity affects privacy leakage in shared gradients. Batch sizes refer throughout to 32-token sequences, not whole reports: each report is tokenized and split into multiple nonoverlapping 32-token windows; a single discharge summary or radiology report typically contributes between 5 and 40 sequences depending on its length, so the per-client local datasets contain ≥5000 sequences and comfortably exceed the largest batch size of 256. Gradient-inversion attacks of the type considered here operate on the gradient produced by a single client during a single training round, which constitutes the standard threat-surface unit in the gradient-leakage literature [30]; privacy leakage was therefore quantified per (client and round) rather than over the aggregated federation-level update.

XSL•FO
RenderX

Figure 1. Gradient-inversion attack pathway in federated radiology natural language processing. A malicious central server coordinates model training across multiple hospitals. By inserting a lightweight linear probe at the embedding stage, the server exposes token-level representations and, from the probe's gradients, reconstructs token embeddings in closed form. Decoding these embeddings via the tokenizer's embedding table yields patient text, illustrating that federated learning can leak confidential report content even without raw data sharing.

Threat Model

Overview

We characterize the adversary in this study as an active malicious server, following the worst-case threat-model conventions used in prior FL gradient-inversion analyses [31,32]. Formally, the adversary controls the central FL server and possesses the following capabilities. (C1) Architecture modification (active, white box on the server side): the server may insert auxiliary parameters into the shared model before the first communication round, provided the resulting model still trains end-to-end. We exercise this capability by inserting a single analytic imprint module (see section "Background and Preliminaries") immediately before the positional embedding. (C2) Per-round per-client gradient observation: the server observes the full set of weight and bias gradients $\nabla\theta$ returned by each client at each round. We do not assume access to intermediate activations, hidden states, or any nongradient signal—that is, the protocol is standard FedAvg/FedSGD, not split learning. (C3) Knowledge of the public model and tokenizer: the server knows the model architecture (since it distributed it) and the tokenizer's embedding table (since it is part of the shared model). The adversary does not observe raw client data, client-side optimization state, or any cryptographic key material. We assume no defenses are enabled at any layer of the FL stack: no differential privacy (DP), no secure aggregation, no client-side architecture verification, no gradient anomaly detection. This intentionally maximal threat model isolates the upper-bound leakage attributable to gradient inversion alone, which is the quantity our experiments seek to characterize.

Detectability and Stealthiness

The architecture modification in C1 is in principle detectable by any client that compares the received model's parameter signature to a published reference. In current production FL frameworks, no such signature verification is mandatory, and small architectural modifications could in principle be disguised by representing the imprint module as a benign feature-extractor or input-normalization layer. However, the imprint module itself adds approximately (1000×96) + (96×1000)+1000≈193 K parameters—roughly 1.4% of the 13.4-million-parameter base model—and would therefore be detectable by any routine client-side parameter-size audit or cryptographic attestation of the published model signature. We therefore treat detectability as a deployment-policy mitigation, not a fundamental defense, and we recommend in section "Practical and Regulatory Implications" that mandatory client-side architecture attestation be considered as part of clinical FL audit protocols.

Scope of These Findings

The reported reconstruction rates correspond to a worst-case adversary: a malicious central server that (1) owns and modifies the shared model architecture before distributing it to clients, (2) observes per-round per-client gradients on weight and bias parameters, and (3) operates in a setting with no privacy defenses enabled—no DP, no secure aggregation, no gradient clipping, and no client-side model integrity verification. Under typical real-world cross-silo FL deployments, where institutional clients verify the received model architecture, secure aggregation conceals individual client updates, and lightweight differential-privacy noise is applied, these reconstruction rates would be expected to fall substantially. We therefore interpret our numbers as an upper bound on residual leakage when defenses are absent, not as expected leakage in defended

XSL•FO
RenderX

deployments. This framing is consistent with the worst-case methodology of prior gradient-inversion studies [30].

Background and Preliminaries

Let the token-embedding dimension be m, and the probe output dimension be k. For a single token position, the hidden vector $x \in {}^{m}$ is produced by the embedding table before positional addition and attention mixing. We insert a small linear probe (an "imprint" module in the sense of [30]) on top of this hidden state:

$y=W_2 \cdot \mathrm{ReLU}(W_0 x+b_0)$ with $W \in {}^{k\times m}$, $b \in {}^{k}$, and $W_2 \in {}^{m\times k}$, where k denotes the number of probe bins. The probe is appended once at initialization and trained jointly with the rest of the model. As in standard cross-silo FL (FedAvg [11]), each client transmits only the parameter gradient $\nabla\theta$ of its local loss back to the server; no intermediate activations or hidden states are exchanged. This rules out split-learning style leakage and isolates the threat surface to the gradient update itself.

We initialize b to the cumulative quantiles of a Laplace prior over the expected preactivation distribution and W to a random Gaussian matrix; W_2 is initialized so that $y \approx x$ in expectation, leaving downstream training behavior essentially unchanged. Under this construction, the bins partition the input space into cumulative half-spaces of geometrically decreasing measure, so that for sufficiently large k at most one sample in a mini-batch activates each bin after consecutive-bin differencing. In general, batch aggregation destroys per-sample information: the transmitted gradient $\nabla\theta$ averages over all B samples in the batch and is not invertible without optimization [30]. The cumulative-bin imprint construction circumvents this barrier by analytic design rather than by optimization—the contribution of each individual token to ∇W and ∇b is structurally separated by bin index i, so the server can isolate per-sample gradients even though it only ever observes the batch sum.

From these 2 captured gradients, the input hidden vector x can be recovered in closed form without optimization: $\hat{x}_j = \nabla W_{0,i} \oslash \nabla b_{0,i}$

where i is the bin uniquely activated by token j after the cumulative-bin differencing step $\nabla W_{,i} \leftarrow \nabla W_{,i} - \nabla W_{,i-1}$ (and analogously for $\nabla b_{,i}$). We apply this per token and per sample in a batch; sentence reconstructions are formed by decoding each x_j to the nearest token in the active tokenizer's embedding table $E \in {}^{V\times m}$ under cosine similarity, where V is the tokenizer vocabulary size. We set k=1000 bins and m=96, with x_j L2-normalized before decoding; when $\| \nabla b_{,i} \|_2$ is below a numerical threshold ε, we add a ridge term ε to the denominator for numerical stability.

Ties or near-ties (cosine margin < δ) among candidate tokens are broken by rescoring with the model's language-model-head logits in a server-side forward pass conditioned on the previously-decoded prefix of the same sample—feasible because the malicious server holds the full shared model and can run forward passes on partial reconstructions. Token j is therefore resolved in left-to-right context rather than in isolation; the very first position falls back to the unconditional logit prior.

Attack Implementation

Overview

We implement the gradient-inversion attack as a deterministic, server-side procedure operating on per-round gradients. The analytic probe and closed-form inversion are defined in the section "Background and Preliminaries"; below we describe the practical instrumentation, data capture, and decoding steps used in our experiments.

Step 1: Instrumentation

The server augments the shared transformer with a lightweight linear probe $y=Wx+b$ inserted immediately after the token embedding lookup and before positional additions and attention mixing (see the "Background and Preliminaries" section). This placement exposes token-level representations prior to any token mixing, ensuring reconstructed vectors reflect tokenizer segmentation rather than later architectural effects.

Step 2: Gradient Capture

During each client training round, the server records the probe gradients returned in the aggregation step—specifically, the per-round weight gradient $\nabla W \in {}^{k\times m}$ and bias gradient $\nabla b \in {}^{k}$ of the imprint module's first linear layer (notation as in "Background and Preliminaries"). The "upstream signal" $\partial / \partial y$ referenced in prior gradient-inversion literature is not transmitted by clients; it is reconstructed server-side from the captured weight and bias gradients under the cumulative-bin construction. These per-round gradients are stored for subsequent inversion and auditing; we retain round identifiers and batch metadata to link reconstructions to training conditions (dataset, tokenizer, and batch size).

Step 3: Closed-Form Inversion and Stabilization

For each captured token gradient in a round, we compute the closed-form embedding estimate $\hat{x}$ following the expression in the "Background and Preliminaries" section. After inversion, each $\hat{x}$ is L2-normalized to match embedding norm scaling; when $\| \nabla b_{,i} \|_2$ is near zero, we add a small ridge term ε to the denominator for numerical stability (implementation: $\hat{x}_j = \nabla W_{0,i} \oslash (\nabla b_{0,i} + \varepsilon)$, $\varepsilon = 10^{-8}$.

Step 4: Token Decoding

Overview

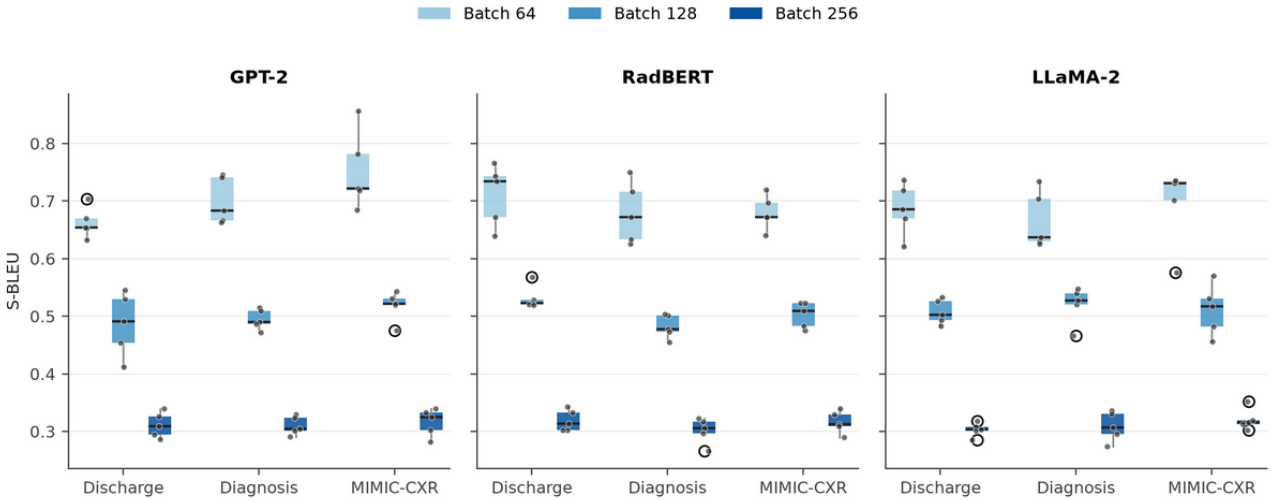
Each recovered vector $\hat{x}$ is decoded by nearest-neighbor search over the active tokenizer's embedding table using cosine similarity (top-1). When multiple vocabulary entries are within a small cosine-similarity margin δ of the maximum, the server breaks the tie by rescoring candidates using the model's language-model-head logit at that position, computed in a server-side forward pass conditioned on the previously-decoded prefix. This is feasible because the malicious server holds the full shared model (it distributed the model in the first place) and can execute forward passes on partial reconstructions; the very first position falls back to the unconditional logit prior. Decoded tokens are concatenated in positional order to yield sentence-level reconstructions.

XSL•FO
RenderX

Clarification on Positional Order Recovery

Positional order is determined by an optimal-assignment matching between recovered breached embeddings and the 32 known positional embeddings of the sequence, implemented as scipy.optimize.linear_sum_assignment (the Hungarian algorithm) in the breaching library, following Fowl et al [30]. The language-model-head logit rescoring described above operates within each assigned position to resolve vocabulary ambiguity; it does not itself determine position. The phrase "immediately before the positional embedding" in our previous revision refers to topological placement within the encoder stack (before the attention and token-mixing layers); the recovered breached embeddings nonetheless carry the positional signature used by the matching stage above.

Step 5: Design for Fair Tokenizer Comparison



Overview

To isolate tokenization effects from architecture or training hyperparameters, we hold the model architecture, embedding dimension m, probe output dimension *k*, and probe placement constant across experiments. The same inversion and decoding hyperparameters (ridge ε, L2 normalization, and nearest-neighbor metric) were applied to GPT-2, RadBERT, and LLaMA-2 tokenizer evaluations without per-tokenizer tuning. Because decoding uses each tokenizer's own embedding table, reconstruction fidelity reflects vocabulary segmentation and tokenizer-induced exposure (single-token entities vs fragmented subwords).

Implementation Notes and Novelty

All inversion and decoding steps were implemented in Python (NumPy/PyTorch). Nearest-neighbor lookup used a brute-force cosine search for reproducibility; for large vocabularies, the same pipeline is compatible with approximate nearest-neighbor libraries (Facebook AI Similarity Search [FAISS]). Per-round artifacts (timestamps and batch composition) were retained to permit round-level analyses and the box plots reported in Figure 2 and Multimedia Appendices 1 and 2. The analytic probe itself follows prior work [30]; our novelty lies in (1) its embedding-stack placement to isolate tokenizer-specific effects, (2) a tokenizer-controlled, architecture-fixed evaluation showing that tokenizer choice does not significantly change leakage, and (3) clinical entity-level leakage quantification using MedGemma named-entity recognition (NER) [33], which quantifies the recovery of clinical concepts (diagnoses, procedures, anatomy, and medications).

Figure 2. Box plots (with the individual runs overlaid as points) showing the distribution of sentence-level bilingual evaluation understudy scores across 5 runs for each tokenizer (GPT-2, RadBERT, and LLaMA-2) on 3 datasets: discharge, diagnosis, and MIMIC-CXR (Medical Information Mart for Intensive Care Chest X-Ray). Each box represents performance at a given batch size (64, 128, and 256), with color-coded distinctions shown in the legend. The plots illustrate both central tendency and variability, showing that the tokenizer distributions overlap substantially, with no consistent tokenizer advantage in reconstruction fidelity. Distributions compress as batch size increases, reflecting reduced sentence-level recoverability. S-BLEU: sentence-level bilingual evaluation understudy.

Clarification on the Cumulative-Bin Regime

The k=1000 bins are allocated globally over the batch rather than per token position, so the expected per-bin occupancy is (B×T)/k over the full pool of B×T token activations (*t*=32 here). The strict single-occupancy regime (B<k) is therefore not strictly achieved even at our smallest batch: at B=64 the 2048 token activations already exceed the 1000 bins, so a minority of bins are multiply occupied, and multioccupancy grows with batch size until it is pervasive at B=256 (8192 activations). The analytic recovery rule $\hat{x}_j = \nabla W_i / \nabla b_i$ is exact only in the single-occupancy regime; under multioccupancy it yields a per-bin weighted average of the active samples' embeddings, producing a blurred but nonvacuous reconstruction. Because the recovered vector approximates the occupancy-weighted mean of the colliding token embeddings, its nearest neighbor in the embedding table is generally a token near that centroid rather than any single constituent; empirically, this biases decoding toward high-frequency, generic tokens (common subwords and scaffolding words), so specific low-frequency clinical terms are the first to be lost while frequent structural tokens are still recovered—which is why reconstruction degrades gracefully with batch size rather than collapsing to noise. Positional disambiguation in this regime is performed by the optimal-assignment matching stage described in the "Attack Implementation" section (Step 4) operating on the recovered

XSL•FO
RenderX

continuous embeddings. The reconstruction-accuracy degradation we report across batch sizes 64 → 128 → 256 is consistent with this graceful degradation rather than a strict pigeonhole failure.

Dataset and Experimental Setup

Overview

We evaluated privacy leakage using 3 clinical-text datasets drawn from 2 public corpora. The Dischargesum [27] dataset contained 98,206 discharge summaries and 368,751 diagnostic reports, which were evenly distributed across 6 simulated institutional clients. To complement these structured reports, we also included a subset of 1500 free-text MIMIC-CXR [28] radiology reports, similarly partitioned across the 6 clients.

MIMIC-CXR Sample

From the full MIMIC-CXR free-text corpus (≈227,000 reports), we sampled 1500 reports uniformly at random without replacement, conditional on each report being nonempty after standard whitespace stripping. No filtering was applied by clinical content, report length, institutional source, or temporal range. The sample identifier list is included in our reproducibility package and available from the corresponding author on reasonable request, subject to the PhysioNet Data Use Agreement.

Each client trained a GPT-2–style transformer locally and transmitted only gradient updates to the central server for aggregation, emulating a standard cross-institutional FL workflow. Reports were uniformly sampled at random across the 6 clients, producing an approximately independent and identically distributed (IID) partition for the purposes of this study. Experiments systematically varied the local batch size (64, 128, and 256 sequences) to evaluate its effect on gradient-level privacy leakage. Every configuration was repeated across 5 independent runs to account for stochastic training variability and to ensure reproducibility; 95% CIs across runs are reported in Multimedia Appendix 3 (eg, 64.7%, 95% CI 60.2 - 69.2, for GPT-2 on discharge at batch size 64), and a 3-way variance decomposition attributed 94% of the variance in exact-sentence accuracy to batch size versus under 1% to tokenizer; exact paired *t* tests are reported in Multimedia Appendix 4. Training details and reproducibility configuration are reported in Multimedia Appendix 5. At each measurement point, the malicious server captures the gradient transmitted by one client in a given round and applies the analytic reconstruction described in "Background and Preliminaries" to that single update, in line with the standard single-step formulation adopted in the gradient-inversion literature [30]. Each batch-size configuration was evaluated under this per-client, per-round setting across the 5 independent runs.

Evaluation Metrics

We assessed reconstruction fidelity using 3 complementary metrics chosen to capture both exact and partial text recovery, following established evaluation practice for reconstructed clinical text [14-17,24]. These metrics together quantify the extent to which patient-identifiable information can be recreated from shared model updates.

- Exact sentence accuracy: The percentage of reconstructed 32-token sequence windows—the fixed-length units into which reports are tokenized (see the "Threat Model" section), for which "sentence" is used as shorthand—that match the ground-truth window exactly, reflecting the proportion of complete exposures of patient text. A reconstructed sentence is counted as an exact match if, after the following normalization steps, every token at every position equals the corresponding token in the original sentence: (1) unicode NFKC normalization, (2) lower-casing, (3) collapsing all runs of internal whitespace to a single space, and (4) preserving punctuation as part of the token sequence rather than stripping it. Sentences are extracted from the concatenated stream of decoded 32-token windows by segmenting at terminal punctuation; the metric is therefore evaluated on these reconstructed sentence units rather than directly on the raw 32-token chunks. We report a stricter case-sensitive variant on the same 5-run experiment for completeness; the qualitative ordering of tokenizers is unchanged across both variants. Exact-sentence accuracy is reported as the conservative upper bound on full-sentence exposure: token-level partial recovery (a single recovered diagnostic noun phrase, for instance) can constitute clinically meaningful leakage even when the full sentence is not reconstructed exactly; this regime is captured by the n-gram and longest-common-subsequence metrics described below. The two metric families together bracket the true leakage rate.
- Sentence-level bilingual evaluation understudy (S-BLEU) [34,35]: Calculates n-gram precision, where an n-gram is a contiguous sequence of n words (eg, unigrams, bigrams, trigrams, and 4-grams). Bilingual evaluation understudy (BLEU) compares 1 - 4 word sequences in the reconstructed sentence against the reference, with a brevity penalty to discourage overly short outputs. Higher scores indicate stronger local overlap and preservation of clinical phrasing.
- Recall-oriented understudy for gisting evaluation (ROUGE-L) [36]: Measures recall based on the longest common subsequence (LCS) between reconstruction and reference, capturing the extent to which key clinical terms and their order are retained in longer spans.

By combining these 3 metrics, we quantify both the frequency of perfect reconstructions and the degree of partial text recovery, offering a comprehensive assessment of patient data exposure under our FL attack.

Choice of Metrics

BLEU and ROUGE-L were originally proposed for translation and summarization quality, where their numerical values are bounded by human-level n-gram overlap. In the gradient-inversion context, we use them as information-recovery metrics rather than as quality metrics: a higher BLEU or ROUGE-L between a reconstructed sentence and the original indicates more shared n-gram content—that is, a greater amount of original wording recovered. Exact-sentence accuracy provides the strict-recovery upper bound; S-BLEU and ROUGE-L provide the partial-recovery signal that captures cases where most of a sentence is recovered but a small number of tokens are misdecoded. This complementary use of strict and partial

XSL•FO
RenderX

metrics is consistent with prior gradient-inversion text studies [37]. We deliberately do not adopt semantic-similarity metrics such as BERTScore in the main results because they can credit paraphrastic matches that do not constitute literal information leakage, which is the privacy question of interest here.

Named-Entity Reference-Vocabulary Overlap Evaluation

Overview

We quantified recovery of clinically meaningful content using the Google MedGemma medical NER model [33]. MedGemma was run on the original reports in each dataset to build a per-dataset reference vocabulary of unique clinical entity surface forms (diagnoses, procedures, anatomical structures, and medications). The same model was applied to the reconstructed text for each tokenizer configuration and dataset.

Normalization and Matching

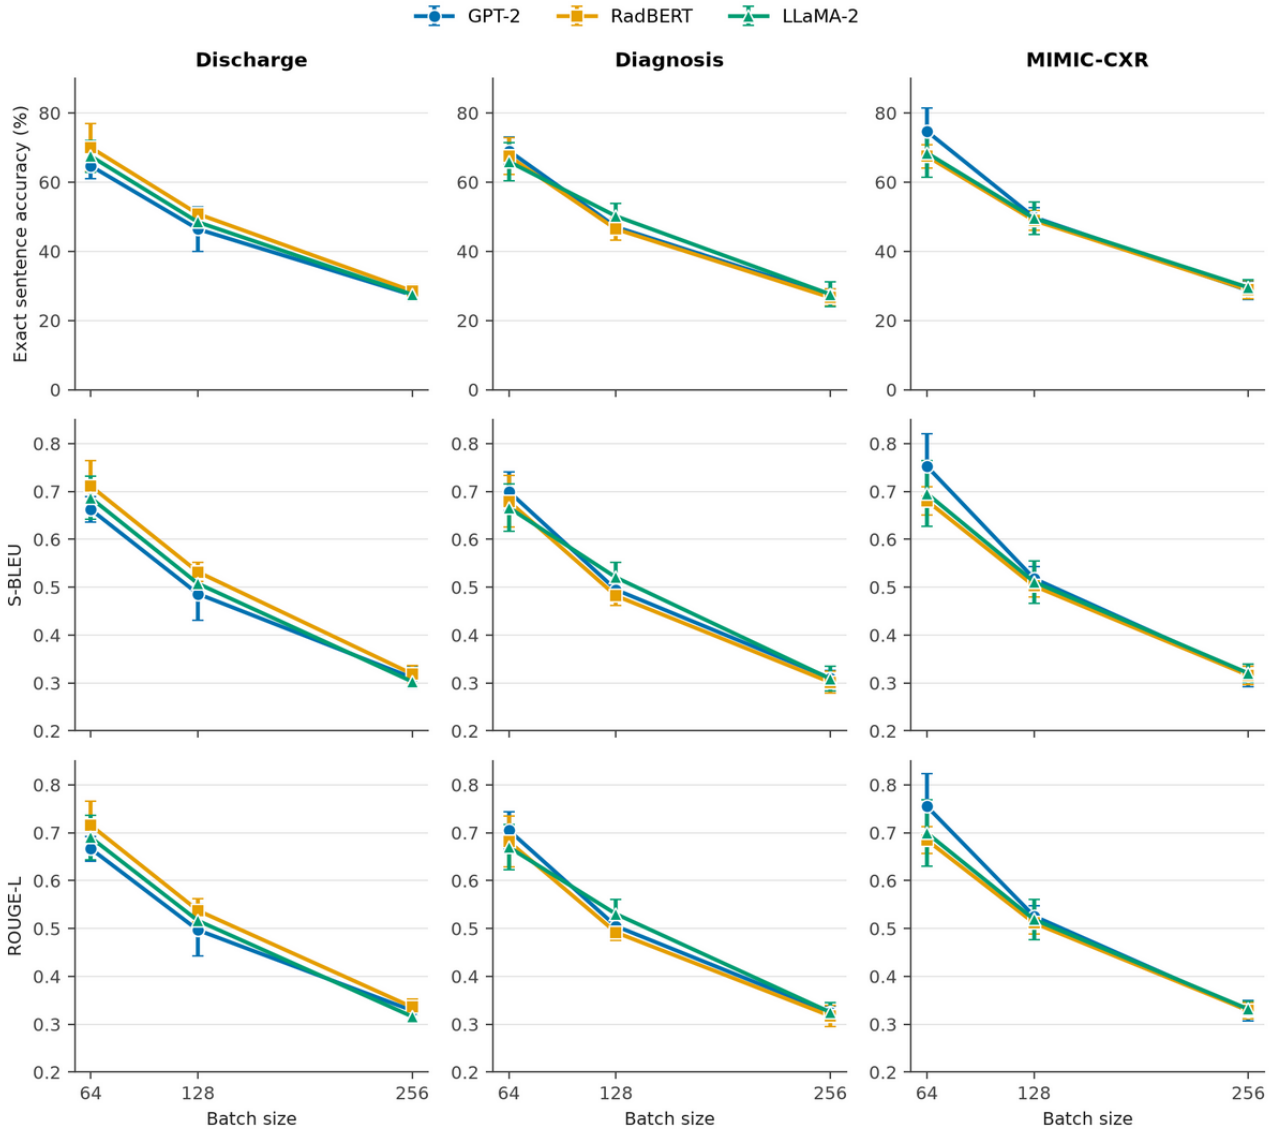
Entity strings were lowercased and whitespace-trimmed; internal punctuation was preserved. An entity was counted as recovered if its surface form exactly matched any term in that dataset's reference vocabulary (case-insensitive). Because this is a corpus-level criterion, it measures reference-vocabulary overlap and represents an upper bound on identifiable leakage: it confirms that a clinical term was reconstructed within the batch but does not by itself establish alignment to a specific source report or patient. No fuzzy matching, synonym expansion, or manual adjudication was used.

Metric

For each tokenizer and dataset, we report reference-vocabulary overlap (%), defined as the percentage of the dataset's MedGemma-extracted reference clinical-concept vocabulary that appears in the reconstructed text, averaged over 5 random seeds (mean and SD); this is a corpus-level recall measure and is not aligned to the specific source report. We report per-dataset and pooled overlap across datasets.

Results

Quantitative Reconstruction Success



On the discharge dataset, exact sentence reconstruction accuracy across tokenizers and batch sizes was as follows:

- GPT-2 tokenizer: 64.7%/46.4%/27.3% at batch sizes 64/128/256
- RadBERT tokenizer: 70%/50.8%/28.5%
- LLaMA-2 tokenizer: 67.5%/48.4%/ 27.5%

On MIMIC-CXR, reconstruction ranged from 28.7% to 74.7% of sentences (Figure 3), showing that neither tokenizer choice nor larger batch sizes fully mitigates data leakage. Detailed accuracy results are provided in Multimedia Appendix 6. All reported reconstruction metrics represent the mean of 5 independent runs; 95% CIs across runs are reported in Multimedia Appendix 3; exact paired *t* tests are reported in Multimedia Appendix 4. Across configurations, per-cell SDs ranged from approximately 1.5 to 7 percentage points.

XSL•FO
RenderX

Figure 3. Reconstruction fidelity across datasets and tokenizers at varying batch sizes. Top row: exact sentence reconstruction accuracy; middle row: sentence-level bilingual evaluation understudy scores; bottom row: ROUGE-L scores. Each column corresponds to a dataset (discharge, diagnosis, and MIMIC-CXR [Medical Information Mart for Intensive Care Chest X-Ray]), and colors indicate tokenizers (GPT-2, RadBERT, and LLaMA-2). Across metrics and datasets, reconstruction fidelity is comparable among the 3 tokenizers, with differences within seed-to-seed variability. Increasing the batch size from 64 to 256 reduces reconstruction quality across all models, illustrating a trade-off between training granularity and patient data privacy. S-BLEU: sentence-level bilingual evaluation understudy.

Impact of Batch Size on S-BLEU

Increasing the batch size led to a clear reduction in average reconstruction fidelity across all metrics (Multimedia Appendix 7; Figure 2). For discharge reports, mean S-BLEU decreased from 0.69 at a batch size of 64 to 0.31 at 256; diagnosis reports fell from 0.68 to 0.31; and MIMIC-CXR from 0.71 to 0.32. Parallel trends were observed for ROUGE-L, confirming that coarser gradient aggregation generally mitigates privacy leakage. Notably, across datasets and batch sizes, the 3 tokenizers achieved statistically indistinguishable reconstruction scores. This indicates that domain-specific tokenization does not measurably facilitate more accurate recovery of clinical language, and that tokenizer choice is not a privacy-relevant design lever in this setting. Corresponding mean S-BLEU and ROUGE-L scores are summarized in Multimedia Appendix 7.

Variability in Gradient-Inversion Severity Across Training Rounds

While average reconstruction fidelity declined with larger batch sizes across all metrics, individual training rounds revealed substantial fluctuations in leakage severity. We illustrate this variability using S-BLEU in Figure 2, as it provides a balanced measure of local n-gram precision and sentence-level structure, making it particularly sensitive to round-to-round differences. However, similar variability patterns were also observed for exact sentence reconstruction accuracy and ROUGE-L, which are summarized in Multimedia Appendices 1 and 2. Even at the highest batch size (256), certain rounds produced high-fidelity reconstructions comparable to those at batch size 64, underscoring a persistent privacy risk. Coarser gradient aggregation therefore reduces but does not eliminate patient information exposure in FL.

XSL•FO
RenderX

In real-world medical AI deployments, even a single outlier round with high leakage could compromise patient confidentiality. Therefore, it is essential to characterize not just average-case leakage but also variability across rounds, to ensure that system-level guarantees account for worst-case scenarios.

Clinical-Concept Reference-Vocabulary Overlap in Reconstructed Text

As presented in Table 1, reference-vocabulary overlap was high and statistically indistinguishable across tokenizers: MedGemma-extracted clinical-concept overlap averaged 75.1% (GPT-2), 74.1% (RadBERT), and 72.9% (LLaMA-2) across datasets and seeds, with no pairwise difference reaching significance.

These findings demonstrate that gradient-inversion attacks can reveal not only structural sentence fragments but also clinically meaningful entities, posing a tangible privacy risk. That overlap remains high (approximately 75%) regardless of the tokenizer indicates that this leakage is intrinsic to the attack rather than a property of any particular tokenizer in federated training settings.

Table . Recovery of clinically meaningful terms from gradient-inverted reconstructions using GPT-2, LLaMA-2, and RadBERT tokenizers[a].

Tokenizer	Discharge, mean (SD)	Diagnosis, mean (SD)	MIMIC-CXR[b], mean (SD)	Pooled, mean (SD)
GPT-2	71.0 (5.7)	73.0 (3.5)	81.3 (7.1)	75.1 (7.0)
RadBERT	73.7 (5.8)	72.4 (7.9)	76.3 (7.6)	74.1 (6.8)
LLaMA-2	71.8 (7.6)	72.6 (3.0)	74.2 (10.1)	72.9 (7.0)

[a]Clinical named entities were identified via the Google MedGemma model across all 3 datasets and 5 random seeds. Values are clinical-concept reference-vocabulary overlap (%)—the percentage of each dataset's reference clinical-concept vocabulary appearing in reconstructions, a corpus-level recall measure—mean (SD); differences across tokenizers are not statistically significant. Pooled pairwise comparisons (n=15): RadBERT vs GPT-2 Δ=−1.0 pp; RadBERT vs LLaMA-2 Δ=+1.2 pp; GPT-2 vs LLaMA-2 Δ=+2.2 pp—none statistically significant.

[b]MIMIC-CXR: Medical Information Mart for Intensive Care Chest X-Ray.

Qualitative Reconstruction

Tables 2-4 showcase original and reconstructed outputs from the dischargesum, radiology, and MIMIC-CXR datasets, illustrating the clinical content recoverable across all 3 tokenizers (aggregate metrics show no significant tokenizer difference). These examples use oracle alignment for readability only: the positional ordering shown is not available to the attacker, who observes an unordered or partially ordered set of recovered tokens, so the aligned display illustrates recoverable content rather than an attacker's verbatim output. Across the reconstructions, all 3 tokenizers recovered substantial clinical content while also dropping or fragmenting individual terms; in the specific example shown, recovered entities included terms such as "catheter" and "nodularity." Which terms were retained or dropped varied from example to example, and—consistent with the aggregate analysis, which found no significant tokenizer difference—these single-example observations should not be read as a systematic tokenizer ordering. These qualitative results reinforce the quantitative findings, demonstrating that even domain-adapted transformer models remain susceptible to gradient-based inversion attacks, recovering not only template phrases but also clinically meaningful patient information.

[a]The original report and reconstructions are aligned by model. Recovered content varies across models in this single example; aggregate reconstruction metrics do not differ significantly across tokenizers (Figure 3; Table 1). The [DROP] marker indicates unreconstructed spans (native source redactions in Table 3 are preserved as asterisks). Note on alignment. The [DROP] marker indicates token positions for which the gradient-inverted reconstruction did not produce a valid token (a bin collision or numerical-instability bin). For visual clarity, these positions are aligned against the original text using oracle alignment, which the attacker does not have access to in a real attack setting; the attacker would observe an unordered or partially ordered set of recovered tokens without knowledge of where reconstruction failed. Oracle alignment is used here purely for reader interpretability and does not reflect adversary capability.

[a]MIMIC-CXR: Medical Information Mart for Intensive Care Chest X-Ray.

[b]GPT-2 and RadBERT captured anatomical and pathological keywords such as “fibrosis” and “catheter” more faithfully than LLaMA-2. In this single example, structural fidelity was higher in the RadBERT output; aggregate metrics show no significant tokenizer difference (Figure 3; Table 1). Note on alignment. The [DROP] marker indicates token positions for which the gradient-inverted reconstruction did not produce a valid token (a bin collision or numerical-instability bin). For visual clarity, these positions are aligned against the original text using oracle alignment, which the attacker does not have access to in a real attack setting; the attacker would observe an unordered or partially ordered set of recovered tokens without knowledge of where reconstruction failed. Oracle alignment is used here purely for reader interpretability and does not reflect adversary capability.

Discussion

Principal Results

This study demonstrates that even with domain-specific tokenization and larger batch sizes, transformer models in an FL setup leak substantial patient information. The active server reconstructed up to approximately 75% of radiology-report sentences. On the Discharge dataset, exact-sentence accuracy was 64.7%/46.4%/27.3% for GPT-2, 70%/50.8%/28.5% for RadBERT, and 67.5%/48.4%/27.5% for LLaMA-2 at batch sizes 64/128/256. S-BLEU similarly declined with batch size (eg, GPT-2 on discharge reports from 0.66 to 0.31), yet even at the largest batch sizes roughly a quarter of sentences were fully recovered. Across batch sizes and datasets, reconstruction fidelity did not differ significantly among the 3 tokenizers (mean exact-sentence accuracy 48.3% for each; no pairwise comparison significant). After Holm correction for the 27 pairwise comparisons, no tokenizer difference remained significant (all adjusted P=1.00), and a 3-way variance decomposition attributed 94% of the variance in exact-sentence accuracy to batch size versus less than 1% to tokenizer, corroborating batch size—not tokenizer choice—as the dominant factor; the pairwise tokenizer effect sizes were negligible (mean differences ≤0.05 percentage points; Cohen d≤0.03). All 3 tokenizers, including the domain-specific RadBERT, leaked substantial clinical content, and none eliminated leakage. These findings confirm that neither increasing batch sizes nor specialized tokenizers alone can ensure patient privacy in FL - trained LLMs.

To further disambiguate templated language from truly clinical leakage, we applied MedGemma NER to the reconstructed text across all 3 datasets. Across models, approximately 75% of reference clinical entities were recovered (Table 1). These

XSL•FO
RenderX

findings confirm that privacy risks extend beyond boilerplate phrasing to include clinical concepts relevant to diagnosis and care.

Our findings underscore that tokenizer design is not a decisive factor in privacy leakage under gradient inversion attacks. In a controlled named-entity analysis, clinical-concept reference-vocabulary overlap was statistically indistinguishable across tokenizers, with approximately 75% of each dataset's reference vocabulary appearing under each (GPT-2 75.1%, RadBERT 74.1%, LLaMA-2 72.9%; no pairwise difference significant). This indicates that domain-specific vocabulary segmentation does not, by itself, make reidentification-relevant clinical content easier to reconstruct. Within the evaluated architecture, attack, datasets, and metrics, tokenizer choice should therefore not be treated as a privacy safeguard; batch size and explicit defenses are the privacy-relevant levers. Future privacy audits and risk assessments of federated clinical models should focus on batch size and explicit defenses rather than tokenizer choice, especially as domain-specific LLMs become more prevalent in medical AI.

Hypothesized Mechanism and Why It Is Not Borne Out

We initially reasoned that domain-specific tokenization should heighten reconstruction. The reconstruction step decodes each recovered token-embedding vector back to the nearest token in the active tokenizer's embedding table. A clinical concept such as "pneumothorax" is encoded as a single token in RadBERT's domain-specific vocabulary, so a successful nearest-neighbor decode would yield the entire concept verbatim, whereas the same concept is segmented into multiple subwords (eg, "p/neu/moth/orax") in GPT-2's byte-pair encoding, where recovering it requires every subword embedding to be reconstructed correctly and placed in the correct positional order. Under this reasoning, single-token clinical terms should present fewer points of failure. We tested this prediction directly—including a prespecified analysis restricted to clinical terms that GPT-2 fragments into multiple subwords, where any single-token advantage should be largest—and found no significant tokenizer difference in exact-sentence accuracy, clinical-concept overlap, or the fragmented-term subset. The hypothesized single-token advantage is therefore not borne out empirically: across the datasets and batch sizes studied, the closed-form attack recovers clinical content at comparable rates regardless of tokenizer, and batch size is the dominant factor. This controlled negative result indicates that, in this setting, tokenizer selection should not be treated as a privacy safeguard.

Clinical Concepts Versus Directly Identifiable Protected Health Information

The MedGemma NER model used in this study captures clinical concepts (diagnoses, procedures, anatomical structures, and medications) rather than direct identifiers under the HIPAA Safe Harbor enumeration (names, medical record numbers, dates more granular than year, full-face photographic images, and so on). Direct identifiers are largely already redacted in the public Dischargesum and MIMIC-CXR corpora before release. The recovered terms therefore reflect reidentification potential through clinical context—for example, an unusually rare diagnosis, a unique procedure pattern, or a specific medication regimen that, in combination with auxiliary recovered context, could plausibly contribute to reidentifying a patient—rather than direct exposure of an enumerated identifier. We make this distinction explicit because the regulatory framing of "PHI" is broader than "direct identifier"; HIPAA's expert-determination standard (45 CFR §164.514(b)(1)) treats clinical context recoverable from a record as part of identifiability risk, and the same logic is reflected in the GDPR's notion of indirect identifiability via singling out.

Why Batch Size Reduces Leakage in This Attack

The imprint module's analytic recovery rule $\hat{x}_j = \nabla W_{,i} / \nabla b_{,i}$ relies on the assumption that bin i is activated by at most one sample in the batch. With k=1000 bins and batch size B, the expected number of samples per bin is B/k, and the probability that any given bin is hit by ≥2 samples grows approximately quadratically in B (a birthday-paradox argument). When 2 or more samples share a bin, the recovered ratio $\nabla W_{,i} / \nabla b_{,i}$ becomes a gradient-weighted average of distinct embeddings rather than a clean single-sample recovery, and the corresponding nearest-neighbor decode is corrupted. This explains why exact-sentence accuracy decays with batch size while never reaching zero: as long as some bins remain singly occupied, the corresponding samples are recovered cleanly. The same argument predicts that increasing k relative to B would partially compensate for batch growth—a direction we leave to future work.

Key Contribution

We provide the first systematic evaluation of how different transformer tokenizers impact gradient‐inversion vulnerability on radiology text, showing that domain‐specific tokenization (RadBERT) does not significantly change leakage risk relative to general-purpose tokenizers, even as it better preserves clinical terminology, whereas batch size does.

Comparison With Prior Work

Overview

Our results extend prior demonstrations of gradient-inversion attacks in generic NLP models [32,38] and imaging domains [20] to the structured and template-rich text of radiology reports. Earlier works such as DLG (deep leakage from gradients) [38] and iDLG (improved deep leakage from gradients) [39] reconstructed generic sentences or pixel-level images from shared gradients but did not examine how tokenizer design mediates privacy leakage. Subsequent privacy-preserving FL frameworks in medical imaging [18-20] primarily focused on architectural defenses rather than language-specific vulnerabilities. Unlike these approaches, our study isolates the tokenizer as a controllable privacy variable by holding the transformer architecture and training hyperparameters constant across GPT-2, RadBERT, and LLaMA-2. This tokenizer-controlled setup reveals that vocabulary segmentation alone does not significantly influence gradient-based reconstruction fidelity. This comparison against prior gradient-inversion literature is summarized in Table 5. While Akinci et al [21] first discussed text leakage risks in clinical LLMs, no prior work systematically compared multiple

XSL•FO
RenderX

tokenization schemes or evaluated reconstruction across both discharge and imaging-report corpora. Our findings therefore provide the first controlled evidence that domain-adapted tokenizers, though beneficial for clinical utility, do not measurably reduce or amplify privacy leakage in federated radiology LLMs; batch size, not tokenizer choice, governs reconstruction risk.

Table . Comparison with prior gradient-inversion studies. To our knowledge, this is the first study to explicitly hold the foundation-model architecture constant and vary only the tokenizer, in the clinical radiology NLP[a] domain.

Practical Significance

Earlier closed-form gradient inversion attacks on text models report exact-sentence recovery rates of approximately 30% - 50% at small batch sizes on generic English corpora [30,37]; our radiology-domain experiments reach comparable and, at small batch sizes, higher rates (27% - 75%), confirming that the threat extends from generic to clinical NLP and is, if anything, more severe at the strict-recovery level. The practical significance is, however, qualitatively different in the clinical setting: radiology corpora encode clinical context (diagnoses, procedure types, and anatomical findings) at higher density per token than newswire or web text, so equivalent reconstruction rates translate to higher clinical informativeness per recovered sentence. A single recovered sentence in a clinical context may contain a rare diagnosis or unusual procedure combination that contributes meaningfully to reidentification risk, whereas a single recovered sentence from generic web text typically carries no analogous reidentifying signal.

Scope of the Tokenizer Comparison

Because we hold the foundation-model architecture fixed at a small, well-characterized baseline, our findings reflect the effect of vocabulary segmentation on gradient-inversion leakage, not the privacy properties of the GPT-2, RadBERT, or LLaMA-2 foundation models themselves. Larger frontier-scale foundation models exhibit different gradient sparsity and noise dynamics that can change inversion vulnerability in either direction; we do not claim that our results extend to those regimes, and explicit characterization at frontier scale is an important target for future work.

XSL•FO
RenderX

Practical and Regulatory Implications

Focus on Attack Characterization

This study deliberately isolates the gradient‐inversion attack vector and does not evaluate or compare privacy defenses. Instead, we quantify the worst-case leakage risk under an unconstrained adversary. Subsequent work should build on these findings to empirically evaluate and optimize defense mechanisms in realistic radiology FL pipelines. Our results demonstrate that generic FL defenses such as DP [40], secure aggregation [41], and gradient‐anomaly detection have yet to be empirically validated for the structured, high‐risk text found in radiology reports. Injecting noise via DP may reduce reconstruction fidelity but requires careful calibration to avoid degrading critical diagnostic language. Similarly, cryptographic secure aggregation can obscure individual updates but may introduce prohibitive latency in hospital networks. Real‐time gradient‐anomaly detection promises early warning of inversion attacks, yet its thresholds must be tuned to the unique update patterns of clinical text to prevent both false alarms and missed breaches. Because the attack characterized here depends on the server altering the shared model graph (inserting a linear imprint probe), the most direct and low-cost safeguard is client-side model-graph integrity verification: before each local training round, clients should validate the received architecture against an expected specification and verify a cryptographic checksum of the model state and its parameter count, rejecting any model whose computation graph or parameter budget deviates. Production FL frameworks such as NVIDIA FLARE, Intel OpenFL, and Owkin Substra already expose client-side hooks and secure-provisioning mechanisms that can enforce this static computation-graph validation and attestation, making the safeguard practical to deploy today. To ensure compliance with HIPAA and GDPR, health care organizations may benefit from running pilot evaluations of these defenses under realistic conditions and document performance trade‐offs. Regulatory bodies could consider developing formal audit protocols for FL systems, encompassing threat modeling, reconstruction testing, and defense efficacy, before granting approval for clinical deployment.

Defenses and Practical Mitigations

While this study focused on characterizing gradient inversion risk, effective deployment of federated radiology models requires integrating strong privacy defenses [41]. Common mitigation strategies such as synthetic data generation [42] and DP alone remain insufficient for LLMs [43-45]. Synthetic data can leak statistical artifacts and fail to preserve downstream clinical performance [43,44], whereas DP often requires large privacy budgets to maintain utility, limiting its protective value [46].

In practice, more robust protection arises from hybrid approaches that combine secure aggregation to mask individual updates with task-tuned DP noise, gradient clipping, and auditable privacy monitoring. Cryptographic protocols such as homomorphic encryption or secure multiparty computation offer mathematically proven safeguards but may introduce computational overhead in hospital networks [47]. Future implementations of federated clinical NLP should adopt layered defenses that balance efficiency, regulatory compliance, and measurable privacy guarantees [41,47].

Limitations

This study was designed as a worst-case evaluation, assuming a fully active malicious server capable of modifying model architecture and exploiting gradient updates. While extreme, this assumption is appropriate for international or cross-consortium federated settings, where governance may be inconsistent and insider threats cannot be ruled out.

Several constraints limit the generalizability of our findings:

1. Dataset scope. We used publicly available radiology corpora (dischargesum and MIMIC-CXR), which lack multimodal components (eg, images), free-text notes, and operational metadata such as timestamps or identifiers. Future evaluations should test gradient inversion on richer, production-like datasets to better estimate clinical leakage risk.
2. Within-batch sequence correlation. Reports were split into nonoverlapping 32-token windows; multiple windows from the same report may co-occur within a single training batch. This violates the IID assumption implicit in our bin-collision analysis and may either inflate or deflate empirical reconstruction success relative to the theoretical per-token collision rate. A correlation-aware extension of the analytic inversion bound is left to future work.
3. Reference-vocabulary overlap scope. The MedGemma NER analysis was applied across all 3 datasets (discharge summaries, diagnostic reports, and MIMIC-CXR) over 5 random seeds (Table 1); overlap was high and statistically indistinguishable across tokenizers in every dataset. Because it is based on exact surface-form matching, it is a lower bound on semantic recovery, and because it is measured against a corpus-level reference vocabulary rather than the specific source report, it is an upper bound on source-aligned recovery.
4. Single reproducible experiment. All reported values—including the paired *t* tests in Multimedia Appendix 4—derive from one reproducible execution of the experimental grid, run under a single fixed configuration with the same random seeds throughout; there is no separate primary or verification experiment. The complete code and per-seed outputs are released, and every reported value can be reproduced by reexecuting the released grid.
5. Retrospective attack focus. This study focused solely on post hoc attack analysis. No privacy-preserving defenses (eg, differential privacy, secure aggregation, and anomaly detection) were implemented or evaluated. While this allows for a clean assessment of leakage potential, it leaves open questions about mitigation feasibility and deployment cost.
6. Tokenizer isolation versus full model effects. We controlled for model architecture to isolate the effect of tokenization on inversion risk. While informative, real-world systems often use both tokenizer and model coadaptation. Thus, privacy risks may be higher or lower depending on the full pipeline design.
7. Data partitioning. Our experiments use an approximately IID partition across 6 simulated clients. Real-world

XSL•FO
RenderX

cross-institutional federated deployments are typically non-IID—site-specific protocols, demographic skew, and specialty-specific report distributions can introduce heterogeneity that affects gradient sparsity and consequently inversion vulnerability. The direction of this effect is not a priori clear (non-IID gradients carry stronger per-client signal but also higher variance), and a systematic non-IID evaluation is left for future work.

8. Sequence length. The 32-token regime adopted here is shorter than typical clinical narrative passages. Longer sequences increase the input dimensionality m×L of each per-sample reconstruction, which raises the number of bins k required for unambiguous disentanglement and thereby reduces single-step reconstruction success in practice. Our reported leakage rates are therefore an upper bound for the 32-token regime; longer-sequence regimes are expected to be harder to attack with a single fixed k, all else equal. Quantitatively, the expected per-bin occupancy scales as B×L/k, so an adversary can restore single-occupancy—and hence attack efficacy—by scaling k approximately linearly with L (eg, moving from L=32 to L=512 requires roughly a 16-fold increase in k). This is a linear resource cost rather than an exponential barrier, so longer contexts do not intrinsically prevent closed-form inversion; the practical brake is detectability, since k bins enlarge the injected linear probe by approximately k×(m+1) parameters, making the larger k required for long contexts correspondingly more conspicuous to the parameter-count attestation we recommend below. Extending the analysis to longer-sequence training is left for future work.
9. Client count. Our experiments fix the simulated client count at 6, reflecting a typical small-consortium clinical collaboration. The analytic gradient-inversion attack characterized in this study operates on a single client's gradient at a single round, and the per-client per-round recovery rate is independent of the number of other clients participating in the federation. Aggregation effects across clients (which arise specifically under cryptographic secure aggregation or weighted averaging schemes that obscure individual client updates) are absent from this evaluation by design and are an explicit target for future defense-oriented work.
10. Probe placement. The imprint module is inserted immediately before the positional embedding so that token-level representations are exposed prior to any token-mixing layer (positional addition and attention). Placement at later layers would conflate tokenizer-segmentation effects with the dynamics of attention and feed-forward mixing, and would not be informative for the central question of this study. A systematic placement ablation across preembedding, postembedding, and postattention positions—holding the tokenizer fixed—would isolate the contribution of placement itself and is identified here as a target for future work.

Taken together, these limitations do not diminish the central contribution highlighting a structural vulnerability in federated clinical NLP but emphasize the need for prospective, defense-integrated evaluations in more realistic medical AI pipelines.

Future Work

Several extensions to this study are warranted. First, systematic ablation of the imprint module's placement (preembedding, postembedding, and postattention) would empirically validate the design rationale used here. Second, evaluation of differential privacy as a defense—including utility-privacy trade-off curves at multiple ε values, per-example clipping schedules, and interaction with secure aggregation—is a substantial study in its own right and is the explicit subject of our planned follow-up work. Third, extension of the reference-vocabulary overlap analysis to source-report-aligned entity recovery and to non-IID federated partitions would strengthen the external validity of the leakage estimates reported here.

Conclusions

FL holds great promise for enabling collaborative, multisite radiology AI without centralizing patient records. However, our gradient-inversion experiments demonstrate that current FL pipelines can leak substantial portions of patient text, raising significant concerns under HIPAA and GDPR standards. In worst-case scenarios, up to approximately 75% of sentences were exactly reconstructed from shared gradients, and approximately 75% of clinical entities, including diagnoses, procedures, and medications, were recovered from the reconstructed text.

Importantly, domain-adapted tokenizers such as RadBERT, while improving semantic fidelity, did not show significantly greater vulnerability to data reconstruction attacks than general-purpose alternatives such as GPT-2 and LLaMA-2. The privacy risk is substantial for all tokenizers and is governed by batch size rather than tokenizer choice.

To ensure safe deployment of federated clinical models, radiology departments and AI developers should rigorously evaluate privacy vulnerabilities in real-world settings, balancing utility with exposure risk. Regulatory bodies and standardization agencies may consider establishing clear audit pathways and certification frameworks tailored to the unique threats posed by clinical text.

Acknowledgments

The authors thank Maximilian Zenk (Division of Medical Image Computing, DKFZ) for his valuable insights during manuscript preparation. We also appreciate the guidance and prior work of Jonas Geiping and Liam Fowl in developing federated transformer methods. We acknowledge the developers of PyTorch and Hugging Face for their machine learning frameworks, and the curators of the Dischargesum dataset for enabling access to radiology report data. Generative AI tools (Anthropic Claude) were used to

Abstract

Background: Large language model–based chatbots are increasingly used by the public to access medical information. Although these tools can improve access and convenience, their quality, clarity, and transparency remain uncertain for rare and diagnostically complex neurological conditions, such as myelin oligodendrocyte glycoprotein antibody–associated disease (MOGAD).

Objective: This study aimed to evaluate the scientific quality, understandability, citation transparency, and readability of responses generated by widely used artificial intelligence chatbot platforms to a standardized, patient-centered query on MOGAD.

Methods: We conducted a cross-sectional content analysis using the query, "What is MOGAD, and how is MOGAD treated?" Ten widely accessible chatbot platforms were queried once on the same day in new sessions. Responses were anonymized and independently evaluated by 7 blinded neurologists using DISCERN (treatment-related scientific quality), Patient Education Materials Assessment Tool for Printable Materials (PEMAT-P), and the Web Resource Rating (WRR; citation transparency). Readability was assessed using the Flesch-Kincaid Grade Level (FKGL) and Coleman-Liau Index, and word count was recorded. Platforms were compared by functional orientation and the access model. Mann-Whitney *U* and Kruskal-Wallis tests with Dunn post hoc tests were used. Interrater reliability was assessed using intraclass correlation coefficients.

Results: Significant differences were observed across platforms for DISCERN, PEMAT-P, and WRR scores (all $P<.001$). Search-focused platforms achieved higher understandability than conversation-focused platforms (median PEMAT-P 52.6, IQR 47.4-54 vs 46.7, IQR 42-47.3; $P=.04$), whereas conversation-focused platforms had higher WRR scores (median 26.8, IQR 19.6-26.8 vs 19.6, IQR 19.6-25.9; $P=.001$). DISCERN scores did not differ significantly by functional orientation ($P=.11$). Paid-access platforms outperformed free-access platforms in DISCERN (median 42, IQR 36-45 vs 33, IQR 23.8-41.3; $P<.001$), PEMAT-P (median 52.6, IQR 46-54 vs 46, IQR 26.3-47.4; $P=.002$), and WRR (median 26.8, IQR 23.2-26.8 vs 10.7, IQR 3.57-19.6; $P<.001$). However, no statistically significant differences were observed between paid and free platforms in response length (median word count 336, IQR 271-369 vs 206, IQR 116-294; $P=.11$) or readability metrics. FKGL scores were comparable between paid and free outputs (median 17.54, IQR 16.6-18.4 vs 17.56, IQR 16.5-17.6; $P=.61$), and Coleman-Liau Index values similarly showed no significant difference by access model (median 21.30, IQR 20.6-22.3 vs 21.71, IQR 20.9-22.1; $P=.91$). Readability remained limited: all outputs exceeded recommended public health readability thresholds (FKGL≥8). High interrater agreement was observed (intraclass correlation coefficient=0.902 for DISCERN, 0.887 for WRR, and 0.838 for PEMAT-P).

Conclusions: Artificial intelligence chatbot responses to a patient-centered MOGAD query varied substantially in scientific quality, understandability, transparency, and readability. Search-focused systems were more understandable, whereas conversation-focused systems showed greater citation transparency. Paid-access platforms achieved higher quality and transparency

XSL•FO
RenderX

scores, without differences in readability or response length. All outputs exceeded recommended public health readability thresholds. These findings highlight the need for context-sensitive evaluation of chatbot outputs in rare and clinically complex conditions such as MOGAD.

KEYWORDS

artificial intelligence; large language models; chatbots; patient education; myelin oligodendrocyte glycoprotein antibody–associated disease; readability; health information quality; citation transparency

Introduction

Artificial intelligence (AI) is rapidly reshaping health care, influencing how patients access, interpret, and interact with medical information. One of the most visible applications of this technology is the rise of large language models (LLMs), now widely available through chatbot interfaces. These systems can generate fluent, natural-sounding responses to health-related questions, offering the promise of more accessible and personalized communication. However, the consistency, accuracy, and clarity of their responses remain uncertain, especially when the topic involves rare or diagnostically challenging conditions [1-4].

Myelin oligodendrocyte glycoprotein antibody–associated disease (MOGAD) is one such condition. It is a rare, immune-mediated disorder of the central nervous system that can present in a variety of ways, including optic neuritis, transverse myelitis, and acute disseminated encephalomyelitis [5]. The publication of international diagnostic criteria in 2023 has improved the ability to distinguish MOGAD from related disorders such as multiple sclerosis and aquaporin-4 antibody-positive neuromyelitis optica spectrum disorder [6]. Despite this progress, clinical awareness of MOGAD remains limited, and many patients and caregivers turn to online resources in search of reliable information [7,8].

In this context, AI-powered chatbots have emerged as promising tools for bridging knowledge gaps, especially for people affected by rare diseases. These platforms can offer quick, conversational responses to health-related questions, simulating interaction with a knowledgeable guide. Yet most prior studies evaluating chatbot performance have focused on common medical conditions [9,10]. Very few have investigated how these tools respond to queries about complex and less-recognized diseases like MOGAD, and even fewer have used multidimensional, validated instruments to assess the quality, clarity, and transparency of the information provided [11,12]. Furthermore, studies involving blinded expert evaluations and structured comparisons across different chatbot platforms remain limited [13,14].

To address these gaps, this study systematically evaluated the responses of ten widely used AI chatbot platforms to a standardized, patient-centered query regarding MOGAD. Using established instruments, we assessed the quality, comprehensibility, citation transparency, and readability of each response. Chatbot performance was also compared based on access model (free or paid) and functional design (chat-based or search-based). All responses were independently evaluated by experienced neurologists who were blinded to the source of each answer. This study aims to provide insight into the reliability and educational value of chatbot-generated medical content in the context of rare diseases and to inform best practices for the safe and effective use of AI in digital health communication.

Methods

Study Design, Query Selection, and Chatbot Sampling

This cross-sectional content analysis was designed to evaluate the quality, readability, comprehensibility, and source transparency of medical information generated by AI chatbot platforms in response to a standardized, patient-centered query related to MOGAD. Only publicly accessible chatbot outputs were used, and no human participants, personal health information, or clinical interactions were involved.

To identify the most relevant public-facing search terms related to MOGAD, a 5-year global search trend analysis (from May 20, 2020, to May 20, 2025) was conducted using Google Trends. The term “MOGAD” exhibited a marked increase in popularity, reflecting growing public awareness. Among the top ten co-occurring search terms, those most directly related to the disease included: “mogad disease,” “mog,” “what is mogad,” “mogad treatment,” “mogad symptoms,” and “mogad radiology.” Other common terms such as “nmosd,” “ms,” “nmo,” and “adem” were excluded because they were not specific to MOGAD.

Based on these findings, a standardized, patient-oriented question was formulated to reflect a realistic information-seeking behavior of individuals affected by MOGAD. The final query selected for evaluation was: “What is MOGAD, and how is MOGAD treated?”

This question was submitted on May 24, 2025, to ten widely accessible AI chatbot platforms. These platforms were purposefully chosen to represent diversity in model architecture, developer affiliation, and access modality (ie, free vs paid). The chatbot platforms evaluated included Copilot (Microsoft), Claude 3.5 and Claude 3.7 (Anthropic), Perplexity Pro (Perplexity AI), Grok 3 (xAI), Gemini Advanced and Gemini 2.5 Pro (Google), ChatGPT-4 and ChatGPT-4.5 (OpenAI), and DeepSeek (DeepSeek AI).

For consistency and ecological validity, each chatbot was queried only once in a newly initiated session. No follow-up prompts, rephrased questions, or clarifications were used. During data collection, all internet-browsing and retrieval features embedded within chatbot interfaces (eg, “Browse with Bing”

XSL•FO
RenderX

or comparable web access modes) were disabled. Responses were generated in newly initiated sessions using a single standardized prompt, without follow-up queries, external link clicks, or activation of plugins or tools, and the first unedited output was captured verbatim and included in the evaluation dataset.

Data Collection and Blinding Procedures

The study team consisted of 9 individuals. Two experienced neurologists (MTS and MFY) were responsible for the study design. MTS conducted a standardized training session outlining the study rationale and the evaluation instruments, while MFY remained blinded throughout the assessment phase and served as one of the independent raters.

NDÇ, who was not involved in the study design or evaluation, submitted all chatbot queries and anonymized the resulting outputs by assigning random numeric codes (1-10). These coded responses were then distributed to the evaluators without revealing the originating platforms.

Seven neurologists (MTS, MFY, DAM, MBE, PÖ, YEA, and SM), all blinded to chatbot identities, independently evaluated the anonymized responses. This group included MFY and 6 additional experts, each with at least 5 years of experience in diagnosing and managing demyelinating disorders. MTS and NDÇ were not blinded because they were directly responsible for preparing, coding, and distributing the response dataset. For transparency and reproducibility, chatbot platform names are shown in Multimedia Appendix 1; however, these identifiers were removed from the materials provided to blinded expert raters during the scoring process.

Evaluation Instruments

Each chatbot response was evaluated in its original, fully formatted, and verbatim form as generated at the time of data capture. DISCERN, Patient Education Materials Assessment Tool for Printable Materials (PEMAT-P), and WRR scoring were conducted exclusively on these unedited outputs. Validated instruments and standardized measures were applied across four domains:

1. Scientific quality: DISCERN Tool, a 16-item instrument with a 5-point Likert scale (range: 16 - 80), used to evaluate clarity, risk-benefit balance, citation of evidence, and overall reliability of treatment-related information. Higher scores indicate higher quality [15].
2. Comprehensibility: PEMAT-P (understandability domain) developed by the U.S. Agency for Healthcare Research and Quality (AHRQ), this tool measures the clarity of language, sentence structure, layout, and logical flow of information. Scores are expressed as percentages. Although PEMAT-P items are scored binarily, the overall percentage score derived from the 7 expert ratings was used as a continuous variable for the calculation of interrater reliability (intraclass correlation coefficient [ICC]) [16].
3. Source transparency: Web Resource Rating (WRR) assesses citation practices, author disclosure, source traceability, and update recency. Final scores are expressed as percentages [17]. In this study, WRR scoring was applied to the response content as presented to the user at the time of data capture. References were evaluated based on their visibility to the reader, accessibility, and explicit association with specific statements in the response text. Both hyperlink-based references and text-based citations were eligible for scoring. Hyperlinks were recorded as accessible references, whereas text-based citations were evaluated according to whether the source could be clearly identified and traced by the reader.
4. Readability: Coleman-Liau Index (CLI) and Flesch-Kincaid Grade Level (FKGL). CLI is based on character and sentence length [18]; FKGL considers word syllables and sentence structure [19]. Both metrics estimate the US grade level required to understand the text. Scores <8 indicate content appropriate for general public health communication [12]. Word counts were also recorded. For readability analysis only, URL strings, embedded hyperlinks, and reference lists were computationally removed prior to calculating word count, CLI, and FKGL in order to prevent artificial inflation of character and word counts. This preprocessing step was applied solely for quantitative readability assessment and did not affect expert scoring or the evaluation dataset.

Instrument Licensing and Accessibility

All instruments used, DISCERN, PEMAT-P, CLI, FKGL, and WRR, are freely accessible, open-source tools. DISCERN and PEMAT-P are provided by Oxford University and AHRQ, respectively. CLI and FKGL use publicly available formulas, and WRR is distributed under a Creative Commons license. This ensures transparency, reproducibility, and ethical adherence in the methodology.

Chatbot Categorization by Function and Access

For subgroup-level comparisons, chatbot platforms were classified according to 2 independent parameters: functional orientation and access model.

Functional orientation was defined based on the primary design characteristics of the chatbots. Platforms emphasizing natural dialogue, contextual flow, and conversational interaction were categorized as conversation-focused and included ChatGPT-4, ChatGPT-4.5, Claude 3.5, Claude 3.7, and Grok 3. In contrast, platforms optimized for information retrieval, structured responses, and search-enhanced outputs were designated as search-focused, comprising Copilot, DeepSeek, Gemini Advanced, Gemini 2.5 Pro, and Perplexity Pro.

The access model was defined based on the user entry cost at the time of data collection. Chatbots available without subscription or payment were categorized as free-access platforms: ChatGPT-4, Claude 3.5, Copilot, and DeepSeek. Platforms requiring a subscription or premium tier to access advanced versions were classified as paid-access, including ChatGPT-4.5, Claude 3.7, Gemini Advanced, Gemini 2.5 Pro, Perplexity Pro, and Grok 3.

Qualitative Assessment of Content Depth

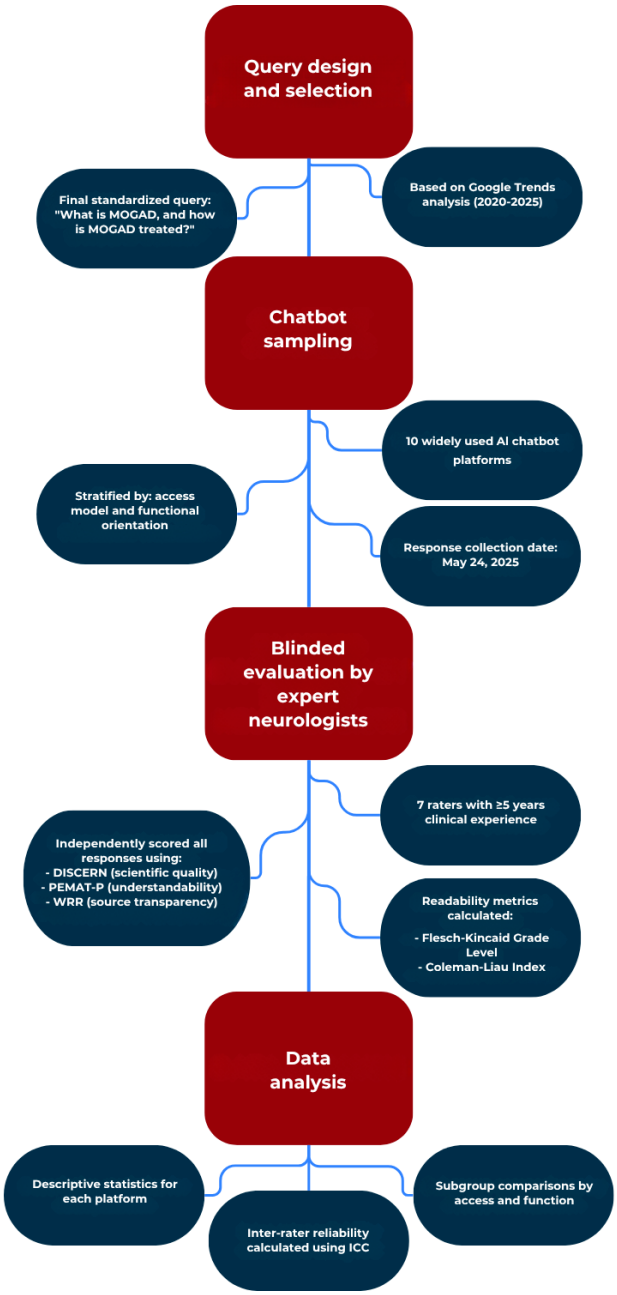
In addition to quantitative scoring, the 7 expert raters provided structured qualitative notes regarding specific content gaps (eg, absence of specific drug classes and lack of clinical nuance) for

XSL•FO
RenderX

each response. These observations were aggregated to identify recurring thematic deficiencies across platforms.

Statistical Analysis

Descriptive statistics were used to summarize chatbot performance across all predefined evaluation domains. For each AI platform, median (IQR) values and full ranges were calculated for 3 primary quality metrics: DISCERN (evidence-based treatment information), PEMAT-P (understandability), and WRR (reference transparency). Additionally, readability and response length were assessed using CLI, FKGL, and total word count.



Chatbots were further stratified by functional orientation (conversation-focused vs search-focused) and access model (free vs paid). To compare performance across these subgroups, nonparametric inferential statistics were applied. Specifically, the Mann-Whitney *U* test was used to compare median scores for DISCERN, PEMAT-P, and WRR between the 2 subgroups in each classification. Given the small subgroup sample sizes (n=5 per group), exact 2-sided tests were performed to ensure accurate *P* value estimation. Differences among multiple chatbot platforms were assessed using the Kruskal-Wallis test. For statistically significant Kruskal-Wallis results, pairwise comparisons were performed using the Dunn post hoc test with Bonferroni correction to control for the family-wise error rate. A *P* value less than .05 was considered indicative of statistical significance for all comparisons.

To assess interrater reliability, ICCs were computed for the 3 primary metrics. DISCERN and WRR scores were treated as continuous variables. Although PEMAT-P items are scored binarily, the overall percentage score derived from the 7 expert ratings was used as a continuous variable for the calculation of ICC, using a 2-way random-effects model with absolute agreement (ICC [1,2]). ICC values were interpreted according to conventional thresholds: values less than 0.50 indicate poor reliability, 0.50 - 0.75 indicate moderate reliability, 0.75 - 0.90 indicate good reliability, and values equal to or greater than 0.90 indicate excellent reliability [20].

All statistical analyses were conducted using R software (version 4.4.3; R Core Team, R Foundation for Statistical Computing) and IBM SPSS Statistics (version 25.0). The study workflow is illustrated in Figure 1, which outlines the sequential methodology involving standardized query formulation, chatbot selection, anonymized response collection, blinded expert evaluation, and statistical analysis.

XSL•FO
RenderX

Figure 1. Stepwise workflow of the study evaluating artificial intelligence chatbot responses to a standardized myelin oligodendrocyte glycoprotein antibody–associated disease query. The process includes query design, chatbot selection, anonymized response collection, expert evaluation using validated tools, readability assessment, and statistical analysis. AI: artificial intelligence; ICC: intraclass correlation coefficient; MOGAD: myelin oligodendrocyte glycoprotein antibody–associated disease; PEMAT-P: Patient Education Materials Assessment Tool for Printable Materials; WRR: Web Resource Rating.

Ethical Considerations

This study did not involve human participants, patient data, biological specimens, or any clinical intervention. All analyzed material consisted exclusively of publicly available, nonidentifiable text generated by AI chatbot platforms in response to a standardized informational query. The neurologists who served as blinded expert raters were not research participants, and no personal or identifiable information about them was collected, stored, or analyzed. Therefore, institutional ethics committee review and informed consent were not required. This determination is consistent with internationally recognized principles for research ethics, including the World Medical Association's Declaration of Helsinki. In addition, under national research ethics regulations in Türkiye, ethical review is required primarily for studies involving identifiable human participants, human data, or clinical interventions; therefore, this study does not fall within the scope requiring institutional ethics approval [21].

Results

Overview of Chatbot Performance

Descriptive statistics for chatbot performance across key quality, readability, and transparency indicators are summarized in Table 1. Statistically significant differences were observed among platforms for DISCERN, PEMAT-P, and WRR scores (all $P<.001$, Kruskal-Wallis test).

XSL•FO
RenderX

Table . Descriptive statistics of chatbot responses regarding myelin oligodendrocyte glycoprotein antibody–associated disease information quality, readability, and transparency[a].

Metric	ChatGPT-4	ChatGPT-4.5	Claude 3.7	Claude 3.5	Copilot	DeepSeek	Gemini 2.5 pro	Gemini advanced	Grok 3	Perplexity pro	*P* value
DISCERN[b], median (IQR)	38 (38-41)	36 (33-38)	36 (34-36)	24 (23.5-29)	23 (20-24.5)	48 (43.5-52)	45 (43-45.5)	44 (43-44.5)	50 (48-52)	40 (39-44)	<.001
PEMAT-P[c], median (IQR)	47.3 (46.7-47.3)	46 (46-47.3)	46 (42-50.7)	33 (29.7-33)	17 (17-21.7)	52.6 (50-54)	54 (53.3-58.5)	63 (57.8-63)	46 (46-50)	52.6 (52.6-53.3)	<.001
WRR[d], median (IQR)	23.2 (19.6-26.8)	23.2 (21.5-26.8)	26.8 (26.8-26.8)	10.7 (3.6-10.7)	2.6 (3.6-3.6)	19.6 (19.6-19.6)	23.2 (19.6-25)	23.2 (21.4-23.2)	32.1 (26.8-32.1)	26.8 (26.8-28.5)	<.001
Word count	293	260	210	110	118	295	369	419	369	303	—[e]
CLI[f]	21.42	21.10	23.16	22.41	19.22	22.00	22.53	21.49	20.23	20.48	—
FKGL[g]	17.62	16.90	18.59	17.50	13.47	17.63	18.17	18.54	16.54	16.55	—

[a]Values are presented as median (IQR) for DISCERN, Patient Education Materials Assessment Tool for Printable Materials, and Web Resource Rating, and as single values for readability indices and word count. Chatbot evaluation comparisons for applicable variables across independent groups were performed using the Kruskal-Wallis test.

[b]DISCERN indicates the quality of treatment-related information.

[c]PEMAT-P: Patient Education Materials Assessment Tool for Printable Materials.

[d]WRR: Web Resource Rating.

[e]Not applicable.

[f]CLI: Coleman-Liau Index.

[g]FKGL: Flesch-Kincaid Grade Level.

DISCERN scores, reflecting the quality of treatment-related information, demonstrated notable variability across chatbots. Grok 3 exhibited the highest median DISCERN score (median 50, IQR 48-52), followed by DeepSeek (median 48, IQR 43.5-52) and Gemini 2.5 Pro (median 45, IQR 43-45.5). Intermediate median scores were observed for ChatGPT-4 (median 38, IQR 38.0-41), ChatGPT-4.5 (median 36, IQR 33-38), and Claude 3.7 (median 36, IQR 34-36). In contrast, lower median DISCERN scores were recorded for Claude 3.5 (median 24, IQR 23.5-29) and Copilot (median 23, IQR 20-24.5).

Understandability, as assessed using the PEMAT-P, varied across chatbots, with median scores ranging from 17 (IQR 17-21.7) for Copilot to 63 (IQR 57.8-63) for Gemini Advanced. Among free-access platforms, Copilot exhibited the lowest median PEMAT-P score (median 17, IQR 17-21.7), followed by Claude 3.5 (median 33, IQR 29.7-33).

WRR scores, reflecting citation transparency, varied across chatbots. The highest median WRR values were observed for Grok 3 (median 32.1, IQR 26.8-32.1), Claude 3.7 (median 26.8, IQR 26.8-26.8), and Perplexity Pro (median 26.8, IQR 26.8-28.5). In contrast, lower median WRR scores were recorded for Copilot (median 3.6, IQR 3.6-3.6) and Claude 3.5 (median 10.7, IQR 3.6-10.7).

In terms of readability, CLI values ranged from 19.22 (Copilot) to 23.16 (Claude 3.7), while FKGL scores varied from 13.47 (Copilot) to 18.59 (Claude 3.7). All FKGL values exceeded the recommended Grade 8 threshold for public health communication. Word count ranged from 110 words (Claude 3.5) to 419 words (Gemini Advanced).

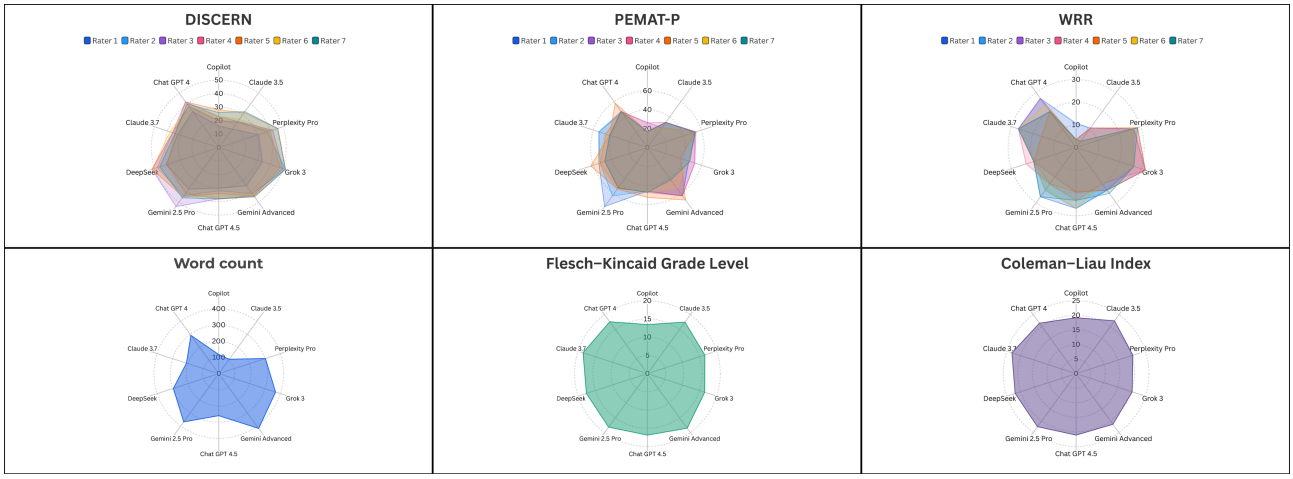
A visual summary of each chatbot's multidimensional performance across 6 metrics is provided in Figure 2, illustrating differences in content quality, transparency, readability, and response length.

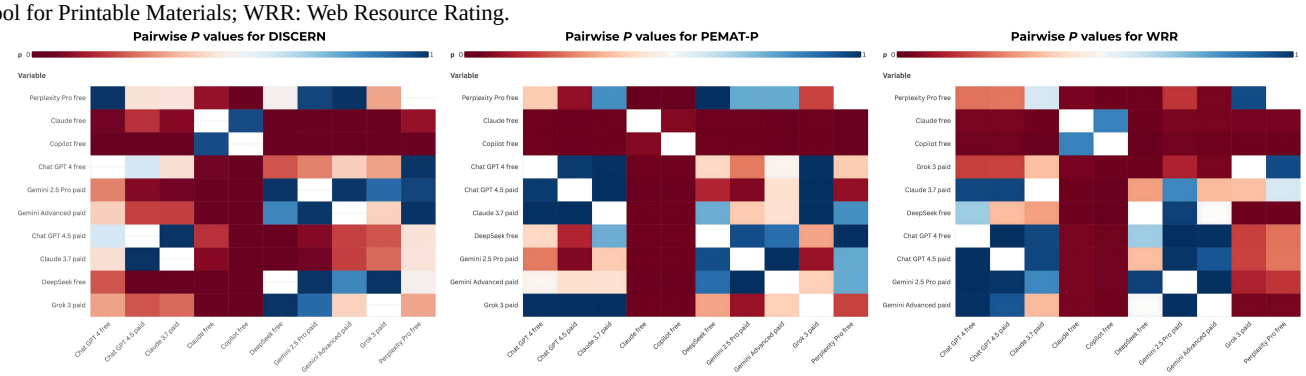
Figure 3 displays pairwise comparisons using the Dunn post hoc test following Kruskal-Wallis analysis, further emphasizing the performance variability among platforms.

The comparative readability assessment of responses generated across the 10 evaluated AI chatbot platforms is graphically presented in Figure 4.

XSL•FO
RenderX

Figure 2. Multidimensional performance profiles of ten artificial intelligence chatbot platforms in response to a standardized myelin oligodendrocyte glycoprotein antibody–associated disease query. Radar plots illustrate chatbot performance across six key metrics: DISCERN (scientific quality), Patient Education Materials Assessment Tool for Printable Materials (understandability), Web Resource Rating (source transparency), word count (response length), Flesch-Kincaid Grade Level, and Coleman-Liau Index (readability). The top row shows interrater variability for expert-rated metrics (DISCERN, Patient Education Materials Assessment Tool for Printable Materials, and Web Resource Rating), while the bottom row presents readability and length scores derived from single-response outputs. PEMAT-P: Patient Education Materials Assessment Tool for Printable Materials; WRR: Web Resource Rating.





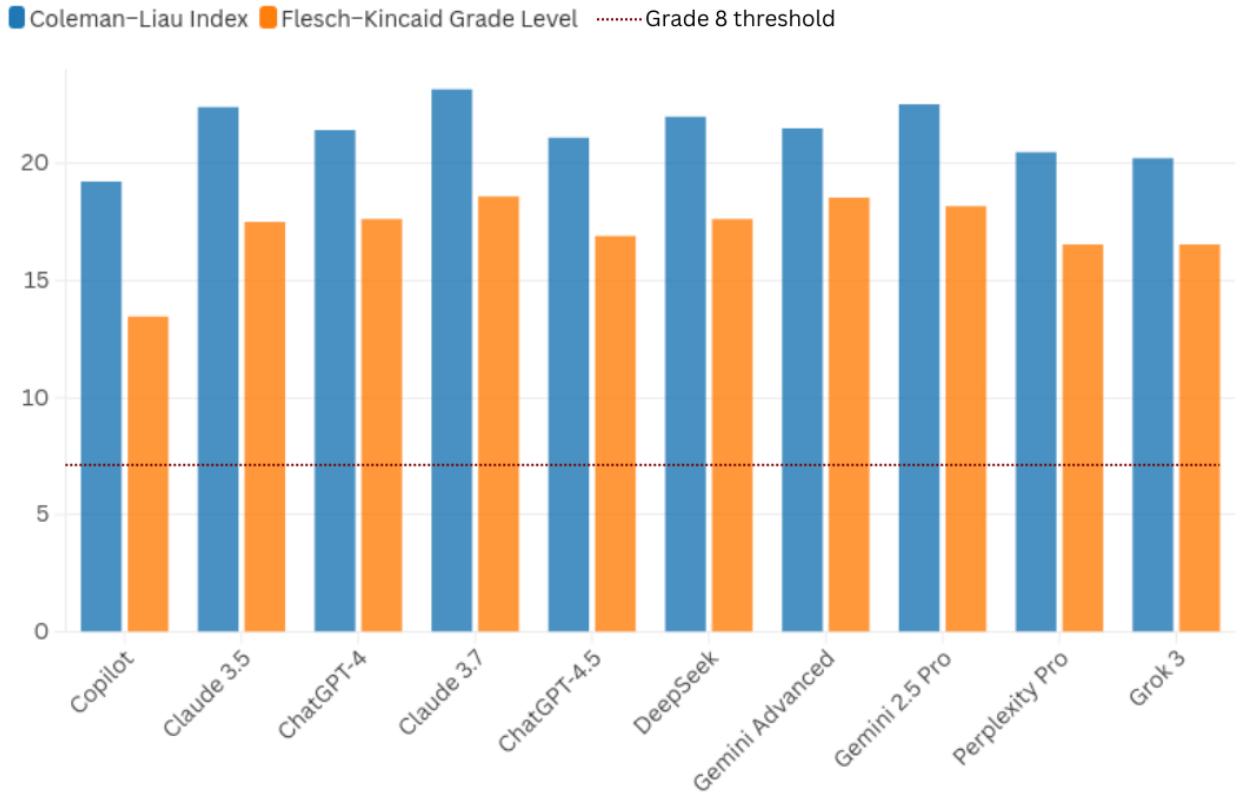


Figure 3. Pairwise statistical comparisons of ten artificial intelligence chatbot platforms across three expert-rated performance metrics (DISCERN, Patient Education Materials Assessment Tool for Printable Materials, and Web Resource Rating). This figure presents three separate heatmaps illustrating the results of the Dunn post hoc test with Bonferroni correction, which was applied following the overall significant Kruskal-Wallis test results (P<.001) across the ten evaluated chatbot platforms (n=10 platforms, assessed by seven independent expert neurologists). The heatmaps compare all possible pairs of the ten platforms based on their median scores for DISCERN (scientific quality of treatment information), Patient Education Materials Assessment Tool for Printable Materials (understandability), and Web Resource Rating (source transparency). The X-axis and Y-axis represent the ten unique artificial intelligence chatbot platforms compared in this study. The color intensity in each cell represents the adjusted P value of the pairwise comparison. Deep red tones (higher P values) indicate no statistically significant difference between the two compared platforms (P>.05), while deep blue tones (lower P values) denote a statistically significant difference in performance (P<.05). These heatmaps are essential for identifying the specific platform pairings responsible for the high overall performance variability observed in the expert-rated metrics. PEMAT-P: Patient Education Materials Assessment Tool for Printable Materials; WRR: Web Resource Rating.

Figure 4. Combined readability scores of chatbot responses based on Coleman-Liau Index and Flesch-Kincaid Grade Level. Comparative readability scores for the ten artificial intelligence platforms using Coleman-Liau Index (blue bars) and Flesch-Kincaid Grade Level (orange bars). Scores are plotted against the recommended maximum Grade 8 threshold (red dashed line) for public health communication. CLI: Coleman-Liau Index; FKGL: Flesch-Kincaid Grade Level.

Comparison Between Conversation-Focused and Search-Focused Chatbots

Performance metrics stratified by chatbot functionality are summarized in Table 2. Although search-focused models showed higher median DISCERN scores (median 44, IQR 36.5-45.5) than conversation-focused models (median 38, IQR 32.5-39), this difference did not reach statistical significance (*P*=.11).

Table . Comparison of quality, readability, and transparency metrics by functionality[a].

Metric	Conversation-focused, median (IQR)	Search-focused, median (IQR)	*P* value
DISCERN	38 (32.5-39)	44 (36.5-45.5)	.11
PEMAT-P[b]	46.7 (42-47.3)	52.6 (47.4-54)	.04
WRR[c]	26.8 (19.6-26.8)	19.6 (19.6-25.9)	.001
Word count	260 (210-293)	303 (295-369)	.21
CLI[d]	21.42 (21.10-22.41)	21.49 (20.48-22)	.75
FKGL[e]	17.50 (16.90-17.62)	17.63 (16.55-18.17)	.92

[a]Values are presented as median (IQR). DISCERN refers to the quality of treatment-related information. Patient Education Materials Assessment Tool for Printable Materials indicates understandability. Web Resource Rating reflects transparency and citation of external sources. The Coleman-Liau Index measures textual complexity; higher scores indicate more complex language. Flesch-Kincaid Grade Level represents the U.S. school grade level required to comprehend the text; higher scores denote reduced accessibility for the general public. Conversation-focused chatbots: ChatGPT-4, ChatGPT-4.5, Claude 3.7, Claude 3.5, Grok 3. Search-focused chatbots: Gemini Advanced, Gemini 2.5 Pro, Perplexity Pro, Copilot, DeepSeek. Group comparisons were performed using the Mann-Whitney *U* test.

[b]PEMAT-P: Patient Education Materials Assessment Tool for Printable Materials.

[c]WRR: Web Resource Rating.

[d]CLI: Coleman-Liau Index.

[e]FKGL: Flesch-Kincaid Grade Level.

XSL•FO
RenderX

Search-focused platforms also showed higher median PEMAT-P scores compared with conversation-focused platforms (median 52.6, IQR 47.4-54 vs 46.7, IQR 42.0-47.3). Although this difference reached statistical significance (*P*=.04), the small subgroup sample size (n=5 per group) warrants cautious interpretation. In contrast, WRR scores were higher among conversation-focused platforms than search-focused platforms (median 26.8, IQR 19.6-26.8 vs 19.6, IQR 19.6-25.9; *P*=.001).

Median word count was greater among search-focused platforms (median 303, IQR 295-369) than conversation-focused platforms (median 260, IQR 210-293), but this difference was not statistically significant (*P*=.21).

No statistically significant differences were observed between functional orientations for readability metrics, including CLI (median 21.49, IQR 20.48-22 vs 21.42, IQR 21.10-22.41; *P*=.75) and Flesch-Kincaid Grade Level (median 17.63, IQR 16.55-18.17 vs 17.50, IQR 16.90-17.62; *P*=.92).

Comparison Between Paid and Free Chatbots

Chatbots were also compared based on their access model, distinguishing between paid-access platforms and free-access platforms. Comparative performance metrics are summarized in Table 3.

Table . Comparison of quality, readability, and transparency metrics by access type[a].

Metric	Paid, median (IQR)	Free, median (IQR)	*P* value
DISCERN	42 (36-45)	33 (23.8-41.3)	<.001
PEMAT-P[b]	52.6 (46-54)	46 (26.3-47.4)	.002
WRR[c]	26.8 (23.2-26.8)	10.7 (3.57-19.6)	<.001
Word count	336 (271-369)	206 (116-294)	.11
CLI[d]	21.30 (20.6-22.3)	21.71 (20.9-22.1)	.91
FKGL[e]	17.54 (16.6-18.4)	17.56 (16.5-17.6)	.61

[a]Values are presented as median (IQR). DISCERN reflects the quality of evidence-based treatment information. Patient Education Materials Assessment Tool for Printable Materials indicates understandability based on the Patient Education Materials Assessment Tool. Web Resource Rating assesses transparency and use of external references. The Coleman-Liau Index evaluates textual complexity; higher values indicate more difficult language. Flesch-Kincaid Grade Level denotes the U.S. school grade level required for comprehension; higher scores correspond to decreased readability. Paid chatbots: Perplexity Pro, ChatGPT-4.5, Claude 3.7, Gemini Advanced, Gemini 2.5 Pro, Grok 3. Free chatbots: ChatGPT-4, Claude 3.5, Copilot, DeepSeek. Group comparisons were performed using the Mann-Whitney *U* test.

[b]PEMAT-P: Patient Education Materials Assessment Tool for Printable Materials.

[c]WRR: Web Resource Rating.

[d]CLI: Coleman-Liau Index.

[e]FKGL: Flesch-Kincaid Grade Level.

Overall content quality, as assessed by the DISCERN total score was significantly higher among paid chatbots than free chatbots (median 42, IQR 36-45 vs 33, IQR 23.8-41.3, respectively; *P*<.001). Similarly, understandability scores measured using the PEMAT-P tool were greater in the paid group (median 52.6, IQR 46-54) compared with the free group (median 46, IQR 26.3-47.4; *P*=.002).

Transparency, evaluated using the WRR, differed markedly between access models. Paid chatbots achieved substantially higher WRR scores than free chatbots (median 26.8, IQR 23.2-26.8 vs 10.7, IQR 3.57-19.6; *P*<.001), reflecting more frequent inclusion of external references and source information.

Median word count did not differ significantly between access models, although paid chatbots generated numerically longer responses than free chatbots (median 336, IQR 271-369 vs 206, IQR 116-294; *P*=.11).

For readability metrics, no statistically significant differences were observed between paid and free platforms. FKGL scores were comparable between paid and free platforms (median 17.54, IQR 16.6-18.4 vs 17.56, IQR 16.5-17.6; *P*=.61). Similarly, CLI values did not differ significantly between groups (median 21.30, IQR 20.6-22.3 vs 21.71, IQR 20.9-22.1; *P*=.91).

The comparative strengths and limitations of each AI chatbot platform evaluated in this study are summarized in Table 4, highlighting the variability in treatment quality, citation transparency, comprehensibility, and readability across different models.

XSL•FO
RenderX

Table . Summary of strengths and limitations of artificial intelligence chatbot platforms in response to a standardized myelin oligodendrocyte glycoprotein antibody–associated disease-related patient query based on DISCERN, Patient Education Materials Assessment Tool for Printable Materials, Web Resource Rating, Flesch-Kincaid Grade Level, and Coleman-Liau Index assessments.

AI[a] chatbots	Strengths	Limitations
ChatGPT-4	Freely accessible; offers moderate citation visibility (WRR[b]); designed for conversational interaction	Demonstrates only moderate performance in treatment quality (DISCERN); suboptimal understandability; exceeds recommended readability thresholds (FKGL[c] >8)
ChatGPT-4.5	Strong citation practices; consistently high-quality content regarding treatment information (DISCERN)	Textual density compromises accessibility; readability metrics exceed public health communication standards
Claude 3.5	Open-access platform; conversationally fluent interface	Among the lowest in treatment quality (DISCERN) and source transparency (WRR); limited medical detail and citation support
Claude 3.7	Integrates citations effectively; maintains coherent conversational flow	Despite improved content structure, textual complexity remains high; readability concerns persist
Grok 3	Highest overall performance across DISCERN and WRR; provides comprehensive and well-referenced responses	Subscription required; lengthy and lexically dense outputs may reduce usability for non-expert audiences
Perplexity Pro	Search-augmented design; uses structured formatting (eg, bullet points); relatively strong performance in understandability	Exhibits high linguistic complexity (FKGL and CLI)[d]; demonstrates RAG[e] errors, including acronym confusion, resulting in the inclusion of clinically irrelevant citations
Gemini Advanced	Achieved the highest score in understandability (PEMAT-P)[f]; benefits from search-enhanced architecture	Moderate citation transparency; content complexity remains above recommended readability thresholds
Gemini 2.5 Pro	Search-optimized structure; favorable DISCERN performance; clearly organized responses	Dense language and elevated FKGL scores limit accessibility; moderate citation performance
Copilot	Freely accessible; concise responses	Performed lowest in both understandability (PEMAT-P) and transparency (WRR) in this study; superficial content
DeepSeek	Freely accessible; balanced performance profile; favorable DISCERN scores; search-focused output generation	Moderate understandability and citation transparency; readability metrics exceed recommended limits for patient education

[a]AI: artificial intelligence.

[b]WRR: Web Resource Rating.

[f]PEMAT-P: Patient Education Materials Assessment Tool for Printable Materials.

Interrater Reliability Analysis

To assess the consistency of expert evaluations across chatbot-generated outputs, interrater reliability was evaluated using ICC. A 2-way random-effects model with absolute agreement (ICC [1,2]) was applied for continuous scores. The ICC for DISCERN total scores was 0.902, indicating excellent agreement among evaluators. Similarly, WRR scores demonstrated strong reliability with an ICC of 0.887. The PEMAT-P understandability scores also showed a high level of consistency, yielding an ICC of 0.838. These results suggest robust interrater agreement across all evaluated dimensions.

These findings provide a detailed snapshot of current chatbot performance across multiple dimensions and serve as a foundation for interpreting their implications in the broader context of digital health communication.

Discussion

Principal Findings

To the best of our knowledge, this is the first study to systematically evaluate chatbot-generated responses on MOGAD using a validated, multidimensional assessment framework. Across ten widely used platforms, we found statistically significant differences in scientific quality, understandability, and source transparency as measured by DISCERN, PEMAT-P, and WRR (P<.001 for all instruments). These differences were evident both between paid and free models and among chatbots with similar functional orientations. Paid-access platforms

XSL•FO
RenderX

generally demonstrated higher scientific quality and citation transparency. Grok 3, a subscription-based conversational system, consistently produced the highest scores, whereas free-access platforms such as Copilot and Claude 3.5 showed lower performance. However, performance was not determined solely by access model, and marked individual variability across platforms was evident. Importantly, all chatbots generated content that exceeded recommended public health readability thresholds according to FKGL and CLI metrics, indicating a uniformly high level of linguistic complexity across platforms. No statistically significant differences were observed between paid and free platforms in readability (FKGL and CLI) or response length. Interrater reliability among the 7 blinded neurologists was high (ICC=0.902 for DISCERN, 0.887 for WRR, and 0.838 for PEMAT-P), supporting the robustness of our evaluation protocol.

Taken together, these results demonstrate marked variability in the clarity, scientific reliability, and source transparency of AI-generated medical information on MOGAD. Notably, improvements in scientific quality and transparency did not consistently translate into greater readability or easier comprehension for general audiences. Given that patients and caregivers may rely on such tools when navigating a rare and clinically complex neuroimmunological disorder, the observed differences across platforms underscore the importance of systematically evaluating chatbot outputs before integrating them into patient-facing contexts.

Comparison With Prior Work

The performance differences we observed between paid and free access models are largely consistent with prior research. In our study, subscription-based platforms produced higher scores in scientific quality (DISCERN, $P<.001$), understandability (PEMAT-P, $P=.002$), and source transparency (WRR, $P<.001$). These findings align with studies reporting that premium systems tend to deliver more comprehensive and clinically aligned health information [12,22,23]. Such advantages may reflect differences in model architecture, update frequency, and overall technological capacity in favor of paid platforms [9].

However, higher cost does not necessarily translate into superior clarity or usability. Previous research has shown that some free access models can perform strongly, particularly in common and well-determined clinical topics. A striking example is found in the work of Şahin et al [13], who demonstrated that Copilot, the lowest scoring model across all metrics in our study, achieved the highest DISCERN score in an independent evaluation of erectile dysfunction content. This contrast illustrates how strongly chatbot performance can depend on clinical context and the formulation of the question.

Topic-dependent variability is a recurring theme in broader literature. Carlson et al [10] reported a wide range of performance across chatbots responding to vasectomy-related queries, with no platform demonstrating consistent superiority. Similar heterogeneity in accuracy, clarity, and transparency has been documented across studies involving sarcoidosis, chronic rhinosinusitis, appendicitis, benign anorectal disorders, and dental implantology [11,23-26]. In line with these observations, our analysis shows that variability becomes even more pronounced in MOGAD, a rare and phenotypically heterogeneous neuroimmunological disorder. The limited availability of high-quality open-access resources on MOGAD may further contribute to narrower or less comprehensive responses generated by certain models.

Across published evaluations of AI chatbots, a model's functional orientation plays a central role in shaping the structure, clarity, and reliability of the medical information it produces. Studies conducted in areas such as sarcoidosis, chronic rhinosinusitis, appendicitis, and dental implantology consistently show that search-focused systems tend to generate more structured and easily navigable content that incorporates bullet points, subheadings, and hierarchical formatting [11,23-25]. In contrast, conversation-focused models typically provide a smoother narrative flow and stronger contextual coherence, allowing users to follow complex medical explanations more intuitively [13,24,27]. Our findings reflect this broader pattern: search-oriented platforms achieved higher PEMAT-P scores, while conversational systems demonstrated stronger WRR performance by integrating citations in a manner that was more consistent with the surrounding text.

Previous research also highlights a recurring vulnerability among search-focused platforms that rely on retrieval-augmented generation. Although these models often supply a larger number of citations, their references may not consistently align with the clinical context, and some may be only partially related to the queried topic [28]. In our study, this limitation was most clearly illustrated by Perplexity Pro, which achieved high WRR scores yet produced retrieval-related errors, including acronym confusion between "MOGAD" and unrelated terms such as "Monad." This resulted in the inclusion of clinically irrelevant sources, including pharmaceutical products and conditions unrelated to neuroimmunology.

This finding underscores an important methodological limitation of the WRR instrument when applied to AI-generated content. WRR captures the visibility and quantity of cited web resources, but it does not assess the clinical appropriateness or accuracy of those citations. As a result, high transparency scores may coexist with retrieval errors that carry potential patient safety implications, particularly in search-based chatbots.

Conversely, while conversation-focused systems tend to produce more coherent narratives, they may be more prone to hallucinating mechanistic or treatment-related details when faced with topics that are uncertain or poorly represented in the literature [29]. Collectively, these findings indicate that each functional orientation carries distinct strengths and limitations. For rare and clinically heterogeneous conditions such as MOGAD, effective patient communication may require a balanced approach that draws on the structural advantages of search-focused models and the contextual strengths of conversational systems.

In our study, readability emerged as a consistent limitation across all platforms. As illustrated in Figure 4, every chatbot generated FKGL and CLI scores exceeding the recommended Grade 8 threshold for public health communication, indicating that the linguistic complexity of these outputs may pose

XSL•FO
RenderX

challenges for users with limited health literacy. Similar findings have been reported in previous evaluations, where chatbot-generated medical information frequently exceeded recommended reading levels [11,12,23,24,27]. Taken together, the evidence suggests that elevated readability demands constitute a structural characteristic of current language models rather than a condition-specific exception.

For MOGAD, the implications of this burden are likely amplified. As a rare and clinically heterogeneous neuroimmunological disorder, MOGAD requires nuanced explanations of diagnostic criteria, relapse patterns, and treatment approaches, which may already be difficult even for medically literate users. When this level of clinical complexity is expressed through dense vocabulary and abstract phrasing, the cognitive load on patients and caregivers increases substantially. This interaction between disease complexity and high readability demands may heighten the risk of misunderstanding, false reassurance, or overly simplified self-directed interpretations. Ensuring that chatbot-generated information is linguistically accessible, therefore, remains essential for improving the safety and usability of AI-based medical communication in neuroimmunology.

Limitations

This study has several limitations. First, the analysis was based on a single standardized patient query, which strengthened internal validity but limited generalizability to the more varied and interactive ways patients seek information in real-world settings. Second, only English-language outputs were evaluated, so performance in other languages or multilingual models remains uncertain. Third, chatbot responses were collected on a single day to minimize temporal drift, yet LLMs evolve rapidly, and their performance may change with future updates. Fourth, although validated instruments such as DISCERN, PEMAT-P, and WRR provided a structured basis for comparison, these tools were developed for traditional static educational materials and may not capture the dynamic and adaptive features of AI-generated content. Finally, we did not perform a formal qualitative or thematic analysis, meaning that nuanced impressions about clinical depth or emphasis were not systematically assessed.

Future Directions

Future research should adopt evaluation designs that better reflect how individuals seek health information in real-world settings. Because this study used a single standardized question, future work would benefit from multiscenario approaches that incorporate sequential prompts, follow-up queries, and patient-specific contexts. Such designs may offer a more realistic understanding of how chatbots manage evolving information needs and uncertainty, particularly in complex neuroimmunological disorders such as MOGAD.

There is also a need for tools specifically developed to assess AI-generated medical content. While DISCERN, PEMAT-P, and WRR remain valuable, they were designed for static patient education materials and do not fully capture the adaptive and conversational nature of LLMs. Future metrics should evaluate hallucination risk, citation quality, internal consistency, and clinical safety. They should also integrate usability testing with patients and caregivers to clarify how tone, framing, and readability influence understanding.

Multilingual and culturally sensitive assessments represent another important direction. As chatbots expand globally, their performance across different languages, health systems, and literacy levels should be examined to identify potential disparities in access to reliable online health information. Longitudinal evaluations will also be important, as rapid updates to model architecture may lead to meaningful changes in accuracy and transparency over time.

Finally, incorporating qualitative methods such as thematic or discourse-level analysis may provide deeper insight into how chatbot responses structure complex concepts, communicate uncertainty, and present risk–benefit information. Blending qualitative insights with quantitative scoring may support the development of safer and more clinically meaningful AI tools for individuals seeking information about MOGAD and other rare neurological disorders.

Conclusions

This study provides a multidimensional evaluation of AI chatbot responses to a patient-centered MOGAD query and demonstrates marked variability across platforms in scientific quality, understandability, transparency, and readability. Paid-access models achieved significantly higher scores in scientific quality, understandability, and citation transparency, whereas search-focused systems showed modest but statistically significant advantages in understandability, highlighting a trade-off rather than uniform superiority across model types. Importantly, all evaluated chatbots produced content exceeding recommended readability thresholds, indicating persistent barriers to linguistic accessibility, particularly for patients and caregivers navigating a rare and clinically complex disorder.

These findings underscore that strong citation practices or higher transparency scores do not necessarily guarantee clinical relevance or usability, and that current evaluation instruments may incompletely capture risks specific to AI-generated medical content. For rare diseases such as MOGAD, ensuring safe and patient-centered use of chatbots will require assessment frameworks that better account for readability, contextual accuracy, and potential retrieval-related errors, alongside traditional measures of quality and transparency.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request. The source material consisted of chatbot responses obtained from publicly accessible platforms and anonymized prior to expert evaluation. No human participant data were collected or analyzed in this study.

Authors' Contributions

MTS and MFY conceived the study and planned its overall design. DAM contributed to the development of the study methodology. NDC submitted all chatbot queries, collected the raw outputs, and anonymized the responses. MFY, DAM, MBE, PÖ, YEA, ERK, and SM participated in the evaluation process as blinded expert raters. Data analysis and interpretation were performed by MTS and MFY. The manuscript was drafted by MTS and MFY and critically revised by all authors for important intellectual content. All authors approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Most clinically relevant information in emergency department (ED) visits is documented in free text, limiting reuse for research and clinical decision support. Despite growing interest in large language model (LLM)–based feature extraction, very few studies have examined it directly on ED reports. Existing work has mainly addressed binary tasks and rarely evaluated their impact on downstream prediction models. Furthermore, evidence for small multilingual LLMs remains limited, especially for underrepresented languages such as Dutch. Locally deployable LLMs could enable automated feature extraction for decision support systems without increasing physician workload.

Objective: We aim to evaluate whether a small open-source LLM (Qwen 2.5:14B) can automatically extract 16 clinical signs and symptoms from ED reports and use these as input for an appendicitis prediction model. LLM performance under minimal and optimized 0-shot prompts was assessed against researcher annotations (reference standard) and physician annotations.

Methods: This retrospective study used 336 ED reports from patients presenting with acute abdominal pain to a Dutch teaching hospital (2016-2023). One hundred reports were randomly selected to develop a minimal and an optimized 0-shot prompt strategy. The remaining 236 reports, reserved for evaluation, were annotated by 2 ED physicians and processed by the LLM to extract 16 signs and symptoms, covering binary, multiclass, and multilabel classification tasks. These features were used as input to the HIVE (History, Intake, Vitals, Examination) appendicitis prediction model. LLM extraction accuracy, sensitivity, and specificity were measured against the researcher's (reference standard) and physician annotations. The HIVE model's area under the receiver operating characteristic curve was evaluated using LLM-extracted vs physician-annotated features.

Results: Among 336 ED reports from patients with acute abdominal pain (median age 41, IQR 22 - 62 years, 205/336, 61% female), 50% (167/336) had appendicitis. The LLM achieved weighted average accuracies of 0.910 (95% CI (0.018) with minimal prompts and 0.929 (95% CI ±0.016) with optimized prompts, vs 0.961 (95% CI ±0.012) and 0.951 (95% CI ±0.015) for physicians. Corresponding HIVE model area under the receiver operating characteristic curves were 0.871 (95% CI ±0.019) and 0.911 (95% CI ±0.014) with LLM inputs under the minimal and optimized prompts, compared to 0.917 (95% CI ±0.015) and 0.924 (95% CI ±0.018) for physician inputs.

Conclusions: A small locally deployable multilingual LLM can approach physician-level accuracy in extracting structured binary, multiclass, and multilabel clinical data from free-text Dutch ED reports, while preserving patient privacy, interpretability, and statistical transparency for downstream diagnostic modeling.

KEYWORDS

large language models; natural language processing; electronic health records; machine learning; predictive modeling; health informatics; emergency medicine

Introduction

In the emergency department (ED), clinical information is primarily documented as free-text. While this documentation style aligns with routine clinical practice, it presents challenges for reusing data in research and decision support applications [1-5]. Structured templates in the electronic health record (EHR) system offer a common workaround, but impose extra workload on already time-pressed ED physicians and are rarely adopted in practice [6,7]. Automated feature extraction using natural language processing (NLP) offers a more sustainable alternative. To date, extracting clinical data from ED reports has primarily relied on long short-term memory and BERT (Bidirectional Encoder Representations From Transformers) models, which perform reasonably well but require extensive preprocessing, large manually annotated corpora, and model retraining [8-10].

Generative pretrained large language models (LLMs) present an alternative, as they can be optimized using only prompting, making them more accessible for downstream tasks. While these LLMs have proved effective in extracting diverse features from radiology and pathology reports [11-13], their use in automated feature extraction from ED reports is limited. Unlike radiology or pathology reports, ED reports contain extensive abbreviations, succinct phrasing, and domain-specific terminology, presenting unique challenges to NLP. Recent work has begun to explore LLM-based information extraction in emergency medicine. McMurry et al [14] demonstrated LLM-based identification of binary respiratory symptoms using 0-shot prompting and multicenter validation, while Bejan et al [15] phenotyped symptomatic kidney-stone presentations using a range of prompting and fine-tuning strategies. Gao et al [16] used LLM-generated severity scores, supported by in-context learning and retrieval-augmented generation, to improve early triage predictions. Collectively, recent studies demonstrate the potential of LLM-based feature extraction from ED reports. However, these efforts primarily addressed binary outcomes or limited symptom sets, or did not investigate the downstream impact on diagnostic model performance. Prior work also relied mainly on large LLMs or Chinese bilingual LLMs, leaving open whether smaller multilingual LLMs can perform reliably in underrepresented languages [17]. This is particularly relevant for the Dutch, where the inherent complexity of ED reports is compounded by limited representation in LLM training corpora.

This study addresses these gaps by evaluating whether a small multilingual LLM (Qwen 2.5:14B) can automatically extract binary, multiclass, and multilabel clinical features from Dutch ED reports and provide reliable inputs for a downstream prediction model. Our focus is a clinically relevant use case: acute abdominal pain (AAP). Extracted features are used as input for the HIVE (History, Intake, Vitals, Examination) model, a previously established appendicitis prediction model based on 16 contributing clinical signs and symptoms [18]. These features were originally annotated manually, a process that is labor-intensive and difficult to scale. This study evaluates whether an LLM can automate this extraction and produce comparable inputs by developing and validating two 0-shot prompting strategies. Secondary outcomes included comparison to physician annotations and assessing the appendicitis prediction model using LLM-extracted vs physician-annotated features. We hypothesize that, with appropriate prompting, a small locally run multilingual LLM could achieve near-expert accuracy in feature extraction and maintain comparable predictive models' performance, supporting the feasibility of a scalable, privacy-preserving workflow for decision support systems at the ED.

Methods

Data Collection

Data from 350 patients with AAP were retrospectively collected at Jeroen Bosch Hospital, a Dutch teaching hospital, between July 2016 and January 2023. Patient inclusion criteria and cohort construction are detailed in our previous study [18]. This dataset included 167 appendicitis cases with 169 other AAP presentations. Among other AAP presentations, those suspected of appendicitis were balanced with those having nonspecific or other AAP causes based on initial ED assessments by triage nurses or referring physicians. Cases lacking sufficient medical history or physical examination data or missing more than 70% (n=14) of vital signs were excluded, resulting in 336 cases. Each case contained triage and intake data, vital signs, and the medical history and physical examination sections. Further cohort details are in Supplemental Tables 1A-E of our previous publication [18]. No exclusions were made based on age, comorbidities, medication use, or symptom presentation. Data were extracted and pseudonymized using CTcue (IQVIA Nederland B.V.).

Study Design

All 336 ED reports were independently annotated by 2 lead researchers to establish the reference standard for 16 clinical signs and symptoms, as previously described [18] (Multimedia Appendix 1). Interrater agreement, assessed on a random sample of 80 reports, demonstrated high reliability, with average Krippendorff α values of 0.93 for binary features and 0.95 for the multiclass feature, and an average Jaccard similarity of 0.76 for multilabel features. The 16 features were derived from our previous HIVE model, in which XGBoost (Extreme Gradient Boosting) and SHAP (Shapley Additive Explanations) analyses were used to identify features contributing more than 95% of the model's predictive output (Multimedia Appendix 2). Their discriminative performance was previously assessed using the area under the receiver operating characteristic curve (AUROC) to determine the optimal feature set. The final selection comprised 11 medical history and 5 physical examination features, covering 8 binary, 1 multiclass, and 7 multilabel outputs.

LLM-based feature extraction using a 0-shot prompting strategy was chosen over conventional tokenization-based text

XSL•FO
RenderX

classification because the goal was to extract clinically meaningful variables and integrate them with structured vital signs and intake information directly available from the EHR. Traditional token-based NLP methods focus on identifying or classifying text spans and cannot reliably capture negation, multilabel outputs, or nuanced clinical context, and typically provide token-level outputs that obscure the contribution of specific clinical findings. This reduces interpretability and alters feature-importance patterns (eg, via SHAP), limiting transparency and alignment with the structured design of the HIVE model.

For the present analysis, 100 reports were used to optimize two 0-shot prompting strategies for extracting these features using an LLM. Zero-shot prompting directly instructs the LLM without examples [19]. The remaining 236 reports were reserved to evaluate manual labeling by 2 ED physicians and automated extraction by the LLM (Figure 1A).

These reports were also used for the HIVE appendicitis prediction model. Of the 336 reports, 268 had previously been labeled by the lead researchers and were used for model training and tuning. The remaining 68 reports, drawn from the 236 physician-labeled and LLM-processed reports for evaluation, served as 4 identical validation sets (Figure 1B). This validation set was selected before model development, contained no cases used in LLM prompt construction or hyperparameter tuning, and matched the validation size used in our previous study [18]. This ensured a fully independent and consistent benchmark for assessing the effect of LLM-based feature extraction on downstream model performance. Given the modest dataset size (n=336) and single-center design, this study aimed to evaluate feasibility rather than generalizable performance. The results should therefore be interpreted as proof-of-concept.

Workflow and Prompting Strategies

The primary objective of this study was to evaluate the LLM's automated extraction of 16 clinical signs and symptoms from ED reports, all of which contributed to our ML (HIVE) model (Multimedia Appendix 2). To that end, a 4-step workflow was implemented (Figure 2). First, ED reports were compiled into a JSON file. Next, a base prompt was designed, consisting of an instruction specifying which symptom or sign to extract and an output with a predefined set of answer options. From this base prompt, two 0-shot prompting strategies were derived. The minimal prompt strategy extended the base prompt with a limited set of essential clarifications, identical to the annotation rules provided to ED physicians to ensure equal comparison. The optimized prompt strategy further integrated additional elements aimed at steering performance, including broader context (artificial intelligence [AI] persona and report type), additional instructions (section limitations, and negations or constraints of symptoms), and specific context (domain-specific terminology or abbreviations, and symptom explanations). To quantify the contribution of individual elements, an ablation study was conducted at the start of the study on a development set of 100 ED reports. Each element was sequentially added to the base prompt, and performance was compared against the researcher's annotations. Only elements that improved performance were included in the optimized prompt. Both prompts used the same annotation rules; any differences between them are due to the prompt design, not to different instructions. All prompts and reports were provided to the LLM in Dutch. The LLM processed each report from the development (n=100) and evaluation sets (n=236), producing structured output in JSON format. The JSON format consisted of a pseudonymized patient identifier, the name of the target symptom, and the predefined answer options of the target symptom (eg, {"uid": "82547948A6A5E91B93B2BAACAE3F943508FD7EFA," "abdominal pain location": ["right lower quadrant," "diffuse"]}). Third, features extracted from 68 of 236 evaluation reports were combined with structured intake data and vital signs. Finally, these datasets were used for ML model validation. The remaining 268 cases, annotated by the research team, were used for developing the ML model.

Figure 2. Modular workflow for extracting clinical signs and symptoms using a local LLM, followed by appendicitis prediction. ED reports in JSON format (1) were processed using a base prompt (0-shot) (2A) containing an instruction and predefined output format. From this base, two prompting strategies were derived (2B): a minimal prompt, which included essential clarifications also provided to ED physicians for equal comparison, and an optimized prompt, integrating additional elements that were sequentially evaluated through an ablation study. Feature outputs from both strategies were combined with ED intake and vital-sign data (3) and entered into the HIVE ML model to predict appendicitis (4). AI: artificial intelligence; ED: emergency department; HIVE: History, Intake, Vitals, Examination; LLM: large language model; ML: machine learning.

LLM Selection

In December 2024 and January 2025, four popular LLMs available on the Ollama platform were evaluated using 4 representative features varying in complexity and output type. Selected models, Mistral-Nemo 12B Instruct [20], Qwen2.5:14B [21], DeepSeek R1:14B distilled from Qwen2.5 [22], and Gemma2:9B [23], were chosen for their multilingual capabilities, input length, and compact size (<10 GB), allowing deployment on a 12 GB GPU laptop without requiring connection to a computational cluster, which may be impractical in ED settings.

After evaluation, Alibaba's Qwen2.5:14B Instruct was selected based on performance on the development set (n=100). All LLMs were assessed on the same data, prompts, and settings (eg, temperature=0.1), supporting deterministic output [24]. Ollama was chosen for its capability to facilitate local LLM deployment. The underlying LLM extraction tool for this study is available in a repository (10.6084/m9.figshare.28931030)

XSL•FO
RenderX

and on GitHub [25] with a complete walkthrough to adopt the framework and tooling, and incorporates components from a previously published data extraction repository [26].

Postprocessing of LLM Outputs

LLM outputs were checked against the predefined answer options. To mimic daily practice, where manual postprocessing is infeasible, responses outside these options were removed. Occasionally, the LLM returned descriptive terms accurately copied from the ED report but not listed among the predefined answers. These nonconforming terms were removed, and the feature was labeled as "not reported." All performance metrics presented reflect this postprocessing step.

Reader Study–Manual Labeling

A reader study was conducted to compare LLM outputs, under the minimal and optimized prompt strategies, with manual labeling of 2 ED physicians using the same evaluation set (n=236). Each ED report was presented in its original format and independently reviewed by 2 ED physicians, one with 2 years of residency experience and one with 5 years of postqualification experience. Physicians labeled 16 clinical signs and symptoms using an Excel (Microsoft Corp) spreadsheet. Predefined answer options matched those given to the LLM and were provided as drop-down menus: single-choice for binary and multiclass features, and multiple-choice for multilabel features. If a sign or symptom was absent or not reported, the field was left blank.

Statistical Analysis

LLM- and physician-labeled features were evaluated using specificity, sensitivity, and accuracy. The HIVE model's performance was assessed via AUROCs. For multiclass and multilabel features, LLM performance metrics were calculated for each positive class and averaged over all positive classes. 95% CIs were estimated through bootstrapping with replacement.

ML Model Development and Validation

An XGBoost (version 2.1.1) algorithm was selected to estimate the probability of appendicitis, following the approach described in our previous study [18,27]. Referred to as the HIVE model, it incorporates ED intake information, vital signs, medical history, and physical examination features. As explained in this study's design, only routinely measured vital signs and intake information, combined with medical history and physical examination features that contributed most to our previous HIVE model, were included in this model. Following the same set-up, 336 cases were divided into 268 cases for training or tuning (researcher-labeled), and 68 validation cases relabeled by the LLM, under 2 prompting strategies, and by 2 ED physicians. This allowed comparison against the original reference annotations.

For model tuning, repeated stratified 10-fold cross-validation was used to preserve class distributions. Categorical parameters were encoded using CatBoost (version 2.6.3) into numerical representations derived from training data [28,29]. Hyperparameters were optimized to maximize AUROC using Bayesian optimization with Optuna (version 3.6.1) over 100 trials [30]. The optimized hyperparameters were a learning rate (η) of 0.012, a maximum tree depth of 3, a minimum sum of weights in a child of 4, a subsample ratio of features for each tree of 0.64, and 156 boosting rounds. Class weights were not adjusted, given that the dataset was approximately balanced (167 appendicitis vs 169 other AAP causes). Feature contributions to model predictions were quantified using TreeSHAP (version 0.46.0). To examine whether downstream performance depended on model choice, we trained a random forest on the same 236 researcher-labeled cases and evaluated it on the same 68-case validation set using the LLM-extracted features. Preprocessing matched the HIVE pipeline, with numeric missing values imputed using an Iterative Imputer (max_iter=10) for compatibility with the random forest model. A standard configuration was used (n_estimators=500, max_depth=None, bootstrap=True). The TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) checklist was followed to ensure methodological transparency (Checklist 1), and all code including the LLM extraction tool are available via figshare (10.6084/m9.figshare.28931030).

Ethical Considerations

This study was conducted according to the Declaration of Helsinki and Guidelines for Good Clinical Practice. The execution of this retrospective observational study of patient records was approved by the local review board of the Jeroen Bosch Hospital (number 2023.11.22.02), and was judged by the Medical Research Ethics Committee Brabant, which waived this study to be subject to the regulations of the Dutch Medical Research Involving Human Subjects Act, including a waiver of informed written consent and a consent for publication (Medical Research Ethics Committee number NW2024-05) [31].

Data were extracted from the EHR using CTcue (IQVIA) and handled in a pseudonymized manner. No directly identifiable patient information was accessed by the researchers. Data extraction and analysis were performed in a secure environment in accordance with institutional and European and national data protection regulations. Participants received no compensation.

Results

Overview

Among 336 patients with AAP (median age 41, IQR 22 - 62 years, 205/336, 61% were female), 50% (167/336) had appendicitis (Table 1, Table 2). Reports were authored by various physicians over 7 years. Feature prevalence ranged from 6% (n=20) for pollakiuria to 91% (n=303) for pain location (Table 3).

Ablation Study

An ablation study on the development set (n=100) quantified the contribution of individual prompt elements (Tables 4-6). Sequentially adding each element to the base prompt showed the largest performance gains for negation or constraint, domain-specific context, and explanation, while section limitation, AI persona, and report type produced smaller and less consistent improvements across features (Tables 5 and 6). These findings are incorporated into the composition of the optimized prompts (Table 4). Some clarifying elements, particularly negation or constraint elements, were also integrated into the minimal prompt to ensure an equal comparison with manual annotations by ED physicians. Certain elements were not applicable to specific features (eg, when no negation or explanation was possible) and are therefore left blank in Tables 5 and 6. Table 7 lists the minimal prompts used to extract each of the 16 features; these incorporate the same annotation rules that were provided to ED physicians. Table 8 presents the corresponding optimized prompts, which integrate the prompt elements identified in the ablation study as improving extraction performance. Multimedia Appendix 3 presents all prompt elements evaluated for each feature in the ablation study.

[a]Each prompt element shows the isolated incremental effect compared to the base prompt.

[b]Element retained in the minimal prompt configuration. (Additional instruction shared with physician)

[c]Element retained in the optimized prompt configuration.

[d]Prompt element was not applicable and evaluated for that specific variable.

XSL•FO
RenderX

Table . Minimal 0-shot prompts as presented to the LLM.[a]

	Feature	Prompt[b]
1	Abdominal pain location	Report where abdominal pain is present in this patient. If multiple locations of abdominal pain are mentioned, report the most painful location (PM[c]).[d] Limit your answer to the following options: “right lower quadrant,” “right upper quadrant,” “left lower quadrant,” “left upper quadrant,” “entire upper abdomen,” “entire lower abdomen,” “entire left abdomen,” “entire right abdomen,” “periumbilical,” “epigastric,” “hypogastric,” “diffuse,” or “absent.” Report “absent” if abdominal pain is not mentioned or explicitly absent.
2	Nausea	Report whether this patient has nausea based on the last status in the report. Ignore vomiting. Vomiting is not the same as nausea.[d] Limit your answer to the following options: “yes” or “no.” Report “no” if nausea is not mentioned or explicitly absent.
3	Development of complaints	Report whether there is an increase or decrease in the development of complaints after the onset in this patient. A decrease in the development of complaints occurring after the administration of pain medication must be ignored and should not be reported as a decrease.[d] Limit your answer to the following options: “increase,” “decrease,” or “not reported.” If none of the mentioned options are explicitly stated in the text, the answer should be “not reported.”
4	Onset of pain	Report whether there is a description of how the onset of pain started in this patient. Limit your answer to the following options: “acute,” “gradual,” or “not reported.” If none of the mentioned options are explicitly stated in the text, the answer should be “not reported.”
5	McBurney’s sign	Report whether this patient has abdominal pain at McBurney’s point. If McBurney’s sign is dubious, report “no.”[d] Limit your answer to the options: “yes” or “no.” Report “no” if abdominal pain at McBurney's point is not mentioned or explicitly absent.
6	Rebound tenderness	Report whether this patient has rebound tenderness. Ignore contralateral rebound tenderness.[d] Limit your answer to the options: “yes” or “no.” Report “no” if rebound tenderness is not mentioned or explicitly absent.
7	Anorexia	Report whether this patient has anorexia. Limit your answer to the options: “yes” or “no.” Report "no” if anorexia is not mentioned or explicitly absent.
8	Pain migration to the right lower quadrant	Report whether the abdominal pain has migrated to the right lower quadrant in the patient. Limit your answer to the options: “yes” or “no.” Report “no” if migration to the right lower quadrant is not mentioned or explicitly absent

XSL•FO
RenderX

	Feature	Prompt[b]
9	Fever	Report whether this patient has a fever. Limit your answer to the options: “yes” or “no.” Note that the term may not be mentioned exactly as written. Yes=recorded elevated temperature, feeling of fever, measured fever, feverish, temperature or “T” of 38°C or higher. No=temperature or “T” of 37.9°C or lower, no fever, not feverish, no elevated temperature.[d] Report “no” if fever is not mentioned or explicitly absent.
10	Abdominal inspection	Report whether any abnormalities are noted in the inspection of the abdomen for this patient. Limit your answer to the following options: “adipose,” “distended abdomen,” “scars,” “no abnormalities,” or “not reported.” If none of the mentioned options are explicitly stated in the text, answer “not reported.”
11	Pollakiuria	Report whether this patient has pollakiuria. Limit your answer to the options: “yes” or “no.” Report “no” if pollakiuria is not mentioned or explicitly absent.
12	Stool consistency	Report whether stool consistency is described for this patient. Limit your answer to the following options: “diarrhea,” “loose,” “normal,” “stiff/obstipation,” or “not reported.” If none of the mentioned options are explicitly stated in the text, answer “not reported.”
13	Pain location	Report where the pain initially started in this patient. Ignore pain resulting from displacement, migration, or radiation. Ignore abdominal tenderness. Ignore findings from the physical examination.[d] Limit your answer to the following options: “right lower quadrant,” “right upper quadrant,” “left lower quadrant,” “left upper quadrant,” “entire upper abdomen,” “entire lower abdomen,” “entire left abdomen,” “entire right abdomen,” “around the navel,” “epigastric,” “hypogastric,” “diffuse,” “bilateral flanks,” “right flank” “left flank,” and “absent.” Report “absent” if the location where the pain initially started is not mentioned.
14	Pain manifestation	Report whether this patient has a specific abdominal pain pattern. Limit your answer to the following options: “attack wise,” “continuous,” or “not reported.” If none of the mentioned options are explicitly stated in the text, answer “not reported.”
15	Nature of pain	Report whether the nature of pain is described for this patient. Limit your answer to the following options: “stabbing,” “aching,” “cramping,” “burning,” or “not reported.” If none of the mentioned options are explicitly stated in the text, answer “not reported.”
16	Palpation tenderness	Report whether this patient has a supple abdomen upon palpation. Limit your answer to the options: “yes” or “no.” Report “no” if a supple abdomen upon palpation is not mentioned or explicitly absent.

[a]LLM: large language model.

[b]All prompts and emergency department reports were provided to the large language model in Dutch and have been translated into English for readability.

[c]PM: punctum maximum.

[d]Annotation rules shared with or instructed to emergency department physicians for manual labeling and included in the minimal prompt.

XSL•FO
RenderX

Table . Optimized 0-shot prompts as presented to the LLM.[a]

	Feature	Prompt[b]
1	Abdominal pain location	You are a medical information extraction specialist.[c] Report where abdominal pain is present in this patient. If multiple locations of abdominal pain are mentioned, report the most painful location (punctum maximum/PM).[d] Limit your answer to the following options: "right lower quadrant," "right upper quadrant," "left lower quadrant," "left upper quadrant," "entire upper abdomen," "entire lower abdomen," "entire left abdomen," "entire right abdomen," "periumbilical," "epigastric," "hypogastric," "diffuse," or "absent." Note that these terms may not be mentioned exactly as listed. Right lower quadrant=RLQ, RLA, McBurney, right iliac fossa. Right upper quadrant=RUQ, Murphy. Left lower quadrant=LLQ, LLA, left iliac fossa. Left upper quadrant=LUQ. Entire right abdomen=right hemiabdomen. Entire left abdomen=left hemiabdomen. Periumbilical=around the navel, paraumbilical, supraumbilical. Epigastric=stomach region. Hypogastric=uterus, suprapubic, above pubis. Diffuse=entire abdomen. Absent=no abdominal pain. During the physical examination, the physician presses on all these locations and describes where pain is felt.[e] Report "absent" if pain is not mentioned or explicitly absent.
2	Nausea	You are a medical information extraction specialist.[c] Your task is to report from the emergency department report whether[c] this patient has nausea based on the last status in the report. Ignore vomiting. Vomiting is not the same as nausea.[d] Limit your answer to the following options: "yes" or "no." Note that these terms may not be mentioned exactly as listed. Yes=N+, N+. No=N−, N−. "N" stands for nausea. "N" often appears in combination with "V," for example, "N+ V−." "+" means nausea is present. "−" means nausea is absent.[e] Report "no" if nausea is not mentioned or explicitly absent.
3	Development of complaints	Report whether there is an increase or decrease in the development of complaints after the onset in this patient. A decrease in the development of complaints occurring after the administration of pain medication must be ignored and should not be reported as a decrease.[d] Ignore migration and radiation of abdominal pain. These do not count as an increase in the progression of abdominal pain complaints.[f] Limit your answer to the following options: "increase," "decrease," or "not reported." If none of the mentioned options are explicitly stated in the text, the answer should be "not reported."
4	Onset of pain	Report whether there is a description of how the onset of pain started in this patient. Ignore the timing of onset and focus only on how the complaints began.[f] Limit your answer to the following options: "acute," "gradual," or "not reported." If none of the mentioned options are explicitly stated in the text, the answer should be "not reported."

XSL•FO
RenderX

	Feature	Prompt[b]
5	McBurney's sign	Report whether this patient has abdominal pain at McBurney's point. If McBurney's sign is dubious, report "no."[d] Limit your answer to the options: "yes" or "no." Note that the term may not be mentioned exactly as listed. Yes=McBurney +, PM McBurney, punctum maximum McBurney. No=McBurney −, no pain at McBurney's point, not at McBurney.[e] Report "no" if abdominal pain at McBurney's point is not mentioned or explicitly absent.
6	Rebound tenderness	__[g]
7	Anorexia	__[g]
8	Pain migration to right lower quadrant	__[g]
9	Fever	__[g]
10	Abdominal inspection	Report whether any abnormalities are noted in the inspection of the abdomen for this patient. Limit your answer to the following options: "adipose," "distended abdomen," "scars," "no abnormalities," or "not reported." Note that the terms may not be mentioned exactly as listed: adipose=obese, adiposity. Distended abdomen=bloated, distended, tense. Scar=Pfannenstiel.[e] If none of the mentioned options are explicitly stated in the text, answer "not reported."
11	Pollakiuria	Report whether this patient has pollakiuria. Limit your answer to the options: "yes" or "no." Note that the term may not be mentioned exactly as listed: Yes=urinating in small amounts, frequent urination, urinating more often than normal, pollakiuria +. No=pollakiuria −.[e] Report "no" if pollakiuria is not mentioned or explicitly absent.
12	Stool consistency	Report whether the stool consistency is described for this patient. Limit your answer to the following options: "diarrhea," "loose," "normal," "stiff/obstipation," or "not reported." Note that the terms may not be mentioned exactly as listed: diarrhea=watery, liquid stool, extremely loose, explosive. Normal=na (no abnormalities), no notable findings, no deviations, no diarrhea or obstipation. Constipation=difficult passage. Stool may also be referred to as defecation or def.[e] If none of the mentioned options are explicitly stated in the text, answer "not reported."

XSL•FO
RenderX

	Feature	Prompt[b]
13	Pain location	Report where the pain initially started in this patient. Limit yourself to the medical history section.[c] Ignore pain resulting from displacement, migration, or radiation. Ignore abdominal tenderness. Ignore findings from the physical examination.[d] Limit your answer to the following options: "right lower quadrant," "right upper quadrant," "left lower quadrant," "left upper quadrant," "entire upper abdomen," "entire lower abdomen," "entire left abdomen," "entire right abdomen," "around the navel," "epigastric," "hypogastric," "diffuse," "bilateral flanks," "right flank," "left flank," "absent." Note that the terms may not be mentioned exactly as listed: right lower quadrant=RLQ, RLA. Right upper quadrant=RUQ. Left lower quadrant=LLQ, LLA. Left upper quadrant=LUQ. Around the navel=periumbilical, para-umbilical. Entire right abdomen=right hemiabdomen. Entire left abdomen=left hemiabdomen. Entire lower abdomen=lower part of the abdomen. Hypogastric=uterus, suprapubic, above pubis. Epigastric=stomach region. Diffuse=entire abdomen.[e] Report "absent" if the location where the pain initially started is not mentioned.
14	Pain manifestation	Report whether this patient has a specific abdominal pain pattern. Ignore descriptions of acute, sudden, or stabbing abdominal pain, as these are not specific pain patterns.[f] Limit your answer to the following options: "attack wise," "continuous," or "not reported." Note that the terms may not be mentioned exactly as written: attack wise=worsening in waves, peak periods, fluctuating, intermittent, variable in intensity, flare-ups, colicky pain, on and off.[e] If none of the mentioned options are explicitly stated in the text, answer "not reported."
15	Nature of pain	You are a medical information extraction specialist.[c] Report whether the nature of pain is described for this patient. Limit your answer to the following options: "stabbing," "aching," "cramping," "burning," or "not reported." If none of the mentioned options are explicitly stated in the text, answer "not reported."
16	Palpation Tenderness	—[g]

[a]LLM: large language model.

[b]All prompts and emergency department reports were provided to the large language model in Dutch and have been translated to English for readability.

[c]Broader context: (1) artificial intelligence persona or (2) report type. These are prompt elements included in the optimized prompt.

[d]Annotation rules shared with or instructed to emergency department physicians for manual labeling and included in the minimal prompt.

[e]Specific context: (5) domain-appropriate terminology or abbreviations, or (6) explanation of the symptom.

[f]Instruction: (3) section limitation or (4) negations or constraints.

[g]No prompt element improved performance compared with the minimal prompt; the minimal prompt was retained.

Minimal vs Optimized Prompt Strategies

Table 9 presents the feature-level performance of the LLM under both prompt strategies, evaluated against a reference standard based on lead researcher annotations, shown alongside manual labeling by ED physicians on the evaluation set (n=236). Using the minimal prompt strategy, the LLM achieved an average specificity of 0.929 (95% CI ±0.020), sensitivity of 0.810 (95% CI ±0.058), and accuracy of 0.910 (95% CI ±0.018). Lower feature prevalence in the ED reports did not consistently result in lower LLM accuracy (Table 3). When applying the optimized prompt strategy, performance improved across all metrics; specificity increased to 0.943 (95% CI ±0.017), sensitivity to 0.859 (95% CI ±0.055), and accuracy to 0.929 (95% CI ±0.016). The 5 largest gains in accuracy were observed for nausea, pain manifestation, onset of pain, pain location, and

XSL•FO
RenderX

abdominal pain location. No gains appeared for rebound tenderness, anorexia, pain migration to the right lower quadrant, fever, and palpation tenderness. Optimized prompts were particularly beneficial for features involving domain-specific terminology, abbreviations, or overlapping definitions, such as nausea and vomiting.

XSL•FO
RenderX

Table . Extraction performance of the LLM[a], under both prompting strategies, vs ED[b] physicians on the evaluation set (n=236). Each row represents a clinical feature with the number of positive answer options (classes).

[a]LLM: large language model.

[b]ED: emergency department.

[c]Δ Accuracy columns show pairwise accuracy differences. Δ values indicate improved accuracy of optimized prompts compared with minimal prompts or those of physicians.

[d]Each class is evaluated as a separate binary classification (present vs absent), meaning the number of binary decisions equals twice the number of classes.

[e]Spec.: specificity.

[f]Sens.: sensitivity.

[g]Acc.: accuracy.

[h]Accuracy difference (Δ) between minimal vs optimized prompts.

[i]Accuracy difference (Δ) between emergency department physician 1 vs optimized prompts.

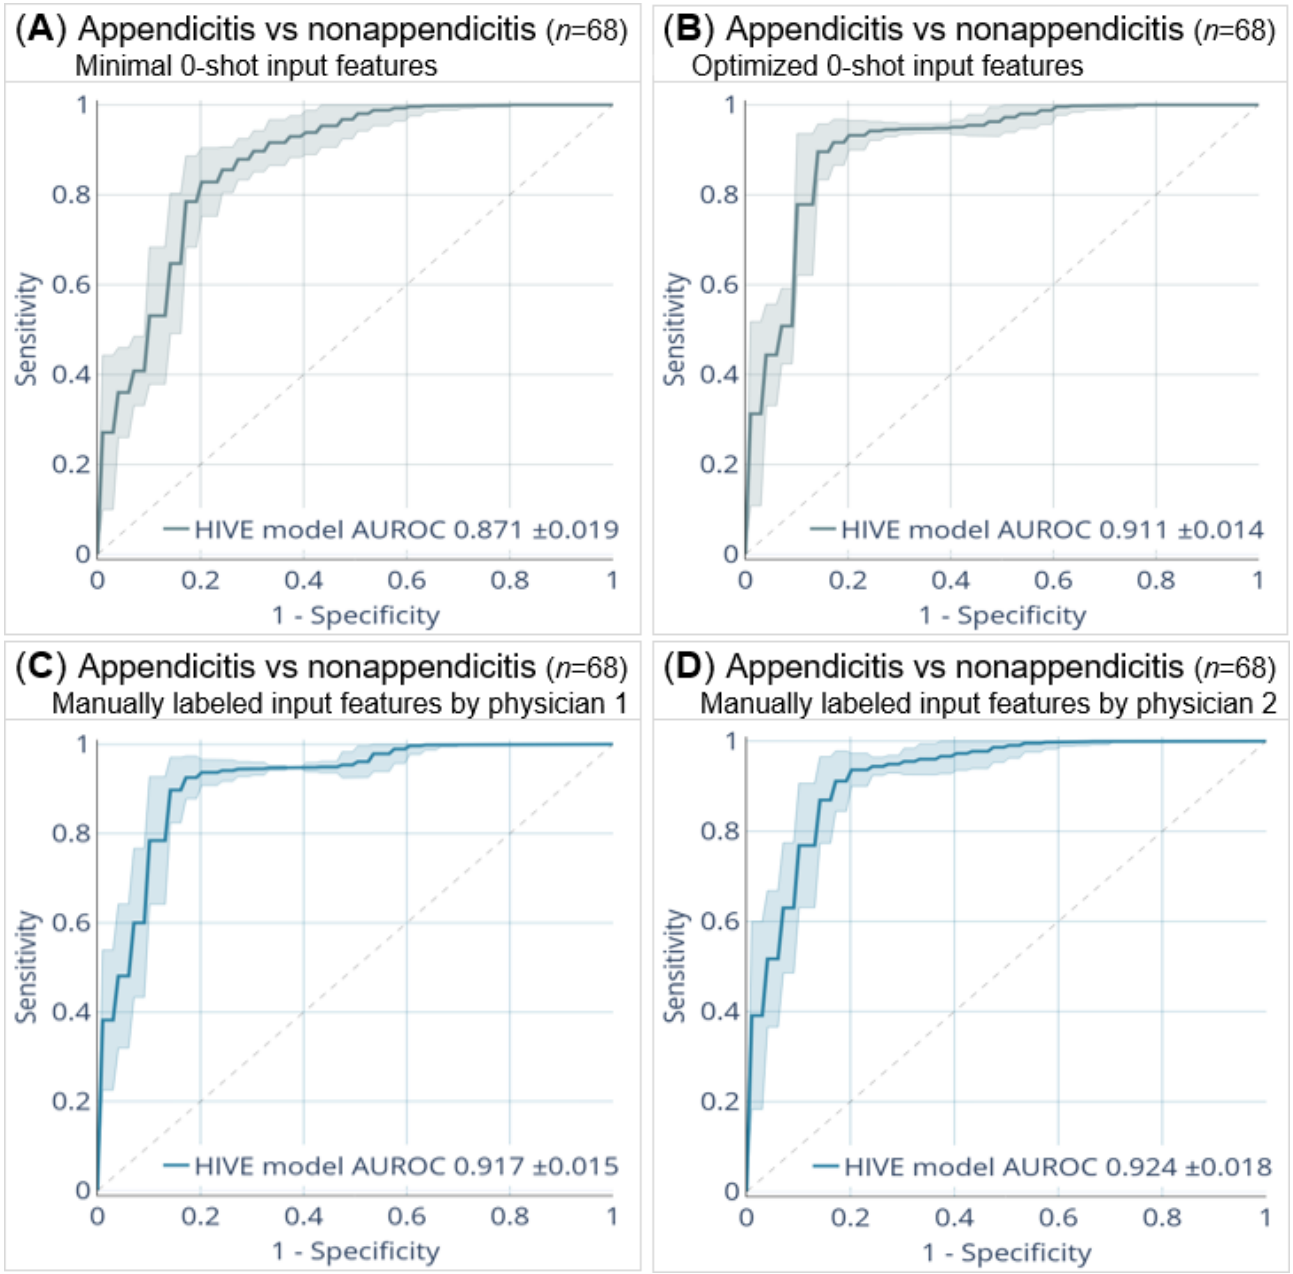
[j]Accuracy difference (Δ) between emergency department physician 2 vs optimized prompts.

[k]Optimized prompts were retained only when they improved performance on the development set; otherwise, the minimal prompt was used).

[l]Weighted averages account for the number of classes per feature. CIs (95% CI) were estimated using bootstrapping.

LLM vs Physician Labeling

Both physicians achieved higher weighted average specificity and accuracy on the evaluation set than the LLM under either prompting strategy. Physician 1 reached a specificity of 0.978 (95% CI ±0.011), sensitivity of 0.859 (95% CI ±0.015), and accuracy of 0.961 (95% CI ±0.012), while physician 2 achieved a specificity of 0.980 (95% CI ±0.008), sensitivity of 0.793 (95% CI ±0.056), and accuracy of 0.951 (95% CI ±0.015; Table 2).



At the feature level, the LLM using the optimized prompt matched or exceeded the accuracy of physician 1 for 8 of 16 features, and for physician 2 for 9 of 16. Notably, both physicians outperformed the LLM on the onset of pain, migration to the right lower quadrant, and pain manifestation. For the remaining features, physician performance was slightly higher, with marginal accuracy differences. All feature-level outputs for this comparison are available in Multimedia Appendix 4.

HIVE Model Performance Using LLM vs Physicians' Inputs

To compare predictive performance using LLM- vs physician-labeled input features, the HIVE model was evaluated for its ability to distinguish appendicitis from other AAP causes on the validation set (n=68; Figure 3). Using LLM-extracted features, the HIVE model achieved an AUROC of 0.871 (95% CI ±0.019) with the minimal prompt, and 0.911 (95% CI ±0.014) with the optimized prompt. In comparison, AUROCs were 0.917 (95% CI ±0.015) using features labeled by physician 1, and 0.924 (95% CI ±0.018) using those from physician 2.

XSL•FO
RenderX

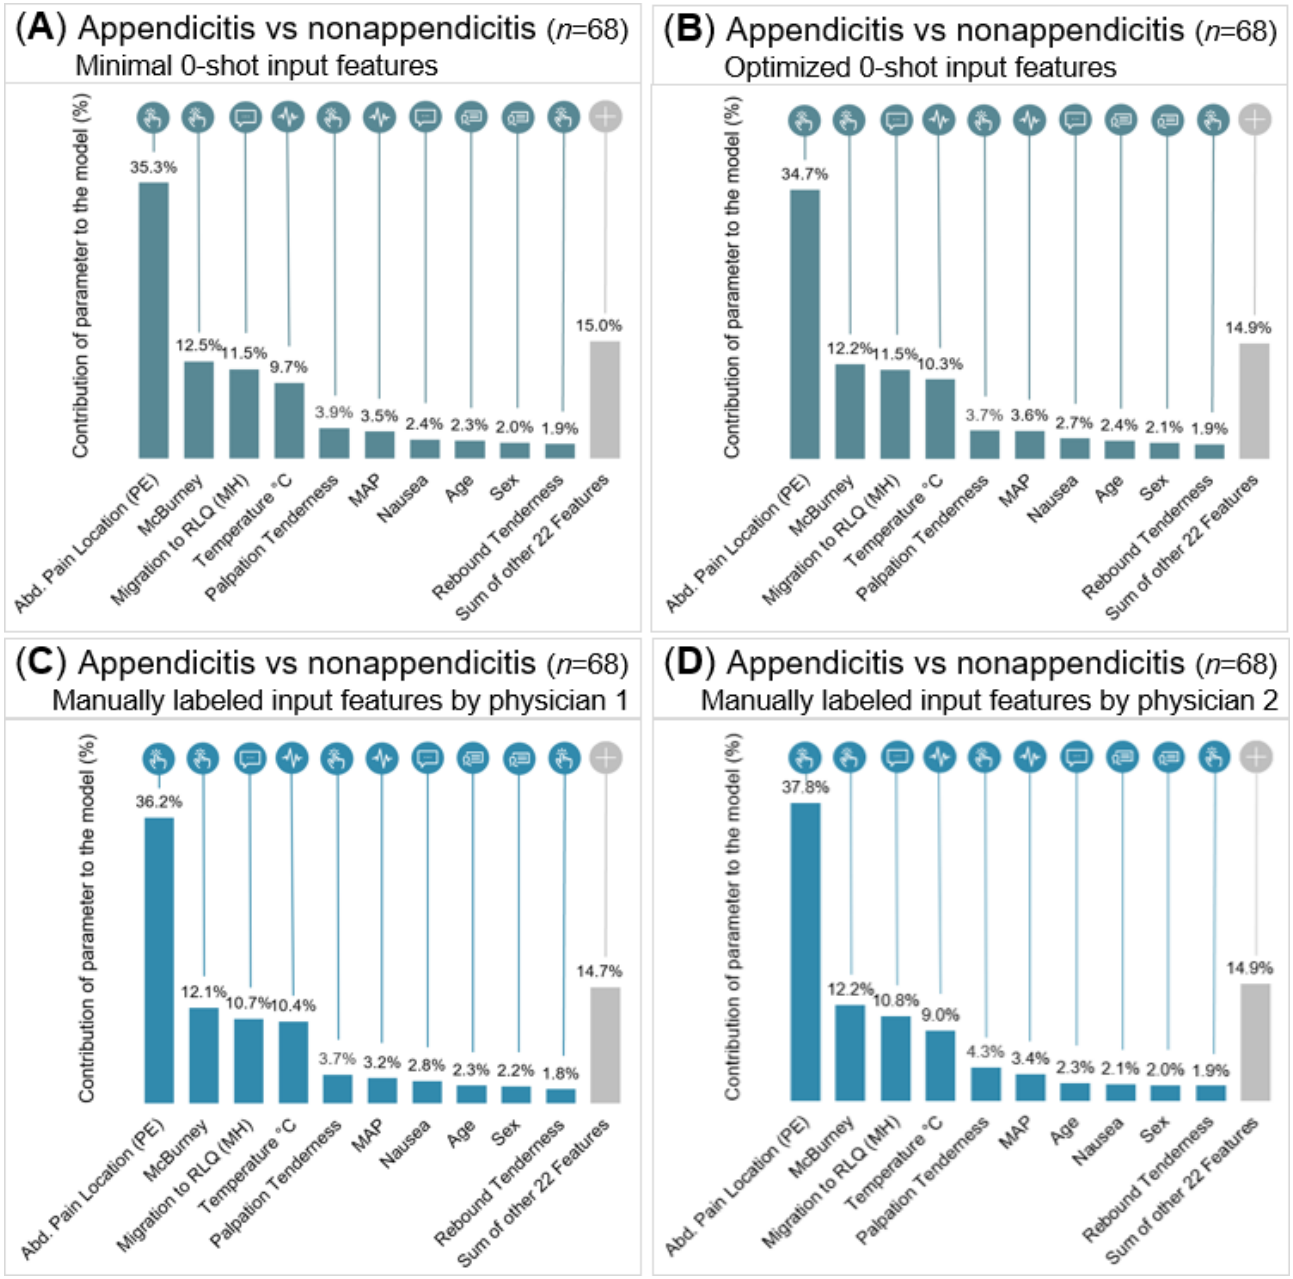


Figure 3. AUROC of the HIVE model for predicting appendicitis vs other AAP causes (ie, no appendicitis) in the validation set (n=68). (A,B) HIVE model performance using LLM-extracted features obtained through the minimal and optimized 0-shot prompting, respectively. (C,D) HIVE model performance using manually labeled features by ED physician 1 and physician 2, respectively. 95% CIs. AAP: acute abdominal pain; AUROC: area under the receiver operating characteristic curves; HIVE: History, Intake, Vitals, Examination; LLM: large language model.

SHAP analysis demonstrated consistent feature importance across all input types (Figure 4). Features are displayed in descending order of their mean absolute SHAP contributions. The overall SHAP distributions were nearly identical, with the top 10 features cumulatively contributing 85% to 85.9% of the model output (full list in Multimedia Appendix 5). Although the minimal 0-shot prompt achieved a lower AUROC of 0.871 (95% CI ±0.019), its feature importance pattern closely resembled those of the optimized and physician-labeled inputs.

XSL•FO
RenderX

Figure 4. Feature contributions to the HIVE model across 4 different input types on the validation set (n=68). Contributions of each feature to the model are SHAP (Shapley Additive Explanations) values scaled and plotted as percentage contributions to the prediction. (A,B) Feature contributions to the HIVE model performance using LLM-extracted features obtained through the minimal and optimized 0-shot prompting, respectively. (C,D) Feature contributions to the HIVE model performance using manually labeled features by ED physician 1 and physician 2, respectively. Abd.: abdominal; ED: emergency department; HIVE: History, Intake, Vitals, Examination; LLM: large language model; MAP: mean arterial pressure; MH: medical history; PE: physical examination; RLQ: right lower quadrant.

The random forest performed similarly to the XGBoost-based HIVE model, with AUROCs of 0.909 (95% CI ±0.13) using the optimized prompt strategy and 0.883 (95% CI ±0.13) using the minimal prompt strategy (Multimedia Appendix 6).

Error Analysis LLM

To examine misclassifications, 8 evaluation cases from the 4 lowest-performing features, pain manifestation, complaint development, pain onset, and abdominal-pain location, were reviewed to illustrate diverse error types.

The first 4 cases in Figure 5 highlight challenges with multilabel outputs, where the LLM was expected to report a combination of applicable labels but instead provided only a single answer. Specifically, in cases 1 and 2, pain manifestation evolved from continuous to attack-wise, yet the LLM recognized only 1 label. Similarly, in cases 3 and 4, the LLM missed fluctuating symptom development over time. In Figure 6, cases 5 and 6 illustrate 2 reports lacking explicit mention of the onset of pain; the LLM inferred labels such as “acute” or “gradual,” whereas reference was “not reported.” In case 7, the ED report described a punctum maximum located 4 cm to the right of the umbilicus. While this was labeled as “periumbilical” in the reference standard, the LLM returned “right lower quadrant.” In case 8, despite instructions to report only the primary pain location, the LLM provided both “entire right abdomen” and “diffuse” for a

XSL•FO
RenderX

case describing diffuse abdominal pain with pronounced tenderness in the right hemiabdomen.

Each panel presents a snippet from an ED report alongside the corresponding LLM output. Words highlighted in magenta within the ED report indicate incorrect (false negative or false positive) or missed interpretations by the LLM, while words in green represent correct (true positive) interpretations. On the right-hand side, the LLM's JSON output displays the unique patient identifier, the target clinical feature (magenta), and the extracted output (green). All prompts and ED reports were provided to the LLM in Dutch and have been translated into English for readability.

Figure 5. Case analysis of 8 ED reports across 4 features from the evaluation set. ED: emergency department; LLM: large language model.

Discussion

Conventional ML prediction models typically require structured input, posing a significant barrier to clinical integration, especially in EDs where physicians predominantly use free-text reports. This study demonstrates that a locally deployable LLM can automatically extract clinically relevant signs and symptoms from unstructured text, including binary, multiclass, and multilabel features. Using an optimized prompt strategy, the LLM reliably extracted features from free-text ED reports, enabling the appendicitis prediction model to achieve diagnostic performance comparable to that based on manually labeled features by ED physicians. This performance was consistent with that achieved in our previous study [18], underscoring the reliability of the LLM in this context.

Numerous ML prediction models have relied on clinical signs and symptoms to support early disease detection and guide ED workflows. While NLP techniques are commonly used to structure this data, each comes with limitations. Conventional techniques, such as bag-of-words, term frequency-inverse document frequency, and phrase skip-gram, rely on word frequency or co-occurrence, with limited ability to capture contextual meaning [32-36]. As a result, they often miss subtle language cues, such as symptom affirmation, negation, or uncertainty, which are essential in clinical interpretation. Topic modeling can uncover broad textual themes but may not align well with specific clinical concepts [33]. Moreover, these techniques are unsupervised, meaning they do not rely on labeled data, which makes their output more difficult to interpret and control. Deep learning models used in this context (eg, long short-term memory or BERT) understand the meaning of words in a broader context [37-40] but require fine-tuning to handle domain-specific language, large annotated datasets, and are challenged by imbalanced data distributions, limiting their performance and generalizability in real-world settings [41,42].

XSL•FO
RenderX

A small, locally hosted LLM for feature extraction can be deployed with modest requirements, offering advantages in data security and independence from external infrastructure. In comparison with conventional NLP or deep learning models, the LLM used in this study required neither extensive preprocessing nor fine-tuning nor large annotated datasets. Instead, it successfully extracted relevant features directly from raw text using relatively simple 0-shot prompting strategies. Importantly, the LLM was used solely for feature extraction; diagnostic predictions were generated by a separate ML prediction model. This modular approach preserves interpretability and statistical transparency, including calibrated probabilities and CIs. SHAP analysis confirmed that the model's internal reasoning remained stable across input types: AUROC differences primarily reflected feature extraction accuracy rather than alterations in model reasoning. A random forest benchmark produced similar AUROCs to the XGBoost algorithm, indicating that the predictive signal in the LLM-extracted features is consistent across ML algorithms and not dependent on a specific model choice. Although the approach is lightweight and easy to deploy, real-world use still requires seamless EHR integration and fast inference. Modern EHR systems increasingly provide vendor APIs and Python-based toolkits for AI integration, but embedding such workflows into routine EHR practice remains a significant challenge [43]. Given the diagnostic complexity of appendicitis [44-46], this workflow could function as a safety net by flagging high-risk presentations and supporting diagnostic decisions. Larger multicenter evaluations, including physician performance with and without AI assistance, will be needed to determine real-world value.

The ablation study showed that adding specific, symptom-related context, including explanatory cues, domain-specific terminology, and negation or constraint handling, most consistently improved extraction performance. These elements enhanced the LLM's ability to interpret synonyms and abbreviations commonly used in Dutch ED reports (eg, "misselijkheid," "nausea," or "N+" for nausea present) and to distinguish related but distinct concepts (eg, ignore vomiting when assessing nausea). In contrast, broader context elements such as report type, AI persona, or section limitation contributed little to performance. The LLM generalized well across features, classes, and prevalence levels, without requiring balancing strategies, and the close agreement with physician annotations suggests that more complex prompting strategies (eg, few-shot or chain-of-thought) add limited value for this task.

Despite its strengths, error analysis revealed that the LLM struggled with multilabel features, particularly when symptoms evolve over time. Clearly and consistently described features such as nausea or stool consistency were extracted more reliably than the onset of pain, which the LLM may have inferred from the surrounding context. In some cases, the LLM failed to prioritize the most prominent symptom, possibly due to reliance on textual similarity over clinical meaning, as observed in determining abdominal pain location. The LLM occasionally returned descriptive terms that matched the ED report but not the prescribed answer options. Some discrepancies also reflected inherent ambiguities between LLM output and manual annotations. Importantly, the LLM did not hallucinate nonexistent features outside the instructed features and answer options. These findings highlight the potential of LLM-based feature extraction, but also have limitations in handling time discrepancies or ambiguity, which are common challenges in clinical narratives.

This study has several limitations. Only 1 LLM (Qwen 2.5:14B) was evaluated, and performance may differ across models with different architectures or training corpora. As LLMs evolve, future LLMs with improved language understanding or instruction-tuned capabilities may outperform current results and reduce the need for prompt optimization. Nonetheless, given the complexity of ED reports, including abbreviations, medical jargon, and ambiguous phrasing, a structured prompting framework, as presented in this study, will likely remain necessary to ensure consistency and clinically accurate outputs. This study focused on Dutch-language ED reports, reflecting the clinical and linguistic context of our setting. While the prompting framework may be transferable, prompt content must be tailored to language-specific clinical conventions [47]. Translating Dutch reports would not serve as a valid proxy for cross-lingual evaluation because it measures translation quality rather than the LLM's ability to process native clinical text. Although most open-source multilingual LLMs perform best in English, Chinese, and Spanish [17,48,49], the LLM in this study achieved strong results in Dutch, suggesting that carefully designed prompts can support effective use in underrepresented languages. Despite the single-center scope, the dataset spans 7 years and includes reports from many ED physicians with varying documentation styles, supporting robustness, but external validation across linguistic and clinical contexts is needed [50]. Finally, this study focused on extracting signs and symptoms, not numeric values as laboratory results or vital signs, which are typically stored in structured EHR fields.

This study demonstrates that a locally deployable LLM can automatically extract clinical signs and symptoms from free-text Dutch ED reports with performance comparable to manual labeling by two ED physicians using a structured prompt framework, even in a less widely represented language. This approach has the potential to support scalable implementation of our ML prediction models across clinical contexts, without extensive human annotation or computational resources. Ultimately, it may inform future development of real-time integration of prediction models into clinical workflows, facilitating more scalable, transparent, and privacy-preserving decision-support systems.

Acknowledgments

ChatGPT 4o (OpenAI) was used to improve grammar and spelling. We would like to express our gratitude to Harm Geraerdts, MSc, for his contribution to the publication of this paper. We thank Kim Jie, PhD, MD, for contributions to the conceptual framework.

Funding

The authors received financial support from Radboudumc, Jeroen Bosch Hospital and Health~Holland (LSHM20103) for this research, authorship, and publication of this paper. The funders had no involvement in this study's design, data collection, analysis, interpretation, or the writing of this paper.

Data Availability

Information and the raw data are available from the corresponding author upon reasonable request. The underlying code for the large language model data extraction tool, the HIVE (History, Intake, Vitals, Examination) model, as well as the saved HIVE model, is available in a figshare repository (10.6084/m9.figshare.28931030).

Authors' Contributions

All authors have accepted responsibility for the entire content of this paper and approved its submission. AS, PB, MR, and BvG initiated and designed this study. AS collected the patient data. AS and PB created the reference standard and designed the features; KJ (Kim Jie, MD, PhD) and RDoC reviewed these features for annotation in a previous study. LvdW and RDoC manually annotated the emergency department reports in the reader study. JSB contributed to the analysis of large language model–based feature extraction. AS and PB developed and finetuned the prompts. AS analyzed the data and developed the History, Intake, Vitals, Examination prediction models for appendicitis prediction. All authors provided input and improved this paper. SK, RK, MR, and BvG supervised this project. AS wrote the paper with input from all authors.

Abstract

Background: Large language models (LLMs) are increasingly used to summarize clinical documents; yet, automated metrics often inadequately capture clinical relevance and safety. In the initial phase of the "Framework and Implementation of AI Tools," an expert-driven, cocreated evaluation methodology was established to assess LLM-generated discharge letter summaries, combining prompt design considerations with intuitive expert appraisal.

Objective: This study aimed to quantify expert agreement and interrater reliability on LLM summaries of discharge letters, identify frequent and clinically relevant errors, and evaluate practical implications for integrating LLMs into documentation workflows.

Methods: Thirty expert-curated synthetic Dutch discharge letters were summarized. Thirty-one clinicians from Flemish care settings (1 university hospital, 2 private hospitals, and 2 general practice circles) evaluated the summaries. The evaluation framework consisted of 61 binary layout items assessing whether required sections and formatting were correctly present, 33 content items (correct or complete vs incorrect, subcategorizing missing, irrelevant, and hallucinated information), a 4-point global quality rating, and an open comment. Statistical analyses included descriptive statistics, mixed effects ordinal regression on the global score, consensus (agreement per question or letter) percentages, interrater reliability (Cohen κ, intraclass correlation coefficient [ICC], Fleiss κ, and prevalence index), and thematic synthesis of comments.

Results: Layout adherence was high (88%), especially in the conclusion section. The positive response rate for content was overall moderate (78%), with the best performance observed in the medical history section and the lowest performance observed in the medication section, which also showed the highest rate of hallucinations and the weakest interrater consensus. Across all sections, missing information was the most common error. Nearly 70% of global ratings were "good" or "very good." Higher positive response rates for content predicted better global scores (β=.079; P<.001), while layout and participant specialty were not relevant to global scoring. Consensus was high for the layout questions (median 96.8%, IQR 90.2%-100%) and somewhat lower for content (median 83.9%, IQR 67.7-96.8), with the lowest agreement in the medication section. Interrater agreement was moderate (median Cohen κ=0.36, IQR 0.29-0.43; range 0.07 - 0.56), but overall reliability was high (ICC 0.945, 95% CI 0.942-0.948), indicating strong consistency at the global level despite interrater variability. The prevalence index demonstrated that high ICC values were partly driven by the strong prevalence of affirmative responses in layout items, while content items showed more balanced distributions and lower agreement.

Conclusions: Our framework offers a robust approach for evaluating LLM-generated discharge summaries, balancing usability and clinical relevance. Semantic integrity, especially regarding medication details, was identified as a key vulnerability. Perceived overall quality was driven by a positive response rate for content. High ICC values for global score, with lower item-level agreement lead toward the need for clearer, context-specific prompts and standardized evaluation criteria to reduce interrater variability. Human oversight and targeted automated checks for omissions and hallucinations are essential for safe clinical deployment.

Introduction

The evaluation of large language models (LLMs) in health care has predominantly centered on accuracy metrics; yet, only a small fraction of studies (6.45%) specifically address the evaluation of medical LLMs [1]. Recognizing the limitations of this narrow focus, the "Framework and Implementation of AI Tools" (FRAIT) project [2] established a collaborative, cocreative workflow with hospital providers to develop a more comprehensive evaluation approach. Building on the structured planning principles outlined by Tam et al [3], the FRAIT project emphasized the importance of preparatory phases before human evaluation.

Unlike prior studies that often relied on general or model-centric questions [4], our approach prioritized trustworthiness and a detailed examination of individual sections within medical summaries. A key innovation was the separation of evaluation criteria into "layout" (the presence and structure of required sections) and "content" (the accuracy and completeness of clinical information). This distinction acknowledges that while layout can be objectively assessed, content evaluation is inherently more complex and nuanced.

Recent literature [5] underscores the necessity of using real-world patient care data to ensure that LLM evaluations reflect actual clinical conditions. There is a growing consensus on the need for standardized frameworks that define evaluation tasks and dimensions, address specialty-specific gaps, and mitigate potential biases. Additionally, comprehensive cost-benefit analyses and transparent reporting of AI system failures are essential for the responsible integration of LLMs into clinical workflows.

Traditional automated metrics such as ROUGE and BLEU, although widely used, have been shown to correlate poorly with expert human assessments in clinical contexts [6,7]. These metrics often overlook critical aspects such as semantic accuracy, clinical relevance, and contextual appropriateness. Consequently, expert-driven, consensus-based evaluation frameworks are increasingly advocated.

LLM-powered summarization tools hold significant promise for distilling essential information from lengthy discharge letters and medical records, thereby supporting clinicians in making timely, informed decisions [8]. Reliable summarization methods can enhance workflow efficiency, reduce cognitive burden, and improve care quality. However, the adoption of LLMs in clinical documentation also raises concerns regarding accuracy, safety, and interpretability.

To address these challenges, the FRAIT project systematically evaluated LLM-generated summaries of expert-curated synthetic letters using a diverse panel of health care professionals. An intuitive evaluation tool was developed and applied to medical discharge letters, enabling a thorough analysis of both structural and semantic aspects.

The aim of this study was to systematically evaluate the reliability, accuracy, and usability of LLM-generated summaries of clinical discharge letters using the consensus-based FRAIT framework. By engaging a multidisciplinary panel and using a structured evaluation tool, we sought to (1) quantify expert agreement on summary quality, (2) identify the most frequent and clinically relevant errors, and (3) assess the practical implications of integrating LLMs into clinical documentation workflows.

Methods

We followed the QUEST (Quality of Information, Understanding and Reasoning, Expression Style and Persona, Safety and Harm, and Trust and Confidence) human evaluation framework [3] to set up our method in Appendix 1.1 in Multimedia Appendix 1.

Participants

A total of 33 clinicians (including 2 nonphysicians) were recruited from 3 hospitals (University Hospital Ghent, AZ Sint-Lucas Ghent, and AZ Oudenaarde) and 2 general practitioner circles (Huisartsenkring Schelde en Leie and Huisartsenvereniging Ghent). Two physicians did not complete the evaluation due to technical login issues (n=1) or time constraints (n=1). Half of the group (n=16, 51.6%) were hospital-based specialists, followed by general practitioners (n=13, 42%), with the remainder consisting of other health care professionals (n=2, 6.5%; Table 1). All participants evaluated 30 summaries from the respective medical discharge letters. More details on the number of years of clinical practice for each participant type can be found in Appendix 1.2 in Multimedia Appendix 1.

Table . Overview of organization and participants.

Type of organization (n=31) and name	Values, n (%)
Hospital (n=19, 61.29%)	
AZ Oudenaarde	5 (16.13)
AZ Sint-Lucas Ghent	6 (19.35)
Ghent University Hospital	8 (25.81)
GP[a] circles (n=12, 38.71%)	
Huisartsenvereniging Ghent	10 (32.26)
Huisartsenkring Schelde en Leie	2 (6.45)

Workshop Design

A workshop on user interface and user experience design was conducted on October 23, 2024, at Ghent University Hospital. The primary objective was to explore how an evaluation tool for LLM-generated summaries should be structured from a physician's perspective. A total of 26 participants attended, representing all participating organizations. Feedback collected during the workshop was synthesized and shared with technical implementers to finalize the design of the evaluation tool. The user interface was tested by 2 individuals, one data scientist (MD) and one physician (HR). A subsequent test session involved 5 additional technical participants and 3 physicians. These sessions focused on usability, clarity, and alignment with clinical workflows.

Evaluation Timeline

The evaluation phase timeline is illustrated in Figure 1. A total duration of 6 weeks was allocated for the completion of the evaluation. From April 1 to April 30, 2025, initial testing of the evaluation tool was conducted by 2 physicians and 1 data scientist. A pilot demonstration was held for the Data Science Institute from Ghent University Hospital on April 29, 2025. Following feedback from this session, a slide-based walkthrough was developed to clarify procedural steps prior to demonstrating the tool. An online presentation for (local) coordinators at participating institutions took place on May 5, 2025; participants received a manual with screenshots and keyboard shortcuts. All coordinators evaluated the tool over a week and reported no major issues.

Figure 1. Evaluation timeline on the Framework and Implementation of AI Tools (FRAIT) project. Starting from April 1, 2025, with the initial testing until the demonstration of the tool at the FRAIT symposium on October 22, 2025. FAQ: frequently asked question.

A broader online demonstration for all participants occurred on May 15, 2025, and was announced via newsletter and email. This session included login instructions for the secure platform and a comprehensive walkthrough of the evaluation tool. For those unable to attend, a recording of the session was made available. On May 19, 2025, a follow-up feedback session addressed questions, which were subsequently compiled into a frequently asked questions document distributed to all users. The formal evaluation phase spanned from May 15 to June 15, 2025, with an extended period continuing until June 30, 2025. Subsequently, a brief demonstration was presented by a general practitioner during the FRAIT symposium on October 22, 2025.

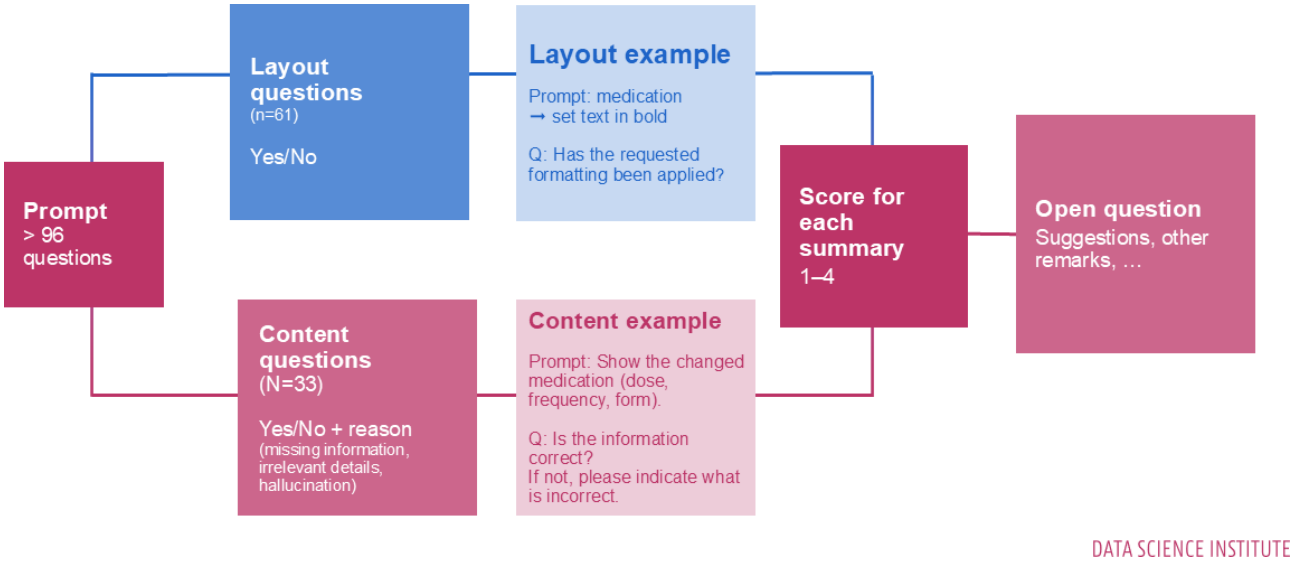
Several educational resources were provided for physicians, including an extensive manual with sections such as examples of potential questions, a live demonstration with an available recording, and a dedicated question-and-answer session. Additionally, during the evaluation phase, support was offered via email and telephone during working hours.

Input for the Evaluation Tool

The evaluation was conducted using a standardized prompt derived from the FRAIT questionnaire [2]. This prompt was designed to capture essential clinical and structural elements of discharge summaries across predefined categories: *general*, *medical history*, *investigations*, *hospital course*, *medication*, *follow-up*, and *conclusion*. An overview of the number of questions per category is provided in Appendix 2.1 Multimedia Appendix 2.

Data and Materials

Thirty expert-curated synthetic Dutch medical discharge letters were generated according to the protocol outlined in Appendix 3 in Multimedia Appendix 3. For the purpose of this study, we used the term synthetic clinical letters to describe synthetically modified clinical documents derived from real patient records that were systematically transformed to prevent reidentification while preserving clinical structure and plausibility. This process included complete removal of all direct and indirect personal identifiers, temporal shifting of dates, and targeted modification of clinical content (eg, laterality, diagnoses not relevant to the clinical scenario, and physiological and laboratory parameters) where deemed necessary. To minimize the risk of medical logic drift introduced by shifting dates, all synthetic letters were manually generated by 1 physician and independently reviewed by a senior physician to ensure that clinical decisions, treatments, and guideline-based care remained historically plausible despite the temporal adjustments. The resulting letters do not correspond to any real individual but retain realistic clinical narratives suitable for evaluation purposes. All data were processed to eliminate any risk of patient reidentification,



XSL•FO
RenderX

and the approach was reviewed and approved by the relevant institutional committees (reference ONZ-2024 - 0273 and ONZ-2024 - 0304). These letters served as the source material for summarization and subsequent evaluation. The LLM used for this task was GPT-4o, configured with a temperature setting of 0 to minimize interpretative variability. In this phase, one single prompt was used to be able to evaluate the same results.

Evaluation Framework

The evaluation questions were organized into 4 categories (Figure 2). Layout questions (n=61) were binary and assessed whether the specific sections requested in the prompt were present in the generated summary (for instance, evaluators were asked: *"Show the General section in the summary. Is the requested section included?"*). Additionally, these questions assessed the format in which sections should be presented, such as bullet points or plain text. Content questions (n=33) examined the correctness and completeness of individual items. Responses could be *yes* or *no*, with the latter requiring further classification as *incomplete, too much or irrelevant information*, or *incorrect information or hallucination*. When answering *no*, evaluators were required to indicate the erroneous content in either the source or the summary. An example question was *"Show the Admission Date. Is the content correct? If not, indicate what is incorrect."* In addition, the evaluation framework comprised 4 distinct categories of items: layout, content, global scoring, and an open question. Layout items assessed compliance with prompt-specified structural requirements and were scored as binary (yes or no). For each layout item, participants were able to view the original prompt and asked to evaluate whether the LLM-generated summary adhered exactly to the requested formatting and structure (eg, presence of specific section headings, use of bold formatting, bullet lists with a maximum number of items, or mandated section titles such as "medication"). Strict adherence was required for layout items to reflect real-world prompt-based use of LLMs in clinical documentation workflows.

Figure 2. Overview of the 96 evaluation questions: layout, content, global score, and open question. A full overview of all questions can be found in Appendix 2.2 in Multimedia Appendix 2.

Content items evaluated the correctness and completeness of the generated summaries relative to the original clinical text and were also scored binary (yes or no). When content was rated as incorrect (no), participants were required to assign one or more predefined error categories: missing information (clinically relevant information present in the source text but absent from the summary), irrelevant details (information present in the source text but not requested or inappropriate for the section, including excessive or misplaced detail), or hallucinations (information not present in the original clinical text).

The global score question (n=1) asked evaluators to provide a global rating of the summary quality on a 4-point scale: *very bad*, *bad*, *good*, and *very good*. Finally, an open question (n=1) invited evaluators to add comments, provide suggestions, or note blind spots in the original letter that were not captured by the prompt.

This structured approach ensured a comprehensive assessment of both structural fidelity and semantic accuracy. Figure 2 provides an overview of the evaluation question types. The set of evaluation questionnaire, including all layout and content items, is provided in Appendix 2.2 in Multimedia Appendix 2.

Statistical Analysis

General Approach

Descriptive statistics were computed to characterize participants, organizational affiliation, and medical specialty, expressed as frequencies (n) and percentages. In addition, descriptive analyses summarized the overall performance on layout and content questions, both globally and stratified by category.

Score Analysis

The global score question offered 4 ordinal response options: *very bad* (1), *bad* (2), *good* (3), and *very good* (4). We deliberately selected a 4-point Likert scale without a neutral midpoint to avoid noncommittal responses and to encourage evaluators to make a clear judgment on the overall quality of each summary. These were reported as frequencies and percentages and visualized using heatmaps by participant and by discharge letter. To explore associations between summary

XSL•FO
RenderX

quality and evaluation metrics, a mixed effects ordinal regression model was applied. The dependent variable was the global score (treated as ordinal, 1 - 4), while predictors included the number of "yes" responses for content and layout questions (analyzed separately) and participant specialty. Participant identity was modeled as a random effect to account for intrarater correlation.

Consensus Assessment

For each question pertaining to the same discharge letter, agreement among participants was examined. Responses were dichotomized as yes or no, without distinguishing the reason for a negative response in content-related items. Disagreement within a question-letter pair was recorded, and consensus was aggregated across dimensions (content and layout) and categories.

Interrater Reliability

To evaluate consistency among raters, multiple measures of interrater agreement were used. Pairwise agreement was quantified using Cohen κ for all rater pairs across content and layout questions. The median κ values per rater were compared using the Kruskal-Wallis test, followed by Dunn post hoc test when significant differences were observed. The number and proportion of significant differences were reported (n, %). The intraclass correlation coefficient (ICC) was calculated for all questions combined (content treated as binary: yes or no) and for the global score assigned to each summary. ICC was recalculated after excluding outlier raters to assess robustness. For multirater agreement on content questions, Fleiss κ was computed, both overall and by category. As Fleiss κ lacks a standard CI, a 95% CI was estimated via bootstrapping (10,000 iterations). Results were visualized using heatmaps and box-violin plots for pairwise Cohen κ and point plots with error bars for ICC and Fleiss κ estimates.

To better understand discrepancies between agreement metrics, we calculated the prevalence index (PI) for all binary items. The PI measures how strongly responses lean toward "yes" or "no," ranging from 0 (balanced) to 1 (highly skewed). High prevalence can lower Cohen κ and inflate ICC because ICC is influenced by between-item variance rather than categorical balance. We therefore computed the PI both overall and per category for layout and content items to assess how prevalence contributed to differences between κ and ICC. We also calculated the mean PI per category to capture item-level skewness. While the overall PI reflects global imbalance across the dataset, the mean PI shows how consistently individual items display skewed response patterns. Reporting both helps distinguish whether prevalence effects stem from a few extreme items or from systematic imbalance across categories.

Sensitivity Analysis

A sensitivity analysis was performed comparing results from all raters with those obtained exclusively from the physician cohort. Further details can be found in Multimedia Appendix 4.

Qualitative Analysis

Responses to the open-ended question were analyzed manually and summarized thematically to identify recurring topics and suggestions.

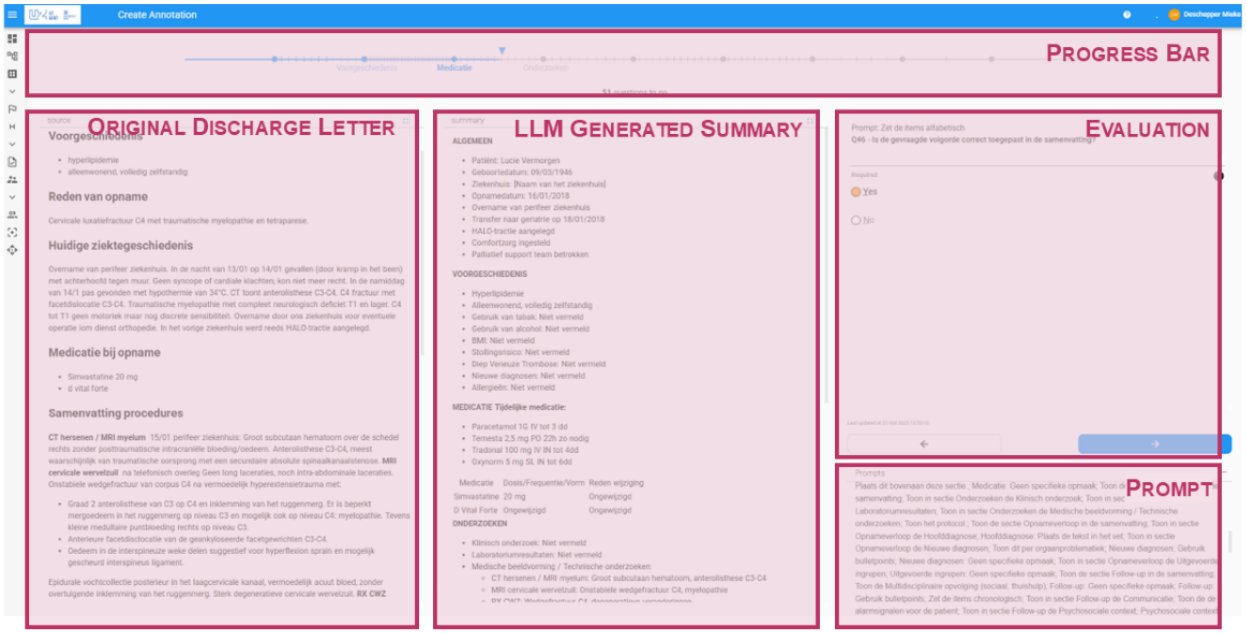
Ethical Considerations

This study involved the evaluation of LLM-generated summaries of *synthetically modified* discharge letters. All procedures complied with institutional and national regulations governing the secondary use of clinical data for research.

1. Human subjects research ethics review, exemptions, and approvals: The protocol for generating and using synthetic clinical discharge letters was reviewed and approved by the Ethical Committee of Ghent University Hospital (reference ONZ20240273 and ONZ20240304). The Ethical Committees of AZ Sint-Lucas Ghent and AZ Oudenaarde were informed of the study in accordance with institutional governance requirements. The Committee determined that the study met applicable national and institutional regulatory requirements governing secondary use of health data. The institutional Data Protection Officer (DPO) was formally consulted during protocol preparation. The DPO reviewed the planned data flow, synthetic transformation procedures, and external private cloud deployment. Given that only synthetically transformed data were processed externally, the DPO and Ethics Committee determined that the study did not meet the institutional threshold for a full Data Protection Impact Assessment. The residual privacy risk was classified as low and proportionate to the research objectives.
2. Informed consent or waiver language: The source documents used to generate the synthetic letters originated from previously collected hospital records of deceased patients. For this retrospective secondary use, the Ethics Committee granted approval and waived the requirement for additional patient consent. The Committee determined that, given the exclusive inclusion of deceased patients, the retrospective design, and the implementation of structured deidentification and synthetic transformation procedures prior to further processing, the study did not require renewed consent. Although no anonymization method can guarantee absolute elimination of risk, all direct identifiers were removed, and the transformation process was designed to minimize any potential risk of reidentification.
3. Privacy and confidentiality protection: All clinical discharge letters underwent a rigorous structured deidentification and synthetic transformation procedure by protocol before use in the evaluation tool, including the removal of direct identifiers and the generalization or modification of indirect identifiers, temporal shifting of dates, modification of clinical elements when necessary to reduce reidentification risk, and internal review of transformed letters to assess residual linkage risk. These procedures were designed to preserve clinical realism while minimizing the likelihood of reidentification. Although no anonymization strategy can fully eliminate risk, the applied safeguards were considered proportionate to the study objectives and were reviewed as part of the approved protocol. The evaluation

XSL•FO
RenderX

was conducted within a secure, access-controlled hospital environment with authenticated access and governance in accordance with institutional data protection standards.



4. Compensation: The study was supported by governmental research funding. Participating institutions received financial support to facilitate clinician participation in accordance with local institutional policies. Compensation arrangements were managed at the institutional level and reflected time commitment only; they were not dependent on performance or evaluation outcomes.
5. Protection of participant identity in figures and supplementary material: All clinician participants were assigned anonymized alphanumeric codes (eg, “Z19”) for all analyses and visualizations. Figures and appendices have been updated to replace any synthetic first names with anonymous codes. No identifiable images or personal information of participants are included in the manuscript or supplementary material. If identifiable material were to be included in future dissemination, explicit written consent would be obtained and submitted as required.

Results

Evaluation Tool

The workshop generated numerous suggestions for enhancing the FRAIT evaluation tool. A comprehensive list of implemented features is provided in Appendix 5.1 in Multimedia Appendix 5. Examples include keyboard shortcuts for navigation, progress indicators, autosave functionality, and text highlighting. Figure 3 illustrates the main components of the evaluation interface, while additional screenshots and examples of the content question user interface are included in Multimedia Appendix 5.

Figure 3. Screenshot of the evaluation tool highlighting its main components.

Evaluation Outcomes

Across all layout-related questions, 88% of responses were rated as “yes,” with the highest proportion observed in the *conclusion* section. For content-related questions, 78% of responses were affirmative, with the *medical history* category achieving the highest score. In contrast, the *medication* section demonstrated the lowest positive response rate and the highest proportion of hallucinations. Overall, hallucinations accounted for 3% of content-related responses. When content questions were answered “no,” missing information was the predominant reason, particularly in the *conclusion* section. The *general* section contained the largest proportion of irrelevant details (Table 2).

XSL•FO
RenderX

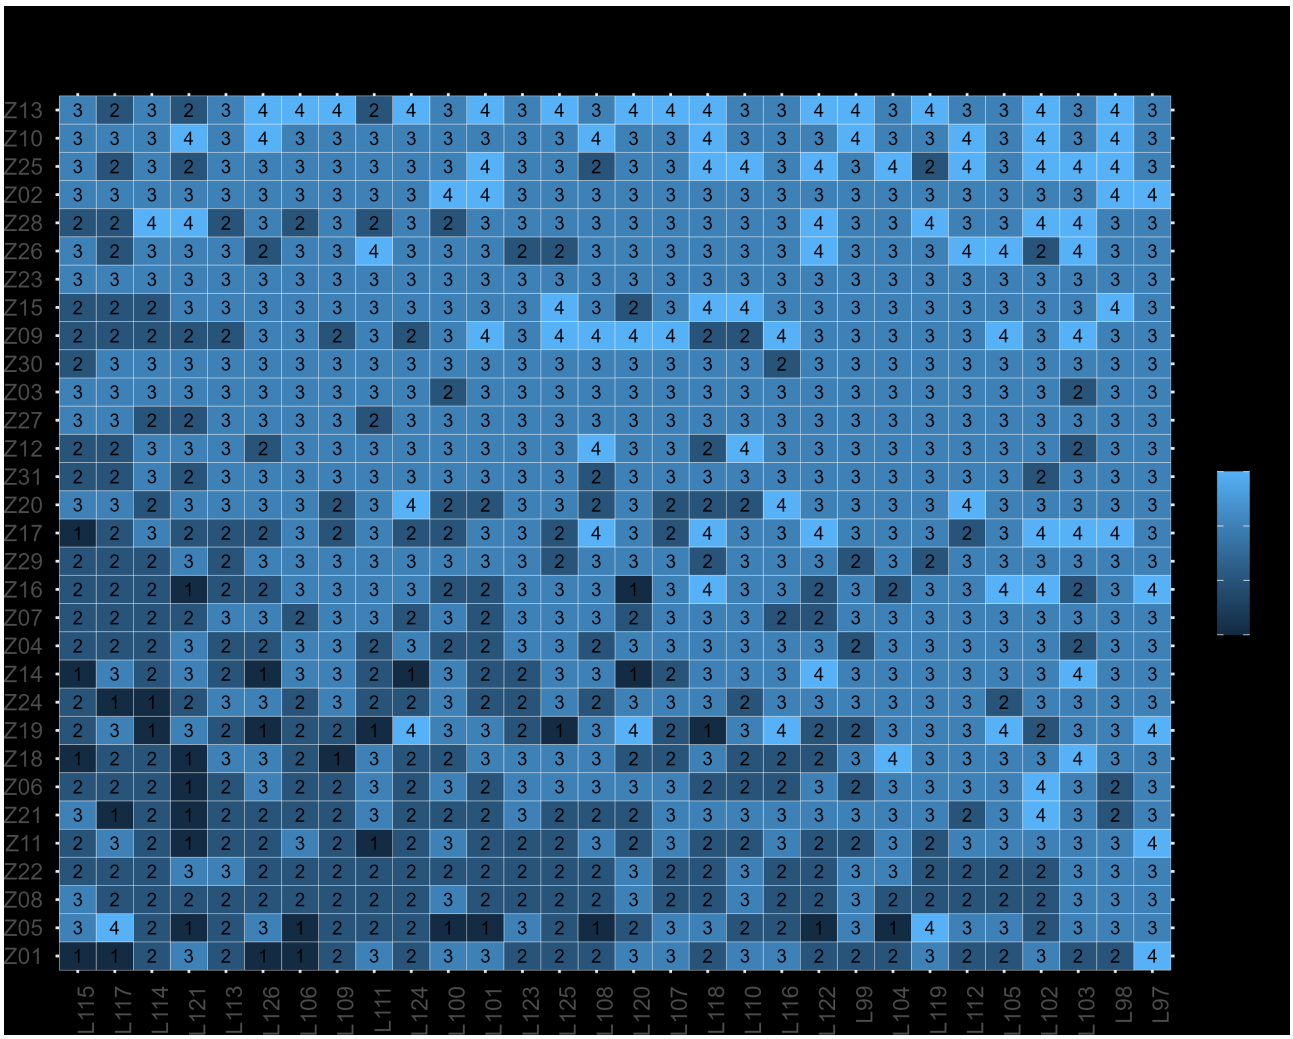


Table . Percentage of answers divided by content and layout and by category.

Category	Domain: content (%)				Domain: layout (%)
	Yes (total=77.5)	No missing information (total=15.6)	No irrelevant details (total=4.8)	No hallucination (total=3.1)	Yes (total=88.4)
General	72.8	3.4	20.1	3.8	90.3
Medical history	83.7	12.6	1.8	1.9	83.8
Investigations	74.1	22.9	2.1	0.9	94.3
Hospital course	81.1	12.8	4.4	1.7	93.2
Medication	67.8	18.1	6.3	7.8	83.2
Follow-up	80	11.2	3.6	5.2	87.7
Conclusion	68.4	25.9	4.6	1.2	97.8

Global Scores

Nearly 70% of participants rated summaries as *good* or *very good*. A detailed visual overview is presented in Appendix 6 in Multimedia Appendix 6. Figure 4 displays an ordered heatmap of global scores (1-4) by participant and discharge letter.

Figure 4. Heatmap of the global scores by participant (y-axis) and generated summary (x-axis).

Mixed effect ordinal regression results are summarized in Table 3. The proportion of "yes" responses for content questions was significantly associated with higher global scores (β=.079; *P*<.001), whereas layout performance showed no significant effect. Participant specialty did not exhibit a significant influence on scoring.

XSL•FO
RenderX

Table . Mixed effects ordinal regression on global score versus content, layout, and participant specialty.

Predictor	β (SE)	z-score	*P* value	95% CI
Content[a]	.079 (0.008)	9.781	<.001	0.063 to 0.095
Layout[b]	.006 (0.011)	0.558	.58	−0.016 to 0.028
Specialization				
GP[c]	Reference	Reference	Reference	Reference
Specialist	−0.404 (0.380)	−1.062	.29	−1.149 to 0.341
Other caregiver	−0.544 (0.774)	−0.703	.48	−2.061 to 0.973

[a]Yes on the content question (%).

[b]Yes on the layout questions (%).

[c] GP=general practitioner.

Consensus

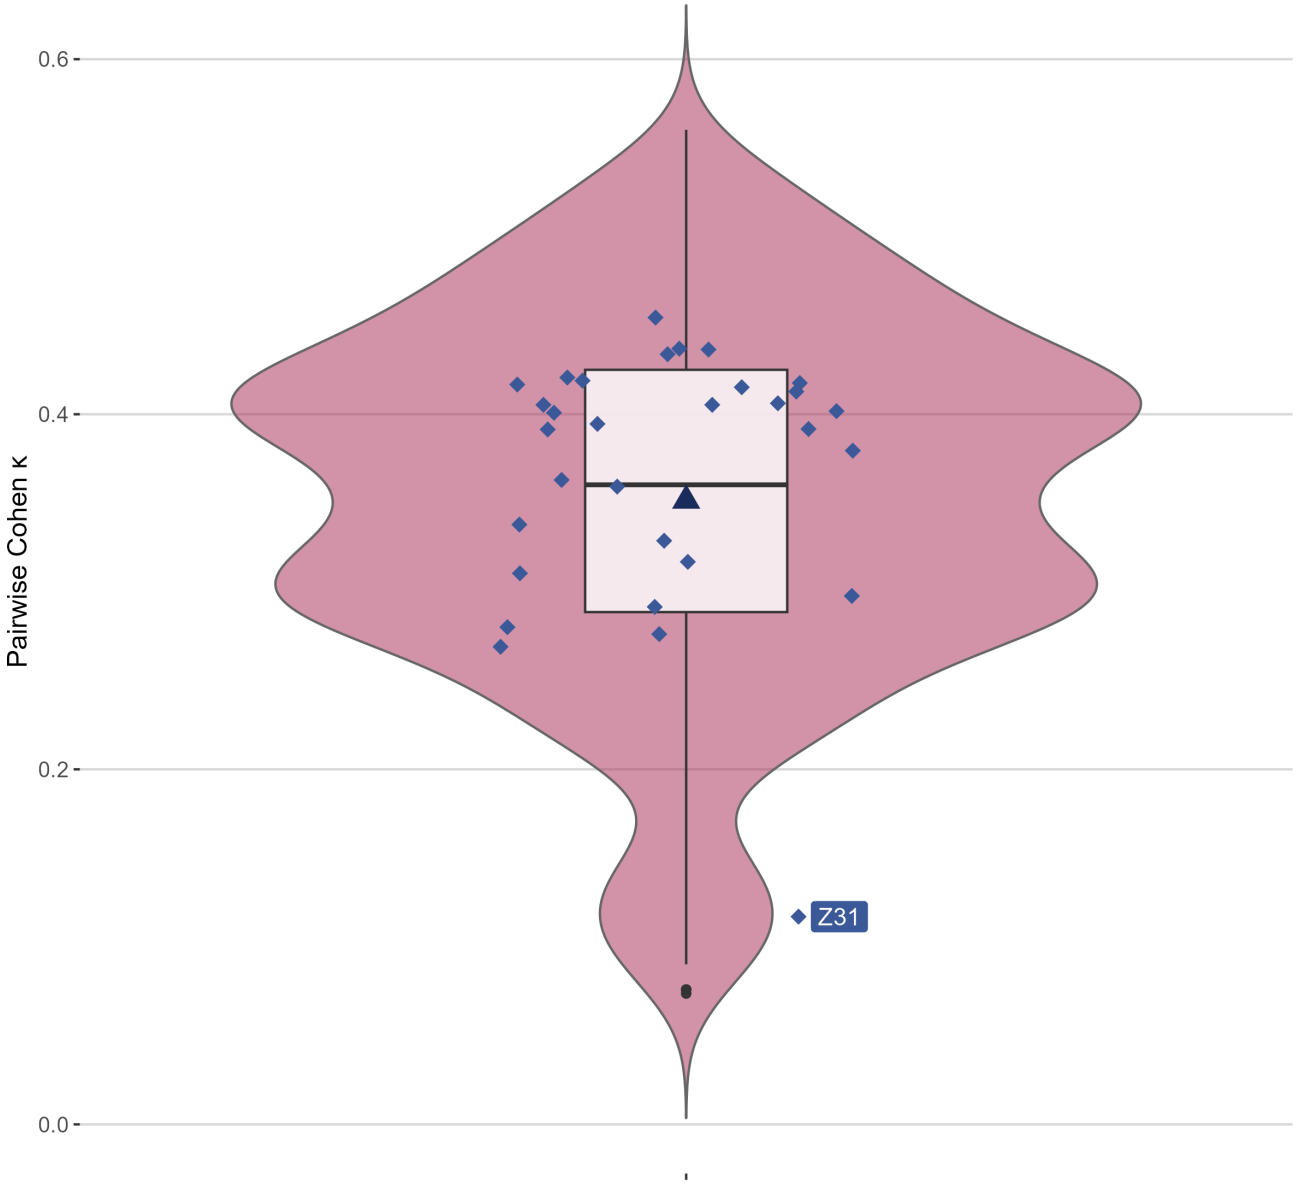
Consensus for layout questions was high, with a median of 96.77% (IQR 90.22 - 100.00). Content questions showed lower agreement (median 83.87%, IQR 67.74 - 96.77). The overall consensus of both categories was 93.55% (IQR 80.65 - 100.00; Appendix 7 in Multimedia Appendix 7). When examining the items in detail, consensus levels were substantially lower for the no categories (Appendix 7 in Multimedia Appendix 7, Figure 7.2 in Multimedia Appendix 7).

Category-level analysis showed that the *medication* section had the lowest consensus for both layout and content, while the *conclusion* section achieved perfect agreement for layout but lower for content (Table 4).

Table . Consensus by question category and type.

Question category	Content, median (IQR)	Layout, median (IQR)	All[a] (content % layout), median (IQR)
General	82.3 (61.3 - 96.8)	96.8 (83.9 - 100)	96.8 (77.4 - 100)
Medical history	91.9 (74.2 - 100)	96.8 (90.3 - 100)	96.8 (87.1 - 100)
Medication	69.4 (58.1 - 83.9)	93.5 (80.6 - 100)	87.1 (71.0 - 96.8)
Investigations	80.6 (65.3 - 90.3)	100 (96.8 - 100)	93.5 (74.2 - 100)
Hospital course	88.7 (74.2 - 93.5)	100 (93.5 - 100)	96.8 (87.1 - 100)
Follow-up	87.1 (71.0 - 96.8)	96.8 (90.3 - 100)	93.5 (87.1 - 100)
Conclusion	82.3 (64.5 - 93.5)	100 (96.8 - 100)	98.4 (89.5 - 100)

[a]Combination of content and layout questions.



Additional information can be found in Appendix 7 (Figure 7.3 and Figure 7.4) in Multimedia Appendix 7, which presents the consensus for each summary and question.

Interrater Agreement

Pairwise Cohen κ values ranged from 0.07 to 0.56, with a median of 0.36 (IQR: 0.29 - 0.43), indicating generally low agreement among raters (Figure 5; Appendix 8.1 in Multimedia Appendix 8). Participant Z31 demonstrated notably lower agreement compared to others. A Dunn post hoc test confirmed significant differences for this participant (Appendix 8.2 in Multimedia Appendix 8).

XSL•FO
RenderX

Figure 5. Pairwise Cohen κ between all participants. Diamonds represent median κ for each interrater; triangles represent mean pairwise Cohen κ. Z31=participant Z31.

The ICC for all questions combined was 0.945 (95% CI 0.942 - 0.948). Layout questions achieved slightly higher ICC (0.961, 95% CI 0.958 - 0.963), while content questions treated as binary yielded 0.908 (95% CI 0.899 - 0.916). Excluding participant Z31 did not produce a significant difference in the ICC (Appendix 8.3 in Multimedia Appendix 8), so we continued including this participant in our analysis.

The ICC for global scores was 0.776 (95% CI 0.649 - 0.875). Fleiss κ for content questions was lower (0.221, 95% CI 0.205 - 0.237), with category-specific values ranging from 0.198 to 0.240 (Table 5).

XSL•FO
RenderX

Table . Interrater overview: intraclass correlation coefficient (ICC) for binary content and layout questions and Fleiss κ for categorical content questions.

Methods and group	Cohen κ	95 % CI
ICC		
Content (binary) and layout	0.945	0.942 - 0.948
Layout	0.961	0.958 - 0.963
Content—binary (yes/no)	0.908	0.899 - 0.916
Fleiss		
Content—categorical	0.221	0.205 - 0.237
OK	0.240	0.223 - 0.257
Missing information	0.198	0.177 - 0.218
Irrelevant details	0.202	0.170 - 0.232
Hallucinations	0.235	0.173 - 0.293

Further category-specific ICC analysis (Table 6; Appendix 8.4 in Multimedia Appendix 8) confirmed patterns observed in descriptive consensus measures. Interrater reliability was excellent across most sections, with median ICCs around 0.92 for the majority of items. The highest reliability was observed in the *medical history*, *follow-up*, and *conclusion* sections, where ICCs reached up to 0.96. The medication section showed comparatively lower, but still substantial, reliability for content (ICC=0.83). Notably, the *conclusion* section had a lower ICC for layout (0.65), indicating more variability among raters in assessing structural aspects of this section.

Table . Intraclass correlation coefficient layout and content question-by-question category.

Question category	Content	Layout	Content and layout
General	0.927 (0.902 - 0.947)	0.904 (0.887 - 0.920)	0.927 (0.916 - 0.938)
Medical history	0.923 (0.910 - 0.935)	0.977 (0.974 - 0.980)	0.964 (0.960 - 0.968)
Medication	0.825 (0.777 - 0.867)	0.938 (0.926 - 0.948)	0.919 (0.907 - 0.930)
Investigations	0.870 (0.838 - 0.898)	0.934 (0.918 - 0.948)	0.919 (0.905 - 0.931)
Hospital course	0.897 (0.868 - 0.922)	0.915 (0.899 - 0.929)	0.917 (0.904 - 0.928)
Follow-up	0.900 (0.875 - 0.922)	0.974 (0.970 - 0.979)	0.955 (0.949 - 0.961)
Conclusion	0.931 (0.904 - 0.954)	0.654 (0.559 - 0.737)	0.953 (0.942 - 0.962)

Further inspection of the medication section showed that lower agreement among raters was partly associated with ambiguous prompt wording, particularly instructions such as “show temporary medication.” These ambiguities led evaluators to apply different interpretations of what information should be included in the summary, contributing to reduced consensus even in cases where the model output itself was not incorrect. This indicates that both the characteristics of the model output and the clarity of the prompt influenced the observed agreement patterns in this section.

PI Analysis

The PI revealed substantial differences between layout and content items. Layout questions exhibited a high degree of prevalence skew, with an overall PI of 0.768 and a mean PI of 0.856 (SD 0.211). Several categories showed PI values above 0.90, indicating that layout-related items were almost always rated identically (typically “yes”), resulting in limited variability across raters. Content items demonstrated more balanced response distributions, with an overall PI of 0.550 and a mean PI of 0.622 (SD 0.316). Category-specific PI values ranged from 0.430 (medication) to 0.720 (medical history), reflecting greater heterogeneity in item difficulty and a broader range of rater judgments.

A detailed overview of PI values per category is presented in Table 7.

XSL•FO
RenderX

Table . Overview of prevalence index (PI) values for layout and content items by question category.

Category	Layout PI[a], mean (SD)	Content PI[b], mean (SD)
General	0.824 (0.244)	0.573 (0.351)
Conclusion	0.956 (0.087)	0.573 (0.294)
Follow-up	0.886 (0.160)	0.665 (0.274)
Medication	0.754 (0.258)	0.430 (0.282)
Investigations	0.905 (0.196)	0.545 (0.300)
Hospital course	0.875 (0.227)	0.675 (0.282)
Medical history	0.864 (0.178)	0.720 (0.317)

[a]Overall PI: 0.768; PI, mean (SD): 0.856 (0.211).

[b]Overall PI: 0.550; PI, mean (SD): 0.622 (0.316).

These findings confirm that layout items were highly homogeneous, while content items displayed more meaningful variability. Importantly, the high PI values for layout items help explain the discrepancy between the relatively low median Cohen κ and the high ICC: skewed response distributions can suppress κ, whereas ICC remains elevated because it is driven by between-item variance rather than categorical balance.

Finally, responses to the open-ended question were analyzed qualitatively and summarized by topic (Multimedia Appendix 9).

Discussion

Principal Findings

This study examined expert evaluation and interrater agreement in the assessment of LLM-generated discharge summaries, using the FRAIT framework, to assess structural fidelity, semantic accuracy, and usability.

Regarding the evaluation of structural integrity, layout adherence was consistently high, whereas content accuracy, particularly for medication details, remains a critical challenge. These findings align with prior research on clinical text summarization, which identifies medication and follow-up instructions as frequent sources of error and hallucination [9,10]. Although layout adherence was 88%, the remaining 12% reflects structural inconsistencies that may hinder automated processing and pose challenges for electronic health record integration. Even infrequent deviations from required section formatting can disrupt downstream workflow steps, indicating that layout performance should be considered a potential vulnerability rather than a strength.

The strong association between the positive response rate for content and global scores underscores the importance of semantic integrity in clinical documentation. Evaluators prioritized correctness over format, reinforcing FRAIT's emphasis on clinically meaningful metrics rather than purely structural criteria. Future iterations should therefore incorporate automated validation of medication-related information. This also aligns with the context-aware evaluation by Agrawal et al [6].

Interrater reliability analysis revealed high ICC values for global scores but low pairwise agreement for individual questions, especially in complex categories such as medication. Our PI findings confirm that the discrepancy between item-level κ and overall ICC is partly attributable to prevalence skew in layout items, rather than true inconsistency in evaluator behavior. This suggests that while evaluators share similar global impressions, item-level judgments are subject to interpretation variability, a challenge also noted in previous discharge summary studies. A deeper analysis of the medication section revealed that ambiguous prompts (eg, "show temporary medication") contributed to low agreement.

The medication section warrants particular attention, as it exhibited the highest hallucination rate (7.8%) among all content categories. A deeper review showed, however, that most of these hallucinations were related to start, stop, or change medication status rather than incorrect drug content. For example, in one case, vitamin D was listed on admission but not repeated in the discharge medication; the model labeled it as "unchanged," which some raters considered a hallucination because no corresponding entry was present. This section also showed the lowest positive response rate and weakest interrater consensus, reflecting both its clinical complexity and the fact that some prompt instructions were interpreted differently by different raters. These findings highlight that LLM-generated medication summaries cannot be relied upon without human validation. When using this model and prompt configuration, human-in-the-loop verification remains essential to ensure clinical safety, and future implementations should include targeted safeguards, such as automated checks for omissions and medication-related inconsistencies. This highlights the need for clearer, context-specific prompts to optimize both LLM output and evaluation consistency, as suggested by Borse et al [11]. Follow-up workshops were organized to refine prompt design and ensure unambiguous interpretation, which is essential for improving interrater agreement.

The PI analysis clarifies the discrepancy between the moderate median Cohen κ (0.36) and the high ICC (0.945). Layout items showed consistently high PI values, indicating minimal variability and near-uniform "yes" responses. Such skewed distributions suppress κ (the prevalence paradox [12]) while inflating ICC, which is driven by between-item variance rather than categorical balance. Content items showed lower and more variable PI values, reflecting a more balanced mix of responses and greater item-level complexity. This explains why κ was

XSL•FO
RenderX

lower for content judgments: raters disagreed more frequently on clinically nuanced items, although overall rating patterns remained consistent enough to keep ICC high. Together, these findings show that the high ICC partly reflects the high prevalence of affirmative responses in structural items rather than purely strong interrater consistency. Reporting PI alongside κ and ICC therefore provides a more accurate basis for interpreting agreement patterns.

Usability enhancements generated during the workshop, such as keyboard shortcuts, progress indicators, and autosave, reflect user-centered design principles and are expected to improve efficiency and reduce evaluator fatigue. These improvements support FRAIT's goal of creating a scalable, reproducible evaluation environment for clinical LLMs.

An additional observation concerns infrastructure and security considerations. Although these aspects were outside the scope of this article, they represented the largest portion of the project's budget. Establishing a secure, cloud-based environment was essential to ensure compliance with data protection standards and enable safe collaboration. This underscores the resource-intensive nature of deploying LLMs in clinical settings and highlights the importance of planning for robust infrastructure early in implementation.

While our findings confirm earlier reports of promising outcomes for LLMs in clinical documentation [9,10,13], infrastructure and human factors remain critical determinants of success. Addressing these challenges will be essential for scaling LLM-based solutions in health care.

Limitations

A key limitation of this study is the exclusive use of a single standardized prompt and a single LLM (GPT-4o). Although GPT-4o is recognized for its advanced capabilities, our findings should not be generalized to other model families, including open-weight systems or medical-specific models, nor to alternative prompting strategies. While this controlled design was necessary to ensure consistent comparison across evaluators, it also restricts the generalizability of our findings. LLM performance evolves rapidly, and outputs can vary substantially across models, model versions, and prompt formulations. As a result, this study should be interpreted primarily as a validation of the FRAIT evaluation framework, rather than a definitive benchmark of LLM summarization performance.

As our task is clinical summarization, it is plausible that smaller, domain-specific models trained on medical corpora could outperform general-purpose models on factuality, medication handling, and terminology precision while also reducing hallucination risk and computational overhead. The growing adoption of domain-specific models, such as Meditron and HuatuoGPT, which have demonstrated strong performance in clinical contexts [1], suggests that specialized models may offer advantages in higher positive response rates and interpretability that general-purpose models cannot match. Furthermore, larger general-purpose LLMs may introduce unnecessary complexity and increase the risk of hallucinations compared to smaller, clinically optimized models, as noted by Lehman et al [14]. These considerations highlight the need for comparative studies involving multiple LLMs to better understand the generalizability, safety, and optimal balance between model size and specialization in health care applications. We did not test such models here. Therefore, our results may underestimate the attainable accuracy and safety for targeted deployments.

Our evaluation used expert-curated synthetic discharge letters, developed to maintain clinical plausibility while omitting direct identifiers. The original section structure and general layout were largely maintained; however, the transformation process may have reduced certain real-world irregularities such as incomplete phrasing, extraneous noise, or ambiguous references that commonly occur in routine documentation. This distribution shift may have resulted in inflated performance metrics, particularly regarding layout adherence, compared to those expected from more variable and unstructured real-world notes, and may similarly overstate content accuracy. Therefore, our results should be regarded as an upper bound established under controlled conditions, rather than indicative of field performance.

The free-text explanations accompanying "no" responses could not be systematically analyzed because many raters did not follow the intended instructions for marking errors. As a result, the raw annotations were inconsistent in format and therefore unsuitable for reliable qualitative or quantitative reporting. Although the rater pool included clinicians from different specialties, it may not fully capture the diversity of clinical perspectives. Variability in interpretation between GPs and hospital physicians, especially for nuanced categories such as medication details, could have influenced agreement scores and overall evaluations. Ensuring broader representation across specialties and experience levels would strengthen the reliability of future assessments.

Certain sections of the discharge summaries, such as the conclusion, contained limited data. This imbalance restricted the robustness of evaluation for those components and may have skewed the overall usability and accuracy metrics. Future research should aim for more balanced datasets to enable thorough analysis across all content categories. Furthermore, as multiple layout categories exhibited PI values exceeding 0.90, certain reliability measures, especially κ, should be interpreted with caution because high prevalence can restrict their capacity to distinguish genuine agreement from systematic response patterns.

Analysis of pairwise Cohen κ identified one rater whose agreement consistently differed from that of the other evaluators. A post hoc review indicated that delays in initiating and completing the evaluation tasks may have contributed to this variability. This finding highlights the importance of voluntary participation and adequate protected time for expert evaluation to support data quality integrity in future studies. Notably, overall interrater reliability remained high despite this variability, suggesting that the evaluation approach was robust under routine clinical conditions.

A reliable measure of time-on-task could not be obtained because participants were free to pause or take breaks while completing evaluations. Although the platform recorded start and end times, these time stamps do not reflect actual working

XSL•FO
RenderX

time and therefore cannot be used to assess efficiency. This limits our ability to draw conclusions about the workflow impact of the evaluation process.

Implications and Future Work

The findings of this study have several practical implications for the integration of LLMs into clinical workflows. While LLMs show promise in assisting with documentation tasks, they should not replace expert review. Human oversight remains essential to ensure patient safety and compliance with clinical standards. Automated quality assurance mechanisms, particularly those targeting omissions and hallucinations in critical areas, such as medication and follow-up instructions, will be vital for real-world deployment.

Prompt design emerged as a key factor influencing evaluation consistency. Ambiguous or poorly defined prompts contributed to variability in interrater agreement and model output quality. Future research should therefore prioritize the development of clear, context-specific prompts and explore adaptive prompt optimization strategies to enhance reliability.

Model refinement is another important area for future work. Comparative evaluations of multiple LLMs, including domain-specific models, are needed to identify configurations that balance positive response rate, interpretability, and computational efficiency. Additionally, longitudinal studies should assess the real-world impact of LLM-assisted documentation on clinical workflows, patient outcomes, and resource allocation. These investigations will provide critical insights into the scalability and sustainability of LLM integration in health care.

To ensure standardization, the evaluation was restricted to a single medical prompt, despite participants having previously developed personalized prompts in a separate workshop [2]. As emphasized by Verma et al [8], the value of summarization is maximized when outputs are tailored to the specific needs of different clinical roles and contexts. Customized summaries, adapted for specialists, general practitioners, or administrative staff, ensure that each user receives the most relevant and actionable information for their responsibilities. This approach not only improves usability but also supports safer and more effective integration of AI tools into diverse health care environments.

Building on recent insights from Croxford et al [7], future research should explore the potential of LLMs not only as tools for generating clinical documentation but also as evaluators, or "judges," of their own outputs. They propose that context-aware LLMs, when properly calibrated and validated, could assist in the assessment of clinical summaries by providing rapid, scalable, and consistent feedback on accuracy, completeness, and relevance. Integrating LLMs as judges within expert-driven frameworks such as FRAIT may enhance the efficiency of evaluation processes, support continuous quality improvement, and facilitate benchmarking across diverse clinical scenarios. However, this approach will require rigorous validation to ensure that automated judgments align with clinical standards and expert consensus and that potential biases or limitations are systematically addressed.

Conclusions

The FRAIT framework demonstrates strong potential for evaluating LLM-generated discharge summaries, offering a structured approach that balances usability and clinical relevance. While layout fidelity was consistently high, content accuracy, particularly for medication details, remains a critical challenge. Interrater reliability findings highlight the need for clearer prompts and standardized evaluation criteria to reduce variability. Usability enhancements developed through co-creation with clinicians further support FRAIT's scalability and practical adoption. Overall, LLMs show promise as an aid in clinical documentation, but robust validation mechanisms and expert oversight are essential to ensure safety and accuracy. Future work should focus on prompt optimization, model refinement, and automated quality checks to advance reliable integration of LLMs into health care workflows.

Acknowledgments

We would like to express our sincere gratitude to the entire team at the Data Science Institute of Ghent University Hospital, as well as to the management, program participants, and coordinators representing the participating organizations. Artificial Intelligence is used within the project to enhance efficiency: generating the summaries using GPT-4o (as stated within the *Methods* section). This manuscript was improved with the assistance of Enterprise Copilot.

Funding

The "FRAIT" project was funded by the Belgian Government with the Data Innovation project.

Data Availability

The synthetic discharge letters analyzed in this study are not publicly available due to governance restrictions. Access to these materials can be requested through the institutional Data Access Committee of Ghent University Hospital, subject to approval and data use conditions.

Abstract

Background: Clinical note documentation is a vital yet time-intensive task in health care. While advancements in natural language processing have transformed many domains, generating accurate summaries of doctor-patient conversations remains underexplored due to the limited availability of open-source datasets. Large language models (LLMs), with their training on vast datasets, present a promising solution to this challenge.

Objective: Precision in clinical summarization is crucial, as it directly impacts patient care and safety. This study aimed to evaluate the effectiveness of parameter-efficient, fine-tuned, decoder-only LLMs for clinical note generation from doctor-patient conversations. We focus on assessing medical accuracy, robustness, and the feasibility of parameter-efficient fine-tuning (PEFT) approaches under practical resource constraints.

Methods: We used the Medical Training Summarization Dialog dataset containing 1700 doctor-patient conversations paired with clinical notes. Several decoder-only LLMs, including Mistral, Meditron, and Llama, were fine-tuned using PEFT techniques to reduce computational and memory overhead. Evaluation was performed using standard automatic metrics, including the Recall-Oriented Understudy for Gisting Evaluation score and bidirectional encoder representations from transformers score, to assess content overlap and semantic similarity between generated and reference clinical notes. In addition, an expert physician assessed the LLM-generated notes for medical accuracy, completeness, concision, relevance, and clinical coherence and readability.

Results: Model performance was evaluated using the Recall-Oriented Understudy for Gisting Evaluation score and bidirectional encoder representations from transformers scores, demonstrating that Meditron-7B and Llama3-8B achieved state-of-the-art results among open-source, parameter-efficient, fine-tuned models, with Mistral-7B also performing competitively. The findings indicate that decoder-only LLMs, particularly Llama variants, outperform traditional models. Moreover, fine-tuning with higher quantization has the potential to further enhance performance. Human expert evaluation further indicated that Llama3-8B and Mistral-7B produced clinically coherent and accurate summaries, with Meditron-7B and Llama3-3B also performing reliably across evaluation criteria. The findings suggest that higher quantization during fine-tuning may improve efficiency without substantially compromising performance.

Conclusions: This study underscores the potential of the PEFT of decoder-only LLMs to transform clinical workflows by streamlining medical documentation, thereby enabling health care professionals to dedicate more time to patient care. These models offer a scalable and resource-efficient alternative to traditional architectures and have the potential to streamline clinical documentation workflows.

Introduction

Background

Manually creating clinical notes has always been a time-consuming and exhausting task for health care providers. As health care systems grow increasingly complex and large-scale, the need for faster and more accurate documentation methods has become more pressing. Transformer architecture has brought significant advancements to various natural language processing (NLP) tasks, including text summarization—a fundamental task in NLP. These advancements, driven by transformer-based large language models (LLMs) and the availability of large-scale datasets, have the potential to revolutionize health care systems. An NLP-powered system can analyze doctor-patient conversations, identify relevant clinical facts, structure the information, and generate coherent medical reports. By automating the generation of clinical notes, such systems provide timely insights and support to medical professionals during patient interactions. Real-time information retrieval ensures clinicians have immediate access to relevant medical data and patient histories, which can aid in making critical decisions. This, in turn, leads to more accurate diagnoses, personalized treatment strategies, and improved patient outcomes. Beyond individual patient interactions, the ability to analyze data at scale enables medical facilities to make data-driven decisions that enhance overall treatment quality, optimize resource use, and improve patient satisfaction. These innovations promise to streamline health care processes and elevate the standard of care.

The challenge lies in ensuring these automated notes are precise. Any mistakes or *hallucinations* in medical facts could have serious consequences. Summarizing clinical dialogues is tricky, but we tackled this by using decoder-only transformer models, which we found outperform traditional sequence-to-sequence models (such as Flan-T5-Large) on metrics such as Recall-Oriented Understudy for Gisting Evaluation (ROUGE) and bidirectional encoder representations from transformers (BERT) scores. Using the Medical Training Summarization Dialog (MTS-Dialog) dataset [1] containing 1700 doctor-patient conversations and their summaries, we explored models such as Mistral [2] and Llama [3]**,** with Llama3 [4] emerging as the top performer, even beating the best results from the 2023 MEDIQA-Chat challenge [5].

Motivation

Manual note-taking can be time-consuming, diverting health care providers' attention from patient care. On average, physicians dedicate approximately 52 to 102 minutes each day documenting clinical notes based on their patient interactions [6]. Automatic clinical note generation can be a solution to this problem. It can reduce the burden of paperwork on health care providers and improve the accuracy of the medical records. This allows doctors to focus more on patient care rather than on paperwork. During the COVID-19 pandemic, face-to-face doctor visits were restricted. For that reason, health care systems experienced over a 100% surge in virtual urgent care appointments and more than a 4000% rise in virtual nonurgent care visits [7]. Automatic clinical note generation can help us to overcome this kind of situation. Clinical notes can vary widely in terms of content, format, and quality. Automated systems can help to standardize documentation, improve data quality, and facilitate analysis. Nevertheless, automated systems can extract valuable insights from clinical notes, enabling data-driven decision-making and improving patient care.

Research Objective

Our research set out to fine-tune the LLMs to craft high-quality clinical notes that make a real difference. We aimed to find a model that balances speed and precision, fine-tuning it on MTS-Dialog to adapt to the dataset's unique demands. Our ambition was to go beyond the current leader, Flan-T5-Large, and establish a new benchmark for automated documentation. To measure our success, we compared our model's ROUGE and BERT scores against Flan-T5-Large, assessing its ability to summarize accurately while preserving every essential detail.

Literature Review

The study by Ben Abacha et al [1] introduced the MTS-Dialog dataset, pairing simulated doctor-patient dialogues with clinical notes. They tested transformer models such as Bidirectional and Auto-Regressive Transformers (BART) [8] and Pegasus [9], finding BART, especially when prefinetuned and guided, produced the most accurate notes. However, issues such as hallucinations and missing key details persisted, highlighting both the promise of automation in health care documentation and the need for better factual accuracy. The study by Ozler and Bethard [10] explored LLMs for summarizing medical dialogues in the MEDIQA-Chat 2023 competition. Using models such as Clinical-T5 and Roberta-base on Medical Information Mart for Intensive Care datasets, they hit a peak accuracy of 72.3%. Limited hardware and dataset size posed challenges, but their work shows LLMs' potential for medical documentation, with room for improvement through advanced models and techniques. The study by Sharma et al [11] tackled the same competition, fine-tuning BART-large on datasets such as Medical Information Mart for Intensive Care-IV-Note and introducing an N-pass strategy to summarize long dialogues. Data augmentation (DA) with synthetic dialogues boosted results, though hallucinations remained an issue. Their research pushes clinical NLP forward, suggesting future integration of medical knowledge. The study by Wang et al [12] used ChatGPT and BioMedLM in a doctor-patient loop system for MEDIQA-Chat 2023, excelling in dialogue generation and note summarization. While effective, gaps in medical knowledge and handling lengthy conversations need work, pointing to future refinements in segmentation and expertise. The study by Suri et al [13] evaluated transformer models such as Bio-Bart and DialogLED for the same challenge. DialogLED-Large outperformed GPT-3, offering a cost-effective alternative despite limited training data. They recommend DA to improve reliability. The study by Tang et al [14] fine-tuned BART and CONFIT while leveraging GPT-4 for MEDIQA-Chat 2023. GPT-4's natural outputs impressed human experts, though privacy concerns with external application programming interfaces surfaced. Their findings underscore LLMs' role in streamlining clinical notes. The study by Srivastava [15] tested local-sparse-global BART ensemble methods, finding that

XSL•FO
RenderX

section-wise models outperformed single approaches for chart note summaries. Multilayer techniques and PubMed fine-tuning fell short, suggesting specialization as a key focus moving forward. The study by Milintsevich and Agarwal [16] fine-tuned FLAN-T5 and LongT5, using multitask learning to cut hallucinations in clinical notes. While effective, adding clinical named entity recognition tags unexpectedly hurt quality, indicating a need for better augmentation strategies. The study by Zhang et al [17] combined an SVM classifier with GPT-3 for summarization, with GPT-3.5 outperforming a fine-tuned Curie model. Their hybrid approach hints at the power of blending traditional and modern techniques. Finally, the study by Mathur et al [18] used GPT-4 with in-context examples, topping MEDIQA 2023 rankings. Despite concise outputs, brevity and privacy risks remain challenges, marking a step forward in applying LLMs to health care. In another research, the study by Heilmeyer et al [19] demonstrated that hospitals can use smaller, open-source LLMs running on their own computers to handle sensitive documentation, rather than relying on commercial systems. They found that a model specifically optimized for the local language (German) performed exceptionally well, generating medical reports that doctors rated as usable 93% of the time. The study by Savage et al [20] showed that while basic fine-tuning is enough for simple medical checklist tasks, using the more advanced direct preference optimization method allows LLMs to handle complex clinical reasoning and triage by teaching them to distinguish between high-quality and poor responses.

Methods

Ethical Considerations

This study uses the MTS-Dialog dataset [1], a publicly available collection of simulated doctor-patient conversations. As the dataset contains no protected health information or real patient interactions, this research does not classify as human participants research. A qualified physician participated in this study to evaluate the clinical accuracy of the generated notes. This involvement was strictly in a professional capacity as a domain expert to assess text quality, rather than as a research participant. No personal data were collected from the evaluator.

Main Dataset

Overview

There are around 1700 brief doctor-patient conversations paired with clinical notes and summaries in the MTS-Dialog dataset. The main aim behind creating this dataset is to help researchers create tools that automatically summarize doctor-patient conversations and generate clinical notes [1]. The training set comprised 1201 pairs for model training. The validation set comprised 100 pairs for fine-tuning. The test sets comprised 2 sets of 200 pairs each: test set 1 (used in MEDIQA-Chat 2023, task A) and test set 2 (used in MEDIQA-Sum 2023, tasks A and B). MEDIQA-Chat 2023 tasks encompassed task A: predict section headers (eg, HISTORY of PRESENT ILLNESS) and content from short dialogues, task B: generate complete clinical notes from full conversations, and task C: create synthetic dialogues from clinical notes. MEDIQA-Sum 2023 tasks encompassed task A: generate clinical note summaries from dialogues and task B: produce section-specific summaries (eg, ASSESSMENT and PLAN).

Section-Header Categories

The MTS-Dialog dataset is divided into 20 categories of section headers: fam/sochx, genhx, pastmedicalhx, cc, pastsurgical, allergy, ros, medications, assessment, exam, diagnosis, disposition, plan, edcourse, immunizations, imaging, gynhx, procedures, other_history, and labs. The statistics of the dataset shared in the paper [1] can be found in Table 1.

Table . Descriptive statistics of the Medical Training Summarization Dialog dataset.

	Count	Values, mean (SD)	Values, maximum	25th percentile	50th percentile	75th percentile
Dialogue						
Turns	15,969	9 (8.72)	103	4	6	12
Sentences	18,406	11 (13.03)	136	4	7	14
Words	2,41,685	142 (144.03)	1951	48	88	176
Summary						
Sentences	5870	3 (4.35)	3	1	2	4
Words	81,299	48 (72.02)	48	6	18	55

Data Quality

The MTS-DIALOG dataset undergoes a thorough 3-step process to ensure its quality. First, only those with medical backgrounds, such as former medical scribes, were selected to serve as annotators. Second, during the early stages of their work, each annotator received one-on-one feedback from an experienced trainer to help refine their skills. Finally, after the dataset was completed, an independent validation process took place. This separate review used a grading rubric to assess how well the annotated conversations followed the guidelines and how relevant the content was to the original clinical notes. Minor corrections, such as fixing typos or filling in missing information, were made during this stage to make sure the final dataset was even more accurate than the initial version [5].

Comparison With Real Data

The MTS-Dialog dataset includes both real medical notes and simulated conversations that mirror doctor-patient interactions, helping to avoid any breaches of confidentiality. To understand

XSL•FO
RenderX

the impact of relying heavily on synthetic data, a blind review was conducted to compare the MTS-Dialog data with real conversations. Distinguishing between the simulated and real data in the dataset is a challenging task. While statistical analysis shows that the simulated conversations have fewer speech errors and pauses, medical experts noted that the dialogues generally feel authentic. In some cases, the clarity, directness, and ease of understanding, even with sudden shifts in topics, made synthetic data mistaken for real interactions. On the other hand, actual data, known for their honesty and minimal speech flaws, were often confused for simulated content due to its polished nature. This difficulty highlights the dataset's value as a foundation for training and evaluating models in practical, real-world settings.

Back-translation augmentation stands out as a valuable method. It involves converting the original text into another language and then translating it back into the original language. This process introduces natural linguistic variations while preserving the core meaning, thus expanding the training dataset and helping models generalize better to unseen data. To reduce translation errors, French and Spanish were chosen because their vocabulary is similar to English, and they have high-performing translation models [21]. It was implemented using the following three steps: (1) translation: the original text is translated from its source language (English) to a target language (French and Spanish) using a machine translation model, (2) back-translation: the translated text is then translated back to the original language (English) using another machine translation model, and (3) augmentation: the back-translated text is added to the original training dataset, creating a larger and more diverse corpus.

After DA, the dataset includes 3.6k pairs of medical dialogues and their corresponding summaries, generated from an initial 1200 training pairs through back-translation using French and Spanish, as outlined in the study [1]. Back-translation can significantly increase the size of a training dataset. Theoretically, it can improve the performance of the summarization model. By exposing models to different linguistic variations, back-translation can help them generalize unseen data better. Nevertheless, by increasing the diversity of training data, back-translation helps prevent overfitting, which is a common problem in NLP.

Fine-Tuning Techniques

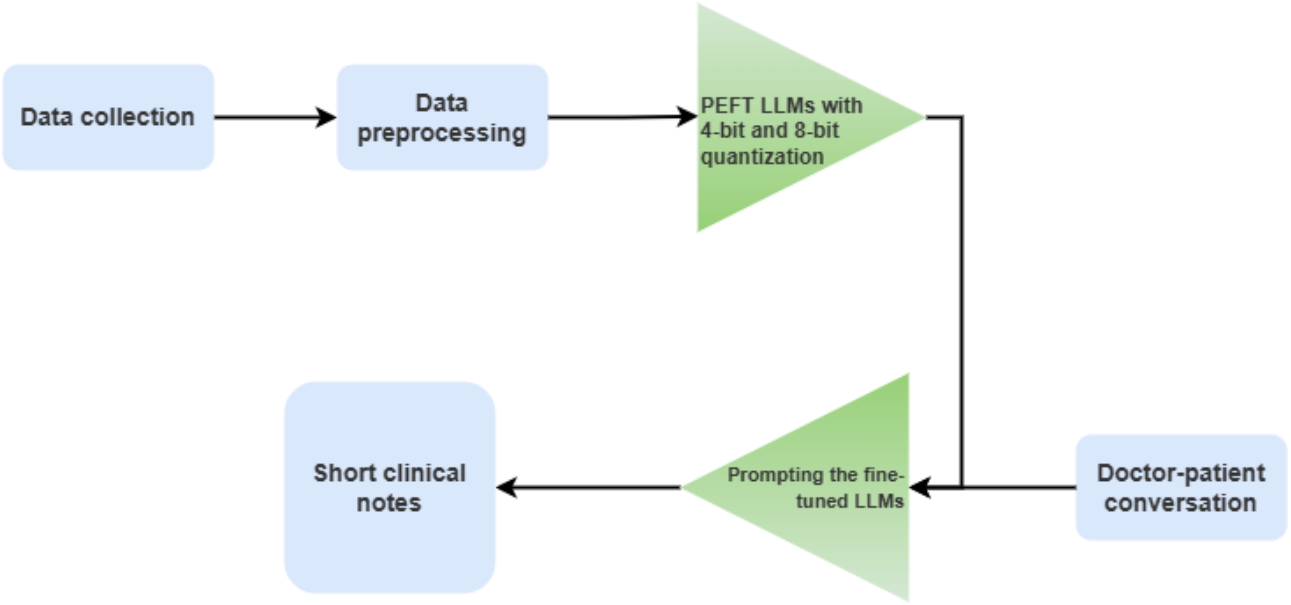
In most cases, the graphics processing unit (GPU) hardly has enough memory to fine-tune any decoder-only LLM. To overcome this problem, we used the parameter-efficient fine-tuning (PEFT) technique proposed in the study by Houlsby et al [22]. The authors in the paper proposed a parameter-efficient transfer learning technique for NLP that introduces small trainable adapter modules into every layer of a pretrained model with frozen original model weights. The technique minimizes trainable parameters, leading to efficient and scalable fine-tuning across various tasks. We also used 8-bit quantization, where the original pretrained weights of the model are quantized to 8-bit and kept fixed during fine-tuning. This method is known as quantized low-rank adapter (QLoRA) [23].

Research Methodology

Overview

This research introduces a new task in text generation. To solve this, a text-generation model must be created to generate clinical notes from the conversation between doctor and patient Textbox 1. A training-inference diagram of this text-generation model is shown in Figure 1.

Textbox 1. Algorithm 1: training procedure for clinical note generation.



Given dataset: *C,N, where* $C=\{C_0,C_1,...,C_i\}$ *[set of doctor-patient conversations] and* $N=\{N_0,N_1,...,N_i\}$ *[set of clinical notes]*

Objective: learn a generative model $F(C_j)$ such that it produces a valid N_j, where $N_j \notin \{N_0,N_1,...,N_i\}$ and N_j is not generated from $\{C_0,C_1,...,C_i\}$

A valid generated note N_k must follow the syntax of the target language, maintain clinical integrity, follow the semantics of the target language, and not be a hallucination.

XSL•FO
RenderX

Figure 1. Training and inference diagram of the clinical note generation model. LLM: large language model; PEFT: parameter-efficient fine-tuning.

Data Preprocessing

The dataset was passed through the following preprocessing steps:

- Removing unnecessary spaces: some unnecessary tags in the dataset were removed by an empty string. Certain spaces and line gaps were eliminated for text processing and analysis to streamline the training.
- Tokenization: tokenization is one of the most vital steps in this research. In this particular research, HuggingFace models were mostly used. For this reason, HuggingFace's AutoTokenizer class is used for tokenization.

Evaluation Metrics

To ensure a robust assessment of the generated clinical notes, we used both automated quantitative metrics and qualitative human expert evaluation:

- ROUGE: this metric measures the lexical overlap between the machine-generated notes and the reference summaries. We report ROUGE-1 (unigram overlap), ROUGE-2 (bigram overlap), and ROUGE-L (longest common subsequence) [24].
- BERTScore: This metric evaluates semantic similarity by leveraging contextual embeddings to compare the generated text with the reference text, capturing meaning beyond exact word matches [25].
- To validate clinical utility, a qualified physician evaluated a subset of the generated notes. The evaluation followed a 5-point Likert scale (where 1 is the lowest and 5 is the highest) across five critical clinical dimensions: (1) medical accuracy: verification of the correctness of clinical facts, (2) completeness: ensuring no vital information from the dialogue was omitted, (3) conciseness and relevance: assessing the model's ability to filter out nonessential information, (4) clinical coherence and readability: evaluating the logical flow and professional tone of the note, and (5) overall clinical quality: an aggregate score representing the general utility of the note in a professional setting.

Training Setup

We used the online platform Kaggle to fine-tune our dataset. NVIDIA Tesla T4 GPU was used for both the computationally intensive fine-tuning process and the inference phase. The hardware configuration was as follows: Tesla T4, CUDA version: 12.4, and available RAM: 29 GB.

Fine-Tuning the Llama and Mistral Variants

At first, we tried different sequence-to-sequence models with DA techniques to beat the current state-of-the-art (SOTA) model, but the result was not satisfactory. Next, several SOTA decoder-only models, such as variants of Mistral and Llama, were evaluated. The "Meta-Llama-3-8B" model, an updated version of the Llama family with 8B parameters, outperformed the SOTA Flan-T5-Large model in the ROUGE and BERT metrics, while the "Mistral-7B-v0.3" outperformed in the BERT metric only. A smaller variant of the Llama family "Llama-3.2-3B" was also fine-tuned. Due to low hardware resources, full model fine-tuning was not feasible. We have also used "Meditron-7B." It is a suite of open-source medical language models with 7B and 70B parameters, addressing gaps in medical artificial intelligence [26]. Built on Llama-2, the models are pretrained on a curated medical corpus, including PubMed articles and guidelines, using Nvidia's Megatron-LM framework. We used the 7B variant of the model in this research. The decoder-only models were fine-tuned using PEFT [22] with the low-rank adaptation (LoRA) [27] method. Eight-bit quantization was used while loading the models. This method is known as QLORA [23]. In this approach, the model's original pretrained weights are converted to 8-bit formats and remain unchanged during fine-tuning. A small number of trainable parameters, called low-rank adapters, are added during the fine-tuning process [27]. These adapters are trained to adjust the pretrained model for the specific task during fine-tuning using the 32-bit floating-point format. During computations, such as forward and backward passes in training or during

XSL•FO
RenderX

inference, the 8-bit quantized weights are converted back to 32-bit floating-point numbers. After fine-tuning, the model includes the original weights in their 8-bit form, along with the low-rank adapters in their higher-precision format. A significant percentage of this research and analysis is devoted to fine-tuning. For this procedure, the MTS-Dialog dataset was used. Meta-Llama-3-8B, Llama-3.2-3B, Meditron-7B, and Mistral-7B-v0.3 LLMs were used for fine-tuning with the following hyperparameters. All the models were loaded with 8-bit quantization, and the following LoRA hyperparameter configurations were maintained and described in Table 2. The prompt that was used as a prefix to summarize the doctor-patient dialogue to generate clinical notes was as follows:

> *Summarize the following patient-doctor dialogue. Include all medically relevant information, including family history, diagnosis, past medical (and surgical) history, immunizations, lab results, and known allergies.*

This primary prompt was used to generate all quantitative performance metrics reported in Table 3. For the evaluation of our fine-tuned models, we calculated performance metrics independently for test set 1 and test set 2. These independent scores were subsequently averaged to ensure comparability with baseline models reported in the literature. Furthermore, we explicitly confirm that there is no data overlap between the training set and these test sets.

Table . Hyperparameter settings used for fine-tuning the large language models, including parameters for training arguments and generation. Detailed configuration of the training environment and model parameters used to adapt Mistral, Llama, and Meditron variants for clinical note generation.

Hyperparameters	Settings
per_device_train_batch_size	1

Table . Performance metrics for fine-tuned large language models on the clinical note generation task, measured by Recall-Oriented Understudy for Gisting Evaluation (ROUGE) and bidirectional encoder representations from transformers score (BERTScore).

Method	ROUGE-1	ROUGE-2	ROUGE-L	BERTScore-F1
Llama-3.2-3B	0.3686	0.1517	0.2895	0.8901
Llama-3-8B	*0.4574*[a]	*0.2079*	*0.3636*	*0.9060*
Llama-3-8B (DA[b])	0.4131	0.1888	0.3410	0.8956
Mistral-7B	0.3889	0.1431	0.3184	0.8933
Mistral-7B (DA)	0.3679	0.1112	0.3014	0.8898
Meditron-7B	*0.4560*	0.1931	*0.3667*	*0.9056*

[a]Best scores are italicized.

[b]DA: data augmentation.

While training, the following "TrainingArguments" class's hyperparameter configuration was used, shown in Table 2. Given the severe computational and memory constraints of fine-tuning LLMs on a single Tesla T4 GPU, conducting an

XSL•FO
RenderX

exhaustive algorithmic hyperparameter search (such as a grid search) was computationally prohibitive. Instead, we used an empirical, manual tuning strategy. We iteratively tested a targeted subset of hyperparameter combinations based on established best practices for PEFT. For example, we evaluated LoRA α values of 8, 16, and 32, observing empirically that an alpha of 16 provided the most stable validation loss and convergence speed for our dataset without triggering out-of-memory errors. Pytorch "generate()" method generates clinical notes from the fine-tuned LLMs. The hyperparameters used for generating clinical notes are also shown in Table 2. These same hyperparameters were maintained for all the models that are used in this research.

We used a maximum sequence length of 512 tokens due to hardware memory constraints. Though the dataset contains dialogues exceeding this length, truncation was applied to fit the inputs within this limit.

Results

The results are shown after fine-tuning the Llama3-8B and Mistral-7B models in Table 3. ROUGE [24] and BERTScore [25] were used as evaluation metrics. The performances with and without DA are displayed in the table. The fine-tuned Llama-3-8B and Meditron-7B models achieved comparable SOTA performance. Llama-3-8B attained a ROUGE-1 score of 0.4574 and BERTScore-F1 of 0.9060. Notably, Meditron-7B achieved a slightly higher ROUGE-L score (0.3667 vs 0.3636), suggesting strong performance in structural coherence, likely due to its domain-specific pretraining. Given the marginal differences in ROUGE-1 scores (0.0014 difference), we classify both models as top-tier performers among the open-source variants tested, rather than declaring a single definitive winner.

For some reason, Llama-3-8B with DA performs lower than this. With DA, we get a ROUGE-1 score of 0.4131, a ROUGE-2 score of 0.1888, a ROUGE-L score of 0.3410, and a BERTScore-F1 score of 0.8956. A smaller version of the Llama model, "Llama-3-3B," is also fine-tuned, but the performance was not good enough, indicating that model parameter size remains a critical factor for this specific task. The model gave ROUGE-1 score of 0.3686 and BERTScore-F1 of 0.8901. The fine-tuned Mistral model also delivered competitive results, achieving a BERTScore-F1 of 0.8933. However, in the case of ROUGE scores, it lags behind Llama3. With DA, the performance of the Mistral-7B model decreased.

An expert physician evaluated the LLM-generated clinical notes using a 5-point Likert scale (1-5) across five dimensions: medical accuracy, completeness, conciseness and relevance, clinical coherence and readability, and overall clinical quality (average of all these criteria). Higher scores indicate better performance across all criteria. The human evaluation result is shown in the Table 4.

Table . Physician-rated clinical quality evaluation of the large language model–generated notes. A qualitative assessment conducted by a qualified domain expert to validate the clinical utility of the models. Five key dimensions were evaluated using a 5-point Likert scale: medical accuracy, completeness, conciseness and relevance, clinical coherence and readability, and overall clinical quality.

Model	Medical accuracy, mean (SD)	Completeness, mean (SD)	Conciseness and relevance, mean (SD)	Clinical coherence and readability, mean (SD)	Overall clinical quality, mean (SD)
Llama-3.2-3B	4.29 (1.14)	4.38 (1.02)	4.43 (1.05)	4.65 (0.91)	4.44 (0.93)
Llama-3-8B	4.66 (0.86)	4.65 (0.89)	4.73 (0.82)	4.83 (0.74)	4.72 (0.75)
Mistral-7B	4.55 (0.68)	4.68 (0.60)	4.73 (0.60)	4.89 (0.42)	4.71 (0.51)
Meditron-7B	4.43 (0.90)	4.47 (0.90)	4.73 (0.55)	4.89 (0.35)	4.63 (0.52)

Discussion

Principal Findings

The results of this study demonstrate that decoder-only transformer models, specifically Llama3-8B and Meditron-7B, achieve SOTA performance among open-source, parameter-efficient, fine-tuned models in generating clinical notes from doctor-patient dialogues. Our findings indicate that PEFT with 8-bit quantization (QLoRA) allows these large models to perform effectively under hardware constraints while maintaining high medical accuracy. The results clearly show that DA did not enhance the performance of either model; both the Mistral and Llama variants performed better without it. A similar phenomenon has been noted and explained in a previous research paper [28]. Notably, an expert physician's evaluation confirmed that these models produce clinically coherent and accurate summaries, with Llama3-8B and Mistral-7B leading in overall clinical quality.

Comparison With Prior Work

Our research establishes a new benchmark by surpassing the previous leader, Flan-T5-Large, in automatic evaluation metrics such as ROUGE and BERTScore. Unlike some entries in the MEDIQA-Chat 2023 competition that relied on DA to boost performance, our experiments showed that DA actually decreased performance for Mistral and Llama variants, aligning with findings in other specialized medical NLP research.

Limitations

Table 5 shows the training and inference times for different models. Training time is measured in seconds/epoch. All fine-tuned models are inferred with a Tesla T4 GPU. From Table 5 it is visible that the inference time for Mistral-7B is better than Llama-3-8B, but it is worse than Meditron-7B. However, for real-world applications, it needs to be improved further. Training time for both models is quite long.

XSL•FO
RenderX

Table . Computational efficiency and latency analysis per clinical note generation. This table compares the training duration (seconds/epoch) and average inference latency (seconds/note) across the four primary model architectures. Conducted on a Tesla T4 graphics processing unit, these metrics evaluate the feasibility of deploying decoder-only large language models in real-time clinical settings where documentation speed is critical for reducing physician burnout.

Model	Training time	Average inference time
Llama-3.2-3B	1406.6	12.49
Llama-3-8B	2588.9	13.41
Mistral-7B	2171.6	8.68
Meditron-7B	2566.06	6.27

All the fine-tuned models had some gender biases. As the "MTS-Dialog" dataset is a short doctor-patient conversation dataset, sometimes it is quite difficult to understand the patient's gender from the conversation. In these situations, all of the fine-tuned models mostly assume the patient's gender as male. In a few cases, the model predicts the gender as female, while in the annotation, the patient is identified as male. In some cases in the dataset, the gender pronoun is used incorrectly. We assume that most of the model's pretraining dataset could be biased, which is causing this type of problem. In some cases in the dataset, the gender pronoun is used incorrectly. To overcome this, we use the following new prompt during inference:

> *Summarize the following patient-doctor dialogue. To ensure a comprehensive summary, follow these steps:*
>
> *Gender identification: identify the patient's gender based on the context and use appropriate pronouns throughout the summary.*
>
> *Medical history: summarize the patient's family history, past medical and surgical history, and known allergies. Ensure each detail is categorized.*
>
> *Current visit: identify the main concerns discussed, including symptoms, lab results, and diagnosis.*
>
> *Immunizations: list any relevant immunization history.*
>
> *Plan and recommendations: note any treatment plan, medications prescribed, or follow-up actions recommended by the doctor. Ensure your summary flows logically, preserving the order of the conversation, while focusing on medically relevant details.*

However, even after using this prompt, there was still no significant improvement. This gender-aware prompt was evaluated qualitatively but is not reflected in these baseline quantitative results.

Another major limitation of our quantitative evaluation is the reliance on a single expert physician, which introduces potential evaluator bias and precludes the calculation of interrater reliability metrics such as Cohen κ. Future studies should use multiple independent evaluators to mitigate individual bias.

Future Work

The amount of data in the medical domain are very limited. It is also very hard to get access to this type of data because of the physician-patient privilege. Most of the patients are not comfortable sharing their private data. It is essential to develop more data, which will make it easier to create an automatic clinical note generation system. The dataset used in this research is short conversations between doctors and patients. A more and longer real-world doctor-patient conversation corpus is needed in the future to improve the quality of clinical note generation.

Domain-specific pretrained decoder-only LLMs have improved the domain-specific task a lot in recent years. A pretrained model such as Code Llama is one example in the coding domain [29]. Developing a decoder-only model that is pretrained on a large medical corpus might help to create clinical note generation tasks.

In diverse health care settings, doctors and patients may converse in different languages. A cross-lingual summary can help bridge this language gap by automatically summarizing conversations in one language and translating the summary into another, making it accessible to a wider range of health care providers. Creating a cross-lingual clinical note generator could greatly impact this domain.

In this research, text data from doctor-patient conversations are used. Generating clinical notes directly from the spoken interactions between doctors and patients could provide a more accurate and practical solution.

The maximum sequence length was set to 512 tokens due to hardware memory constraints. This truncation represents a methodological limitation that may have affected the completeness of the generated notes for longer dialogues. Future implementations should consider sliding window approaches to handle lengthy conversations without information loss.

It is also shown that just updating the prompt while doing inference is not a solution to this problem. The hypothesis of the authors of this paper suggests these steps to overcome the problem. The wrongly addressed gender in the dataset should be corrected manually in the reference note, and the patient's gender information should be included in the conversation. After that, the prompt should be updated by including the information to detect the correct gender of the patient and use this prompt to fine-tune the model. By doing all these tasks, it may be possible to solve the problem.

Conclusions

In this research, we experimented with various decoder-only transformer architectures to fine-tune models for generating clinical notes by summarizing conversations between doctors and patients. The results demonstrate that decoder-only models such as Llama3 and Mistral outperform classical

XSL•FO
RenderX

encoder-decoder models such as Flan-T5 and Pegasus in summarizing medical discussions. Larger models tend to deliver better results compared to smaller ones. By fine-tuning the Llama-3-8B and Meditron-7B models, SOTA performance among open-source, parameter-efficient models was achieved in terms of ROUGE-1 score and BERTScore. However, none of the models underwent full fine-tuning. Instead, PEFT methods were applied across the board. The study highlights the importance of domain-specific pretraining and high-quality annotated datasets. While our methods show promising results, there are still challenges to overcome, such as hardware limitations, gender bias, and the lack of diverse medical datasets. Ultimately, automating clinical documentation through decoder-only LLMs has the potential to enhance health care efficiency. However, given the unresolved gender bias observed in this study, these models are currently best suited as assistive tools in human-in-the-loop workflows rather than autonomous systems, requiring further research into bias mitigation before they can ensure fully accurate patient records.

Acknowledgments

The authors would like to express their gratitude to Dr Mazidul Islam Nahid (MBBS, PGT [ENT], DLO [Course]; BMDC RN: 129195) of Sir Salimullah Medical College and Mitford Hospital for his essential contribution as the domain expert. His clinical expertise was instrumental in evaluating the generated notes across five critical dimensions: medical accuracy, completeness, concision, relevance, and clinical coherence and readability.

All authors declared that they had insufficient or no funding to support open-access publication of this manuscript, including from affiliated organizations or institutions, funding agencies, or other organizations. JMIR Publications provided APF support for the publication of this article.

Generative artificial intelligence (ChatGPT and Gemini) was used solely for grammatical polishing and readability improvement, while the scientific concept and experimental design remain exclusively the work of the authors.

Funding

No financial support was received for the research, authorship, and/or publication of this article.

Data Availability

The study used the Medical Training Summarization Dialog dataset, which is a publicly available collection of simulated doctor-patient conversations. It can be accessed through the official MEDIQA-Chat 2023 shared task repository.

Abstract

Background: Large language model (LLM) proofreaders for radiology reports generate many false positives (FPs) due to the low prevalence of errors.

Objective: This study aimed to determine whether an optimized LLM framework could improve both precision and cost-efficiency without compromising error detection capability.

Methods: In this retrospective study, 1000 radiology reports (radiography, ultrasonography, computed tomography, and magnetic resonance imaging; 250 each) were sampled from the Medical Information Mart for Intensive Care III database. Two public chest radiography corpora (CheXpert and Open-i) served as external test sets. Three LLM frameworks were evaluated: single-prompt detector (framework 1); report extractor plus single-prompt detector (framework 2); and extractor, detector, and FP verifier (framework 3). Precision for each framework was assessed using positive predictive value (PPV) and detected errors per 1000 reports. Overall efficiency was estimated using model inference costs and reviewer labor costs.

Results: PPV increased from 0.063 (95% CI 0.036 - 0.101) in framework 1 to 0.079 (95% CI 0.049 - 0.118) in framework 2 and 0.159 (95% CI 0.090 - 0.252) in framework 3 (P<.001). Despite improved PPV, detected errors remained stable (detected errors per 1000 reports: 12 - 14). Human review burden decreased from 192 to 88 reports. Framework 3 also reduced model inference costs to US $5.57 per 1000 reports (vs US $9.72 and US $6.85 for frameworks 1 and 2; 42.6% and 18.5% reductions, respectively). External validation confirmed similar improvements. Qualitative analysis revealed that remaining FPs in framework 3 were largely confined to cases requiring deep clinical context (clinically equivalent rephrasing: 53%; unsupported discrepancy assertions: 43%). By eliminating structural FPs (eg, section mismatches and lexical errors: 0%), the framework effectively shifted the quality assurance burden to a smaller set of ambiguous cases, enabling a targeted human-in-the-loop workflow.

Conclusions: The multipass LLM improved the precision and cost-efficiency of radiology report error detection in real-world, low-error prevalence settings. The framework demonstrates the feasibility of synergistic artificial intelligence–radiologist collaboration and provides a cost-effective and scalable approach to artificial intelligence–assisted quality assurance in both radiological practice and research.

Introduction

Large language models (LLMs) are increasingly being explored as an additional set of eyes for proofreading radiology reports [1,2]. However, when applied to real-world data, this extra "eye" often results in frequent false alarms. The precision of these models—also referred to as positive predictive value (PPV)—remains low because, despite "good" model specificity, the underlying error rate in clinical practice is extremely low. For example, in a setting with a 1% error prevalence, even a

XSL•FO
RenderX

highly sensitive model with 90% specificity would still generate approximately 10 false alarms for every true error detected. In one experiment involving 10,000 real reports, GPT-4 achieved a PPV of only 6% despite good specificity, producing roughly 15 false alerts for each true error [3]. These excessive notifications contribute to alert fatigue among radiologists, prompting them to ignore subsequent warnings, hindering effective human-artificial intelligence (AI) collaboration, and—ironically—increasing the real-world workload [4].

Although continued advances in LLMs are expected to address these shortcomings, the anticipated gains present a double-edged sword in terms of overall utility [5]. Parameter scaling, task-specific fine-tuning, and deployment of multiagent systems [6,7] can certainly enhance model performance and clinical efficiency. However, these improvements come at substantial computational costs. Deploying multiagent systems, for example, routinely produces execution traces averaging more than 15,000 lines per session [8], while scaling to larger models dramatically increases resource demands—a recent study showed that LLaMA-3-70B incurred over 400 times the inference time and cost of a lightweight 3B-parameter model for radiology report structuring [9]. Consequently, AI-driven radiology report error detection faces a dual imperative: it must increase precision to reduce human workload while also remaining computationally feasible and cost-effective for routine clinical deployment.

Despite these limitations, previous studies still benchmark LLMs on error-inflated datasets and rarely explore strategies for improving PPV in low-error, real-world settings [1,10,11]. Similarly, strategies to improve operational cost-efficiency remain largely unexplored. Consequently, achieving clinical viability requires a framework capable of explicitly resolving the inherent trade-off between sensitivity and specificity observed in single-pass models [3].

To address these gaps, we present a multipass LLM framework designed to optimize both precision and efficiency. The pipeline (1) employs a lightweight report extractor to isolate clinical findings from structural noise, (2) applies stepwise reasoning to decouple error detection from verification, thereby mitigating the sensitivity-specificity trade-off, and (3) provides a user interface to facilitate rapid review of the model's structured output by radiologists. A benchmark with 2 nonoptimized baselines was performed to quantify improvements in precision and efficiency.

Methods

Ethical Considerations

This study used only publicly available, deidentified radiology datasets (Medical Information Mart for Intensive Care III [MIMIC-III], CheXpert, and Open-i). Institutional Review Board approval and written informed consent were not required.

Dataset Curation

Radiology reports were retrieved from the MIMIC-III database [12]. Using the "ISERROR" column in the database, which identifies physician-flagged erroneous notes, the study included only those reports that had been confirmed as error-free. To validate robustness across the heterogeneous nature of radiology reports and facilitate performance comparison across modalities, modality-level stratified random sampling was performed to construct a balanced primary test set comprising 1000 reports, with 250 reports each from radiography, ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI). An additional hold-out set of 50 predominantly radiography reports was reserved for prompt tuning and reviewer calibration. To assess the external generalizability of the proposed pipeline, 2 publicly available radiology report datasets—CheXpert and Open-i chest X-ray [13,14]—were used as external test sets. The characteristics of the final reports across all datasets are summarized in Table 1.

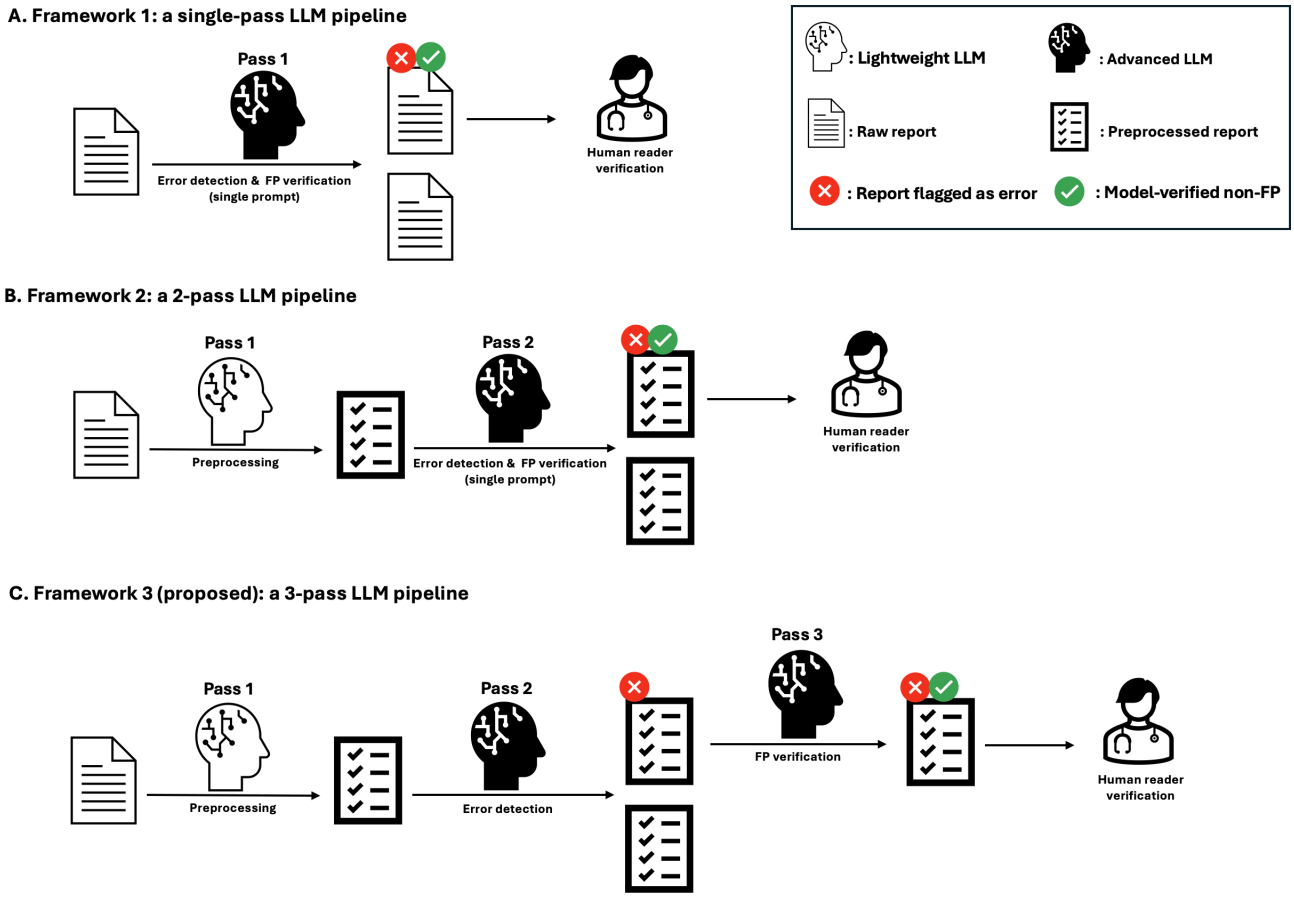
Error Definition

The process of generating radiology reports can be divided into the following two main steps: (1) detecting abnormalities from images and (2) documenting the detected abnormalities [3]. Efforts have been made to use natural language processing models, including LLMs, to correct errors occurring in the second step [3,15-17]. Examples of these second-step errors may result from the misinterpretation of findings or the inclusion of factually inconsistent content in the report text. Following the classification proposed by Kim et al [3], errors were categorized into interpretive errors (addition, omission, and substitution) and factual errors (discrepancy in location/numerical measurement). The detailed description of error types is described in Table S1 in Multimedia Appendix 1.

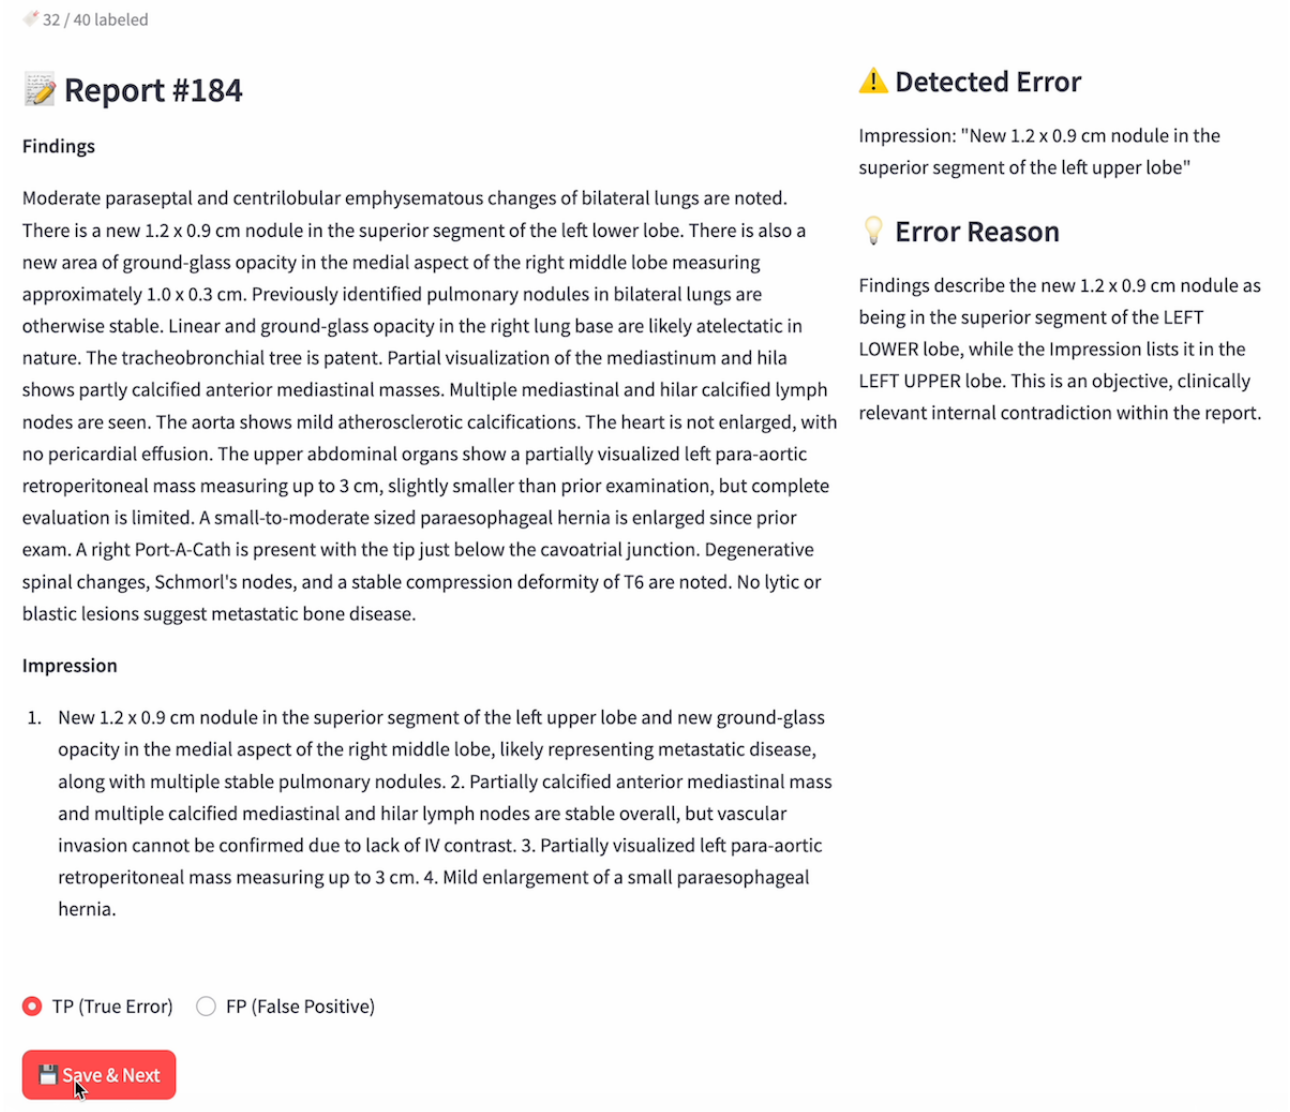
Proposed Framework and Experimental Design



Three LLM pipelines were compared (Figure 1). In framework 1, the original report was input directly into an advanced LLM, which performed both error detection and false-positive (FP) verification within a single prompt. In framework 2, a lightweight LLM first extracted and structured the relevant portion of the radiology report by removing content outside the “Findings” and “Impression” sections—such as clinical information, technique notes, and headers—and seamlessly merging any addenda into this section. The resulting structured Findings or Impression block was then passed to an advanced LLM, which performed combined error detection and FP verification in a single prompt. Framework 3 retained the preliminary extraction step but divided the downstream reasoning across 2 successive prompts: candidate errors were first enumerated and then reexamined to verify potential FPs.

Final model responses were structured to include the radiology report, identified errors, and corresponding error reasoning [18]. The resulting outputs were streamed to a web-based quality assurance interface, which displayed the flagged report alongside the model’s error reasoning, allowing human reviewers to accept or reject each suggestion with a single click (Figure 2).

The lightweight LLM used in this experiment was executed by OpenAI’s GPT-4.1-nano, selected for its favorable cost-effectiveness, and the advanced LLMs were O3, chosen for their superior reasoning performance at the time of the study [19]. The 2 models have a 100-fold difference in cost per token. All pipelines were executed on the institution’s private Azure OpenAI Service, with each LLM API (application programming interface) call launched within an isolated API session. Detailed descriptions of the prompts and parameters are provided in Multimedia Appendix 1.



XSL•FO
RenderX

Figure 1. Experimental design of large language model (LLM) pipelines for radiology report error detection. In the single-pass framework (A), each report is processed once by an advanced LLM that simultaneously performs error detection and false-positive (FP) verification before reader's review. In the 2-pass framework (B), a lightweight LLM first performs preprocessing, and an advanced LLM subsequently conducts combined detection and verification before reader's review. In the proposed 3-pass framework (C), preprocessing is followed by error detection in a second pass and isolated FP verification in a third pass by an advanced LLM, prior to reader's review.

XSL•FO
RenderX

Figure 2. User interface for the multipass large language model (LLM) radiology report error detector. The review screen loads the preprocessed structured output, displaying the "Findings" and "Impression" sections in the left panel, while the right panel shows the detected error and the model-provided rationale using the error and error_reason keys. This structured layout enables reviewers to classify each finding as either a true positive (TP) or a false positive (FP) with a single click.

Precision Evaluation

Each flagged report underwent a 2-step review. Two board-certified physicians (with 9 and 10 years of clinical experience, respectively) screened each model-generated alert against the original report using a standardized rubric aligned with our error taxonomy, labeling them as true positive (TP) or FP. Subsequently, 2 board-certified radiologists (with 8 and 9 years of clinical experience, respectively) adjudicated these labels to establish the final ground truth. Reviewer calibration on the held-out prompt-tuning set (n=50) showed an overall percent agreement of 94% (47/50). The performance of the framework was evaluated using PPV (PPV=TP/[TP+FP]) and the detected errors per 1000 reports (DE/1k=(TP/N)×1000), where N denotes the size of the test set. Here, TP refers to a model-flagged report in which a genuine error was confirmed, while FP refers to a flagged report that did not contain a true error. To analyze failure modes, 30 adjudicated FP alerts per framework were randomly sampled from the MIMIC-III test set (n=90). Each case was independently reviewed and classified into a 6-category taxonomy by 2 board-certified radiologists to track the evolution of error patterns.

Operational Cost-Efficiency Evaluation

A cost-minimization analysis was conducted under the assumption of equal true error detection across all 3 frameworks. The estimated running cost was defined as the sum of (1) model inference costs and (2) reviewer labor costs [20]. Because the exact computational cost of the closed-source LLM could not be measured directly, we used per-token API charges as a proxy measure. This choice is supported by the evidence that electricity and graphics processing unit rental costs dominate token pricing in commercial LLMs [21,22]. Consequently, the model inference costs were calculated based on text volume and provider pricing rates (Eq S1 in Multimedia Appendix 1).

Reviewer labor cost was approximated by multiplying the total number of reports sent for manual inspection—comprising both

XSL•FO
RenderX

TPs and FPs—by the mean compensation paid per report (Eq S2 in Multimedia Appendix 1).

Reviewer labor costs were modeled using the median annual compensation for diagnostic radiologists (US $568,327) reported in the 2024 Medical Group Management Association (MGMA) compensation survey [23]. Assuming a standard 2,000-hour work year, this corresponds to an hourly rate of approximately US $284 or US $4.74 per minute. Consistent with review durations reported in prior literature [1,3], the analysis was performed by varying the review time per flagged report (30, 60, and 120 s) to estimate labor costs across different clinical scenarios.

The estimated running cost for each framework was therefore defined as the sum of the 2 components (Eq S3 in Multimedia Appendix 1) and is reported separately to permit direct operational cost-effectiveness comparisons. Formal derivations and the full set of symbols are provided in Multimedia Appendix 1.

Statistical Analysis

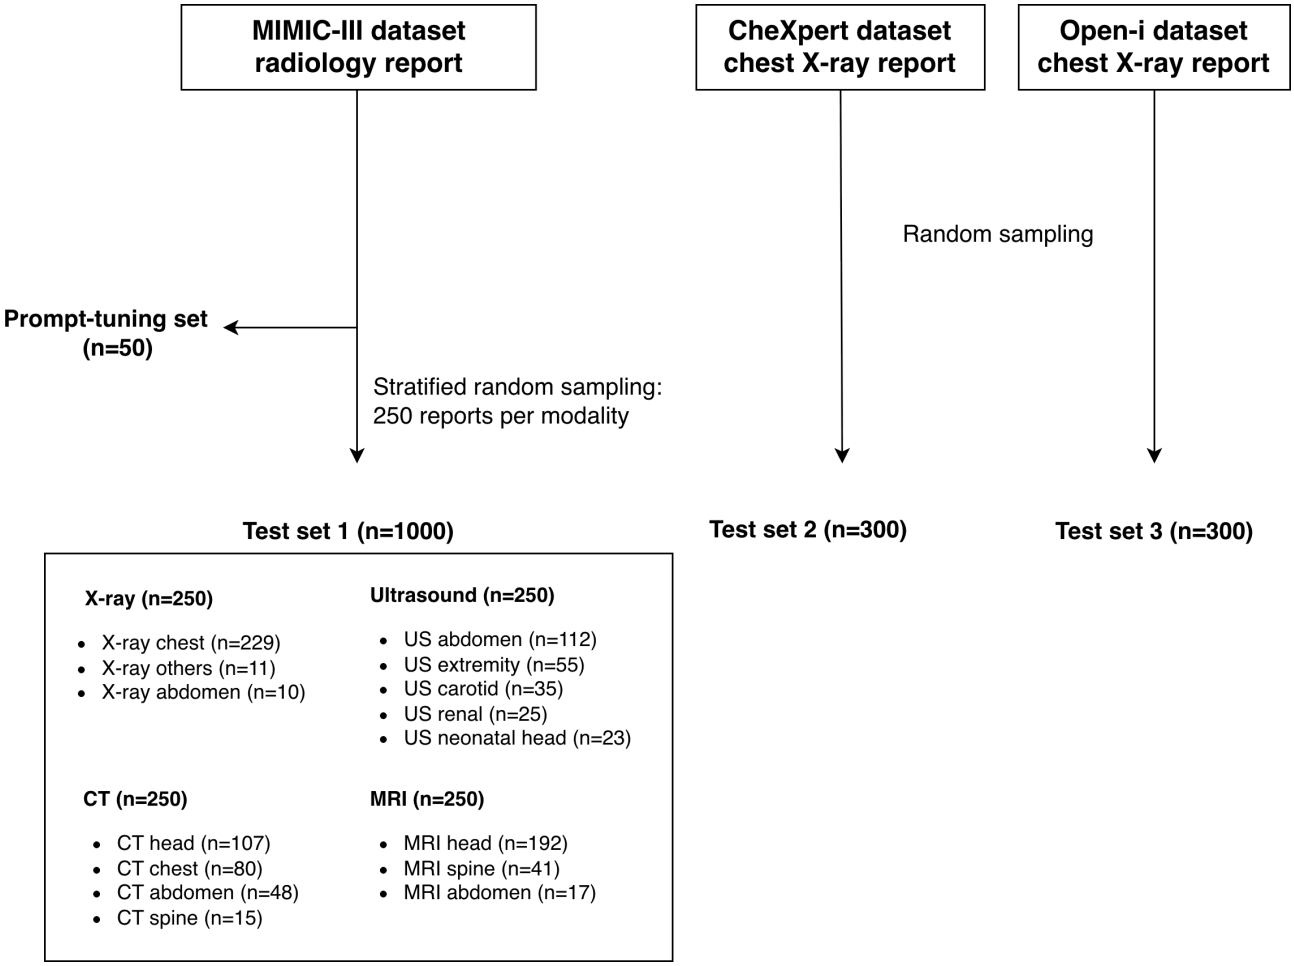
Continuous variables are reported as mean (SD) when normally distributed (Shapiro-Wilk test, $P>.05$) and as median (IQR) otherwise. Categorical variables are summarized as counts and percentages. Between-dataset differences were assessed using the Kruskal–Wallis test for continuous variables and the Fisher exact test for categorical variables. PPV and DE/1k are expressed with 2-sided 95% exact (Clopper-Pearson) CIs [24].

For PPV comparisons, pairwise differences among the 3 frameworks were assessed using report-level paired-cluster bootstrap (10,000 replicates). Two-sided *P* values were extracted from the bootstrap distributions, and the family-wise error rate across the 3 comparisons was controlled using the Holm-Bonferroni procedure [25]. Modality-specific PPV analyses were regarded as exploratory and reported without multiplicity adjustment. When the frameworks followed a prespecified ordinal sequence, a Cochran-Armitage trend test was additionally applied to detect monotonic trends in PPV across the ordered groups.

For DE/1k comparisons, within-case differences among the 3 frameworks were evaluated using the exact McNemar test, with the family-wise error rate controlled via the Holm-Bonferroni procedure. When comparing 3 or more frameworks, an overall Cochran Q test was conducted; if significant, pairwise McNemar tests with Holm correction were performed. All tests were 2-tailed, with an α of .05.

The sample size was calculated based on the MIMIC-III dataset. The baseline PPV of the reference pipeline was assumed to be 6%, as previously reported [3]. A 2-fold improvement with the proposed pipeline was deemed a meaningful difference. Treating the comparison as a 2-sided test of the difference between 2 independent proportions and adopting α=.05 with a statistical power of 80%, a minimum of 716 reports was required. Consequently, the final sample of 1000 reports satisfied and exceeded this requirement, thereby ensuring adequate power for the primary hypothesis test. Analyses were performed in Python 3.11 using pandas 2.2.2, SciPy 1.12.0, and statsmodels 0.15.0 for statistical procedures and matplotlib 3.9.0 for visualization.

Results



Detected Errors and FP Cases

The true errors identified in each dataset are summarized in Table S4 in Multimedia Appendix 1. Fourteen errors were detected in the MIMIC-III dataset—2 in chest radiographs, 3 in carotid ultrasonography studies, 1 in a neonatal brain ultrasonography study, 3 in head CT scans, 2 in chest CT scans, and 3 in head MRI examinations (Figure 3). Two errors were found in both the CheXpert and Open-i datasets. The error distribution included discrepancies in anatomical location (9/18, 50%), omission (3/18, 17%), addition (3/18, 17%), and discrepancies in numeric measure (3/18, 17%); notably, errors detected by each framework followed a strict subset relationship, and the per-framework breakdown is provided in Table S5 in Multimedia Appendix 1.

Table 2 summarizes representative FP cases. FPs that occurred only in framework 1 arose chiefly from a rigid comparison of superficial header elements—such as date strings or minor omissions in the clinical history—with the body text, causing spurious contradiction flags. Once the header metadata had been removed, such false flags were not observed in framework 2 or 3. Framework 2 still produced many FPs because it compared sentences at the strict word level, with little regard for anatomical or contextual nuance. Framework 3 subsequently reexamined the candidate contradictions identified by framework 2 in the context of the full report and reclassified statements deemed acceptable in routine practice, thereby reducing the overall FP burden.

Report excerpt	Framework 1	Framework 2	Framework 3	False-positive rationale
Header: "Comparison: 10/20." "1. Compared to prior study from October 5th, 20, interval increase in..."	Error	No error	No error	Two legitimate comparison dates were interpreted as contradictory.
Header: "s/p MVC[b], s/p chest removal" "status post MVC and chest tube removal, "	Error	No error	No error	Typographic omission of "tube" was mistaken for a clinical conflict.
"…image degradation in the low pelvis because of patient's size, but no masses or fluid collections are seen." "osteolytic and mixed osteosclerotic metastases are seen in the pelvic bones, most prominent at the right iliac…"	Error	Error	No error	Separate reporting of the pelvic cavity and pelvic bone was overlooked, and the statements were therefore flagged as contradictory.
Chest section: "The heart, pericardium, and great vessels are normal." Abdomen section: "The IVC[c] is markedly compressed; however, remains patent."	Error	Error	No error	Separate reporting of chest and abdomen was overlooked, and the statements were therefore flagged as contradictory.
"The liver demonstrates normal morphology without signal dropout...There are numerous ill-defined lesions within the liver which are hypointense to the liver parenchyma..."	Error	Error	No error	Failure to distinguish overall morphology from focal lesions produced a false positive.

[a]All reports contained no actual errors. "Error" indicates false positive by framework; "No error" indicates correct assessment by framework.

[b]MVC: motor vehicle collision.

[c]IVC: inferior vena cava.

Precision of LLM Frameworks

The precision of the LLM frameworks improved as the pipeline complexity increased (Table 3, Figure 4A). In framework 3, the overall PPV was 0.159 (95% CI 0.090 - 0.252), compared with 0.079 in framework 2 and 0.063 in framework 1. The superiority of framework 3 over both framework 1 and framework 2 remained significant after multiple comparison correction (all paired-cluster bootstrap $P<.001$; all Holm-adjusted $P<.001$). A prespecified Cochran-Armitage trend test confirmed a significant upward trend in PPV across the 3 ordered frameworks ($P=.02$), indicating that successive refinements effectively reduced FP alerts.

Figure 4. Performance comparison of the 3 error detection frameworks across the Medical Information Mart for Intensive Care III (MIMIC-III), CheXpert, and Open-i datasets. (A) Positive predictive value. (B) Detected errors per 1000 reports. Statistical significance was determined by the paired bootstrap test: *P*<.05, **P*<.01, ****P*<.001, *****P*<.0001. Trend analysis was performed using the Cochran-Armitage test: †*P*<.05. CT: computed tomography; MRI: magnetic resonance imaging; US: ultrasound.

The observed increase in precision was not accompanied by a reduction in TP detections (Table 4, Figure 4B). The overall DE/1k was 14 (95% CI 8 - 23) for framework 3, compared with 13 (95% CI 7 - 22) for framework 2 and 12 (95% CI 6 - 21) for framework 1. None of the pairwise comparisons reached statistical significance (all *P*≥.84), indicating that framework 3 reduced FP flags without compromising error detection.

[f]MRI: magnetic resonance imaging.

In the CheXpert and Open-i datasets, framework 3 achieved the highest PPVs (0.133 and 0.105, respectively; paired-cluster bootstrap $P \geq .26$; Holm-adjusted $P \geq .79$) and maintained identical DE/1k across frameworks (7 for both datasets; all $P > .99$), demonstrating robustness across diverse datasets. However, in the Open-i dataset, framework 2 yielded a lower PPV than framework 1—the only instance in which PPV did not increase monotonically with pipeline complexity. This exception may be due to the Open-i dataset already being extensively preprocessed, reducing the relative benefit of the first-pass LLM.

When framework 3 was executed using the o4-mini model instead of o3, the overall PPV significantly declined to 0.081 ($P < .001$; Table S6 in Multimedia Appendix 1), while the DE/1k

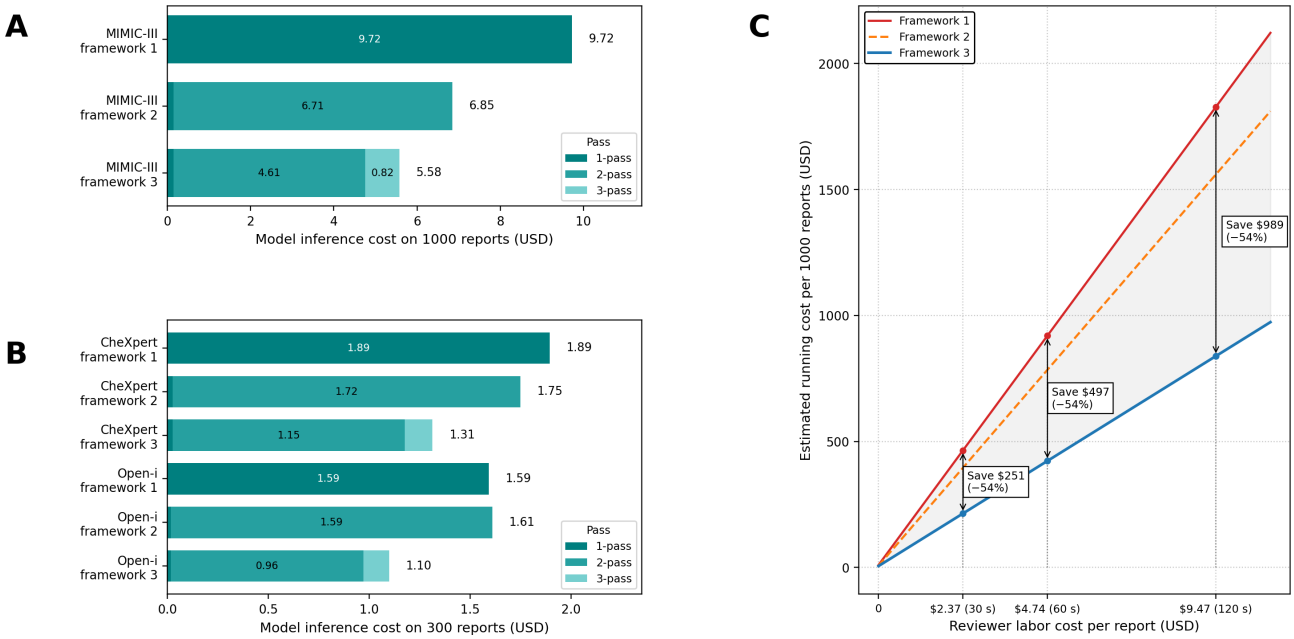
XSL•FO
RenderX

decreased slightly to 12 without reaching statistical significance (*P*=.69; Table S7 in Multimedia Appendix 1).

Analysis of FP Patterns

The distribution of FPs shifted distinctly toward semantic categories as the pipeline evolved (Table 5, Figure S2 in Multimedia Appendix 1). Superficial errors were effectively filtered by preprocessing, with header/metadata artifact cases decreasing from 3 out of 30 (10%) in framework 1 to 0% (0/30) in framework 2. However, rare preprocessing-induced artifact cases (1/30, 3%) emerged as a minor trade-off. Subsequently, structural mismatches were suppressed by the verifier step, resulting in the elimination of section/scope mismatch and lexical/abbreviation/typographical mismatch (0/30, 0%) in framework 3. Consequently, residual FPs in the final framework were predominantly concentrated in complex semantic categories, specifically clinically equivalent rephrasing (16/30, 53%) and unsupported discrepancy assertions (13/30, 43%).

Table . Characterization of false-positive categories across frameworks.



False-positive category	Definition	Framework 1 (n=30), n (%)	Framework 2 (n=30), n (%)	Framework 3 (n=30), n (%)
Header/metadata artifact	Header/history/technique/comparison text is treated as a body-text discrepancy.	3 (10)	0 (0)	0 (0)
Section/scope mismatch	Statements from different sections or anatomical scopes (eg, chest vs abdomen) are compared as if the same scope.	2 (7)	1 (3)	0 (0)
Lexical/abbreviation/typographical mismatch	Minor lexical differences (abbreviations, spelling, and formatting) are flagged as discrepancies.	2 (7)	1 (3)	0 (0)
Clinically equivalent rephrasing	Clinically acceptable wording is rewritten to a "preferred" term and the original is flagged as discrepant.	12 (40)	14 (47)	16 (53)
Unsupported discrepancy assertions	A discrepancy is asserted despite insufficient support (eg, wrong matching or compatible statements treated as conflict).	11 (37)	13 (43)	13 (43)
Preprocessing-induced artifact	Preprocessing (segmentation/normalization/removal) introduces artificial discrepancies.	0 (0)	1 (3)	1 (3)

Operational Cost-Efficiency of LLM Frameworks

The token counts for each pass are summarized in Table S8 in Multimedia Appendix 1. Framework 3 achieved the lowest model inference cost, at US $5.57 per 1000 reports, compared with US $9.72 and US $6.85 for frameworks 1 and 2, respectively—corresponding to cost reductions of approximately 42.6% and 18.5% relative to frameworks 1 and 2, respectively (Figure 5A). Framework 2 achieved most of its savings through token reduction via preprocessing, relative to framework 1. In framework 3, additional savings beyond those of framework 2 were primarily attributed to the FP verifier being triggered for only 88 candidate errors, rather than for all cases.

XSL•FO
RenderX

Figure 5. Cost analysis of the radiology report error detection frameworks and their component passes. (A) Model-only inference cost per 1000 reports in the Medical Information Mart for Intensive Care III (MIMIC-III) dataset. (B) Corresponding inference cost for 300 reports in the CheXpert and Open-i datasets. (C) Estimated total running cost per 1000 MIMIC-III reports plotted against reviewer labor cost per report. The analysis considers labor costs of US $2.37, US $4.74, and US $9.47, corresponding to review times of 30, 60, and 120 seconds, respectively. Annotations indicate the projected savings of framework 3 compared to framework 1.

Based on the MGMA-derived rate (US $4.74/min), the estimated reviewer labor costs per report were US $2.37 (30 s), US $4.74 (60 s), and US $9.47 (120 s). Under these assumptions, framework 3 demonstrated a consistent advantage in reviewer labor cost. Compared to framework 1, framework 3 yielded estimated savings of US $251 (30-s scenario), US $497 (60-s scenario), and US $989 (120-s scenario) per 1000 reports in estimated running costs (Figure 5C).

A similar trend was observed in the CheXpert and Open-i datasets (Figure 5B), where framework 3 consistently demonstrated the lowest model inference costs per 300 reports (US $0.1374 and US $0.1271, respectively), compared with framework 1 (US $1.8943 and US $1.5930, respectively). However, in the Open-i dataset, framework 2 incurred a higher model inference cost than framework 1—representing the only instance in which model inference cost did not decrease with increased pipeline complexity.

Discussion

The proposed 3-pass LLM framework improved precision and reduced estimated running costs without compromising error detection capability on datasets that approximate real-world error prevalence. On the MIMIC dataset, a PPV of 16% was achieved—more than twice that of a single-prompt, single-extraction baseline—while maintaining the detected error counts. The model inference cost decreased by 42.7% (US $9.72 vs US $5.57 per 1000 reports), and the number of alerts requiring human review declined by 54.2% (192 vs 88). These improvements remained robust across 2 independent datasets and within modality-specific subgroups.

Widely adopted clinical decision support systems, such as sepsis prediction or drug interaction alerts, typically exhibit low PPV in real-world settings because the cost of missing a critical event is unacceptable [26-28]. Radiology report error detection shares inherent challenges due to the low prevalence of errors in routine practice. To address these challenges, previous studies have often relied on synthetic error injection, based on the assumption that prevalence does not influence the sensitivity or specificity of the model [1,10,11]. However, this approach has notable limitations. Specifically, synthetic error injection may introduce bias in performance evaluation and error characterization, as the distribution and nature of injected errors may not accurately reflect real-world conditions. Furthermore, artificially inflating error prevalence can substantially overestimate the PPV, thereby misrepresenting the practical utility of the model in real-world scenarios. A low PPV—implying a high rate of false alarms—can increase the workload for radiologists and introduce potential biases for researchers conducting quality assurance on curated datasets; furthermore, it often induces distrust in the system, leading to “alert fatigue,” where alarms are habitually ignored [29]. Kim et al [3] demonstrated that few-shot prompting could improve GPT-4’s PPV to 0.12 on a dataset without injected errors. However, this improvement was derived from a post hoc analysis that reprompted only those cases previously identified as FPs, limiting the generalizability of the findings.

Thus, the proposed multipass architecture improves precision in real-world settings. This improvement is driven by 2 key components. First, a preprocessing LLM transforms raw radiology reports into cleaned, structured output before passing them to the primary LLM. During prompt tuning, we frequently observed that artifacts—such as embedded metadata, addenda, and page breaks—were misinterpreted as report content, thereby inflating FP rates. The preprocessor mitigates this issue by removing such noise, which not only reduces the likelihood of FPs but also decreases the input size for downstream tasks.

XSL•FO
RenderX

However, these preprocessing prompts yielded minimal benefits on the already cleaned Open-i dataset. The FP analysis even identified a small number of cases where the preprocessing itself generated artifacts. Consequently, to achieve optimal performance, preprocessing strategies must be carefully adapted to the reporting conventions and dataset characteristics unique to each institution.

Second, the framework uses a detector-verifier cascade. When the detector is prone to FPs, separating detection and verification into 2 distinct steps allows the LLMs to complement each other: the detector prioritizes sensitivity, whereas the verifier enhances specificity. This arrangement parallels the tiered double-reading workflow commonly used in radiology; however, in this framework, the 2 LLMs perform the initial "double read," and a human radiologist provides the final adjudication—effectively constituting a tiered triple read [30]. Prior evidence supports the benefits of task separation: in one study, 2 GPT-4 prompts for radiology report error detection were compared, revealing a trade-off between sensitivity and specificity, while the overall F_1-score remained constant [3]. This suggests that, for error detection—where high sensitivity is essential—a 2-stage cascade that first maximizes sensitivity and then applies a highly specific verifier offers a more effective balance between error detection and alert fatigue.

The remaining FPs in this framework are largely confined to cases requiring deeper clinical context, highlighting an inherent limitation of LLMs in adjudicating nuanced clinical equivalence. This may partly explain why X-ray/ultrasound achieved relatively higher PPV than CT/MRI, as CT/MRI reports are typically longer and contain more complex, multifinding narratives. Importantly, this FP profile motivates a human-in-the-loop quality assurance design: AI can triage potential errors to shift the workflow from an "unguided" to a "targeted search," while a secondary verifier layer filters out many structural FPs. Consequently, clinicians can focus their expertise on the smaller set of clinically ambiguous alerts that require high-level judgment, suggesting a complementary division of labor between AI speed and human expertise.

Successful clinical translation requires workflow-tailored integration. This framework is envisioned as an asynchronous background service that analyzes draft reports after initial dictation and surfaces only clinically meaningful report internal inconsistencies before final sign-off. To optimize the radiologist's workload, notification timing should be adapted to the clinical context—for example, near-real-time alerts for emergency or intensive care unit studies, notifications before discharge for routine inpatient studies, and batched alerts before the next scheduled visit for outpatient studies. Initial deployment should be focused on high-acuity settings or predefined high-risk cohorts to maximize clinical benefits while minimizing alert fatigue; accumulated adjudication outcomes can then be leveraged for institution-specific refinement. To reduce the cognitive burden associated with alert review, it is essential that the error rationale be displayed alongside the flagged discrepancy, as implemented in the present framework. The seamless integration of these elements into the Picture Archiving and Communication System reading environment is equally critical to ensure that adjudication occurs within the radiologist's existing workflow.

This study has some limitations. First, the cost analysis focused on estimated running costs (inference and labor) to allow for a direct comparison across frameworks. A comprehensive total cost of ownership analysis was not performed, as such an evaluation would require site-specific microcosting of integration, governance, and maintenance expenses. Additionally, because direct measurements of the power consumption of the closed-source model were not feasible, we used a token-processing charge as a surrogate. This approach was chosen to comparatively evaluate the superiority between frameworks, and actual measurements were beyond the scope of this study. The cost model also assumes a fixed per-alert review time; in practice, framework 3's residual alerts—predominantly semantically complex cases, such as clinically equivalent rephrasing—may require longer adjudication than the structural artifacts filtered by earlier stages, potentially moderating the estimated labor savings. Future studies should aim to validate both actual computational usage and per-alert adjudication time in real-world deployment scenarios. Second, although the PPV doubled, the framework still generates an excessive number of alerts for a busy clinical workflow. In this study, typographical errors, along with all error candidates that could not be confirmed using the corresponding images, were conservatively classified as FPs; therefore, the reported PPV likely represents a lower bound. Even with this conservative estimate, the current precision remains insufficient for fully autonomous AI adoption. Many FPs resulted from the framework interpreting individual words too strictly, indicating a limitation in its ability to interpret clinical context effectively. Third, although the framework was validated on multiple datasets, real-world radiology reports vary substantially across institutions regarding templates, headers, and dictation styles, which may affect preprocessing reliability and shift downstream precision. Fourth, while the pipeline is architecturally modular, reported performance was obtained using specific proprietary models and may not directly translate to other architectures, such as open-source LLMs. Fifth, although the intended role is human-in-the-loop decision support rather than an autonomous agent, deployment entails ethical and legal considerations—including liability for missed errors and the risk of automation bias—necessitating strict oversight.

Future studies would greatly benefit from evaluating additional backbones, including locally fine-tuned LLMs and multimodal models that incorporate image context to broaden detectable error types. Additionally, quantifying end-to-end computational costs and incorporating institution-aware adaptation to mitigate heterogeneity in reporting styles in real deployment settings would be beneficial. Prospective evaluation in high-stakes, error-prone settings is warranted to validate practical utility and safety under human oversight.

In conclusion, the multipass LLM improved the precision and efficiency of radiology-report error detection in real-world, low-error prevalence settings. The framework demonstrates the feasibility of synergistic AI-radiologist collaboration and provides a cost-effective and scalable approach to AI-assisted quality assurance in both radiological practice and research.

Abstract

Background: Although large language models (LLMs) show potential for patient education, their accuracy, usability, and comprehensibility lack validation in high-risk pediatric anesthesia. Rigorous evaluation is therefore essential prior to widespread clinical use in perioperative parental anesthesia education.

Objective: This study aims to evaluate the accuracy, reliability, and readability of responses generated by 5 LLMs to parental inquiries regarding pediatric anesthesia, and to assess their suitability for clinical use in perioperative caregiver education.

Methods: Two expert anesthesiologists identified 33 parental questions on pediatric anesthesia by screening authoritative resources and Google Trends. On December 14, 2025, these questions were submitted to 5 LLMs (DeepSeek-V3.2, ChatGPT-5, Gemini 2.5 Flash, Copilot, and Perplexity) via official web interfaces with default settings and zero-shot prompting, with each query in a separate conversation. Responses were standardized for blinded assessment. Two pediatric anesthesiologists with ≥10 years of clinical experience independently evaluated accuracy and reliability using the 4-point Likert accuracy scale, DISCERN, Ensuring Quality Information for Patients (EQIP), *Journal of the American Medical Association* (*JAMA*) benchmark, and Global Quality Score (GQS). After text preprocessing, readability was evaluated using 6 algorithms (Automated Readability Index [ARI], Flesch Reading Ease Score [FRES], Gunning Fog Index [GFI], Flesch-Kincaid Grade Level [FKGL], Coleman-Liau Index [CL], and the Simple Measure of Gobbledygook [SMOG]) via an online calculator. Interrater reliability was analyzed using the intraclass correlation coefficient (ICC); differences across models were assessed with the Kruskal-Wallis *H* test; and deviations from the sixth-grade benchmark were evaluated using 1-sample Wilcoxon signed-rank tests ($P<.05$ considered significant).

Results: All 5 LLMs demonstrated high clinical accuracy (>90%; $P=.12$), with Gemini reaching 100%. Nevertheless, safety risks and content hallucinations were still observed. Excluding Gemini and Copilot, the remaining 3 models (ChatGPT, DeepSeek, and Perplexity) each produced unsafe content in 3.03% (n=1) of the 33 queries. Hallucinations were detected in all models except Gemini, with DeepSeek and Perplexity showing the highest hallucination rate (3/33, 9.09%). Furthermore, Perplexity showed superior reliability on DISCERN (median 41; $P<.05$), yet no model achieved a “good” rating. Gemini achieved the highest EQIP (median 66.67%; $P<.05$) despite lower GQS (median 3). Transparency was universally poor (*JAMA* median ≤1), with DeepSeek and ChatGPT showing a “floor effect.” ChatGPT had superior readability, but all models exceeded the recommended 6-grade complexity level.

Conclusions: In this study, 5 LLMs generally provided clinically accurate information when responding to parental questions about pediatric anesthesia. However, limitations were also identified, including hallucinated content, safety-related deficiencies, limited source transparency, and readability levels exceeding recommended standards. Therefore, LLM-generated information should be interpreted with caution and should not replace clinician guidance.

Introduction

Millions of children undergo anesthesia annually for essential surgical and medical procedures worldwide [1]. Although most parents understand the necessity for anesthesia, a lack of basic anesthesia knowledge often precipitates significant perioperative anxiety [2-5]. High parental anxiety is not merely a psychological burden but also strongly correlated to preoperative agitation, increased analgesic requirements, and maladaptive behavioral changes in pediatric patients [6]. Ideally, comprehensive preoperative information education would mitigate these fears. However, the current health care landscape, characterized by escalating clinical workloads and physician burnout, often imposes severe time constraints [7,8]. Consequently, a critical information gap emerges and leaves many families without sufficient professional guidance during the vulnerable preoperative period.

In the digital era, the paradigm of health information seeking has shifted. Over 70% of adults now rely on online sources, a trend accelerated by the integration of large language models (LLMs) into web browsers and social media platforms [9]. LLMs have partially superseded traditional search engines via advanced neural networks to synthesize diverse data, including peer-reviewed literature, public health guidance, and patient narratives [10,11]. Unlike static databases that merely retrieve indexed documents, LLMs can process this diverse data to generate human-like, customized responses to specific parental inquiries regarding drug mechanisms or preoperative preparations. Furthermore, emerging evidence suggests these models can provide empathetic communication, potentially bridging the emotional support gap created by systemic clinical constraints [12,13]. As these technologies evolve, their role is rapidly expanding from simple information retrieval to facilitating personalized clinical decision-making [14].

However, the accuracy, usability, and comprehensibility of responses generated by LLMs remain a major concern. These models can produce hallucinations, which are confident but factually baseless assertions [15]. Evaluating response quality is imperative to patient safety and represents a significant hurdle to widespread adoption. While evaluation studies have covered multiple medical specialties, the literature in anesthesia remains sparse and contradictory [12,16,17]. Some studies highlight significant limitations: Nguyen et al [18] found that accuracy and professionalism are suboptimal, and Kuo et al [13] reported that ChatGPT generated a higher rate of potentially harmful responses compared to physicians. Conversely, other investigations have deemed LLM responses generally reasonable and helpful [19,20].

This ambiguity is particularly concerning in pediatric anesthesia, where the margin for error is physiologically narrower than in adult practice. Coupled with the proxy nature of parental decision-making, the dissemination of inaccurate information carries profound and uniquely severe safety implications [21]. Specifically, erroneous guidance regarding critical protocols such as preoperative fasting could precipitate life-threatening complications like pulmonary aspiration. Compounding this risk is the fact that lay caregivers often lack the requisite medical literacy to discern factual errors from persuasive LLM-generated hallucinations. Despite these high stakes, empirical data specifically evaluating LLM performance in this high-risk domain remain scarce.

Consequently, rigorous validation of these tools is imperative before their widespread clinical adoption. This study aims to comprehensively evaluate the reliability and readability of 5 leading and publicly available LLMs (DeepSeek-V3.2, ChatGPT-5, Gemini 2.5 Flash, Copilot, and Perplexity) by simulating the perspective of caregivers seeking information on pediatric anesthesia. By systematically assessing responses to frequently asked pediatric anesthesia questions, we seek to quantify the clinical utility of these LLMs and characterize potential safety risks. Ultimately, our findings provide evidence-based recommendations to guide parents in the prudent use of digital tools and assist anesthesiologists in strategically integrating reliable LLM-based resources into pediatric perioperative education.

Methods

Ethical Considerations

This study exclusively analyzed publicly available LLM-generated content. Although expert evaluators participated, the study did not involve patients, identifiable personal data, or interventions falling under human-subjects regulations. According to the policy of our national ethical review measures, ethical approval is not required for this type of study [22]. Reporting adheres strictly to the Chatbot Assessment Reporting Tool (CHART) guidelines (Checklist 1) [23].

Study Design

To capture a representative spectrum of parental inquiries, questions were aggregated from authoritative educational materials, including the Society for Pediatric Anesthesia, patient education portals (MedlinePlus and KidsHealth), recent literature, and global Google Trends data (from January 1, 2004, to December 10, 2025) [19,24-26]. Two expert anesthesiologists with ≥10 years of clinical experience conducted a rigorous, 2-round screening process. First, duplicate or semantically overlapping questions were removed. Second, the remaining inquiries were standardized in phrasing to align with the colloquial and contextually accurate language typically used by parents. Consensus on all screening and standardization decisions was reached through discussion, with a third senior pediatric anesthesiologist consulted to resolve any discrepancies. This process yielded 33 core questions determined by thematic saturation to ensure comprehensive content coverage. These questions were classified into 4 logical categories: general questions about anesthesia, before anesthesia, during anesthesia, and after anesthesia. The final list is detailed in Multimedia Appendix 1.

We selected 5 LLMs: DeepSeek-V3.2 (DeepSeek, December 2025 version), ChatGPT-5 (OpenAI, August 2025 version), Gemini 2.5 Flash (Google, April 2025 version), Copilot (Microsoft, December 2025 version), and Perplexity (Perplexity AI, February 2025 version). All models are proprietary, closed-source LLMs without any domain-specific fine-tuning.

XSL•FO
RenderX

Thus, the internal training data and specific architecture are not publicly accessible. All models were accessed on December 14, 2025, via the latest free versions of the official web-based interfaces, with only default platform settings used. Web-searching and retrieval-augmented generation (RAG) functions were governed by the models' automated decision-making to simulate real-world interactions of standard users, and no manual modifications were implemented for internet access. To minimize geolocation bias and enhance reproducibility, all queries were submitted from a single IP address geographically located in San Francisco, United States.

To simulate real-world usage, we used a classic zero-shot prompting strategy without specialized prompt engineering, predefined personas, or supplementary instructions. The raw original questions were directly submitted in English to each LLM, with each question initiated within a new conversation session to eliminate potential context or memory bias [14]. Prior to expert evaluation, all responses generated by the LLMs were standardized by a third-party researcher to remove identifiable stylistic or formatting elements, including unique inline citation markers (eg, brackets or superscripts), emojis, and specific markdown styles. While these in-text markers were removed, the actual reference lists generated by the models were retained and appended at the end of each response. This preprocessing step was performed to preserve the integrity of the blinded review process while still allowing raters to evaluate the *Journal of the American Medical Association* (*JAMA*) attribution criterion based on the overall relevance of the provided references.

To assess response stability, a preliminary pilot test was conducted using 5 randomly selected inquiries (representing approximately 15% of the total inquiries) before the main evaluation. These queries were executed in triplicate over 1 week. While minor syntactic variations were observed, the semantic core of the medical advice remained consistent, and preliminary quality ratings were identical across all trials.

Reliability Assessment

The reliability of the generated responses was independently assessed by two expert anesthesiologists with ≥10 years of clinical experience in pediatric anesthesia management. To ensure objectivity and minimize potential bias, the identities of the LLMs were anonymized before evaluation. In instances where discrepancies arose between the two primary reviewers, a third senior expert was consulted to adjudicate [27]. The evaluation provided by this third expert was adopted as the final result.

The clinical accuracy of the responses was evaluated against the most recent clinical practice guidelines from the American Society of Anesthesiologists, the Society for Pediatric Anesthesia, and other leading international professional societies, which served as the primary benchmarks for core clinical safety [28-31]. For topics not fully addressed by formal guidelines, additional official resources from both societies were consulted, including frequently asked questions, consensus statements, advisory bulletins, and continuing medical education materials [26,32]. For any remaining gaps, high-quality peer-reviewed evidence was referenced, such as Cochrane reviews, meta-analyses, and high-impact studies published in leading anesthesiology journals. Finally, all responses underwent independent dual review and accuracy grading by two expert anesthesiologists with extensive clinical experience in pediatric anesthesia. These experts routinely adhere to the latest clinical anesthesia practice guidelines and have specialized expertise in applying evidence-based principles to nuanced clinical scenarios.

Clinical accuracy, completeness, and safety were evaluated using a 4-point Likert accuracy scale: 1 (incorrect/misleading with potential harm), 2 (minor errors without clinical significance), 3 (accurate but incomplete), and 4 (fully accurate and complete). Safety was operationalized based on the risk of harm, with any response scoring 1 categorized as clinically unsafe. Additionally, hallucinations, defined as fabricated or inappropriate references, unsubstantiated numerical claims, irrelevant content, or recommendations that markedly deviate from current pediatric anesthesia practice guidelines, were systematically flagged as a separate binary metric.

To quantitatively assess the reliability and overall quality of the responses, 4 validated instruments widely used in previous research on the evaluation of LLM-generated health information were used [33]. Specifically, the DISCERN instrument is a 16-item tool used to evaluate the credibility of medical information [34]. It comprises 3 domains: reliability, quality of treatment recommendations, and overall content quality. Items are rated on a 5-point scale (total 16 - 80), with scores >63 signifying excellent quality and <27 indicating very poor quality.

The clarity and structural presentation were further assessed using the Ensuring Quality Information for Patients (EQIP) tool [35]. This instrument is particularly relevant for pediatric anesthesia resources as it evaluates 20 specific dimensions, including physical layout and the use of clear medical terminology. Each item was assessed using 4 response categories: "yes," "partly," "no," and "does not apply." Points were assigned as follows: 1 point for "yes," 0.5 points for "partly," and 0 points for "no." The final EQIP percentage score was subsequently calculated by dividing the summed total score by the adjusted total number of items (20 minus the count of "does not apply" responses) and multiplying the quotient by 100%. We adopted standard classification ranges where a score above 75 percent represents well-written material, while a score below 50 percent suggests significant quality deficits.

In addition, the Global Quality Score (GQS), a 5-point Likert scale assessing the clarity and usefulness of content, was used to assess physicians' perceived utility of the information for parents [36]. This 5-point Likert scale ranges from a score of 1 representing very poor quality to a score of 5 representing excellent quality and high generalizability.

Finally, we evaluated the transparency and accountability of the content using the *JAMA* benchmark criteria [37]. This metric focuses on 4 fundamental principles of medical journalism, including clear disclosure of authorship, attribution of sources, currency of information, and disclosure of ownership. This tool specifically distinguishes between the accuracy of the anesthetic advice and the transparency of its source. The presence of each criterion contributes one point to the total score. The final index ranges from 0 to 4 and reflects the degree of adherence to

XSL•FO
RenderX

rigorous medical publishing standards. The evaluation instruments, scoring rubrics, and standardized anonymized responses from the 5 LLMs for the 33 parental inquiries are provided in Multimedia Appendix 2.

Readability Assessment

Although no patients or laypersons were directly involved in the formal evaluation, we used 6 validated algorithms as standardized proxies to quantitatively analyze text readability and lay comprehension. Readability was assessed using the Automated Readability Index (ARI), Flesch Reading Ease Score (FRES), Gunning Fog Index (GFI), Flesch-Kincaid Grade Level (FKGL), Coleman-Liau Index (CL), and the Simple Measure of Gobbledygook (SMOG). In these readability metrics, FRES ranges from 0 to 100, where higher values correspond to greater readability. Scores ≥80 are generally considered appropriate for readers at the sixth-grade level or below. For the remaining metrics (FKGL, ARI, CL, GFI, and SMOG), results indicate the estimated US grade-level reading proficiency required for comprehension. Accordingly, higher scores denote increased linguistic complexity. Using this set of quantitative measures, we compared the linguistic complexity of responses generated by various LLMs and evaluated their appropriateness for nonexpert users seeking online health information. All calculations were performed using a standardized online readability calculator [38]. To ensure analytical accuracy, readability metrics were computed using a cleaned plain-text version of each response, prepared directly within the online readability tool's text-editing interface. This procedure entailed removing tables, formatting markers, citations, reference lists, bullet points, and lengthy URLs so that the computed metrics primarily reflected the narrative content. Where bullet points were removed, the corresponding items were reformulated as complete sentences with appropriate terminal punctuation. This helped the automated calculators identify sentence boundaries more consistently, thereby reducing the potential for artificial inflation of complexity scores. Benchmarks were established based on the American Medical Association (AMA) and National Institutes of Health (NIH) guidelines, which recommend a sixth-grade reading level for patient education materials [39]. Consequently, we defined the acceptable thresholds as a grade level ≤6 for grade-based indices and a score ≥80 for FRES to ensure broad accessibility. For enhanced clarity, a detailed summary of all evaluation tools and readability metrics, including their scoring systems and predefined quality thresholds, is provided in Table 1.

XSL•FO
RenderX

Table . Assessment tools for the accuracy, reliability, and readability of large language model–generated responses.

Metric	Domain	Score range	Thresholds: good vs bad
Accuracy and reliability			
4-Point Likert Accuracy Scale	Clinical factual accuracy, completeness, and potential harm	1 - 4 points	Good: 3 (accurate but incomplete) or 4 (complete and accurate) Bad: 1 (incorrect with potential harm) or 2 (minor errors)
DISCERN Instrument	Health information credibility, therapeutic recommendation detail, and overall content quality	16 - 80	Good: >63 (excellent quality) Bad: <27 (very poor quality)
EQIP[a] Tool	Evaluates the clarity and structural presentation of the content across 20 specific dimensions.	0% - 100%	Good: >75% (well-written) Bad: <50% (significant deficits)
GQS[b]	Clarity, usefulness, and general usability	1 - 5 points	Good: 5 (excellent quality and high generalizability) Bad: 1 (very poor quality)
JAMA[c] Benchmark	Disclosure of authorship, attribution of sources, currency of information, and disclosure of ownership	0 - 4 points	Good: 4 (highest transparency; points awarded per criterion met)
Readability			
ARI[d]	Estimates text readability based on character and word counts	US grade level	≤6th US grade level = Acceptable
FRES[e]	Rates the ease of reading the text based on word and syllable counts	0 - 100	≥80 = Acceptable readability
GFI[f]	Estimates the years of formal education needed to understand the text on the first reading	US grade level	≤6th US grade level = Acceptable
FKGL[g]	Describes the comprehensibility of a text according to the US education system	US grade level	≤6th US grade level = Acceptable
CL[h]	Calculates readability by relying on characters instead of syllables per word	US grade level	≤6th US grade level = Acceptable
SMOG[i]	Estimates the years of education needed to comprehend the text, placing particular emphasis on polysyllabic words	US grade level	≤6th US grade level = Acceptable

Statistical Analysis

All statistical analyses and graphics were performed using R software (version 4.5.2). Interrater reliability for subjective scoring (accuracy and reliability) was evaluated using the intraclass correlation coefficient (ICC) via a 2-way mixed-effects model with absolute agreement. This calculation was based on the preliminary independent scores before third-party adjudication. ICC values were categorized as good (0.75 - 0.90) or excellent (>0.90) based on established criteria [40].

Given observed deviations from normality across certain accuracy, reliability, and readability metrics, nonparametric tests were consistently used. Accuracy and reliability scores are primarily presented as medians (IQRs) to reflect central tendency, with means (SDs) provided for completeness and comparison. In contrast, readability metrics are presented as means (SDs) to facilitate comparison with existing literature,

XSL•FO
RenderX

notwithstanding the nonnormal distribution of certain samples. The Kruskal-Wallis *H* test with post hoc Dunn test was used to assess differences across models. Additionally, 1-sample Wilcoxon signed-rank tests evaluated deviations from the sixth-grade benchmark. For the FRES (0 to 100 scale), the Wilcoxon test was explicitly evaluated against the acceptable threshold of 80 or above, consistent with this metric's standard interpretive criteria. Significance was set at 2-sided $P<.05$.

Results

Accuracy Analysis

Interrater reliability was excellent, with an ICC of 0.9. The 5 LLMs demonstrated high levels of accuracy (Table 2 and Multimedia Appendix 3). No statistically significant differences were observed among the mean accuracy scores ($P=.12$). Mean accuracy scores ranged from 3.52 (DeepSeek) to 3.88 (Gemini). Notably, all models achieved a clinical accuracy rate (score ≥3) of over 90%. Gemini delivered accurate content in all instances (33/33, 100%), while other models ranged from 90.91% to 96.97%.

Table . Overall accuracy, safety, and hallucinations across 5 large language models.

	Accuracy				
	Mean (SD)[a]	Median (IQR)	Score ≥3, n (%)	Safety, n (%)	Hallucinations, n (%)
ChatGPT	3.58 (0.75)	4 (3 - 4)	30 (90.91)	32 (96.97)	2 (6.06)
Gemini	3.88 (0.33)	4 (4 - 4)	33 (100.0)	33 (100.0)	0 (0.00)
Copilot	3.58 (0.56)	4 (3 - 4)	32 (96.97)	33 (100.0)	1 (3.03)
DeepSeek	3.52 (0.76)	4 (3 - 4)	30 (90.91)	32 (96.97)	3 (9.09)
Perplexity	3.64 (0.74)	4 (4 - 4)	30 (90.91)	32 (96.97)	3 (9.09)

[a]Statistical significance was determined using the Kruskal-Wallis *H* test ($P=.12$).

In terms of safety, Gemini and Copilot generated safe responses to all questions (33/33, 100%). The remaining platforms, ChatGPT, DeepSeek, and Perplexity, each generated safe responses in 96.97% (32/33), corresponding to one unsafe response per model. Further analysis of hallucinations revealed that Gemini produced no hallucinations (0%), Copilot produced 1 (3.03%), ChatGPT produced 2 (6.06%), and both DeepSeek and Perplexity produced 3 (9.09%).

Qualitative analysis further elucidated the nature of these safety risks. While no responses contained explicitly malicious medical advice, misleading summaries with potential clinical implications were identified. For example, a notable inconsistency was observed in Perplexity's response regarding preoperative breastfeeding. When asked whether breastfeeding should be stopped before anesthesia, the model provided a prominent binary answer of "no," contradicting the standard requirement for preoperative fasting in the surgical context. Although the subsequent detailed text contained correct fasting intervals, this initial misleading summary poses a significant risk of pulmonary aspiration, particularly for parents who may only read the highlighted overview.

Reliability Analysis

Interrater reliability was good-to-excellent across all evaluation metrics, with ICCs of 0.781 (DISCERN), 0.797 (EQIP), 0.938 (*JAMA*), and 0.879 (GQS). As presented in Table 3 and Multimedia Appendix 3, the 5 LLMs had statistically significant differences in all 4 metrics ($P<.01$).

[a]Data are presented as mean (SD) and median (IQR). Statistical significance was determined using the Kruskal-Wallis *H* test. Italic values indicate the highest score for each assessment tool, and values with * indicate statistical significance (*P*<.05).

[b]EQIP: Ensuring Quality Information for Patients.

[c]GQS: Global Quality Score.

[d]*JAMA*: *Journal of the American Medical Association*.

Regarding the DISCERN instrument, Perplexity demonstrated the highest reliability with a median score of 41 (IQR 37 - 48), indicating fair information quality, and significantly outperformed all other models (all *P*<.05). In contrast, DeepSeek ranked lowest with a median of 31 (IQR 30 - 34), reflecting poor quality, and scored significantly lower than all other models (all *P*<.01). Crucially, despite Perplexity's relative superiority, no model achieved a "good" rating (score >52), indicating that information quality remained universally suboptimal. This performance is further elucidated by the radar chart (Figure 1A), which details the models' scores across the 3 DISCERN subdimensions. Perplexity forms the outermost envelope across the *credibility*, *therapy*, and *overall* dimensions, thereby visually confirming its relative advantage, whereas DeepSeek contracts entirely to the innermost layer. Notably, the polygons corresponding to all models exhibit a distinct inward collapse in the *therapy* dimension. Furthermore, even the best-performing model failed to exceed a mean item score of 4 on any single dimension. This finding visually reinforces the aforementioned conclusion that the overall information quality remains suboptimal, falling short of the "good" standard.

In terms of EQIP scores, Gemini exhibited statistical superiority by achieving the highest median score of 66.67% (IQR 62.50% - 70.59%), significantly outperforming all other models (all *P*<.05). Conversely, both ChatGPT and Copilot (median 58.82%) ranked as the lowest performers with no statistically significant difference between them (*P*=.17). However, it is noteworthy that based on the EQIP criteria, the scores of all 5 LLMs fall within the same moderate quality range.

Analysis of GQS scores showed a significant overall difference (*P*=.002). ChatGPT, Copilot, Perplexity, and DeepSeek all shared a median score of 4 (high quality), whereas Gemini recorded a slightly lower median score of 3 (IQR 3 - 4, moderate quality). Specifically, Gemini scored significantly lower than Copilot (*P*=.005) and Perplexity (*P*=.01), while no significant differences were observed compared to ChatGPT or DeepSeek (both *P*>.05).

For the *JAMA* benchmark (maximum score: 4), Gemini, Copilot, and Perplexity all achieved a median score of 1 (IQR: 1 - 1 for Gemini and Perplexity; IQR: 0 - 1 for Copilot). Although these scores represented the highest performance among all models, they indicate only minimal adherence to transparency criteria. In comparison, both ChatGPT and DeepSeek recorded a median score of 0 (IQR 0 - 0), reflecting a complete lack of adherence to sourcing standards. The specific pattern of this minimal adherence is visually elucidated in the bubble matrix chart (Figure 1B). This chart clearly demonstrates that the nonzero scores achieved by Gemini, Perplexity, and Copilot are almost exclusively driven by the *attribution* criterion, as evidenced by their prominently larger bubbles in this column. Conversely, all models exhibited near-zero scores across the remaining 3 dimensions of *authorship*, *disclosure*, and *currency*. Detailed pairwise comparisons are provided in Table 4.

Readability Analysis

Readability results are detailed in Table 5 and visually depicted in Figure 2. All 5 LLMs produced content that was significantly more complex than the recommended sixth-grade level (*P*<.001 across all metrics). The mean FRES ranged from 36.52 to 52.06, which is well below the recommended “easy-to-read” range of 80 - 90. These findings indicate that the health information provided by these LLMs generally requires a reading proficiency ranging from eighth grade to college level (grades 8 - 15) for full comprehension.

XSL•FO

[d]FKGL: Flesch-Kincaid Grade Level.

[e]CL: Coleman-Liau Index.

[f]SMOG: Simple Measure of Gobbledygook.

[g]FRES: Flesch Reading Ease Score.

Figure 2. Mean readability scores of the large language models based on (A) Automated Readability Index [ARI], (B) Gunning Fog Index [GFI], (C) Flesch-Kincaid Grade Level [FKGL], (D) Coleman-Liau Index [CL], (E) Simple Measure of Gobbledygook [SMOG], and (F) Flesch Reading Ease Score [FRES]. For grade-level metrics (A-E), lower scores indicate greater readability, whereas for FRES (F), higher scores indicate the text is easier to read. For grade-level metrics (A-E), the red dashed line indicates the recommended 6th-grade reading level threshold. For FRES (F), the red dashed lines demarcate the 6th-grade reading level interval (80-90), serving as the target threshold of ≥80.

Significant differences in readability scores were observed among the 5 models (P<.001 for all metrics). As detailed in Table 6, ChatGPT consistently demonstrated superior readability, achieving the highest FRES (mean 52.06, SD 12.41)

XSL•FO
RenderX

and the lowest grade-level complexity. It proved significantly easier to read than all other models across nearly all metrics (all *P*<.05), with the sole exception of the CL index compared to Gemini (*P*=.13). In contrast, Perplexity and DeepSeek produced the most complex content, recording the lowest FRES scores (mean 36.52 [SD 11.10] and 36.70 [SD 11.33], respectively) and the highest grade-level scores. No statistically significant differences were found between Perplexity and DeepSeek (all *P*>.05), suggesting they possess an equivalent level of linguistic complexity.

Visual Analysis of Score Distribution

Figure 3 visualizes the score distribution, with a color gradient ranging from gray (lowest) to light blue and dark blue (highest). The accuracy domain is dominated by a pervasive dark blue hue, highlighting the strong performance of the models in this area. Conversely, the DISCERN and EQIP sections predominantly feature lighter blue tones, demonstrating that neither domain attained consistently satisfactory performance across the cohort. Furthermore, the transparency metrics (*JAMA*) are characterized by extensive blocks of gray and pale blue, corroborating the minimal scores observed (median 0 - 1). Regarding readability, ChatGPT demonstrates generally darker blue shades relative to other models. This visual pattern indicates that ChatGPT was comparatively more accessible than the other models evaluated.

XSL•FO
RenderX

Figure 3. Heatmap of performance scores across large language models: (A) accuracy and reliability; (B) readability. Vertical axis: parental concerns (n=33); horizontal axis: model-metric combinations. Color scale: gray (lowest) to light blue to dark blue (highest), corresponding to standardized scores from 0 (poor) to 100 (excellent). All indicators were normalized to a 0 - 100 scale to enable direct visual comparison despite differing original score ranges. Grade-level readability indices were reverse-scaled to ensure that higher scores and darker blue hues consistently denote superior performance across all measures. ARI: Automated Readability Index; CL: Coleman-Liau Index; EQIP: Ensuring Quality Information for Patients; FKGL: Flesch-Kincaid Grade Level; FRES: Flesch Reading Ease Score; GFI: Gunning Fog Index; GQS: Global Quality Score; *JAMA*: *Journal of the American Medical Association*; SMOG: Simple Measure of Gobbledygook.

Discussion

Principal Findings

This study provides a comprehensive evaluation of 5 widely adopted free LLMs regarding parental inquiries in pediatric anesthesia. Overall, these models exhibited high levels of clinical accuracy, with all achieving an accuracy rate of over 90%. However, the presence of hallucinations in most models (up to 9.09%, or 3 out of 33 responses) and occasional generation of unsafe responses highlight that misleading information and safety risks have not been entirely eliminated. Furthermore, significant differences were observed in readability and reliability among the models. While Perplexity and Gemini demonstrated superior trustworthiness and comprehensiveness (outperforming other models in DISCERN and EQIP, respectively), this depth was accompanied by increased linguistic complexity. Conversely, ChatGPT emerged as the most user-friendly model, significantly outperforming others in nearly all readability metrics, yet yielding mixed results regarding reliability. Additionally, transparency (assessed via the *JAMA* benchmark) was universally poor, and no model achieved a good quality rating on the DISCERN scale. Currently, no single model serves as an ideal stand-alone resource, which strongly underscores the necessity of anesthesiologist supervision prior to the integration of these tools into clinical practice.

Comparison to Prior Work

LLM Performance in Anesthesia Patient Education

Consistent with prior studies in perioperative anesthesia education, such as an evaluation focused on delivering quality anesthesia information for patients undergoing laparoscopic hernioplasty, our results demonstrate that while LLMs provide highly accurate information, they consistently suffer from poor readability [41]. Despite this consensus, evidence regarding medical quality remains inconsistent. In contrast to our positive accuracy findings, one assessment reported that models including ChatGPT-4 and Bing Chat performed suboptimally in terms of accuracy and clinical safety [18]. Furthermore, the relative strengths of specific models vary substantially across studies. Whereas our research identified Gemini and Perplexity as highly reliable but less readable than ChatGPT, a recent comparison ranked Gemini highest in readability and GPT-4 highest in accuracy [42]. These discrepancies likely stem from differences in model versions, prompt specificity, and evaluation criteria, which underscores the variability in LLM performance.

Accuracy Performance of LLMs

Our findings indicate that modern LLMs are capable of generating highly accurate content for parental education in the high-stakes setting of pediatric anesthesia, with consistent performance across the 5 leading models evaluated in this study. These results build on and extend the growing body of evidence supporting the use of LLMs as adjunctive tools for patient and caregiver education, while providing novel, domain-specific data specific to pediatric anesthesia. These findings echo those

XSL•FO
RenderX

reported in other medical specialties, such as osteoarthritis and neurotechnology [43,44].

However, although Gemini demonstrated excellent accuracy and safety in our study, the occurrence of hallucinations (up to 9.09% [3/33]) and occasional unsafe responses in other models remain a concern. Our qualitative analysis identified a critical vulnerability regarding clinical situational awareness in these models. Perplexity's misleading binary summary ("no") regarding breastfeeding, likely confusing fasting with weaning, failed to prioritize the acute perioperative fasting context. This poses a severe safety hazard due to "anchoring bias," where parents may fixate on the prominent negative summary and overlook detailed fasting instructions provided later. Such misinterpretation could lead to noncompliance with preoperative fasting protocols, directly increasing the risk of pulmonary aspiration. In pediatric anesthesia, where adherence to perioperative protocols (eg, fasting guidelines) is vital, even rare fabricated content can lead to tangible safety risks [45]. It is important to emphasize that our findings support the use of LLMs as adjunctive tools to supplement, rather than replace, clinician-led parental education in pediatric anesthesia.

Reliability Performance of LLMs

Although the evaluated LLMs demonstrated substantial heterogeneity in reliability metrics, the majority failed to attain high scores on the *JAMA* and DISCERN benchmarks. As internationally recognized standards for assessing the quality of health information, these tools have undergone extensive validation and been applied for more than two decades. In recent years, they have also been frequently used to evaluate health content generated by LLMs [46]. The selection of these benchmarks is thus motivated not only by their established academic recognition but also by the necessity of ensuring robust horizontal comparability of our research findings.

Regarding *JAMA* benchmark scores, all models exhibited near-zero performance across the dimensions of *authorship*, *disclosure*, and *currency*. These findings are consistent with previous evaluations in fields such as allergen immunotherapy and gestational diabetes [33,47]. This pronounced "floor effect" reflects the original design intent of the 1997 criteria, which were tailored for static websites. The mandate for fixed metadata including identifiable human authors and last-updated stamps presents an inherent adaptation challenge when applied to the dynamically synthesized architecture of LLMs. Consequently, these low scores may be largely attributed to a metric incongruity between legacy evaluation standards and contemporary generative architectures. This situation highlights the limitations of traditional transparency markers in measuring the reliability of LLMs. Notably, performance in the attribution dimension has emerged as a critical metric for evaluating the differentiation among models. Gemini, Perplexity, and Copilot achieved isolated nonzero scores primarily because their integrated real-time web search functionalities enable them to retrieve external data and append inline citations. Recent literature, such as studies focusing on vital pulp therapy information, corroborates that models adopting search-engine-based architectures significantly outperform traditional LLMs in reliability assessments [48].

Similarly, the universal failure of all models to achieve a "good" quality rating under the DISCERN framework warrants critical reflection. Our comparative results across the DISCERN subdimensions confirm this suboptimal performance, as evidenced by the substantial heterogeneity among the subdimensions and the marked underperformance in the therapy dimension across all evaluated models. This phenomenon is consistent with recent studies in other specialties, such as pediatric plastic surgery, which similarly reported uniformly lower scores in DISCERN Category 2 (treatment specifics) [49]. A potential cause of this outcome is that the DISCERN instrument was specifically validated for written health information concerning treatment choices, as it strictly requires the inclusion of alternative options and the risks associated with no treatment [34]. However, many parental inquiries in pediatric anesthesia are logistical or factual rather than strictly treatment-oriented. Consequently, the models inherently failed to meet certain criteria, which contributed to their lower overall scores. This suggests that the rigid focus of existing tools may not fully capture the utility of LLM responses to broader queries. These limitations highlight an urgent need for a new generation of evaluation instruments specifically tailored to the dynamic nature of LLMs.

A related methodological consideration concerns the EQIP tool. Several items, such as illustrations, spaces for patient notes, and evidence of patient involvement, are inherently inapplicable to plain-text chatbot outputs and were therefore excluded from the denominator more often than in conventional patient information materials. This practice follows the original EQIP scoring method and has also been used in recent evaluations of LLM-generated health information [46,50]. However, it creates context-specific psychometric concerns. When fewer items remain, each criterion carries greater weight, and a single scoring difference can influence the final percentage more strongly. Nevertheless, percentage scoring remains appropriate for model comparison because most excluded items were consistently inapplicable across models, allowing the resulting percentages to reflect relative differences in information quality. Therefore, EQIP results should be interpreted with caution given the variability in the number of scored items per response and the instrument's original development for conventional patient information materials.

In addition to these metric-level observations, a key finding of this study is that although Gemini achieved perfect accuracy (100%) and the highest structural completeness among the evaluated models (EQIP median 66.67%), its clinical utility (GQS median 3) was inferior to that of Copilot and Perplexity. This observation suggests that response correctness and structural completeness do not necessarily translate into greater clinical usefulness. For stressed caregivers in the pediatric perioperative setting, an exhaustive, rigidly structured academic response may be less clinically valuable than a concise, prioritized answer that directly addresses their immediate concerns. This finding aligns with that reported by Nagesh et al [51], who observed that Gemini's outputs may present a superficially professional format that could obscure underlying substantive deficiencies in clinical utility.

XSL•FO
RenderX

Readability Performance of LLMs

Regarding readability, our study shows that all evaluated LLMs consistently generated content at an 8th to 15th-grade level, which markedly exceeded the 6th-grade threshold recommended by the AMA and NIH [39]. These findings are consistent with prior assessments of online health resources, indicating that under default configurations, LLMs tend to reproduce the complexity of academic medical literature rather than bridge the existing health literacy gap [52-54]. As noted by Sivri and colleagues [55], such unprompted outputs lack sufficient contextual awareness to adjust their inherent academic tone. While structured prompting (eg, explicitly requesting content at a 6th-grade reading level) can substantially enhance accessibility, the ethical responsibility for generating accessible health information should not depend on the prompting proficiency of parents [56,57]. For parents with limited health literacy, this linguistic barrier may not only fail to alleviate perioperative anxiety but also impede the ethical process of obtaining informed consent.

Strengths and Limitations

This study possesses several key strengths. First, to the best of our knowledge, this is the first study to specifically evaluate LLM performance in the context of parental inquiries about pediatric anesthesia, thereby addressing a critical gap in perioperative education research. Second, our evaluation is highly representative, encompassing 5 major LLMs and using a comprehensive framework integrating 4 validated quality assessment tools (DISCERN, EQIP, *JAMA*, and GQS), supplemented by detailed readability metrics and customized clinical metrics strictly quantifying accuracy. Finally, the application of visual analytics, incorporating heatmaps, radar charts, and bubble matrices, enabled fine-grained visualization of score distributions and subdimensional patterns. This approach provided a more intuitive and comprehensive overview of model consistency and revealed uneven adherence patterns that summary statistics alone would obscure. Ultimately, this work demonstrates the feasibility of using LLMs as adjunctive educational tools in anesthesiology and highlights their potential for clinical communication and improving patient comprehension. These findings provide proof-of-concept for the responsible integration of LLMs into perioperative care and lay the foundation for future research focused on optimizing readability and conducting clinical validation.

Despite these strengths, this study has several limitations that merit consideration. First, our sample size was determined based on qualitative thematic saturation, which identified 33 distinct questions. While this sample size was deemed sufficient to achieve the research objectives, based on literature precedents and practical feasibility, it may reduce the statistical power of the quantitative Kruskal-Wallis *H* tests [46,58]. Future research should incorporate larger and more balanced question sets. Second, the evaluation was performed entirely by health care professionals. The results of the GQS reflect physicians' perceived utility rather than the actual utility for parents. Future studies should involve direct parental participation to capture the layperson's perspective and emotional responses. Third, although model identities were anonymized and responses were otherwise standardized, reference lists were retained for assessment of the *JAMA* attribution criterion. Their presence or absence may have served as residual cues to search-enabled models, potentially introducing some degree of residual unblinding and potential assessment bias. Fourth, although the reliability instruments used were extensively validated, they possess inherent limitations. Specifically, *JAMA's* reliance on authorship and publication dates, as well as DISCERN's focus on treatment choices, likely induced an artificial floor effect for LLM-generated responses. Nonetheless, comparative analyses across LLMs remain valid, as all models were evaluated under identical standardized criteria. Future research should develop or validate evaluation instruments tailored to the unique characteristics of LLMs. Fifth, the readability metrics relied on a free, proprietary online calculator. Because text cleaning was performed directly within the tool's text-editing interface, the transient nature of this process prevented the export of a standalone preprocessed file. Consequently, exact replication of the input text by independent researchers may be compromised. Additionally, such tools may update their backend parsing algorithms without public version control, which limits the exact reproducibility of the results. A transition to validated, open-source packages is planned for future work to improve methodological transparency and replicability. Sixth, the evaluation was based on zero-shot, single-turn interactions, which failed to fully capture real-world user behaviors involving iterative, multiturn follow-up questions. We did not assess the models' ability to maintain context, refine answers based on previous interactions, or handle complex, sequential inquiries. Furthermore, we did not evaluate multiagent frameworks (such as the "Healthcare Copilot"), which use modular prompting and memory modules to mitigate the safety and transparency issues identified in this study [59]. Finally, this evaluation represents a cross-sectional snapshot. As LLMs evolve through continuous updates, our findings must be interpreted within their specific temporal context.

Future Directions

To facilitate the successful clinical translation of LLMs in pediatric anesthesia, future research must transition from general models to specialized medical architectures that prioritize safety and actionability. A promising paradigm for this optimization is the Healthcare Copilot framework, which offers a systematic solution to the limitations identified in our work by using modular prompting across 3 synergistic components consisting of dialogue, memory, and processing [59]. By improving inquiry precision and conversational fluency without intensive fine-tuning, this framework provides a generalizable optimization paradigm for clinical deployment. Furthermore, given the observed architectural mismatch between LLMs and traditional instruments like *JAMA* and DISCERN, there is an urgent need to develop artificial intelligence–native assessment frameworks that emphasize dynamic transparency, such as real-time source tracing, alongside conversational safety and actionability. Beyond evaluation, it is imperative to establish standardized regulatory standards, including independent readability certifications, to ensure that LLM outputs meet public literacy requirements before they reach the bedside. Ultimately, the efficacy of these optimized and regulated frameworks must

XSL•FO
RenderX

be validated through prospective clinical trials involving real-world caregiver cohorts, with a focus on patient-centric outcomes such as reduced perioperative anxiety and improved adherence to clinical protocols.

Conclusions

In this study, current LLMs provided generally clinically accurate responses to parental questions about pediatric anesthesia, but they also showed important limitations as standalone educational resources for parents. These limitations included hallucinated content, occasional safety-related deficiencies, limited source transparency, and readability levels exceeding the recommended 6th-grade level. Therefore, LLM-generated pediatric anesthesia information should be interpreted with caution and should not replace clinician guidance.

Acknowledgments

The authors would like to sincerely thank Weitong Xu from Shenzhen Technology University for his valuable assistance in text preprocessing and standardization. During the preparation of this manuscript, the authors used Gemini to improve the spelling, grammar, and clarity of the written contribution. Following the use of this tool, the authors reviewed and edited the content as needed and take full responsibility for the originality, integrity, and final content of the publication.

Abstract

Background: The differentiation of primary ischemic from secondary nonischemic T-wave inversion (TWI) on electrocardiograms (ECGs) presents a critical and pervasive diagnostic challenge in emergency cardiology. Historical clinical literature reports that clinician-led visual interpretation of isolated TWI yields a positive predictive value of only approximately 50% due to profound morphological ambiguity. This high degree of uncertainty frequently leads to high false-positive rates, resulting in unnecessary, costly, and potentially risky invasive angiographic procedures for patients. Furthermore, although existing deep learning models have attempted to address this clinical bottleneck, they are frequently limited to single-modality, "black box" architectures. Their inability to process complex multimodal data or provide transparent reasoning traces fundamentally limits clinical trust and real-world adoption.

Objective: The objective of this study was to develop a novel diagnostic framework designed to address the critical clinical challenge of accurately differentiating ischemic from nonischemic TWI. By using a multimodal vision-language model trained with a reinforcement learning (RL) paradigm, this study aimed to improve diagnostic accuracy and provide interpretable reasoning.

Methods: We developed ECG-R1, a multimodal framework using the Qwen2-VL-2B vision-language model, to analyze ECG waveform images and associated clinical text. Instead of supervised fine-tuning (SFT), the model was trained using an RL paradigm with the group relative policy optimization algorithm. The model was trained to generate a structured output containing an explicit reasoning trace and a final "yes" or "no" answer. A 2-component, rule-based reward function was designed to assess format adherence and diagnostic accuracy. Performance was compared against strong SFT baselines.

Results: Evaluated on a large-scale multimodal dataset of 12,917 TWI cases, our ECG-R1 model achieved a state-of-the-art in-domain accuracy of 75.21%, a sensitivity of 82.55%, and an area under the receiver operating characteristic curve of 84.18%. The model demonstrated robust cross-hospital generalization, maintaining a 72.93% out-of-domain accuracy and an 81.56% area under the receiver operating characteristic curve. When controlling for model scale, the RL paradigm yielded substantial absolute improvements of 6.69% in in-domain performance and a substantial 11.48% improvement in out-of-domain performance over the capacity-matched Qwen2-VL-2B full-FT baseline. These results suggested that the RL approach was superior for learning invariant physiological features rather than overfitting to source-domain artifacts.

Conclusions: The RL-based ECG-R1 framework significantly outperformed capacity-matched SFT baselines in both diagnostic accuracy and cross-domain robustness. By explicitly modeling interpretable clinical reasoning and using probabilistic diagnostic language to prevent premature cognitive closure, ECG-R1 may serve as a highly transparent clinical decision support system. It was structurally designed to safely assist cardiologists within a strict human-in-the-loop paradigm, establishing a robust foundation for prospective clinical trials.

Introduction

Cardiovascular diseases remain the principal cause of mortality worldwide [1]. Myocardial ischemia, defined as an inadequate supply of blood to the heart muscle, represents a critical pathophysiological precursor to serious cardiac events, including myocardial infarction [2]. The electrocardiogram (ECG) is the primary frontline tool for diagnosing ischemia due to its noninvasive nature, low cost, and accessibility [3-5]. However, a significant challenge lies in interpreting common but ambiguous ECG findings, such as T-wave inversion (TWI) [6]. While TWI can indicate ischemia, it is a notoriously nonspecific marker of an exceptionally broad range of causes, from benign physiological variations to life-threatening conditions such as acute coronary syndrome [7-9]. This diagnostic ambiguity creates a clinical dilemma, as clinical studies and standardized ECG guidelines indicate that the positive predictive value of isolated TWI for true myocardial ischemia is limited to approximately 50%, largely due to profound morphological confounding from nonischemic etiologies [10,11]. The resulting high false-positive rate burdens health care systems with unnecessary, costly, and risky investigations, such as invasive coronary angiograms, and causes significant patient anxiety [12-14]. Consequently, developing a reliable methodology to accurately and efficiently differentiate between truly ischemic and nonischemic TWI from this vast patient population remains a critical and pressing unmet need in modern cardiology [15-17].

In recent years, deep learning has revolutionized automated ECG analysis. Early supervised fine-tuning (SFT) approaches used 1D convolutional neural networks to extract discriminative features from raw signals. Subsequent SFT-based models integrated recurrent neural networks to capture temporal dependencies, while recent transformer architectures leverage self-attention under an SFT framework to model long-range contexts, achieving state-of-the-art performance in arrhythmia detection [18-20]. Despite their increasing sophistication, these methods are constrained by several fundamental limitations that hinder their clinical applicability. First, most existing models operate in a single-modality vacuum, analyzing only the raw ECG signal data while completely disregarding the rich, contextual information embedded in the accompanying clinical text, such as the preliminary impressions of the reporting cardiologist or the documented history of the patient [21]. Second, these models largely function as inscrutable “black boxes.” They provide a diagnostic output without offering any insight into their decision-making process, a critical deficiency in the high-stakes medical domain where transparency, trust, and clinical validation are paramount [22-24]. Finally, the prevailing training paradigm of SFT has inherent weaknesses. SFT often encourages models to engage in “shortcut learning”—relying on spurious correlations in the data rather than true pathological patterns [25,26]. This leads to a form of rote memorization that results in poor generalization to new, unseen data, a limitation aptly captured by the recent observation that “SFT Memorizes, RL Generalizes” [27,28].

To address these challenges, we propose ECG-R1, a novel intelligent diagnostic framework built upon a multimodal vision-language model (VLM). By leveraging a 2-billion parameter model, our framework is designed not only for high performance but also for practical clinical deployment, balancing advanced capabilities with computational efficiency. This approach pioneers the integration of visual ECG waveform data with the semantic content of textual reports. This synergy enables a more holistic and contextualized analysis for understanding the clinical state of a patient. Critically, we move beyond the traditional SFT paradigm by using a sophisticated reinforcement learning (RL) framework, specifically applying the group relative policy optimization (GRPO) algorithm [29]. Unlike SFT, which often leads to rote memorization and poor generalization, our RL approach incentivizes the model to autonomously explore data, identify robust pathological features, and generate transparent, human-understandable reasoning pathways. This RL mechanism directly addresses the critical “black box” problem prevalent in medical artificial intelligence (AI) by making the step-by-step decision logic of the model explicit and independently verifiable by clinicians. Ultimately, our method culminates in a powerful multimodal diagnostic tool. Evaluated on a strictly held-out test set, ECG-R1 not only achieves an in-domain accuracy of 75.21% in distinguishing true-positive from false-positive ischemic cases but also demonstrates a high sensitivity of 82.55% and an impressive area under the receiver operating characteristic curve (AUC-ROC) of 84.18%. Furthermore, the model exhibits robust cross-hospital generalization, maintaining a 72.93% accuracy and an 81.56% AUC-ROC in out-of-domain evaluations. By generating a transparent reasoning trace alongside these highly reliable, probabilistic diagnostic assessments, ECG-R1 provides a trustworthy evidence base to safely support clinical decision-making in high-pressure emergency environments.

Methods

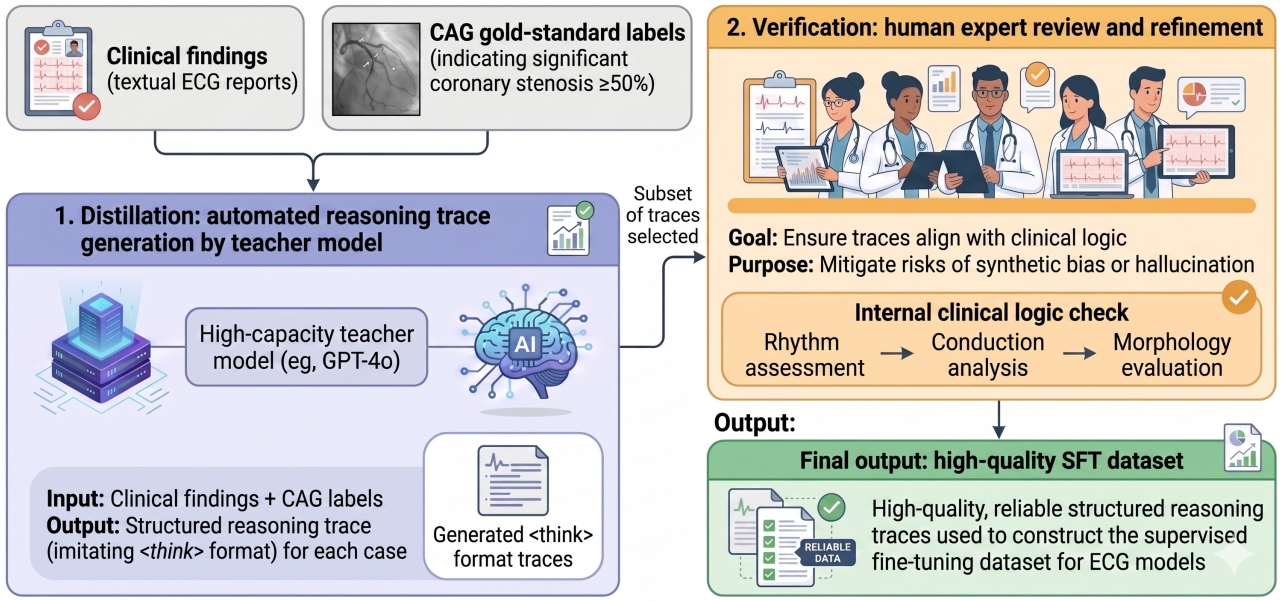
Overview

We used RL to enhance explicit reasoning capabilities in medical VLMs, adopting GRPO for its efficiency and demonstrated effectiveness. While GRPO has been primarily applied to reasoning tasks in coding and mathematics, we adapted this framework to the medical domain, with a focus on ECG analysis. Our approach integrated ECG waveform images as visual inputs and incorporated custom reward functions that promote structured clinical reasoning and domain-compliant response formats.

Ethical Considerations

This retrospective study used strictly deidentified clinical data, with all protected health information fully redacted from ECG images and textual reports to ensure patient privacy and safety. Because this research involved exclusively the secondary analysis of pre-existing, fully anonymized data, it was exempt from formal ethical review and the requirement for an approval number by the institutional ethics committees of the First Affiliated Hospital of Naval Medical University (Changhai Hospital) and Shanghai Xinhua Hospital (Xin Hua Hospital). This exemption was in accordance with Article 32 of the “Ethical Review Methods for Life Sciences and Medical Research Involving Humans” (2023) issued by the National Health Commission of the People’s Republic of China [30].

XSL•FO
RenderX



For prospective clinical application, ECG-R1 was designed strictly as an assistive clinical decision support system operating under a "human-in-the-loop" paradigm.

Data Acquisition and Preprocessing Pipeline

The dataset for this study was sourced from the First Affiliated Hospital of Naval Medical University (hospital A), comprising 12,917 cases, and Shanghai Xinhua Hospital (hospital B), comprising 1356 cases. Each case included both an ECG waveform image and associated text. Representative, deidentified examples illustrating the varying quality and format of this textual modality—including cardiologist impressions and patient histories—are provided in Table S1 in Multimedia Appendix 1. A key characteristic of this dataset was that all ECG images exhibited TWI. The dataset was well-distributed across patients of varying ages, genders, and medical histories. The ground truth for myocardial ischemia was established based on coronary angiography (CAG), the clinical gold standard. In cases where multiple CAG records were available, the one closest to the ECG acquisition time was used. This ensured that the model learned to identify waveform features associated with proven anatomical obstruction rather than subjective clinician interpretation. Data from hospital A (in-domain) were randomly partitioned at the patient level into training and internal test sets at a 7:3 ratio. In contrast, the entire dataset from hospital B served as an out-of-domain external validation set to assess model generalizability.

To construct a high-quality SFT dataset, we implemented a "Distillation-then-Verification" pipeline (Figure 1). First, a teacher model (GPT-4o; OpenAI) generated structured reasoning traces (<think> format) based on clinical findings and CAG gold-standard labels (≥50% stenosis). Subsequently, to mitigate synthetic hallucinations, expert clinicians verified the traces against strict clinical logic—covering rhythm, conduction, and morphology—thereby ensuring the reliability of the final dataset.

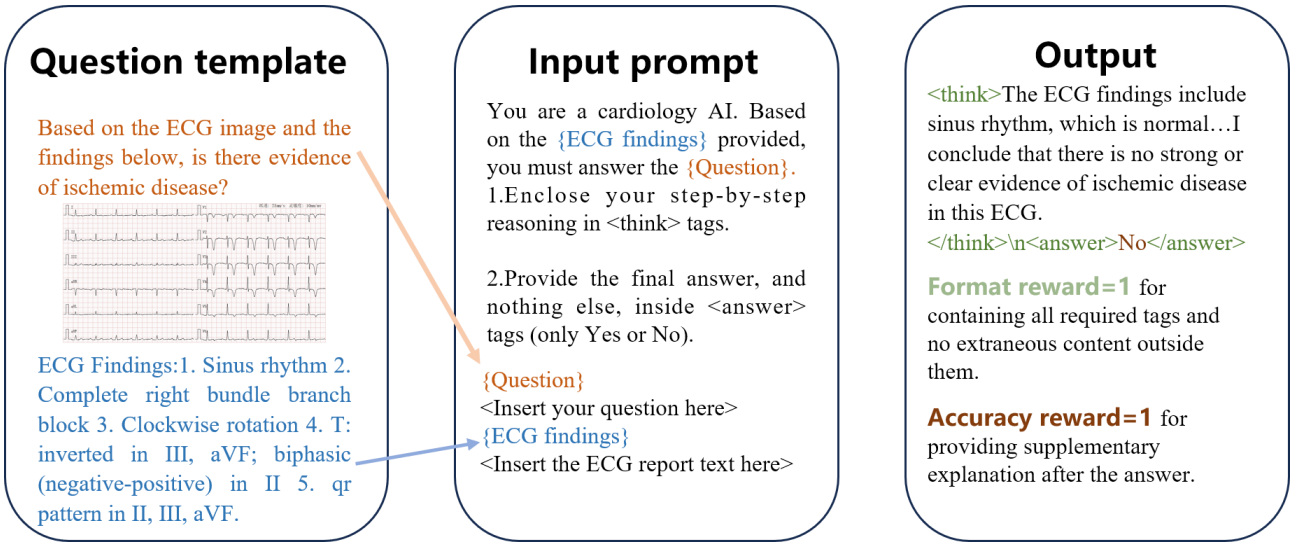


Figure 1. Schematic illustration of the "Distillation-then-Verification" pipeline for supervised fine-tuning (SFT) dataset construction. CAG: coronary angiography; ECG: electrocardiogram.

We used the Qwen2-VL-2B as our base model, denoted by $\pi\theta$, where θ represents its trainable parameters. The model was trained on a dataset, where each sample consisted of (1) an image depicting an ECG waveform and (2) a text prompt comprising a user question and a fixed system prompt, as shown in Figure 2. The VLM generated an output that includes both a reasoning trace and a final answer, structured within specific XML-style tags (ie, <think>...</think> and <answer>...</answer>). Our RL objective was to optimize $\pi\theta$ such that the model produced accurate answers, adhered to the desired output format, and demonstrated transparent clinical reasoning.

XSL•FO
RenderX

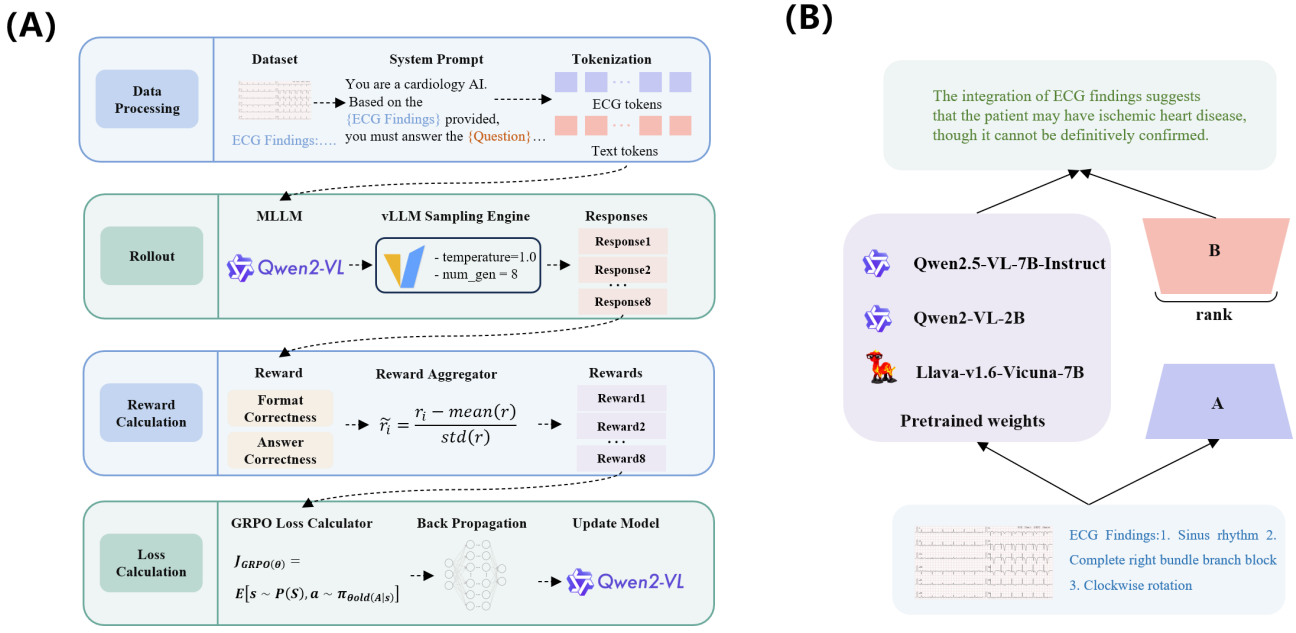

Figure 2. The process illustrates how multimodal inputs (electrocardiogram [ECG] image and text report) are integrated into a structured prompt, guiding the model to generate an output containing its reasoning (<think> tag) and final answer (<answer> tag). The system then assigns rewards based on format and accuracy to optimize the diagnostic capabilities of the model.

GRPO Training Pipeline

As illustrated in Figure 3A, our model training pipeline used the GRPO algorithm. As a RL algorithm, GRPO directed the policy updates of the model using a reward signal meticulously designed for the task of ECG analysis.

Figure 3. (A) Architectural overview of the group relative policy optimization (GRPO) training pipeline for the ECG-R1 model. The workflow includes data processing, sampling multiple candidate responses from the Qwen2-VL model, calculating rewards based on format and accuracy, and updating the model parameters using the GRPO loss. (B) Illustration of the comparative framework used to evaluate different pretrained vision-language model baselines. AI: artificial intelligence; ECG: electrocardiogram; MLLM: multimodal large language model.

Unlike standard proximal policy optimization, which doubles the memory footprint by requiring a separate value network, GRPO was highly efficient for large VLMs [31]. It extends proximal policy optimization [32] by using a group-relative advantage instead of a learned value function. In each training step, the algorithm began by sampling a group of G candidate outputs {Oi}i=1G from the current policy, πθold using vLLM sampling. A core component of this process was the calculation of a reward score ri, for each candidate. The effectiveness of this reward signal guided the direction and efficiency of optimization. For our binary ECG classification task (eg, "Is there evidence of ischemic disease?"), we designed a 2-component, rule-based reward function.

First, a format reward incentivized adherence to a predefined output structure. A score of 1 point was awarded if the output strictly contained a single <think> block and a single <answer> block with no extraneous content; any deviation from this format (eg, missing or duplicated tags) yielded 0 points. Conditioned on meeting the format requirements, an accuracy reward was then assessed. If the content within the <answer> tag was an exact, case-insensitive match to the ground-truth label ("yes"

XSL•FO
RenderX

or “no”), an additional 1 point was awarded. Any incorrect or verbose answer received 0 points. The total reward for each candidate, ri, was the sum of these 2 components, resulting in a value in the range [0,2]. This hierarchical reward structure, which prioritized format before accuracy, guided the model to first master the response schema before optimizing the clinical accuracy of its judgments.

After obtaining the reward ri for each candidate, we calculated the group-relative advantage, Ai=ri−μrσr, by normalizing the reward against the statistics of the group, where μr and σr were the mean and SD of the rewards in that group. Outputs with above-average rewards received a positive advantage, thereby incentivizing the model to learn a superior generation policy. Finally, the parameters θ were updated by maximizing the following GRPO objective function:

This objective function leveraged the reward-based advantage signal and used a clipped importance sampling ratio, riratio, to ensure training stability. Additionally, a Kullback-Leibler (KL) divergence regularization term, DKL(πθ∨πref), penalized significant deviations from the initial reference model πref to prevent catastrophic forgetting. The model was then updated via back propagation, completing the training loop.

SFT-Low-Rank Adaptation Baseline

To evaluate the efficacy of our proposed GRPO-based approach, we established a strong baseline using SFT, with the evaluation framework illustrated in Figure 3B. We applied this method to several VLMs, including Qwen2.5-VL-7B-Instruct, Llava-v1.6-Vicuna-7B, and the same Qwen2-VL-2B used in our GRPO experiments for a direct comparison. The SFT process adapted these pretrained models by training them on a dataset of curated (input, output) pairs to maximize the likelihood of generating the ground-truth output.

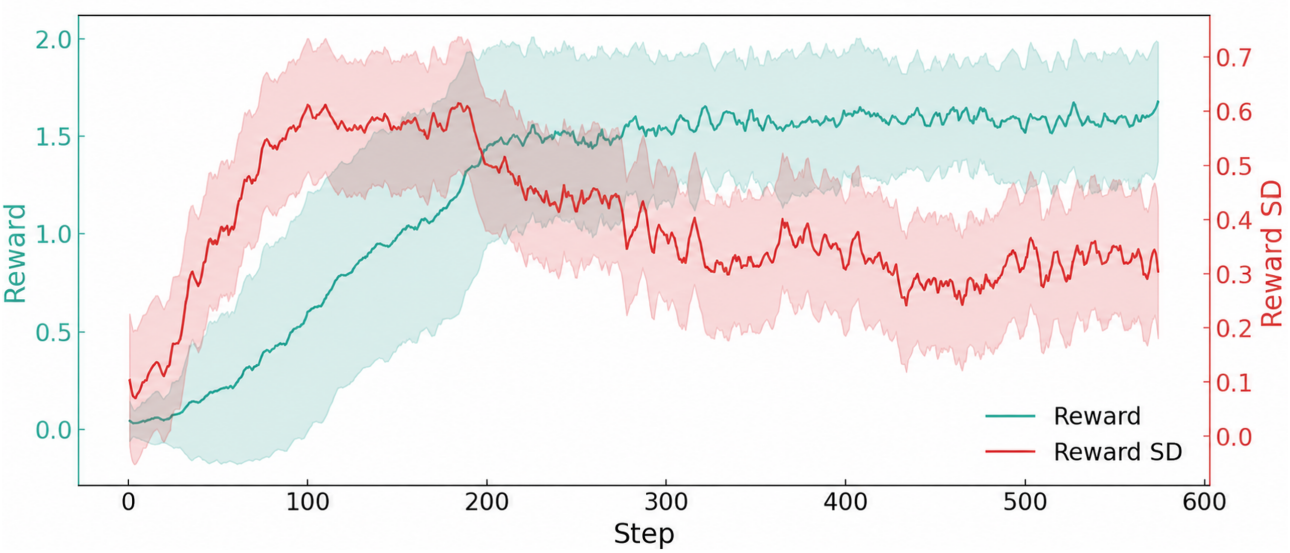
To enhance computational efficiency and mitigate the risk of catastrophic forgetting, we used low-rank adaptation (LoRA). Instead of fine-tuning the entire set of model parameters, LoRA injects trainable, low-rank matrices into the transformer layers of the VLM. During training, only these lightweight matrices were updated, while the original pretrained weights remained frozen. For a direct and fair comparison, the training data for SFT mirrored the format used in our RL setup. Each ground-truth output consisted of a complete reasoning trace enclosed in <think>...</think> tags followed by a definitive answer in <answer>...</answer> tags. The model was trained by minimizing the standard cross-entropy loss between its predicted token sequence and the ground-truth sequence. Specifically, for a given ground-truth sequence Y=(y1,y2,…,yT), the SFT loss was formulated as the negative log-likelihood of the target tokens:

$$L_{SFT}(\theta) = -\sum_{t=1}^{T} \log P_\theta(y_t \mid x, y_i, t)$$

Where θ represents the trainable model parameters, x is the input, and Pθ(yt|x,yt) is the probability of the model predicting the correct token yt given the input and the preceding ground-truth tokens yt. This SFT-LoRA baseline represented a standard and powerful adaptation technique, providing a crucial benchmark to assess the unique advantages of applying RL to this medical reasoning task.

Quantization Methodology

To evaluate the deployment feasibility of ECG-R1 in resource-constrained clinical settings, we implemented posttraining quantization to reduce computational precision (from BF16 to INT8 or INT4). This technique substantially lowered video RAM (VRAM) requirements and increased inference speed. Specifically, we used the bitsandbytes library for INT8 quantization and the activation-aware weight quantization algorithm for INT4 [33]. Activation-aware weight quantization was selected to preserve the salience of model weights critical for interpreting complex ECG waveforms while minimizing memory use. This approach ensured an optimal balance between diagnostic performance and high-speed inference on low-cost hardware.



Results

Training and Implementation Details

Our study used Qwen2-VL-2B as the base VLM. While this model was originally trained on a diverse corpus of web pages, open-source datasets, and synthetic data, we adapted it for the medical domain using the GRPO RL framework described in the methodology. Our implementation was built upon open-source VLM inference libraries [34-36]. The model underwent full fine-tuning for 594 steps on 4 NVIDIA A6000 graphics processing units (GPUs; 48 GB VRAM each). With a batch size of 1, the total training time was approximately 32 hours. For the GRPO algorithm, the number of G was set to 8. All other training and optimization hyperparameters were configured in accordance with the recommendations in [35]. The progression of the GRPO training process, demonstrating the continuous improvement in reward and the stabilization of the reward SD, is illustrated in Figure 4.

XSL•FO
RenderX

Figure 4. Group relative policy optimization reward and reward SD.

For our SFT baseline experiments, we used LoRA for the Qwen2-VL-2B, Qwen2.5-VL-7B-Instruct, and Llava-v1.6-Vicuna-7B models. To ensure a fair and consistent comparison, we used a unified LoRA configuration for all 3 models. Specifically, the LoRA rank was set to 16 with a scaling factor of 32. We applied LoRA to the query, key, value, and output projection layers within the transformer blocks, with a dropout rate of 0.01. These models were trained for 3 epochs using the AdamW optimizer with a learning rate of 2×10−4 and a batch size of 8. The training was also conducted on 4 NVIDIA A6000 GPUs.

Figure 4 tracks GRPO training for Qwen2-VL-2B over 594 steps. The rising reward (green) indicates continuous improvement in medical reasoning accuracy. The decreasing then stabilizing reward SD (red) reflects reduced performance variability as the policy converges, confirming stable and effective RL.

Comparative Performance on TWI Reasoning

To comprehensively evaluate our proposed method, we compared its performance against several baselines on the ECG TWI reasoning task. The evaluation was conducted under 2 settings to assess generalizability: in-domain, where the model was trained and tested on data from the same hospital (eg, hospital A→hospital A), and out-of-domain, where the model was trained on data from one hospital and tested on data from another (eg, hospital A→hospital B). This cross-hospital validation served as a stringent test of the ability of the model to generalize to unseen data distributions.

The comprehensive clinical metrics (accuracy, sensitivity, specificity, positive predictive value, negative predictive value, and AUC-ROC) are summarized in Table 1 across 3 model categories: zero-shot/ViTs, SFT VLMs (baselines), and our GRPO VLM. As the results show, zero-shot models performed near random chance. While vision-only baselines (eg, ViT-L/14) established a functional 62.21% in-domain accuracy, they were consistently outperformed by multimodal SFT models, confirming that the synergistic integration of visual waveforms and clinical text was essential for diagnostic precision.

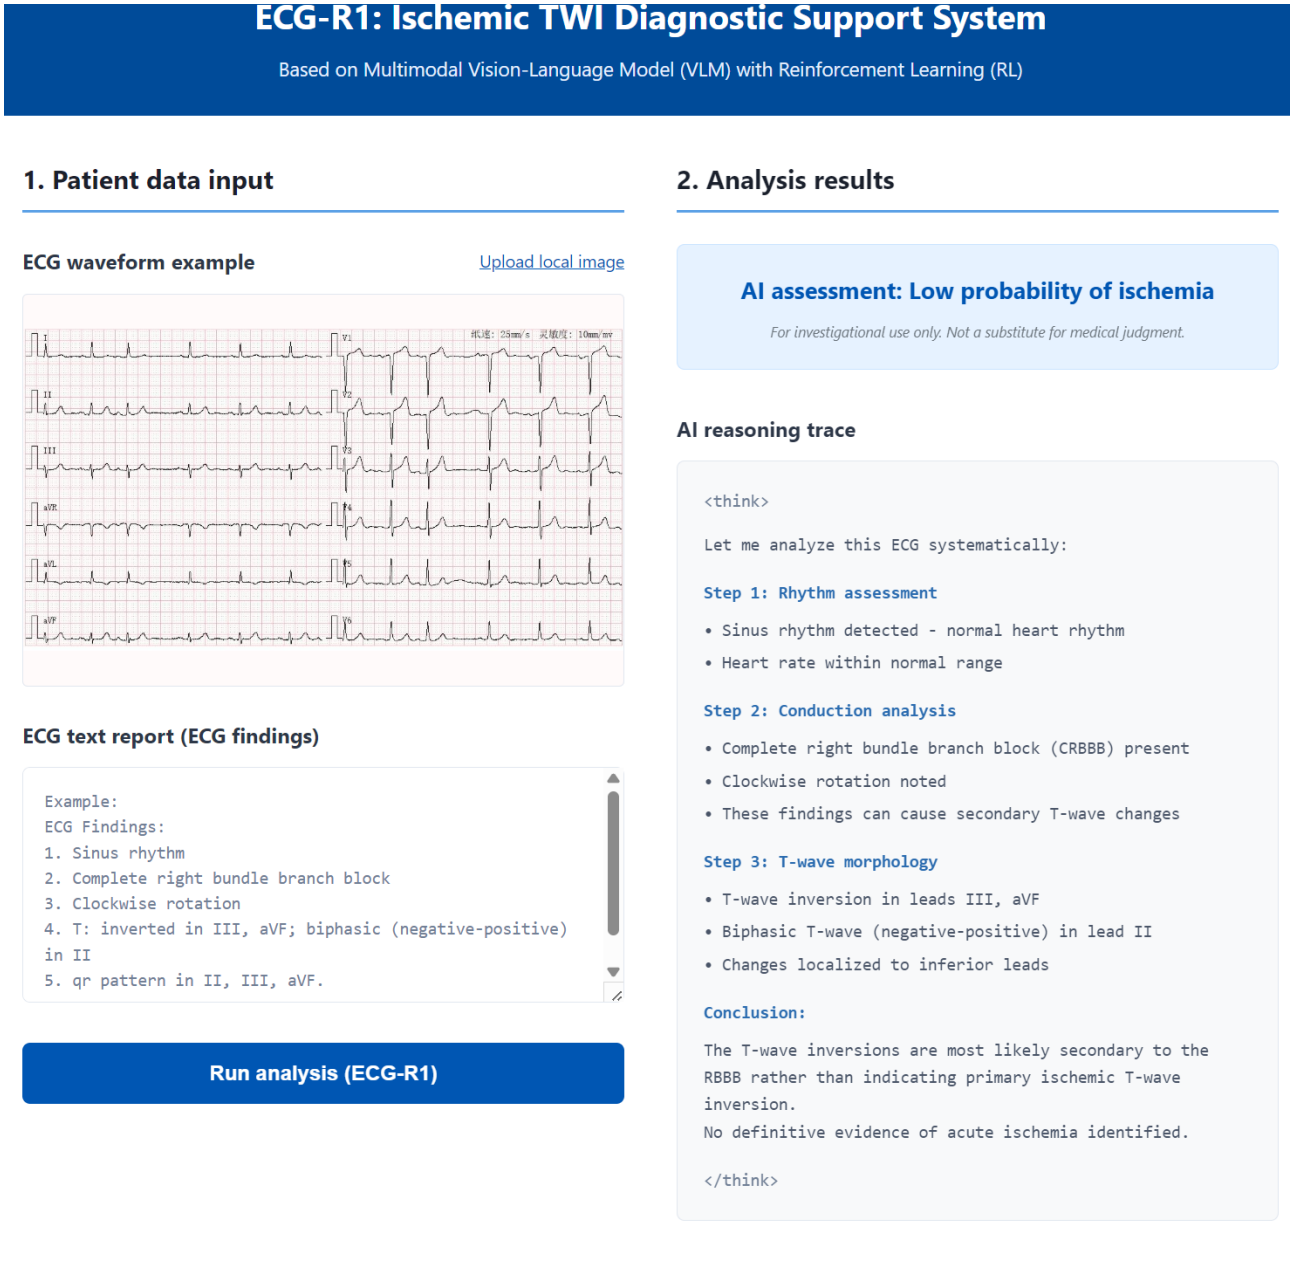
Although SFT baselines demonstrated strong in-domain capabilities (eg, Llava-v1.6-Vicuna-7B achieved 69.40% accuracy and 73.41% AUC-ROC), they suffered notable performance drops in the out-of-domain setting (accuracy degrading to 62.33%), indicating overfitting to the source hospital's specific artifacts. In stark contrast, our GRPO-based approach achieved a new state-of-the-art performance. It achieved the highest in-domain accuracy (75.21%) and AUC-ROC (84.18%), with an exceptional sensitivity of 82.55% that effectively minimized critical false negatives. While the in-domain specificity of ECG-R1 (68.43%) was marginally lower than certain SFT baselines such as Qwen2-VL-2B full-FT (72.58%), this represented a deliberate algorithmic trade-off; prioritizing sensitivity over specificity was an essential design feature for a frontline triage tool. Crucially, the GRPO model exhibited remarkable out-of-domain robustness, maintaining 72.93% accuracy and 81.56% AUC-ROC. This minimal cross-hospital degradation proved that optimizing for clinical reasoning via RL allowed the model to learn invariant, generalizable physiological features rather than overfitting to surface-level patterns.

As detailed in our methodology, all inference benchmarks—including inference speed and VRAM consumption (GB) visualized in Figure 5—were measured on a single NVIDIA GeForce RTX 4090 GPU with 24 GB of memory. The trade-offs between accuracy, speed, and VRAM use across different models and quantization levels are visualized in Figure 5. Compared with the larger 7B models, ECG-R1 maintained the highest accuracy across all quantization levels. This demonstrated that ECG-R1 can achieve high-speed inference on low-cost hardware, striking an optimal balance between diagnostic performance and resource consumption.

Figure 5. Comprehensive evaluation of vision-language model performance under quantization. The charts illustrate the trade-offs between (A) accuracy (%), (B) inference speed (token/s), and (C) video RAM (VRAM) use (GB) at different precision levels (BF16, INT8, and INT4).

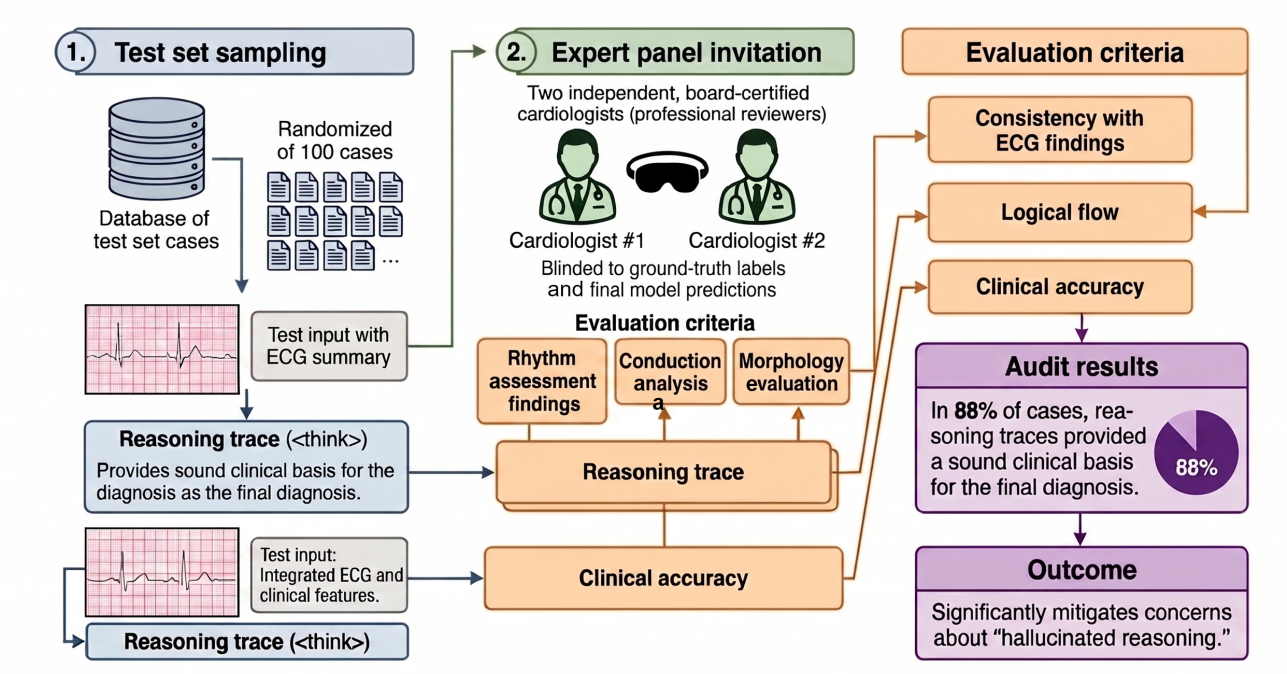


Furthermore, our framework directly addressed the critical need for transparency and safety in medical AI. By integrating multimodal inputs with a reward structure that mandates an explicit reasoning trace, the model's decision-making process

XSL•FO
RenderX

became highly interpretable. As illustrated in the clinical decision support interface (Figure 6), the system was intentionally designed to output probabilistic assessments rather than definitive diagnoses. To achieve this, while the model was prompted to generate a definitive "yes" or "no" answer token, the inference engine extracted the underlying softmax confidence score (log probabilities) of this final generated token. These mathematically derived, continuous probability scores were then mapped to risk-stratified textual categories (eg, "low probability of ischemia") presented in the user interface. This structural choice was vital to mitigate the risk of premature cognitive closure, ensuring the tool acted strictly as an assistive triage flag that complemented, rather than replaced, human clinical judgment.

Figure 6. Demonstration of the ECG-R1 clinical decision support interface. To align with responsible artificial intelligence (AI) practices and prevent premature cognitive closure, the system uses probabilistic language. The underlying continuous probability score is mapped to risk-stratified categories: P(yes)≥0.80 as "high probability," 0.20 - 0.79 as "intermediate," and <0.20 as "low probability." The output panel displays a risk-stratified "AI Assessment," accompanied by the interpretable reasoning trace (the <think>... block). This transparent design ensures the attending physician can independently verify the AI's logic and retain ultimate diagnostic authority. ECG: electrocardiogram.



XSL•FO
RenderX

Qualitative Evaluation of Reasoning

As illustrated in Figure 7, to assess the clinical validity of the reasoning, we conducted a blinded qualitative audit on 100 randomly sampled test cases. Two independent, board-certified cardiologists reviewed the generated reasoning traces (<think> blocks) based on 3 specific criteria: consistency with ECG findings, logical flow, and clinical accuracy. The reviewers remained strictly blinded to ground-truth labels and predictions to ensure objectivity. Audit results demonstrated that in 88% of cases, the traces provided a sound clinical basis for the diagnosis, significantly mitigating concerns about "hallucinated reasoning" and confirming that the model's decision-making was grounded in valid clinical evidence.

Figure 7. Schematic illustration of the blinded qualitative audit workflow for evaluating generated reasoning traces. ECG: electrocardiogram.

Ablation Results

To verify that ECG-R1 did not rely on linguistic shortcuts, we compared it against image-only models. As shown in Table 2, the ViT-B/16 and ViT-L/14 models achieved in-domain accuracies of 60.18% and 62.21%, respectively. The superior performance of ECG-R1 (75.21%) over these image-only baselines demonstrated that the RL paradigm successfully leveraged the complementary information between visual waveforms and objective clinical text to achieve higher diagnostic precision.

Discussion

Principal Findings

This study introduced ECG-R1, a multimodal RL model designed to address the significant clinical challenge of differentiating ischemic from nonischemic TWI. It confronted the limitations of existing deep learning models, namely, their single-modality reliance, "black box" nature, and poor generalization. Our results provided strong evidence for the superiority of the RL-based approach over SFT baselines. Critically, while SFT models exhibited poor performance in out-of-domain (cross-hospital) evaluations, likely due to "rote memorization," our GRPO-trained model (75.21% in-domain accuracy) demonstrated substantially better generalization. This suggested that RL incentivized the model to learn more robust pathological patterns. Furthermore, the strategic selection of a 2-billion parameter model achieved a pragmatic balance between high performance and clinical deployment feasibility, rendering it suitable for resource-constrained hospital environments. Finally, the framework successfully addressed the transparency challenge in medical AI by mandating explicit reasoning traces via an effective 2-component reward function assessing both format and accuracy. Acting as an automated triage tool to flag high-risk ischemic patterns, the model generates independently verifiable reasoning traces to mitigate automation bias. This structural transparency ensures that the attending physician consistently retains ultimate diagnostic authority and legal liability.

Real-world clinical text inherently contains noise, including abbreviations (Table S1 in Multimedia Appendix 1), typos, and missing information. Our multimodal VLM handled these issues through 2 key mechanisms. First, the base model's extensive pretraining provided robustness against linguistic irregularities and clinical shorthand. Second, the multimodal architecture ensured diagnostic redundancy; when text was fragmented or absent entirely, the model dynamically shifted its attention to extract compensatory features directly from the ECG waveform, maintaining stable diagnostic performance.

Limitations

While our findings demonstrated the significant potential of the ECG-R1 framework, several critical limitations must be addressed before clinical deployment. Although our cross-hospital validation established a robust baseline for generalizability, the dataset was sourced from only 2 institutions. Because large VLMs are pretrained on vast, uncurated internet corpora, they may inherently harbor demographic or socioeconomic biases. Consequently, future research must validate the model across larger, multicenter cohorts and conduct comprehensive fairness audits evaluating performance across diverse racial, ethnic, and age groups to prevent the perpetuation of health care disparities. Additionally, addressing the current error rate of approximately 24.79% was paramount. In cardiology, the clinical cost of errors is highly asymmetric; false negatives can lead to severe, life-threatening outcomes. Future iterations must therefore be strictly calibrated to prioritize sensitivity, ensuring the system operated as a highly conservative safety net.

A fundamental algorithmic constraint of the current framework lay in its reward mechanism. The rule-based system functioned effectively as an outcome-supervised reward model, optimizing primarily for structural formatting and the final diagnostic label. This sparse reward signal left the model vulnerable to "reward hacking," a phenomenon where the model generated plausible but medically flawed intermediate logic to arrive at the correct final answer. In our current framework, this risk was implicitly mitigated by the KL divergence regularization term within the GRPO objective. Because the policy was anchored to an SFT reference model trained on expert-verified reasoning traces, the KL penalty effectively prevented severe semantic degradation or spurious keyword repetition. Overcoming this bottleneck required a transition to process-supervised reward models (PRMs). Implementing PRMs would provide a dense reward signal capable of explicitly evaluating and guaranteeing the logical validity of each step within the clinical reasoning chain, thereby securing the integrity of the model's interpretability. Because developing PRMs was highly resource intensive, demanding expert step-by-step annotation, practical interim strategies included rigorous post hoc clinical audits (as in our study) or "AI-as-a-Judge" pipelines to automatically score reasoning steps.

Furthermore, using CAG as the ground truth introduced a verification bias, skewing the dataset toward patients with a higher pretest probability of ischemia. Consequently, our reported metrics primarily reflected a higher-risk subpopulation, as benign or asymptomatic TWI cases were underrepresented.

Finally, the retrospective design of this study implied that the true utility of the system within a live clinical workflow remained unproven despite its high offline diagnostic precision. The essential next step is the rigorous evaluation of ECG-R1 within prospective, randomized clinical trials to measure its tangible impact on physician decision-making and patient outcomes. Furthermore, addressing the complex ethical and liability concerns of AI deployment dictates a strict "human-in-the-loop" paradigm. To ensure clinical safety, the system must function exclusively as an assistive decision support tool—such as an automated triage flag—guaranteeing that the attending physician retains ultimate diagnostic authority and legal responsibility.

Conclusions

In conclusion, our study demonstrated that applying RL to multimodal VLMs is a highly effective strategy for complex medical reasoning tasks. The ECG-R1 framework enhanced diagnostic accuracy, improved generalization, and promoted transparency, offering a powerful tool to augment clinical expertise and mitigate the risks of misdiagnosis in cardiology.

Acknowledgments

The authors would like to express their gratitude to the clinical staff at the First Affiliated Hospital of Naval Medical University and Shanghai Xinhua Hospital for their invaluable assistance in data collection and expert annotation. They also thank the open-source community for providing the vision-language model inference libraries and base models used in this study. The authors acknowledge the use of generative artificial intelligence (specifically ChatGPT) solely for language polishing and grammar correction to improve the readability of the manuscript. The entire research process, including data analysis, model development (ECG-R1), and the interpretation of results, was conducted by authors. The authors take full responsibility for the final content and intellectual integrity of this work.

Funding

This work is supported by the Shanghai Engineering Research Center of Interventional Medical Device (grant 18DZ2250900).

Data Availability

Data underlying the results presented in this paper are not publicly available at this time but may be obtained from the authors upon reasonable request.

Abstract

Background: Artificial intelligence–based medical devices (AIMDs) have emerged as transformative technologies in modern health care. However, comprehensive analysis of recent approval trends and characteristics of AIMDs in China remains limited.

Objective: This study aimed to provide an up-to-date overview of AIMDs approved in China up to June 2025.

Methods: We conducted a search of the Drugdataexpy database to identify AIMDs approved up to June 30, 2025, using artificial intelligence–related keywords in the "structural composition" and "intended use" fields. After manual verification and exclusion of non-AIMDs, we collected key characteristics, including name, manufacturer, approval date, risk class, clinical evaluation pathway, medical specialty, data source, review pathway, and algorithm type. Statistical analysis encompassed descriptive statistics and trend analysis. We used the Fisher exact test and Pearson chi-square test to assess the associations between risk class and categorical variables.

Results: A total of 154 AIMDs were identified since the first approval in 2020, with annual approvals increasing from 9 in 2020 to 45 in 2024 (a 49.53% compound annual growth rate), although the 20 approvals in the first half of 2025 suggest a potential moderation in pace. Most AIMDs (123/154, 79.9%) were categorized as class III, and the risk class was significantly associated with approval year (P=.03), manufacturer location (P=.03), and medical specialty (P=.004). Of the 123 class III devices, 19 (15.4%) were approved through innovation review, and 2 (1.6%) each were approved through priority and emergency approval. Deep learning was the dominant algorithm (143/154, 92.9%). Radiology dominated the field (106/154, 68.8%), with computed tomography serving as the primary data source (96/154, 62.3%), particularly for applications in pulmonary nodule detection and cardiovascular assessment. Clinical trials were the primary evaluation pathway for 76.6% (118/154) of all AIMDs. This approach was predominant for class III devices (116/123, 94.3%), whereas most class II devices (21/31, 67.7%) used a clinical exemption pathway. Market concentration was evident, with the top 4 manufacturers accounting for 38.3% (59/154) of all approvals and geographically clustered in major innovation hubs such as Beijing, Shanghai, Shenzhen, and Hangzhou.

Conclusions: China's AIMD ecosystem is experiencing growth, heavily focused on radiology and computed tomography–based solutions within a risk-proportionate regulatory framework. The market is characterized by significant manufacturer and geographic concentration.

(JMIR Med Inform 2026;14:e85538) doi:10.2196/85538

KEYWORDS

medical device; artificial intelligence; AI; artificial intelligence–based medical device; AI-based medical device; medical device approval; regulatory science; China; deep learning; radiology

Introduction

Artificial intelligence (AI) has emerged as a transformative force in modern health care, offering unprecedented capabilities in data analysis, pattern recognition, and clinical decision support [1,2]. Among its many applications, AI-based medical devices (AIMDs) have gained substantial traction, particularly in medical imaging, diagnostics, and predictive analytics [3]. These technologies promise to enhance diagnostic accuracy; reduce physician workload; and, ultimately, improve patient outcomes [4].

Worldwide, regulatory authorities have responded to the rapid development of AIMDs by establishing frameworks to ensure their safety, efficacy, and clinical utility [5-8]. In the United States, the Food and Drug Administration approved 691 AI- and machine learning (ML)–based medical devices by October 2023, with most cleared through the 510(k) pathway and concentrated in radiology and cardiology [9,10]. Similarly,

XSL•FO
RenderX

Europe has witnessed a substantial increase in CE-marked AIMDs, with approval numbers growing significantly since 2015 [11].

China, as a major player in both AI innovation and health care digitalization, has also made significant strides in this domain [12,13]. The National Medical Products Administration (NMPA) approved its first AIMD in 2020. Since then, the number of approvals has grown steadily, reaching 59 by mid-2023, all categorized as class III [14]. In China, medical devices are categorized into 3 classes based on increasing risk: class I (low risk), class II (medium risk), and class III (high risk). This classification dictates the regulatory pathway for market approval. Class III devices, deemed to pose the highest risk, require centralized registration approval from the NMPA itself and are subject to the most stringent review of clinical evidence. Class II devices may receive approval from provincial-level medical product administrations. AIMDs in China are typically categorized as class II or class III. The classification is determined by the algorithm's maturity and its role in clinical decision-making. Specifically, AIMDs with lower algorithm maturity are managed as class III devices if they are intended for auxiliary decision-making. Conversely, if they are intended for non–decision support tasks, they are managed as class II devices. In China, the clinical evaluation pathway for medical devices consists of 3 types: clinical trials, clinical comparison with similar products, and exemption from clinical evaluation. The clinical exemption pathway relies on the *Catalogue of Medical Devices Exempt From Clinical Evaluation* issued by the NMPA [15].

In recent years, the NMPA has actively refined and optimized its review processes for AIMDs. Key efforts include issuing evaluation guidelines, clarifying regulatory classifications, developing clinical evaluation guidance for specific product types, and introducing comprehensive support measures spanning the entire product life cycle [16-19]. These advancements have spurred a new wave of submissions and approvals, fostering a more structured and efficient ecosystem for AIMD market entry. Despite this progress, the literature to date primarily documents AIMD approvals in China up to 2023. There remains a lack of comprehensive analyses covering the most recent developments, particularly those in 2024 and 2025—a period likely marked by regulatory maturation and increased approvals. This study adopted innovation diffusion theory [20] as its primary analytical lens. This theory posits that the adoption rate and pattern of an innovation are influenced by its perceived attributes, including relative advantage, compatibility, complexity, trialability, and observability, within a specific social system.

Therefore, this study aimed to provide an up-to-date analysis of AIMDs approved in China as of June 2025. By examining trends in approval numbers, device characteristics, and regulatory pathways, it may offer insights into the evolving AIMD landscape in China and its implications for future health care innovation.

Methods

Data Source and Search Strategy

To identify AIMDs approved up to June 30, 2025, we searched the Drugdataexpy database [21]. As this is a Chinese-language database, the keyword search was performed using the Chinese equivalents of the following English-language terms in the database fields for "structural composition" and "indications" or "intended use": "deep learning," "machine learning," "neural network," "artificial intelligence," or "algorithm." The NMPA's official website, while providing free access to regulatory announcements, lacks keyword-based filtering capabilities in its search function, thereby limiting efficient retrieval of AIMDs.

This study included AIMDs regulated under the Guidelines for Registration Review of Artificial Intelligence Medical Devices [16], encompassing stand-alone software as a medical device and software in a medical device (SiMD) where AI is a core component. After manual review of full-text descriptions, we excluded records that did not meet the AIMD definition. We also removed entries corresponding solely to routine administrative renewals without changes to the device's core AI software or intended use. Substantive approvals for major changes or modifications to existing devices (eg, the addition of new AI functionality) were retained. Details of the search strategy and process are provided in Multimedia Appendix 1. To minimize omissions, we reran the search for each retained product name to capture devices manufactured by other companies. Our results were cross-validated against the AIMDs approved before July 2023 as listed in the study by Liu et al [14]. Ambiguous entries were checked against the corresponding NMPA evaluation reports or the manufacturers' websites.

Data Extraction

For each eligible AIMD, we extracted the approval number, device name, manufacturer, approval date, structural composition, intended use, risk class, clinical evaluation pathway (clinical trials, clinical comparison with similar products, or exemption from clinical evaluation), and review pathway (innovative, priority, or emergency special review vs standard). From these fields, we derived the city of the manufacturer, medical specialty, body area, and data source of the AIMD. The medical specialty for each AIMD was assigned based on the device's registered intended use and its core function. For devices with applications relevant to multiple specialties, the specialty was determined by the primary clinical context and decision support role stated in the indications for use. The body area for each device was functionally classified into nonoverlapping categories based on the primary anatomical structure and type of clinical analysis specified in the device's intended use: "heart" referred to devices targeting cardiac muscle, chambers, or electrophysiology (eg, electrocardiogram analysis); "cardiovascular" referred to devices focused on the vascular system (eg, computed tomography [CT] or magnetic resonance angiography); "lung" referred to devices analyzing lung parenchyma (eg, nodule detection); and "thorax" referred to devices assessing nonparenchymal structures within the thoracic cavity (eg, rib fracture detection). Algorithm type was determined through a tiered review: it was first identified from

XSL•FO
RenderX

the "structural composition" and "intended use" fields. If not specified there, the full registration dossier was consulted for explicit technical descriptions.

To facilitate downstream data processing, minor lexical variants in device names referring to the same product—such as "medical image" vs "imaging"—were standardized to a single, consistent terminology. For the analysis of market concentration, "manufacturer" referred to the ultimate parent corporate entity. AIMDs approved under the legal names of subsidiaries belonging to the same corporate group were aggregated under the parent company's name. A customized extraction form was piloted on 10 AIMDs and then applied independently by 2 reviewers (LZ and JY). Any disagreements were resolved through discussion until consensus was reached.

Statistical Analysis

Descriptive statistics were used to summarize the extracted variables and assess temporal trends. We calculated the compound annual growth rate for annual approvals from 2020 to 2024 and applied the Mann-Kendall trend test to assess the significance of the growth trend. For AIMDs that used multiple data sources, each modality was counted separately in the subsequent analysis of data source distribution. Associations between categorical variables (approval year, medical specialty, and manufacturer's city) and AIMD risk class were evaluated. The Fisher exact test was used for analyses involving variables with low expected cell counts (approval year and medical specialty), whereas the Pearson chi-square test was used for other comparisons. All tests were 2 sided, with $P<.05$ indicating statistical significance. Analyses were conducted using SPSS Statistics for Windows (version 27.0; IBM Corp).

Ethical Considerations

This study was a secondary analysis of publicly available regulatory records retrieved from a database. No data from human participants or identifiable personal information were used, and no primary data collection was conducted. The data are anonymized and publicly accessible. In accordance with the institutional policy of China Pharmaceutical University, ethics board approval was not required for this study. This study complies with China's Data Security Law [22] and Personal Information Protection Law [23].

Results

Overview of AIMD Approvals in China

As of June 30, 2025, a total of 154 AIMDs had been approved in China since the initial authorization in 2020. Figure 1 shows the inclusion flowchart for AIMDs approved in China. All devices were intended for use by health care professionals, with none designed for direct patient use. The annual approval numbers exhibited a clear upward trend from 2020 to 2024: 9 in 2020, a total of 16 in 2021, a total of 26 in 2022, a total of 38 in 2023, and 45 in 2024. From 2020 to 2024, the compound annual growth rate was 49.53%, and the trend test confirmed a statistically significant increasing trend in annual approvals ($P<.001$). Data for the first half of 2025 show 20 approvals, indicating that the trend may be entering a phase of moderation or plateau (Figure 2). Detailed information on these AIMDs sorted by approval date is provided in Multimedia Appendix 2.

Among the 154 AIMD approvals, 15 device types had at least 3 approvals (Table 1). Pulmonary nodule CT image auxiliary detection software ranked first with 14 (9.1%) approvals. It was followed by coronary artery CT angiography image vessel stenosis auxiliary assessment software with 8 (5.2%) approvals. Coronary artery CT fractional flow reserve calculation software and intracranial hemorrhage CT image auxiliary triage software tied for third, each with 7 (4.5%) approvals. Diabetic retinopathy fundus image auxiliary diagnosis software and pneumonia CT image auxiliary triage and assessment software each had 6 (3.9%) approvals. Pediatric hand x-ray image auxiliary bone age assessment software had 4 (2.6%) approvals. A total of 8 additional products each obtained 3 (1.9%) approvals, spanning various applications from CT image processing and electrocardiogram analysis to specialized endoscopic, angiographic, and x-ray–based diagnostic tools.

Table . Artificial intelligence–based medical devices with ≥3 approvals in China (2020 - 2025; n=154).

Device description	Approvals, n (%)
Pulmonary nodule CT[a] image auxiliary detection software	14 (9.1)
Coronary artery CT angiography image vessel stenosis auxiliary assessment software	8 (5.2)
Coronary artery CT fractional flow reserve calculation software	7 (4.5)
Intracranial hemorrhage CT image auxiliary triage software	7 (4.5)
Diabetic retinopathy fundus image auxiliary diagnosis software	6 (3.9)
Pneumonia CT image auxiliary triage and assessment software	6 (3.9)
Pediatric hand x-ray image auxiliary bone age assessment software	4 (2.6)
CT image processing software	3 (1.9)
Dynamic electrocardiogram analysis software	3 (1.9)
Electrocardiogram analysis software	3 (1.9)
Electronic lower gastrointestinal endoscopy image auxiliary detection software for intestinal polyps	3 (1.9)
Head and neck CT angiography image auxiliary assessment software	3 (1.9)
Breast x-ray image auxiliary detection software	3 (1.9)
Medical image processing software	3 (1.9)
Rib fracture CT image auxiliary detection software	3 (1.9)

[a]CT: computed tomography.

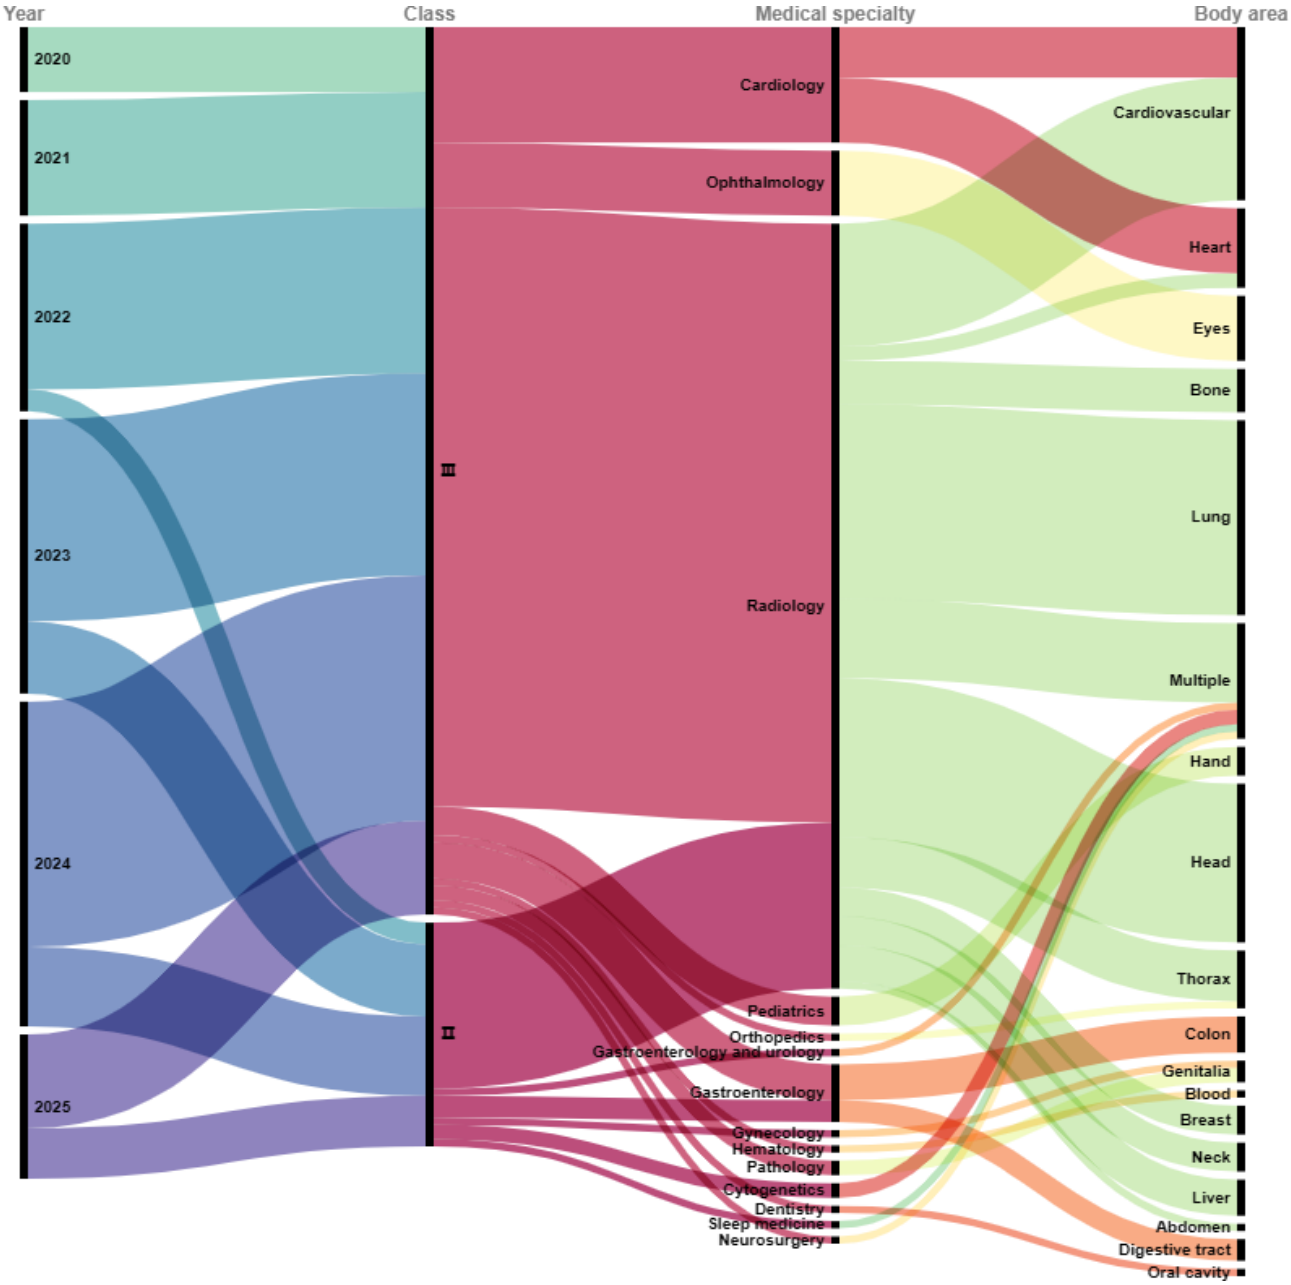
Data Source of AIMDs

As shown in Table 2, CT was the predominant data source for these AIMDs, identified in 62.3% (96/154) of approvals. This markedly exceeded other data sources, including x-ray (18/154, 11.7%), magnetic resonance imaging (12/154, 7.8%), endoscopy (9/154, 5.8%), electrocardiography (9/154, 5.8%), and fundus photography (9/154, 5.8%).

Table . Data sources used in approved artificial intelligence–based medical devices in China (2020 - 2025). Devices using multiple data sources were counted under each relevant modality. Therefore, the sum of counts exceeds the total number of devices (n=154).

Data source	Devices, n (%)
CT[a]	96 (62.3)
X-ray	18 (11.7)
MRI[b]	12 (7.8)
Electrocardiogram	9 (5.8)
Endoscopy	9 (5.8)
Fundus photography	9 (5.8)
Microscopic images	6 (3.9)
Ultrasound	3 (1.9)
Polysomnography	1 (0.6)

[a]CT: computed tomography.



[b]MRI: magnetic resonance imaging.

Risk Class and Correlation Analysis

The vast majority of AIMDs (123/154, 79.9%) were categorized as class III, with 20.1% (31/154) categorized as class II (Figure 3). Significant associations were found between risk class and 3 key variables: the year of approval (P=.03), the manufacturer's city (P=.03), and the medical specialty (P=.004). In 2020 and 2021, only class III AIMDs were approved. After 2022, the share of class II AIMDs rose each year, from 11.5% (3/26) in 2022 to 35% (7/20) in 2025. The proportion of class III AIMDs was markedly higher in Hangzhou (16/16, 100%) and Beijing (47/54, 87%) than in other cities. The distribution of risk classes varied substantially across medical specialties. Ophthalmology and cardiology exhibited a 100% (16/16) class III rate, whereas 21.7% (23/106) of AIMDs in radiology were class II.

Review Pathway and Algorithm

Of the 154 AIMDs, 23 (14.9%) gained market access through national-level special review pathways, which were exclusively for class III devices. Specifically, of the 123 class III devices, 19 (15.4%) were approved via innovation review, 2 (1.6%) were approved via priority review, and 2 (1.6%) were approved via emergency approval, constituting a combined 18.7% (23/123) of all class III approvals. The remaining 85.1% (131/154) of the devices followed the standard review process. Of the 154 AIMDs, 143 (92.9%) used deep learning architectures; 3 (1.9%) used classic ML methods; and for the remaining 8 (5.2%) devices, the algorithmic approach was not disclosed in the available registration materials.

Clinical Evaluation Pathways

Analysis of the clinical evaluation pathways for the 154 AIMDs (Table 3) showed that most (n=118, 76.6%) submitted clinical trial reports as their primary evidence. The remaining devices were approved either through an exemption from clinical evaluation (n=23, 14.9%) or via a clinical comparison with similar products already available on the market (n=13, 8.4%).

Of the 123 class III devices, 116 (94.3%) used clinical trials, whereas clinical comparison with similar products and clinical exemption were less common (n=5, 4.1% and n=2, 1.6% of devices, respectively). In contrast, among the 31 class II devices, clinical exemption was the most frequent pathway (n=21, 67.7%), followed by clinical comparison with similar products (n=8, 25.8%) and clinical trials (n=2, 6.5%).

XSL•FO
RenderX

Table . Clinical evaluation pathways for approved artificial intelligence–based medical devices in China (2020 - 2025; n=154).

	Total, n (%)	Class III devices (n=123), n (%)	Class II devices (n=31), n (%)
Clinical trial	118 (76.6)	116 (94.3)	2 (6.5)
Exemption from clinical evaluation	23 (14.9)	2 (1.6)	21 (67.7)
Clinical comparison with similar products	13 (8.4)	5 (4.1)	8 (25.8)

Medical Specialty and Body Area

The 154 AIMDs spanned 14 medical specialties. Radiology dominated with 68.8% (n=106) of approvals, followed by cardiology (n=16, 10.4%), ophthalmology (n=9, 5.8%), and gastroenterology (n=9, 5.8%). The remaining AIMDs covered pediatrics, pathology, cytogenetics, sleep medicine, orthopedics, neurosurgery, hematology, gynecology, urology, and dentistry (Table 4).

The most common body areas for these AIMDs were the lung (27/154, 17.5%), the cardiovascular system (24/154, 15.6%), and the head (22/154, 14.3%), with the heart accounting for 7.1% (11/154). Additionally, 10.4% (16/154) of the AIMDs were used across multiple body areas (Table 5).

Table . Distribution of artificial intelligence–based medical devices by medical specialty in China (2020 - 2025; n=154).

Medical specialty	Devices, n (%)
Radiology	106 (68.8)
Cardiology	16 (10.4)
Ophthalmology	9 (5.8)
Gastroenterology	9 (5.8)
Pediatrics	4 (2.6)
Others	10 (6.5)

Table . Distribution of artificial intelligence–based medical devices by target body area in China (2020 - 2025; n=154).

Body area	Devices, n (%)
Lung	27 (17.5)
Cardiovascular system	24 (15.6)
Head	22 (14.3)
Multiple	16 (10.4)
Heart	11 (7.1)
Eyes	9 (5.8)
Thorax	8 (5.2)
Bone	6 (3.9)
Liver	5 (3.2)
Colon	5 (3.2)
Neck	4 (2.6)
Hand	4 (2.6)
Breast	4 (2.6)
Others	9 (5.8)

Manufacturer and Geographic Distribution

We identified 67 manufacturers in total, with a high degree of market concentration. The top 4 companies alone produced 38.3% (59/154) of the AIMDs: Yukun and United Imaging led with 11% (17/154) of the devices each, followed by Infervision with 9.1% (14/154) and Deepwise with 7.1% (11/154). In contrast, 48 manufacturers had only 1 or 2 products each. Manufacturers with more than 2 approved AIMDs are shown in Table 6.

Geographically, of the 154 approved AIMDs, 54 (35.1%) were from manufacturers headquartered in Beijing, 32 (20.8%) were from Shanghai, 18 (11.7%) were from Shenzhen, and 16 (10.4%) were from Hangzhou (Table 7). Thus, these 4 cities accounted for 77.9% (n=120) of all the approved AIMDs. Beijing was home to Yukun and Infervision, Shanghai was home to United

XSL•FO
RenderX

Imaging, and Hangzhou was home to Deepwise, which were precisely the top 4 companies listed above. Shenzhen hosted a broader ecosystem, including Carewell, Tencent Smart Healthcare, RuiXin, and Edan Instruments, but none brought more than 10 AIMDs to market.

Table . Manufacturers with ≥2 approved artificial intelligence–based medical devices in China (2020‐2025; n=154).

Manufacturer	Devices, n (%)
Yukun	17 (11.0)
United Imaging	17 (11.0)
Infervision	14 (9.1)
Deepwise	11 (7.1)
Yizhun	5 (3.2)
SenseTime	4 (2.6)
Carewell	4 (2.6)
Tongxin	3 (1.9)
Tencent Smart Healthcare	3 (1.9)
Siemens	3 (1.9)
RuiXin	3 (1.9)
Neusoft	3 (1.9)
Longwood Valley Medical	3 (1.9)

Longyan	1 (0.6)
Hefei	1 (0.6)
Guiyang	1 (0.6)

Discussion

Principal Findings

This study provided an overview of AIMDs in China up to June 2025. A total of 154 AIMDs were approved, and annual approvals showed an upward trend. Most of these AIMDs (123/154, 79.9%) were class III and relied on deep learning. They were concentrated in radiology, particularly CT-based; produced by a small number of manufacturers; and located in a few cities.

China did not approve its first AIMD until 2020, later than both the United States and Europe, where approvals for AIMDs occurred as early as 2015 [10] despite variations in the definitions of AIMDs. The number of AIMD approvals in China remains lower than that in the United States and Europe. However, we have observed a rapid increase in AIMD approvals in China, reflecting technological advancements and a supportive regulatory environment.

Our analysis, extending the timeline to mid-2025, built on and updated the foundational work of Liu et al [14]. While confirming the continued dominance of radiology and class III devices previously reported, our data revealed new dynamics. Specifically, we observed a marked increase in the absolute number of approvals and a significant shift with the emergence of class II AIMDs after 2022—a trend that was not fully evident in the earlier data. Furthermore, the sustained market concentration among top manufacturers and in key geographic hubs suggests that these early structural characteristics consolidated rather than dispersed as the market grew. These comparisons highlight the rapid evolution of this field and underscore the value of longitudinal tracking to inform regulatory and market strategies. It should be noted that our counts for 2021 to 2022 were slightly higher than those reported by Liu et al [14]. We identified additional AIMDs, including image processing software and CT fractional flow reserve calculation software. A primary reason for this discrepancy is a fundamental difference in data scope. Our dataset encompassed both centrally approved class III devices and provincially approved class II devices, whereas Liu et al [14] primarily focused on class III approvals granted by the NMPA. Additionally, differences can be attributed to distinct search strategies: our approach incorporated AI-related keywords—such as “deep learning” and “algorithm”—within the “structural composition” and “intended use” fields, whereas their search relied on device-naming conventions, using terms such as “computer-assisted detection” and “computer-assisted triage.”

A prime example of an AIMD category with significant clinical penetration in China is pulmonary nodule CT image auxiliary detection software. This category had 14 approved variants from multiple manufacturers, making it the most widespread AIMD type. According to manufacturer data, United Imaging has deployed its solution in over 2000 hospitals nationwide. Their

XSL•FO
RenderX

clinical evaluations indicate that the software can increase the detection rate of pulmonary nodules by approximately 32% and improve radiologists' reading efficiency by approximately 26% compared with conventional methods [24].

Regarding risk classification, most Chinese AIMDs are designated as class III, whereas all US AIMDs are cleared as class II [25] and Europe has only approximately 1% of AIMDs in class III [11]. The large share of class III in China suggests that many AIMDs were treated as high risk and required the strictest review. From 2020 to 2021, only class III AIMDs were observed; from 2022 onward, this pattern shifted, with a steady influx of class II products. The observed change can be attributed to the *Principles for the Classification Defining of AI-Based Medical Software Products* issued by the NMPA in 2021 [26], which applies to both software as a medical device and SiMD. For SiMD, the assigned risk class applies to the product as a whole, reflecting a holistic regulatory assessment of the AI functionality's clinical role within the device. This guideline allowed AIMDs with mature algorithms that provided only non–real-time assistance—such as measurement, marking, or workflow optimization—to be placed in class II. Previously, any software bearing AI technology had been categorized as class III. The significant association between risk classification and the manufacturer's city likely reflects regional policy support and the clustering of expertise in cities such as Beijing and Hangzhou, where high-risk AIMD development appears concentrated.

Our analysis further revealed that the vast majority of approved AIMDs were supported by premarket clinical evidence through clinical trials or clinical comparison with similar products. Exemption from clinical evaluation was granted for only 23 AIMDs, 21 (91.3%) of which were class II and predominantly consisted of image processing software. This pattern reflects the practical implementation of a risk-based regulatory framework: higher-risk AIMDs generally necessitate more robust premarket clinical validation, while pathways such as exemption or comparison are more frequently applied to lower-risk AIMDs to facilitate efficient market access. Nevertheless, reliance on exemptions and comparative assessments for lower-risk approvals raises concerns about the sufficiency and transparency of premarket evidence. To strengthen the regulatory framework, we recommend clarifying exemption eligibility criteria and tightening the evidentiary standards for demonstrating equivalence.

We did not identify any safety-related recalls among the 154 AIMDs approved as of June 2025. A recent study of Food and Drug Administration–authorized AI and ML devices found that 5.2% were linked to adverse events and 5.8% were recalled, primarily due to software issues [27]. The lack of similar public reports in China may stem from its later market start and differences in data transparency. Accordingly, establishing a robust postmarket surveillance system is essential to detect risks arising from algorithm or workflow changes, and it requires commitments from regulators and manufacturers to ensure the ongoing safety of AIMDs.

Radiology dominated China's AIMD landscape, with an emphasis on CT-based applications, reflecting alignment with the nation's health care needs and its existing technological infrastructure. This focus is evident in the concentration of devices targeting pulmonary nodules and cardiovascular conditions, both representing substantial disease burden. Pulmonary nodules are clinically significant as early indicators of lung cancer, which remains the most common cancer type and the leading cause of cancer death in China [28]. Similarly, cardiovascular diseases rank as the leading cause of overall mortality, accounting for approximately 2 out of every 5 deaths [29].

The high proportion of radiology-related AIMDs approved in China aligns with the trend observed in the United States [25]. Medical imaging modalities such as CT, magnetic resonance imaging, and x-ray generate structured, digital data well suited for AI applications. Among these modalities, CT images have formed the basis for most AIMDs developed in China. The widespread availability of CT scanners in Chinese health care facilities, together with relatively uniform imaging protocols, has accelerated the growth of AI diagnostic software based on CT.

Market concentration emerged as another notable finding, with a limited number of manufacturers accounting for a large share of approved AIMDs. Notably, these dominant manufacturers were primarily headquartered in major cities such as Beijing, Shanghai, and Hangzhou. This market dominance appears to stem from the convergence of several reinforcing factors. These include the concentration of technical and regulatory expertise, preferential access to high-quality medical data through partnerships with leading hospitals, and the availability of substantial venture capital in these regions [30,31].

The observed characteristics of China's AIMD market, specifically its pronounced concentration in clinical specialties and geographic regions, were interpreted through the lens of innovation diffusion theory. First, radiology dominated the field, especially CT-based applications, illustrating innovations with high compatibility through seamless integration into digital imaging workflows and a clear relative advantage in improving efficiency during high-volume screenings, which promotes rapid early adoption. Second, the geographic concentration of approvals in Beijing, Shanghai, Shenzhen, and Hangzhou reflects the social system effect. These megacities concentrate critical resources for diffusion, such as policy incentives, venture capital, and technical talent, forming powerful hubs that accelerate local development and initial market penetration of AIMDs.

The observed approval trends could not be fully understood without considering China's evolving regulatory framework. Our data showed sustained growth consistent with the aims of recent NMPA reforms. Notably, the 2025 measures to optimize full life cycle supervision and support the innovative development of advanced medical devices explicitly aimed to accelerate reviews of advanced devices, optimize premarket processes, and strengthen postmarket surveillance. This policy shift provided essential context for interpreting market dynamics and indicated a regulatory environment oriented toward facilitating efficient innovation while ensuring safety throughout a product's life cycle. Furthermore, the emphasis on fostering

XSL•FO
RenderX

high-level industrial clusters offered a lens to interpret the pronounced geographic concentration of approvals observed in this study. The synergy between concentrated innovation resources in hubs such as Beijing and Shanghai and proactive regulatory support appears to be a defining feature of China's AIMD ecosystem.

Limitations

This study has several limitations. First, the identification of an AIMD depended on the explicit mention of AI techniques in its functional components or intended use. Devices that did not explicitly state the use of AI might have been missed despite cross-checking ambiguous cases with review reports and websites. Second, classifying medical specialties was challenging because many devices spanned multiple clinical domains. We assigned a single primary specialty, which may underrepresent secondary applications. Third, although we standardized device names by merging minor variations that referred to the same product, some inconsistencies may persist, underscoring the need for unified naming conventions.

Conclusions

This analysis indicated that AIMDs in China are experiencing rapid growth. The regulatory landscape is dominated by radiology applications, with CT-based solutions for pulmonary nodules and cardiovascular conditions especially prominent. There is also a high degree of market concentration among leading manufacturers.

Abstract

Background: Medical discharge letters are critical for continuity of care but often lack clarity and personalization, making it difficult for health care providers to retrieve essential information. While large language models (LLMs) offer potential for automating summary generation, their effectiveness depends heavily on the quality and contextual relevance of the prompts used.

Objective: The objective of this study was to develop and describe a human-centered, replicable framework for creating individualized prompts that guide LLMs in generating summaries tailored to the specific needs of health care providers.

Methods: A multidisciplinary workshop was conducted at Ghent University Hospital with 26 health care providers from 5 institutions, including hospitals and general practitioner networks. Participants brainstormed ideal summary formats, generating 170 ideas categorized into themes such as "structure," "medical history," "medication," and "follow-up." These insights informed the development of a 110-item structured questionnaire distributed to 33 participants. Responses were used to generate personalized and generic prompts, refined using the context, objective, style, tone, audience, and response (CO-STAR) framework.

Results: "Structure and layout" (40/170, 23.5%) and "follow-up" (27/170, 15.9%) were the most emphasized categories in the workshop. The questionnaire confirmed the importance of the "follow-up" and "medical history" sections. Prompts were generated per participant and by health care type, incorporating frequently selected responses. The CO-STAR framework was applied to improve prompt clarity and alignment with clinical expectations. Communication emerged as a new category during the workshop and was universally valued in the questionnaire.

Conclusions: This study presents a novel, systematic approach to prompt engineering in clinical artificial intelligence applications. By translating qualitative input into structured, individualized prompts, the framework is designed to improve the usability and relevance of artificial intelligence–generated summaries. It proposes a scalable approach for integrating human-centered design into LLM deployment in health care, with the aim of supporting more accurate, context-aware clinical documentation. However, these outcomes remain to be empirically validated; this study is limited to the design and implementation of a human-centered prompt construction pipeline in a specific multicenter setting.

KEYWORDS

large language models; clinical artificial intelligence integration; clinical AI integration; prompt engineering; discharge summaries; human-centered design; artificial intelligence; AI

Introduction

Background

Medical discharge letters are essential communication tools, yet their length, complexity, and variability often hinder efficient information retrieval by health care professionals, who frequently encounter difficulties in identifying key elements such as medication changes, follow-up recommendations, and significant diagnostic findings. Moreover, the informational needs of a general practitioner, a surgeon, an intensivist, and other health care providers could differ substantially.

This complexity not only hinders continuity of care but also introduces risk. In recent years, large language models (LLMs) have shown promise in helping extract, summarize, or restructure clinical documents such as medical discharge letters [1]. However, evaluating the quality and safety of such applications remains a human-centered task requiring careful planning and expert validation.

XSL•FO
RenderX

Numerous studies have evaluated the use of LLMs for generating medical discharge letters [2-4]. Despite the growing sophistication of these models, human evaluation remains indispensable for assessing the clinical accuracy, completeness, and safety of the generated outputs. Physicians, in particular, play a critical role in validating whether artificial intelligence (AI)–generated summaries address the nuanced informational needs of health care providers [2,3]. As Tam et al [5] emphasize, a structured planning phase is essential before initiating human evaluation. This phase begins with clearly defining the evaluation objectives and the specific tasks to be assessed. However, while the final evaluation is typically conducted by clinicians, the development of the prompts that guide LLMs is often carried out by engineers or a single physician. This disconnect may result in prompts that do not fully reflect the diverse and context-specific requirements of end users [2-4,6,7].

Effective medical prompt engineering is emerging as a critical skill for health care professionals navigating the integration of AI into clinical practice. As Meskó [8] emphasizes, the rise of LLMs such as ChatGPT represents a paradigm shift in health care, offering unprecedented opportunities for enhancing clinical workflows, patient communication, and decision-making. However, realizing these benefits depends heavily on the clinician's ability to craft precise, context-aware prompts that guide AI systems toward generating accurate and relevant outputs. Patil et al [9] further highlight that well-designed prompts—grounded in medical knowledge and aligned with evidence-based guidelines—are essential for eliciting clinically meaningful responses from AI tools. They argue that prompt engineering should be recognized as a core competency in medical education, enabling physicians to harness AI effectively while maintaining ethical standards and minimizing bias. These perspectives underscore that prompt engineering is not solely a technical task. However, at present, it is neither a skill that all health care professionals possess nor one that they have time to develop in depth. Moreover, as generative AI continues to evolve, its evaluation should be approached as an ongoing process, recognizing that performance, reliability, and clinical relevance may shift over time and require continuous monitoring and adaptation. Furthermore, due to the variability in ChatGPT's responses, evaluating its performance in health care requires repeated testing to ensure reliability. Without incorporating repetition, research findings may be biased and lack credibility [10].

In our project, Framework & Implementation of AI Tools (FRAIT), we aim to develop AI-driven solutions that are tailored to the specific needs of health care providers. The first phase of the project adopts a design thinking approach to design a prompt that accurately reflects the unique requirements and expectations of individual health care professionals. This involves close collaboration to understand their workflows and information needs and the specific clinical contexts in which they operate. Once this tailored prompt is established, the second phase will involve evaluating its effectiveness by applying it to Dutch medical discharge letters, assessing how well it extracts or summarizes relevant information. In this paper, we concentrate on the initial phase: constructing a prompt that is both meaningful and practical for the health care provider, ensuring that it aligns with their clinical and administrative objectives.

Objectives

The aim of this study was to develop a comprehensive process that starts by identifying the needs of health care providers regarding the ideal format for medical discharge letter summaries and results in creating an individualized prompt to generate such summaries effectively.

Methods

Part 1: Workshop

Overview

Health care providers, primarily physicians, were recruited from 5 different institutions: 3 hospitals (Ghent University Hospital, AZ Oudenaarde, and AZ Sint-Lucas Ghent) and 2 general practitioner circles (Huisartsenvereniging Ghent and Huisartsenkring Schelde Leie). The target recruitment range was 20 to 30 health care providers.

The workshop took place on Wednesday, October 16, 2024, at Ghent University Hospital. The workshop followed a 3-part structure consistent with design thinking principles: an energizer to foster engagement, a brainstorming session to elicit ideas, and a feedback round to collaboratively refine and prioritize outputs.

A set of 7 questions, each with 3 possible responses (blue, yellow, and green; Table S1 in Multimedia Appendix 1) was provided to assess the level of LLM use. Results were presented as numbers and percentages. Data were collected through 2 different persons manually counting the groups and a validation based on pictures (Figure S1 in Multimedia Appendix 1).

Following an introduction to the project, the participants were organized into 6 groups, each encompassing a diverse array of institutions and specializations. We used the digital platform Padlet [11] to conduct this brainstorming session, which allowed us to document all steps in the process. The participants had the option to enter their ideas on an available laptop or through their smartphones, which did not require any log-in credentials or other personal information.

The main question for the brainstorming session was the following:

> *What does my ideal generated summary from a medical discharge letter look like? Eg: use of bullet points, Eg: include history. Take us through your thinking: what should be included? All ideas are welcome – personal preference counts. No consensus required, the groups are for cross-pollination / inspiration.*

The emphasis was placed on both layout and content (eg, "I would like to see the accurate medical history, and I would like it to be highlighted").

All ideas were free text, although they required a label or category. The available labels at the start of the brainstorming session were "history," "current problems," "medication,"

XSL•FO
RenderX

"decision," "follow-up," "structure and layout," and "other" or "I don't know." New categories could be added during the brainstorming session.

A preliminary feedback session was held after 15 minutes to discuss the label "other" in more detail for refinement. Subsequently, an additional 15-minute brainstorming session was scheduled.

Statistics

A word cloud was used to visualize and cluster tokens and words based on their frequency within various ideas. The number of ideas by group and category was reported as frequencies and percentages, means and SDs, and medians and IQRs.

During the workshop, results were presented by category as well as the most common words within each category. The full text of the ideas for these specific words was provided to facilitate further discussion within the group if any clarification was required.

Part 2: Questionnaire

The ideas generated from the brainstorming session were systematically categorized. Two independent researchers (MD and HR) conducted data cleaning to eliminate duplicates and segment the ideas into smaller, manageable components. A structured table was developed (Table S2 in Multimedia Appendix 1) where each row represented a primary idea and subsequent columns contained subquestions. Each idea was assigned to a predefined category. For multiple-choice questions, the possible answers were maintained in a separate table (Table S3 in Multimedia Appendix 1). Using this structured table, a complete list of questions was generated. Additionally, we developed a prompt for each potential response in this questionnaire in Dutch, as well as an automated English translation. The questionnaire was designed using Microsoft Forms, with the embedded Microsoft Copilot used to streamline the automation process.

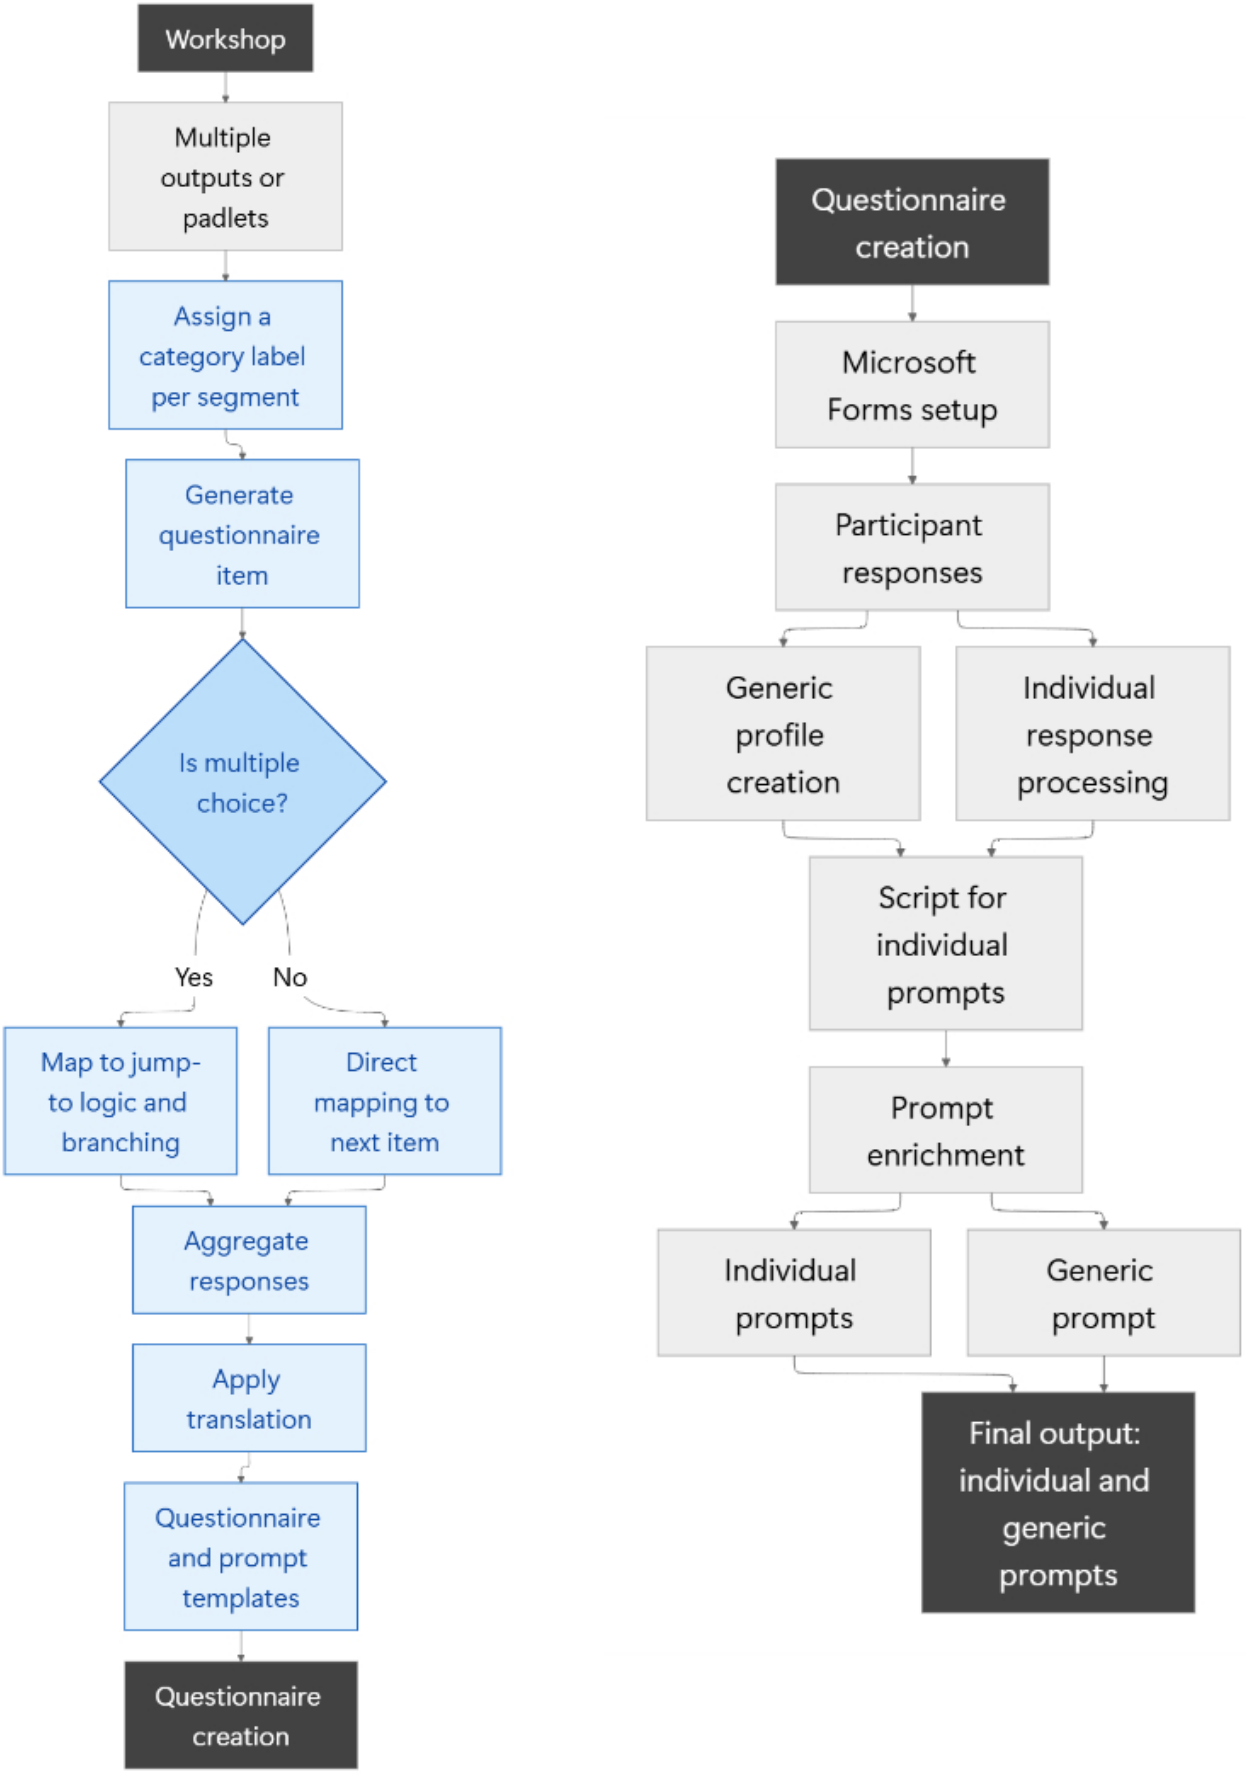
Initially, some general questions were added regarding the type of health care provider and the number of years in practice. An open-ended question for suggestions was included at the end. This questionnaire was distributed to all participants of the workshop and an additional group of general practitioners who will be involved in the ongoing process of the FRAIT project.

The results of the questionnaire were combined with the predetermined prompt for each answer, resulting in a unique prompt for each participant. Additionally, a generic prompt was created overall and by type of health care provider. This generic prompt selected the most frequently chosen answer for each question. For multiple-choice questions, an option must be present in at least one-third of the answers.

To transform the workshop ideas into a structured questionnaire and prompt templates, we applied a systematic multistep process. Each free-text idea was carefully reviewed and split into the smallest meaningful units, with each segment representing a single, actionable suggestion. For example, a statement such as "I want the summary to highlight medication changes and provide a clear follow-up plan" was divided into 2 distinct ideas: highlighting medication changes and providing a clear follow-up plan. Segmentation was guided by the principle that each unit should be assignable to a single category and actionable in prompt design.

Segments were then assigned to predefined categories, such as "medical history," "medication," "follow-up," and "structure and layout." If a segment fit multiple categories, it was assigned to all relevant categories (multilabel coding). New categories were created when multiple participants raised themes not covered by existing categories.

The coding process was iterative and collaborative. Two researchers independently segmented and categorized all ideas. Rather than aiming for consensus or exclusion of divergent ideas, we used a structured framework (Tables S2 and S3 and Figure S2 in Multimedia Appendix 1) to ensure that all contributions from the workshop were systematically included. MD constructed the initial framework by segmenting and categorizing all ideas, whereas HR independently reviewed the results for completeness and accuracy. Any ambiguities or uncertainties were discussed, but the primary objective was the comprehensive inclusion of all perspectives, not convergence on a single interpretation. This approach maximizes methodological transparency and reproducibility, as every idea generated during the workshop is traceable through the coding and questionnaire development pipeline.



Two Python scripts (Python Software Foundation) were created to automate data processing and prompt generation. The first script constructs a dynamic questionnaire by normalizing text, analyzing response frequencies, and reshaping data for optimal mapping between questions and answers. The second script translates completed responses into individualized and generic AI prompts using index-based mapping and neural machine translation for Dutch-to-English conversion. Both scripts aggregate and profile responses to ensure that generated prompts reflect the most common preferences among health care providers, supporting transparent and reproducible prompt engineering.

Finally, we enhanced all prompts by incorporating segments before and after the original prompts, adhering to the context, objective, style, tone, audience, and response (CO-STAR) framework [12-14]. To operationalize the CO-STAR framework, we incorporated both participant input and established clinical communication standards during the prompt enrichment phase. Workshop and questionnaire participants were asked to articulate their preferences regarding the presentation of discharge summaries, including aspects such as clarity, formality, and professional perspective. These responses informed the initial drafting of prompts. Figure 1 illustrates the complete process.

We compared responses in the questionnaire for each category of health care provider, ensuring that there were at least 5 responses per type. Our primary emphasis was on content questions, not layout questions. Because our sample size was limited, we restricted our analysis to descriptive statistics only.

Ethical Considerations

All approvals were granted by the ethical committee of Ghent University Hospital (ONZ-2024 - 0304). The ethical committees of AZ Sint-Lucas Ghent and AZ Oudenaarde were informed of the study. Each participating organization, both hospitals and general practitioner circles, handled recruitment themselves, using their own internal communication channels and procedures to invite participants. The recruitment letter was included with our submission to the ethical committee. Informed consent was obtained from all participants before the start of the workshop (Figure S3 in Multimedia Appendix 1).

To ensure participant anonymity and data privacy, all responses collected during the workshop and questionnaire phases were anonymized before analysis. No personally identifiable information was linked to the responses, and participants were given the option to contribute via digital platforms without requiring log-in or personal credentials. Data were stored securely and accessed only by authorized research team members. These measures were implemented in accordance with institutional guidelines and approved by the relevant ethical committees.

Participants received compensation for the time they spent contributing to the project. This compensation acknowledged the substantial effort required to evaluate the summaries and attendance to the workshop, to ensure that clinicians were remunerated for their professional expertise and time commitment. No additional financial or material incentives were provided beyond this time-based compensation.

Results

Part 1: Workshop

A total of 26 health care providers were recruited for this workshop (Tables S4 and S5 in Multimedia Appendix 1). However, 7.7% (2/26) of the individuals were not present during the first half hour and did not respond to the initial questions. Overall, 5 groups were formed: 4 groups consisting of 5 participants each and 1 group consisting of 6 participants.

Table S1 in Multimedia Appendix 1 lists the questions at the start of the workshop and outlines the profiles of the participants. Figure S4 in Multimedia Appendix 1 presents the outcomes of tokenizing all ideas, which are visualized using a word cloud. Figure S5 in Multimedia Appendix 1 also contains an example of the initial concepts as presented to the participants from one of the groups.

Following a 15-minute feedback session and a plenary discussion on topics categorized as “other,” a new “communication” category was established based on requests from 2 separate groups, demonstrating responsiveness to participant input. Through an iterative process of coding and review, all ideas, including those applicable to multiple categories, were systematically preserved.

At the conclusion of the workshop, a comprehensive compilation of 170 ideas generated by all groups was assembled. The complete list, along with corresponding group names, can be found in Table S6 in Multimedia Appendix 1. The “structure and layout” category contained the greatest number of ideas (40/170, 23.5%), whereas only 6.5% (11/170) of the ideas were left unlabeled by participants. “Communication,” introduced during the second round, constituted the smallest category (Table 1).

The finalized coded table served as the foundation for developing a 110-item questionnaire using branching logic for multiple-choice questions. This systematic approach facilitated the creation of both individualized and generic prompt templates.

Table . Distribution of workshop-generated ideas by category, illustrating the thematic focus and relative emphasis placed by health care providers on different aspects of discharge summary design.

Category	Participant group	Ideas (N=170), n (%)	Ideas (n), mean (SD)	Ideas (n), median (IQR)
Communication	4	8 (4.7)	2 (1.2)	2 (1-3)
Current problems	5	20 (11.8)	4 (2)	5 (3-5)
Decision	5	19 (11.1)	3.8 (1.9)	3 (3-4)
Follow-up	5	27 (15.9)	5.4 (1.1)	5 (5-6)
Medical history	5	24 (14.1)	4.8 (3.8)	4 (3-5)
Medication	5	21 (12.4)	4.2 (3.3)	3 (2-6)
Other or “I don’t know”	4	11 (6.5)	2.8 (1.5)	2 (2-3)
Structure and layout	5	40 (23.5)	8 (2.5)	8 (7-8)

Part 2: Questionnaire

After refining the ideas, a structured table was created as the foundation for the questionnaire. These 2 files, along with their interpretations (available only in Dutch), are included in Tables S2 and S3 and Figure S2 in Multimedia Appendix 1. We provide a Python script that can be used to generate a list of questions and the appropriate “jump-to” points where necessary starting from these files. The resulting 110 questions were uploaded to Microsoft Forms, ready to be answered by the participants. The complete list of questions is available in Table S7 in Multimedia Appendix 1, and a (translated) snippet of these questions can be found in Figure 2. In the same script, when creating questions with multiple possible answers, the corresponding prompt for each answer was also added.

XSL•FO
RenderX

Figure 2. Snippet from the resulting questionnaire list translated into English demonstrating the mapping of provider needs to specific questions and corresponding artificial intelligence prompt template.

Number	Label	Section	Answer	Jump to question	Prompt	Question type
27	Do you want to see Coagulation risk in the History section?	Medical History	['Yes', 'No']	[28, 29]	['Show the coagulation risk in section History Section', '']	item
28	What formatting should be used for this?	Medical History	['None', 'Underlined', 'Italic', 'Bold', 'Strikethrough', 'Fluorescent marking']	[29, 29, 29, 29, 29, 29]	['Coagulation risk: No specific formatting', 'Coagulation risk: Underline the text', 'Coagulation risk: Place the text in italic', 'Coagulation risk: Place the text in bold', 'Coagulation risk: Strike out the text', 'Coagulation risk: Use fluorescent marking']	layout
29	Do you want to see Deep Vein Thrombosis in the History section?	Medical History	['Yes', 'No']	[30, 31]	['Show in section History De Diep Venous Thrombosis', '']	item
30	What formatting should be used for this?	Medical History	['None', 'Underlined', 'Italic', 'Bold', 'Strikethrough', 'Fluorescent marking']	[31, 31, 31, 31, 31, 31]	['Deep Vein Trombosis: No specific formatting', 'Deep Vein Trombosis: Underline the text', 'Deep Vein Trombosis: Place the text in italic', 'Deep Vein Trombosis: Place the text in bold', 'Deep Vein Trombosis: Strike out the text', 'Deep Vein Trombosis: Use fluorescent marking']	layout
31	Do you want to see New diagnoses in the History section?	Medical History	['Yes', 'No']	[32, 33]	['Show the new diagnoses in section History', '']	item

38	Do you want to see section Medication in your summary?	Medication	['Yes', 'No']	[39, 53]	['Show the Medication section in the summary', 'Do not show the medication section in the summary']	section
39	What medication do you want to see?	Medication	['None', 'All Medication', 'Medication on Admission', 'Medication on	[40, 40, 40, 40, 40, 40, 40]	['Show the none', 'Show the all medication', 'Show the medication upon admission', 'Show the medication upon dismissal', 'Show the changed	item

Table S8 in Multimedia Appendix 1 shows the number of questions for each section. “Medical history” and “admission history” constituted the largest parts of the questionnaire.

Most health care providers (30/33, 90.9%) were physicians, with over 81.8% (27/33) having more than 5 years of experience (Figure S6 in Multimedia Appendix 1). The “follow-up” section was highly valued by all participants, whereas the “examination” section received the least interest (Figure S7 in Multimedia Appendix 1).

An example of the resulting individualized and final generic prompt can be found in Figure S8 in Multimedia Appendix 1.

The implementation of the CO-STAR framework produced prompts that effectively reflected both health care provider preferences and established professional standards. The “style” component was defined as “written from the perspective of a medical professional,” and the “tone” element specified the use of formal language. These parameters were selected based on aggregated participant feedback, which underscored the importance of professionalism and clarity in clinical communication. Consequently, the final prompts incorporated user-driven insights alongside best practices, ensuring that AI-generated summaries were both contextually relevant and professionally suitable. A comprehensive overview of the adjustments made to the CO-STAR framework is provided in Figure 3. The prompt structure was enhanced with an introductory segment and a concluding section, whereas the central portion, labeled “<Individual preference>,” reflects findings from the questionnaire.

Table 2 shows the differences in the 10 most common preferences regarding discharge summaries between general practitioners and specialists. General practitioners tend to seek additional details regarding medication and follow-up, whereas specialists more frequently request information pertaining to admission history and examinations.

XSL•FO
RenderX

Figure 3. Illustration of the context, objective, style, tone, audience, and response framework application in prompt engineering: integrating health care provider preferences and clinical standards to optimize artificial intelligence–generated discharge summary prompts.

Color code: C=context - O=objective - S=style - T=tone - A=audience - R=response

"This text is a medical discharge letter (the report of a hospital admission). I would like a summary in Dutch. The intention is that I, as a healthcare provider, can use this letter to properly follow up the patient. The summary must be a maximum of one page long and clearly structured. Use formal language based on the expertise of a physician. Start with the patient's name, date of birth and the name of the hospital. All dates must be in the format day/month/year. If a requested part is not in the letter, bundle the missing parts at the bottom per section in one sentence and use 'Not mentioned' as an indication. “

<Individual preferences>

“We would like to provide some additional explanation: The name of the sections should be translated like: General = Algemeen, Medical History = Voorgeschiedenis, Medication = Medicatie, Examinations = Onderzoeken, Admission history = Opnameverloop, Follow-up = Follow-up, Decision = Besluit. If new diagnoses are requested in the history, this means that you add the new diagnoses that were made during admission to the history. By interventions we mean operations. The admission process describes the path that the patient takes during the admission, the evolution of the condition and the steps that are taken during the admission in chronological order. Here we also expect to report the administration of blood transfusions, radiotherapy or chemotherapy, the performance of diagnostic examinations such as biopsies, endoscopies, the placement of feeding tubes, etc. In Medical imaging / Technical examinations we mean by the protocol all actions that are performed during this examination and all findings that are made in this. If changes in medication are requested, we mean changes in dose, frequency and form and whether medication has been stopped completely or new medication has been started. To do this, make a comparison between the medication on admission on the one hand and the medication on discharge and the medication at the therapy proposal on the other. Medication that has remained the same is not mentioned in the case of changed medication. If the question is about the risk of clotting, mention blood clots/thrombosis and embolisms and the use of blood-thinning medication. Also mention here if you find anything about cerebral infarction/CVA or heart attack/AMIAMI. Clotting disorders should also be mentioned here. Communication is about discussing the condition and the further policy with the patient and his family. If a section should not be mentioned, leave it out of the summary completely. The information in the summary should come from the original letter. An exception to this is if ICD codes or ICPC codes are mentioned. When asking for ICD codes, the ICD-10 code should be mentioned next to the diagnosis, as can be found at https://icd10be.health.belgium.be/. When asking for ICPC codes, you can find them at https://browser.icpc-3.info/. If a patient has come from another hospital, mention this under general.”

XSL•FO
RenderX

Table . Comparison of discharge summary preferences between general practitioners (GPs) and specialists, highlighting the top 20 content areas with the greatest differences in selection rates. Options with negative percentages were favored by specialists, whereas those with positive percentages were preferred by GPs.

Section	Preference	Difference between GPs and specialists (%)
Admission history	Showing acquisition of the interventions performed	−25.3
Admission history	Showing consultations	−14.0
Examinations	Showing the protocol	−13.3
Medical history	Showing life-threatening allergies	−13.3
Examinations	Showing laboratory test results	−12.6
Admission history	Showing main diagnosis	−11.6
Medical history	Showing reaction to allergy	−11.6
Admission history	Showing new diagnoses	−9.8
Examinations	Showing clinical investigation	−8.6
Examinations	Showing medical imaging or technical investigations	−8.6
Follow-up	Showing inclusion in specific care processes	26.8
Follow-up	Showing message for GP	18.7
General	Showing whether the patient is palliative	16.6
Follow-up	Showing the institutions involved	16.6
Medication	Showing changed medication (dose, frequency, and shape)	15.1
Medication	Showing new medication	14.4
Follow-up	Showing in section “follow-up” the communication	13.2
Follow-up	Showing multidisciplinary follow-up (social and home help)	13.2
Medication	Showing stopped medication	12.5
Medication	Showing duration of medication use	12.3

Discussion

Principal Findings

From a single workshop with motivated health care providers, it was possible to generate an automated, individualized prompt tailored to their respective needs, enabling the creation of an ideal medical discharge summary. The process began with the identification of key areas that required attention, such as medical history, medication details, and follow-up procedures. Participants provided input on what specific information should be included in each section, ensuring that the final generated summary would be comprehensive and tailored to the needs of health care professionals. To the best of our knowledge, this is the first study to begin with a multidisciplinary workshop involving physicians from diverse specialties and translate their input into tailored AI prompts.

The collaboration between specialists and general practitioners resulted in an exchange of ideas, leading to a broader perspective from both groups. This synergy allowed for a more holistic approach to the creation of the summary, taking into account both the specialized and general aspects of patient information. At the same time, it became clear that reflecting on one’s ideal summary is not always easy—despite it being a personal matter. Sparring with others did not necessarily lead to adopting their viewpoints but proved valuable in helping participants critically reassess and refine their own preferences.

Dividing the scope into layout and content made the resulting ideas more concrete. By separating these 2 elements, participants were able to focus more effectively on each aspect, leading to clearer and more actionable suggestions. This also leads to a clearer prompt for further evaluation possibilities (in future work), providing a solid foundation for future improvements and refinements based on feedback from health care professionals.

Within the workshop, numerous ideas were generated. The open question at the end—“Do you have any additional comments or suggestions regarding this questionnaire? Are there aspects that you think are missing or not sufficiently addressed? Please note them below.”—received responses primarily on practical issues from only a few participants.

During the workshop, it was observed that all groups contributed an equal number of ideas. Most ideas were related to the

XSL•FO
RenderX

structure of the generated summary, primarily due to the existence of a single category for the broader theme. The "follow-up" category encompassed the highest number of ideas, although there was significant overlap with other categories. The "communication" category, introduced during the workshop, predominantly contained ideas that pertained to the "follow-up" category. This trend was also evident in the questionnaire, where the "communication" section was the only one indicated as desirable by all participants.

The "medical history" and "admission history" sections often included diverse content, resulting in numerous questions from participants. The "medication" and "follow-up" sections also encompassed a wide range of topics, which necessitated their inclusion as multiple-choice questions. This strategy allowed for a targeted approach, meaning that only 1 detailed question on content was asked for each selected topic (eg, "What information do you want to see for the medication? 'Start date,' 'Duration,' 'Dose,' 'Time of intake,' 'Frequency,' 'Form e.g. oral,' 'Show drug substance name,' 'Clinical effect,' 'Criteria for stopping/changing specific medication,' 'Reason for starting, stopping, changing'").

Such a detailed and structured approach ensures that all relevant aspects are thoroughly explored and addressed, providing a comprehensive framework for summarizing medical discharge letters efficiently and effectively.

Comparison With Prior Work

The most significant refinement aligned with the CO-STAR prompt engineering framework was introduced in the "response" section, with a particular emphasis on clarifying the definitions of key terminology embedded within the prompt. This adjustment is crucial for enhancing the model's interpretability and ensuring consistent semantic alignment between the prompt and the generated summary. As demonstrated in the work on SARA [13], a generative AI for legal summarization, precise control over terminology and density within prompts directly influences the coherence and legal validity of the summaries produced. Similarly, the Institute of Electrical and Electronics Engineers Computer Society's International Conference on Computers, Software, and Applications 2024 study [12] on automatic smart contract generation underscores the importance of terminological precision in the response phase to mitigate ambiguity and improve automation reliability. Furthermore, the insights from Teo [14] from the GPT-4 prompt engineering competition highlight how nuanced refinements in prompt structure—especially in the response section—can significantly elevate performance in competitive and real-world applications.

Our findings align with broader trends in health informatics that emphasize the centrality of user needs and adaptive information delivery. For instance, psychoeducational mobile health interventions for parents of small-for-gestational-age fetuses have shown how adaptive, user-centered systems can enhance engagement and outcomes [15]. The ADEPT framework further illustrates how optimizing data flow in dynamic, real-world environments supports effective, personalized care [16]. By translating qualitative input from health care providers into structured, individualized prompts, our framework extends these principles to the domain of clinical AI, ensuring that LLM-generated discharge summaries are not only technically robust but also contextually relevant and responsive to end user needs.

Limitations

An important aspect of this framework's broader impact is its adaptability beyond its original Dutch-speaking setting. Future efforts should focus on translation and cultural adjustment of all materials, questionnaires, and prompts used in workshops. This will require close collaboration with language specialists and domain specialists to ensure accurate terminology, workflows, and compliance. Owing to its modular design, the framework allows for easy alignment of categories and prompts with various health care systems' specific summarization needs. This methodology is applicable across medical specialties by engaging domain experts during assessment and prompt development, ensuring that specialty-specific information needs are addressed. By taking these steps, the framework will become more valuable and help develop AI tools that are effective, equitable, and well-suited to diverse clinical contexts.

Despite aiming for comprehensiveness, the balance between breadth and depth sometimes required trade-offs, prioritizing clarity and efficiency over detailed customization. For instance, preferences were gauged using a multiple-choice question such as "What do you want to see..." followed by only a single question about layout preferences for each item.

This initial prompt is a first step in the improvement in the quality and relevance of AI-generated summaries. It is evident that further refinement is necessary. This ongoing fine-tuning will involve a meticulous evaluation of the generated summaries, taking into account detailed feedback from health care professionals. Such iterative adjustments aim to enhance the precision and contextual accuracy of the summaries, ensuring that they meet the nuanced needs of diverse medical specializations.

Future Steps

The subsequent phase will involve evaluating the generic and individual prompts, with the assessment being developed collaboratively with the health care providers. The prompt will be broken down into smaller components, generating binary questions regarding layout and more specific inquiries related to content accuracy (eg, if an outcome is incorrect, does it constitute a hallucination?). A collection of representative medical discharge letters will be made available for this purpose. Upon completion of the evaluation, it will likely be necessary to review the prompt to identify opportunities for further optimization and integrate additional content informed by the evaluation findings.

Conclusions

This study presents a novel, systematic framework for developing individualized prompts to summarize medical discharge letters grounded in the real-world needs of health care providers. A key strength of this approach lies in the deliberate separation between layout and content preferences, which proved highly effective in capturing both structural and informational expectations.

XSL•FO
RenderX

By translating qualitative input into structured, personalized prompts, this framework aims to improve the relevance and usability of AI-generated summaries and serve as a replicable model for diverse clinical and research settings, although empirical validation remains necessary. The framework supports applications in data collection, data analysis, and personalized feedback generation. This study is limited to the design and implementation of a human-centered prompt construction pipeline in a specific multicenter setting; direct evaluation of AI-generated outputs and broader scalability will be addressed in future work.

Acknowledgments

The authors would like to express their sincere gratitude to the entire team at the Data Science Institute of Ghent University Hospital, as well as to the management, program participants, and coordinators representing the participating organizations. Artificial intelligence was used within the project to enhance efficiency: Figure 1 was created with assistance from Claude (Anthropic). The questionnaire was created in Microsoft Forms using Microsoft Copilot under the Microsoft Office license of Ghent University Hospital.

Funding

The Framework & Implementation of AI Tools project was funded by the Belgian government through the Data Innovation project.

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information files (Multimedia Appendix 1). The supporting Python scripts are available in a public GitHub repository [17]. The script frait_part1_questions.py generates a dynamic questionnaire for the Framework & Implementation of AI Tools system. Its primary output is an organized set of questions designed to assist health care providers in selecting relevant sections and details for inclusion in a medical summary. The script frait_part1_prompt.py translates completed questionnaire responses into artificial intelligence prompts, which are used for medical document summarization.

Abstract

Background: Scars and keloids impose significant physical and psychological burdens on patients, often leading to functional limitations, cosmetic concerns, and mental health issues such as anxiety or depression. Patients increasingly turn to online platforms for information; however, existing web-based resources on scars and keloids are frequently unreliable, fragmented, or difficult to understand. Large language models such as GPT-4 show promise for delivering medical information, but their accuracy, readability, and potential to generate hallucinated content require validation for patient education applications.

Objective: This study aimed to systematically evaluate GPT-4's performance in providing patient education on scars and keloids, focusing on its accuracy, reliability, readability, and reference quality.

Methods: This study involved collecting 354 questions from Reddit communities (r/Keloids, r/SCAR, and r/PlasticSurgery), covering topics including treatment options, pre- and postoperative care, and psychological impacts. Each question was input into GPT-4 in independent sessions to mimic real-world patient interactions. Responses were evaluated using multiple tools: the Patient Education Materials Assessment Tool-Artificial Intelligence for understandability and actionability, DISCERN-AI for treatment information quality, the Global Quality Scale for overall information quality, and standard readability metrics (Flesch Reading Ease score, and Gunning Fog Index). Three plastic surgeons used the Natural Language Assessment Tool for Artificial Intelligence to rate the accuracy, safety, and clinical appropriateness, while the Reference Evaluation for Artificial Intelligence tool validated references for reference hallucination, relevance, and source quality. We conducted the same analysis to assess the quality of GPT-4–generated content in response to questions from 3 medical websites.

Results: GPT-4 demonstrated high accuracy and reliability. The Patient Education Materials Assessment Tool-Artificial Intelligence showed 75.5% understandability, DISCERN-AI rated responses as "good" (26.3/35), and the Global Quality Scale score was 4.28 of 5. Surgeons' evaluations averaged 3.94 to 4.43 out of 5 across dimensions (accuracy 3.9, SD 0.7; safety 4.3, SD 0.8; clinical appropriateness 4.4, SD 0.5; actionability 4.1, SD 0.8; and effectiveness 4.1, SD 0.8). Readability analyses indicated moderate complexity (Flesch Reading Ease Score: 50.13; Gunning Fog Index: 12.68), corresponding to a 12th-grade reading level. Reference Evaluation for Artificial Intelligence identified 11.8% (383/3250) hallucinated references, while 88.2% (2867/3250) of references were real, with 95.1% (2724/2867) from authoritative sources (eg, government guidelines and the literature). The overall results about questions from medical websites were consistent with the answers to Reddit questions.

Conclusions: GPT-4 has serious potential as a patient education tool for scars and keloids, offering reliable and accurate information. However, improvements in readability (to align with sixth to eighth grade standards) and reduction of reference hallucinations are essential to enhance accessibility and trustworthiness. Future large language model optimizations should prioritize simplifying medical language and strengthening reference validation mechanisms to maximize clinical utility.

(JMIR Med Inform 2026;14:e78838) doi:10.2196/78838

KEYWORDS

scar; keloid; GPT-4; patient education; generative AI; generative artificial intelligence; readability; large language model

Introduction

Scars and keloids are common skin healing outcomes [1], often causing discomfort during the proliferative phase [2]. When located on visible areas such as the face, they can severely impact a patient's appearance, leading to psychological distress such as low self-esteem, anxiety, and depression, which may further hinder social interactions and career development [3]. Scars near joints may cause functional limitations, while perineal scars can result in long-term complications such as dyspareunia and dysmenorrhea [4,5]. Many patients urgently seek to improve both the aesthetic and functional aspects of scars or keloids. However, treatments often require multimodal approaches over weeks to months, making high patient adherence crucial.

XSL•FO
RenderX

Consequently, access to accurate, timely, and comprehensive management information is critical for patients to better understand treatment expectations, options, prognosis, and potential complications [6-9].

Currently, patients increasingly rely on internet-based health information [10]. This trend faces multifaceted challenges, including information overload, variability in source credibility and content accuracy, and the health literacy required to understand the contents [11,12]. Notably, many online resources on scars or keloids are often unreliable, fragmented, or difficult to understand, failing to tackle the fundamental needs of patients with scars or keloids [13].

In recent years, artificial intelligence (AI) tools powered by large language models (LLMs), such as GPT-4 (used by ChatGPT), have demonstrated significant potential in delivering medical information [14]. GPT-4's capacity to generate natural language responses through interactive conversions could aid users in understanding intricate medical concepts, treatment, and management strategies, positioning it as a potentially valuable alternative to traditional search engines for accessing knowledge associated with scars or keloids [15-17].

It is reported that 52% of US adults have used LLMs, and GPT-4, as a leading LLM, receives over 5 billion monthly visits. In total, 39% of LLM users have used LLMs for health care queries [18]. Despite the increasing use of LLMs in health care [19-21], there remains a research gap, and it is currently unclear whether GPT-4 can generate high-quality patient education content related to scars and keloids. Thus, we conducted this study to comprehensively assess the use of GPT-4 in keloid and scar patient education by performing a multidimensional evaluation (encompassing accuracy, reliability, readability, and reference quality) of GPT-4 responses.

Methods

Study Objective

This study aimed to investigate the potential of GPT-4 to provide reliable, accurate, readable, and actual medical information for patients with scars or keloids. To achieve this, we used GPT-4 (OpenAI) to evaluate its accuracy, reliability, readability, and hallucinations in answering questions related to treatments of scars or keloids.

Question Collection

The research questions were manually collected by the authors from Reddit. First, the authors analyzed all posts on the "Hot" page (the most popular and recently active posts) of the r/Keloids subreddit, all posts on the r/SCAR subreddit, and all posts on the r/PlasticSurgery subreddit as of April 6, 2025. We extracted the main text of each post that included the keywords "Scar" or "Keloid" and organized the data using Microsoft Excel. Second, one author (MR) excluded the posts that contained no questions, were duplicates, or had repeated questions. In addition, the same author (MR) performed the initial classification of the questions. To ensure reliability and minimize bias, another author (WH) independently reviewed the process. Consistency between the two authors' classifications was confirmed through discussion. This data collection approach has been adopted in previous Reddit-based research [22]. Furthermore, we adopted 49 questions about keloids or scars from 3 medical websites.

Ethical Considerations

The institutional review board of the People's Hospital of Guizhou Province, affiliated with Guizhou University, deemed this study exempt from ethics approval.

Quality Assessment

Overview

Each question was input individually into GPT-4. Following previous research protocols, a new chat session was initiated for each question to avoid context contamination and to simulate real-world patient interactions [23]. Consistent with real-world activities using GPT-4, no specialized prompt instructions were appended to the question inputs. The contents generated by ChatGPT-4 were evaluated using a modified version of existing health information quality assessment tools.

Patient Education Materials Assessment Tool-AI Tool

The Patient Education Materials Assessment Tool (PEMAT) was used to assess the understandability and actionability of ChatGPT-generated content. The original PEMAT includes 17 items for understandability and 7 for actionability. Since all contents generated by ChatGPT are pure text, the PEMAT was simplified to 8 items for understandability and 3 items for actionability (Multimedia Appendix 1). Each item received 1 point if it met the standard, and scores were reported as percentages. A score of 70% or greater was recorded as a "pass" per PEMAT guidelines [24].

DISCERN-AI Tool

The DISCERN standard, a previously validated tool to help health care consumers and professionals evaluate the quality of treatment information, was adapted for ChatGPT-generated content. Since all contents generated by ChatGPT are pure text, 7 items (questions 3 - 9 from the 15-item DISCERN tool) were selected and scored on a 1 to 5 scale (Multimedia Appendix 2). Each output was rated as follows: very poor (7 - 12 points), poor (13 - 17 points), fair (18 - 23 points), good (24 - 28 points), and excellent (29 - 35 points) [24,25].

Global Quality Scale

The Global Quality Scale (GQS) is a 5-point Likert scale used to evaluate information quality and the flow and ease of use of information. The scores range from 1 (low quality) to 5 (high quality), while scores of 4 or 5 indicated high-quality outputs, a score of 3 was considered moderate quality and scores of 1 or 2 were categorized as low quality.

Readability Assessment

The readability of the ChatGPT-generated content was evaluated using several established readability formulas, including Flesch Reading Ease score, Gunning Fog Index, Flesch-Kincaid Grade Level, Coleman-Liau Index, and Simple Measure of Gobbledygook (SMOG). Each output was copied into Microsoft Word and analyzed via the Readable website [26]. The Flesch Reading Ease score ranges from 0 to 100, and higher scores

XSL•FO
RenderX

indicate greater readability. A score between 60 and 70 corresponds to reading levels of grades 8 and 9 and is generally understandable by the average adult. The Gunning Fog Index and Flesch-Kincaid Grade Level are used to estimate sentence complexity; the scores represent the years of formal education required to understand the contents. For example, a score of 12 implies the output is suitable for readers at the 12th-grade level. The Coleman-Liau Index is similar to the Gunning Fog Index and Flesch-Kincaid Grade Level but uses character counts instead of syllables, making it more suitable for languages where syllable counts may not accurately reflect complexity. The SMOG Index measures syllable density, often used to assess health information materials. A score of 12 indicates that the material is suitable for readers at the 12th-grade level or higher.

Natural Language Assessment Tool for Artificial Intelligence

Three experienced plastic surgeons independently reviewed each GPT-4–generated content using a specially developed Natural Language Assessment Tool for Artificial Intelligence (NLAT-AI) [24]. Using this tool, we assessed accuracy, safety, appropriateness, actionability, and effectiveness. Each output was rated using a 5-point Likert scale (1=strongly disagree, 5=strongly agree; Multimedia Appendix 3). All results were summarized using descriptive statistics.

Reference Evaluation for AI

Given known issues of LLM hallucination (ie, generating plausible but nonexistent references), a brief evaluation tool, Reference Evaluation for AI, was developed to analyze references provided in ChatGPT-generated content [27]. Each reference was verified through direct links or a Google search. The tool assessed (1) reference hallucination (whether references were real or fabricated), (2) relevance and consistency between references and AI output, and (3) source quality (based on the authority of the issuing institution or organization, such as government guidelines, health care organizations, or scientific research; Multimedia Appendix 4).

Results

Question Collection and Classification

A total of 507 posts were identified and analyzed (posts from the r/Keloids subreddit: n=193, 38.1%; posts from the r/Keloids subreddit: n=211, 41.6%; and posts from the r/Scar subreddit: n=103, 20.3%). After removing posts that merely shared information or were duplicates, 354 unique questions were obtained. The questions were categorized into 16 groups based on their contents (Table 1). Furthermore, we obtained 49 questions from 3 medical websites that included 38 unique questions (Table S1 in Multimedia Appendix 5).

Table . Questions on scars or keloids from Reddit (N=354).

Question group	Questions, n (%)
Questions on other respects	28 (7.9)
Questions on other treatments for scars or keloids	4 (1.1)
Questions on common treatments for scars or keloids	46 (13)
Questions on trauma-related scars or keloids	16 (4.5)
Questions on psychological issues caused by scars or keloids	9 (2.5)
Questions on at-home scar or keloid care	3 (0.8)
Questions on preoperative scar or keloid consultation	37 (10.5)
Questions on postoperative scar or keloid consultation	55 (15.5)
Questions on selection of treatments for scars or keloids	80 (22.6)
Questions on impact of scars or keloids on daily life	2 (0.6)
Questions on scar or keloid symptoms	7 (2)
Questions on scar camouflage	6 (1.7)
Questions on the impact of nutrition on scars or keloids	3 (0.8)
Questions on choosing physicians for scar or keloid treatment or related costs	32 (9)
Questions on old scars	14 (4)
Questions on scar or keloid prevention	12 (3.4)

Evaluation of GPT-4–Generated Content

GPT-4 generated content that provided a wide range of medically accurate information. Using the PEMAT-AI, DISCERN-AI, and GQS patient education material evaluation tools, the output of GPT-4 was assessed, with all tools indicating high scores. The overall understandability score using PEMAT-AI easily surpassed the 70% threshold for acceptability (mean 75.5%, SD 12.2%). The DISCERN-AI tool resulted in an overall rating of “good” quality (mean 26.3, SD 3.4), with all 16 groups of questions rated as “good.” The GQS score averaged 4.3 out of 5 (SD 0.8), categorizing the outputs as high quality. More details are shown in Table S1 in Multimedia Appendix 6. Intraclass correlation coefficient (ICC) for

XSL•FO
RenderX

PEMAT-AI, DISCERN-AI, and GQS were 0.73, 0.69, and 0.78, respectively (Table S2 in Multimedia Appendix 5). The results of the ICC demonstrated high reliability of the evaluation tools.

Plastic Surgeons' Evaluation via the NLAT-AI Tool

Using the NLAT-AI tool, 3 independent plastic surgeons evaluated the GPT-4–generated content. All dimensions of the contents received scores above the neutral midpoint of 3 on a 5-point Likert scale. The overall average scores for each dimension were as follows: accuracy 3.9 (SD 0.7), safety 4.3 (SD 0.8), appropriateness 4.4 (SD 0.5), actionability 4.1 (SD 0.8), and effectiveness 4.1 (SD 0.8). More detailed descriptive statistics for each question are presented in Table S2 in Multimedia Appendix 6. Internal validity tests showed an ICC of 0.76 (Table S2 in Multimedia Appendix 5), indicating high reliability.

Readability Assessment

The results of the readability assessments indicated that the GPT-4–generated content was "difficult to read." The average Flesch Reading Ease score was 50.1 (SD 8.1), which is considered moderately difficult. The Gunning Fog Index averaged 12.7 (SD 3.3), and the Flesch-Kincaid Grade Level was 12.4 (SD 2.5), indicating that the text was at a high school level (approximately suitable for individuals aged 16 - 17 years). The Coleman-Liau Index averaged 12.8 (SD 2.6), and the SMOG Index averaged 11.3 (SD 3.16). More detailed evaluation results are shown in Table S3 in Multimedia Appendix 6.

Reference Evaluation for AI Assessment

Most of the references provided in GPT-4's output effectively supported the content. A total of 88.2% (2867/3250) of the references were from actual sources (actual websites or academic papers), while 383 hallucinated references were identified. Among these 2867 real references, 2746 (95.8%) references effectively supported the content. In addition, a total of 95.1% (2724/2867) of the real references were from authoritative sources (government guidelines, health care organizations, or scientific research). More detailed evaluation results are shown in Table S4 in Multimedia Appendix 6.

The Assessment of Questions From Websites

The evaluation results of GPT-4 responses to website-sourced questions were broadly consistent with those from Reddit-derived questions across all assessments (Tables S3-S6 in Multimedia Appendix 1).

Discussion

Principal Findings

This is the first study to assess the overall quality of ChatGPT responses to real-world questions from Reddit about keloids or scars. The results revealed that the content generated by GPT-4 was generally comprehensive and aligned with current medical guidelines and the literature. Using several assessment tools, as well as plastic surgeons' evaluations, the scores were robust, and the plastic surgeons' evaluations were largely positive. The overall results indicate that GPT-4–generated content is reliable, accurate, safe, and actionable, despite there being room for improvement in terms of readability and hallucination.

Over 80% of dermatology outpatients obtain medical information through social media or the internet, with 47% considering it an important source of information [28]. Although patients have access to a wealth of information, studies evaluating the quality of online health information have identified significant deficiencies [29]. As for scars and keloids, the information available to patients contains a lot of low-quality content. A previous study assessing 88 websites related to "burn scars" showed that most of the commercial websites provided information of moderate to poor quality [13]. In contrast, LLMs provide a broad range of fundamentally accurate information and real-time dynamic interactions compared to traditional webpages [30,31]. As a leading LLM, GPT-4 exhibits certain advantages over other LLMs and has demonstrated top-tier performance across diverse evaluations in health care. In answering questions from the American Board of Surgery In-Training Examination, GPT-4 achieved an accuracy rate comparable to that of Copilot, while significantly outperforming Gemini [32]. In other fields of clinical medicine, GPT-4 also attained superior performance relative to other LLMs [33,34]. However, in a substantial number of evaluative scenarios, the performance of GPT-4 did not yield statistically significant differences when compared with Copilot or Gemini. Collectively, the performance of GPT-4 currently represents the best capability of LLMs.

In our study, experienced plastic surgeons evaluated the outputs of GPT-4, confirming that the contents were reliable and accurate. The accuracy of GPT-4 in patient education has also been studied in other clinical contexts (eg, rhinoplasty, sleep apnea, and prostate cancer) where it demonstrated high accuracy and strong reliability [24,35,36]. Such high accuracy and reliability suggest that LLMs such as GPT-4 can effectively address clinical questions from patients with scars or keloids, serving as a valuable auxiliary tool in clinical medicine.

Despite GPT-4's significant potential in responding to keloid or scar patient queries, its outputs commonly had high reading difficulty. Our study revealed that the average reading level of GPT-4–generated content was at a high school level. The results suggest that ChatGPT does not always meet the comprehension needs of all patients. The relatively low readability of GPT-4 can hinder accessibility for certain socioeconomic populations with limited health literacy [37]. Among the latest generation of young adults in the United States, up to 13% have not graduated from high school. This rate reaches 20% among people of color (including African Americans and Native Americans) [38], who are also identified as high-risk groups for developing malignant scars [39]. Due to poor readability, GPT-4 has apparent barriers in its application among these populations [40,41]. To enhance the utility of LLMs for populations with lower educational attainment, it is recommended that developers consider training specialized LLMs based on datasets with good readability [42]. Biomedical text can be simplified through hyperparameter substitution techniques, improving patient understanding [43]. In addition, structured prompting can also contribute to enhancing readability [44].

XSL•FO
RenderX

Moreover, our study also revealed the existence of hallucination, where GPT-4 cited nonexistent references or websites. Fabricated references not only mislead readers and distort their understanding of keloid or scar but also—given the presence of numerous seemingly authoritative yet false information sources—may lead patients to overtrust the content generated by GPT-4 [45,46]. Given the presence of hallucinations, specific clinical diagnosis and treatment must rely on clinicians; LLMs can only serve as auxiliary tools. To address the hallucination issue in LLMs, it is recommended that developers effectively apply retrieval-augmented generation to retrieve documents from an external corpus (such as academic library systems), as this can significantly reduce the hallucinations [47-49]. Integrating external, structured knowledge sources (such as knowledge graphs, databases, or other domain-specific resources) into LLMs can also help ensure that LLMs produce responses with fewer hallucinations [50]. Furthermore, prompt engineering can mitigate hallucination by improving the reasoning capabilities [51].

GPT-4 can provide comprehensive and generally accurate information, which can further assist patients with keloids or scars in accessing timely and precise information. However, current LLMs exhibit limitations, such as hallucinations and relatively low readability; therefore, they are not recommended as the sole source of information for patients. Limited by the lack of clinical background in current LLMs; the insufficient ability to process audio, image, and video information; limited ability to access academic libraries; and the noninterpretability of black box algorithms, current LLMs still require further development to be adapted for applications in health care [52]. The AI agent, as a promising approach, can extend the capabilities of LLMs by enabling them to use external tools, plan and execute multistep tasks, as well as interact dynamically [53]. Multimodal LLM is promising to process text (eg, clinical notes and user-input questions), medical images (eg, photos and computed tomography scans), and videos (eg, treatment procedures) provided by patients, which will more effectively assist patients and health care providers in clinical practice about keloid and scar management [54].

Limitations

Most of the questions collected from Reddit were posts from patients who had not yet sought medical care. Consequently, the questions posed may be biased toward pretreatment information needs, as fewer questions were reported during the treatment phase. This may compromise the generalizability of GPT-4's evaluation across different patient care stages. In addition, Reddit users are concentrated in the age group of 18 to 49 years, with an average age of 23 years, and the majority are aged under 30 years. Thus, the data collected from Reddit clearly fails to represent the middle-aged and older population [55]. Relying solely on Reddit posts for data collection introduces demographic selection bias.

In terms of assessment tools, the qualitative assessment conducted by experienced plastic surgeons was inherently at risk of bias, given the surgeons' attitudes toward the use of GPT-4. Nevertheless, they provided valuable insights owing to their in-depth understanding of scar and keloid education materials. Furthermore, exploratory assessment tools (DISCERN-AI, PEMAT-AI, and NLAT-AI) were used in this study, while their validity requires further testing. LLMs differ from traditional printed educational materials in that their responses to repeated queries of the same question are generated instantaneously and may vary. Currently, existing assessment tools lack the ability to detect such variability in LLM outputs when the same question is posed multiple times [56]. Furthermore, content generated by LLMs is often conveyed with excessive certainty, as these models lack the ability to accurately express information involving uncertainties. Providing definitive answers to such uncertain content may mislead patients, yet current assessment scales fail to evaluate this critical limitation [57,58]. Further research is needed to develop specific tools to enable more robust evaluation of LLM output quality.

Conclusions

Our analysis found that GPT-4 provided high-quality responses to real-world questions related to scars and keloids, suggesting its potential as a useful patient education tool in scar and keloid treatment. The GPT-4 outputs were generally reliable and accurate but need improvement, primarily in readability and hallucinations.

Abstract

Background: Large language models (LLMs) have emerged as promising tools for enhancing public access to medical information, particularly for chronic diseases such as atherosclerotic cardiovascular disease (ASCVD). However, their effectiveness in patient-centered health communication remains underexplored, especially in multilingual contexts.

Objective: Our study aimed to conduct a comparative evaluation of 3 advanced LLMs—DeepSeek R1, ChatGPT-4o, and Gemini—in generating responses to ASCVD-related patient queries in both English and Chinese, assessing their performance across the domains of accuracy, completeness, and comprehensibility.

Methods: We conducted a cross-sectional evaluation based on 25 clinically validated ASCVD questions spanning 5 domains—definitions, diagnosis, treatment, prevention, and lifestyle. Each question was submitted 5 times to each of the 3 LLMs in both English and Chinese, yielding 750 responses in total, all generated under default settings to approximate real-world conditions. Three board-certified cardiologists blinded to model identity independently scored the responses using standardized Likert scales with predefined anchors. The assessment followed a rigorous multistage process that incorporated randomization, washout periods, and final consensus scoring.

Results: DeepSeek R1 achieved the highest "good response" rates (24/25, 96% in both English and Chinese), substantially outperforming ChatGPT-4o (21/25, 84%) and Gemini (12/25, 48% in English and 17/25, 68% in Chinese). DeepSeek R1 demonstrated superior median accuracy scores (6, IQR 6-6 in both languages) and completeness scores (3, IQR 2-3 in both languages) compared to the other models (P<.001). All models had a median comprehensibility score of 3; however, in English, DeepSeek R1 and ChatGPT-4o were rated significantly clearer than Gemini (P=.006 and P=.03, respectively), whereas no significant between-model differences were observed in Chinese (P=.08). Interrater reliability was moderate (Kendall W: accuracy=0.578; completeness=0.565; comprehensibility=0.486). Performance was consistently stronger for definitional and diagnostic questions than for treatment and prevention topics across all models. Specifically, none of the models consistently provided responses aligned with the latest clinical guidelines for the following key guideline-facing question "What is the standard treatment regimen for ASCVD?"

Conclusions: DeepSeek R1 exhibited promising and consistent performance in generating high-quality, patient-facing ASCVD information across both English and Chinese, highlighting the potential of open-source LLMs in promoting digital health literacy

XSL•FO
RenderX

and equitable access to chronic disease information. However, a clinically critical weakness was observed in guideline-sensitive treatment: the models did not reliably provide guideline-concordant standard treatment regimens, suggesting that LLM use should be limited to lower-risk informational subqueries (eg, definitions, diagnosis, and lifestyle education) unless augmented by expert oversight and safety controls.

KEYWORDS

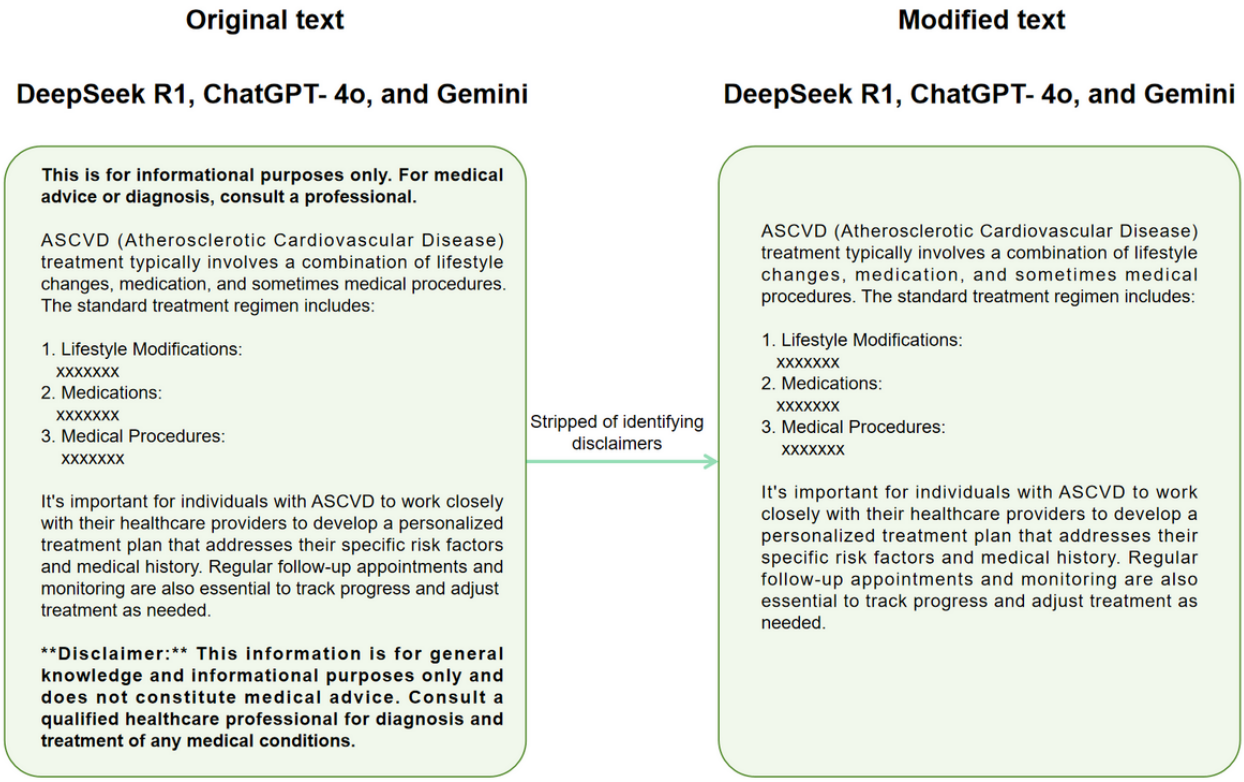
atherosclerotic cardiovascular disease; large language models; DeepSeek R1; ChatGPT-4o; Gemini; artificial intelligence; AI

Introduction

Atherosclerotic cardiovascular disease (ASCVD) is a major public health concern worldwide, significantly affecting morbidity and mortality rates and contributing to the global burden of disease [1]. Effective management and prevention strategies are paramount in reducing its impact on human health and longevity. In recent years, the development of advanced natural language processing technologies, particularly large language models (LLMs), has introduced a novel paradigm in health care communication [2]. LLMs are deep learning models trained on massive corpora of text data, enabling them to generate humanlike responses, summarize complex information, and interact with users in natural language. Models such as ChatGPT exemplify this technological advancement, offering scalable tools for disseminating medical information and supporting patient education, with the potential to enhance chronic disease prevention and self-management [3,4].

Despite their promise, the application of LLMs in health care—especially in clinical decision-making—remains constrained by several limitations [5,6]. First, LLMs do not inherently possess medical reasoning capabilities; their outputs are generated based on learned language patterns rather than grounded clinical judgment [7]. This introduces risks of producing plausible-sounding but clinically inappropriate advice. Second, the variability in training data sources and lack of domain-specific fine-tuning may result in inconsistent or outdated information [8]. Finally, while individual models may excel in certain tasks, performance can vary widely across different LLMs, especially in medical settings where accuracy and contextual appropriateness are vital [9]. Therefore, rigorous comparative evaluations are needed to identify the models that are most reliable, transparent, and suitable for patient-centered communication within health care and public health contexts.

To our knowledge, there have been no studies specifically focused on the performance of LLMs in providing information about ASCVD. Therefore, this study aimed to assess the performance of various advanced LLMs (ChatGPT-4o [OpenAI], Gemini [Google], and DeepSeek R1) in delivering accurate, comprehensive, and comprehensible information related to ASCVD. Using open-ended questions and simulated patient scenarios, we evaluated the quality and reliability of responses from a patient-centered perspective.



Methods

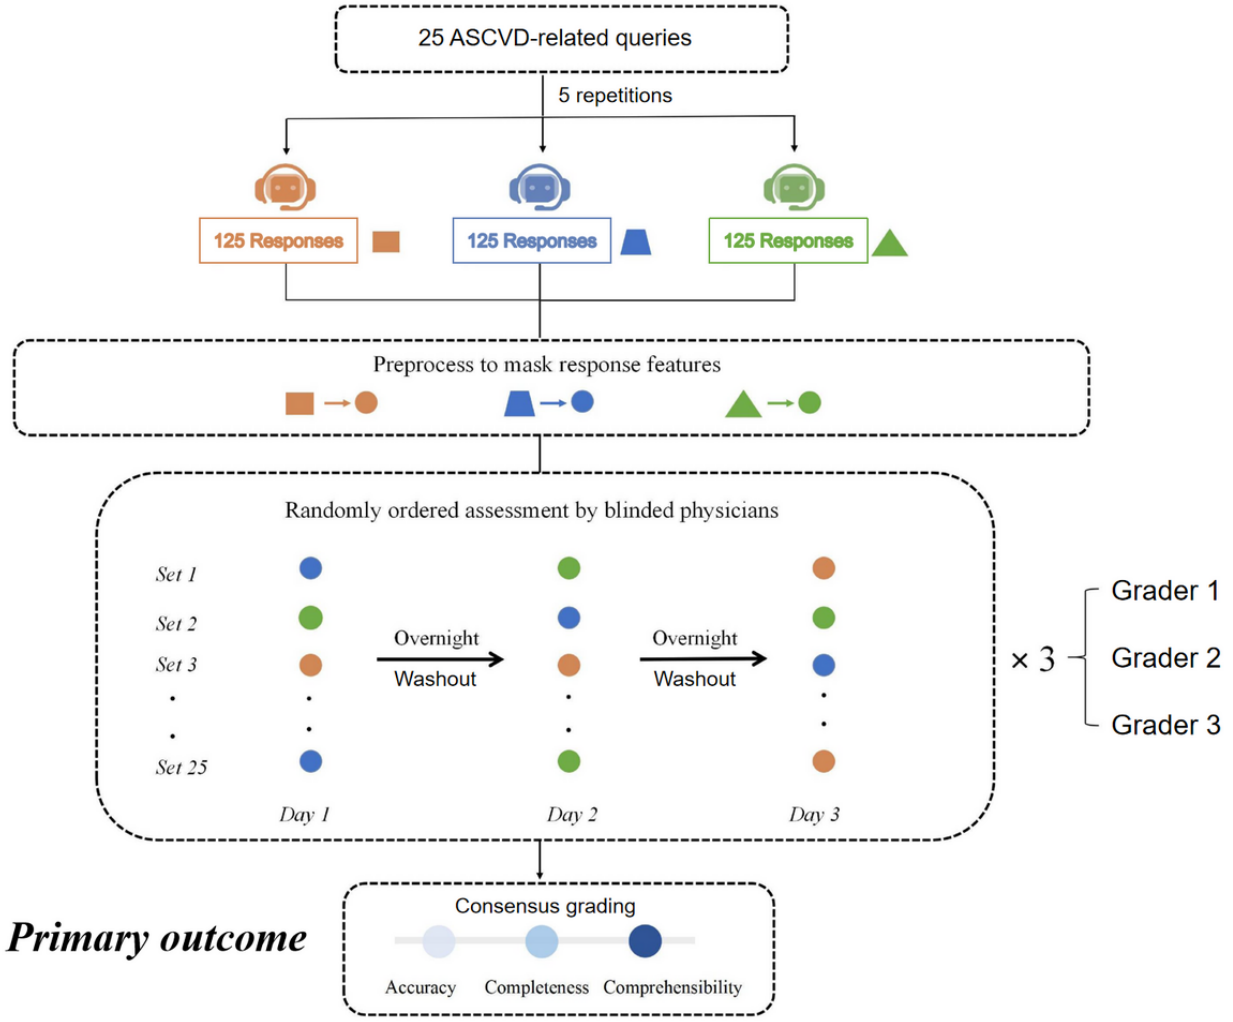
Question Design and Acquisition of Responses

Our study was conducted from May 15 to 30, 2025. Three qualified physicians (PL, YX, and YW) devised 25 comprehensive questions based on common concerns of patients regarding ASCVD, focusing on patient-centered care and disease management. These queries covered definitions, diagnosis, treatment, prevention, and lifestyle. To mitigate language bias and evaluate multilingual performance, each question was posed in both English and Chinese. To reduce randomness and assess response consistency, each question was submitted 5 separate times to 3 state-of-the-art LLMs—DeepSeek R1, ChatGPT-4o, and Gemini—in both languages, generating a total of 750 responses (25 questions × 3 models × 2 languages × 5 repetitions). To simulate real-world use scenarios, all models were assessed using their default, publicly available versions without any parameter adjustments (eg, temperature, maximum tokens, or top-p nucleus sampling). Crucially, the web-browsing or retrieval-augmented generation capabilities enabled by default in these public interfaces were allowed to function. This ensured that our findings reflected the typical performance accessible to end users who rely on these tools for real-time information retrieval. Each chat was conducted using the “new chat” function to avoid bias from correlation interference and ensure that each session was unaffected by previous prompts. All generated responses were exported as plain text. For DeepSeek R1, the reasoning content and blocks were programmatically removed before human review. Subsequently, all responses were stripped of identifying disclaimers (Figure 1). The complete set of 750 generated responses has been made publicly available in Multimedia Appendix 1 to ensure full transparency and facilitate further research.

XSL•FO
RenderX

Figure 1. Deidentification and preprocessing of model outputs before blinded scoring: raw large language model responses were exported as plain text and stripped of disclaimers and model-identifying metadata, yielding anonymized text for review by 3 cardiologists.

Assessment Methodology



An evaluation panel of 3 board-certified cardiologists assessed the model outputs through a rigorous multistage process. For each of the 25 questions in both languages, 5 independent responses were generated per model. To avoid model selection bias, responses were randomly shuffled within their respective question sets, ensuring that the reviewers remained unaware of the specific language model that generated each response.

To minimize memory bias, 3 cardiologists independently assessed the responses in 3 separate rounds, each conducted on a distinct day with an overnight washout period. Assessments were benchmarked primarily to the 2021 European Society of Cardiology guidelines for cardiovascular disease prevention and the 2024 guidelines for managing chronic coronary syndromes, with cross-checks against the 2025 ACC/AHA/ACEP/NAEMSP/SCAI Guideline for the Management of Patients With Acute Coronary Syndromes [10-12]. We verified that no major guideline updates relevant to our end points were released during the evaluation window (May 15-30, 2025). Using predefined anchors detailed in Table S1 in Multimedia Appendix 2, each reviewer rated every response on 3 dimensions: accuracy (6-point Likert scale: 1="completely incorrect"; 6="completely correct"), completeness (3-point Likert scale: 1="incomplete"; 3="complete"), and comprehensibility (3-point Likert scale: 1="difficult to understand"; 3="easy to understand") [13]. The scoring protocol comprised 3 steps. First, for each question, each model generated 5 responses; the 3 reviewers independently rated every response on the 3 dimensions. Second, the reviewers convened to finalize one consensus score per response per dimension: identical ratings were carried forward, whereas discrepancies were resolved through discussion until unanimity was reached—or, if needed, with brief input from a senior cardiologist. Third, for each question, the arithmetic mean of the 5 consensus scores served as the final per-question score; because per-question scores were nonnormally distributed, between-platform comparisons used the median of the 25 per-question scores. Detailed scoring procedures for the blinded assessment are provided in Tables S2 to S4 in Multimedia Appendix 2.

The overall study design and process are illustrated in Figure 2. We established the following quality thresholds based on the arithmetic mean of the 5 repeated responses per question: an accuracy score of at least 4 was considered acceptable, whereas a score of at least 2 was required for both comprehensibility and completeness. Within the acceptable performance levels, we introduced a new concept called "good response" to facilitate the comparison of the LLMs' excellent responses. A "good response" was defined as having a mean accuracy score of ≥4, mean comprehensibility and completeness scores of ≥2, and a mean total score (sum of accuracy, completeness, and comprehensibility) score of ≥10. The total score threshold (10) was intentionally set higher than the sum of the minimum component scores (8) to ensure that a "good response" exceeded the baseline requirements in at least one dimension (eg, higher accuracy or completeness) rather than merely meeting the minimum acceptable standard in all categories.

RenderX

Figure 2. Study design and data flow for the blinded comparison of large language models on atherosclerotic cardiovascular disease (ASCVD) questions. Outputs were generated under default settings; all model-identifying markers and disclaimers were removed; and responses were randomized and presented model blind to cardiologists for independent rating, consensus finalization, per-question aggregation, and cross-model comparison.

Data Analysis

All data analyses were performed using Prism (version 9.5.1; GraphPad Software) and SPSS (version 26.0; IBM Corp). Continuous variables were described using measures of central tendency and dispersion expressed as median and range. Graphical representations were used to enhance the clarity and interpretability of the data. When the data deviated from a normal distribution, differences between 2 groups were assessed using the Mann-Whitney *U* test, whereas differences among the 3 LLMs were evaluated using the Kruskal-Wallis rank sum test followed by the Dunn multiple-comparison test. The Fisher exact test was used for categorical variables. Interrater reliability was assessed using the Kendall *W* coefficient of concordance, with levels of agreement interpreted as follows: poor (0-0.2), fair (0.21-0.4), moderate (0.41-0.6), good (0.61-0.8), and excellent (0.81-1) [14]. A 2-sided *P* value of <.05 was considered statistically significant.

Ethical Considerations

The data analyzed in our study consisted of deidentified, synthetic outputs generated by LLMs in response to 25 guideline-informed ASCVD questions curated from publicly accessible sources; no patients or personal data were involved. Accordingly, participant recruitment and written informed consent were not applicable, and—per institutional policy—this work did not constitute human participant research and did not require ethics committee review.

Results

Performance

Overview

The "good response" rates for the 3 LLMs were as follows (Table 1): DeepSeek R1 achieved a "good response" rate of 96% (24/25) in both English and Chinese, outperforming ChatGPT-4o (21/25, 84%) and Gemini (12/25, 48% in English and 17/25, 68% in Chinese). Figure 3 illustrates the comparative distribution of scores across the 3 dimensions. In terms of accuracy, DeepSeek R1 maintained a dominant profile with high consistency, whereas Gemini exhibited the widest score variance. Regarding completeness, DeepSeek R1 frequently achieved maximum scores, whereas ChatGPT-4o often provided partially complete responses. Comprehensibility remained high for all models, with DeepSeek R1 and ChatGPT-4o showing slightly more stability than Gemini. Performance analysis revealed a critical pattern: model performance was consistently

XSL•FO
RenderX

and substantially weaker in the treatment domain than in all others, with "good response" rates of 80% (8/10) for DeepSeek R1, a total of 60% (6/10) for ChatGPT-4o, and 30% (3/10) for Gemini (Multimedia Appendix 3). For instance, none of the models consistently provided answers that aligned with the latest clinical guidelines in response to the question "What is the standard treatment regimen for ASCVD?" Similarly, the responses varied significantly in accuracy and detail for the question "How common is coronary artery bypass grafting (CABG) in ASCVD patients?" The following sections provide a detailed analysis of each model's performance across the domains of accuracy, completeness, and comprehensibility.

Table 1. Performance of the 3 large language models on atherosclerotic cardiovascular disease (ASCVD) questions in a blinded, bilingual evaluation. Questions spanned 5 domains (definitions, diagnosis, treatment, prevention, and lifestyle) and were scored by 3 board-certified cardiologists using predefined anchors. A "good response" was defined as an arithmetic mean score across the 5 repetitions of ≥4 for accuracy, ≥2 for completeness, and ≥2 for comprehensibility, with a mean total score (sum of accuracy, completeness, and comprehensibility) of ≥10 after consensus.

Figure 3. Distribution of accuracy, completeness, and comprehensibility ratings for large language model (LLM) responses to atherosclerotic cardiovascular disease–related questions. (A) Shows the distribution of accuracy scores across LLMs. (B) Shows the distribution of completeness scores across LLMs. (C) Shows the distribution of comprehensibility scores across LLMs.

Accuracy

Regarding accuracy, 97% (146/150) of the questions met the acceptable standard, with English-language responses reaching 99% (74/75) accuracy and Chinese-language responses reaching 96% (72/75) accuracy. For both English- and Chinese-language questions, the median accuracy score for DeepSeek R1 was consistently 6 (IQR 6-6 for both languages), whereas for ChatGPT-4o and Gemini, it was 5 (ChatGPT: IQR 5-6 for both languages; Gemini: IQR 4-5 for English and 5-6 for Chinese; Table 2). As detailed in Table 3, for all English-language queries, the mean accuracy score of DeepSeek R1 responses was 5.88 (SD 0.33), whereas the mean scores for ChatGPT-4o and Gemini were 5.40 (SD 0.64) and 4.84 (SD 0.68), respectively. For all Chinese-language queries, the mean

XSL•FO
RenderX

accuracy score for DeepSeek R1 responses was 5.80 (SD 0.40), whereas the mean ChatGPT-4o and Gemini scores were 5.20 (SD 0.76) and 5.00 (SD 0.86), respectively.

Table 2. Median scores for responses from the 3 large language models.

Assessment metric	DeepSeek R1, median (IQR)		ChatGPT-4o, median (IQR)		Gemini, median (IQR)	
	English	Chinese	English	Chinese	English	Chinese
Accuracy (1-6)	6 (6-6)	6 (6-6)	5 (5-6)	5 (5-6)	5 (4-5)	5 (5-6)
Completeness (1-3)	3 (2-3)	3 (2-3)	2 (2-2)	2 (2-2)	2 (2-2)	2 (2-3)
Comprehensibility (1-3)	3 (3-3)	3 (3-3)	3 (3-3)	3 (3-3)	3 (2-3)	3 (3-3)

Table 3. Mean scores for responses from the 3 large language models.

Assessment metric	DeepSeek R1, mean (SD)		ChatGPT-4o, mean (SD)		Gemini, mean (SD)	
	English	Chinese	English	Chinese	English	Chinese
Accuracy (1-6)	5.88 (0.33)	5.80 (0.40)	5.40 (0.64)	5.20 (0.76)	4.84 (0.68)	5.00 (0.86)
Completeness (1-3)	2.72 (0.45)	2.76 (0.43)	2.24 (0.43)	2.12 (0.43)	2.00 (0.57)	2.36 (0.63)
Comprehensibility (1-3)	2.96 (0.20)	2.92 (0.27)	2.88 (0.33)	2.84 (0.37)	2.64 (0.48)	2.92 (0.27)

Completeness

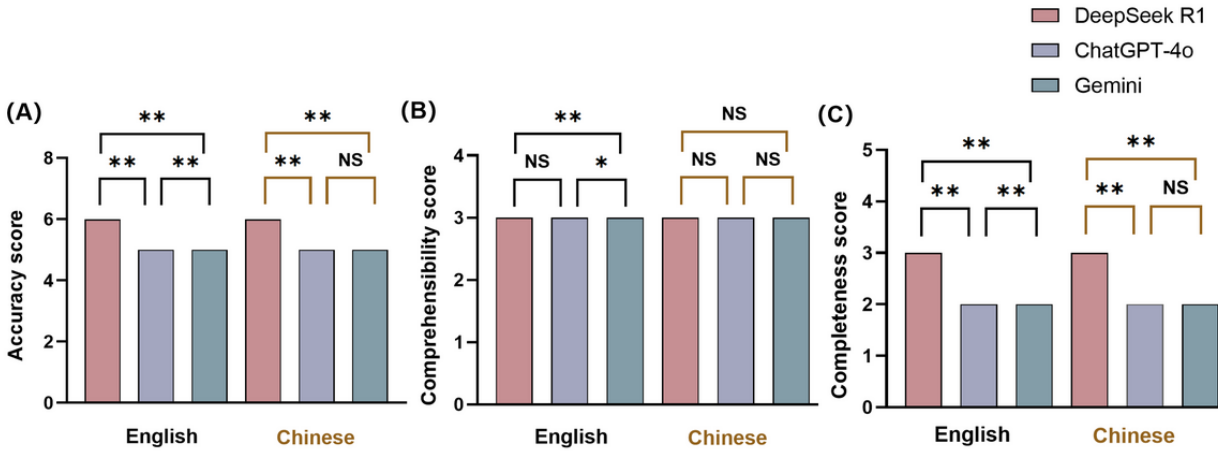
In terms of completeness, 95% (142/150) of responses were acceptable, including 95% (71/75) in both English and Chinese. Regardless of the language of the questions, the median completeness score for DeepSeek R1 was consistently 3 (IQR 2-3 for both languages), with ChatGPT-4o and Gemini both achieving median scores of 2 (ChatGPT: IQR 2-2 for both languages; Gemini: IQR 2-2 for English and 2-3 for Chinese; Table 2). For all English-language questions, the mean completeness score for DeepSeek R1's responses was 2.72 (SD 0.45), with ChatGPT-4o and Gemini achieving mean scores of 2.24 (SD 0.43) and 2.00 (SD 0.57), respectively. For all Chinese-language questions, the mean completeness score for responses from DeepSeek R1 was 2.76 (SD 0.43), with ChatGPT-4o and Gemini scoring a mean of 2.12 (SD 0.43) and 2.36 (SD 0.63; Table 3), respectively.

Comprehensibility

Regarding comprehensibility, all responses were at an acceptable level. Regardless of the language of the questions or the model used, the median comprehensibility score for all questions was consistently 3 (DeepSeek R1 and ChatGPT: IQR 3-3 for both languages; Gemini: IQR 2-3 for English and 3-3 for Chinese; Table 2). As shown in Table 3, for all English-language questions, the mean comprehensibility score for DeepSeek R1's responses was 2.96 (SD 0.20), whereas ChatGPT-4o and Gemini scored a mean of 2.88 (SD 0.33) and 2.64 (SD 0.48), respectively. For all Chinese-language questions, the mean comprehensibility score for DeepSeek R1 responses was 2.92 (SD 0.27), with ChatGPT-4o and Gemini scoring a mean of 2.84 (SD 0.37) and 2.92 (SD 0.27), respectively.

Interrater Reliability

For accuracy scores, the Kendall *W* coefficient of concordance ranged from 0.434 to 0.732, with a mean of 0.578 (SD 0.15). In terms of completeness scores, the coefficient varied from 0.360 to 0.782, averaging 0.565 (SD 0.21). For comprehensibility scores, the range was between 0.386 and 0.581, with a mean value of 0.486 (SD 0.10). This indicates that the scores for accuracy, completeness, and comprehensibility were at a moderate level of agreement.



Model Comparison

In the overall comparison of English- and Chinese-language questions, DeepSeek R1 consistently outperformed the other models in terms of accuracy and completeness. For English-language questions, DeepSeek R1 achieved the highest median accuracy score of 6, significantly surpassing both ChatGPT-4o and Gemini (P<.001 for each pairwise comparison), whereas ChatGPT-4o also outperformed Gemini (P=.008). All 3 models received a median comprehensibility score of 3; the difference between DeepSeek R1 and ChatGPT-4o was not significant (P=.07), although DeepSeek R1 was significantly clearer than Gemini (P=.006), and ChatGPT-4o was moderately clearer than Gemini (P=.03; reflecting significant differences in mean ranks per the Mann-Whitney *U* test despite identical medians). Regarding completeness, DeepSeek R1 again led the models, scoring significantly higher than both ChatGPT-4o and Gemini (P=.009), with ChatGPT-4o also providing more complete responses than Gemini (P=.007). For Chinese-language questions, DeepSeek R1 maintained a significant lead in accuracy over ChatGPT-4o and Gemini (P<.001 in both cases), whereas the difference between ChatGPT-4o and Gemini was not statistically significant (P=.07). All 3 models achieved the same median comprehensibility score of 3, with no significant differences (P=.08). In terms of completeness, DeepSeek R1 again outperformed both ChatGPT-4o and Gemini (P<.001), whereas no significant difference was observed between ChatGPT-4o and Gemini (P=.06). Overall, DeepSeek R1 demonstrated consistently superior performance in both accuracy and completeness across languages. Differences in comprehensibility were minor, with Gemini showing slightly lower clarity in English. These findings affirm DeepSeek R1's leading capabilities and highlight subtle language-specific variations in the outputs of the other models (Figure 4). Specific

XSL•FO
RenderX

examples of LLM failures contrasted with superior responses are detailed in Table S5 in Multimedia Appendix 2.

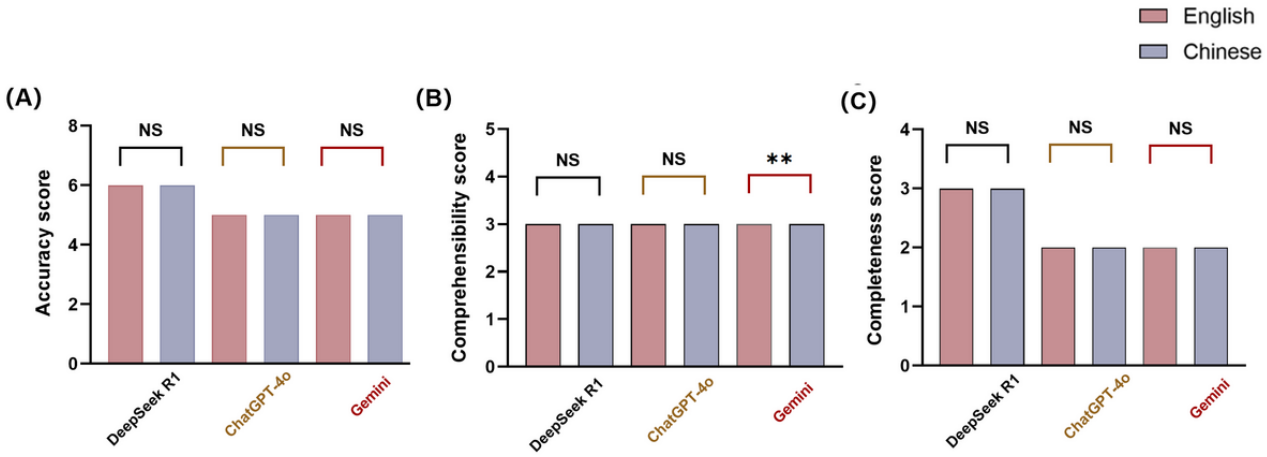


Figure 4. Comparison of large language model performance on atherosclerotic cardiovascular disease–related questions within languages. Scores are shown for accuracy, completeness, and comprehensibility. *P<.05; **P<.01; NS: not significant.

Language-Based Response Comparison

For DeepSeek R1, there were no significant differences between English and Chinese in terms of accuracy, completeness, and comprehensibility scores. Similarly, for ChatGPT-4o, there were no significant differences between English and Chinese across the same metrics, indicating a comparable performance in both languages. For Gemini, the accuracy and completeness scores showed no significant differences between English and Chinese. However, there was a significant difference in comprehensibility scores (P<.001) as the median comprehensibility score for English was 3 (IQR 2-3), whereas for Chinese, it was 3 (IQR 3-3). This indicated that the comprehensibility scores were more consistent in Chinese compared to having more variability in English (Figure 5).

Figure 5. Comparison of large language model performance on atherosclerotic cardiovascular disease–related questions across languages within models. For each model, scores for accuracy, completeness, and comprehensibility are shown for English and Chinese. **P<.01; NS: not significant.

Discussion

Principal Findings

Our study evaluated the performance of 3 advanced LLMs—DeepSeek R1, ChatGPT-4o, and Gemini—in providing accurate, comprehensive, and comprehensible information on ASCVD in both English and Chinese. This evaluation was conducted using a rigorous, blinded study design that incorporated randomization, washout periods, and consensus-based physician assessments. While the widespread emergence of LLMs has significantly expanded public access to medical information—particularly for underserved or non–English-speaking populations [15,16]—concerns about their reliability persist [17,18]. By systematically evaluating multiple LLMs across languages and using patient-centered ASCVD scenarios, our study offers a more holistic perspective on their capabilities and limitations. From a public health standpoint, this approach not only highlights the potential of LLMs to enhance digital health literacy and self-management of chronic diseases but also underscores the need for ongoing oversight and model validation to prevent the spread of misinformation [19,20].

The results demonstrated that DeepSeek R1 generally outperformed the other models in terms of accuracy and completeness and also achieved a slightly higher average score for understandability. Several factors may contribute to this superior performance. DeepSeek R1 is reported to rely heavily on reinforcement learning, which may contribute to improved

XSL•FO
RenderX

logical coherence and multistep reasoning. Additionally, the model is open source under the Massachusetts Institute of Technology license and may offer lower operating costs compared to proprietary models. This open-source nature confers several advantages—including reduced dependency on commercial application programming interfaces (APIs), lower implementation costs, and the potential for institution-specific fine-tuning—making it particularly attractive for health care systems with limited technical resources [21]. Critically, this open-source architecture offers a decisive advantage for clinical implementation: data sovereignty. Unlike proprietary cloud-based models (eg, ChatGPT-4o and Gemini) that necessitate the transmission of sensitive patient data to external commercial servers—raising significant compliance challenges with regulations such as HIPAA (Health Insurance Portability and Accountability Act; United States) and the General Data Protection Regulation (Europe)—DeepSeek R1 allows for local, on-premise deployment [22,23]. Health care systems can host the model within their secure firewalls, ensuring that patient data never leave the institution's control. This capability not only resolves privacy concerns but also creates a secure environment for the aforementioned fine-tuning on proprietary medical records. Furthermore, it is important to clarify that the high comprehensibility scores in this study were achieved without the reasoning chains being visible to the raters. This indicates that DeepSeek R1's internal chain-of-thought process effectively structures the final response for clarity independent of the visible reasoning trace [24]. Taken together, these characteristics suggest that DeepSeek R1 may be a promising candidate for disseminating reliable, cost-effective, and customizable medical information in both clinical and public health contexts.

Language-based comparisons revealed no significant performance differences between English and Chinese for both DeepSeek R1 and ChatGPT-4o. Although Gemini exhibited slightly higher scores in Chinese—particularly in comprehensibility—this difference was not statistically significant, indicating that the variation likely reflects incidental model behavior rather than a systematic language-based advantage. Achieving consistent performance across languages is essential for the global applicability of LLMs in health care communication. Our evaluation indicates a consistent and clinically relevant pattern: across all 3 LLMs, recommendations in the treatment and prevention domain were less reliable than responses to definitional and diagnostic queries. This observation is consistent with external reports that therapeutic, guideline-facing tasks show variable concordance and that performance can be highly sensitive to task framing and evaluation metrics beyond headline accuracy [25-27]. Recent benchmarks likewise describe mixed adherence across clinical scenarios, underscoring the difficulty of encoding and operationalizing rapidly evolving therapeutic knowledge within free-text generation [26-28]. Taken together, these findings suggest that, without explicit retrieval and provenance controls, current general-purpose architectures may not consistently reflect the most up-to-date evidence at inference time, which in turn can pose risks in high-stakes areas such as medication dosing and care timing [25-27]. They also help explain why standard offline evaluations may overestimate real-world reliability ("evaluation illusion") and why even low omission or error rates can have high clinical salience in treatment contexts [9,29].

In practical terms, our findings offer concrete guidance for implementing LLMs in clinical ASCVD care. The encouraging performance of models such as DeepSeek R1 supports adjunctive, nonautonomous use in patient-facing education platforms and, with clinician oversight, selective clinical decision support. For instance, models excelling in comprehensibility are best suited for generating patient education materials, whereas those with superior accuracy on guideline-specific content may better support the drafting of clinical summaries for specialist review. Successful integration will require attention to electronic health record interoperability; comprehensive staff training programs that cover the capabilities, limitations, and appropriate use of these artificial intelligence (AI) tools; and governance (privacy, auditability, and provenance). From a real-world clinical relevance standpoint, cost and deployment considerations (eg, licensing, API use, computing capacity and infrastructure, and local IT constraints) should inform model selection and scaling within existing health care workflows. In particular, open-source options (eg, DeepSeek R1) can lower licensing costs, enable local or hybrid deployment under strict data governance controls, and permit institution-specific tuning with auditable provenance—benefits that may improve feasibility in resource-constrained settings [30]. Given the observed fragility in guideline-sensitive domains, we recommend a clinician-in-the-loop workflow with tiered risk classification, automated guideline-concordance audits, and retrieval-augmented generation to anchor outputs in current evidence, with explicit human sign-off before the information enters care pathways [31,32]. Furthermore, transparent processes for obtaining patient consent for the use of AI-generated content in their care are essential. In addition, institutions should address regulatory and ethical implications (data protection, provenance, and accountability) and establish postdeployment monitoring and incident reporting processes to detect and mitigate potentially harmful responses [33].

Comparison to Prior Work

Unlike prior studies that have primarily examined single models within narrow clinical contexts [34,35], our investigation extends earlier designs by conducting a head-to-head, bilingual comparison of 3 advanced LLMs—DeepSeek R1, ChatGPT-4o, and Gemini—under a rigorous, blinded methodology incorporating randomization, washout, and consensus-based physician scoring. This design enabled more systematic cross-model comparisons than evaluations focused on 1 system or 1 language. The need for such rigor is underscored by reports from multidisciplinary areas such as cardio-oncology, where ChatGPT has answered only 68% of guideline-based queries correctly [36], highlighting the challenges that general-purpose models face when integrating complex clinical knowledge.

Focusing on ASCVD-related patient education and chronic disease self-management, we found that DeepSeek R1 achieved higher scores for accuracy and completeness and acceptable comprehensibility in both English and Chinese in our dataset,

XSL•FO
RenderX

suggesting suitability for patient-facing communication when used nonautonomously. These findings are concordant with recent *Nature Medicine* benchmarks showing that open-source systems can approach the performance of proprietary models in selected tasks [25,37]. Moreover, the open-source nature of DeepSeek R1 may enable privacy regulation–compliant local deployment and institution-specific fine-tuning—features that can support data-governed health systems—whereas its stable bilingual performance in our study aligns with goals of equitable information access [38]. At the same time, our domain-level analysis echoes and extends prior observations by showing that guideline-sensitive content remains comparatively fragile, reinforcing the need for clinician oversight and regular guideline concordance checks [39].

Limitations

Our study has several methodological limitations that should be considered when interpreting the findings. First, composite constraints in study design, item construction, and the evaluation perspective were present. The question set was clinician led, which may introduce selection bias; it used a fixed, evenly distributed, 5-domain preset (ie, definitions, diagnosis, treatment, prevention, and lifestyle) without direct patient involvement for external validation; model comparison was limited to 3 mainstream LLMs; and assessment relied entirely on expert review without patient-side measures such as comprehension or patient-reported outcomes. Collectively, these factors may affect clinical representativeness, diversity, and ecological validity [40].

Second, we acknowledge a moderate level of interrater agreement among the expert cardiologists as measured using the Kendall *W* (accuracy=0.578; completeness=0.565; comprehensibility=0.486). While such moderate reliability is not uncommon when evaluating nuanced, open-ended medical text where a degree of clinical subjectivity is inherent, it must be noted as a key limitation. To mitigate the impact of this disagreement, we used standardized anchors and a consensus adjudication step, and our statistical analysis (using medians and IQRs with nonparametric tests) was specifically chosen to limit the influence of rater heterogeneity. Nevertheless, this variability introduces uncertainty into the statistical significance of the differences found between models and suggests that expert opinions on AI-generated text quality can vary nontrivially. This is particularly relevant for clinical applications, where the use of such AI-generated content, especially for medical pathways or decision support, demands an even higher degree of caution. Consequently, the findings warrant a cautious interpretation. To enhance reliability in future work, we recommend developing more detailed scoring criteria with concrete examples and implementing a formal rater training and calibration process, including a pilot evaluation to establish baseline agreement.

Third, sample size and statistical power were not determined a priori. As an exploratory benchmarking study in a nascent area lacking established effect sizes, we did not perform an a priori power analysis. We used a coverage and stability-oriented design (25 items across 5 domains and 5 independent generations per model per language; 750 responses in total) to balance breadth and response stability. Although primary between-model contrasts reached statistical significance ($P<.001$)—suggesting adequate sensitivity post hoc—the absence of prespecified power planning limits generalizability; future confirmatory studies should use effect sizes and variance estimates from this work for formal power and sample size planning.

In addition, language and cultural generalizability are limited. Performance was evaluated only in English and Chinese. Differences in health beliefs, communication norms, and linguistic nuance across other languages and cultures may affect acceptability and applicability; broader multilingual, multicultural validation is needed.

Finally, geographic variation and reliance on the chosen reference guidelines (“benchmark binding”) may influence concordance judgments across health systems. While we benchmarked against specific international guidelines, ASCVD management varies by region and health system (eg, drug availability, targets, pathways, and reimbursement). Consequently, judgments of being concordant or nonconcordant are bound to the chosen reference standards, and local calibration is advisable for cross-region application.

Future Directions

First, longitudinal performance tracking should be prioritized. Standardized benchmarking with regular retesting across model updates, languages, and domains should be established to quantify performance drift, with early warning triggers for degradation; preregistered, multicenter confirmatory studies should be favored.

In addition, direct head-to-head comparisons with human materials should be conducted. LLM outputs should be benchmarked against human-authored patient education materials, assessing quantitative metrics (eg, accuracy and readability) and qualitative outcomes (eg, patient preference and trust) within a composite evaluation framework.

Moreover, pragmatic integration with clinical systems should be pursued. Low-coupling approaches to clinical systems under data minimization and privacy constraints (eg, standardized APIs, compliance and audit trails, and provenance and version management) should be explored to improve deployability.

Furthermore, communication should be tailored to patient literacy, language, culture, and context. Adaptive presentation methods based on health literacy, cultural background, preferred language, and clinical context should be developed and validated, maintaining clinical correctness while improving accessibility and understanding [41]. To ensure that these tailored communication strategies are effective, future work must include patient-centered validation, assessing the correlation between expert ratings and actual patient understanding and incorporating patient-reported outcome measures.

Finally, safety governance should be strengthened with structured risk management and monitoring. Future work should refine scoring anchors and operational definitions, broaden and diversify rater panels with structured calibration, conduct sensitivity and robustness analyses, implement routine guideline

XSL•FO
RenderX

concordance audits and a risk stratification framework (eg, dosing errors, contraindications, and care delay advice) [27], and establish continuous monitoring and incident reporting mechanisms to detect and mitigate potentially harmful or misleading outputs [26].

Conclusions

Our study evaluated the performance of several advanced LLMs in delivering information related to ASCVD, a major chronic disease burden in public health. In a blinded, bilingual comparison of DeepSeek R1, ChatGPT-4o, and Gemini, DeepSeek R1 demonstrated the highest accuracy and completeness, whereas all models showed comparable comprehensibility. Performance was consistently stronger for definitional and diagnostic queries than for treatment and prevention queries, indicating lower alignment with current therapeutic guidance in those domains. Notably, for the core question regarding the standard treatment regimen for ASCVD, none of the models consistently provided answers aligned with the latest clinical guidelines, representing a safety-relevant limitation of current general-purpose LLMs. These results delineate the present capability profile of LLMs for patient information on ASCVD and establish an empirical baseline for subsequent validation.

Acknowledgments

This work was supported by the National Science and Technology Major Project (2023ZD0503900 and 2023ZD0503902). The authors also wish to acknowledge the developers of the large language models evaluated in this study, whose groundbreaking work made this research possible. While drafting this manuscript, the authors used DeepSeek with the sole purpose of checking the grammar of the text.

Abstract

Background: Emergency triage accuracy is critical but varies with clinician experience, cognitive load, and case complexity. Mis-triage can delay care for high-risk patients and exacerbate crowding through unnecessary prioritization. Large language models (LLMs) show promise as triage decision-support tools but are vulnerable to hallucinations. Retrieval-augmented generation (RAG) may improve reliability by grounding LLM reasoning in authoritative guidelines and real clinical cases.

Objective: This study aimed to evaluate whether a dual-source RAG system that integrates guideline- and case-based evidence improves emergency triage performance versus a baseline LLM and to assess how closely its urgency assignments align with expert consensus and outcome-defined clinical severity.

Methods: We developed a dual-source RAG system—Multi-Evidence Clinical Reasoning RAG (MECR-RAG)—that retrieves sections from the Hong Kong Accident and Emergency Triage Guidelines (HKAETG) and cases from a database of 3000 emergency department triage encounters. In a retrospective single-center evaluation, MECR-RAG and a prompt-only baseline LLM (both DeepSeek-V3) were tested on 236 routine triage encounters to predict 5-level triage categories. Expert consensus reference labels were assigned by blinded senior triage nurses. Primary outcomes were quadratic weighted kappa (QWK) and accuracy versus consensus labels. Secondary analyses examined performance within 3 operationally and clinically relevant triage bands—immediate (categories 1 and 2), urgent (category 3), and nonurgent (categories 4 and 5). In 226 encounters with follow-up, we also assigned outcome-based severity tiers (R1-R3) using a published 3-level urgency reference standard and defined a disposition-safety composite.

Results: MECR-RAG achieved a mean QWK of 0.902 (SD 0.0021; 95% CI 0.901-0.904) and accuracy of 0.802 (SD 0.0082; 95% CI 0.795-0.808), outperforming the baseline LLM (QWK 0.801, SD 0.004; accuracy 0.542, SD 0.0073; both $P<.001$) and demonstrating expert-comparable agreement with triage nurses (interrater QWK 0.887). In 3-group analysis, MECR-RAG reduced overtriage from 68/236 (28.8%) with the baseline LLM to 30/236 (12.7%) and maintained low undertriage from 4/236 (1.7%) to 3/236 (1.3%), with the largest gains in the diagnostically ambiguous yet operationally important categories 3 and 4. In a secondary outcome-based analysis defining high-severity courses as R1+R2, MECR-RAG detected high-risk patients more sensitively than initial nurse triage (124/130, 95.4% vs 117/130, 90.0%; $P=.02$) while maintaining nurse-level specificity. MECR-RAG yielded the lowest weighted harm index (13.7, 19.5, and 20.3 per 100 patients for MECR-RAG, nurses, and the baseline LLM, respectively).

Conclusions: A dual-source RAG triage system that combines guideline-based rules with case-based reasoning achieved expert-comparable agreement, reduced overtriage, and better aligned urgency assignments than a prompt-only baseline LLM. Secondary outcome–based analyses in this cohort suggested more favorable triage patterns than initial nurse triage, supporting MECR-RAG as a concurrent decision-support layer that flags discordant or high-risk assignments; prospective multicenter implementation studies are needed to determine effects on emergency department crowding, delays, and patient outcomes.

Introduction

Emergency triage is a critical step in emergency department (ED) operations, determining which patients are seen first when demand exceeds capacity. However, triage accuracy varies with clinicians' experience, cognitive load, and the complexity of presenting symptoms, and even trained nurses may misclassify a substantial minority of encounters [1,2]. Undertriage risks delayed recognition of life-threatening illness and preventable morbidity or mortality, whereas overtriage diverts scarce resources toward lower-acuity patients and can exacerbate ED crowding and boarding, both of which are associated with worse outcomes [2]. These challenges are particularly pronounced in mid-acuity categories, which represent most ED visits and where small changes in urgency assignment can translate into large differences in waiting time, crowding pressure, and exposure to harm.

Large language models (LLMs) have emerged as potential tools for clinical decision support because they can interpret free-text notes, integrate medical knowledge, and generate structured recommendations. In emergency care, LLMs have been tested for triage on simulated vignettes and curated cases, but reported performance has been highly variable, with agreement with human raters (Cohen κ) ranging from 0.125 to 0.899 across models, datasets, and evaluation frameworks [3-8]. A fundamental limitation of current "prompt-only" LLMs is their tendency to hallucinate, generating outputs that appear plausible but are factually incorrect or unsupported [9]. In emergency triage, such hallucinations may lead to urgency levels being assigned based on fabricated reasoning, outdated rules, or misinterpretation of presenting complaints, posing potential risks to patient safety and consistency.

Retrieval-augmented generation (RAG) has been proposed as a way to mitigate hallucinations by grounding LLM outputs in external, task-specific knowledge sources such as clinical guidelines, textbooks, electronic health records, and biomedical literature [10-12]. By retrieving relevant evidence at inference time and conditioning generation on that material, RAG can improve access to current, domain-specific knowledge and make model reasoning more transparent. Early work in emergency care has shown that adding retrieval can improve triage or referral accuracy compared with nonretrieval models. Yazaki et al [13] integrated RAG with a triage guideline database and tested GPT-3.5 on 100 structured, simulated scenarios derived from the Japanese National Examination for Emergency Medical Technicians, finding that the RAG-enhanced model achieved 70/100 (70%) accuracy and outperformed both emergency medical technicians and physicians. Gaber et al [14] used a curated dataset of 2000 real-world ED cases from the MIMIC-IV (Medical Information Mart for Intensive Care IV) database and retrieved evidence from a corpus of 30,000 PubMed abstracts, demonstrating superior triage-level prediction and exact-match accuracy compared with nonretrieval workflows.

Despite these advances, existing applications of RAG to emergency triage and referral have important gaps. One study relied largely on textbook-style, simulated examination cases [13], whereas another used routine labels from structured research datasets without clinician-adjudicated ground truth [14]. In both studies, RAG was applied to a single knowledge source—either structured triage guidelines or biomedical literature—rather than explicitly combining protocol-based rules with experiential knowledge from prior cases.

To our knowledge, no prior work has evaluated a dual-source RAG system that jointly retrieves local triage guidelines and real-world past triage cases, or directly compared such a system with a prompt-only LLM using raw, unstructured triage documentation paired with a blinded expert consensus reference standard and outcome-based validity checks. This design better captures the complexity and variability of real-world practice and strengthens the translational relevance of performance estimates.

There is also growing recognition that agreement with human labels alone is an incomplete measure of triage quality. Large cohort studies of systems such as the Emergency Severity Index (ESI) and the Manchester Triage System (MTS) have shown that nurse-assigned categories can underestimate or overestimate "true" acuity when judged against downstream outcomes such as hospitalization, intensive care unit (ICU) transfer, revisits, and short-term mortality [15-17]. In parallel, a *Journal of the American Medical Association* (*JAMA*) editorial on artificial intelligence (AI) in medicine has argued that evaluations of AI tools should prioritize clinically meaningful outcomes, patient-centered care, quality, and equity rather than focusing solely on narrow technical accuracy metrics [18]. Accordingly, evaluations of LLM-enabled triage should explicitly examine how assigned urgency levels align with downstream clinical severity and sentinel safety events, rather than treating concordance with nurse labels as sufficient.

In this context, we developed a dual-source RAG system—Multi-Evidence Clinical Reasoning RAG (MECR-RAG)—that retrieves both structured local triage guidelines (Hong Kong Accident and Emergency Triage Guidelines [HKAETG]) and analogous past triage cases and applies a structured Multi-Evidence Clinical Reasoning (MECR) framework to assign 5-level urgency categories. We retrospectively evaluated MECR-RAG on real ED triage notes, benchmarking it against a prompt-only baseline LLM and against expert nurse consensus labels. Our primary aim was to determine whether a dual-source RAG triage system (MECR-RAG) improves 5-level triage accuracy and agreement (quadratic weighted κ and accuracy) with expert nurse consensus compared with a prompt-only baseline LLM and to benchmark its performance against expert triage nurses. We hypothesized that MECR-RAG would achieve higher agreement than the baseline LLM and noninferior agreement relative to expert nurses. As a secondary aim, in a subset with follow-up data, we

XSL•FO
RenderX

assessed outcome-informed validity by examining how MECR-RAG, the baseline LLM, and initial nurse triage aligned with downstream clinical severity tiers and a composite of sentinel safety outcomes. This early-phase, single-center evaluation, reported in accordance with TRIPOD-LLM (Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis - Large Language Models) [19], is intended to provide a methodologically rigorous foundation for future prospective and implementation studies of RAG-enhanced triage decision-support systems designed to augment, rather than replace, nurse-led triage.

Methods

Study Design and Setting

This study was a retrospective, proof-of-concept evaluation of a RAG-enhanced LLM for ED triage classification. The primary objective was to compare the performance of an RAG-based LLM that referenced both historical case data and the HKAETG against a prompt-only baseline LLM in assigning triage urgency levels.

The HKAETG is a 5-level triage system implemented across all 18 government-funded public EDs in Hong Kong. Its structure is conceptually aligned with other internationally recognized systems such as the MTS and ESI. Under the HKAETG, patients are assigned to 1 of 5 categories based on clinical urgency and time-to-treatment targets: category 1 (critical, 0 minutes), category 2 (emergency, 10 minutes), category 3 (urgent, 30 minutes), category 4 (semiurgent, 120 minutes), and category 5 (nonurgent, 180 minutes).

All study data were sourced from a single center, Princess Margaret Hospital (PMH), a major acute public hospital in Hong Kong and one of the city's largest tertiary care facilities. PMH operates a 24-hour ED and manages a high volume of complex and time-sensitive cases. In 2023 and 2024, the ED recorded 113,974 and 110,812 visits, respectively, highlighting its central role in emergency care delivery.

Pilot Study, Sample Size Calculation, and Model Selection

Before the main evaluation, we conducted a pilot study to inform model selection, prompting strategy, and sample size estimation. We randomly sampled 1000 ED triage cases from December 2024; 200 cases were used for pilot testing, and the remaining 800 cases were reserved to simulate a retrieval database. All pilot cases were excluded from the final study.

Three commercially available LLMs (DeepSeek-V3, GPT-4o, and Claude 3.7 Sonnet) were compared in both prompt-only and RAG configurations, with performance assessed against clinician-assigned triage labels using quadratic weighted kappa (QWK) and accuracy. Across models, performance was statistically similar in this pilot. DeepSeek-V3 was therefore selected as the backbone model for the main study primarily on the basis of its inference cost, application programming interface (API) accessibility, and comparable pilot performance.

In the pilot setting, the MECR-RAG configuration achieved an approximate QWK of 0.75 compared with 0.50 for the prompt-only baseline. Using the formula for comparing 2 kappa coefficients described by Fleiss, with α=.05 and power=.80 [20], the minimum required sample size to detect this difference was 48 cases. We nevertheless included 236 consensus-labeled triage cases in the final study to improve the precision of performance estimates and enhance generalizability.

Data Sources and Participants

The test set comprised ED triage cases collected at PMH between January 1 and December 31, 2023. All ED visits during this period were eligible regardless of age, sex, or presenting problem. To ensure temporal representativeness and reflect real-world variation in case mix, we used a stratified sampling strategy in which 1 calendar day was randomly selected from each month and 20 cases were sampled from that day. Within each sampled day, triage categories were sampled to approximate overall category distributions while modestly oversampling rare categories to improve precision for high-acuity strata. Four cases were excluded because case-number identification errors prevented data retrieval, yielding a final test set of 236 triage cases.

Reference labels were assigned using a blinded, multirater consensus process. Two advanced practice nurses with more than 10 years of emergency experience independently reviewed each case. Raters were blinded to the original nurse-assigned triage category and saw only information available at the time of triage: presenting complaint, condition on arrival, vital signs, and relevant past medical history when documented. Downstream data, including investigations, diagnoses, treatments, and ward progress, were withheld so that labels reflected only the initial triage decision context and matched the information provided to the LLMs. Disagreements were adjudicated by a third senior triage nurse to obtain a final consensus category for each encounter.

For retrieval, we constructed a separate database of 3000 anonymized ED visits to PMH between January 1 and December 31, 2024. All encounters in 2024 were eligible, with no clinical exclusion criteria, to preserve the natural diversity of documentation and presentations. Days were randomly sampled from each month, and cases were then drawn from those days to achieve broad temporal coverage; modest oversampling of rare triage categories (categories 1, 2, and 5) ensured sufficient representation while maintaining the real-world skew toward categories 3 and 4. The final database contained 94/3000 (3.1%) category 1, 120/3000 (4.0%) category 2, 1705/3000 (57.0%) category 3, 1035/3000 (34.5%) category 4, and 46/3000 (1.5%) category 5 encounters, with detailed monthly and category-specific sampling shown in Table S1 in Multimedia Appendix 1. To stress-test temporal robustness and reduce bias from contemporaneous documentation habits, 2023 test cases were evaluated against a 2024 retrieval database using the same triage guideline version; the full rationale is provided in Textbox S1 in Multimedia Appendix 1.

Preprocessing

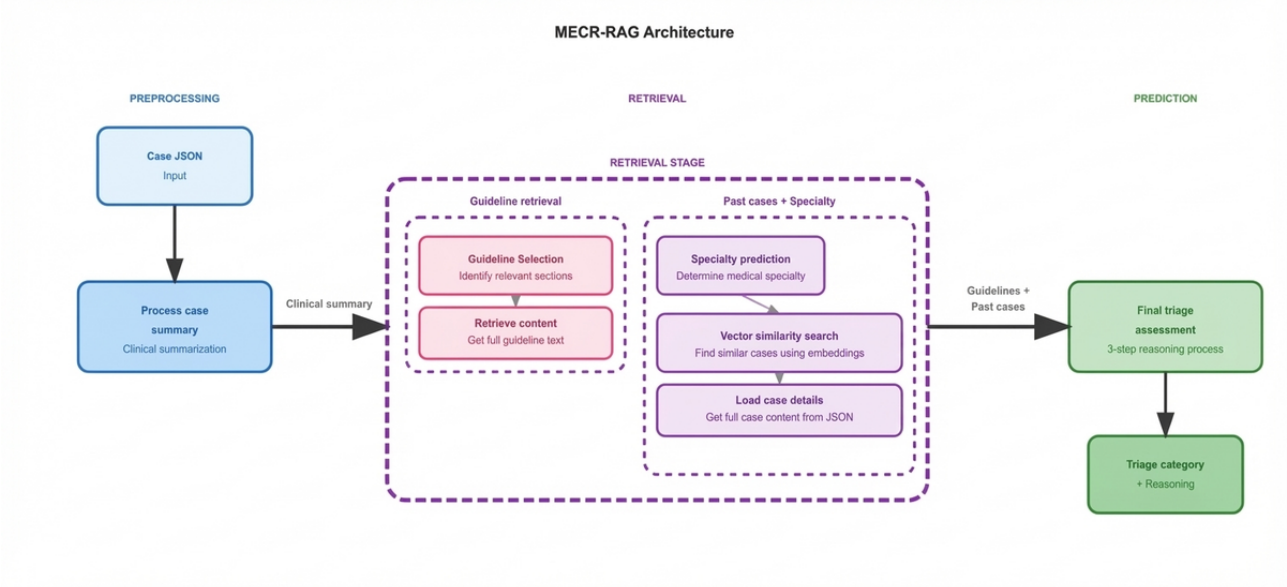
Raw, unstructured triage documentation for both test cases and retrieval-database cases was exported from the electronic medical record, deidentified, and converted into a structured,

XSL•FO
RenderX

machine-readable text format. We retained only nurse-entered information available at the time of triage (eg, demographics, presenting complaint, condition on arrival, vital signs, and relevant past medical history) and excluded any downstream assessments, investigations, treatments, and outcomes. The latest version of the HKAETG (version 6, revised 2022) was similarly digitized and segmented into retrievable guideline sections. Both triage notes and guideline sections were then processed for semantic retrieval; further preprocessing and summarization details are provided in Textbox S2 in Multimedia Appendix 1.

LLM and RAG System Description

For all primary analyses, we used DeepSeek-V3 as the base LLM, accessed via a commercial API without any additional fine-tuning or architectural modification. In what follows, we refer to the DeepSeek-V3 model without retrieval as the "baseline LLM" and the dual-source retrieval-augmented configuration as MECR-RAG. Within each experimental configuration, the same LLM instance handled all stages of the pipeline (preprocessing, retrieval, and generation) with deterministic generation (temperature=0) to minimize stochastic variability. A separate embedding model was used to generate vector representations for semantic retrieval, and the same embedding configuration was applied during database construction and at query time to ensure consistency.



The pipeline was implemented in Python and executed on a standard desktop workstation without graphics processing unit acceleration. End-to-end processing time for the full MECR-RAG configuration was approximately 1 minute per case, including preprocessing, retrieval, and triage prediction, suggesting that near-real-time decision support would be technically feasible. Detailed model versions, libraries, and runtime benchmarks are provided in Section A1 in Multimedia Appendix 1.

MECR-RAG System Architecture

The MECR-RAG system follows a 5-stage pipeline designed to mirror how expert triage nurses combine protocol knowledge with experiential reasoning. First, the raw triage note is summarized into a concise, structured representation optimized for retrieval. Second, the model selects the most relevant sections of the HKAETG using an agentic reasoning step that prioritizes life-threatening conditions and documented physiologic abnormalities. Third, the system predicts the most likely attending specialty (eg, medicine, surgery, and orthopedics) to constrain subsequent case retrieval. Fourth, a hybrid retrieval module identifies similar past triage cases by combining metadata filters (age group and predicted specialty) with vector similarity search. Finally, the model applies a structured, MECR prompt that integrates guideline excerpts, retrieved cases, and the index presentation to assign a 5-level urgency category and provide a textual rationale.

The overall architecture is orchestrated using a modular, node-based workflow that preserves intermediate states, supports full audit trails, and enables systematic component ablation. A schematic overview of the MECR-RAG pipeline is shown in Figure 1, and additional implementation details are provided in Section A2 in Multimedia Appendix 1.

Figure 1. Overview of the Multi-Evidence Clinical Reasoning retrieval-augmented generation system architecture. MECR-RAG: Multi-Evidence Clinical Reasoning retrieval-augmented generation.

The MECR-RAG pipeline consists of 5 sequential processing stages: clinical case summarization, agentic guideline section selection, specialty prediction for metadata filtering, hybrid past-case retrieval combining metadata and vector similarity search, and multievidence reasoning for the final triage assessment. LangGraph nodes manage state transitions and data flow throughout the pipeline.

Indexing and Database Construction

To support efficient retrieval, both historical triage cases and guideline content were converted into structured, machine-readable representations and indexed in a vector database. Historical cases were transformed into standardized triage-time summaries that captured presenting complaints, key vital signs, and brief clinical context, while preserving links to

XSL•FO
RenderX

metadata such as age group, triage category, and attending specialty. The same summarization template was applied to both database cases and incoming test cases to ensure that queries and indexed documents occupied a comparable embedding space.

The HKAETG document was similarly segmented into discrete sections and summarized to highlight the spectrum of presentations covered by each rule set. Each guideline section was stored with a short synopsis and structural metadata (eg, system, chief complaint, and red-flag criteria) to facilitate targeted retrieval during triage. The combined indexing strategy was designed to balance retrieval quality, computational efficiency, and scalability to larger case repositories. Details of prompt templates, sectioning rules, and indexing parameters are described in Section A3 in Multimedia Appendix 1.

Retrieval System Design

The retrieval layer implements a dual-source strategy that distinguishes authoritative protocol knowledge from experiential case patterns. Guideline retrieval is performed via an agentic selection step: given the summarized index case and a list of guideline section titles and synopses, the LLM selects up to 2 sections it deems most relevant, explicitly favoring conditions associated with high short-term risk or abnormal vital signs. This approach avoids purely lexical matching and aligns guideline selection more closely with clinical reasoning.

Past-case retrieval uses a multistage, hybrid approach. The model first predicts 1 or 2 likely specialties using triage-available information only, then filters the case database by age group and specialty to construct a clinically plausible candidate pool. Within this subset, vector similarity search identifies the closest matches based on the summarized clinical text. A small number of top-ranked cases are returned, along with similarity scores and metadata, for use in the final reasoning step. Similarity thresholds, top-k values, and fallback strategies were chosen empirically and are reported in Section A4 in Multimedia Appendix 1.

Generation and Prompting Strategy

The generation stage uses an MECR prompt that extends conventional chain-of-thought reasoning for the specific demands of triage. Rather than a single undifferentiated reasoning path, the prompt enforces a 3-tier structure: (1) a clinical risk assessment aligned with formal triage category definitions, (2) integration of condition-specific recommendations from the retrieved HKAETG sections, and (3) comparison with retrieved past cases to identify contextual factors that may support escalation or de-escalation (eg, frailty, social circumstances, and borderline physiology). Each evidence source produces an independent provisional triage recommendation.

The model is then instructed to reconcile these recommendations into a single final category, explicitly justifying the choice and indicating which sources carried the most weight. Outputs include the predicted triage category, a structured explanation, and a coarse confidence label (high, medium, or low), enabling clinicians to audit the reasoning process and gauge when additional scrutiny is warranted. The complete MECR prompt details are provided in Section A5 in Multimedia Appendix 1.

Ablation Configurations

To isolate the contribution of individual retrieval components, we implemented 3 reduced configurations alongside the full MECR-RAG system. The baseline configuration used the same triage definition table and reasoning structure but removed all retrieval, relying only on the index case description. The guideline-only configuration added agentic guideline selection but did not use past-case retrieval, whereas the case-only configuration retrieved similar past cases without guideline sections. In all ablation variants, preprocessing steps, LLM model, and evaluation procedures were held constant to ensure that performance differences could be attributed to the presence or absence of specific retrieval sources rather than to implementation artifacts. The details are provided in Section A6 in Multimedia Appendix 1.

Outcome Definition and Label-Based Evaluation

The primary outcome was the 5-level triage category (categories 1-5) predicted by each LLM configuration, compared with consensus labels assigned by expert triage nurses. Two configurations were evaluated: the MECR-RAG system, which incorporated both the HKAETG and retrieval of past triage cases, and a prompt-only baseline model with no retrieval component. Model outputs were assessed against the final adjudicated triage category for each case.

The primary performance metric was QWK, chosen because it accounts for the ordinal nature of triage categories and penalizes larger discrepancies more heavily, in line with their greater clinical consequence. Overall accuracy was reported as a complementary measure summarizing the proportion of exact matches between model predictions and consensus labels.

To provide a more clinically grounded view of performance, we also calculated precision, recall, and F_1-score for each triage category and for a post hoc grouping of triage levels into 3 urgency bands: immediate (categories 1 and 2), urgent (category 3), and nonurgent (categories 4 and 5). This mapping reflects local operational workflows, in which small changes in urgency assignment can translate into large differences in waiting time and risk exposure. These group-level metrics were used to characterize overtriage and undertriage patterns beyond aggregate QWK and accuracy estimates.

Because LLM outputs are probabilistic, all primary comparisons between MECR-RAG and the baseline LLM were repeated across 5 independent runs using identical test cases, prompts, retrieval databases, and API settings. For these analyses, we summarized performance as mean values with 95% CIs calculated across runs. For analyses based on a single representative run—for example, evaluations using the median-performing prediction set or post hoc subgroup comparisons—95% CIs were obtained via nonparametric case-level bootstrapping (1000 resamples). The specific CI method used is reported alongside each result, and full resampling details are provided in Textbox S3 in Multimedia Appendix 1.

XSL•FO
RenderX

Secondary Outcome-Based Validity Analysis

Because there is no universally accepted gold standard for "true" acuity at ED presentation, triage tools are typically judged against surrogate outcomes such as hospitalization, ICU admission, revisits, and short-term mortality [15,16]. Large observational studies have shown that nurse-assigned categories can substantially underestimate or overestimate severity, with mis-triage affecting up to one-third of patients in some cohorts [17,21]. To complement our consensus label-based evaluation, we therefore derived outcome-based severity tiers and a disposition-safety composite (DSC) and re-examined how MECR-RAG, the baseline LLM, and initial nurse triage aligned with downstream clinical courses.

For all encounters with sufficient follow-up, we assigned an ordinal outcome-based severity tier (R1-R3) adapted from the multilevel reference standard used in MTS validation work, in which a multidisciplinary expert panel defined 3 urgency levels [15]. R1 represented high-acuity courses analogous to the "immediate or very urgent" reference category and was defined by the presence of any marker of life-threatening illness, such as markedly abnormal vital signs with modified early warning score ≥5 or depressed consciousness, emergency surgery or other high-intensity interventions shortly after ED arrival, or death in the ED, ICU, or during the index admission. R2 corresponded to an "urgent" course and included patients who did not meet R1 criteria but required substantial acute treatment (eg, intravenous medication, fluids, and nebulizers) or hospitalization. R3 comprised lower-acuity courses in which none of the R1 or R2 markers were present. Patients who left without being seen (LWBS) were coded separately and excluded from outcome-based binary analyses. Full operational definitions and mapping of specific outcome elements to R1-R3 are provided in Table S2 in Multimedia Appendix 1.

To capture sentinel deterioration events that may reflect underrecognition of severity at triage, we additionally defined a DSC based on components commonly used as ED quality and safety indicators. DSC was coded as positive if any of the following occurred after the index ED visit: (1) unplanned ICU transfer within 72 hours of ward admission, (2) ED revisit within 72 hours resulting in unplanned hospital admission (including ICU admission when present), or (3) all-cause death within 7 days [22-24]. A binary variable, DSC_any, was set to 1 if at least one component was present. Outcome adjudication for R1-R3 and DSC_any was performed using routinely collected outcome data and was fully blinded to the index triage category and all model outputs.

Using these constructs, we prespecified 4 binary analytic "lenses" for sensitivity analyses. A classic lens defined outcome+ as R1 only and outcome– as R2 or R3, with test+ as triage categories 1-2 versus 3-5, mirroring conventional MTS validation [15]. An operational lens defined outcome+ as R1 or R2 versus R3 and test+ as categories 1-3 versus 4-5, reflecting the separation between patients who should not wait in the lowest-priority stream and those who can safely do so. Two augmented lenses incorporated DSC_any: an augmented classic lens (outcome+=R1 or DSC_any; test+=categories 1 and 2) and an augmented operational lens (outcome+=R1 or R2 or DSC_any; test+=categories 1-3). These lenses were intended to test robustness across different, clinically motivated definitions of high severity and to align with prior recommendations on composite triage outcomes. Full definitions are provided in Textbox S4 in Multimedia Appendix 1.

For each lens and each triage method (nurse triage, baseline LLM, and MECR-RAG), we constructed 2×2 tables of test+ versus outcome+ and calculated sensitivity, specificity, and 95% CIs, along with positive and negative likelihood ratios (LR+ and LR–) and diagnostic odds ratios (DORs). To compare models on the same patients, we used paired McNemar tests to assess differences in sensitivity (within outcome+ cases) and specificity (within outcome– cases). As additional clinically interpretable summaries, we examined (1) the proportion of R1 cases assigned to immediate (categories 1 and 2), (2) the proportion of R2 cases assigned to nonurgent (categories 4 and 5), and (3) a weighted harm index per 100 patients that assigns higher penalties to more dangerous errors (R1 or R2 assigned to nonurgent) than to overtriage of R3 cases. Case-level harm scores were compared between models using paired signed tests. Detailed formulas for likelihood ratios, DORs, CIs, and harm index computation are provided in Textbox S5 in Multimedia Appendix 1.

Statistical Analysis

All analyses were conducted using R (version 4.5.0; R Core Team). Interrater agreement and kappa statistics were calculated using standard packages for reliability analysis. Classification metrics were obtained using established machine learning libraries, and nonparametric CIs were estimated using bootstrap resampling. Between-model comparisons used tests appropriate to the data structure, including Friedman tests with Nemenyi post hoc procedures for repeated-run summary metrics and Cochran Q and McNemar tests for paired binary outcomes. Exploratory subgroup, scaling, and cross-model generalizability analyses were treated as descriptive and were not formally powered for hypothesis testing. Full details of the statistical workflow, including package names, resampling schemes, handling of multiple runs, and exploratory analyses, are provided in Textbox S6 in Multimedia Appendix 1.

Ethical Considerations

This study was approved by the Hospital Authority Central Institutional Review Board (reference number CIRB-2024-561-4). Because this was a retrospective analysis of anonymized patient records with no impact on clinical care, the Central Institutional Review Board granted a waiver of informed consent. All data used in this study were fully anonymized prior to analysis, and no identifiable patient information was retained or accessible to the study team. No compensation was provided, as no participants were recruited or contacted for this study.

Results

Participants

The final test set comprised 236 ED triage encounters from 2023. After expert consensus adjudication, the distribution of triage categories was 23/236 (9.7%) category 1, 23/236 (9.7%)

XSL•FO
RenderX

category 2, 82/236 (34.7%) category 3, 98/236 (41.5%) category 4, and 10/236 (4.2%) category 5. The mean patient age was 55.1 (SD 26.2; range 0.3-98.0) years. Overall, 131/236 (55.5%) patients were male and 105/236 (44.5%) were female. The most common clinical specialties were medicine (115/236, 48.7%), orthopedics (36/236, 15.3%), surgery (33/236, 14.0%), and pediatrics (13/236, 5.5%), with the remaining 39/236 (16.5%) classified as other specialties.

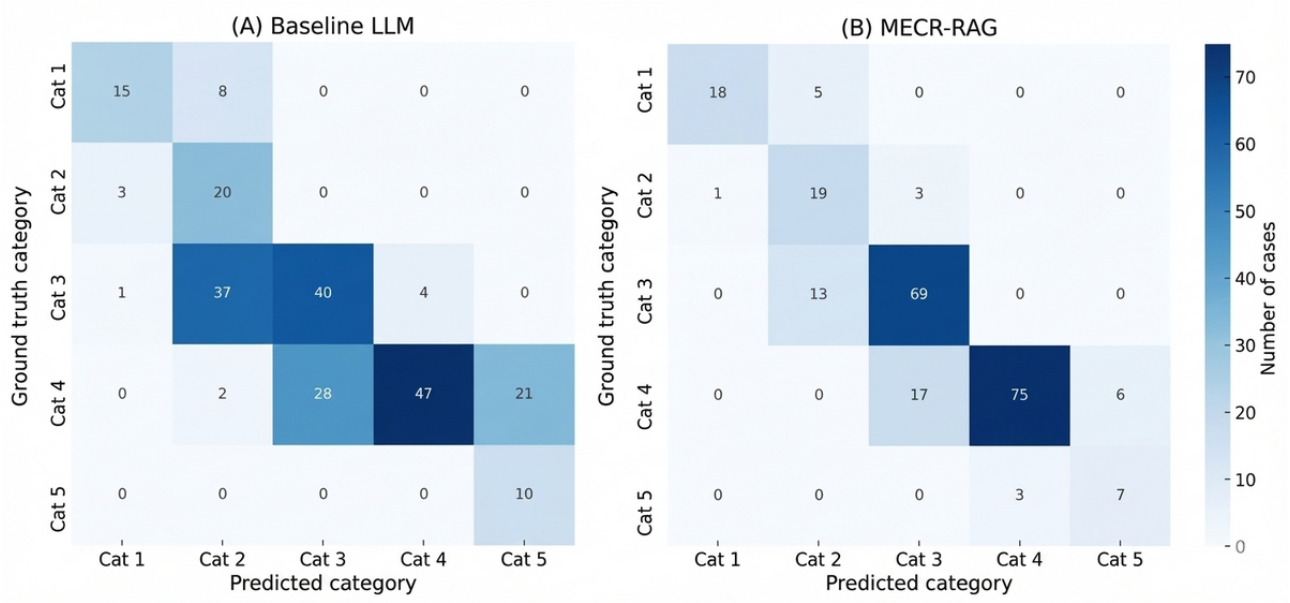
The retrieval database used by the MECR-RAG system consisted of 3000 anonymized ED encounters from 2024. The triage category distribution was constructed to reflect real-world attendance patterns, which are typically skewed toward lower-acuity presentations, with modest upsampling of categories 1, 2, and 5 to ensure adequate representation of rare but clinically important groups. The mean age in the retrieval database was 56.7 (SD 25.6; range 0.2-104.0) years, with an equal sex distribution (1500/3000, 50.0% male and 1500/3000, 50.0% female). The specialty mix was similar to the test set, with medicine accounting for 1395/3000 (46.5%) encounters, followed by orthopedics (441/3000, 14.7%), surgery (435/3000, 14.5%), pediatrics (210/3000, 7.0%), and other specialties (519/3000, 17.3%). Baseline characteristics of both datasets are summarized in Table 1, and characteristics of the 1000- and 2000-case retrieval subsets used in the scaling analysis are provided in Table S3 in Multimedia Appendix 1.

Table 1. The demographic and triage category distribution of the test set and 3000-case retrieval-augmented generation database.

Characteristic	Test set (N=236)	3000-case database (N=3000)
Age (years), mean (SD; range)	55.1 (26.2; 0.3-98.0)	56.7 (25.6; 0.2-104.0)
Sex, n (%)		
Male	131 (55.5)	1500 (50.0)
Female	105 (44.5)	1500 (50.0)
Triage categories, n (%)		
Category 1	23 (9.7)	94 (3.1)
Category 2	23 (9.7)	120 (4.0)
Category 3	82 (34.7)	1705 (57.0)
Category 4	98 (41.5)	1035 (34.5)
Category 5	10 (4.2)	46 (1.5)
Specialty, n (%)		
Medicine	115 (48.7)	1395 (46.5)
Orthopedics	36 (15.3)	441 (14.7)
Surgery	33 (14.0)	435 (14.5)
Pediatrics	13 (5.5)	210 (7.0)
Others	39 (16.5)	519 (17.3)

Age is presented as mean (SD). Triage category and specialty values are reported as percentages of total cases within each dataset. Other specialties include dentistry; dermatology; ear, nose, and throat; neurosurgery; obstetrics and gynecology; oncology; ophthalmology; and psychiatry. Both datasets were constructed to reflect real-world triage distributions, with modest oversampling of rare categories (eg, categories 1, 2, and 5) to ensure sufficient representation for model evaluation. Full sampling rationale is provided in the “Methods” section. The test set and retrieval database exhibited broadly comparable distributions in age, sex, and specialty.

Comparative Performance of MECR-RAG and the Baseline LLM, Benchmarked Against Expert Rater Agreement



The MECR-RAG system showed substantially higher agreement with consensus triage labels than the baseline LLM. Across 5 independent runs, MECR-RAG achieved a mean QWK of 0.902 (SD 0.0021; 95% CI 0.901-0.904), compared with 0.801 (SD 0.004; 95% CI 0.798-0.804) for the baseline model (mean paired difference 0.101, SD 0.0058; 95% CI 0.097-0.106; P<.001). Classification accuracy followed the same pattern, with a mean accuracy of 0.802 (SD 0.0082; 95% CI 0.795-0.808) for MECR-RAG versus 0.542 (SD 0.0073; 95% CI 0.536-0.548) for the baseline LLM (mean paired difference 0.264, SD 0.0150; 95% CI 0.251-0.278; P<.001). Similar effect sizes were observed when analyses were repeated using single median-run prediction sets, indicating that MECR-RAG’s advantage was robust to run-to-run variability.

To benchmark model performance against human experts, we evaluated interrater reliability between the 2 professional triage nurses who generated the reference labels; their QWK was 0.887. By comparison, MECR-RAG achieved a mean QWK of 0.902 (SD 0.0021; 95% CI 0.901-0.904). Using a prespecified noninferiority margin of −0.05, MECR-RAG met criteria for noninferiority to expert agreement, and this conclusion was unchanged in sensitivity analyses restricted to single median-performing runs. Taken together, these findings suggest that MECR-RAG attains expert-comparable consistency in 5-level triage classification while clearly outperforming a

XSL•FO
RenderX

prompt-only LLM. Confusion matrices comparing triage classification performance between the baseline LLM and MECR-RAG are shown in Figure 2. Results are shown for the median-performing run across 5 stochastic trials in this figure.

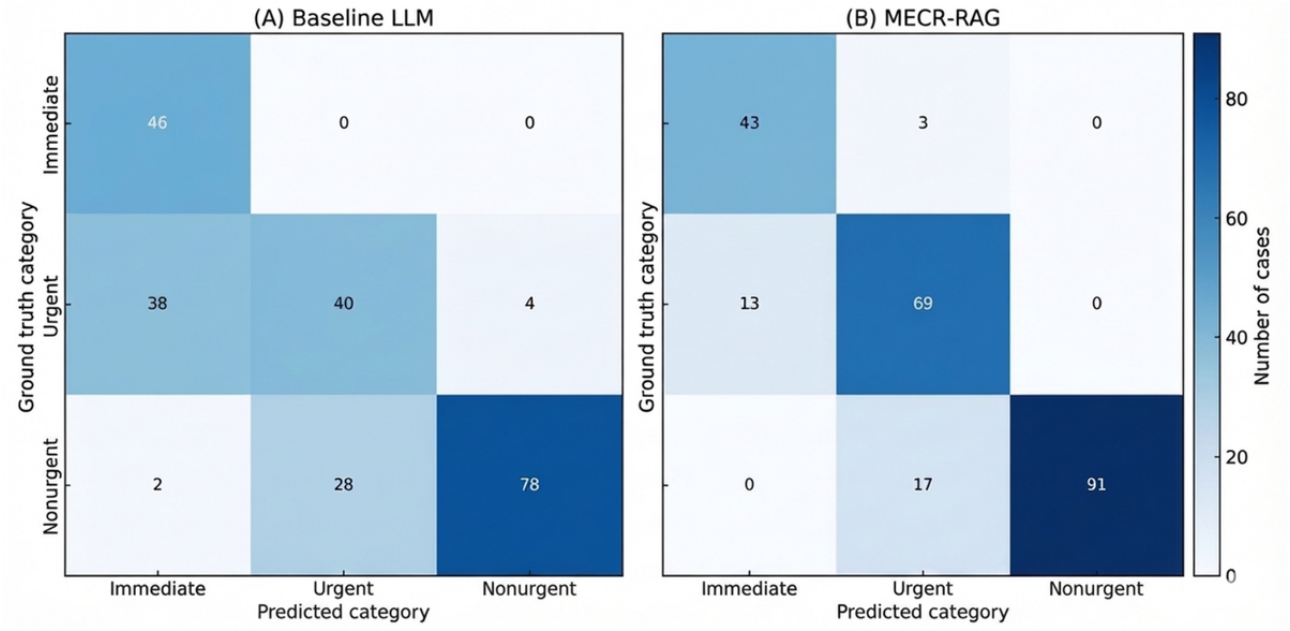


Figure 2. Confusion matrices comparing 5-level triage classification performance between the baseline prompt-only large language model (panel A) and the Multi-Evidence Clinical Reasoning retrieval-augmented generation system (panel B) on 236 emergency department triage encounters in the test set. LLM: large language model; MERC-RAG: Multi-Evidence Clinical Reasoning retrieval-augmented generation.

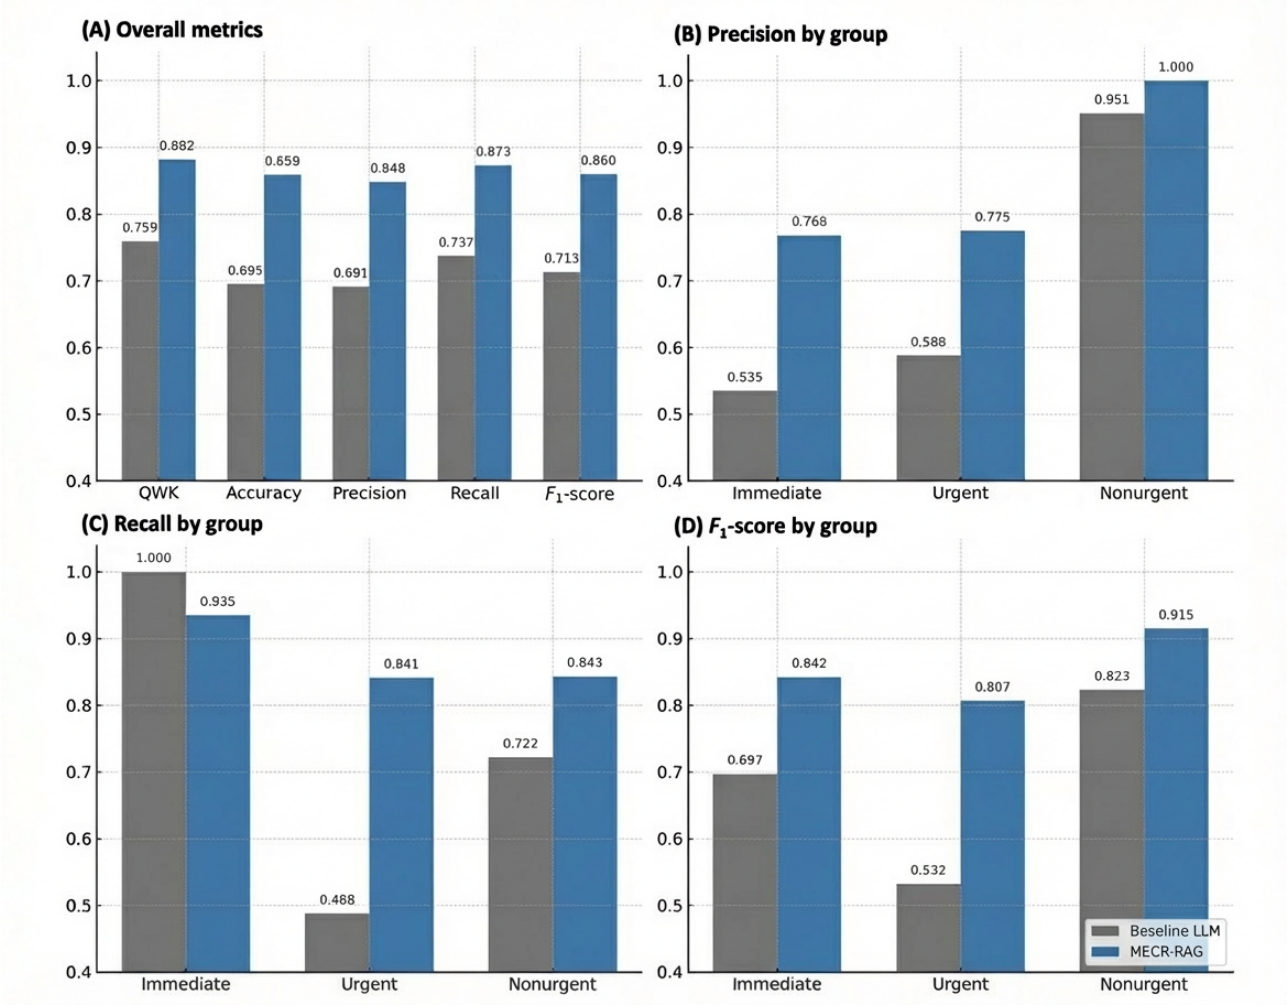
Performance Using Clinically Grouped Triage Categories

To reflect operational priorities in the ED, we conducted a post hoc analysis collapsing the 5 triage categories into 3 clinically meaningful groups: immediate (categories 1 and 2), urgent (category 3), and nonurgent (categories 4 and 5). This schema mirrors local workflows, in which immediate cases are seen without delay, urgent cases typically wait approximately 32 minutes, whereas nonurgent cases typically wait approximately 240 minutes based on 2024 institutional data. All metrics in this analysis were derived from the median-performing model run to approximate single-run deployment. Confusion matrices for grouped predictions are shown in Figure 3. Results reflect the median-performing run across 5 stochastic trials in this figure.

Figure 3. Confusion matrices comparing triage group classification performance between the baseline prompt-only large language model (panel A) and the Multi-Evidence Clinical Reasoning retrieval-augmented generation system (panel B) under a 3-group schema. LLM: large language model; MERC-RAG: Multi-Evidence Clinical Reasoning retrieval-augmented generation.

Under this 3-group schema, MECR-RAG maintained high overall performance, achieving a QWK of 0.882 (95% CI 0.840-0.920) compared with 0.759 (95% CI 0.700-0.813) for the baseline LLM (paired difference 0.125, 95% CI 0.077-0.174; $P<.001$). Accuracy similarly favored MECR-RAG (0.859 vs 0.695; paired difference 0.164, 95% CI 0.110-0.225; $P<.001$).



XSL•FO
RenderX

Macrolevel precision, recall, and F_1-score were also higher for MECR-RAG (precision 0.848 vs 0.691; recall 0.873 vs 0.737; F_1-score 0.860 vs 0.713).

Error-pattern analysis showed that MECR-RAG slightly reduced undertriage compared with the baseline LLM (3/236, 1.3% vs 4/236, 1.7%; McNemar P=.69), while substantially reducing overtriage. Overtriage decreased from 68/236 (28.8%) with the baseline LLM to 30/236 (12.7%) with MECR-RAG (McNemar P<.001). Thus, the model reduced unnecessary escalation without compromising detection of higher-acuity cases.

Performance advantages for MECR-RAG were consistent across triage groups. For immediate cases, MECR-RAG had slightly lower recall than the baseline LLM (0.935 vs 1.000) but substantially higher precision (0.768 vs 0.535), yielding a higher F_1-score (0.842 vs 0.697). Overall correctness did not differ significantly (McNemar P=.25), suggesting comparable sensitivity with fewer false positives. In the urgent group, MECR-RAG markedly outperformed the baseline model (recall 0.841 vs 0.488; precision 0.775 vs 0.588; F_1-score 0.807 vs 0.532; McNemar P<.001), indicating improved discrimination in this diagnostically challenging and operationally dominant band. For nonurgent cases, MECR-RAG again showed higher recall (0.843 vs 0.722) and F_1-score (0.915 vs 0.823), with perfect precision (1.000 vs 0.951; McNemar P=.01). These patterns, summarized in Figure 4, suggest that MECR-RAG delivers a more favorable balance between safety and operational efficiency, particularly in the mid- and low-acuity groups that account for most ED visits and drive waiting-time differentials.

Figure 4. Comparative model performance across overall and triage group-specific metrics. LLM: large language model; MERC-RAG: Multi-Evidence Clinical Reasoning retrieval-augmented generation. QWK: quadratic weighted kappa.

Comparative model performance across overall and triage group-specific metrics. Performance is evaluated using a clinically relevant 3-level grouping: immediate (categories 1 and 2), urgent (category 3), and nonurgent (categories 4 and 5), corresponding to local time-to-physician targets and resource prioritization. Panel A summarizes overall performance across QWK, accuracy, precision, recall, and F_1-score for the baseline prompt-only LLM and the MECR-RAG system; MECR-RAG achieved higher QWK (0.882) and accuracy (0.859) than the baseline LLM (QWK 0.759; accuracy 0.695; both P<.001). Panels B-D show precision, recall, and F_1-score, respectively, by triage group, with MECR-RAG consistently outperforming the baseline LLM across all groups and particularly in the urgent group (F_1-score 0.807 vs 0.532). All results are based on the median-performing model run.

Outcome-Informed Validity Relative to Clinical Severity

Among the 236 triage encounters, 226 (95.8%) had sufficient follow-up information to assign an outcome-based severity tier (R1-R3); the remaining 10 (4.2%) patients were LWBS and were excluded from all outcome-based analyses but retained in label-based performance summaries. Within the 226 encounters with outcome labels, 13/226 (5.8%) met R1 criteria, 117/226 (51.8%) met R2 criteria, and 96/226 (42.5%) were classified as R3. When high-severity outcomes were defined as R1+R2 (n=130) and triage "positive" as categories 1-3 versus 4-5, MECR-RAG achieved the highest sensitivity for high-risk courses at 124/130 (95.4%), compared with 117/130 (90.0%) for initial nurse triage and 122/130 (93.8%) for the baseline LLM. The gain versus nurses was statistically significant (McNemar χ^2_1 =5.14; *P*=.02), whereas sensitivity did not differ from the baseline LLM (χ^2_1 =0.17; *P*=.68). Specificity for low-risk (R3) cases was 77/96 (80%) for MECR-RAG, 78/96 (81%) for nurses, and 66/96 (69%) for the baseline LLM. Thus, MECR-RAG maintained nurse-level specificity (χ^2_1 =0.00; *P*=1.00) while significantly improving specificity over the baseline LLM (χ^2_1 =5.26; *P*=.02). All 3 systems correctly avoided assigning nonurgent (categories 4 and 5) to any R1 cases (0/13 each). The DOR for distinguishing R1+R2 from R3 was 83.8 (95% CI 32.0-218.9) for MECR-RAG, 39.0 (95% CI 18.1-84.1) for nurses, and 33.6 (95% CI 14.6-77.4) for the baseline LLM, consistent with a more favorable overall trade-off between undertriage and overtriage for MECR-RAG, although CIs overlapped because of limited event counts.

To examine clinically important undertriage, we focused on R2 patients assigned to nonurgent triage (categories 4 and 5). Among 117 R2 encounters, 13/117 (11.1%) were initially labeled nonurgent by nurses, compared with 8/117 (6.8%) by the baseline LLM and 6/117 (5.1%) by MECR-RAG. In paired analysis, MECR-RAG approximately halved R2 nonurgent misclassification relative to nurses (13 to 6 cases; McNemar χ^2_1 =5.14; *P*=.02), with a smaller, nonsignificant reduction compared with the baseline LLM (8 to 6 cases; χ^2_1 =0.17; *P*=.68). Considering the entire triage distribution, MECR-RAG also produced the safest nonurgent queue in terms of hidden high-risk patients: among patients predicted as nonurgent, the proportion with R1+R2 outcomes was 6/83 (7%) for MECR-RAG, compared with 13/91 (14%) for nurses and 8/74 (11%) for the baseline LLM. immediate groups were correspondingly enriched for high-severity outcomes, with 47/47 (100%) R1+R2 for nurses, 56/56 (100%) for MECR-RAG, and 82/86 (95%) for the baseline LLM. These patterns suggest that MECR-RAG reduces undertriage of R2 patients into the lowest-priority stream while preserving a clear outcome-based risk gradient across immediate, urgent, and nonurgent groups.

As a complementary summary of mis-triage burden, we constructed a weighted harm index that assigns higher cost to more dangerous errors: R1 assigned to nonurgent (categories 4 and 5) was weighted as 5, R2 assigned to nonurgent as 2, and R3 assigned to immediate or urgent (categories 1-3) as 1. Across the 226 cases with outcome labels, initial nurse triage accumulated a weighted error sum of 44 (harm index 19.47 per 100 patients), the baseline LLM 46 (20.35 per 100 patients), and MECR-RAG 31 (13.72 per 100 patients). At the individual case level, the baseline LLM incurred higher harm scores than MECR-RAG in 19 discordant cases and lower scores in 6, with 201 ties (2-sided sign test *P*=.02), indicating a statistically significant net reduction in weighted harm with MECR-RAG. Compared with nurses, harm scores were lower for MECR-RAG in 14 cases and higher in 8 (204 ties; *P*=.29), suggesting a numerically favorable but underpowered difference. Overall, these outcome-based analyses indicate that MECR-RAG not only improves high-severity sensitivity and reduces R2 undertriage but also yields the lowest aggregate mis-triage burden when accounting for both the direction and severity of errors.

To test robustness to alternative definitions of clinical severity, we repeated binary analyses under classic and augmented outcome "lenses" that defined outcome+ using R1 alone, R1 combined with the DSC, and R1 or R2 combined with the composite (see Methods). Across all lenses, MECR-RAG consistently showed the most favorable trade-off between sensitivity and specificity, with the highest DORs and positive likelihood ratios compared with nurses and the baseline LLM. In a classic Manchester-style lens (outcome+=R1 only; test+=categories 1-2 vs 3-5), all 3 systems achieved perfect sensitivity for R1 cases, but MECR-RAG improved specificity relative to the baseline LLM and approached nurse performance. When the DSC (unplanned ICU transfer within 72 hours, 72-hour revisit with admission, or death within 7 days) was incorporated into augmented lenses, MECR-RAG again maintained the highest discrimination despite wide and overlapping confidence intervals reflecting the small number of sentinel events. Full 2×2 tables, effect estimates, CIs and details for each lens are provided in Tables S4-S7 and Section B in Multimedia Appendix 1. Complementary exploratory analyses, including subgroup performance stratified by age and sex and model behavior on adjudicated disagreement cases, are reported in Sections C and D in Multimedia Appendix 1.

Component-Wise Ablation of Retrieval Mechanisms

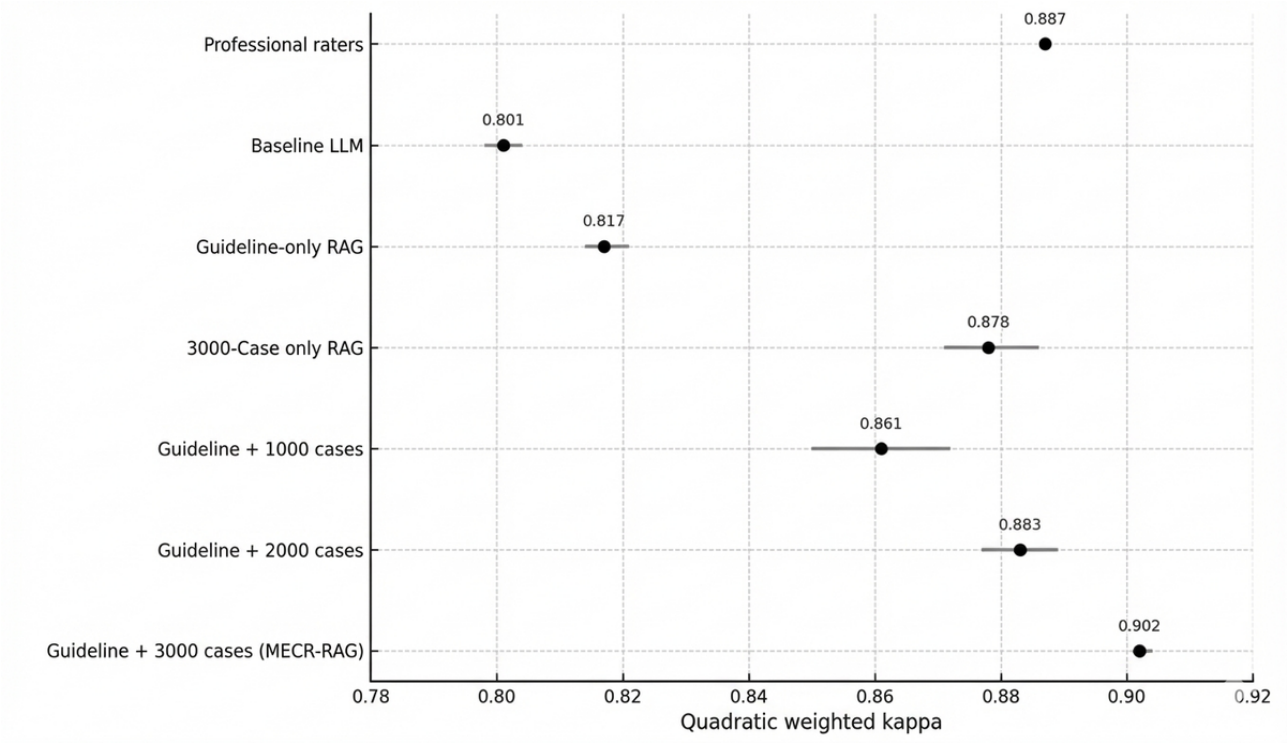
To assess the contribution of individual retrieval components, we conducted a component-wise ablation across four configurations: (1) a prompt-only baseline LLM without retrieval, (2) a guideline-only RAG model retrieving sections from the HKAETG, (3) a case-only RAG model retrieving similar past triage cases, and (4) the full MECR-RAG system combining both guideline and case retrieval. Each configuration used an identical preprocessing and generation pipeline and was evaluated over 5 independent runs. QWK was the primary outcome, with overall accuracy, macrolevel precision, and macrolevel recall as secondary metrics.

Across configurations, MECR-RAG achieved the highest agreement with expert consensus (mean QWK 0.902, SD 0.0021; 95% CI 0.901-0.904; accuracy 0.802, SD 0.0082), followed by the case-only model, then the guideline-only model, and finally the baseline LLM. Both guideline-based and case-based retrieval improved performance relative to the baseline, but their combined use in MECR-RAG produced the largest and most consistent gains. Friedman tests on QWK and accuracy across the 4 models were statistically significant, and

XSL•FO
RenderX

post hoc Nemenyi comparisons identified MECR-RAG as the only configuration with a statistically superior rank to the baseline LLM under conservative multiple-comparison control. Full numerical results are shown in Figure 5 (QWK) and Figure 6 (accuracy) and are detailed in Table S8 in Multimedia Appendix 1.

Figure 5. Quadratic weighted kappa performance of model variants and professional raters. LLM: large language model; MERC-RAG: Multi-Evidence Clinical Reasoning retrieval-augmented generation; RAG: retrieval-augmented generation.



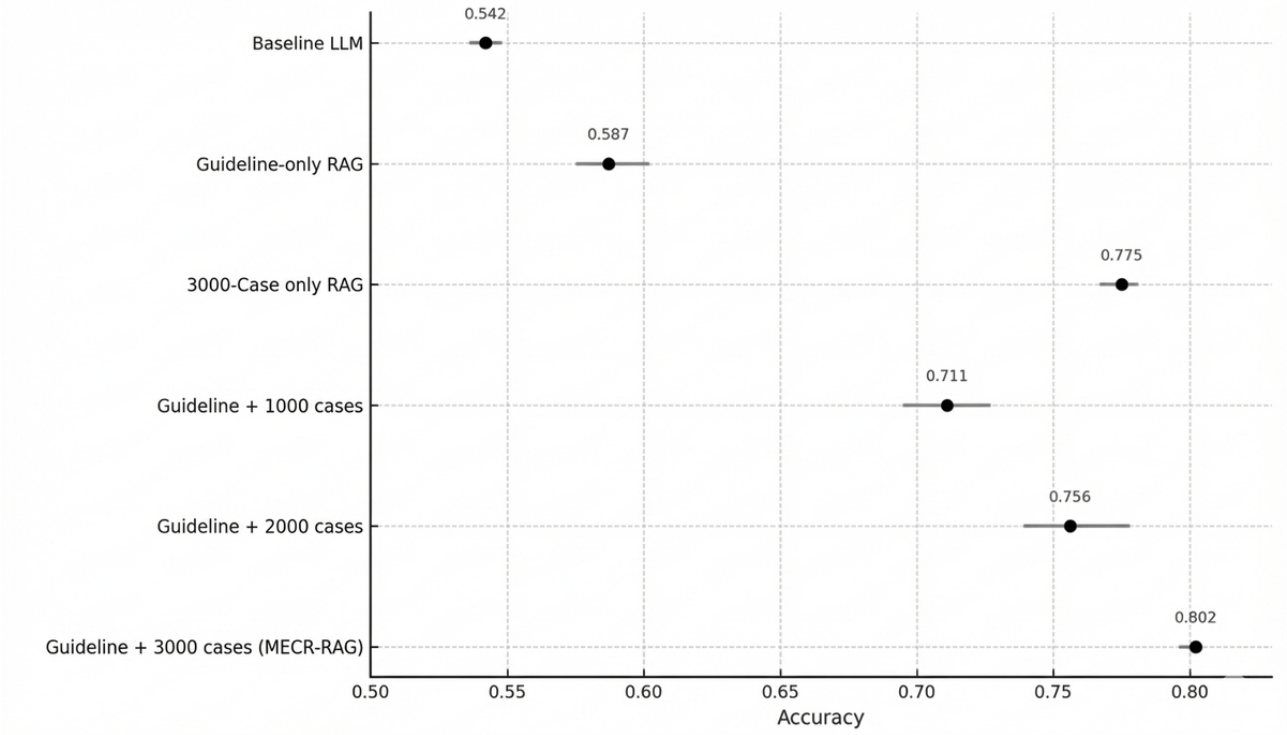


Figure 6. Accuracy performance across model variants. LLM: large language model; MERC-RAG: Multi-Evidence Clinical Reasoning retrieval-augmented generation; RAG: retrieval-augmented generation.

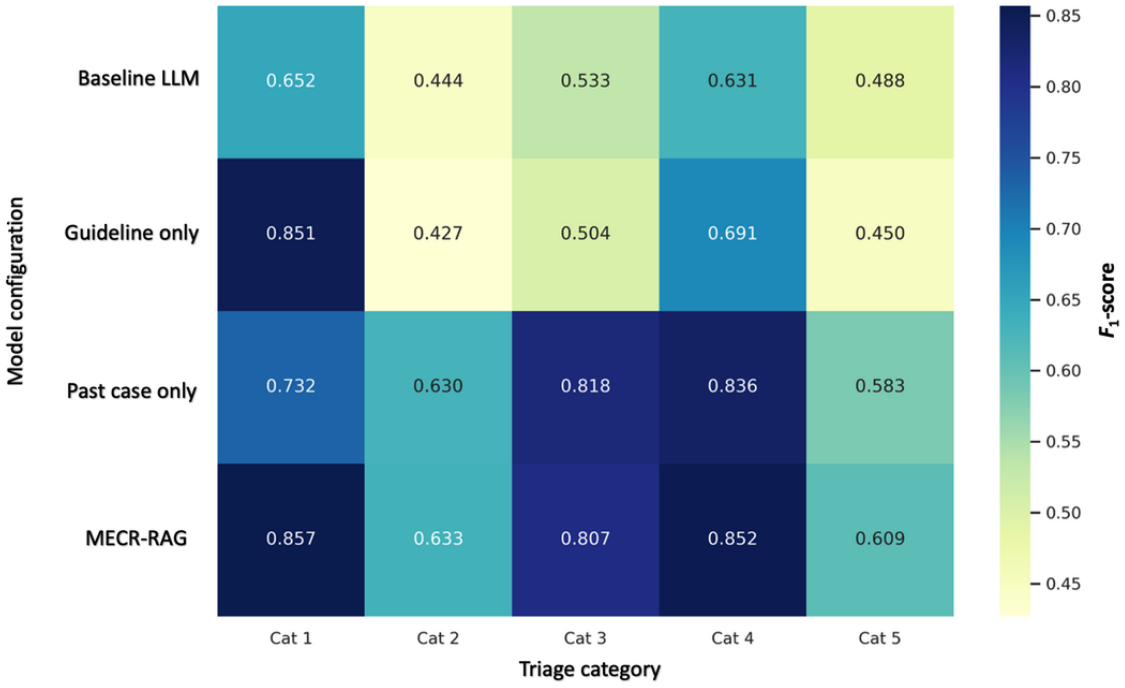


To understand how retrieval affected different acuity levels, we examined per-category accuracy and F_1-scores for triage categories 1-5. Guideline retrieval contributed most strongly to category 1 (critical) performance, where the guideline-only model achieved the highest accuracy and F_1-score, consistent with the value of structured, rule-based protocols for recognizing

XSL•FO
RenderX

life-threatening presentations. In contrast, case retrieval had the largest impact on categories 3 and 4, where the case-only and MECR-RAG models substantially outperformed both the baseline and guideline-only configurations, reflecting the importance of experiential pattern recognition in diagnostically ambiguous, midacuity presentations. For categories 2 and 5, model differences were smaller and not statistically robust, although MECR-RAG generally retained the highest F_1-scores. Overall, MECR-RAG delivered the best balance of precision and recall across all categories, supporting the complementary value of combining guideline-based and case-based retrieval (Figure 7; detailed estimates in Table S9 in Multimedia Appendix 1).

Figure 7. Component-wise ablation analysis of model performance across triage categories. LLM: large language model; MERC-RAG: Multi-Evidence Clinical Reasoning retrieval-augmented generation.

As an exploratory scaling analysis, we also varied the size of the past-case retrieval database from 1000 to 3000 cases and observed monotonic gains in QWK and accuracy with reduced between-run variability at larger retrieval pools (Tables S3 and S10 in Multimedia Appendix 1).

In Figure 5, the mean QWK values with 95% CIs are shown for the baseline and retrieval-augmented model variants. Points represent mean QWK across 5 stochastic runs, and horizontal error bars indicate 95% CIs across these runs. The professional benchmark (QWK 0.887) reflects interrater agreement between 2 expert triage nurses. The figure includes both ablation variants—a guideline-only RAG model and a 3000-case-only RAG model—and scaling variants that combine guideline and past case retrieval with databases containing 1000, 2000, and 3000 past triage cases. The MECR-RAG model (guideline plus 3000 past cases) achieved the highest mean QWK and was statistically superior to the baseline prompt-only large language model (LLM; mean paired difference 0.101, SD 0.0058; 95% CI 0.097-0.106; P<.001), while demonstrating noninferior agreement compared with professional raters.

In Figure 6, the mean accuracy values with 95% CIs are shown for the baseline prompt-only LLM, RAG variants, and combined retrieval configurations. The x-axis shows accuracy, with points representing mean values across 5 stochastic runs and horizontal error bars indicating 95% CIs. The figure includes ablation variants (guideline-only and 3000-case-only RAG) and scaling variants that combine guideline retrieval with 1000, 2000, or 3000 past cases. The MECR-RAG configuration (guideline plus 3000 past cases) achieved the highest accuracy and demonstrated a statistically significant improvement compared with the baseline LLM.

F_1-scores for each triage category (categories 1-5) across 4 model configurations. Rows represent the baseline prompt-only LLM, a guideline-only RAG model, a 3000-case-only RAG model, and the MECR-RAG system, and columns represent triage categories. Values reflect outputs from the median-performing evaluation run. Guideline retrieval contributed most prominently to performance in category 1, while case retrieval improved performance in categories 3 and 4, where patient presentations are more heterogeneous and require contextual interpretation. The MECR-RAG system generally achieved the highest or near-highest F_1-scores across triage categories, illustrating the additive value of combining structured guideline knowledge with experiential case-based retrieval.

XSL•FO
RenderX

Generalizability Across LLM Architectures

The primary model used for all prior evaluations was DeepSeek-V3. To evaluate whether the MECR-RAG framework generalizes beyond this development model, we conducted exploratory assessments using 2 additional foundation models: Claude 3.7 and GPT-4o. Each model was tested on the same 236-case triage dataset with the same 3000-case retrieval database under 2 configurations: the MECR-RAG system and a baseline, prompt-only LLM without retrieval augmentation.

In these single-run evaluations, MECR-RAG consistently outperformed the corresponding baseline configuration. For Claude 3.7, QWK improved from 0.840 under the baseline to 0.890 with MECR-RAG. Similarly, GPT-4o achieved a QWK of 0.890 with MECR-RAG, compared with 0.778 without retrieval. Although these results are based on single inference runs and are not statistically powered for formal comparison, they provide preliminary evidence that the dual-source retrieval framework may confer similar relative gains across distinct LLM back ends. A detailed breakdown of model predictions versus consensus triage labels for Claude 3.7 and GPT-4o, under both MECR-RAG and baseline conditions, is provided in Figures S1 and S2 in Multimedia Appendix 1, respectively.

Taken together, these preliminary findings suggest that the benefits of dual-source retrieval generalize beyond DeepSeek-V3 and may confer cross-model robustness of MECR-RAG across LLMs from different developers, supporting its broader applicability in diverse clinical settings. Further benchmarking across a wider range of model families, input formats, and deployment environments is warranted to validate robustness and assess trade-offs in latency, interpretability, and resource efficiency for real-world clinical deployment.

Discussion

Principal Findings

This retrospective evaluation suggests that a dual-source, retrieval-augmented LLM can achieve expert-comparable agreement with consensus nurse triage labels while substantially outperforming a prompt-only baseline model. MECR-RAG improved QWK and accuracy over the baseline LLM under both the 5-level and 3-group schemas and met prespecified noninferiority criteria compared with professional triage nurses. The largest gains occurred in Categories 3 and 4 and in the urgent versus nonurgent grouping, which together accounted for most ED visits and are operationally dominant, with large differences in waiting times. Ablation analyses indicated that both guideline retrieval and case retrieval contributed to performance, with the full dual-source MECR-RAG configuration consistently outperforming guideline-only and case-only variants. Performance also improved as the retrieval database increased from 1000 to 3000 cases, suggesting that retrieval quality benefits from a richer case pool. Exploratory cross-model experiments with Claude 3.7 Sonnet and GPT-4o further suggested that these benefits generalize across different LLM back ends.

Ground Truth Validity and Construct Interpretation

In this study, the primary reference standard was expert nurse consensus at the time of presentation, which reflects routine clinical decision-making but is an imperfect proxy for underlying acuity. Large US data on ESI version 4 report mis-triage in 32.2% of encounters (3.3% undertriage and 28.9% overtriage), underscoring that nurse-level labels are imperfect proxies for “true” acuity [17]. Even with trained emergency staff, approximately 17% of triage assignments may be inaccurate [21]. To address these limitations, we complemented consensus labels with outcome-informed constructs, ordinal severity tiers (R1-R3) and a DSC, adapted from MTS validation work and recommendations on triage outcome selection [15,22,24].

Within these outcome-based frameworks, MECR-RAG showed higher sensitivity for R1+R2 courses than initial nurse triage at comparable specificity, reduced misclassification of R2 patients into the nonurgent stream, and yielded the lowest weighted harm index, suggesting closer alignment between assigned urgency and downstream clinical course. At the same time, event counts for the most severe outcomes were modest, and both nurse consensus and the composite outcomes remain pragmatic proxies rather than definitive measures of “true” severity. We therefore interpret these findings as supportive evidence that MECR-RAG performs well against clinically grounded, outcome-informed constructs of acuity, rather than as proof that it fully captures an underlying severity state.

Comparison With Prior Work

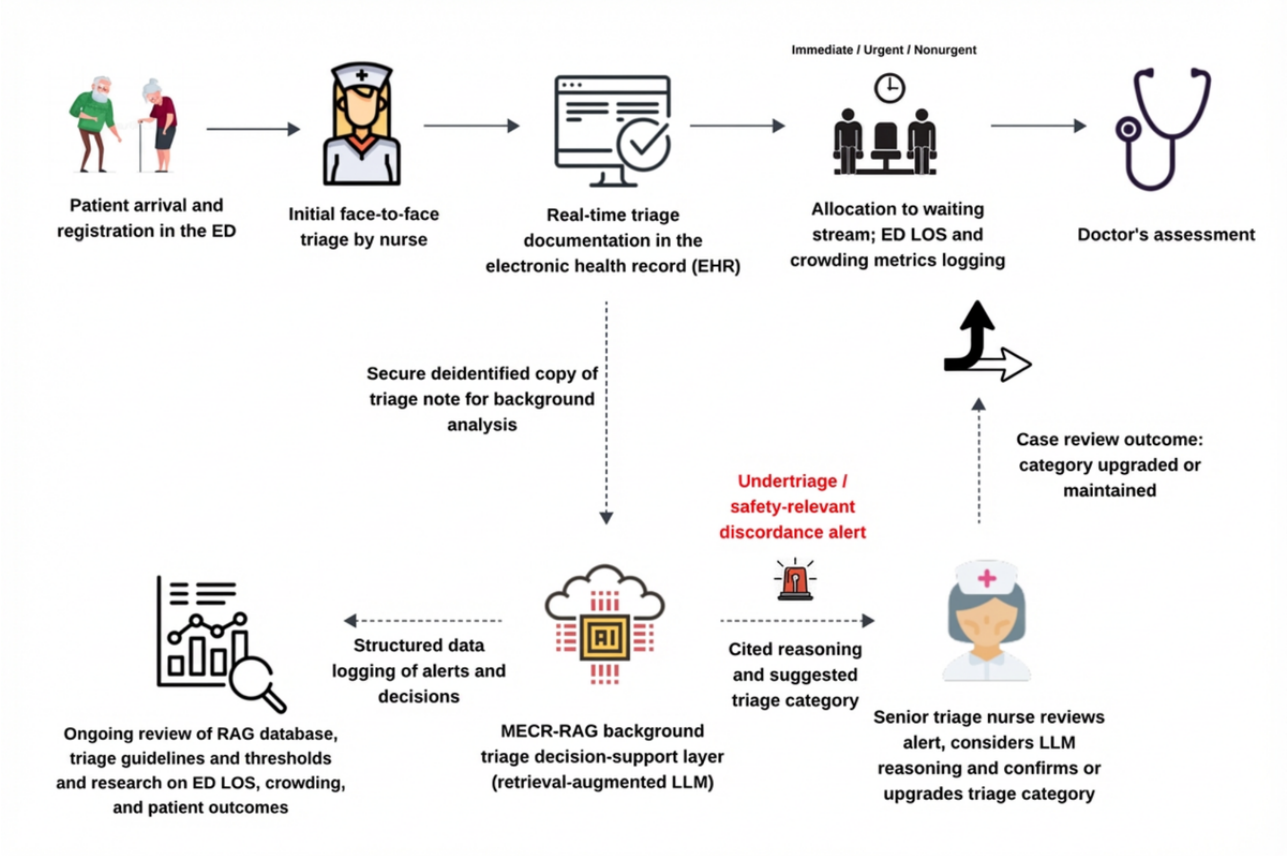
To our knowledge, this is the first study to evaluate a dual-source, RAG-enhanced LLM for emergency triage using raw triage documentation paired with expert-consensus reference labels and complementary outcome-informed severity constructs. Prior RAG studies in emergency care have shown that retrieval can improve triage or referral performance on simulated exam-style cases or curated ED datasets but have relied on structured scenarios or routine triage labels without independent adjudication [13,14]. Our design addresses the broader evidence gap noted in a recent systematic review, in which only 5% of 519 published evaluations of health care LLMs used real patient care data for testing [25]. This provides a more realistic and stringent test of RAG-enhanced triage than has been reported previously.

Masanneck et al [4] established an early benchmark by evaluating LLM triage performance against expert assessments, but their dataset consisted of physician-curated vignettes from a single day, with selected patient attributes adjusted according to predefined standard operating procedures. In contrast, our study applies dual-source RAG to a year-long sample of anonymized triage notes without manual editing or reinterpretation, preserving the fidelity of frontline documentation and temporal variation. Zaboli et al [3] and Paslı et al [7] have likewise emphasized the importance of handling unstructured narratives and integrating local triage frameworks; our dual-retrieval design directly addresses these needs by combining structured guideline content with real-world case patterns.

XSL•FO
RenderX

Our findings also align with broader work on nurse triage systems, showing that midacuity presentations are both the most common and the most difficult to classify. In a large cohort of over 5.3 million adult ED encounters using ESI version 4, Sax et al [17] found that approximately 29% of visits were overtriaged and that the sensitivity of ESI version 4 for identifying low-acuity, low-resource patients (correctly assigning ESI 4-5 among patients using <2 resources and with no critical interventions) was only 50%. A majority of encounters were assigned to the midlevel category ESI 3, highlighting poor differentiation between lower- and higher-acuity patients. Validation of the HKAETG has similarly shown the lowest interrater agreement for categories 3 and 4, reflecting the intrinsic difficulty of distinguishing "urgent" from "semiurgent" presentations [26]. In our cohort, categories 3 and 4 comprised about three-quarters of all cases, and the prompt-only LLM reproduced the overtriage patterns documented in both human and LLM triage studies. In contrast, MECR-RAG substantially reduced overtriage and improved precision and recall specifically in these mid- and low-acuity strata, suggesting that dual-source retrieval may help address a long-standing bottleneck in emergency triage performance.

Clinical and Operational Implications



Although we did not directly measure ED length of stay (LOS), boarding, or mortality, several findings suggest how MECR-RAG could plausibly influence safety and flow if implemented as decision support. Under a 3-group schema (immediate, urgent, and nonurgent), MECR-RAG achieved higher agreement and accuracy than the prompt-only LLM, with markedly less overtriage and similarly low undertriage. Gains were concentrated in the urgent and nonurgent tiers, which dominate the case mix and are associated with substantially longer waits for lower-priority patients at our center. In outcome-based analyses, MECR-RAG showed higher sensitivity for R1+R2 courses than initial nurse triage at nurse-level specificity, reduced misclassification of R2 patients into the nonurgent stream, and yielded the lowest severity-weighted harm index. Together, these patterns indicate fewer high-risk patients "hidden" in the longest-wait queue and fewer low-risk patients unnecessarily occupying high-acuity resources, aligning urgency assignments more closely with downstream clinical course.

These redistributions of risk are clinically relevant because prolonged ED LOS, crowding, and boarding have been repeatedly linked to delayed treatment, longer inpatient stays, and higher short-term mortality. More efficient separation between urgent and nonurgent queues could, in principle, help decompress monitored areas, reduce avoidable time in high-acuity spaces for low-risk patients, and support more timely care for those with high-severity courses. However, our evaluation was retrospective and did not include LOS, crowding, or mortality as prespecified end points. Any potential contribution of MECR-RAG therefore remains hypothesis-generating and must be tested in prospective, outcome-focused studies.

As illustrated in the proposed human-in-the-loop workflow (Figure 8), MECR-RAG is intended to function as a background triage decision-support layer: triage nurses retain primary responsibility for assigning categories, while a secure, deidentified copy of the triage note is analyzed in parallel, with the system remaining silent for most encounters and surfacing alerts only for predefined safety-relevant discordances (eg, potential undertriage of urgent or immediate cases). Alerts and explanations can then be reviewed by a senior nurse, who may confirm or upgrade the triage category, while all alerts, decisions, and associated operational metrics are logged to support ongoing quality assurance and research on ED LOS, crowding, and downstream outcomes. A staged implementation strategy, beginning with shadow-mode deployment and progressing to focused pilots of discordance alerts with monitoring for automation bias, alert fatigue, throughput, and equity, will be essential before wider rollout.

XSL•FO
RenderX

Figure 8. Conceptual human-in-the-loop workflow for Multi-Evidence Clinical Reasoning retrieval-augmented generation as a background triage decision-support layer in the emergency department. ED: emergency department; LLM: large language model; LOS: length of stay; MECR-RAG: Multi-Evidence Clinical Reasoning retrieval-augmented generation; RAG: retrieval-augmented generation.

Patients follow the routine care pathway shown in the top row: arrival and registration in the ED, initial face-to-face triage by a nurse, real-time triage documentation in the electronic health record, allocation to an urgency-based waiting stream (immediate, urgent, or nonurgent) with logging of ED LOS and crowding metrics, and subsequent doctor's assessment. In parallel, a secure deidentified copy of the triage note is sent to the MECR-RAG system, which operates as a background triage decision-support layer. MECR-RAG generates its own triage recommendation with cited reasoning and remains silent for most encounters, but triggers an undertriage or other safety-relevant discordance alert when its recommendation conflicts with the nurse-assigned category. Alerts and explanations are routed to a senior triage nurse, who may confirm or upgrade the triage category; all alerts, decisions, and outcomes are logged to support ongoing quality assurance and research on ED LOS, crowding, and patient-centered outcomes.

Limitations and Future Directions

This study has several important limitations. First, within the staged evaluation pathway outlined by DECIDE-AI (Developmental and Exploratory Clinical Investigations of Decision support systems driven by Artificial Intelligence), this retrospective, offline prediction study represents preclinical (in silico) validation and should not be interpreted as evidence of real-world clinical effectiveness or safety [27]. Moreover, strong offline discrimination does not reliably translate into clinical benefit after implementation; prior early warning and sepsis tools (including the Rothman Index and the Epic Sepsis Model) have shown materially weaker performance and limited impact in independent, postdeployment evaluations, partly due to differences in data quality, missingness, case mix, alert logic, and workflow across sites [28-32]. Retrospective deep learning models are also vulnerable to dataset shift, class imbalance, and missing data, further limiting transportability across settings and time [33]. Randomized evaluations of AI-enabled interventions similarly suggest that even high-performing models may fail to improve primary clinical end points without careful workflow integration and attention to system constraints [34,35]. Accordingly, our retrospective, single-center results for MECR-RAG should be viewed as predeployment evidence and require prospective, multicenter evaluation before inferring equivalent real-time performance or improved patient outcomes.

Second**,** the evaluation was conducted in a single ED using the HKAETG; performance may differ under other triage frameworks (eg, MTS and ESI), languages, documentation practices, workflows, and patient case mix. Although the retrieval-augmented design is modular and could, in principle, be adapted by reindexing local guidelines and locally representative triage notes without retraining the underlying LLM, portability remains an empirical question and requires external validation and prospective multicenter evaluation.

Third, the retrieval database and text summaries were constructed automatically from routine triage notes without manual adjudication, and prompts were generated without clinician editing. This reflects realistic deployment conditions and improves scalability, but some retrieved exemplars may be

XSL•FO
RenderX

mislabeled or incomplete, and clinically relevant nuances may be lost during summarization. In addition, we did not directly evaluate usability, interpretability, automation bias, or workflow impact, which are increasingly recognized as critical determinants of the safety and effectiveness of AI-enabled clinical decision-support systems [32,36].

These limitations point to clear priorities for future work. Prospective, multicenter studies across institutions using different triage frameworks (HKAETG, MTS, and ESI) are needed to assess generalizability and to determine how MECR-RAG performs in real-time workflows. Consistent with DECIDE-AI and recent guidance from major journals and professional societies, future evaluations should move beyond agreement metrics to prespecify patient-centered and operational end points, including ED and hospital LOS, crowding and boarding times, unexpected ICU transfer, time-critical treatment delays, and short-term mortality [18,37-39]. Implementation-focused studies should also examine how MECR-RAG is integrated into practice (eg, as a second reader or discordance alert), its effects on clinician behavior, workload, and equity, and unintended consequences such as alert fatigue or overreliance on model outputs, ideally using pragmatic randomized or quasi-experimental designs where feasible [34,35]. Framing this work as an early-phase evaluation and explicitly outlining the need for prospective, outcome-focused trials in line with current AI evaluation guidance positions MECR-RAG as a promising candidate for further study rather than a tool ready for immediate widespread deployment.

Conclusions

In summary, this retrospective, single-center study provides one of the first evaluations of a dual-source, retrieval-augmented LLM for emergency triage on real triage notes with expert consensus labels, extending prior work beyond simulated scenarios and routine labels. MECR-RAG achieved agreement comparable to expert nurses and clearly outperformed a prompt-only LLM, particularly in the high-volume category 3-4 bands, while approximately halving overtriage and keeping undertriage very low. In exploratory outcome-based analyses within this cohort, MECR-RAG also showed higher sensitivity for high-severity courses, a safer nonurgent queue, and the lowest severity-weighted harm index compared with initial nurse triage. These findings support the potential of retrieval-augmented LLMs as clinically coherent decision-support tools that function as background second readers—surfacing guidelines and analogous cases, flagging discordant or high-risk assignments for senior review—and thereby potentially improving allocation of high-acuity resources in ways that could, if replicated prospectively, help reduce ED crowding, LOS, and related adverse outcomes. However, this remains an early-phase, retrospective, single-center evaluation based on proxy outcomes, and rigorous prospective multicenter studies across different triage frameworks, with prespecified patient-centered and operational end points and careful attention to workflow, usability, and equity, are essential before such systems can be recommended for routine clinical deployment.

Acknowledgments

We would like to thank KH Leung for organizing and facilitating the consensus triage labeling process. We are also grateful to the emergency department nursing staff at Princess Margaret Hospital for their triage assessments, which formed the basis of the clinical documentation used in this study.

Funding

No external financial support or grants were received from any public, commercial, or not-for-profit entities for the research, authorship, or publication of this article.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to institutional and regulatory restrictions imposed by the Hospital Authority of Hong Kong, but are available from the corresponding author on reasonable request. The underlying code supporting the findings of this study is available at MECR-RAG-Clinical-Research [40].

Authors' Contributions

HS conceptualized the study design, developed the methodology, collected and curated the data, performed the analysis, created the figures, and drafted the initial manuscript. TK developed the computational architecture, configured the model framework, implemented and executed the MECR-RAG system.

Conflicts of Interest

None declared.

Abstract

Background: Venous thromboembolism (VTE) is a common and severe complication in intensive care unit (ICU) patients with sepsis. Conventional risk stratification tools lack sepsis-specific features and may inadequately capture complex, nonlinear interactions among clinical variables.

Objective: This study aimed to develop and validate an interpretable machine learning (ML) model for the early prediction of VTE in ICU patients with sepsis.

Methods: This multicenter retrospective study used data from the Medical Information Mart for Intensive Care IV database for model development and internal validation, and an independent cohort from Changshu Hospital for external validation. Candidate predictors were selected through univariate analysis, followed by least absolute shrinkage and selection operator regression. Retained variables were used in multivariable logistic regression to identify independent predictors, which were then used to develop 9 ML models, including categorical boosting, decision tree, k-nearest neighbor, light gradient boosting machine, logistic regression, multilayer perceptron, naive Bayes, random forest, and support vector machine. Performance was evaluated by discrimination (area under the curve [AUC]), calibration, and clinical use (decision curve analysis). A subgroup analysis stratified by the Sequential Organ Failure Assessment score was conducted in the external cohort to assess model stability across sepsis severity levels. Model interpretability was assessed using Shapley Additive Explanations (SHAP) to quantify the contribution of features to the predicted risk.

Results: A total of 25,197 patients from the Medical Information Mart for Intensive Care IV cohort and 328 patients from the external cohort were included, with VTE incidences of 844 out of 25,197 (3.4%) and 30 out of 328 (9.2%), respectively. The light gradient boosting machine model performed best, achieving an AUC of 0.956 in internal validation. Despite the higher VTE incidence and clinical severity in the external validation, the model maintained robust generalization with an AUC of 0.786. Notably, the model achieved enhanced discriminative ability in the severe sepsis subgroup (Sequential Organ Failure Assessment score >6) with an AUC of 0.816, compared with 0.769 in the mild to moderate sepsis subgroup. Calibration curves indicated strong agreement between predicted and observed outcomes, and decision curve analysis showed superior net benefit across clinically relevant thresholds. SHAP analysis identified central venous catheterization, serum chloride and bicarbonate levels, arterial catheterization, and prolonged partial thromboplastin time as the most influential predictors. Partial dependence plots revealed both linear and nonlinear associations between these variables and VTE risk. Individual-level force plots further enhanced interpretability by visualizing personalized risk profiles.

Conclusions: We developed a high-performing and interpretable ML model for predicting VTE in ICU patients with sepsis. The model demonstrated robustness across cohorts and enhanced performance in the severe sepsis population. By integrating

XSL•FO
RenderX

diverse clinical data and leveraging SHAP for transparent explanations, this tool may support personalized prophylaxis and early diagnostic strategies.

Introduction

Sepsis is a life-threatening condition characterized by acute organ dysfunction resulting from a dysregulated host response to infection and remains a leading cause of mortality in the intensive care unit (ICU) [1]. According to the Global Burden of Disease Study, approximately 48.9 million cases of sepsis occur annually worldwide, resulting in an estimated 11.0 million deaths, which accounts for 19.7% of all global deaths [2]. Venous thromboembolism (VTE), comprising deep vein thrombosis and pulmonary embolism (PE), is a common and severe complication of sepsis that significantly worsens patient outcomes. Despite adherence to guideline-recommended thromboprophylaxis, the incidence of VTE in patients with sepsis remains high at 37.2%, up to 10-fold greater than in ICU populations with no sepsis [3]. Previous studies have shown that the presence of VTE is associated with a 28-day mortality rate of 28.6% among patients with sepsis, and the occurrence of PE nearly doubles the risk of in-hospital death (odds ratio [OR] 1.94) [4,5]. These findings underscore the urgent need for early and accurate VTE risk stratification in sepsis to guide timely clinical interventions and reduce morbidity and mortality in this high-risk population.

Current clinical methods for predicting VTE in patients with sepsis have notable limitations. Traditional biomarkers such as D-dimer, although widely used, lack specificity in the context of sepsis, as the condition itself activates coagulation pathways and elevates fibrin degradation products [6,7]. Furthermore, commonly used scoring systems such as the Wells and Autar scores were primarily developed and validated in trauma or postoperative populations. These tools do not account for sepsis-specific indicators, such as the Sequential Organ Failure Assessment (SOFA) score or lactate levels, thereby limiting their predictive use in patients with sepsis [8-10]. Although multivariable logistic regression (LR) models that incorporate clinical and laboratory variables have shown promise, with reported area under the curve (AUC) values reaching up to 0.87, these models are inherently linear and may fail to capture the complex and nonlinear interactions among sepsis-related risk factors [11,12].

Machine learning (ML) techniques have emerged as powerful tools for handling high-dimensional data, uncovering nonlinear associations, and automating feature selection. In recent years, ML models have demonstrated superior performance in predicting complications such as septic shock and acute kidney injury (AKI) in ICU patients, with reported AUC values reaching up to 0.90 [13-15]. However, earlier generations of ML models often functioned as “black boxes,” which limited their adoption in clinical settings due to the lack of interpretability. Explainable ML approaches, such as Shapley Additive Explanations (SHAP), have been developed to address this challenge. By quantifying the contribution of each feature, SHAP enhances model transparency and facilitates clinical understanding [16]. For instance, Liu et al [17] developed an interpretable ML model for septic shock prediction, whose explanatory outputs aligned closely with hemodynamic mechanisms described in the Sepsis-3 guidelines, thereby reinforcing its clinical relevance [18].

Therefore, this study aimed to develop an interpretable ML model that integrates clinical features and laboratory indicators to predict the risk of VTE in ICU patients with sepsis. By applying SHAP to interpret model outputs and identify key predictors, we sought to create a decision support tool that combines high predictive accuracy with strong clinical interpretability, ultimately facilitating personalized prevention strategies.

Methods

Data Sources

The training and internal validation datasets were extracted from the Medical Information Mart for Intensive Care IV version 3.0 (MIMIC-IV v3.0) database, which contains comprehensive and high-quality data from 65,366 patients admitted to the ICU at Beth Israel Deaconess Medical Center between 2008 and 2022. One of the authors (YZ) completed the Collaborative Institutional Training Initiative examination (record ID: 60227322) and was granted access to the database for research purposes.

Ethical Considerations

Ethical approval for the use of MIMIC-IV data was granted by the institutional review boards of Beth Israel Deaconess Medical Center and the Massachusetts Institute of Technology, with a waiver of informed consent due to the use of deidentified data. The data were handled in accordance with the Health Insurance Portability and Accountability Act standards to ensure patient privacy and confidentiality. In addition, ICU patients admitted to Changshu Hospital affiliated to Soochow University between January 2019 and August 2024 were included as an external validation cohort. Ethical approval for this component of the study was obtained from the ethics review committee of Changshu Hospital (number L2024055). As the study was observational in nature and used routinely collected clinical data, the requirement for written informed consent was waived. All electronic data were anonymized before analysis, and access to the dataset was restricted to the primary research team to maintain strict confidentiality. All procedures conformed to the ethical standards set forth in the Declaration of Helsinki. No compensation was provided to any participants involved in this study.

RenderX

Study Population

This study included adult ICU patients (aged 18 years and older) with sepsis. For patients with multiple ICU admissions, only the first admission was analyzed. Sepsis was defined according to the Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3), which require a suspected or confirmed infection accompanied by an increase in the SOFA score of 2 points or more [18]. VTE was defined as an acute episode of deep vein thrombosis (either upper or lower extremities), superficial vein thrombosis (either upper or lower extremities), or PE. VTE diagnoses were identified based on either the *ICD-9* (*International Classification of Diseases, Ninth Revision*; codes 45119, 4512, 45181, 45182, 45183, 45184, 45189, 4519, 4532, 4538, 45381, 45382, 45383, 45384, 45385, 45386, 45387, 45389, 4539, 4150, 41511, 41512, 41513, 41519, 45340, 45341, 45342, 4510, 452, 4530, 4531, and 4533) or the *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*; codes I808, I809, I8290, I82890, I2699, I2692, I2690, I2602, I2609, I8000, I8001, I8002, I81, I820, and I821) in the MIMIC-IV database, or through diagnostic imaging reports from Changshu Hospital, including duplex venous ultrasonography and contrast-enhanced computed tomography. In the Changshu Hospital cohort, the ICU implemented a routine lower limb venous ultrasound screening protocol for all patients with sepsis meeting high-risk criteria. Patients were excluded meeting any of the following criteria: (1) ICU stay of less than 24 hours, (2) a documented VTE diagnosis prior to sepsis onset, and (3) VTE events occurring within 24 hours following the sepsis diagnosis.

Patients from the MIMIC-IV cohort were randomly split into a training set and an internal validation set in a 7:3 ratio. The training set was used for variable selection and model development, while the internal and external validation sets were used to assess model performance. The overall study workflow is illustrated in Figure 1.

Figure 1. Flowchart of patient enrollment and cohort selection. Data Extraction and Processing

Data from the MIMIC-IV database were extracted using Structured Query Language via pgAdmin 4 (version 6.21; pgAdmin Development Team). All clinical and laboratory variables were collected within the first 24 hours of ICU admission, with only the initial measurement included for variables with multiple readings. A set of variables was extracted for each patient, encompassing (1) demographics: age (years), sex, race (Asian, Black, White, Hispanic, and other), height (cm), weight (kg), BMI (kg/m^2), and insurance (Medicare or other); (2) vital signs: heart rate (HR, times per minute), respiratory rate (RR, times per minute), systolic blood pressure (mm Hg), diastolic blood pressure (mm Hg), temperature (°C), and oxygen saturation (SpO_2, %); (3) severity scores: Glasgow Coma Scale, SOFA score, and simplified acute physiology score II (SAPS II); (4) laboratory data: white blood cell count (K/μL), hemoglobin (g/dL), platelet (PLT, K/μL), C-reactive protein (mg/dL), alanine aminotransferase (U/L), aspartate aminotransferase (U/L), albumin (g/dL), creatinine (mg/dL), sodium (mEq/L), potassium (mEq/L), chloride (mEq/L), calcium (mg/dL), blood urea nitrogen (mg/dL), hematocrit (%), glucose (mg/dL), international normalized ratio, prothrombin time (PT, seconds), partial thromboplastin time (PTT, seconds), pH, partial pressure of oxygen (PaO_2, mm Hg), partial pressure of carbon dioxide ($PaCO_2$, mm Hg), base excess (mEq/L), lactic acid (mEq/L), and bicarbonate (HCO_3^-, mEq/L); (5) ventilation parameters: positive end-expiratory pressure (PEEP, cmH_2O), fraction of inspired oxygen (FiO_2, %), and PEEP/FiO_2 ratio; (6) comorbidities: hypertension, diabetes, myocardial infarction (MI), chronic obstructive pulmonary disease (COPD), asthma, pancreatitis, acute respiratory failure (ARF), AKI, acute respiratory distress syndrome (ARDS), and malignant cancer; and (7) therapeutic interventions: arterial catheterization, central venous catheterization, cardiopulmonary bypass, continuous renal replacement therapy (CRRT), ventilation, heparin, aspirin, and vasopressors use. The same set of variables was extracted from the external validation cohort at Changshu Hospital affiliated with Soochow University, ensuring consistency between the datasets.

For missing data, variables with less than 5% missingness were imputed using mean substitution. For those with 5%-30% missing values, multiple imputation methods were used. Variables with more than 30% missing data were excluded from analysis to minimize bias and preserve model robustness. Outliers were identified and treated as missing values and subsequently handled using the same imputation strategies.

Statistical Analysis

All statistical analyses were performed using Stata software (version 16.0; StataCorp LLC), R software (version 4.1.2; R Foundation for Statistical Computing), DecisionLinnc (version 1.0; DecisionLinnc Corp), and Python (version 3.9.12; Python Software Foundation). The Kolmogorov-Smirnov test was used to assess the normality of continuous variables. Variables with a normal distribution were expressed as means and SDs, and group comparisons were conducted using the 2-tailed independent samples *t* test. Non–normally distributed variables were presented as median and IQR and analyzed using the Mann-Whitney *U* test. Categorical variables were summarized as counts (percentages) and compared using the chi-square test. Two-sided *P* values of <.05 were considered statistically significant.

Variable Selection and Model Development

Variables that showed statistically significant differences in the univariate analysis were considered candidate predictors. These variables were further refined using the least absolute shrinkage and selection operator regression to minimize overfitting and reduce multicollinearity. Predictors with nonzero coefficients were subsequently entered into a multivariate LR model. Independent predictors identified through this process were incorporated into the ML models.

Following variable selection, the Synthetic Minority Oversampling Technique (SMOTE) preprocessing algorithm was applied to address class imbalance between VTE and non-VTE cases in the training cohort. In the training cohort, VTE cases (576/17,637, 3.27%) were highly unbalanced compared with non-VTE cases (17,061/17,637, 96.73%). After SMOTE application, the VTE class was balanced to match the non-VTE class, resulting in a 50:50 distribution with a total of 34,122 samples used for model training. This oversampling method helped ensure that the models were trained on a balanced dataset, thereby improving their ability to detect minority class events. A total of 9 ML algorithms were trained on the development cohort, including categorical boosting (CatBoost), decision tree, k-nearest neighbor, light gradient boosting machine (LGBM), LR, multilayer perceptron, naive Bayes, random forest (RF), and support vector machine. For all ML models, we used a 5-fold cross-validation strategy, combined with Grid Search, for hyperparameter optimization and model selection. Notably, SMOTE was applied exclusively to the training folds of the cross-validation process to prevent data leakage into the validation folds or the internal validation set.

Model Evaluation and Interpretation

Model performance was assessed using the internal and external validation datasets. Discrimination was evaluated by plotting receiver operating characteristic curves and calculating the AUC. Calibration curves were used to compare predicted probabilities with observed outcomes. Clinical use was assessed using decision curve analysis, which estimated the net benefit across a range of probability thresholds. In addition, several evaluation metrics were computed, including accuracy, sensitivity, specificity, and the Youden index, to offer a comprehensive assessment of model performance.

The best performing model was selected based on comprehensive evaluation of these metrics. To assess the model's stability and performance in different risk populations, a stratified analysis was conducted on the external validation cohort based on the SOFA score. Patients were divided into 2 subgroups: mild to moderate sepsis (SOFA score ≤6) and severe sepsis (SOFA score >6). To enhance model interpretability, SHAP analysis was conducted. SHAP values were computed to quantify the contribution of individual features to the model's predictions and to explore feature interactions. Visualization

XSL•FO
RenderX

tools from the SHAP package in Python, including feature importance plots, bee swarm plots, force plots, and partial dependence plots (PDPs), were used to provide an intuitive understanding of the model's decision-making process.

Results

Baseline Characteristics

A total of 25,197 patients from the MIMIC-IV cohort and 328 patients from the external validation cohort were included in the study. Among them, 844 out of 25,197 (3.4%) patients in the MIMIC-IV cohort and 30 out of 328 (9.2%) patients in the external cohort developed VTE. The baseline characteristics of all patients are summarized in Table 1. In the MIMIC-IV cohort, patients who developed VTE were younger and exhibited significantly higher HRs and RRs than those with no VTE (all $P<.001$). Laboratory parameters revealed higher PLT counts, serum chloride levels, and PTT in the VTE group (all $P<.05$). In addition, patients with VTE had higher illness severity scores, as indicated by elevated SOFA and SAPS II scores (both $P<.05$). Comorbidities such as ARF, AKI, and ARDS were significantly more common in the VTE group (all $P<.001$). Furthermore, these patients were more likely to have undergone invasive procedures, including arterial and central venous catheterization (both $P<.001$). In the external validation cohort, similar patterns were observed. Patients with VTE demonstrated higher rates of ARDS and more frequent use of mechanical ventilation than patients with no VTE (both $P<.001$). These findings highlight significant differences in demographics, clinical severity, comorbidities, and therapeutic interventions between patients with and with no VTE across both cohorts, emphasizing the relevance of these factors in VTE risk stratification.

[cc]AKI: acute kidney injury.
[dd]ARDS: acute respiratory distress syndrome.
[ee]CPB: cardiopulmonary bypass.
[ff]CRRT: continuous renal replacement therapy.

Selection of Predictors

Patients in the training set were divided into VTE and non-VTE groups. Univariate analysis identified several variables significantly associated with VTE, including admission age, insurance, HR, RR, SAPS II, alanine aminotransferase, potassium, chloride, glucose, PTT, PaO_2, $PaCO_2$, PEEP, and comorbidities such as diabetes, MI, COPD, pancreatitis, ARF, AKI, and ARDS (all *P*<.05). In addition, therapeutic interventions including arterial catheterization, central venous catheterization, cardiopulmonary bypass, CRRT, heparin use, and aspirin use were significantly associated with VTE (all *P*<.05; Table 2). Least absolute shrinkage and selection operator regression identified 18 variables with nonzero coefficients at the optimal lambda value of 0.0029. These included age, insurance, HR, potassium, chloride, PTT, diabetes, MI, COPD, pancreatitis, ARF, AKI, ARDS, arterial catheterization, central venous catheterization, CRRT, heparin use, and aspirin use (Figures 2A and 2B). These variables were subsequently entered into a multivariate LR model, which revealed that potassium (OR 0.8711, 95% CI 0.7541-0.9756; *P*=.02), chloride (OR 1.0206, 95% CI 1.0081-1.0326; *P*=.001), PTT (OR 1.0086, 95% CI 1.0054-1.0115; *P*<.001), MI (OR 0.2851, 95% CI 0.1101-0.5999; *P*=.003), AKI (OR 1.5274, 95% CI 1.2166-1.9369; *P*<.001), arterial catheterization (OR 1.8985, 95% CI 1.4102-2.5648; *P*<.001), central venous catheterization (OR 2.0805, 95% CI 1.5213-2.8382; *P*<.001), and heparin use (OR 1.5509, 95% CI 1.1203-2.0851; *P*=.01) were independently associated with VTE risk (Table 3). We noted instances of complete separation in the training set for comorbidities such as diabetes and COPD, where the VTE subgroup contained zero cases, leading to extreme ORs in the multivariable LR.

Development and Validation of Models

All selected variables were incorporated into the development of 9 ML models to predict the risk of VTE in ICU patients with sepsis. The 9 ML models exhibited varying degrees of predictive performance in the training set (Figure 3A). Internal validation based on receiver operating characteristic curve analysis demonstrated that the LGBM model achieved the highest predictive performance (AUC=0.956), followed by CatBoost (AUC=0.924), RF (AUC=0.794), decision tree (AUC=0.704), k-nearest neighbors (AUC=0.673), multilayer perceptron (AUC=0.660), support vector machine (AUC=0.621), LR (AUC=0.621), and naïve Bayes (AUC=0.588; Figure 3B). Detailed performance metrics, including sensitivity, specificity, accuracy, precision, F_1-score, and AUC for each model, are shown in Table 4. Notably, the LGBM model exhibited the highest specificity (0.942), accuracy (0.910), precision (0.956), and F_1-score (0.921), consistently outperforming the other algorithms across these key evaluation indicators.

[j]SVM: support vector machine.

Calibration analysis revealed that the LGBM model demonstrated strong alignment between predicted probabilities and observed outcomes, reflecting robust reliability (Figure 4A). In the decision curve analysis, the LGBM model consistently provided the highest net benefit across a broad range of clinically relevant threshold probabilities, further supporting its clinical applicability in decision-making scenarios (Figure 4B).

Figure 4. Calibration curve of the LGBM model in the internal validation set (A). Decision curve analysis of the LGBM model in the internal validation set (B). CatBoost: categorical boosting; DT: decision tree; KNN: k-nearest neighbor; LGBM: light gradient boosting machine; LR: logistic regression; MLP: multilayer perceptron; NB: naive Bayes; RF: random forest; SVM: support vector machine.

External validation using an independent test cohort further confirmed the robustness and generalizability of the LGBM model, which achieved an AUC of 0.786, outperforming all other ML models in this cohort (Figure 3C). The consistent performance observed across both internal and external validation cohorts underscores the strong generalizability and clinical potential of the LGBM model for predicting VTE in ICU patients with sepsis.

Following stratification based on SOFA score, the LGBM model demonstrated enhanced discriminative ability in the high-risk group. The AUC for the severe sepsis group was 0.816, which was higher than the AUC of 0.769 observed in the mild to moderate sepsis group. The detailed performance metrics are shown in Table 5.

Explanation of the Model

Figure 5 displays the top 15 predictive features for VTE incidence as identified by the LGBM model using SHAP analysis. The feature importance plot, ranked by the mean absolute SHAP values, highlights the variables with the greatest overall impact on model predictions (Figure 5A). The 5 most influential features were central venous catheterization, chloride, bicarbonate, arterial catheterization, and PTT. The corresponding SHAP beeswarm plot (Figure 5B) illustrates each feature's influence on individual predictions, where SHAP values to the right of zero reflect increased predicted risk. It revealed that the presence of central venous or arterial catheters, elevated chloride and bicarbonate levels, and prolonged PTT consistently contributed to a higher VTE risk.

RenderX

Figure 5. SHAP summary plot for clinical variables contributing to the light gradient boosting machine (LGBM) model. (A) Feature importance ranking plot based on the LGBM model. (B) Scatter plot of variables for SHAP analysis based on the LGBM model. AKI: acute kidney injury; HCO3-: bicarbonate; HR: heart rate; pH: potential of hydrogen; PLT: platelet; PTT: partial thromboplastin time; SHAP: SHapley Additive exPlanations.

To further examine the marginal effects of key predictors on model output, PDPs were generated for the top-ranked features (Figures 6A-6F). These plots depict how the predicted risk of VTE changes on average with varying values of a single feature, while holding others constant. For dichotomous variables such as central venous (Figure 6A) and arterial (Figure 6D) catheterization, the plots showed a marked increase in the average predicted risk when catheters were present compared with their absence. Continuous variables including serum chloride (Figure 6B), bicarbonate (Figure 6C), and HR (Figure 6F) exhibited monotonic relationships, with risk increasing steadily as the values rose. In contrast, PTT (Figure 6E) exhibited a distinct threshold effect. The predicted risk remained low and stable within the normal range and then increased sharply for values beyond approximately 45 seconds before plateauing at highly prolonged levels, confirming its nonlinear risk association identified by SHAP.

RenderX

Interpretation of Individual Prediction

To enhance case-level interpretability, SHAP force plots were used to visualize the contribution of individual features to specific predictions (Figure 7). In these plots, each feature was represented as a colored bar that moves the predicted value away from a baseline, which corresponds to the average prediction across the dataset. Features that increase the predicted risk are shown in red, while those that reduce the risk are shown in blue. The length of each bar reflects the extent of the feature's influence. A longer bar indicates a stronger impact on the final predicted probability.

Figure 7. SHapley Additive exPlanations (SHAP) force plots for explaining of individual's prediction results according to the light gradient boosting machine model. (A) SHAP force plot of a high-risk example. (B) SHAP force plot of a low-risk example. AKI: acute kidney injury; HCO3-: bicarbonate; HR: heart rate; PT: prothrombin time; PTT: partial thromboplastin time; SAPS: simplified acute physiology score II; SBP: systolic blood pressure.

For example, in Figure 7A, the predicted VTE probability for a specific patient was 0.11, which was higher than the baseline value. This elevated risk was primarily attributed to the presence of a central venous catheter, a markedly prolonged PTT of 81.9 seconds, and a high HR of 141 min^{-1}. In contrast, Figure 7B showed a patient with a predicted probability of 0.02, which was lower than the baseline. In this case, protective features including the absence of a central venous catheter, absence of AKI, and a low SAPS II score collectively outweighed the influence of risk factors such as elevated BMI and bicarbonate level. These examples demonstrated that the model was capable of producing clear and clinically relevant explanations for individual predictions.

Discussion

Principal Findings

In this multicenter retrospective study, we developed and validated several ML models to predict the risk of VTE in critically ill patients with sepsis. Among the models tested, the LGBM algorithm demonstrated the highest predictive accuracy with an AUC of 0.956 in the internal validation set and maintained strong generalizability with an AUC of 0.786 in an external cohort. The observed VTE incidence in our external validation cohort (30/328, 9.15%) was substantially higher than the 3.35% (844/25,197) incidence recorded in the MIMIC-IV development cohort. While this difference contributed to the drop in the AUC during external validation, this discrepancy is likely a consequence of multiple factors, including divergent diagnostic practices, disparities in clinical risk profiles, and racial composition differences between the 2 cohorts.

First, variations in VTE surveillance and diagnostic criteria likely served as a primary driver. The MIMIC-IV cohort relied on retrospective identification via *ICD* (*International Classification of Diseases*) codes, a method known to carry a risk of misclassification bias and potential underascertainment, particularly of asymptomatic events. Conversely, the external validation cohort used explicit diagnostic imaging reports and implemented a routine lower limb venous ultrasound screening program for high-risk patients with sepsis. This systematic, active surveillance methodology inherently tends to yield a higher VTE capture rate compared with passive, coding-based case ascertainment. Second, the external validation group exhibited a substantially higher baseline severity and utilization of aggressive life support interventions. Patients with VTE in this cohort showed markedly higher rates of established risk factors such as mechanical ventilation (83.33% vs 49.29% in MIMIC-IV VTE group), ARDS (53.33% vs 30.81%), and CRRT (33.33% vs 11.37%) [19-21]. This heightened clinical severity and iatrogenic risk profile provide a sound clinical explanation for the elevated VTE incidence. Third, the inherent demographic differences between the cohorts represent a major challenge to model generalizability. The MIMIC-IV cohort is composed of a racially diverse population, while the external validation cohort is predominantly Asian, representing a geographically and ethnically distinct cohort. Given that VTE risk is known to vary significantly across different racial groups, this change in demographic distribution may be a contributing factor to the observed performance decrease [22].

Despite these significant differences in cohort characteristics and VTE incidence, the LGBM model maintained the highest predictive performance in both internal and external validation, underscoring its inherent robustness and generalization capacity. These performance advantages align with recent findings that gradient boosting methods often outperform logistic models in predictive accuracy when applied to large clinical datasets [23,24]. Crucially, we applied SHAP to interpret the model's predictions. This analysis identified a set of key risk factors driving VTE predictions, including the presence of central and arterial catheters, serum chloride and bicarbonate levels, and the PTT. By quantifying each feature's contribution to individual risk scores, SHAP facilitated insight into why certain patients

XSL•FO
RenderX

were classified as high-risk. This combination of robust performance and interpretability suggests that our model may assist clinicians in identifying ICU patients with sepsis at an increased risk of VTE, thereby supporting timely prophylaxis or diagnostic evaluation. Conventional instruments such as the Caprini, Padua, or Wells scores were primarily developed for general medical or surgical populations and relied on a linear, additive combination of risk factors [10,25]. These tools lack the specificity required to capture the distinct pathophysiology of sepsis which involves a complex interplay among inflammation, endothelial dysfunction, and coagulopathy collectively referred to as sepsis-induced coagulopathy [26,27]. The pathophysiology of sepsis-induced VTE is inherently nonlinear. Complex interactions among organ failure, systemic inflammation, and iatrogenic factors such as the use of catheters and vasopressors jointly modulate VTE risk in a manner that traditional linear models cannot fully capture [28,29]. In contrast, our LGBM model is consistent with previous ML applications in critical care and automatically captures complex relationships and interactions among predictors while integrating heterogeneous ICU data to generate a more accurate and nuanced risk estimate [30]. Our study found that the LGBM model significantly outperformed the LR model, achieving an AUC value of 0.956 compared with 0.621, which underscores the advantage of advanced ML algorithms in modeling the complex relationships among multiple risk factors. We recognize that prior studies have used advanced ML models for VTE prediction in critically ill patients. For instance, Jin et al [31] developed an RF model for VTE prediction in ICU patients that achieved an AUC of 0.788 in their validation dataset. Our model demonstrates equivalent predictive power in a challenging, sepsis-specific cohort. This robust performance likely stems from 2 key strengths of our approach: first, the inherent efficiency and predictive power of the LGBM algorithm compared with other boosting techniques; second, and more critically, our model's unique inclusion of metabolic and acid-base markers, such as serum chloride and bicarbonate, may offer a more nuanced reflection of the prothrombotic state induced by sepsis-associated organ dysfunction, thereby enhancing predictive accuracy.

The comparative analysis between the LR findings and the SHAP feature ranking reveals the core limitation of traditional statistical approaches in septic VTE prediction. The discrepancy observed for bicarbonate is illustrative. While bicarbonate was not retained in the final LR model, suggesting that its linear signal lacked statistical significance for VTE risk, the LGBM model ranked it as the third most influential predictor overall. This strongly suggests that bicarbonate's predictive power does not stem from a simple linear effect but from its complex nonlinear relationship or crucial interaction with other factors, reflecting the severity of systemic acid-base disturbances. Similarly, MI appeared as a protective factor in the final multivariable regression (OR 0.2851), but its marginal contribution was deemed less vital by SHAP than core metabolic and iatrogenic factors. This protective association in the linear model was likely influenced by confounding or collinearity among chronic conditions, potentially because patients with a history of MI often receive stricter chronic anticoagulation management, which may suppress their VTE risk and mask the true underlying risk in the linear model. The issue of complete separation for variables such as diabetes and COPD further highlights the inherent defect of LR when processing sparse data, as it led to unreliable, extreme coefficients. These findings collectively validate the choice of the nonlinear LGBM model and underscore the necessity of relying on its transparent SHAP feature analysis to evaluate the true, complex VTE risk drivers that are often obscured by the restrictive linearity of traditional statistical methods. Furthermore, the finding that the LGBM model achieved a higher AUC (0.816 vs 0.769) in the severe sepsis subgroup is significant. This enhanced discriminative power in the highest risk population confirms the model's clinical use, suggesting that it is particularly effective for targeted VTE prophylaxis and early intervention in patients with multiorgan dysfunction.

The interpretability enabled by SHAP analysis is essential for clinical translation and offers valuable pathophysiological insights. The top predictors identified by our SHAP analysis are closely related to the pathophysiology of sepsis-associated VTE and reinforce the model's clinical plausibility. The paramount importance of central venous catheterization aligns with Virchow's triad as the catheter can directly cause endothelial injury and lead to local blood flow stasis, both of which are potent triggers for thrombosis [32]. This finding is consistent with numerous studies highlighting indwelling catheters as a major iatrogenic risk factor for VTE in ICU patients [33,34]. The contribution of arterial catheterization, although less pronounced, further underscores the role of endothelial disruption from invasive devices.

Beyond these established risk factors, the model identified the predictive value of metabolic parameters such as serum chloride and bicarbonate. Elevated serum chloride is frequently associated with metabolic acidosis, which commonly develops in severe sepsis and shock [35]. Acidosis has been shown to enhance PLT aggregation and impair fibrinolysis, thereby promoting a prothrombotic state [36]. The association with bicarbonate likely reflects the severity of systemic acid-base disturbances commonly observed in septic shock. These findings suggest that fluid resuscitation strategies and acid-base management may represent modifiable components of VTE risk. The role of PTT is particularly noteworthy. Although a prolonged PTT is traditionally associated with bleeding risk, in sepsis it may paradoxically indicate consumptive coagulopathy in which widespread microthrombosis rapidly consumes clotting factors and leads to their depletion, a hallmark of disseminated intravascular coagulation [37]. The PDP revealed a nonlinear risk profile, where VTE risk increased markedly once PTT exceeded approximately 45 seconds. This nonlinear relationship would likely be overlooked in traditional linear analyses and highlights the model's capacity to identify clinically meaningful physiological thresholds. The contribution of HR appears more direct as its PDP showed a monotonic increase in predicted VTE risk with rising HR. Tachycardia is a cardinal manifestation of the systemic inflammatory response and catecholamine surge in sepsis, reflecting physiological stress and a hyperdynamic state that may promote endothelial dysfunction and a prothrombotic environment [38,39].

Strengths and Limitations

A major strength of our study lies in the integration of rigorous model development with interpretability, which enhances its potential clinical applicability. The model was developed using the large, high-quality public MIMIC-IV database and externally validated it in a geographically and ethnically distinct cohort from our own center. This 2-tiered validation strategy is essential for evaluating model generalizability, which remains a common limitation in single-center ML studies [40]. The decline in AUC from 0.956 to 0.786 during external validation, while still maintaining the best performance among all models, underscores the model's robust generalizability. This performance gap likely reflects intrinsic differences between the 2 cohorts, such as patient genetics, local clinical practices, VTE screening protocols, and data-recording standards. These findings underscore the critical need for local calibration or model retraining before deploying any predictive model in a new clinical setting. In addition, our use of SHAP enhances model transparency and interpretability rather than producing a purely opaque prediction tool. By generating individualized explanations through force plots, our model provides clinicians with transparent and actionable insights that support clinical decision-making and facilitate integration into routine workflows. Such interpretability is essential for translating ML tools from research settings to real-world clinical practice.

Despite these strengths, our study has several limitations. First, its retrospective design allows for the identification of associations but not the establishment of causality. The reliance on *ICD* codes for VTE diagnosis in the MIMIC-IV database may lead to some misclassification, as coding practices can vary and may not capture all clinically recognized events [41]. Second, we included data from only the first 24 hours of ICU admission. While this time frame is critical for early risk stratification, VTE is a dynamic process, and models incorporating time series data may provide greater predictive accuracy [42]. Third, despite comprehensive data extraction, some potential confounders, such as the specific type and dosage of thromboprophylaxis, patient mobility status, or the specific subtypes of malignancy, were not available. This includes the lack of detailed or consistently documented data on heparin dosage, such as prophylactic versus therapeutic, or duration, which forced us to treat heparin use as a binary variable. Finally, although the use of imputation for missing data is standard practice, it may still introduce a small degree of bias.

Future research should aim to prospectively validate our LGBM model in multicenter interventional trials to confirm its clinical use and impact on patient outcomes. Further refinement of the model may involve incorporating dynamic variables throughout the ICU stay and integrating emerging biomarkers related to coagulopathy and endothelial dysfunction. In addition, exploring federated learning approaches could enable the development of more robust and generalizable models across institutions while preserving patient data privacy [43].

Conclusions

This study presents a high-performing and interpretable LGBM model for predicting VTE in ICU patients with sepsis by effectively integrating a broad spectrum of clinical and laboratory data. By leveraging SHAP to enhance transparency, the model extends beyond a simple predictive tool to function as a decision support system capable of elucidating complex risk profiles and enabling clinicians to implement more personalized and effective VTE prevention strategies. This work lays the foundation for the adoption of sophisticated yet interpretable artificial intelligence–driven tools aimed at reducing the burden of VTE in this high-risk patient population.

Acknowledgments

This work was supported by the Suzhou Special Project for Clinical Key Disease Diagnosis and Treatment Technologies (LCZX202334), Key Projects of the Changshu Science and Technology Development Program (CSWS202209), and the Special Research Fund Projects of the China International Medical Foundation (Z-2014-08-2309-1).

Data Availability

The datasets and code used in this study are available from the corresponding author on reasonable request.

Authors' Contributions

YZ and XR designed the study and wrote the manuscript. YZ, XR, and LL collected, analyzed, and interpreted the data. JZ and YG contributed to literature search. XR, and HY critically reviewed and improved the drafts of the manuscript. All authors read and approved the final manuscript.

Abstract

Background: Artificial intelligence tools, particularly large language models (LLMs), have shown considerable potential across various domains. However, their performance in the diagnosis and treatment of breast cancer remains unknown.

Objective: This study aimed to evaluate the performance of LLMs in supporting radiologists within multidisciplinary breast cancer teams, with a focus on their roles in facilitating informed clinical decisions and enhancing patient care.

Methods: A set of 50 questions covering radiological and breast cancer guidelines was developed to assess breast cancer. These questions were posed to 9 popular LLMs and clinical physicians, with the expectation of receiving direct "Yes" or "No" answers along with supporting analysis. The performances of the 9 models, including ChatGPT-4.0, ChatGPT-4o, ChatGPT-4o mini, Claude 3 Opus, Claude 3.5 Sonnet, Gemini 1.5 Pro, Tongyi Qianwen 2.5, ChatGLM, and Ernie Bot 3.5, were evaluated against that of radiologists with varying experience levels (resident physicians, fellow physicians, and attending physicians). Responses were assessed for accuracy, confidence, and consistency based on alignment with the 2024 National Comprehensive Cancer Network Breast Cancer Guidelines and the 2013 American College of Radiology Breast Imaging-Reporting and Data System recommendations.

Results: Claude 3 Opus and ChatGPT-4 achieved the highest confidence scores of 2.78 and 2.74, respectively, while ChatGPT-4o led in accuracy with a score of 2.92. In terms of response consistency, Claude 3 Opus and Claude 3.5 Sonnet led the pack with scores of 3.0, closely followed by ChatGPT-4o, Gemini 1.5 Pro, and ChatGPT-4o mini, all recording impressive scores exceeding 2.9. ChatGPT-4o mini excelled in clinical diagnostics with a top score of 3.0 among all LLMs, and this score was also higher than all physician groups; however, no statistically significant differences were observed between it and any physician group (all

XSL•FO
RenderX

P>.05). ChatGPT-4 also had a higher score than the physician groups but showed comparable statistical performance to them (*P*>.05). Across radiological diagnostics, clinical diagnosis, and overall performance, ChatGPT-4o mini and the Claude models achieved higher mean scores than all physician groups. However, these differences were statistically significant only when compared to fellow physicians (*P*<.05). However, ChatGLM and Ernie Bot 3.5 underperformed across diagnostic areas, with lower scores than all physician groups but no statistically significant differences (all *P*>.05). Among physician groups, attending physicians and resident physicians exhibited comparable high scores in radiological diagnostic performance, whereas fellow physicians scored somewhat lower, though the difference was not statistically significant (*P*>.05).

Conclusions: LLMs such as ChatGPT-4o and Claude 3 Opus showed potential in supporting multidisciplinary teams for breast cancer diagnostics and therapy. However, they cannot fully replicate the intricate decision-making processes honed through clinical experience, particularly in complex cases. This highlights the need for ongoing artificial intelligence refinement to ensure robust clinical applicability.

KEYWORDS

breast cancer; large language models; LLMs; radiology assistance; clinical decision-making; ACR BI-RADS; NCCN guidelines; radiologist; National Comprehensive Cancer Network; American College of Radiology Breast Imaging-Reporting and Data System

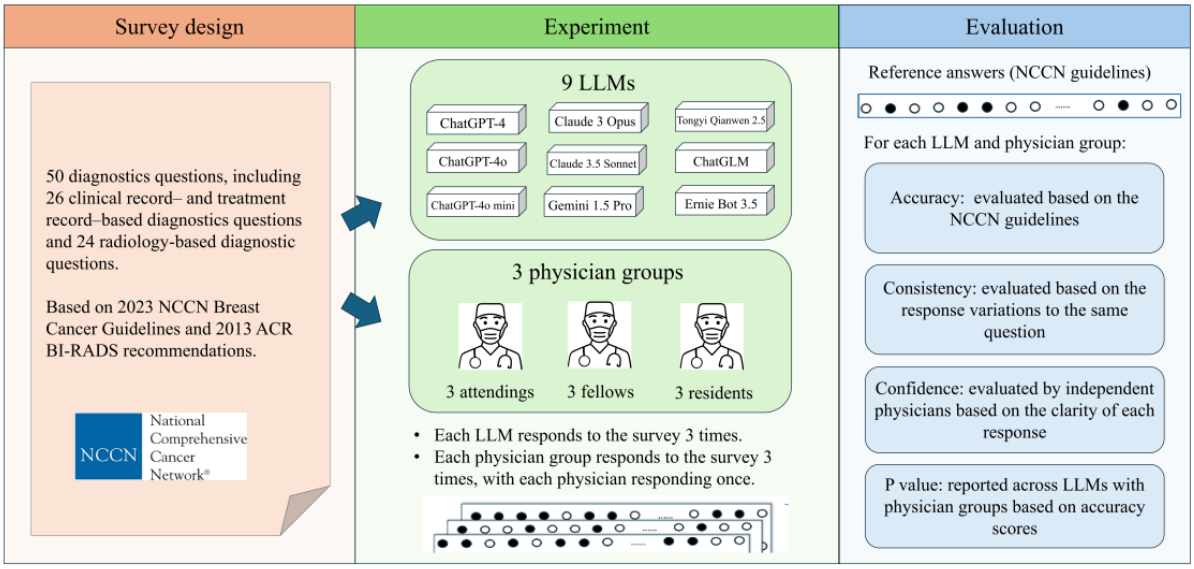
Introduction

Breast cancer is one of the most common malignancies in women worldwide, with over 2 million diagnoses each year, and it remains the leading cause of cancer-related deaths in women [1,2]. According to a World Health Organization departmental news report in 2021, breast cancer mortality and incidence rates are higher in low- and middle-income countries than in high-income nations, largely due to disparities in early detection and treatment. However, the biological characteristics of breast cancer vary significantly, including imaging features, pathological traits, and lymph node assessment, making early screening and personalized treatment challenging yet crucial.

A mature early screening system relies on well-established professional teams and standardized, specialized guidelines. Although there have been recent advancements, developing countries still face significant challenges in breast cancer care in terms of multidisciplinary coordination among specialist teams (surgeons, oncologists, pathologists, and radiologists), well-balanced medical resources, and adequately trained physicians [3,4]. Furthermore, many physicians rely on empiricism and practice medicine rather than evidence-based guidelines [5,6]. Therefore, there is an urgent need for effective artificial intelligence (AI) tools to support health care professionals in resource-limited settings, improve diagnostic accuracy, and enhance patient outcomes [7,8].

In recent years, several prominent large language models (LLMs) have emerged, including ChatGPT (OpenAI), Gemini Advanced (Google LLC), Claude (Anthropic), Tongyi Qianwen (Alibaba Corporation), ChatGLM (Zhipu AI), and Ernie Bot (Baidu). These models, trained on extensive datasets, offer significant potential in health care by generating complex text through deep learning. ChatGPT, for instance, gained rapid popularity, attracting over 1 million users within days of its release. (knowledge base updated as of October 2023). Studies have shown its potential in medicine, performing well on the United States Medical Licensing Examination and the Board of Radiology-style examination [9,10]. ChatGPT can help radiologists simplify cumbersome diagnostic imaging descriptions [11,12]. Notably, the recommendations provided by ChatGPT for the clinical management of early-diagnosed breast cancer closely align with decisions made by multidisciplinary teams (MDTs) [13]. ChatGPT has indicated a level of congruence with the National Comprehensive Cancer Network (NCCN) guidelines in identifying a wide range of therapeutic agents for the treatment of advanced metastases or advanced primary tumors [14]. However, recent studies highlighted significant limitations in ChatGPT-4.0, revealing a "curse reversal," where a model trained on "A is B" may struggle to infer "B is A" [15].

The rapid advancement of AI has ushered in a new era of innovation, with the emergence and continuous refinement of various LLMs profoundly transforming the health care sector. This study evaluates the performance of various LLMs in addressing breast cancer guideline-related questions, comparing them with radiologists of varying expertise levels to assess their potential in enhancing radiologists' diagnostic capabilities.



Methods

Study Design

The study aimed to evaluate the performance of 9 LLMs in breast cancer imaging diagnosis and to compare their performance with that of breast imaging specialists. We developed a set of 50 questions focused on breast cancer diagnosis and treatment based on the 2013 version of the American College of Radiology Breast Imaging-Reporting and Data System (ACR BI-RADS) classification and the 2024 NCCN Breast Cancer Guidelines. The first 24 questions focused on radiological diagnostics, while the remaining 26 questions pertained to clinical diagnosis and treatment. Questions were then presented to breast radiologists and the 9 LLMs for diagnostic responses. The accuracy, confidence, and consistency of each model in responding to the diagnostic queries were assessed. Furthermore, we conducted a comparative analysis of each model's performance against radiologists possessing varying levels of clinical experience. The study design is provided in Figure 1.

XSL•FO
RenderX

Figure 1. Graph in the full-text abstract: the study design, including question categorization, experiment, and evaluation workflow. ACR BI-RADS: American College of Radiology Breast Imaging-Reporting and Data System; LLM: Large Language Model; NCCN: National Comprehensive Cancer Network.

Participants and Models

The 9 LLMs included ChatGPT-4.0, ChatGPT-4o, ChatGPT-4o mini, Claude 3 Opus, Claude 3.5 Sonnet, Gemini 1.5 Pro, Tongyi Qianwen 2.5, ChatGLM, and Ernie Bot 3.5. In addition, the study recruited a total of nine board-certified radiologists, stratified into three distinct experience levels: (1) resident physicians (n=3; 1-5 years of postlicensure experience), undergoing subspecialty training to develop foundational clinical expertise; (2) fellow physicians (n=3; 5-10 years of experience), having completed residency and pursuing advanced fellowship training (1-3 years) to specialize in breast imaging diagnostics; and (3) attending physicians (n=3; >10 years of experience), senior specialists with independent diagnostic authority, responsible for clinical decision-making and trainee supervision. This hierarchical cohort enabled comparative benchmarking of LLM performance against progressive stages of radiologist expertise. Each physician received the same set of 50 questions.

Questions Design

The set of 50 questions was developed based on guidelines extracted from the 2024 NCCN Breast Cancer Guidelines and the 2013 ACR BI-RADS diagnostic criteria, which are widely regarded as the gold standards in clinical breast cancer diagnosis. These criteria are commonly adhered to by physicians in clinical breast cancer diagnosis. In this study, we used these same standards to evaluate the responses provided by the LLMs and physicians to ensure validity and fair comparison. The questions covered a range of common clinical diagnostic decision-making scenarios, providing radiological evidence, such as mammography, ultrasound, and magnetic resonance imaging, as well as clinical information indicators such as medical history, physical examination findings, and laboratory test results, across preoperative, intraoperative, and postoperative stages.

Procedure

Nine physicians were divided into 3 groups based on their experience levels, with each physician answering all 50 questions once. They were prohibited from consulting guidelines or reference materials and were required to complete the questions within 30 minutes. Each physician independently completed the assessment to minimize recall bias. The study aimed to simulate real-world conditions by controlling time and eliminating external aids.

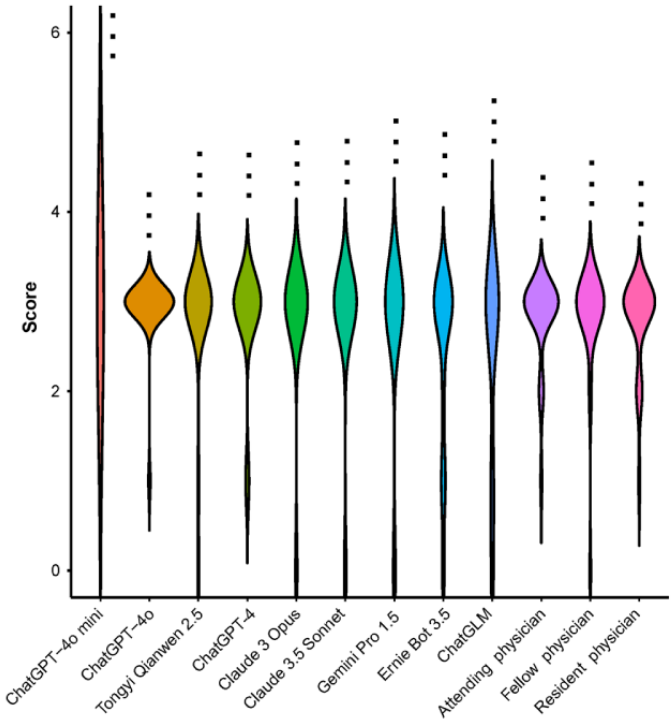
All LLMs were queried via the Google application programming interface on a single date (August 21, 2024) without any additional context (such as task background or medical knowledge priming) and generated responses accordingly. Each LLM independently answered every question 3 times. Standard responses were defined as “yes” or “no.” A response was classified as “yes” if it demonstrated a strong affirmative inclination, supported by compelling theoretical evidence and logical reasoning. Conversely, a response was classified as “no” if it showed a clear negative inclination, backed by equally robust theoretical evidence and sound logic. If an LLM produced an ambiguous response, lacked sufficient evidence, or contained flawed reasoning, it was prompted to reanswer. If the reanswered response remained unsatisfactory, 2 senior physicians with over 10 years of experience were recruited to classify the response based on their professional judgment, thereby evaluating the AI model’s accuracy. In cases of disagreement, the evaluators reevaluated the response based on the 2024 NCCN Guidelines and the 2013 ACR BI-RADS criteria to reach a consensus through discussion.

All LLM-generated responses were anonymized, randomized, and then assessed by evaluators who were blinded to the source (LLM identity) of each response. The accuracy of each response was assessed against the diagnostic NCCN guidelines.

XSL•FO
RenderX

Responses consistent with the guidelines were assigned a score of 1, while inconsistent responses received a score of 0. The accuracy score for each question was calculated by summing the scores of the 3 responses. The overall accuracy performance of both the LLMs and physician groups was determined by averaging the accuracy scores across the 50 questions, resulting in a score ranging from 0 to 3. Subsequently, the accuracy performance of the LLMs was compared to that of the physician groups through rigorous statistical analysis.

Confidence and Consistency



Confidence refers to the clarity of responses, categorized as either "confident" or "nonconfident." A confident answer provides an explicit "yes" or "no" to questions, while a nonconfident answer lacks a direct "yes or no" statement, despite potentially containing detailed explanations, requiring additional prompting to elicit a definitive response. Confident answers received are scored 1, while nonconfident answers are scored 0. The confidence score for each question is calculated by summing the scores from 3 independent response attempts. Each LLM's overall confidence performance is assessed by averaging these scores across 50 questions, resulting in a score ranging from 0 to 3. The confidence ratio represents each LLM's average confidence score divided by the maximum possible score (ie, 3).

Consistency evaluates whether an LLM provides uniform responses across 3 independent attempts to answer the same question. If all 3 answers are identical, the responses are considered consistent, regardless of their alignment with guideline criteria. For consistency assessment, an LLM receives 3 points if all 3 answers to a question are identical, and 2 points if one answer differs from the others. Each LLM's consistency performance is evaluated by averaging these scores across 50 questions, with possible scores ranging from 2 to 3. The consistency ratio is defined as each LLM's average consistency score divided by the maximum possible score (ie, 3).

Statistical Analysis

R software (version 4.4.2; R Foundation for Statistical Computing) was used for data management and statistical analysis. Continuous variables were described using means, and specific group instances were expressed as absolute values. The Wilcoxon rank-sum test was used for score comparisons between 2 different groups. We opted not to perform a Kruskal-Wallis test (for overall multigroup comparison) before pairwise analyses because our research focus was on hypothesis-driven, targeted comparisons between 2 specific groups: each LLM vs each physician subgroup (attendings, fellows, and residents). This design directly aligned with our aim—to evaluate whether single LLMs differ in performance from radiologists at distinct experience levels—rather than testing for overall differences across all groups. Differences between groups were considered significant at $P<.05$. P value correction for multiple comparisons was applied using the Benjamini-Hochberg method. Adjusted P values are provided in Multimedia Appendix 1, Tables 2-4, and corresponding Figures 2-4 to present direct pairwise comparison results; raw P values for multiple comparisons are provided exclusively in Multimedia Appendix 2.

Figure 2. Accuracy scores of large language models (LLMs) compared to physicians in clinical diagnosis and treatment questions of breast cancer. 3-star or dot symbols on each violin from top to bottom represent P values compared to each LLM to attending, fellow, and resident physicians, using the Wilcoxon rank-sum test. Symbols are as follows: "***" represents $P<.001$, "**" represents $.001\leq P<.01$, "*" represents $.01\leq P<.05$, and "black dots" represents $P\geq.05$.

Results

Representative Examples

Textbox 1 provides a representative selection of question-answer examples from the 9 LLMs, while a more comprehensive collection of cases is provided in the Multimedia Appendix 3.

Textbox 1. Representative examples of questions and answers from the 9 large language models (LLMs).

Sample question:

- Can an oval, hypoechoic lesion, growing nonparallel or vertically, with a heterogeneous echo pattern and obscured margins on breast ultrasound, be classified as Breast Imaging Reporting and Data System (BI-RADS 4b)?

ChatGPT-4 response:

- Yes, an oval, hypoechoic lesion growing nonparallel (vertically) with a heterogeneous echo pattern and obscured margins observed on breast ultrasound could be classified as BI-RADS 4b. This classification indicates a moderate suspicion of malignancy, meaning the lesion exhibits characteristics that are more suspicious than those typically found in BI-RADS 4a but not as definitively malignant as those in BI-RADS 4c.
- The characteristics you described—nonparallel orientation (often termed “taller than wide”), heterogeneous echo pattern, and obscured margins—suggest a higher level of concern. These features are often associated with a greater likelihood of malignancy:
  - Nonparallel or vertical orientation: this orientation is more typical of malignant lesions, as benign masses often grow in parallel with the skin.
  - Heterogeneous echo pattern: this can indicate variability within the lesion, which is more common in malignant tumors than in benign growths.
  - Obscured margins: this suggests that the lesion’s borders are not clearly defined, which can be an indication of invasive growth, a characteristic more typical of malignant processes.
- Conclusion: a lesion under 5 mm without a lipid core showing a washout pattern on magnetic resonance imaging should be approached with a high degree of suspicion for malignancy. This situation requires proactive management, including possible biopsy and close imaging follow-up, to ensure timely diagnosis and treatment.

ChatGPT-4o response:

- Yes, an oval, hypoechoic lesion that is growing nonparallel (vertically oriented), with a heterogeneous echo pattern and obscured margins on breast ultrasound can be classified as BI-RADS 4b. BI-RADS 4b is used to describe lesions with a moderate suspicion of malignancy.
- Key features of BI-RADS 4b:
  - Oval shape: while an oval shape can suggest a benign lesion, other features, such as orientation, margin appearance, and internal echo pattern, significantly influence the level of suspicion.
  - Nonparallel growth (vertically oriented): a lesion that grows nonparallel, or “taller than wide,” raises concern for malignancy. This orientation is often associated with invasive tumors because malignant lesions tend to invade tissue in a vertical direction.
  - Heterogeneous echo pattern: a heterogeneous echo pattern, where the lesion appears uneven or varied in echogenicity, is suspicious because it can indicate the presence of both solid and cystic components, or areas of differing cellular density, which is common in malignant tumors.
  - Obscured margins: obscured or indistinct margins are another red flag for malignancy. Clear, well-defined margins are typically seen in benign lesions, while indistinct margins suggest invasion into surrounding tissues.
- In conclusion, the combination of nonparallel growth, heterogeneous echo pattern, and obscured margins justifies a BI-RADS 4b classification, meaning the lesion has a moderate risk of malignancy and requires biopsy for a definitive diagnosis.

ChatGPT-4o mini response:

- Yes, an oval, hypoechoic lesion with a nonparallel (vertically oriented) growth pattern, heterogeneous echo pattern, and obscured margins on breast ultrasound can be classified as BI-RADS 4b.
- Here’s why this classification might be appropriate:
  - Oval shape: while typically less suspicious than irregular shapes, an oval shape alone does not rule out malignancy.
  - Hypoechoic: a darker appearance on ultrasound is often associated with both benign and malignant lesions.
  - Nonparallel growth pattern: a vertical or irregular growth pattern can be more concerning, as it may suggest infiltration into surrounding tissues.
  - Heterogeneous echo pattern: variability in echo patterns within a lesion can be indicative of more complex internal structures, which may be suggestive of malignancy.
  - Obscured margins: margins that are not well-defined or are irregularly shaped can be a sign of malignancy.
- BI-RADS 4b indicates a moderate suspicion of malignancy, with a likelihood of 10%-50%. This classification suggests that while there is a notable suspicion of cancer, the probability is not as high as in BI-RADS 4c. A biopsy is recommended to obtain a definitive diagnosis.

Confidence Level

Claude 3 Opus achieved the highest average score of 2.78, followed by ChatGPT-4 with a score of 2.74. The remaining models scored as follows: ChatGPT-4o 2.52, ChatGPT-4o mini 2.58, Claude 3.5, Sonnet 2.34, Gemini 1.5 Pro 2.28, Tongyi Qianwen 2.5 1.62, ChatGLM 1.98, and Ernie Bot 3.5 1.50. Claude 3 Opus and ChatGPT-4 demonstrated significantly higher confidence compared to the other models (Table 1 and Figure 5).

Table 1. Confidence and consistency levels of the large language models (LLMs).

Methods	Confidence level	Consistency level
ChatGPT-4	2.74	2.90
ChatGPT-4o	2.52	2.96
ChatGPT-4o mini	2.58	2.92
Claude 3 Opus	2.78	3.00
Claude 3.5 Sonnet	2.34	3.00
Gemini 1.5 Pro	2.28	2.96
Tongyi Qianwen 2.5	1.62	2.86
ChatGLM	1.98	2.72
Ernie Bot 3.5	1.50	2.82

Figure 5. Percentage of accuracy, confidence, and consistency levels of large language models (LLMs) across all 50 questions.

Consistency

Claude 3 Opus and Claude 3.5 Sonnet achieved the highest score of 3.0, demonstrating their superiority. The remaining models achieved the following consistency scores: ChatGPT-4o: 2.96, Gemini 1.5 Pro: 2.96, ChatGPT-4o mini: 2.92, ChatGPT4: 2.90, Tongyi Qianwen 2.5: 2.86, Ernie Bot 3.5: 2.82, and ChatGLM: 2.71 (Table 1 and Figure 5).

Performances on Clinical Diagnostics and Treatment Questions

In the comparison of clinical diagnostic problems, the mean accuracy scores are 3 (SD 0), 2.92 (SD 0.39), 2.81 (SD 0.69), 2.81 (0.49), 2.81 (SD 0.63), 2.77 (SD 0.65), 2.77 (SD 0.82), 2.77 (SD 0.82), 2.65 (SD 0.98), 2.38 (SD 1.02), and 2.35 (SD 1.13) for ChatGPT-4o mini, ChatGPT-4o, Tongyi Qianwen 2.5, attending physicians, fellow physicians, ChatGPT-4, Claude 3 Opus, Claude 3.5 Sonnet, Gemini 1.5 Pro, Ernie Bot 3.5, and ChatGLM, respectively. No significant differences were observed between any language modeling group and the various

XSL•FO
RenderX

physician groups. Regarding comparisons among physician groups, no significant differences were detected between different physician subgroups (Table 2, Figure 2, and Multimedia Appendices 1 and 4).

Table 2. Accuracy score comparisons of large language models (LLMs) with physician groups for clinical diagnostic and treatment questions.

Methods	Value, mean (SD)	FDR[a]-adjusted *P* value		
		Attending physician	Fellow physician	Resident physician
ChatGPT-4	2.77 (0.65)	.84	.97	.66
ChatGPT-4o	2.92 (0.39)	.44	.81	.49
ChatGPT-4o mini	3 (0)	.37	.42	.23
Claude 3 Opus	2.77 (0.82)	.62	.90	.49
Claude 3.5 Sonnet	2.77 (0.82)	.62	.90	.49
Gemini 1.5 Pro	2.65 (0.98)	.84	.97	.66
Tongyi Qianwen 2.5	2.81 (0.69)	.62	.90	.49
ChatGLM	2.35 (1.13)	.44	.44	.49
Ernie Bot 3.5	2.38 (1.02)	.44	.42	.49
Attending physician	2.81 (0.49)	—[b]	.90	.74
Fellow physician	2.81 (0.63)	—	—	.66
Resident physician	2.77 (0.51)	—	—	—

[a]FDR: false discovery rate.

[b]Not applicable.

In Figure 2, 3-star or dot symbols on each violin from top to bottom represent *P* values compared to each LLM to attending, fellow, and resident physicians, using the Wilcoxon rank-sum test. Symbols are as follows: "***" represents $P<.001$, "**" represents $.001\leq P<.01$, "*" represents $.01\leq P<.05$, and "." represents $P\geq.05$.

Performances on Radiological Diagnostics Problems

In the comparison of radiological diagnostic problems, the scores were as follows: ChatGPT-4 2.79, ChatGPT-4o 2.92, ChatGPT-4o mini 2.54, Claude 3 Opus 2.75, Claude 3.5 Sonnet 2.75, Gemini 1.5 Pro 2.5, Tongyi Qianwen 2.29, ChatGLM 2.0, and Ernie Bot 3.5 1.58. The attending physicians scored 2.46, the fellow physicians scored 2.04, and the resident physicians scored 2.5. The differences between ChatGPT-4, ChatGPT-4o, ChatGPT-4o mini, Claude 3 Opus, Claude 3.5 Sonnet, and Gemini 1.5 Pro and the fellow physicians were statistically significant ($P<.05$). There were statistically significant differences between ChatGPT-4o and the resident physicians ($P=.04$). In contrast, the differences between Tongyi Qianwen 2.5, ChatGLM, and the physician groups were not statistically significant ($P>.05$). In comparisons among physician groups, the differences were not statistically significant ($P>.05$; Table 3, Multimedia Appendices 1 and 4, and Figure 5).

Table 3. Accuracy score comparisons of large language models (LLMs) with physician groups for radiological diagnostic questions.

Methods	Value, mean (SD)	FDR[a]-adjusted *P* value		
		Attending physician	Fellow physician	Resident physician
ChatGPT-4	2.79 (0.66)	.10	<.001	.07
ChatGPT-4o	2.92 (0.41)	.06	<.001	.04
ChatGPT-4o mini	2.54 (0.93)	.51	.01	.45
Claude 3 Opus	2.75 (0.85)	.09	<.001	.07
Claude 3.5 Sonnet	2.75 (0.85)	.09	<.001	.07
Gemini 1.5 Pro	2.5 (1.06)	.50	.01	.41
Tongyi Qianwen 2.5	2.29 (1.08)	.81	.15	.97
ChatGLM	2 (1.1)	.22	.84	.22
Ernie Bot 3.5	1.58 (1.44)	.09	.49	.09
Attending physician	2.46 (0.78)	—[b]	.07	.99
Fellow physician	2.04 (0.75)	—	—	.07
Resident physician	2.5 (0.66)	—	—	—

[a]FDR: false discovery rate.

[b]Not applicable.

In Figure 3, 3-star or dot symbols on each violin from top to bottom represent *P* values compared to each LLM to attending, fellow, and resident physicians, using the Wilcoxon rank-sum test. Symbols are as follows: "***" represents *P*<.001, "**" represents .001≤*P*<.01, "*" represents .01≤*P*<.05, and "." represents *P*≥.05.

Performances on Full Set Questions

In the comparison of overall performance, the scores were as follows: ChatGPT-4o 2.92, ChatGPT-4 2.78, ChatGPT-4o mini 2.78, Claude 3 Opus 2.76, Claude 3.5 Sonnet 2.76, Gemini 1.5 Pro 2.58, Tongyi Qianwen 2.56, ChatGLM 2.18, and Ernie Bot 3.5 2.0. The attending physicians scored 2.64, the fellow physicians scored 2.44, and the resident physicians scored 2.64. The differences between ChatGPT-4, ChatGPT-4o, ChatGPT-4o mini, Claude 3 Opus, Claude 3.5 Sonnet, and the fellow physicians were statistically significant (*P*<.05). Significant differences were observed between ChatGPT-4o and resident physicians (*P*=.01) and between ChatGPT-4o and attending physicians (*P*=.03). In the comparisons among physician groups, none of the differences were statistically significant (*P*>.05; Table 4, Multimedia Appendices 1 and 4, and Figure 4).

Discussion

Principal Findings

With the global population aging, the rising incidence of cancer, and the increasing complexity of treatment options, there is a growing demand for MDT discussions. However, implementing high-level MDTs in underdeveloped countries remains a significant challenge [16], largely because of the knowledge barriers between specialist doctors. An important question is how specialist doctors in less developed regions can achieve the same medical standards as those in developed regions, easily access authoritative and professional medical knowledge, and overcome barriers between specialties. The recently developed chatbot can theoretically provide instant, evidence-based responses, demonstrating significant potential as an ideal tool for enhancing high-quality health care in underserved regions. In our comparison of 9 LLMs, Claude 3 Opus demonstrated the highest confidence score at 2.78, followed by ChatGPT-4 (2.74) and ChatGPT-4o mini (2.58). These scores suggest that these models exhibit a higher degree of certainty when managing complex medical issues. In contrast, Ernie Bot 3.5's confidence score of 1.50 was significantly lower, indicating a reduced ability to comprehend and process medical problems. These findings underscore the varying levels of proficiency among language models in accurately addressing the same problem. Interestingly, unlike human practitioners, not all chatbots confidently respond to closed-ended questions with a definitive "yes" or "no," suggesting that training data diversity and model architecture significantly impact diagnostic accuracy. This uncertainty may lead to reduced consistency and accuracy of their outputs, thus limiting their independent use in practical clinical applications, making them inseparable from close collaboration with physicians during decision-making.

In addition, in the consistency assessment, Claude 3 Opus and Claude 3.5 Sonnet achieved the highest scores of 3, followed by ChatGPT-4o and Gemini 1.5 Pro, both scoring 2.96, with ChatGPT-4o mini at 2.92. In contrast, ChatGLM and Ernie Bot 3.5 exhibited lower consistency scores of 2.72 and 2.82, respectively. These results highlight the differences in response stability across the LLMs, a factor that is especially critical for clinical decision support. In clinical applications, particularly in dynamic and complex environments, models lacking sufficient consistency may undermine confidence in their outputs. Although Claude 3 Opus and Claude 3.5 Sonnet surpassed the ChatGPT models in response consistency (scoring 3), the ChatGPT models demonstrated superior performance in diagnostic accuracy. However, none of the models provided correct answers to all question sets. Therefore, while AI introduces new possibilities in fields such as medicine, it also presents challenges that require careful expert scrutiny to avoid imposing additional burdens on patients and health care professionals [17,18].

By comparing the nine LLMs with the responses of nine radiologists on the overall 50 guideline questions, ChatGPT-4o achieved the highest score of 2.92, significantly outperforming all physician groups. The difference between ChatGPT-4o and all physician groups (*P*<.05) was statistically significant. ChatGPT-4, ChatGPT-4o mini, Claude 3 Opus, and Claude 3.5 Sonnet all scored higher on average than the physician groups. However, the difference was statistically significant only for the comparison with fellow physicians (*P*<.05). In contrast, Gemini 1.5 Pro and Tongyi Qianwen 2.5 had lower scores, with no statistically significant differences compared to each group

XSL•FO
RenderX

of doctors (P>.05). ChatGLM and Ernie Bot 3.5 showed lower scores than all physician groups, but the differences were not statistically significant. No statistically significant differences (P>.05) were found in the comparisons between each group of doctors, suggesting that attending physicians, fellow physicians, and resident physicians performed comparably in answering the entire question set. Attending physicians and resident physicians both scored 2.64, which may reflect a more consistent ability to answer certain routine questions across all years of experience. Fellow physicians, on the other hand, scored slightly lower, but the difference was not significant, suggesting that their performance in overall diagnostic and therapeutic tasks remains competitive.

In the evaluation of radiological diagnostic performance, ChatGPT-4o scored 2.92. A significant difference was observed between ChatGPT-4o and resident physicians (P=.04), and a significant difference was also detected between ChatGPT-4o and fellow physicians (P<.05). ChatGPT-4 achieved a score of 2.79, surpassing all physician groups on average. However, this difference reached statistical significance solely in the comparison with fellow physicians (P<.05). The difference between ChatGPT-4o mini and the fellow physicians was statistically significant (P=.01). Claude 3 Opus and Claude 3.5 Sonnet both scored 2.75, higher than all physician groups; in particular, the difference between these LLMs and fellow physicians was statistically significant (P<.05), suggesting superior performance in radiological diagnostics. Gemini 1.5 Pro scored 2.50, showing small differences compared with attending physicians and resident physicians but significantly higher than fellow physicians (P=.01). Tongyi Qianwen 2.5 and ChatGLM scored lower, with no statistically significant differences compared to physician groups (P>.05). Ernie Bot 3.5 had the lowest score (1.58) among all LLMs, with no statistical significance compared to any physician group, indicating relatively poorer performance. We conclude that the ChatGPT and Claude series outperform junior medical doctors in addressing complex medical issues, highlighting their potential clinical utility. However, ChatGLM and Ernie Bot 3.5 may require further optimization to improve their performance in medical diagnostics. In the diagnostic radiology domain, the average performance of attending physicians and resident physicians was comparable, whereas the small group of fellow physicians scored lower on average. It is noteworthy that resident physicians, who have recently completed standardized residency training, may be more familiar with the specific guidelines on which the questions were based. Attending physicians, benefiting from extensive clinical experience, would be expected to exhibit an advantage in diagnosing complex imaging findings. The performance variation across the small physician subgroups underscores the preliminary nature of these comparisons.

In the assessment of clinical diagnosis and treatment performance, ChatGPT-4o mini achieved the highest score of 3 among all LLMs, although no statistically significant differences were found when compared with any physician group. ChatGPT-4o scored 2.92 and showed no significant difference compared with physician groups (P>.05); however, it outperformed all physician groups on average. Other LLMs, including ChatGPT-4, Claude 3 Opus, and Claude 3.5 Sonnet, exhibited similar performance to physician groups. ChatGLM and Ernie Bot 3.5 showed weaker performance. Overall, the ChatGPT and Claude series of LLMs outperformed some physician groups with lower seniority in complex health care challenges, indicating potential for clinical applications. Further optimization may be necessary for ChatGLM and Ernie Bot 3.5 to enhance their diagnostic performance. Scores between attending physicians and fellow physicians were identical, while resident physicians scored slightly lower; however, these differences did not reach statistical significance. Radiologists of varying experience levels may possess adequate knowledge of clinical guidelines in diagnosis and treatment, particularly when dealing with standardized procedures or common diseases, resulting in minimal differences. Despite differences in experience, attending physicians and fellow physicians demonstrated similar proficiency in applying clinical guidelines.

It is noteworthy that Tongyi Qianwen 2.5 was the only model unable to generate a response to a specific question, instead providing the feedback, “I’m very sorry, but I don’t think I fully understand what you mean. Let’s change the subject first, shall we?” This issue may be attributable to the complexity and specialized nature of the question, or potential biases and gaps in the model’s training data, leading to insufficient knowledge in specific domains. Our data indicate that when Tongyi Qianwen 2.5 fails to respond, the model’s accuracy may be overstated, and its actual performance is significantly below expectations.

Comparison With Previous Work

In our analysis of the 9 language models, Ernie Bot 3.5, Tongyi Qianwen 2.5, and ChatGLM were more likely to recommend referring the questions to medical experts when faced with specialized imaging terminology and clinical scenarios, rather than providing a definitive answer. In contrast, Claude 3 Opus and the ChatGPT series provided more detailed diagnostic imaging feedback, including recommendations for additional biopsies to support diagnosis and an emphasis on multidisciplinary collaboration. Regarding clinical considerations for surgery, the ChatGPT series excelled by offering surgical recommendations for breast cancer patients, while also demonstrating conventional surgical approaches and discussing recent therapeutic advancements. Furthermore, the ChatGPT family outperformed other language models in breast cancer diagnosis and treatment, with each model excelling in its respective area of expertise. This finding highlights the critical need to select the most appropriate language model based on task-specific performance, thereby enhancing problem-solving across various scenarios. These interactive language models provided feedback significantly faster than breast cancer radiologists, reducing time costs and increasing productivity. With continued iteration and improvement, ChatGPT has demonstrated considerable potential in radiology, including concise report generation, support for medical education, clinical decision aids, patient communication optimization, and data analysis [19,20]. Analyzing the reasons for comparable performance between leading language models reveals several key advantages: (1) large-scale, high-quality training data: both the developers of Claude 3 Opus and Chat

XSL•FO
RenderX

GPT have invested substantial resources in acquiring and curating authoritative medical literature, textbooks, and specialized professional databases; (2) comparable model scale and architecture: as state-of-the-art LLMs, both likely use similar parameter scales and analogous underlying architectural designs; (3) equivalent alignment methodologies: both organizations have likely implemented similar reinforcement learning from human feedback techniques, using extensive human evaluator input to enhance the accuracy of model outputs; (4) competition-driven enhancement: market competition has compelled both companies to continuously improve model performance, particularly in high-value vertical domains such as health care. This competitive environment has resulted in both products demonstrating enhanced logical reasoning capabilities; (5) domain-specific knowledge processing: both models have likely incorporated specialized training methodologies for processing technical terminology and complex semantic relationships within specialized conceptual frameworks; (6) parallel safety control mechanisms: in high-risk domains such as medicine, both models have presumably implemented stringent output controls and prudence measures to ensure responsible performance. Given the continuous evolution of LLMs, their capabilities in complex domains, particularly medicine, are rapidly advancing. Future research should further investigate the potential of these models to maximize their value in clinical diagnosis and treatment [21].

However, LLMs were not specifically trained for the medical field and rely on large datasets collected from public sources, such as web pages, books, and websites. Chinese LLMs have reported average accuracy in general medical question-answering of around 82%; yet, performance drops significantly in complex clinical reasoning tasks, such as breast cancer diagnosis (below 50%) [22]. Advanced models, such as ChatGPT-3.5, ChatGPT-4.0, and Claude-2, achieve slightly higher performance (approximately 60%) in breast cancer clinical assessments, though this still highlights critical limitations in high-stakes medical applications [23]. Despite the vast amount of training data, these models lack comprehensive common sense, which limits their reasoning ability. The literature suggests that LLM performance can be significantly enhanced by guiding reasoning steps incrementally, particularly in tasks involving longer reasoning chains [24,25]. In our study, however, the 9 LLMs were unable to accurately diagnose all rigorous and logical medical problems, and a "curse of reversal" phenomenon was observed. Furthermore, unlike real-time search engines such as Google and Bing, LLMs can only generate responses based on their training data and do not have real-time access to current information [26,27]. In addition, LLMs cannot reliably differentiate between factual and fictional statements, posing a potential risk as sources of misinformation in certain cases [28-30]. Moreover, the training data for these models are not publicly available, and the sources of their information are not disclosed, making it difficult to verify the accuracy of their outputs [31]. Therefore, radiologists must continue to rely on traditional evidence-based education and approach LLMs critically, cross-referencing their outputs with credible medical sources [32].

Limitations

This study has several limitations. First, our findings are subject to the inherent limitations of the author-crafted, closed-ended question format. Although designed for objective assessment, this format may not fully capture the reasoning capabilities of LLMs and could potentially underestimate their performance in real-world, open-ended clinical scenarios. Second, the binary definition of a "confident" response as a direct "yes" or "no" may not adequately reflect clinical decision-making, where acknowledging uncertainty is a sign of expertise. This could have introduced bias by favoring LLMs that generate definitive answers over physicians who appropriately consider diagnostic nuances. Third, the physician sample size, while sufficient for initial comparisons, remains relatively small and may not be fully representative of the broader population of radiologists, which could affect the generalizability of our pairwise comparisons. Fourth, the study's generalizability is constrained by its specific design: the assessment is limited to 50 selected questions that do not encompass all aspects of the guidelines, and the performance of the LLMs was evaluated on a single, specific task (answering structured concordance questions). Consequently, the results may not be directly extrapolated to other clinical datasets or different natural language processing tasks. Fifth, the study conditions, including a strict 30-minute time limit and a "no-consultation" rule for the participating physicians, may not reflect real-world clinical practice, where complex cases often benefit from more time and collaborative discussion. These methodological choices, while necessary for standardization, may have disadvantaged the physicians and thus the conclusions of this study must be heavily qualified by this context. In addition, it has been reported that LLMs may generate different responses to identical prompts at different times, due to model updates [31,33]. Future studies should use larger and more diverse physician cohorts, incorporate more nuanced assessments of confidence, explore the impact of different time constraints and collaborative settings, and use a broader range of question types and clinical tasks to validate and extend our findings.

Future Directions

In medical AI applications, LLMs participating in clinical decision-making face critical responsibility challenges, including decision output liability, misinformation risks, and privacy breach accountability [30]. Typically, LLMs do not independently generate decision outputs but function as tools for physicians. Clinicians must integrate guidelines, relevant literature, and their clinical expertise to formulate final clinical decisions. When using LLMs, it is essential to conceal patients' identifying information to safeguard privacy.

This necessitates establishing explicit legal frameworks that delineate responsibility boundaries among developers, health care institutions, and physicians, while constructing comprehensive accountability mechanisms [34,35]. Concurrently, LLMs present a risk of generating inaccurate medical information that could potentially mislead diagnostic and therapeutic decisions. To address this concern, model developers must implement rigorous content review protocols

XSL•FO
RenderX

and ensure professional, authoritative verification of training corpora.

Conclusions

In conclusion, within the context of our study, Claude 3 Opus and the ChatGPT series, particularly ChatGPT-4o, excelled in addressing breast cancer–related guideline questions and demonstrated significant potential for clinical application. In contrast, the less consistent performance of other LLMs, especially Ernie Bot 3.5 and ChatGLM, suggests that both confidence and consistency should be carefully considered when selecting and applying LLMs to ensure efficacy and stability in clinical practice. This preliminary evaluation indicates that LLMs can provide radiologists with extensive cross-disciplinary knowledge, potentially enhancing contributions within MDTs. However, they cannot fully replace human expertise, particularly in complex diagnostic scenarios that require nuanced decision-making honed by clinical experience.

Acknowledgments

We also sincerely thank Dr Siping Luo, Dr Xiao Luo, Huimei Lü, Zhichunmei Yuan, and Qiuxinmei Chen for their invaluable suggestions in designing the 50 breast cancer questions.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author upon reasonable request.

Funding

This research was funded by the Department of Science and Technology of Guangdong Province (grant no 2023A0505050118) and the research project “Preoperative Localization and Navigation of Non-Mass Breast Cancer with DCE-MRI and Ultrasound Fusion Imaging” (grant no 2023yjlcyj019), and the Shenzhen Basic Research Project (Natural Science Foundation; grant no JCYJ20220530150416036). The funding period was 3 years, starting in June 2023, with a total budget of CNY $35,615 (US $5000).

Authors' Contributions

CY was responsible for conceptualization, developing the conceptual framework, and formulating the ideas for this study. HJ and CY prepared the original draft, including substantive translation, and contributed to manuscript creation. HJ, CY, JY, and CY participated in the review and editing of the manuscript, covering both prepublication and postpublication stages. Supervision of the study was provided by HJ, CY, and JY, who oversaw and took leadership responsibility for the planning and execution of research activities. Resource support, including the provision of breast cancer–related guideline materials, was provided by JY, HJ, and CY. Formal analysis was conducted by WZ, who applied statistical techniques to analyze the research data, while data curation, including management of LLM models and essential software code, was performed by WZ and SZ. Investigation, including data collection during the study, was carried out by GR, WW, and MW. Project administration was coordinated by JY, who ensured the smooth planning and execution of research activities. Funding acquisition was secured by HJ and JY.

Abstract

Background: Triage errors in emergency departments (EDs), including undertriage and overtriage, pose significant risks to patient safety and resource allocation. With increasing patient volumes and staffing challenges, artificial intelligence (AI) integration into triage protocols has gained attention as a potential solution.

Objective: This study aims to develop and compare 3 AI models—natural language processing (NLP), large language model (LLM), and Joint Embedding Predictive Architecture (JEPA)—for predicting triage outcomes according to the French Emergency Nurses Classification in Hospital (FRENCH) scale and to assess their performance relative to nurse triage and clinical expert consensus.

Methods: We conducted a retrospective analysis of prospectively collected data from adult patients triaged at Roger Salengro Hospital ED (Lille, France) over 7 months (June-December 2024). Three AI models were developed: TRIAGEMASTER (NLP with Doc2Vec + MLP), URGENTIAPARSE (LLM with FlauBERT + Extreme Gradient Boosting [XGBoost]), and EMERGINET (JEPA with variance-invariance-covariance regularization). Of 73,236 ED visits, 657 (0.90%) had complete audio recordings and structured data. Data were split 80:20 into training and validation sets with stratification. Gold-standard labels were established by senior clinician consensus (minimum 5 years of ED experience). The primary outcome was concordance with the gold-standard FRENCH triage level, assessed using weighted κ, Spearman correlation, F1-score, area under the receiver operating characteristic (AUC-ROC) curve, mean absolute error (MAE), and root mean square error (RMSE). Secondary analyses evaluated Groupes d'Etude Multicentrique des Services d'Accueil (GEMSA) prediction and performance by input data type.

Results: URGENTIAPARSE demonstrated superior performance, with a composite z score of 2.514 compared with EMERGINET (0.438), TRIAGEMASTER (–3.511), and nurse triage (–4.343). URGENTIAPARSE achieved an F1-score of 0.900 (95% CI 0.876-0.924), an AUC-ROC of 0.879 (95% CI 0.851-0.907), a weighted κ of 0.800 (P<.001), a Spearman correlation of 0.802 (P<.001), an MAE of 0.228, and an RMSE of 0.790. Exact agreement was 90.0%, with near-agreement (+1 or –1 level) of 92.8%. However, training showed perfect accuracy (1.0) with poor validation performance (~0.5), indicating overfitting. EMERGINET achieved moderate performance (F1-score=0.731, AUC 0.686), while TRIAGEMASTER and nurse triage performed poorly (F1-score=0.618 and 0.303, respectively). For GEMSA prediction, URGENTIAPARSE maintained superiority (κ=0.863, Spearman=0.864, P<.001). Class 1 (highest acuity) was underrepresented (4/657, 0.61%), limiting undertriage risk assessment.

XSL•FO
RenderX

Conclusions: The LLM-based architecture (URGENTIAPARSE) demonstrated the highest accuracy for ED triage prediction among the tested models, outperforming traditional NLP, JEPA, and current nurse triage practices. However, severe overfitting, extreme selection bias (657/73,236, 0.90%, inclusion), a monocentric design, and sparse high-acuity representation limit clinical applicability. Before deployment, the model requires regularization, external validation across diverse EDs, prospective testing, and comprehensive safety evaluation, particularly for undertriage detection. Integration of AI triage support systems shows promise but demands rigorous validation, bias mitigation, and transparent uncertainty quantification to ensure patient safety.

KEYWORDS

triage; emergency department; artificial intelligence; natural language processing; large language model; Joint Embedding Predictive Architecture; clinical decision support; FRENCH scale

Introduction

Triage in emergency departments (EDs) is vital for prioritizing patients by severity, directly affecting outcomes, efficiency, and resource use. In busy or understaffed settings, accurate triage is essential to ensure safe and equitable care.

In France, the French Emergency Nurses Classification in Hospital (FRENCH) triage scale has become a standardized reference tool for emergency medical services [1]. This 6-level urgency stratification system (1=immediate life-threatening to 6=nonurgent) was designed to promote consistency and reproducibility. However, in practice, its application often varies [2], shaped by disparities in nurse experience, time pressure, interpretive inconsistencies, and fatigue. These factors lead to 2 key errors: undertriage, in which serious cases are underestimated, risking delays in care and potentially preventable mortality; and overtriage, in which minor cases are overprioritized, leading to crowding and inefficient use of resources [3].

Against this backdrop, artificial intelligence (AI) has emerged as a promising complement to traditional triage [4]. AI systems in emergency medicine can process diverse data, operate continuously, and provide consistent and transparent decisions; however, their success over the past decade has been mixed.

Early AI triage systems relied on natural language processing (NLP) to extract clinical meaning from text, using hand-crafted rules or statistical models [5]. Although these early systems were effective, they lacked the ability to understand context, nuance, or rare cases. Advances emerged with large language models (LLMs) such as Bidirectional Encoder Representations from Transformers (BERT) and its French version, FlauBERT [6]. These transformer-based models provided deep contextual understanding. When combined with boosting algorithms such as Extreme Gradient Boosting (XGBoost), LLMs formed hybrid architectures that balanced high performance with interpretability [7], 2 pillars of clinical deployment. More recently, Joint Embedding Predictive Architectures (JEPA) have introduced a third paradigm. JEPA models do not predict outcomes directly; instead, they embed both inputs and targets (eg, triage categories) into a shared latent space. Using techniques such as energy minimization and variance-invariance-covariance regularization (VICReg) [8,9], these models can uncover subtle cross-modal patterns. However, their complexity poses ongoing challenges for interpretability, an essential requirement in medical contexts.

Few studies have compared AI models under consistent conditions [10,11]. Most focus on narrow tasks, rely on limited or noisy data, and are often developed outside the French health care system, reducing their relevance for users of the FRENCH scale. Furthermore, recent work has highlighted concerns regarding judgment biases in triage [11,12], hallucinations in LLMs [13], and the need for robust calibration and uncertainty quantification in clinical AI systems [14].

This study aims to address this gap. We conducted a retrospective analysis of triage encounters at the Centre Hospitalier Universitaire (CHU) Lille ED, one of France's major academic hospitals [15]. Using rich clinical data and nurse-patient dialogues, 3 AI models—TRIAGEMASTER, URGENTIAPARSE, and EMERGINET—were developed to predict FRENCH triage levels. These models were evaluated against expert consensus to identify the best-performing system and to assess their clinical suitability and limitations.

Methods

Study Design

This study was designed as a retrospective, observational, monocentric analysis conducted in the Adult Emergency Department of the CHU Lille, France. The ED is a high-volume academic tertiary care facility serving a diverse patient population, with approximately 73,000 adult visits annually. The investigation covered a continuous 7-month period from June 1, 2024, to December 31, 2024. This time frame was selected to capture seasonal variations in ED activity and to ensure a sufficiently large and heterogeneous dataset.

Ethical Compliance

The study adhered to strict French and European ethical standards, with approval and registration from the Comité d'Éthique de la Recherche en Santé, Health Data Hub filing (project number 18605502), and Commission Nationale de l'Informatique et des Libertés (CNIL) Méthodologie de Référence-004 compliance [16]. Audio recordings were collected with patient information at triage. Personal data were present before anonymization and underwent rigorous deidentification, including removal of names, dates, identifiers, and geographic information smaller than the department level, with transcript verification performed by 2 independent

XSL•FO
RenderX

reviewers. As this was a retrospective analysis of deidentified data, individual informed consent was waived in accordance with French regulations. The study followed the Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis (TRIPOD)-AI guidelines (see Multimedia Appendix 1). Owing to patient confidentiality, the full dataset and code are not publicly available; only the code used to define the gold standard is shared (see Multimedia Appendix 2).

Population and Inclusion Criteria

The study included adult patients (≥18 years) evaluated in the Lille CHU ED with complete structured clinical data and recorded nurse-patient audio interviews. Exclusion criteria were minors (<18 years), legally protected adults, patients who declined data use (n=2), and cases with incomplete recordings, corrupted files, missing structured data, or failed transcription quality checks (n=22).

Data Acquisition and Preprocessing

The study relied on 2 primary data sources. First, structured clinical data were extracted from the ResUrgences ED management software (version 2024.1.148; Berger-Levrault). Variables collected included age, sex, vital signs (systolic and diastolic blood pressure, heart rate, temperature, oxygen saturation, and supplemental oxygen requirement), pain score (visual analog scale 0-10), time of presentation, comorbidities, chief complaint category, the initial FRENCH triage decision, and the Groupes d'Etude Multicentrique des Services d'Accueil (GEMSA) scale (corresponding to patient outcome after diagnostic evaluation and treatment in the ED) [17].

Unstructured data from nurse-patient triage interviews were audio-recorded using standardized digital recorders and manually transcribed by trained personnel, with accuracy verified by 2 independent reviewers. Transcripts were linked using unique patient identifiers and time stamps, anonymized in accordance with CNIL guidelines, and securely stored on Health Data Hub–approved servers for modeling. Recording participation was limited to volunteer nurses (n<10) during their regular shifts, introducing potential selection bias in conversation style and patient characteristics.

Comparison of Included Versus Excluded Cohorts

To assess selection bias, we compared demographic and clinical characteristics between included patients (n=657) and the broader ED population (n=72,579) during the study period. The included cohort had a similar mean age (42.6 vs 43.2 years, *P*=.68), sex distribution (330/657, 50.2%, male, *P*=.67), and vital sign distributions. However, included patients had slightly lower acuity (mean nurse FRENCH 3.4 vs 3.1, *P*=.02) and higher admission rates (15.5% vs 12.3%, *P*=.03), likely reflecting volunteer nurse participation patterns and recording feasibility during less chaotic triage encounters (Table 1).

[c]GEMSA: Groupes d'Etude Multicentrique des Services d'Accueil.

Gold-Standard Construction

A gold-standard triage label was established through independent review by 3 senior emergency physicians (minimum 5 years of postresidency ED experience, board-certified in emergency medicine) who were strictly blinded to the original nurse triage assignment, all AI model outputs, and patient outcomes (laboratory results, imaging, disposition, and diagnoses established after the index triage encounter). Each adjudicator independently reviewed the complete triage transcript, vital signs, and demographic data, and then assigned a FRENCH level based solely on information available at the time of triage.

Initial interrater agreement was substantial (Fleiss κ=0.72, 95% CI 0.68-0.76). For the cases with disagreement (155/657, 23.6%), adjudicators met for a structured consensus discussion without knowledge of which assignments were discordant. Final consensus was reached in all cases through majority voting after discussion. This gold standard served as the reference for model training and evaluation. To assess potential incorporation bias, we conducted a sensitivity analysis excluding cases in which the gold standard differed from nurse triage by more than 1 level (n=47), and found similar model performance rankings.

Model Architectures and Training Pipelines

Three distinct AI models were developed, each representing a major class of current machine learning techniques. All models were implemented in Python 3.9 (Python Foundation) with PyTorch 1.12 and scikit-learn 1.1, and trained on NVIDIA A100 graphics processing units (40 GB VRAM), with training times of 2-4 hours per model.

Leakage Safeguards and Hyperparameter Tuning

Overview

Critical measures were implemented to prevent data leakage. All preprocessing steps (Doc2Vec fitting, FlauBERT fine-tuning, and feature scaling) were confined strictly to the training folds, with transformations subsequently applied to validation data. Hyperparameter tuning was performed using 5-fold stratified cross-validation nested within the training set only, without accessing validation data. Random seeds were fixed (seed=42) to ensure reproducibility. Early stopping monitored validation loss with a patience of 10 epochs to prevent overfitting.

TRIAGEMASTER (NLP)

This model used paragraph vector embeddings (Doc2Vec, distributed memory model; vector dimension=100, window=5, min_count=2, epochs=40) to represent free-text input [18], concatenated with *z* score–normalized numerical features derived from structured data (age, sex encoded as binary, and all vital signs). The architecture consisted of a 3-layer feedforward neural network (input→128→64→6 output classes) with Rectified Linear Unit activations [19], dropout regularization (P=.32, applied after each hidden layer), batch normalization, and an L2 weight penalty ($\lambda=1\times10^{-5}$). Optimization used the Adam optimizer with an initial learning rate of 0.001, batch size of 32, and learning rate decay (factor=0.5, patience=5 epochs). The maximum sequence length was 512 tokens. Missing data (<2% of vital signs) were imputed using median values from the training set.

Classification probabilities were derived via softmax activation. CIs for the area under the curve (AUC) were calculated using the DeLong method [20]. Model performance was evaluated across the full range of predicted probabilities. Optimal probability thresholds were defined as the predicted probability that maximized the F_1-score [21]. Inference latency averaged 47 ms per patient on production CPU hardware (Intel Xeon Gold 6248R).

URGENTIAPARSE (LLM)

Built on the FlauBERT language model (flaubert-base-cased, 137 million parameters) [6], this architecture fine-tuned contextual embeddings from patient complaints over 5 epochs with a learning rate of 2×10^{-5}, and then extracted the [CLS (classification)] token embedding (768 dimensions). These embeddings were concatenated with normalized structured variables and fed into an XGBoost classifier (n_estimators=200, max_depth=6, learning_rate=0.1, min_child_weight=3, subsample=0.8, colsample_bytree=0.8, reg_alpha=0.1, reg_lambda=1.0, scale_pos_weight adjusted for class imbalance). This hybrid design enabled both interpretability and high-dimensional pattern recognition [22]. Feature importance was derived using Shapley Additive Explanations (SHAP) values [23], providing transparent model behavior traceable to individual tokens and vital signs. The maximum sequence length was 512 tokens with truncation. Class weights were inversely proportional to class frequencies to address imbalance. Inference latency averaged 312 ms per patient.

EMERGINET (JEPA)

This JEPA encoded textual and structured inputs into a shared latent space (dimension=256) through dual encoders (text encoder: FlauBERT base + 2-layer bidirectional Long Short-Term Memory with hidden size 128 [24]; structured encoder: 3-layer MLP with hidden sizes (64, 128, 256)). The loss function minimized contrastive energy between predicted and target class embeddings using cosine similarity, regularized with VICReg (variance weight=1.0, invariance weight=1.0, covariance weight=0.04) to enforce variance >1.0, invariance via mean squared error, and a near-identity covariance matrix [8]. Training used the Adam optimizer (learning rate=1×10^{-4}, batch size=16, 100 epochs). Final classification was performed using nearest-neighbor matching in embedding space with temperature-scaled softmax (temperature=0.07). Inference latency averaged 189 ms per patient.

XSL•FO
RenderX

Training and Validation Procedures

Each model was trained on 80% of the dataset (n=526) and validated on the remaining 20% (n=131), stratified by gold-standard triage level to maintain class balance (class proportions: 1=4/657, 0.61%; 2=86/657, 13.1%; 3B=354/657, 53.9%; 4=118/657, 18.0%; and 5=95/657, 14.5%; classes 3A and 6 had 0 cases). Hyperparameter grids were searched using 5-fold cross-validation on the training data only. All models were trained 3 times with different random initializations to assess stability; reported metrics are means across runs, with SDs <0.03 for all primary metrics. Training and validation loss curves were monitored to detect overfitting.

Evaluation Metrics

Performance Metrics for Ordinal Outcomes

Model performance was assessed using both absolute error measures and classification agreement metrics. Unless otherwise specified, all *P* values were 2-tailed, with a significance threshold of α=.05. Given the ordered nature of the FRENCH scale, metrics that account for ordinality (weighted κ, Spearman correlation, and mean absolute error [MAE]) were prioritized.

MAE

This measures the average deviation between predicted and actual triage levels.

where  is the predicted value, y_i is the true value, and n is the total number of cases.

Root Mean Square Error

This emphasizes larger misclassification errors:

Weighted Cohen κ

This accounts for agreement beyond chance and penalizes larger discrepancies using quadratic weights:

where $fo_{i,j}$ are observed frequencies, $fe_{i,j}$ are expected frequencies under independence, and $w_{i,j}=(i-j)^2/(k-1)^2$ with k classes. Significance was tested via bootstrap (10,000 iterations).

Spearman Correlation Coefficient

This measures the monotonic association between predicted and true ordinal ranks:

$r_s=[\text{cov}(rg_X,rg_Y)]/[\sigma rg_X \sigma rg_Y]$ **(4)**

F1-scores

Macro F_1-score reflects the unweighted average across all triage classes (treating each class equally), whereas micro F_1-score is weighted by class frequency:

F_1-score = (TP)/[TP+1/2(FP+FN)] **(5)**

where TP denotes true positive, FP false positive, and FN false negative. Class-specific F_1-scores were calculated to assess performance in rare high-acuity classes.

Exact Agreement Percentage

This represents the proportion of predictions that exactly match the gold standard.

Near-Agreement Percentage

This represents the proportion of predictions within the +1 or –1 triage level of the gold standard.

Area Under the Receiver Operating Characteristic Curve

This summarizes discrimination across all classification thresholds, calculated using a one-versus-rest strategy for multiclass classification, with 95% CIs estimated via the DeLong method [20].

Composite z Score

This is an integrated performance indicator combining multiple metrics for ranking.

Score = $Z(-\text{MAE}) + Z(-\text{RMSE}) + Z(\kappa_w) + Z(r_s)$ **(6)**

where $Z(X) = (X - \mu_X)/\sigma_X$ standardizes each metric to mean 0 and SD 1 across all models. Negative MAE and RMSE were used, so higher z scores indicate better performance for all components.

Multiclass Brier Score

This is the mean squared difference between predicted probabilities and one-hot encoded outcomes, providing global probabilistic accurac

where  is the predicted probability for class j of case i, y_{ij} is a binary indicator (1 if true class, 0 otherwise), and k is the number of classes.

Asymmetric Error Analysis

Given the clinical importance of undertriage (predicting lower acuity than the true acuity, potentially delaying critical care), we analyzed error asymmetry by calculating the undertriage rate (proportion of predictions <true class) and the overtriage rate (proportion of predictions >true class). For classes 1-2 (highest acuity), we report sensitivity, specificity, positive predictive value, and negative predictive value separately, as undertriage in these categories poses the greatest patient safety risk.

Calibration Analysis

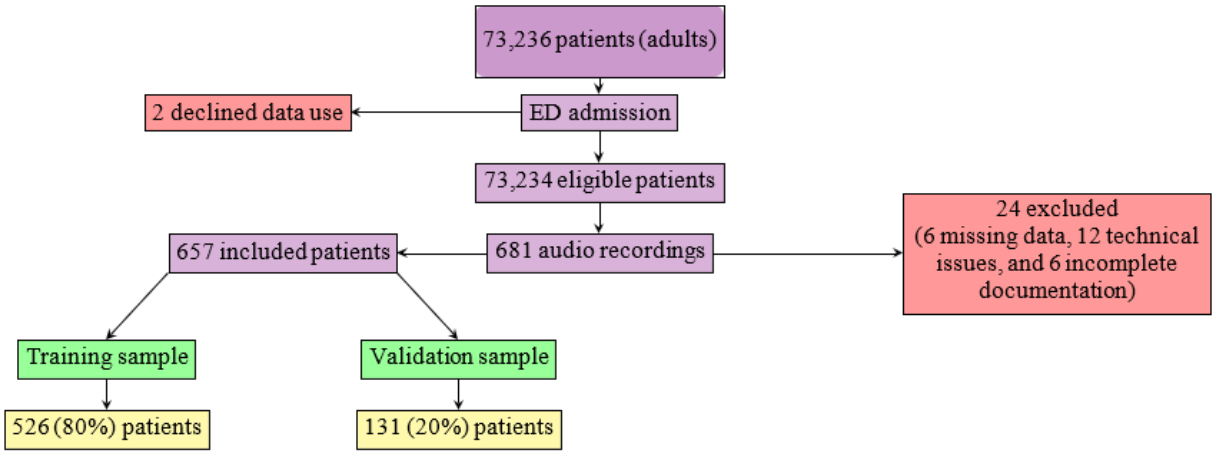
Model calibration was assessed by grouping predicted probabilities into quantile-based bins (10 bins per class) and comparing mean predicted probabilities with observed frequencies. Reliability diagrams plotted mean predicted probability versus observed frequency for each bin, with perfect calibration represented by the diagonal. Expected calibration error and maximum calibration error were computed as measures of calibration quality. Additionally, risk distributions were

XSL•FO
RenderX

visualized using density ridge plots stratified by true triage class and faceted by predicted class.

Secondary Analyses

A secondary analysis compared actual versus AI-predicted GEMSA scores (patient disposition: 2=discharged home, 3=short stay unit, 4=admitted to ward, and 5=intensive care unit [ICU]) using models trained separately on nurse-recorded structured histories and full interview transcripts. Another analysis assessed model performance according to input data type (structured data only vs unstructured transcripts only). Both analyses used evaluation methods consistent with the primary analysis. All statistical analyses were performed in R version 4.2 (R Foundation) and Python 3.9.



Results

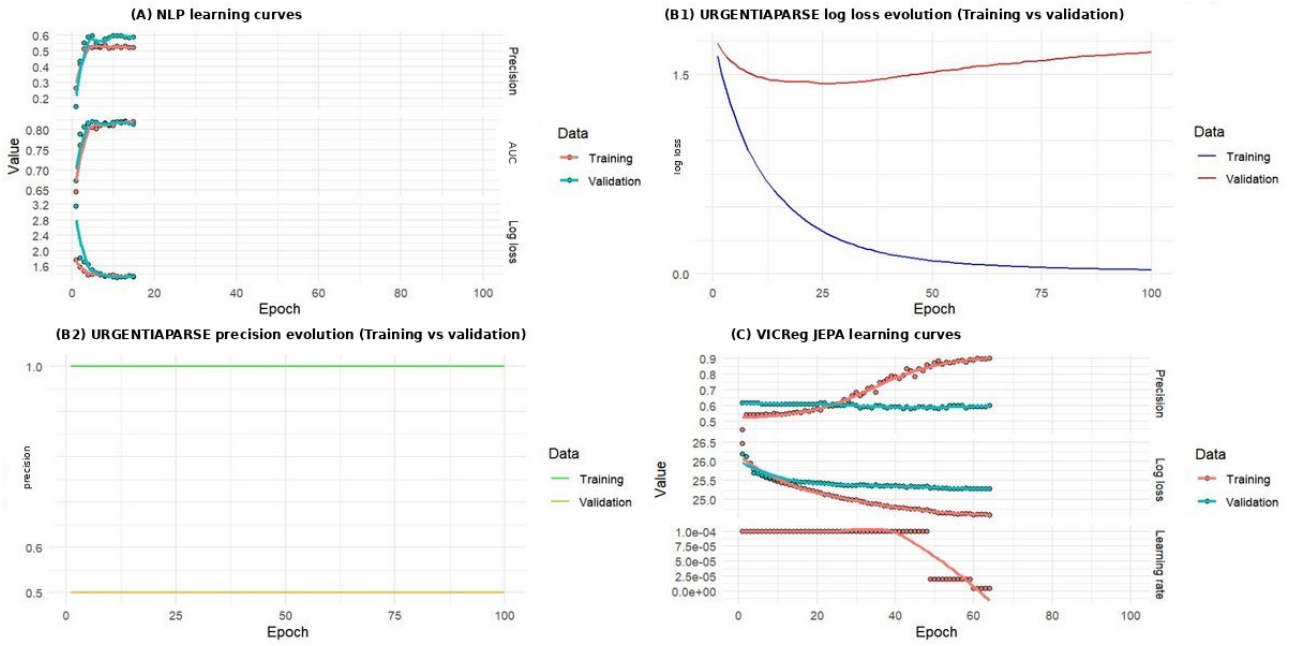
Population Characteristics

During the inclusion period, 73,236 patients visited the ED of Roger Salengro Hospital. Two patients declined data use. Triage nurse interviews were recorded and transcribed for 681 (0.93%) patients. After excluding 24 cases (6 with missing data and 18 with transcription quality issues), 657 (0.90%) patients met the inclusion criteria (Figure 1).

Included patients had a mean age of 42.6 (SD 19.7) years and a median age of 38 years. The sample was gender-balanced (330/657, 50.2%, male). Most admissions occurred during morning hours (241/657, 36.7%, 6 AM-2 PM). The primary chief complaints were trauma (127/657, 19.3%), abdominal (102/657, 15.5%), and cardiovascular (81/657, 13.1%). One-quarter of patients (161/657, 24.5%) had 1 or more comorbidities, predominantly cardiovascular. Most patients were triaged as FRENCH 3B (354/657, 53.9%), with sparse representation in the highest acuity categories (class 1: 4/657, 0.61%).

Figure 1. Patient flow diagram showing inclusion, exclusion, and dataset splitting. ED: emergency department.

Training Performance and Overfitting Assessment



Over 100 training epochs, TRIAGEMASTER achieved a training accuracy plateau of approximately 75%, with validation accuracy similarly stable at 72%, while log loss decreased and stabilized for both sets, indicating reasonable generalization (Figure 2A).

URGENTIAPARSE exhibited severe overfitting, achieving perfect training accuracy (1.0) by epoch 20 but persistently poor validation accuracy (~0.5 throughout training), indicating memorization rather than learning generalizable patterns (Figure 2B.2). Training log loss approached 0, whereas validation loss remained high and flat at approximately 1.5, with an AUC plateau of 0.69 (Figure 2B.1). This discrepancy indicates that, despite strong performance on the training data, the model fails to generalize to unseen cases—a critical limitation for clinical deployment.

EMERGINET reached a training accuracy of 0.85, but validation accuracy remained at 0.60, indicating moderate overfitting (Figure 2C). Training loss declined steadily, whereas validation loss remained higher and stable, reflecting the performance gap.

XSL•FO
RenderX

Figure 2. Learning curves for 3 artificial intelligence models. (A) TRIAGEMASTER shows stable learning with consistent training and validation performance. (B1) URGENTIAPARSE log-loss evolution demonstrates severe overfitting, with training loss approaching 0 while validation loss remains high. (B2) URGENTIAPARSE accuracy evolution confirms perfect training accuracy (1.0) but poor validation accuracy (0.5). (C) EMERGINET VICReg JEPA learning curves show moderate overfitting, with a gap between training and validation performance. JEPA: Joint Embedding Predictive Architecture; NLP: natural language processing; VICReg: variance-invariance-covariance regularization.

Overall Model Performance

URGENTIAPARSE (LLM) achieved the highest composite score (2.514), outperforming EMERGINET (JEPA, 0.438), TRIAGEMASTER (NLP, –3.511), and nurse triage (–4.343; Table 2). URGENTIAPARSE demonstrated strong discrimination, with a micro F_1-score of 0.900 (95% CI 0.876-0.924), macro F_1-score of 0.894 (95% CI 0.869-0.919), and AUC of 0.879 (95% CI 0.851-0.907). Agreement metrics were substantial: weighted κ of 0.800 (P<.001, 95% CI 0.761-0.839) and Spearman correlation of 0.802 (P<.001, 95% CI 0.768-0.832). Error metrics showed an MAE of 0.228 classes (approximately 1 triage level error every 4-5 patients) and an RMSE of 0.790. Exact agreement was 90.0%, with near agreement (+1 or –1 level) of 92.8%.

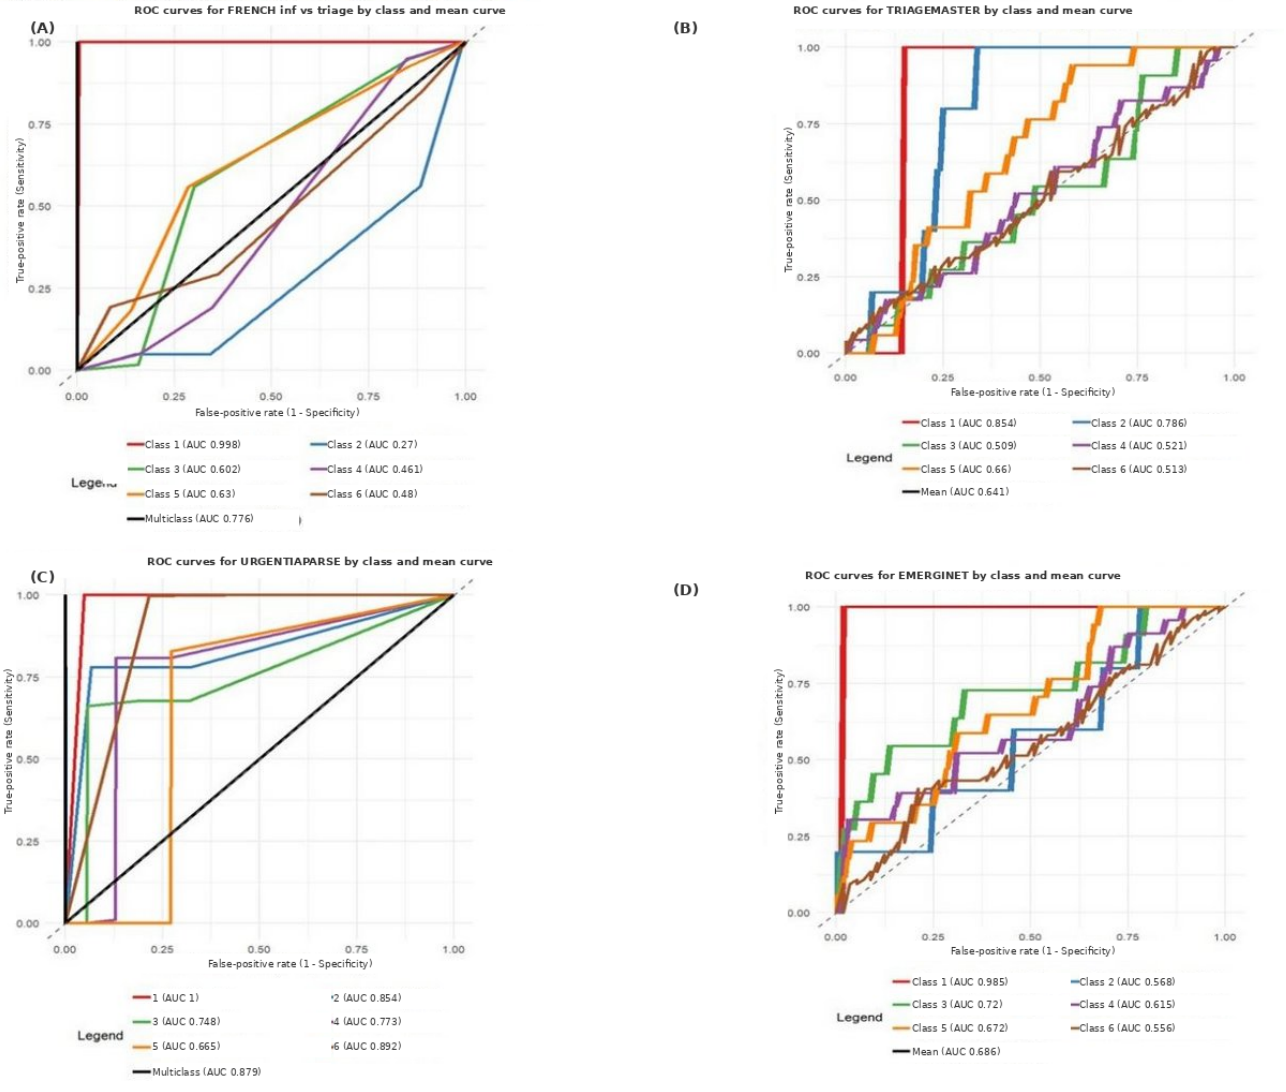
EMERGINET achieved moderate performance (micro F_1-score=0.731, macro F_1-score=0.747, AUC 0.686, κ=0.560, P<.001), whereas TRIAGEMASTER performed poorly (micro F_1-score=0.618, AUC 0.642, κ=0.370, P<.001; Spearman=0.005, P=.95). Current nurse triage showed the lowest performance (micro F_1-score=0.303, AUC 0.776, κ=0.080, P=.08; exact agreement=30.3%), likely reflecting the difference between real-time clinical judgment under time pressure and the gold standard established by senior physicians following comprehensive information review.

Receiver operating characteristic (ROC) curve analysis (Figure 3) confirmed the superiority of URGENTIAPARSE across most triage classes, with particularly strong performance for classes 2, 4, and 5 (AUC >0.85). However, class 1 performance was perfect (AUC 1.0) because of extreme sparsity (n=4), limiting the reliability of this estimate. Performance for class 3 was lower (AUC 0.748), likely reflecting the combined representation of 3A (invasive procedures) and 3B (noninvasive), with no 3A cases in the dataset.

Table 2. Primary analysis comparing triage prediction performance across artificial intelligence models and nurse triage.

Model	Mean absolute error	Root mean square error	κ[a]	Spearman[b]	Micro F_1-score	Macro F_1-score	Exact	Near[c]	z score[d]	Area under the curve
URGENTIAPARSE	0.228	0.790	0.800	0.802	0.900	0.894	0.900	0.928	2.514	0.879
EMERGINET	0.401	0.979	0.560	0.602	0.731	0.747	0.820	0.860	0.438	0.686
TRIAGEMASTER	0.637	1.180	0.370	0.005	0.618	0.613	0.554	0.696	-3.511	0.642
Nurse triage	1.393	1.834	0.080	0.024	0.303	0.275	0.303	0.498	-4.343	0.776

[a]Weighted Cohen κ; for all κ values, P<.001 except nurse triage (P=.08).



[b]Spearman rank correlation; all P<.001 except TRIAGEMASTER (P=.95) and nurse triage (P=.76).

[c]Near agreement: proportion within the +1 or –1 triage level.

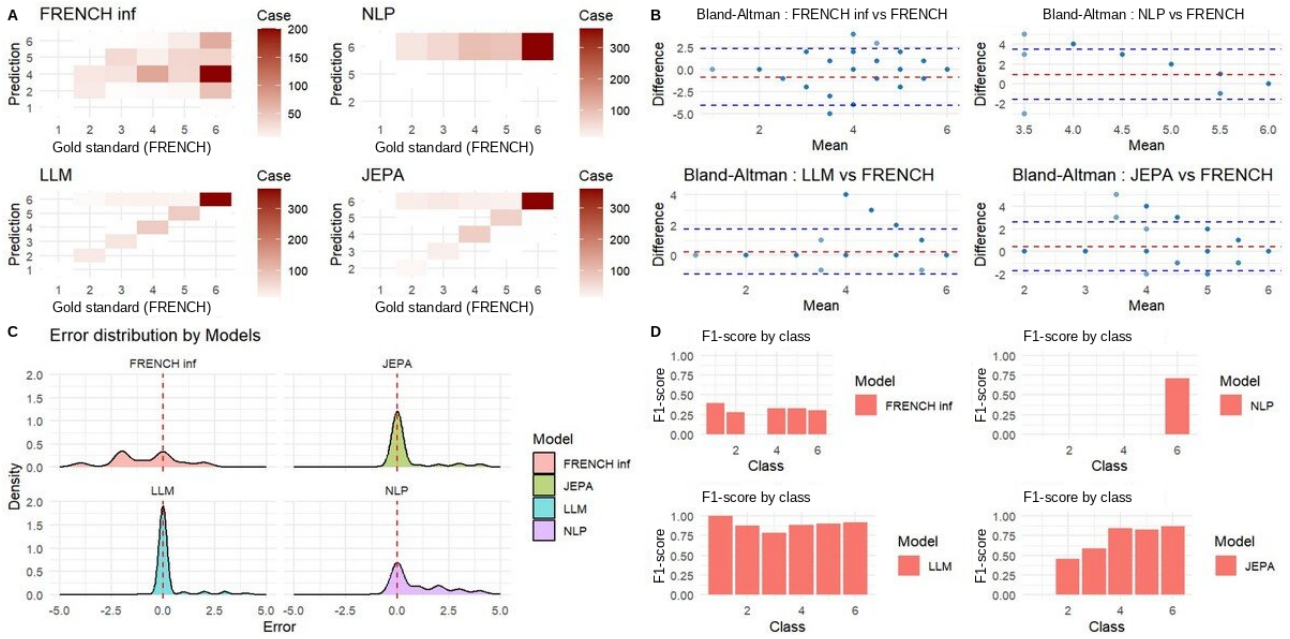
XSL•FO
RenderX

Figure 3. Receiver operating characteristic (ROC) curves for each triage class and the mean curve across all models. URGENTIA-PARSE (large language model) demonstrates superior discrimination for most classes. The results for class 1 (area under the curve [AUC] 1.0 for multiple models) should be interpreted cautiously due to extreme sparsity (n=4). (A) FRENCH inf vs triage — This panel shows ROC curves for a rule-based French triage reference system, where Class 1 achieves near-perfect discrimination (AUC 0.998) but most other classes perform poorly (AUC 0.27–0.63), yielding a modest multiclass AUC of 0.776. (B) TRIAGEMASTER — This panel displays the per-class ROC performance of TRIAGEMASTER, a structured NLP triage model, with moderate overall discrimination (mean AUC 0.641) and relatively homogeneous class-level AUCs ranging from 0.509 to 0.854, suggesting balanced but limited performance across triage levels. (C) URGENTIAPARSE — This panel presents URGENTIAPARSE's ROC curves, the best-performing model overall (multiclass AUC 0.879), with Class 1 achieving perfect separation (AUC 1.0) and strong performance across most classes, reflecting its superior ability to discriminate triage severity levels from free-text clinical notes. (D) EMERGINET — This panel illustrates EMERGINET's ROC curves, showing strong Class 1 discrimination (AUC 0.985) but more heterogeneous performance across the remaining classes (AUC 0.556–0.72), resulting in an intermediate mean AUC of 0.686.

Error Pattern Analysis

Confusion matrices revealed distinct error patterns (Figure 4, top row). URGENTIAPARSE and EMERGINET slightly overestimated acuity for lower triage levels (predicting higher urgency than true), indicating a clinically conservative bias. TRIAGEMASTER systematically underestimated acuity across most classes. Nurse triage showed scattered and inconsistent patterns, with frequent misclassification across nonadjacent categories.



Bland-Altman analysis (Figure 4, middle row) confirmed low, well-centered errors for URGENTIAPARSE (mean difference –0.02, 95% limits of agreement –1.58 to 1.54) and EMERGINET (mean difference 0.08, limits –2.05 to 2.21). TRIAGEMASTER showed larger deviations (limits –3.02 to 2.98), and nurse triage demonstrated extreme disagreement (limits –4.21 to 3.87).

Error distribution analysis (Figure 4, bottom left) showed that URGENTIAPARSE and EMERGINET had narrow, well-centered error distributions (SD <1.0), whereas TRIAGEMASTER and nurse triage exhibited broad, dispersed distributions, indicating less reliable predictions.

Class-specific F_1-scores (Figure 4, bottom right) demonstrated that URGENTIAPARSE maintained consistently high performance across all represented classes (F_1-score >0.75 for classes 2-5), whereas the other approaches showed variable and often poor class-specific performance, particularly for minority classes.

XSL•FO
RenderX

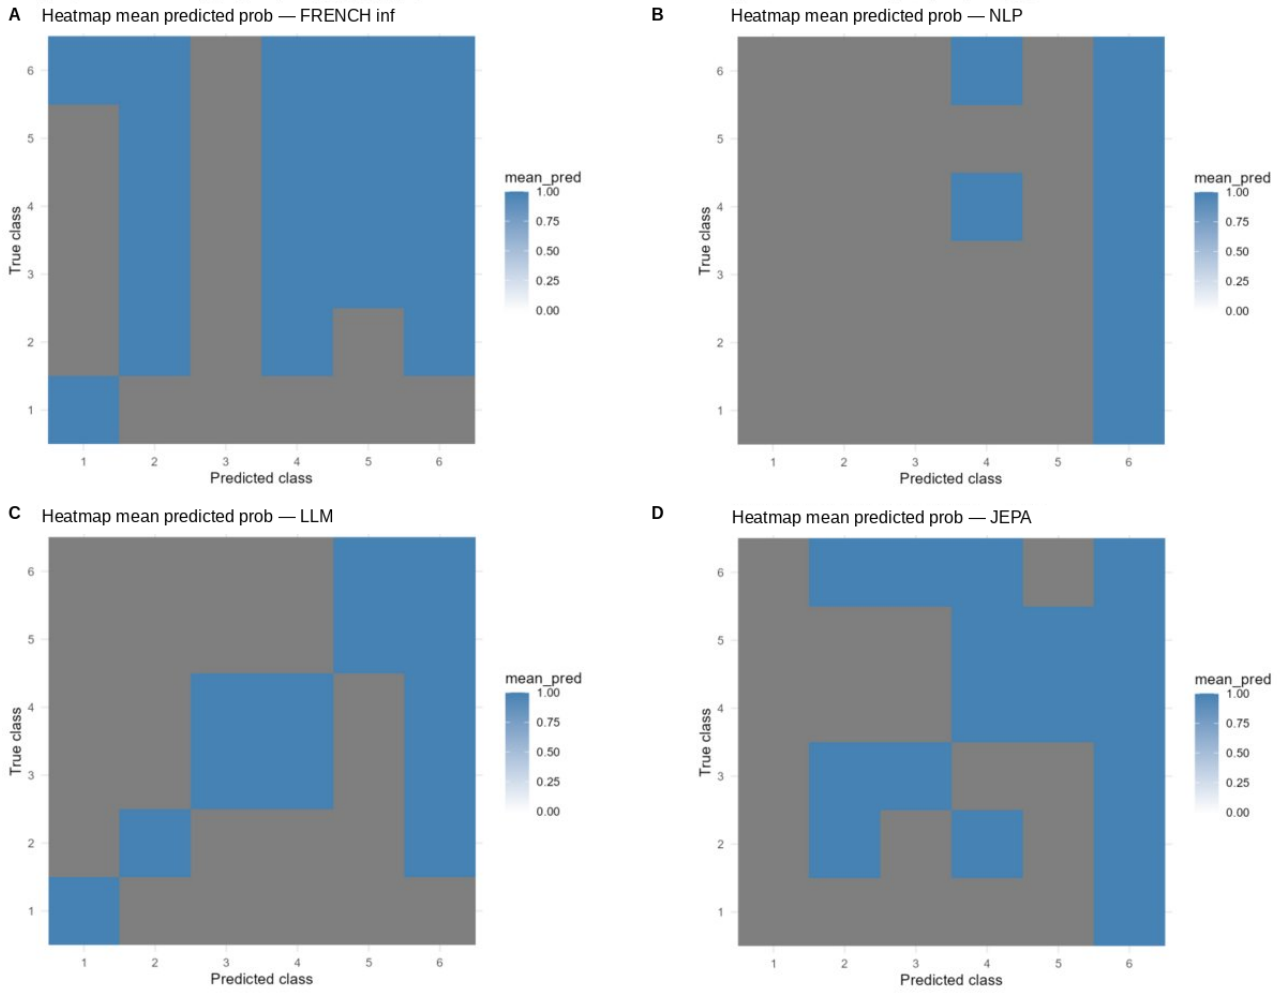
Figure 4. Comprehensive evaluation of four AI-based triage models against the FRENCH gold standard. (A) Confusion matrices comparing predicted versus gold standard triage levels (1–6) for FRENCH inf, NLP, LLM, and JEPA models. (B) Bland-Altman plots assessing systematic bias and limits of agreement between each model and the FRENCH gold standard. (C) Kernel density distributions of prediction errors illustrating the bias and precision of each model. (D) Per-class F1-scores quantifying the discriminative performance of each model across the six triage severity levels.

Asymmetric Error and Undertriage Risk

Given the clinical importance of undertriage, we analyzed error directionality. URGENTIAPARSE had an undertriage rate of 4.6% (predicting lower acuity than true) and an overtriage rate of 5.4% (predicting higher acuity), reflecting a slight conservative bias favoring patient safety. For high-acuity classes (1-2, n=90), URGENTIAPARSE achieved a sensitivity of 87.8% (95% CI 79.2%-93.7%) and a specificity of 95.1% (95% CI 91.3%-97.6%), with a positive predictive value of 86.8% and a negative predictive value of 95.6%. However, the limited representation of class 1 (n=4) constrains the assessment of undertriage risk among the most critical patients. Future deployment would require prospective monitoring, with particular attention to undertriage events and associated patient outcomes.

Calibration and Reliability

Multiclass Brier scores indicated superior probabilistic calibration for URGENTIAPARSE (0.142), compared with EMERGINET (0.385), TRIAGEMASTER (0.524), and nurse triage (0.693). However, detailed calibration analysis revealed heterogeneous reliability across classes (Figure 5).



Class-specific calibration analysis showed the following patterns:

- Class 1: Predictions were overconfident, with limited probability range coverage because of extreme sparsity.
- Class 2: Predictions were dominated by high-probability values (>0.8), indicating limited use of intermediate confidence levels.
- Class 3: Displayed a partially calibrated diagonal trend, but with inconsistencies across probability bins.
- Class 4: Demonstrated the most balanced calibration, with broader probability coverage and closer agreement between predicted and observed frequencies.

These findings highlight substantial class-specific differences and underscore the need for post hoc calibration methods (eg, temperature scaling or isotonic regression) before clinical deployment to ensure reliable probability estimates for risk stratification.

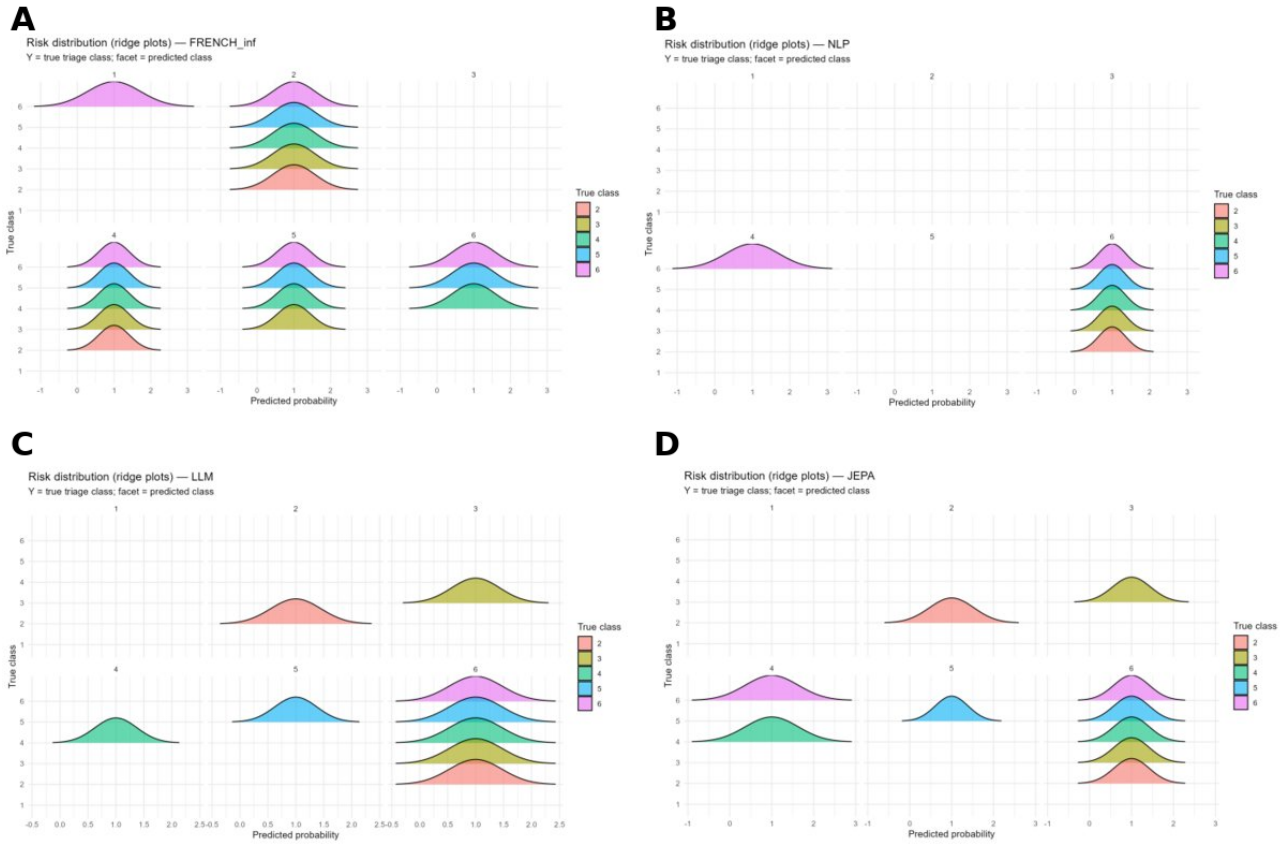
XSL•FO
RenderX

Figure 5. Mean predicted probability heatmaps for the four triage models. Each panel displays, for each true triage class (y-axis, 1–6), the mean predicted probability assigned to each predicted class (x-axis, 1–6), with blue intensity encoding probability magnitude (0–1): (A) FRENCH inf, (B) NLP, (C) LLM, and (D) JEPA — blue blocks concentrated along or near the diagonal indicate well-calibrated class-specific predictions. Perfect calibration would be indicated by high intensity only along the diagonal.

Risk Distribution Analysis

Ridge plot analysis (Figure 6) revealed distinct behavioral patterns across approaches. Nurse triage demonstrated relatively consistent distributional patterns, with moderate overlap between adjacent classes and clear modal peaks, suggesting reasonable discrimination but substantial uncertainty.

TRIAGEMASTER exhibited variable performance, with notable gaps in certain class predictions (particularly panels 1 and 3), indicating an inability to consistently predict across all triage categories. Distributions were concentrated around specific probability values, suggesting either high confidence in limited scenarios or potential overfitting.



URGENTIAPARSE displayed markedly selective characteristics, with substantial gaps in class representation across prediction scenarios. Several triage classes appeared absent in certain combinations, suggesting that the LLM produced more selective predictions. When predictions were generated, distributions were tightly concentrated with distinct modal peaks, indicating high confidence. This sparse prediction pattern may reflect superior discrimination in clear-cut cases but raises concerns regarding coverage across diverse patient presentations. It may also suggest that the model effectively refrains from uncertain predictions—a behavior that requires explicit characterization and validation.

EMERGINET showed heterogeneous patterns, with some classes displaying broad, diffuse distributions and others exhibiting sharp, concentrated peaks, indicating variable predictive confidence across triage categories.

The distinct sparse pattern observed with URGENTIAPARSE warrants careful consideration for clinical implementation. Although it may indicate superior precision in unambiguous cases, the absence of predictions for certain class combinations presents challenges for comprehensive triage coverage. This pattern requires further validation to ensure adequate performance across all patient presentations, including edge cases and ambiguous scenarios.

XSL•FO
RenderX

Figure 6. Risk score distributions by predicted triage class across models (ridge plots). For each model, predicted probability distributions are shown separately per predicted class (facets 1–6, columns) and colored by true triage class (2–6, see legend). (A) FRENCH_inf model (French clinical rule-based inference). (B) NLP model (natural language processing). (C) LLM model (large language model). (D) JEPA model (Joint Embedding Predictive Architecture). The x-axis represents the predicted probability; the y-axis represents the true triage class. Substantial overlap between distributions within a facet indicates high inter-class confusion for that predicted class.

Secondary Analysis: GEMSA Prediction

URGENTIAPARSE substantially outperformed the other models in predicting patient disposition (GEMSA), achieving a composite *z* score of 2.473 versus –2.056 for TRIAGEMASTER and –4.399 for EMERGINET (Table 3). Performance metrics included an MAE of 0.082, RMSE of 0.402, weighted κ of 0.863 (P<.001), Spearman correlation of 0.864 (P<.001), micro F_1-score of 0.957, and macro F_1-score of 0.628. High exact agreement (95.7%) and near agreement (96.0%) further confirmed its accuracy and reliability.

Confusion matrices (Figure 7, top) showed that URGENTIAPARSE produced highly concentrated predictions along the diagonal (accurate), EMERGINET demonstrated moderate accuracy, and TRIAGEMASTER displayed scattered predictions. Bland-Altman analysis (Figure 7, middle) confirmed strong agreement for URGENTIAPARSE (mean difference 0.04, limits –0.83 to 0.91), moderate agreement for EMERGINET (limits –2.12 to 1.96), and large deviations for TRIAGEMASTER (limits –2.51 to 2.25).

Error distributions (Figure 7, bottom left) showed that EMERGINET had small, tightly clustered errors; URGENTIAPARSE exhibited slightly broader but well-centered errors; and TRIAGEMASTER demonstrated wide, poorly centered distributions. Class-specific F_1-scores (Figure 7, bottom right) revealed that URGENTIAPARSE achieved consistently high scores across the represented GEMSA categories, whereas EMERGINET and TRIAGEMASTER showed poorer and more uneven performance.

XSL•FO

Impact of Data Modality: Structured Versus Unstructured Inputs

Analysis of input data type impact (Table 4) revealed that structured data (vital signs, demographics, and chief complaint codes) yielded slightly better performance than unstructured transcripts for URGENTIAPARSE (*z* score 1.806 vs 1.628) and TRIAGEMASTER (–4.790 vs –4.949), whereas EMERGINET showed minimal difference (–1.357 vs –0.993). These findings suggest that (1) vital signs and demographic data contain substantial triage-predictive information; (2) LLMs can extract meaningful patterns from both modalities; and (3) optimal performance likely requires multimodal integration. The relatively small performance gap between modalities for URGENTIAPARSE indicates that the transcript-based LLM captures much of the clinically relevant information, supporting the feasibility of voice-based triage assistance systems.

Discussion

Principal Findings

This retrospective proof-of-concept study developed and compared 3 AI architectures for ED triage prediction using real nurse-patient interaction data and national triage standards. Of 73,236 ED visits over a 7-month period, 657 (0.90%) patients with complete audio recordings and structured data were included in the analysis. The LLM-based model (URGENTIAPARSE) demonstrated superior performance across multiple metrics (composite *z* score=2.514, F_1-score=0.900, AUC 0.879, weighted κ=0.800, $P<.001$) compared with the JEPA-based EMERGINET (*z* score=0.438), the NLP-based TRIAGEMASTER (*z* score=–3.511), and current nurse triage practices (*z* score=–4.343). Secondary analyses confirmed the superiority of URGENTIAPARSE for disposition prediction (GEMSA) and its robustness across structured and unstructured data modalities. However, severe methodological limitations—particularly extreme selection bias, overfitting, sparse representation of high-acuity cases, and the monocentric design—preclude immediate clinical deployment and underscore the need for substantial additional validation.

Comparison With Prior Work

Our findings align with and extend previous research on AI-assisted triage. The URGENTIAPARSE F_1-score (0.900) substantially exceeds that of prior French ED triage models: Clinical BELGPT-2 achieved an F_1-score of 0.62 [12], while external models such as Mistral 7B and Llama 3 8B demonstrated moderate performance, with larger models (Mixtral 8x7B) underperforming [11]. Our results also surpass those reported in the original FRENCH scale validation studies (AUC 0.83-0.86 for hospitalization prediction [1,25]) when applied by nurses, suggesting that AI has the potential to enhance triage accuracy.

However, unlike previous studies, we observed severe overfitting despite the use of regularization techniques. This likely reflects the extremely small effective sample size relative to model complexity (657 cases for the 137-million-parameter FlauBERT base), the high-dimensional input space (768-dimensional embeddings plus structured features), and substantial class imbalance with sparse representation of high-acuity cases. Recent studies on LLM hallucinations [13] and time-series forecasting [26] suggest potential mitigation strategies, including semantic entropy–based uncertainty quantification, prompt engineering, and backbone reprogramming—approaches that warrant investigation in future iterations.

Our calibration analysis revealed class-specific heterogeneity, consistent with recent findings on proper scoring rules for multiclass classification [14]. The observation that URGENTIAPARSE generates sparse, high-confidence predictions rather than well-distributed probability estimates suggests that the model may benefit from postprocessing approaches such as temperature scaling or Platt scaling to improve probability calibration before clinical implementation.

Prior studies have identified biases in triage decisions related to patient sex, nurse experience, and pain reporting [11,12]. Although our study did not explicitly assess these biases, the gold-standard consensus process and AI model evaluation framework established here could facilitate future bias detection studies. For example, systematic perturbation analyses, such as modifying patient sex references in transcripts while holding all other factors constant, could be conducted to evaluate potential model sensitivity to demographic attributes.

Clinical Implications and Deployment Considerations

If validated prospectively across diverse settings, LLM-based triage support could enhance patient safety and operational efficiency through real-time decision support that highlights high-risk cases for immediate review; quality assurance by flagging discrepancies between nurse and AI triage for senior clinician verification; training tools that provide immediate feedback to novice nurses; and workload redistribution during surge periods by prescreening low-acuity cases. However, multiple critical barriers must be addressed before deployment.

The perfect training accuracy (1.0) with poor validation performance (~0.5) observed for URGENTIAPARSE indicates

XSL•FO
RenderX

severe memorization rather than learning generalizable patterns. Potential solutions include substantial data augmentation, such as paraphrasing, synonym replacement, and back-translation for transcripts, combined with controlled perturbations of vital signs. More aggressive regularization strategies, including higher dropout rates, stronger L2 penalties, and techniques such as mixup or cutmix, may also help. Model simplification through adapter layers or low-rank adaptation (LoRA) fine-tuning of FlauBERT, rather than full model fine-tuning, could further reduce overfitting. In addition, ensemble methods that average predictions from multiple diverse architectures, transfer learning from related domains (eg, ambulance call triage or primary care urgency assessment), and active learning to selectively acquire cases with the highest model uncertainty all warrant investigation.

With only 4 (N=657) class 1 cases (0.61%) and 86 (13.1%) class 2 cases, we cannot reliably evaluate model performance for the most critical patients—those for whom undertriage could be fatal. Prospective deployment would therefore require conservative threshold selection that prioritizes overtriage over undertriage; mandatory senior clinician override for any AI-suggested downgrade relative to nurse triage; and real-time monitoring dashboards tracking undertriage events and associated patient outcomes, including ED length of stay, ICU admission, in-hospital mortality, and 72-hour return visits. In addition, automatic model deactivation should be triggered if the undertriage rate exceeds predefined safety thresholds.

Current probability estimates also require post hoc calibration—using methods such as temperature scaling, Platt scaling, or isotonic regression—to ensure reliable confidence estimates. Furthermore, implementing abstention mechanisms, whereby the model declines to issue a prediction when uncertainty exceeds a predefined threshold, may improve safety by deferring ambiguous cases to human judgment. Techniques from conformal prediction could additionally provide statistically rigorous uncertainty quantification with formal coverage guarantees.

Although SHAP values provide token- and feature-level explanations for URGENTIAPARSE predictions, clinicians require intuitive, actionable insights that align with real-world decision-making. Future work should therefore focus on generating natural language explanations—for example: “Triage level 2 suggested due to elevated heart rate (124 bpm), chest pain complaint, and description of respiratory distress.” Contrastive explanations could further enhance interpretability and trust, such as “If the heart rate were within the normal range, the predicted triage level would be 3.” Such counterfactual framing helps clinicians understand which features are most influential and how changes in patient presentation might alter the recommendation.

Real-time deployment requires inference latency under 5 seconds, a requirement met by the current 312-ms latency. However, seamless electronic health record integration without disrupting nurse workflow remains essential. An intuitive user interface that displays AI recommendations with confidence levels and key supporting features, combined with easy override mechanisms requiring mandatory documentation of the rationale, would facilitate adoption. Establishing feedback loops in which clinician corrections are logged for continuous model improvement completes the integration requirements.

AI triage support raises profound liability questions, with unclear responsibility among nurses, AI developers, and hospitals when undertriage occurs. Algorithmic bias is another concern, as model performance may vary by patient demographics, insurance status, or language. Privacy considerations regarding the secure handling of audio recordings and transcripts must be addressed, and equity requires ensuring that all patient subgroups receive accurate predictions. Comprehensive fairness audits, bias mitigation strategies, and clear governance frameworks must precede any deployment.

Limitations

This study has multiple substantial limitations that constrain interpretation and generalizability across several domains.

The severe selection bias represents perhaps the most concerning methodological limitation. Only 657 of 73,236 (0.90%) ED visits had usable recordings, representing <1% of eligible encounters. Recordings were limited to volunteer nurses (fewer than 10) during feasible moments, likely excluding the highest-acuity cases requiring immediate intervention without time for a structured interview; chaotic shifts with multiple simultaneous arrivals; patients with altered mental status, language barriers, or communication difficulties; nurses uncomfortable with recording technology; and specific periods, such as overnight and weekends. The included cohort had slightly lower acuity than the broader ED population (P=.02), introducing systematic bias that limits generalizability to the real-world case mix. Future studies must implement systematic recording protocols that capture consecutive cases across all shifts, nurses, and patient types to obtain representative samples.

The sparse representation of the highest-acuity classes constitutes the most critical limitation for clinical deployment. Out of 657 cases, class 1 included only 4 (0.61%), class 2 included 86 (13.1%), and no class 3A or class 6 cases were observed. This extreme imbalance severely limits model training on high-risk cases, where undertriage has the greatest consequences. Reliable performance estimation for rare but critical categories becomes impossible, as CIs for class 1 metrics are extremely wide. The ability to detect undertriage patterns that could lead to preventable morbidity or mortality therefore remains fundamentally constrained. Generalization to settings with different acuity distributions also cannot be assessed. Class-specific performance metrics, particularly sensitivity for classes 1-2, have limited reliability and require validation in datasets with adequate representation across the full triage spectrum. Techniques such as the synthetic minority oversampling technique or focal loss to address extreme class imbalance should be explored in future work.

The severe overfitting observed for URGENTIAPARSE fundamentally limits real-world applicability. The model achieved perfect training accuracy (1.0), whereas validation accuracy remained approximately 0.5, clearly indicating that the model memorized training examples rather than learning generalizable triage patterns. This overfitting persisted despite

XSL•FO
RenderX

dropout (P=0.3), L2 regularization ($\lambda=1\times10^{-5}$), and early stopping, suggesting that the effective sample size (n=657) is insufficient for the model complexity (137 million parameters in FlauBERT base). Although we report validation set performance rather than training set performance, the marked training-validation discrepancy signals a high risk of catastrophic failure on truly external data with different patient populations, nurse communication styles, or institutional protocols. Prospective external validation across multiple, diverse EDs is therefore essential before any consideration of clinical use. Potential solutions include more aggressive regularization, model simplification through adapter layers or LoRA fine-tuning, ensemble methods, or the collection of substantially larger training datasets, with a target of over 10,000 cases for stable LLM fine-tuning.

The monocentric design severely constrains external validity. Conducted at a single French academic tertiary care hospital, the results may not generalize to community hospitals with different patient demographics, resource levels, and triage processes. Rural or low-volume EDs, with different case mix and staffing patterns, represent an entirely different operational context. Non-French health care systems using alternative triage scales, such as the Emergency Severity Index, Canadian Triage and Acuity Scale, Manchester Triage System, or Australasian Triage Scale, would require complete model retraining and revalidation. Non-French language contexts would likewise necessitate retraining language models on appropriate corpora. EDs serving culturally, linguistically, or socioeconomically distinct patient populations may exhibit fundamentally different triage patterns. Multicenter validation across diverse settings—including academic and community hospitals, urban and rural locations, and multiple countries—is therefore required to assess transportability and identify factors that affect model performance.

The exclusion of repeat ED visits creates an important gap in our understanding of model performance. By including only index visits, we cannot assess model behavior in patients with frequent ED utilization, complex chronic conditions requiring a longitudinal perspective, or evolving clinical presentations across multiple encounters. Repeat visitors often present atypically and may benefit most from AI-assisted triage, yet they were systematically excluded from model development. This exclusion may bias performance estimates upward if repeat visitors are more difficult to triage accurately.

Several concerns regarding gold-standard construction could introduce incorporation bias. Adjudicators reviewed complete transcripts and vital signs with unlimited time for deliberation, in sharp contrast to real-time nurse triage conducted under time pressure and with incomplete information. This fundamental difference in decision-making context may overestimate AI-human agreement, as both the AI and gold-standard adjudicators had access to complete information unavailable to real-time nurses. Although blinded to outcomes, adjudicators were aware that they were establishing a research gold standard rather than making operational decisions with immediate consequences, which may have influenced risk tolerance and the willingness to assign higher acuity levels. The initial interrater agreement (κ=0.72) indicates substantial but not perfect consensus, with a 23.5% disagreement rate suggesting meaningful variability in expert interpretation even with complete information. The gold standard therefore reflects retrospective expert judgment, which may differ from optimal real-time triage, particularly when information available only after initial presentation is considered. A sensitivity analysis excluding cases with nurse-gold-standard discrepancies over 1 level yielded similar results, partially mitigating this concern but not eliminating it.

Limited independent validation of the FRENCH scale itself represents an often overlooked limitation. Although the FRENCH scale serves as the French national standard, independent validation studies remain limited beyond the original 2009 and 2019 publications [1,25]. The original validation reported an AUC of 0.858 for hospitalization prediction and moderate correlations with resource utilization. A 2019 validation study including 29,423 patients reported similar findings, with an AUC of 0.83 and moderate but significant correlations between triage level and resource utilization or testing [25]. Thus, even compared with FRENCH validation studies, the URGENTIAPARSE model demonstrates superior AUC performance relative to nurses who conducted triage in those studies. However, our gold-standard consensus process effectively establishes an “ideal FRENCH application” and does not validate whether FRENCH itself optimally predicts patient outcomes. Future research should therefore evaluate AI predictions against objective clinical end points, such as ICU admission, in-hospital mortality, 72-hour return visits, and length of stay, independent of triage scale assignment, to assess true clinical utility rather than agreement with an imperfect reference standard.

The lack of prospective validation and real-world testing fundamentally limits our ability to make clinical recommendations. This retrospective analysis cannot assess real-time inference performance or the integration challenges that inevitably arise during deployment. The impact on actual triage decisions and nurse acceptance remains unknown and could substantially affect real-world utility. Effects on patient outcomes, ED workflow, and resource utilization also cannot be determined from retrospective data. Model degradation over time, as patient populations, disease patterns, or institutional practices evolve through concept drift, represents a realistic threat that requires prospective monitoring. Rare failure modes and edge cases typically become apparent only during large-scale deployment involving thousands or tens of thousands of predictions. Unintended consequences, such as deskilling of nurses who become overly reliant on AI recommendations, or gaming of the system if performance metrics become targets, could further undermine potential benefits. Prospective stepped-wedge cluster randomized trials comparing AI-assisted versus standard triage across multiple sites, therefore, represent essential next steps before any clinical implementation can be responsibly considered.

The absence of cost-effectiveness and implementation analyses limits informed adoption decisions. We did not evaluate the computational infrastructure costs required for deployment, including graphics processing unit servers, maintenance, and

XSL•FO
RenderX

updates, which may be substantial for resource-constrained hospitals. Training costs for nurses to use the system effectively also remain unknown and could be prohibitive if extensive instruction is required. The impact on triage time and ED throughput could be positive or negative, depending on implementation details. Cost per quality-adjusted life year gained represents the gold standard for health care economic evaluation, but requires long-term outcome data that are currently unavailable. Scalability challenges related to broad dissemination across diverse health care settings also remain unaddressed. Economic evaluation from a health system perspective is therefore essential for adoption decisions in the context of finite health care resources.

The absence of fairness and bias assessment represents a significant ethical limitation. We did not systematically evaluate whether model performance varies by patient demographics—including age, sex, race or ethnicity, insurance status, language, or socioeconomic status—potentially exacerbating health disparities. Prior work has identified sex-based and other biases in human triage decisions [11,12]; AI systems may perpetuate or amplify these biases if they are not explicitly addressed during development. If the model performs worse for already disadvantaged populations, deployment could worsen existing health inequities. Comprehensive fairness audits stratified by protected characteristics are therefore required before deployment, along with bias mitigation strategies if disparities are identified. Partnerships with ethicists, patients, and advocacy groups to define fairness metrics aligned with societal values should precede any clinical implementation.

Technological and data quality constraints affected the study throughout. Audio recording quality varied substantially, leading to transcription errors that may have affected model input quality in unpredictable ways. Equipment loss and technical failures resulted in 24 exclusions (3.5% of recorded cases), suggesting that real-world deployment would encounter similar challenges. Missing data for certain vital signs (<2%) required imputation using training set medians, which may have introduced bias. Real-world deployment would face these and additional challenges, necessitating robust handling of noisy, incomplete, or corrupted inputs with graceful degradation rather than catastrophic failure. The model's behavior when confronted with poor-quality audio, incomplete vital signs, or technical failures remains unknown.

The lack of uncertainty quantification and explicit abstention mechanisms precludes safe clinical deployment. The model currently provides point predictions without well-calibrated CIs or explicit abstention when uncertainty is high. Clinical deployment requires principled uncertainty quantification—using methods such as conformal prediction, Bayesian approaches, or ensemble disagreement—to determine when deferral to human judgment is warranted. Without such mechanisms, the model may generate highly confident yet incorrect predictions in novel situations outside its training distribution. The sparse prediction patterns observed for URGENTIAPARSE may reflect implicit abstention behavior that should be explicitly characterized; however, we have not systematically examined when or why the model declines to issue predictions.

Limited interpretability persists despite SHAP analysis. Although SHAP values provide mathematical attributions indicating which input features most influenced each prediction, they may not align with clinical reasoning patterns or offer actionable insights for clinicians. A nurse or physician may not find numerical feature importance scores intuitive or helpful in understanding why the AI generated a specific recommendation. Natural language explanation generation that translates SHAP values into clinically meaningful statements remains underdeveloped. User studies assessing interpretability from the clinician perspective are therefore needed to determine whether these explanations facilitate, rather than hinder, clinical decision-making.

Regulatory and legal uncertainties cloud the path to clinical implementation. This research prototype has not undergone regulatory review, such as Conformité Européenne (CE) marking in Europe or Food and Drug Administration (FDA) clearance in the United States, which would likely be required for medical device classification of clinical decision support software. The regulatory pathway for AI-based triage support systems remains unclear and continues to evolve. Legal liability frameworks for AI-assisted triage are also poorly defined. When undertriage occurs with AI assistance, responsibility among nurses, AI developers, and hospitals remains ambiguous. These legal and regulatory uncertainties must be resolved before widespread deployment can proceed.

Finally, the absence of a continual learning framework limits long-term sustainability. Static models trained on historical data inevitably degrade as patient populations, diseases, and clinical practices evolve. Deployment would therefore require active monitoring of model performance in production; detection of performance degradation or concept drift; triggered retraining protocols when performance declines; and potentially online learning mechanisms to adapt to changing patterns while maintaining safety. We have not developed or validated any such infrastructure. Without continual learning capabilities, the model would become progressively obsolete, even if initially successful.

Despite these numerous and substantial limitations, this study provides important proof-of-concept evidence that LLM architectures can achieve high accuracy for ED triage prediction when evaluated using carefully collected retrospective data. The study also establishes a rigorous evaluation methodology that incorporates multiple complementary metrics and comprehensive error analysis, upon which future research can build. The limitations outlined above provide a detailed road map for the substantial additional work required before clinical translation can be responsibly considered, including the specific methodological improvements, additional studies, and infrastructure development necessary to support safe and effective deployment.

Future Research Directions

Building on these findings and addressing the identified limitations, future research should prioritize several key areas.

XSL•FO
RenderX

Trials across more than 10 diverse EDs—including academic and community hospitals, urban and rural settings, and varied patient demographics—with systematic consecutive case enrollment targeting more than 10,000 patients would enable assessment of external validity, detection of site-specific effects, and adequately powered subgroup analyses. A stepped-wedge cluster randomized design would allow causal inference regarding the impact on patient outcomes, including mortality, length of stay, ICU admission rate, and 72-hour return visits, while controlling for temporal trends.

Oversampling the highest-acuity encounters in classes 1-2 through deliberate recording protocols during trauma activations, stroke alerts, cardiac arrests, and other critical presentations would enable reliable detection of undertriage and robust safety evaluation. This targeted data collection would address one of the most important current limitations.

Systematic comparison of advanced overfitting mitigation strategies is also warranted. Such evaluation should include parameter-efficient fine-tuning approaches (eg, LoRA, adapters, and prompt tuning); aggressive data augmentation (eg, back-translation, paraphrasing, synonym replacement, and controlled vital sign perturbations); semisupervised learning leveraging unlabeled transcripts; multitask learning jointly predicting triage, disposition, resource utilization, and outcomes; transfer learning from related domains such as ambulance call triage or primary care urgency assessment; and ensemble methods combining diverse architectures with different inductive biases.

Systematic assessment of model behavior under a range of perturbations would strengthen confidence in its robustness. These should include adversarial attacks representing intentional gaming; distribution shifts due to seasonal variation, pandemics, or novel diseases; missing data resulting from incomplete vital signs, silent patients, or technical failures; transcription errors arising from speech recognition failures; and edge cases, such as rare presentations, complex comorbidities, or psychiatric crises. Developing certified robustness guarantees represents an important objective.

Stratified performance evaluation by protected characteristics—including age, sex, race or ethnicity, insurance status, language, and socioeconomic status—combined with detection of disparate impact, root cause analysis of identified biases, and rigorous testing of mitigation strategies (eg, reweighting, fairness constraints, or adversarial debiasing) would address equity concerns. Partnerships with ethicists, patients, and advocacy groups to define fairness metrics aligned with societal values are essential.

Development of natural language explanation generation, contrastive explanations that articulate how predictions would change if specific features differed, visualization tools highlighting salient features, and user interface optimization informed by clinician feedback would enhance interpretability. Human factors studies evaluating how AI recommendations influence decision-making—including risks of automation bias (overreliance) or dismissiveness (underreliance)—would further inform safe implementation.

Rigorous cost-effectiveness analysis from a health system perspective; budget impact modeling; implementation barrier assessment; stakeholder engagement with nurses, physicians, administrators, and patients; workflow redesign; training program development; and sustainment planning would support adoption. Qualitative studies exploring nurse and physician attitudes, concerns, and acceptance would help identify potential obstacles early.

Infrastructure for continual model performance monitoring, concept drift detection, triggered retraining protocols, online learning mechanisms, and transparent reporting to end users and regulators would maintain performance over time. Development of living systematic reviews tracking field performance as deployment expands would build the evidence base.

Exploration of synergies with AI-assisted diagnosis supporting downstream care decisions, predictive models for ED crowding and resource planning, automated documentation reducing nurse burden, and early warning systems for deterioration after initial triage could create an integrated ecosystem. Emerging work on AI transforming health care from acute care to early prevention [27,28] suggests potential for broader impact across the care continuum.

Collaboration with regulatory agencies, including the European Medicines Agency and FDA, to establish appropriate oversight frameworks balancing innovation with patient safety, defining clinical validation requirements, and clarifying liability and postmarket surveillance obligations for AI medical devices would facilitate responsible translation.

Conclusions

This study demonstrates that LLM-based AI (URGENTIAPARSE) can achieve high accuracy for ED triage prediction, outperforming traditional NLP (TRIAGEMASTER), JEPA (EMERGINET), and current nurse triage practices when validated against a senior clinician consensus gold standard. With an F_1-score of 0.900, AUC of 0.879, weighted κ of 0.800, and 90% exact agreement, the LLM model shows promise for enhancing triage consistency and potentially supporting clinical decision-making.

However, severe methodological limitations mandate extreme caution. Critical barriers to clinical deployment include severe overfitting, with perfect training accuracy but poor validation performance indicating an inability to generalize beyond the training data; extreme selection bias, with only a 0.9% (657/73,236) inclusion rate limiting representativeness; sparse high-acuity case representation, with only 4 class 1 cases precluding reliable undertriage risk assessment where stakes are highest; a monocentric design constraining external validity; retrospective analysis without prospective real-world validation; and absent economic, workflow, fairness, and regulatory analyses.

Before any consideration of clinical deployment, this AI triage support system requires large-scale prospective multicenter validation targeting more than 10,000 cases across diverse settings; comprehensive overfitting mitigation and model robustness enhancement; targeted high-acuity case collection

XSL•FO
RenderX

enabling undertriage safety evaluation; fairness audits and bias mitigation strategies; post hoc calibration and uncertainty quantification with abstention mechanisms; interpretability enhancement with natural language explanations; human factors studies and workflow integration testing; economic evaluation and implementation planning; regulatory review and approval; and continuous performance monitoring infrastructure with concept drift detection.

While this proof-of-concept establishes technical feasibility and identifies the most promising architecture among the tested alternatives, the substantial gap between current evidence and safe clinical deployment must be acknowledged transparently. AI-assisted triage holds potential to improve patient safety, enhance consistency, reduce cognitive burden on nurses during surge periods, and support quality assurance—but realizing these benefits responsibly requires rigorous validation, thoughtful implementation, continuous monitoring, and humility about current limitations. This study provides a foundation and road map for that essential future work.

Abstract

Background: In the field of traditional Chinese medicine (TCM), diagnostic work based on tongue images to recognize the physical constitution is a process of collecting clinical information, reasoning, and combining the patient's tongue image features with questioning. It is necessary to simulate the recognition of pathological information of tongue images by TCM practitioners and professional dialogue based on tongue image features, which helps to develop an intelligent interactive system for TCM diagnosis.

Objective: This study aimed to develop and validate a vertical model of the TCM domain with TCM's understanding and reasoning capability for tongue images.

Methods: A TongueVLM multimodal large model is designed, which includes a visual encoder module, a modal fusion module, and a language decoder module. First, the visual encoder based on the CLIP-ViT (Contrastive Language-Image Pre-Training With Vision Transformer) pretrained model is used for image patch, dimensionality reduction, and migration learning, which maps the high-dimensional tongue features into low-dimensional language encoding vectors. Further, a modal fusion module with a residual architecture is applied to map visual features to a natural language word embedding space, realizing the conceptual alignment between visual encoding and TCM terminology. Finally, fine-tuning of visual instructions is performed based on the LLaMA (large language model meta artificial intelligence), and a TCM-domain large language model with 7B parameters is trained.

Results: The constructed multimodal dataset has 3 test datasets, and experiments are conducted using 3000 samples from each test dataset, respectively. Experimental results indicate that the TongueVLM model outperforms general-purpose large models on all 3 tasks. On the multimodal test dataset, the TongueVLM model achieved accuracy rates of 79.8%, 78.6%, and 60.7% in evaluation tasks respectively, it achieves 9.1%, 8.4%, and 1.1% in greater accuracy than LLaVA-OneVision, and is 7.5%, 7%, and 5.9% more accurate than Qwen2.5-VL-7B, with the text generation time being around 24 tokens per second.

Conclusions: The TongueVLM model, which achieves tongue image description generation and physical constitution reasoning in TCM, is suitable for the application of a Chinese medicine intelligent diagnosis system.

KEYWORDS

vision-language model; tongue image description generation; visual constitution reasoning; visual dialogue; intelligent diagnosis of traditional Chinese medicine (TCM)

Introduction

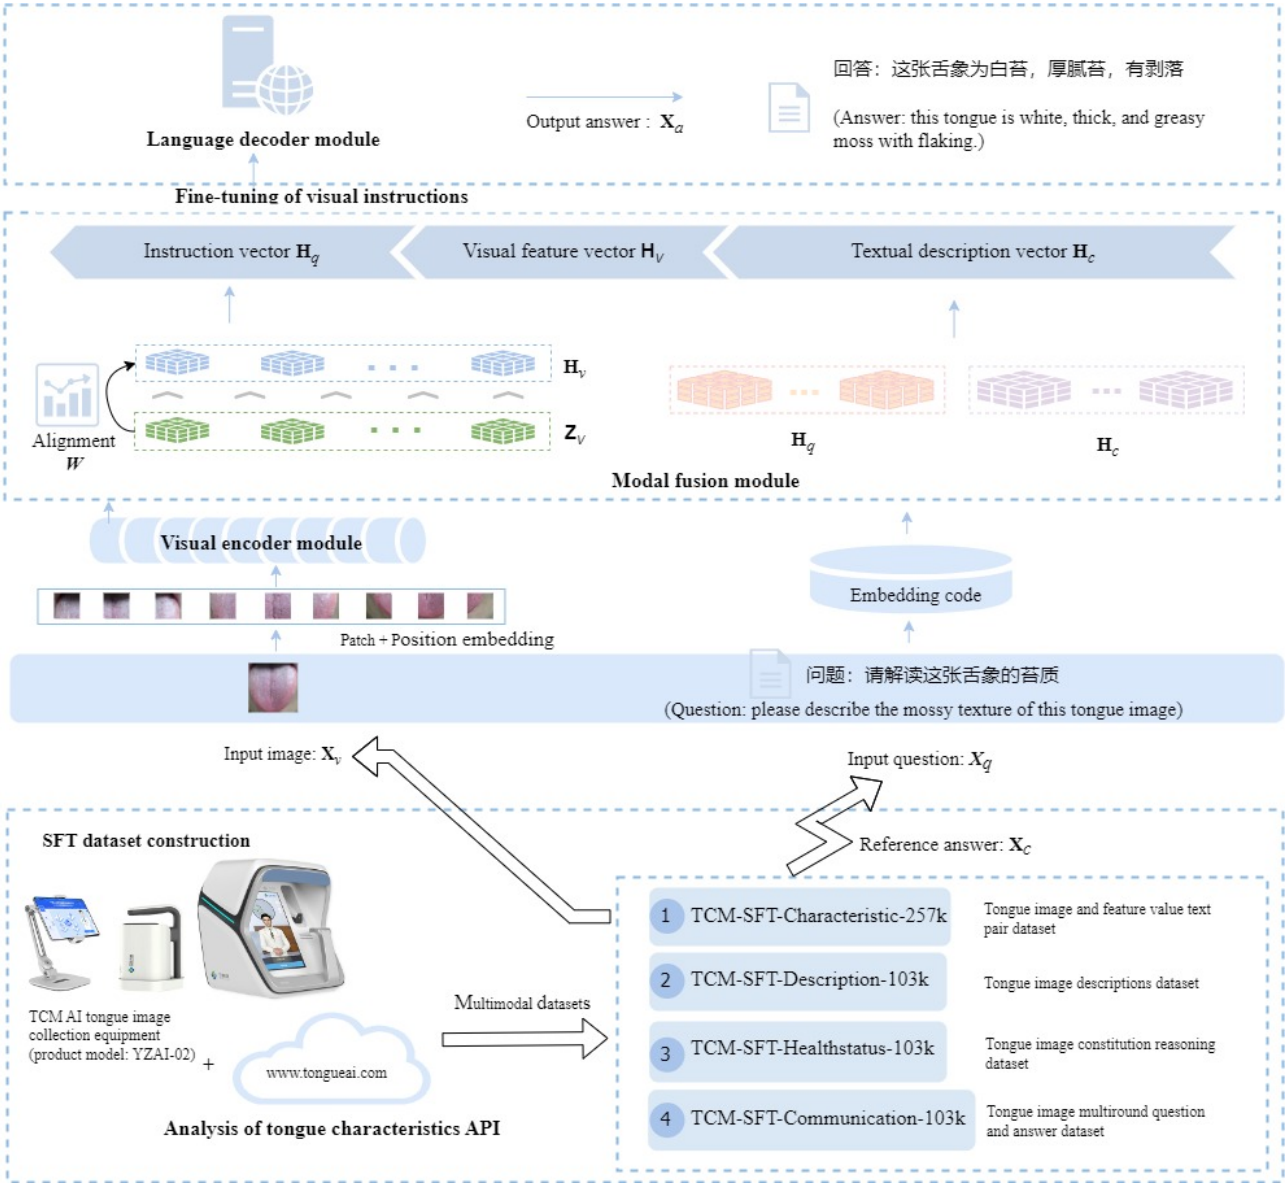
In recent years, the research focus on computer vision has gradually shifted toward innovative transformers and their variant architectures. These studies have made significant progress in the 3 basic tasks of image classification, object detection, and image segmentation, along with in-depth experiments on visual-textual multimodal data validity. The visual transformer model, represented by the vision transformer, approaches or even surpasses the convolutional neural network approach in several benchmark tests [1-14]. The key technique of the vision transformer is to construct image-to-vector transformations and effectively maintain the features of the image, bridging the gap between language and vision. Lava family [15-17], GPT-4v [18], and Gemini 1.5 [19] visual-language multimodal modeling have even ushered artificial intelligence-generated content into a new era of visual applications, and the field of medicine has received increasing attention from researchers [20-26].

In the field of traditional Chinese medicine (TCM), diagnostic work based on tongue images to recognize the physical constitution is a process of collecting clinical information, reasoning, and combining the patient's tongue image features with questioning. It is necessary to simulate the recognition of pathological information of tongue images by TCM practitioners and professional dialogue based on tongue image features, which helps to develop an intelligent interactive system for TCM diagnosis. However, the following limitations still exist in the current investigation: (1) high cost of acquisition equipment and collection of clinical data, mostly relying on publicly available datasets, and prominent data sample noise problems; (2) lack of qualitative or quantitative specialized labeling data; (3) lack of validation and analysis of the visual encoding results at the modal fusion stage; and (4) the evaluation metrics of the trained models focus on technical performance and ignore professional human judgments.

Previous studies have shown that, based on the image recognition model in the field of TCM applications, they fused the traditional image features of the tongue with deep tongue features and combined them with a machine learning model to construct a physical constitution identification, which compensated for the lack of information in a single modality and improved the accuracy of constitution classification [27-29]. In terms of training a vertical model of TCM based on a large language model (LLM), we constructed a pretraining dataset and an instruction fine-tuning dataset oriented to TCM and adopted a 2-phase training method of continuous pretraining and supervised fine-tuning to develop an LLM of TCM [30-35]. This model outperforms the existing models in several evaluation metrics and can play a role in TCM consultation.

Medical applications based on multimodal large models are also favored by researchers. A dataset containing 5.3 million+ image-text pairs was used to train the UniMed-CLIP model, which outperforms the existing health care visual language models (VLM) with 0-shot performance [36]. Multimodal health care models, which introduce evaluation metrics and frameworks and perform well in multimodal Q&A (question and answer) and text-based Q&A tasks [33,37]. BiomedCLIP with LLaMA-3 (large language model meta artificial intelligence) to realize a lightweight and efficient medical visual Q&A model [38]. Med-VQA interpretability by localizing image preference regions [39] enhanced the performance of biomedical VLMs by using instruction fine-tuning and multi-image training, respectively [40,41]. Aligned visual features with medical concepts and Med-VQA, enhanced the generation of large models, and achieved excellent performance on public datasets [42-44].

The primary aim of this study is to develop and validate TongueVLM, a specialized VLM for TCM tongue diagnosis. Specifically, our objectives were to (1) design a novel multimodal architecture that effectively aligns visual features of tongue images with domain-specific TCM textual knowledge; (2) construct a high-quality, multimodal dataset for supervised study, and end-to-end training on the TCM dataset; and (3) evaluate the performance of TongueVLM against established baseline models, and validation multimodal capabilities across 3 tasks of tongue feature description generation, physical constitution reasoning, and multiround dialogue.



Methods

Overall Architecture of TongueVLM

Our TongueVLM model uses a hybrid architecture combining the visual encoder module, modal fusion module, and language decoder module. First, the visual encoder based on the CLIP-ViT (Contrastive Language-Image Pre-Training With Vision Transformer) pretrained model is used for image patch, dimensionality reduction, and migration learning. Further, a multimodal fusion module with a residual architecture is applied to map visual features to the natural language word embedding space, realizing the conceptual alignment between visual encoding and TCM terminology. Finally, a visual-textual instruction dataset is constructed to perform multimodal instruction fine-tuning based on the LLaMA general-purpose LLM. As a result, a vertical model of the TCM domain with TCM understanding and reasoning capability for tongue images is obtained. The realization procedure is shown in Figure 1.

Model Design

Phase 1: Visual Encoder Module

In the first phase, the visual encoder module of the network was designed. Applying tongue images with TCM feature description text pair data in CLIP-ViT pretrained model migration learning. Semantically rich text is used as training labels to project the image feature representations into a kind of encoding that is like the text encoding space, as shown in Figure S1 in Multimedia Appendix 1.

First, we speak of image patch dimensionality reduction preprocessing. Scale the input image $\mathbf{x}_v \in (H,W,C)$ to $\mathbf{x} \in (h,w,C)$ (h is the height, w is the width, and C is the number of channels). Sequence of blocks that transform x into $\mathbf{x}_p \in (N^2,p^2C)$ for image patch operations. The number of blocks is $N^2=(h\times w)/p^2$, and the block dimension is (p^2C); where p is the image patch size. A sequence of blocks is converted into a patch embedding vector $\mathbf{E}_{patch}' \in (N^2,dim)$ by a linear transformation, where dim=1024, p=14, and N= 24. $\boldsymbol{x}_0$ is the zeroth encoding vector taken at the output layer of the transformer encoder, which serves as the visual feature encoding. By adding a learnable embedding vector before the image patch embedding vector E_{patch}, the image block embedding vector becomes $\mathbf{E}_{patch} \in (N^2+1,dim)$. The absolute position encoding algorithm is used to create a learnable position embedding vector $\mathbf{E}_{pos} \in (N^2+1,dim)$ for the block position. The elementwise summation operation on $\mathbf{E}_{patch}$ and $\mathbf{E}_{pos}$ yields an embedding vector $\mathbf{z} \in (N^2+1,\text{dim})$ that incorporates spatial positional encoding and visual representations.

XSL•FO
RenderX

Second, transformer encoder processing. The encoder consists of a stack of **L**=24 encoding layers, and the encoder inputs are image feature embedding vectors $z \in (N^2+1, dim)$. Each encoding layer consists of 2 unitary structures connected: the first unitary structure consists of a multihead self-attention layer and a layer normalization, as well as a residual connectivity module, and the second unitary structure consists of a feedforward fully connected layer multilayer perceptron and a layer normalization, as well as a residual connectivity module.

Phase 2: Modal Fusion Module

The modal fusion module is designed with a multilayer linearly transformed residual architecture, which is a bridging module between the visual model and the language generation model. The tongue visual encoding features are projected into the natural language word embedding vector feature space to solve the conceptual alignment problem of visual encoding with TCM terminology.

The modal fusion module design uses a combination of multiple linear layers and GELU (Gaussian Error Linear Unit) activation functions, as shown in the middle region of Figure S2 in Multimedia Appendix 1. This design allows the modal fusion layers to transform visual features while maintaining essential nonlinear characteristics. In addition, the introduction of the residual structure enables the model to realize efficient feature transformation and projection while fully preserving the integrity of the original visual features.

Splice visual encoding with textual word-embedded encoding to form a sequence of visual-textual instructions. First, the visual encoding feature $\mathbf{Z}_v$ is converted into a visual feature vector $\mathbf{H}_v$, and the textual instruction and textual description are converted into an instruction vector $\mathbf{H}_q$ and a textual description vector $\mathbf{H}_c$ by word embedding encoding, respectively. Thereafter, the vectors are spliced in the order of instruction, visual, and textual description to form the visual-textual fusion instruction sequence data.

Phase 3: Language Decoder Module

The modal fusion module connects the visual encoder and language decoder for end-to-end fine-tuned training on the constructed visual-textual data for a variety of downstream generative output tasks, such as visual quizzing, image description generation, and visual dialogue. The language decoder module chooses LLaMA, a pretrained model with good support for Chinese, which consists of a 32-layer transformer decoder layer, and each decoder layer contains an RMSNorm normalization layer, a grouping attention mechanism, and a multilayer perceptron projection layer. The network architecture is shown on the right side of Figure S2 in Multimedia Appendix 1.

During training, each input image $\mathbf{X}_v$ is associated with a few rounds of dialogue data, where each round of question description  can be defined as follows.

The visual encoder module extracts the visual feature V_x (the feature representation obtained by encoding the input image using a visual encoder) and caches it into the context, and the subsequent t-th round (t>1) of training data only needs to input the new instruction  and answer . The model automatically fuses the historical dialogue information with the initial visual feature $\mathbf{V}_x$ and builds a spliced sequence of instructions  to realize multiple rounds of dialogue training through cross-round dependency.

The instruction sequence  of multiple rounds and the corresponding output reply text  are temporally spliced into a uniform sequence , the autoregressive training objective is used for instruction tuning, and the maximum likelihood function optimization model is formulated as follows:

where θ is a trainable parameter (the training process is to adjust to maximize the likelihood function) and $\mathbf{X}_{instruct,<i}$,$\mathbf{X}_{a,<i}$ is the instruction sequence and answer sequence of all rounds before the current prediction x_i, respectively. $p(\mathbf{X}_a|\mathbf{X}_v,\mathbf{X}_{instruct})$ is the probability of predicting $\mathbf{X}_a$ under the current $\mathbf{X}_v$ and $\mathbf{X}_{instruct}$ is based on the premise of guaranteeing the accuracy of the result of $\mathbf{X}_a$under the premise that the prediction results of all rounds before the current round takes the maximum probability value.

In other words, the model uses the information accumulated in the history of the previous *t*-1 rounds of the conversation (especially the context of the textual instructions) to accurately estimate the probability distribution of the generated results in the t-th round. In this way, the model can maintain its understanding of the context over consecutive rounds of interactions and accordingly generate accurate responses associated with the content of the previous rounds.

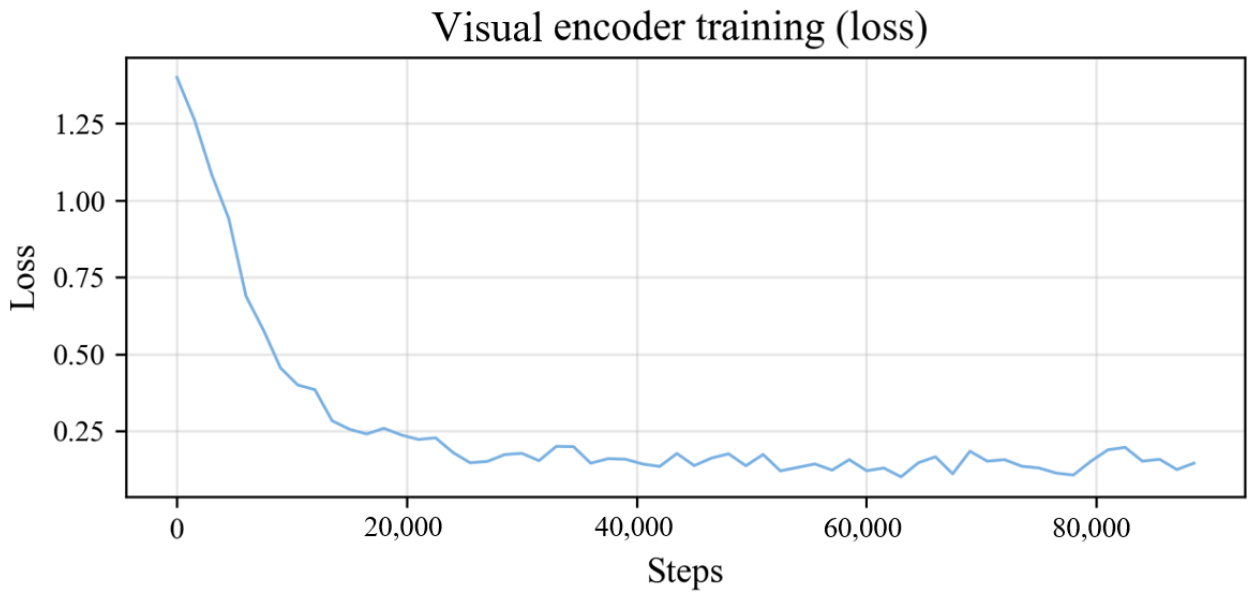
Datasets and Preprocessing

The 90,000 tongue images collected by the TCM artificial intelligence tongue image collection equipment (product model: YZAI-02) jointly developed by Hefei Cloud Diagnostics Information Technology Co and Anhui University of TCM were used, which consists of a standard LED ring light source, a portable collection device, an ultrahigh-definition camera, and a host computer, as well as supporting software. The tongue feature recognition API (application programming interface) was applied to preprocess the collected tongue images with color correction, tongue region segmentation, and tongue moss and tongue texture separation, after which tongue feature analysis was performed on the tongue images to obtain more than 40 types of qualitative or quantitative text containing tongue color, tongue texture, moss color, moss texture, and sublingual collateral data and 10 types of TCM constitution [45].

The TongueVLM training datasets are constructed, including TCM feature description data (traditional Chinese medicine–supervised fine-tuning, TCM-SFT (TCM–supervised fine-tuning)-Characteristic-257k, and TCM-SFT-Description-103k), multiround Q&A data

XSL•FO
RenderX

(TCM-SFT-Healthstatus-103k), and physical constitution reasoning data (TCM-SFT-Communication-103k). The methodology for constructing the dataset is described in Multimedia Appendix 1. The distribution of the tongue image features in the dataset is shown in Figures S3 and S4 in Multimedia Appendix 1.



Model Training Strategy

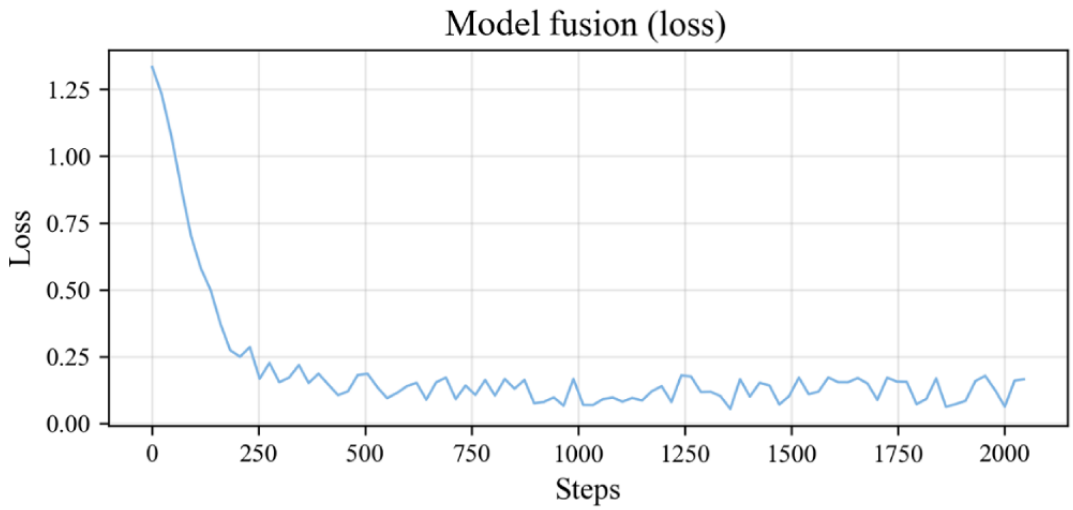
Stage 1: Pretraining of the Visual Encoder

TCM tongue characterization datasets (TCM-SFT-Characteristic-257k) of 257,000 tongue images and characterization texts are constructed, and the zeroth encoding vector used for learning by comparing the similarity between the tongue images and their corresponding tongue manifestation characterization is used for training the fine-tuning of the tongue visual encoder.

The process to obtain the visual encoder model is as follows: first, the training parameters openai/clip-vit-large-patch14-336 (OpenAI Inc, pretrained weights for the clip model on 400 million text-image pairs) were used as the initial weights for the visual encoder and the text transformer encoder. The Adam optimizer was used in the model training, with the smoothing constant betas set to (0.9, 0.999) and the weight decay parameter weight_decay set to 1e-3, the training batch size was set to 8, the learning rate was 5e-5, the number of training epochs was 3, and the maximum sequence length was 77. Second, the loss function uses the cosine similarity $Cos(I_m,T_n),m\in[1\ldots N^2],n\in[1\ldots N^2]$, where I_m is the embedding vector encoded by visual features and T_n is the embedding vector encoded by textual semantics. The optimization objective is to maximize the cosine similarity $Cos(I_j,T_j)$ between correct image-text pair embeddings while minimizing the cosine similarity $Cos(I^j,T^k),j\neq k$ of incorrect image-text pair embeddings. The results show that the loss value stabilizes after 3 epochs of training, and the loss curves are shown in Figure 2.

Figure 2. Visual encoder training loss and dynamic learning rate curves. The loss curve shows that after 3 rounds of training, the training loss of modal fusion has gradually stabilized, indicating that the model is beginning to converge.

Stage 2: Training of the Fusion Modal



TCM tongue description datasets (TCM-SFT-Description-103k) of 103,000 tongue images and description text are constructed, the visual encoder of TongueVLM and the network weights of the LLM are frozen, the visual-textual multimodal instruction data are fed into the LLM, and the modal fusion module is fine-tuned for training.

The process to obtain the modal fusion model is, first, the training method and parameters are as follows: the pretrained visual encoder weight parameters are loaded, the modal fusion layer weight parameters are randomly initialized, and only the modal fusion layer weights are allowed to participate in the gradient update. The Adam optimizer was used in the model training, with the smoothing constant betas set to (0.9, 0.999) and the weight decay parameter weight_decay set to 1e-4, the training batch size on each GPU is 8, the gradient accumulation step is 8, the learning rate is 2e-5, and the total number of iteration rounds is 3. Spend 30 hours to complete all the training on the Ubuntu (version 20.04.6, Canonical Ltd) platform using 2×RTX4090. Second, the loss function adopts the cross-entropy loss , where C is the total number of word lists, L is the length of the prediction sequence, $S_{n,i}$ denotes the probability that the word in the ith position is the nth word in the lexicon based on the previously known sequence, and $y_{n,i}$ denotes the ground-truth labels in the ith position in the prediction sequence (expressed as 1-hot encoding; ie, if the corresponding word in the position is the nth vocabulary word in the lexicon, only the first element of the 1-hot vector is 1 and the rest are 0), the goal is to minimize the loss; when the probability of each word in the prediction sequence is infinitesimally close to the actual vocabulary 1-hot encoding, that is, for any position i in the prediction sequence, $S_{n,i}\approx y_{n,i}$, the loss will be minimized, and

XSL•FO
RenderX

at this time, the model is considered to be in the optimal state. The results show that the loss value stabilizes after 3 epochs of training, and the loss curves are shown in Figure 3.

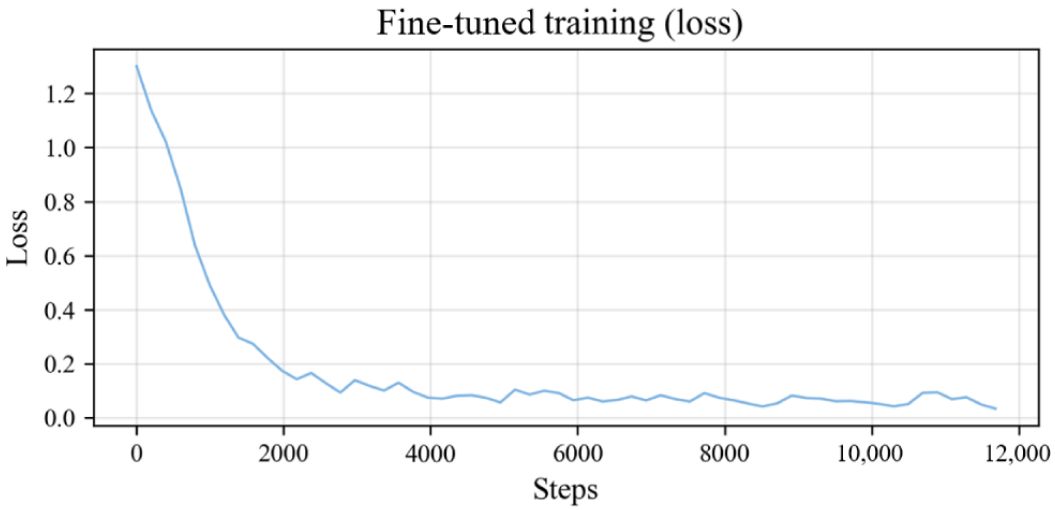


Figure 3. Loss curve of the modal fusion model. It shows that after 3 training epochs, the model enters a stable convergence state, and the loss curve for its modal fusion training stabilizes.

Stage 3: End-to-End Fine-Tuning of TongueVLM

The training data are the TCM multimodal dataset (training set 510,000; validation set 25,000). First, of the training method and parameters, load the pretrained visual encoder weight parameters and modal fusion layer weight parameters, freeze the weight parameters of the visual encoder, and allow only the modal fusion layer and the language decoder weights to participate in the gradient update. The Adam optimizer was used in the model training, with the smoothing constant betas set to (0.9, 0.999) and the weight decay parameter weight_decay set to 1e-4, the training batch size is set to 8 on each GPU, the number of gradient accumulation steps is 8, the learning rate is 2e-5, and the total number of iteration rounds is 3. It takes 135 hours to complete all the training on the Ubuntu (version 20.04.6, Canonical Ltd.) platform using 2×RTX4090. Second, of loss function, the cross-entropy loss function is adopted, and the loss curve is shown in Figure 4. After 4000 iterations, the loss tends to stabilize, and the loss fluctuation is very small when the number of iterations is 8000; currently, the model has converged.

Figure 4. Fine-tuned training loss curve of TongueVLM. It shows that with the increase of training epochs, the fine-tuning training loss of TongueVLM gradually tends to stabilize, indicating the effectiveness of the optimization algorithm and the basic convergence of the model after about 8000 iterations.

Ethical Considerations

This study was conducted in accordance with the ethical standards of the Declaration of Helsinki and was approved by the ethics committee of the Second Clinical Medical School of Anhui University of Chinese Medicine (Anhui Acupuncture and Hospital). The data used in this research were sourced from 2 distinct origins. First, for data from the Yunzhen 365 app, the data consisted of deidentified user-uploaded tongue images and associated text. All users of the app provided informed consent upon registration, agreeing to the use of their anonymized data for research purposes in accordance with the app's terms of

XSL•FO
RenderX

service and privacy policy. Second, for data from hospital records, the clinical data were obtained with approval from the relevant hospital's institutional review board (2022-zjks-25). Patient confidentiality was strictly maintained, and all personal identifiers were removed before analysis.

All procedures involving human data were reviewed and approved by the appropriate ethics committees. No additional identifiable personal information was accessed or used in this study. Participants received no compensation for their involvement in this study.

Results

Overall Performance of TongueVLM on Benchmark Tasks

The performance evaluation of the TongueVLM on the TCM multimodal test dataset is as follows.

To determine whether the answer texts generated by professional TCM practitioners are close in meaning to the standard answer texts in the corresponding test set, the evaluation is divided into 3 results; according to the degree of similarity in meaning, we define a score value Score for it, in descending order: consistent (Score=100), similar (Score=50), and irrelevant (Score=0); the accuracy of TongueVLM on the test set can be expressed as follows: , where N is the number of test datasets and $Score_i$ is the score of the i-th test dataset.

To directly verify the effectiveness of the improved methods proposed in this study for the field of TCM, we selected visual multimodal models with similar architectures for comparison: LLaVA-1.5 (released in October 2023; Meta Platforms, Inc), LLaVA-1.6 (released in January 2024; Meta Platforms, Inc), and LLaVA-OneVision (released in August 2024; Meta Platforms, Inc). To demonstrate that good results can be achieved in the field of TCM through targeted model design without relying on massive general data, we also compared it with the current open-source multimodal large model benchmark Qwen2.5-VL-7B (released in August 2024; Alibaba Cloud). The accuracy and performance are shown in Table 1. The experimental results show that the TongueVLM model outperforms the general-purpose large model on all 3 tasks; it is 9.1%, 8.4%, and 1.1% more accurate than LLaVA-OneVision and 7.5%, 7%, and 5.9% more accurate than Qwen2.5-VL-7B. The generation time efficiency of each large model is similar, with the generation time of text being 24 tokens per second (approximately 40 words per second, given the word-to-token ratio in our dataset). Due to the optimization of the lexicon in the field of TCM, TongueVLM inference speed is slightly faster than the baseline model.

Table 1. Evaluation indicators for the output of the model. Shows the evaluation metrics of the model output. Experiments are conducted using the test dataset of 3 multimodal datasets, with each test dataset containing 3000 samples with detailed data represented as: number of scores 0, number of scores 50, number of scores 100/total number of test datasets.

Ablation Studies on the 3-Stage Training Strategy

Visual Encoding Feature Layer Comparison Experiment

The visual encoder extracts image features and outputs a total of 24 hidden layers (disregarding the hidden layer feature values before being input into the visual encoder), and it is necessary to select the appropriate layer as the visual feature information input. Therefore, comparison experiments were conducted on 3 datasets, and the last 5 hidden layers (20th to 24th) features were selected as the visual feature information to train the TongueVLM model; the accuracies on the test datasets are shown in Table 2 below. The experimental results show that the model performs best in all tasks when the penultimate layer of features output from the visual encoder, that is, the 23rd layer of features, is selected as the final visual feature information. These findings reveal that the visual features extracted at that depth level have significant advantages for multimodal intelligent analysis related to TCM tongue diagnosis.

XSL•FO
RenderX

Table 2. Accuracy of different hidden layers as a visual encoder in the test dataset. A total of 500 samples were randomly selected from each of the 3 multimodal test datasets for experimentation. It shows the accuracy of different hidden layers as visual encoders in the test dataset, with detailed data represented as: number of scores 0, number of scores 50, number of scores 100/total number of test datasets).

Modal Fusion Module Structure Experiment

To verify the reasonableness of the structure of the modal fusion module, 3 different neural network structures, namely, numbers 1 (Linear + GELU), 2 (Linear + GELU + Linear + GELU + Linear), and 3 (Linear + GELU + Linear + GELU + Linear + Linear + Res), are designed, and initial weights are randomized with the same datasets; the accuracy on the test datasets is shown in Table 3. The results show that the difference in the effect of the 3 structures on the final performance is not significant. However, the use of the fusion structure of group number 3, containing multilayer linear transformation, together with a multilayer nonlinear activation function and the introduction of residual connections, slightly outperforms the performance of the other schemes. Therefore, group number 3 is chosen as the neural network structure for modal fusion learning.

Table 3. Comparative analysis of the modal fusion neural network structure in terms of accuracy on the test datasets. A total of 500 samples were randomly selected from each of the 3 multimodal test datasets for experimentation with detailed data represented as: number of scores 0, number of scores 50, number of scores 100/total number of test datasets.

[a]TCM-SFT: traditional Chinese medicine–supervised fine-tuning.

Modal Fusion Module Pretraining Experiment

The weight parameters of the modal fusion are also fine-tuned for training during the overall training of the TongueVLM model; thus, the pretraining of the modal fusion is compared to that of number 1, the pretraining is fine-tuned individually, and number 2 is randomly initialized in TongueVLM without pretraining. The accuracy of the 3 test datasets is shown in Table 4 below. The results show that the accuracy improvement using the individually fine-tuned pretraining approach is significant, with 2.3%, 5%, and 3.5% improvement for the 3 datasets, respectively. Fine-tuning the modal fusion layer using the Chinese interpretation feature description data allows the model to focus more on constructing and optimizing higher-order correspondences between visual-language features.

Table 4. Evaluation of pretraining methods for modal fusion modules. A total of 500 samples were randomly selected from each of the 3 multimodal test datasets for experimentation with detailed data represented as: number of scores 0, number of scores 50, number of scores 100/total number of test datasets.

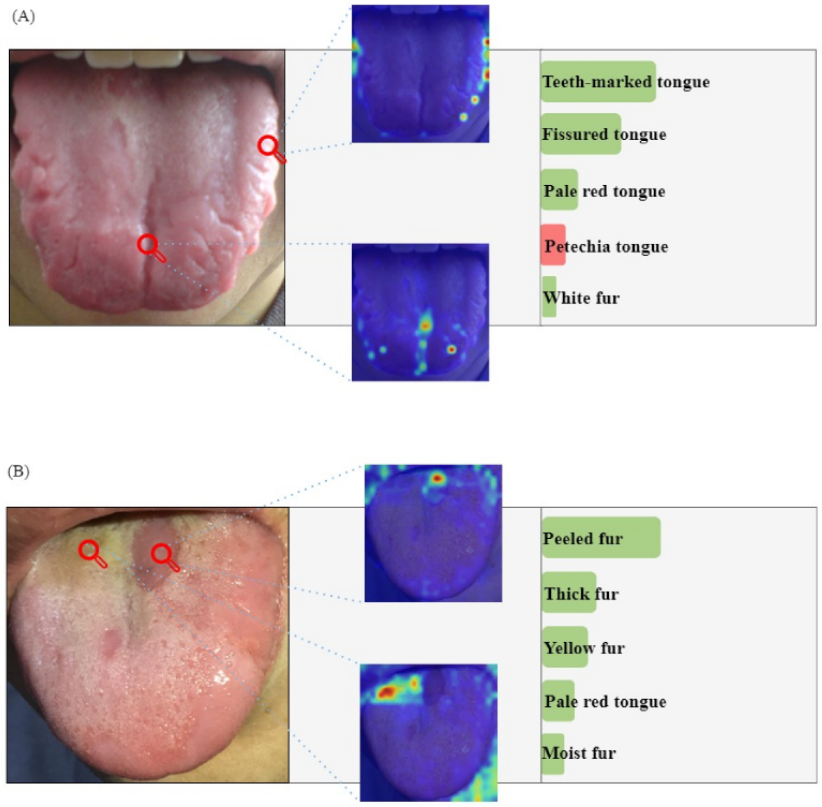
Analysis of Module Effectiveness and Interpretability

In this experiment, the visualization of the projection of the attention weight values of the multihead self-attention layer during the forward computation of the visual encoder to the image is investigated, and pseudo-color maps of the regional thermal response during the visual encoding process for typical texture feature locations on the surface of the tongue image are generated.



XSL•FO
RenderX

The multihead attention weights during the forward propagation of the cached visual encoder are Atten_weights$\in R^{(num_heads,dim,dim)}$, where num_heads$\in$(1,2,…,16) is the number of heads of multihead attention, and *dim*=577 is the length of the encoding sequence. The 0th position of the encoding sequence is the classification head, and the $E_i \in R^{(dim-1,dim-1)}$ vector represents the correlation between the 24 × 24 patches of the image in the ith attention header.

As shown in Figure 5, feature locations were selected in the tongue image; Figure 5A for fissured and teeth-marked tongues, and Figure 5B for peeled fur and yellow moss. The attention weights for the specified location are projected into the pseudo-color map of the original image. The text labels of the top 5 tongue features are obtained as output, with red indicating incorrect prediction and green indicating correct prediction, and the length of the color indicates the magnitude of its probability.

Through the feature attention visualization map, it can be seen that the visual encoder for tongue texture features focuses on localized regional positional responses, while the tongue color feature focuses on the overall area response of the image, so that the visual encoder can learn the effective feature information on the tongue, which provides good support for the subsequent feature fusion.

Figure 5. Visualization of the thermal response of the visual encoder's multihead attention. Presents the top 5 categories and their confidence levels of tongue image features predicted by the model in text form. Green represents correctly predicted labels, red represents incorrectly predicted labels, and the length of the color bars intuitively indicates the probability of the prediction.

Validation of Multimodal Capabilities Across Tasks

Tongue Image Description Generation Capability

In the task of describing the tongue images, we observe that LLaVA-1.6, LLaVA-OneVision, and Qwen2.5-VL-7B all generate output answers according to structured texts. Moreover, the text of LLaVA-1.6's response to the tongue surface image was intermingled with the description of the tongue sublingual veins. This type of response may be a language hallucination of the LLM. The output text of the TongueVLM is relatively short, but in terms of content, it focuses mainly on image color, texture, and morphological information. Representative examples of model outputs are shown in Table S1 in Multimedia Appendix 1. The tongue feature interpretation of the TongueVLM model is closer to the results of visual model recognition, which fully demonstrates that the TongueVLM model, which has been fine-tuned with the tongue multimodal datasets, solves the conceptual alignment between the visual encoding of the images and the TCM terminology.

Physical Constitution Reasoning and Analysis Capability

In the task of physical constitution reasoning about the tongue image, we observe that the output of the LLaVA-1.5 model completely deviates from the TCM context and seems to lack an understanding of the concept of TCM physique, and the LLaVA-1.6 model outputs the reasoning thinking about TCM physique through the tongue image. The LLaVA-OneVision model misjudges the tongue feature as a red tongue, but can reason about the physical constitution in combination with the tongue feature. Of course, the output is also wrong.

XSL•FO
RenderX

QWen2.5-VL-7B still follows some kind of templated output content, which is accurate in understanding the tongue color and color of the tongue fur features, but misclassifies the tongue shape as fat and large and dentate to the extent that the analysis of the physical constitution is not accurate enough.

In contrast, the TongueVLM model shows professional advantages in the TCM field in terms of effectively recognizing the tongue features and then briefly outputs the results through the tongue features, but its language expression level is slightly rough and needs to be further improved. Representative examples of model outputs are shown in Table S2 in Multimedia Appendix 1.

Tongue Image Dialogue Capability

In the multiround dialogue task of TCM with tongue images, we observe that all the models can accurately recognize the teeth-marked tongue feature in the tongue image in the first round of dialogue, and LLaVA-1.6 not only interprets the tongue feature dimension but also associates more scientific knowledge with the physical condition. However, in the second round of dialogue, LLaVA-1.5 and LLaVA-1.6 gave vague answers of "possibly related." Moreover, LLaVA-OneVision and Qwen2.5-VL-7B were able to provide definite answers, but they were not related to the teeth-marked tongue feature in the previous round of dialogue. The TongueVLM model combines the content of the teeth-marked tongue feature and provides the exact answer; thus, the TongueVLM model still outperforms the other models. Representative examples of model outputs are shown in Table S3 in Multimedia Appendix 1.

The experimental results show that the TongueVLM model outperforms the general-purpose large model on all 3 tasks. First, in terms of tongue feature descriptions, the TongueVLM model is closest to the recognition results of the visual model and includes color and morphological features and local positional features, and the parallel computation time of multiple visual models is greater than that of the large model, which fully reflects the image feature retention ability and computational performance of the TongueVLM visual encoder. Second, in terms of physical constitution reasoning, it is obvious that LLaVA-1.5 does not have expertise in TCM. LLaVA-1.6, LLaVA-OneVision, and Qwen2.5-VL-7B are generated by interpreting the text according to the unified paradigm; it cannot distinguish between tongue photos and sublingual photos, and identifying the positive and negative features is difficult. The TongueVLM model, on the other hand, quantitatively analyzes and localizes the positive features of the tongue image and can reason about the physical constitution based on the tongue image features, with an accuracy of 78.6%. The traditional method requires multiple visual models to extract the tongue features and then input the feature data into decision trees, support vector machines, and other classifiers for supervised learning of somatic qualities, which is less efficient to execute. Third, in terms of multiround Q&As, the TongueVLM model's interactive answers are brief, the contextual correlation is stronger, and the language discourse is not as strong as that of LLaVA-1.6, but its overall answers are more precise and concise, and language generation is not an advantage of the visual model.

Discussion

Principal Findings

This study proposes a TongueVLM network architecture design and a 3-stage training framework, achieving state-of-the-art performance on multimodal tongue image diagnosis tasks. Crucially, ablation experiments confirm that the staged training strategy is essential for stable optimization, while visual analysis demonstrates that the model spontaneously focuses on tongue regions relevant to clinical diagnosis.

The TongueVLM multimodal model proposed in this study is characterized by the following key features. First, the visual encoder characterizes the image features with the language encoding of low-dimensional vectors and approximates the feature extraction capability of the visual model by migration learning of TCM images from the CLIP-ViT pretrained model, which is a key step in the visual-to-large language model. Second, the modal fusion module splices visual and textual instruction data, realizes a seamless connection between natural language and image feature information, and unifies the multimodal data format input to the large model. Third, the TongueVLM model is fine-tuned and trained end-to-end on the TCM dataset. The model exhibits high accuracy in all 3 tasks of tongue feature description generation, physical constitution reasoning, and multiround dialogue.

Limitations and Future Work

This study has several limitations. First, the current data modality only includes tongue image and text-based question-answering data, failing to encompass the complete information system of TCM's "observation, auscultation, inquiry, and palpation." Second, the dataset's diversity requires enhancement, with shortcomings in ethnic distribution and standardization of image acquisition environments, which may compromise the model's generalizability. Third, evaluation of generated texts (eg, tongue pattern descriptions) still relies on expert judgments with inherent subjectivity, lacking objective, fine-grained automated assessment criteria. Finally, the model's generalization capability for clinically rare tongue patterns remains to be validated.

Future research may explore the following directions: first, in terms of model architecture, a gating mechanism is introduced to achieve adaptive attention regulation. Meanwhile, it is considered to incorporate modules such as depth-wise separable convolution to compensate for the shortcomings of self-attention mechanisms in capturing local detail features. Second, expand multimodal data sources by systematically integrating comprehensive information from facial diagnosis, pulse diagnosis, olfactory diagnosis, and physical constitution identification to construct a full-disease-course diagnostic model more aligned with TCM's holistic perspective. Third, fuse multidimensional data acquisition technologies such as 400-1000 nm spectral data and thermal infrared imaging data, and 3D tongue morphology to establish a more refined quantitative tongue pattern characterization system. Fourth, explore automated evaluation frameworks based on LLMs to achieve fine-grained quantitative assessments of the professionalism, consistency, and logical coherence of generated content. Fifth,

XSL•FO
RenderX

advance prospective trials in collaboration with clinical institutions to validate the model's auxiliary diagnostic efficacy and clinical applicability in real-world diagnostic settings. Sixth, currently, TongueVLM is built upon a 7B-parameter model, and its deployment still imposes certain computational requirements. We will explore parameter-efficient fine-tuning techniques (eg, low-rank adaptation) and model quantization. Finally, the model will incorporate continuous learning mechanisms to iteratively improve its tongue image recognition accuracy and diagnostic reasoning ability, thereby advancing research on artificial intelligence–assisted TCM tongue diagnosis.

Conclusions

Intelligent diagnosis and treatment technology in the field of TCM is often based on knowledge graphs, deep learning visual models, and machine learning approaches. Traditional supervised learning is limited by the quality and size of the training data, as well as the difficulty of fusion with natural language and its limited generalizability. The findings demonstrate that the TongueVLM model achieves ideal results in terms of understanding tongue images, constitutive reasoning, and dialogue abilities, and provides a foundational framework suitable for future integration into a Chinese medicine intelligent diagnosis system.

Abstract

Background: Breast cancer affects millions of women and presents not only medical challenges but also emotional, financial, and social burdens. Beyond clinical treatment, patients increasingly turn to online cancer communities (OCCs) for informational support, emotional support, and shared coping strategies. OCCs help patients manage daily life and reduce psychological distress through shared experiences and empathetic engagement. Within these communities, emotional expressions serve as critical cues through which patients communicate their situations and needs with other OCC members.

Objective: This study explores the relationship between emotions expressed in patients' initial posts and community reactions and engagement in OCCs. Based on the emotions as social information (EASI) model and Plutchik's Wheel of Emotions, this study investigates whether different emotions function as distinct social signals that lead to different patterns of member response, and whether emotions defined as opposites elicit opposing or similar engagement behaviors.

Methods: This study examines how the 8 primary emotions expressed in an initial post—surprise, anticipation, joy, sadness, trust, disgust, fear, and anger—distinctively influence responses of members in OCCs. We collected data from a breast cancer community from 2002 to 2017 and analyzed 23,633 threads from 9137 patients with breast cancer. Using BERT (Bidirectional Encoder Representations From Transformers), we extract emotion scores from patients' initial posts, measure community engagement across 5 response dimensions, and empirically analyze how different emotions are associated with user response behaviors.

Results: The analysis shows that certain emotions, such as joy and anticipation, consistently elicit significant effects across all measured response categories (P<.001). Most other emotions, except disgust, also demonstrate significant effects in most categories (3 or 4 of 5 categories; P<.05). Consistent with the EASI perspective, different emotional expressions influence how community members allocate attention, effort, and timing in their responses in distinct ways. Moreover, for most pairs of opposite emotions (eg, surprise vs anticipation, joy vs sadness, and anger vs fear), the impacts on the 5 types of community responses move in parallel rather than opposite directions.

Conclusions: By integrating Plutchik's emotion framework with the EASI model, this study advances understanding of how emotional expressions function as social information and signals in OCCs. The findings show that emotions expressed in patients' initial posts influence community engagement not only through emotional valence, but also through the situational context that community members can infer from the initial posts. In addition, modeling emotions as continuous intensity scales helps reveal how emotional strength amplifies engagement across multiple dimensions, including participation, effort, timing, and topical relevance. These insights extend prior OCC research beyond polarity-based sentiment analysis and offer practical implications for patients, community platforms, and health care practitioners seeking to better support peer interaction and psychosocial care in digital health environments.

Introduction

Cancer is a life-threatening medical condition that can overwhelm patients with a wide range of challenges, including physical symptoms, emotional distress, financial difficulties, social isolation, etc [1-3]. For example, breast cancer, one of the most diagnosed cancers in women [4,5], traumatizes, threatens, debilitates, and devastates many female patients all over the world. Men could also endure breast cancer, with a likelihood or frequency much lower than that for women [6]. According to Breastcancer.org [7], about 32% of all new cancer cases each year are expected to be breast cancer, and it is estimated that 13% of American women will develop invasive breast cancer at some point in their lives. Although breast cancer typically has higher survival and recovery rates than some other types of cancer (eg, lung cancer and liver cancer), it usually requires ongoing care over an extended period of time [8].

The complexity of cancer care and the need for comprehensive support motivate society to provide patients with various forms of assistance in addition to medical treatments and care from physicians. Online cancer communities (OCCs) play a vital role in providing patients with cancer with technology-powered solutions to information sharing and social support [9-11]. In these communities, patients engage in interactions with other members through posting messages to share and obtain timely information (eg, treatments, symptoms, and coping strategies), medical or nonmedical experiences, care and empathy, encouragement, and companionship [10,12-18]. The tips they share about managing daily life with cancer, ranging from strategies for dealing with side effects to general nutrition advice, can help improve patients' quality of life. In this sense, engaging in OCCs can contribute to better physical health outcomes and treatment adherence.

Previous research has explored online community engagement from multiple perspectives, such as active vs passive participation, churn behavior, life span in the community, the role of moderators in improving engagement, and community members' responses to different types of initial posts [19-25]. In particular, it has been shown that other community members' responses to initial posts are important to both the initial posters and the community as a whole, because these responses not only improve the initial posters' satisfaction [26] and empowerment [27] but also contribute new information resources that help others [28,29]. Prior research on community members' responses has examined the initial poster's characteristics [21] and content [23,30], various types of social support expressed in the post content [19-22], and how participation can improve community members' emotional states [10,16,31,32]. The emotional support and sense of belonging that patients receive and develop through interacting with other members in OCCs can reduce patients' feelings of isolation and anxiety. These supports can also potentially lower the risk of depression among patients with cancer, which is crucial to their health and recovery [33-36]. Research has shown that emotions can affect a patient's acceptance of the prescribed treatments or therapeutic plan, and influence their responses to the associated stresses and anxieties [37].

Importantly, emotional expressions in OCCs are not merely reflections of patients' internal states but play a central role in affecting social interaction. Prior research conceptualizes emotional expressions as social information that helps others interpret ambiguous situations and decide whether and how to respond. In particular, the emotions as social information (EASI) model states that emotional expressions convey situational appraisals by signaling how individuals evaluate their situations, which allows observers to interpret ambiguous contexts and adjust their responses through inferential and affective processes [38]. Building on this view, Van Kleef et al [39] further argue that emotional expressions function as social signals that guide and coordinate others' behavioral responses in social interaction, with different emotions signaling distinct behavioral responses. These perspectives are especially relevant in digitally mediated health communities, where contextual cues are limited and emotional expressions often serve as primary signals of patients' needs, concerns, and circumstances.

However, most research on emotions in online communities polarized sentiments as being either positive or negative [31,40-45]. Such a dichotomy oversimplifies the complexity of human emotions, especially in situations where one must deal with highly stressful conditions such as cancer. Indeed, emotions can have multiple dimensions and are not always definitively positive or negative. For example, anger is commonly considered a negative emotion; yet, some studies have discovered its positive aspects [46]. Cancer can also evoke fear and sadness in patients when first diagnosed with cancer, and patients may later feel joy and relief when their conditions improve due to treatments. Patient emotions can also change, and their emotional intensity can vary over time [47,48], ranging from mild to strong. Patients experience these ups and downs and various emotions with changing intensities throughout their cancer management journey, and many choose to share their feelings on OCCs. It is important to recognize such complexity in both emotion types and emotion intensities expressed in patient posts and to examine how community members respond to posts that carry emotions.

To capture emotional complexity, we use Plutchik's Wheel of Emotions [49,50] to examine a more comprehensive representation of patient emotions in the context of OCCs. This framework has been widely applied to analyze emotional expressions in online text [51-53]. Figure 1 presents Plutchik's Wheel of Emotions, which consists of 8 distinct emotions: surprise, anticipation, joy, sadness, trust, disgust, fear, and anger [49]. In terms of community members' responses, according to the EASI model and the derived social signal perspective, emotional expressions function as social information and social signals in online interaction, and different types of emotions may have varying impacts on how community members interpret and respond to patient posts. Drawing on Plutchik's identification of distinct primary emotions and the EASI perspective, and taking emotion intensity into consideration, this study asks the following research question: RQ1: in OCC settings, are the type and intensity of emotions expressed in patients' initial posts associated with different patterns of community engagement and response?

XSL•FO
RenderX

Figure 1. Plutchik's 8 primary emotions.

Plutchik arranges the emotions in a circular format, with each primary emotion having an opposite emotion directly across from it on the wheel, forming 4 pairs of opposing emotions [49,50]. We modify the original Plutchik's Wheel of Emotions [49] and Plutchik's Primary Emotion Dyads [54] to show the 8 primary emotions and their opposing counterparts. This study only focuses on the 8 primary emotions in Plutchik's theory and does not consider other emotions, such as the secondary emotions that are the combinations of the primary emotions, as they are not the focus of this study. This structure reflects Plutchik's conceptualization of emotions as adaptive reactions to 4 fundamental life problems: territoriality, temporality, identity, and hierarchy [48,55]. Each life problem can be evaluated as either an opportunity or a threat, and these alternative evaluations activate different adaptive functions and corresponding emotional reactions. Emotions thus reflect not only affective states but also action readiness, such as acceptance vs rejection or protection vs confrontation. Accordingly, territoriality may evoke surprise or anticipation; temporality may evoke sadness or joy; hierarchy may evoke fear or anger, and identity may evoke disgust or trust [49].

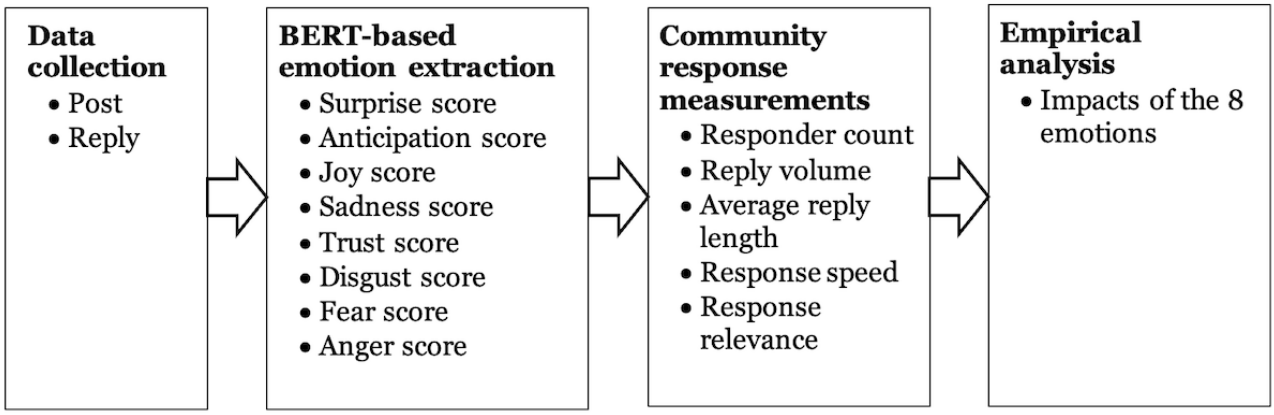
Within the cancer context, the territoriality problem refers to patients' attempts to explore their uncertain health states. As cancer outcomes are often unpredictable, patients may experience anticipation while awaiting scan results or surprise when confronted with unexpected findings. Temporality-related situations reflect concerns about the limited duration of life, which activate patients' emotions related to life longevity (joy) or loss (sadness) as the illness and treatment progress over time. The identity problem concerns inclusion and exclusion (eg, who or what is accepted or rejected), which may reflect trust or disgust toward one's diagnosis, treatment options, or the opinions and support of others. Finally, hierarchy-related threats, such as the perceived power imbalance between oneself and an uncontrollable disease or condition, may elicit patients' fear-oriented avoidance or anger-driven confrontation.

Plutchik's Wheel of Emotions suggests that the same underlying circumstances can lead to opposing emotions through alternative adaptive appraisals. Hence, the same cancer-related situation can elicit opposite emotions, depending on how patients cognitively evaluate the situation and the adaptive reactions that are activated. In contrast, existing EASI-based research has mostly examined individual emotions separately (eg, different emotions signal distinct behavioral responses from observers) [39] and has not explicitly considered how pairs of opposite emotions operate in social interaction, especially in contexts where opposite emotions may be triggered by the same or highly similar situations. If the same situation can produce different emotional expressions, it is unclear whether observers interpret these emotions as signaling different situational contexts, which leads to different responses, or as alternative emotional reactions to the same underlying situation, which leads to similar responses. Although prior studies have linked individual emotions or polarized sentiments to engagement [31,40-45], they have not examined opposing emotions as social signals in breast cancer online communities. As a result, it remains theoretically unresolved whether opposite emotions function as equivalent or opposing social signals in affecting community members' engagement behaviors, such as whether to respond, how quickly to respond, how much effort to invest, and how closely responses align with patients' expressed concerns. To directly address this unresolved issue, we ask the following research question: RQ2: Do opposite emotions elicit opposing or similar engagement behaviors and responses from community members?

By addressing these 2 research questions, we seek to ascertain whether community members' responses are driven primarily by the specific emotion expressed (ie, treating opposite emotions

XSL•FO
RenderX

as distinct social signals) or by the underlying situational context inferred from the post (ie, treating opposite emotions as alternative expressions of the same situation).



In summary, this study is aimed at providing a comprehensive and fine-grained understanding of how different types of emotions and their intensities expressed in patients with cancer's initial posts stimulate community responses in OCCs. By examining 8 primary emotions, this study moves beyond polarity-based sentiment analysis and uncovers the emotional mechanisms that affect patient engagement, peer support, and interaction dynamics in OCCs.

Methods

Study Design

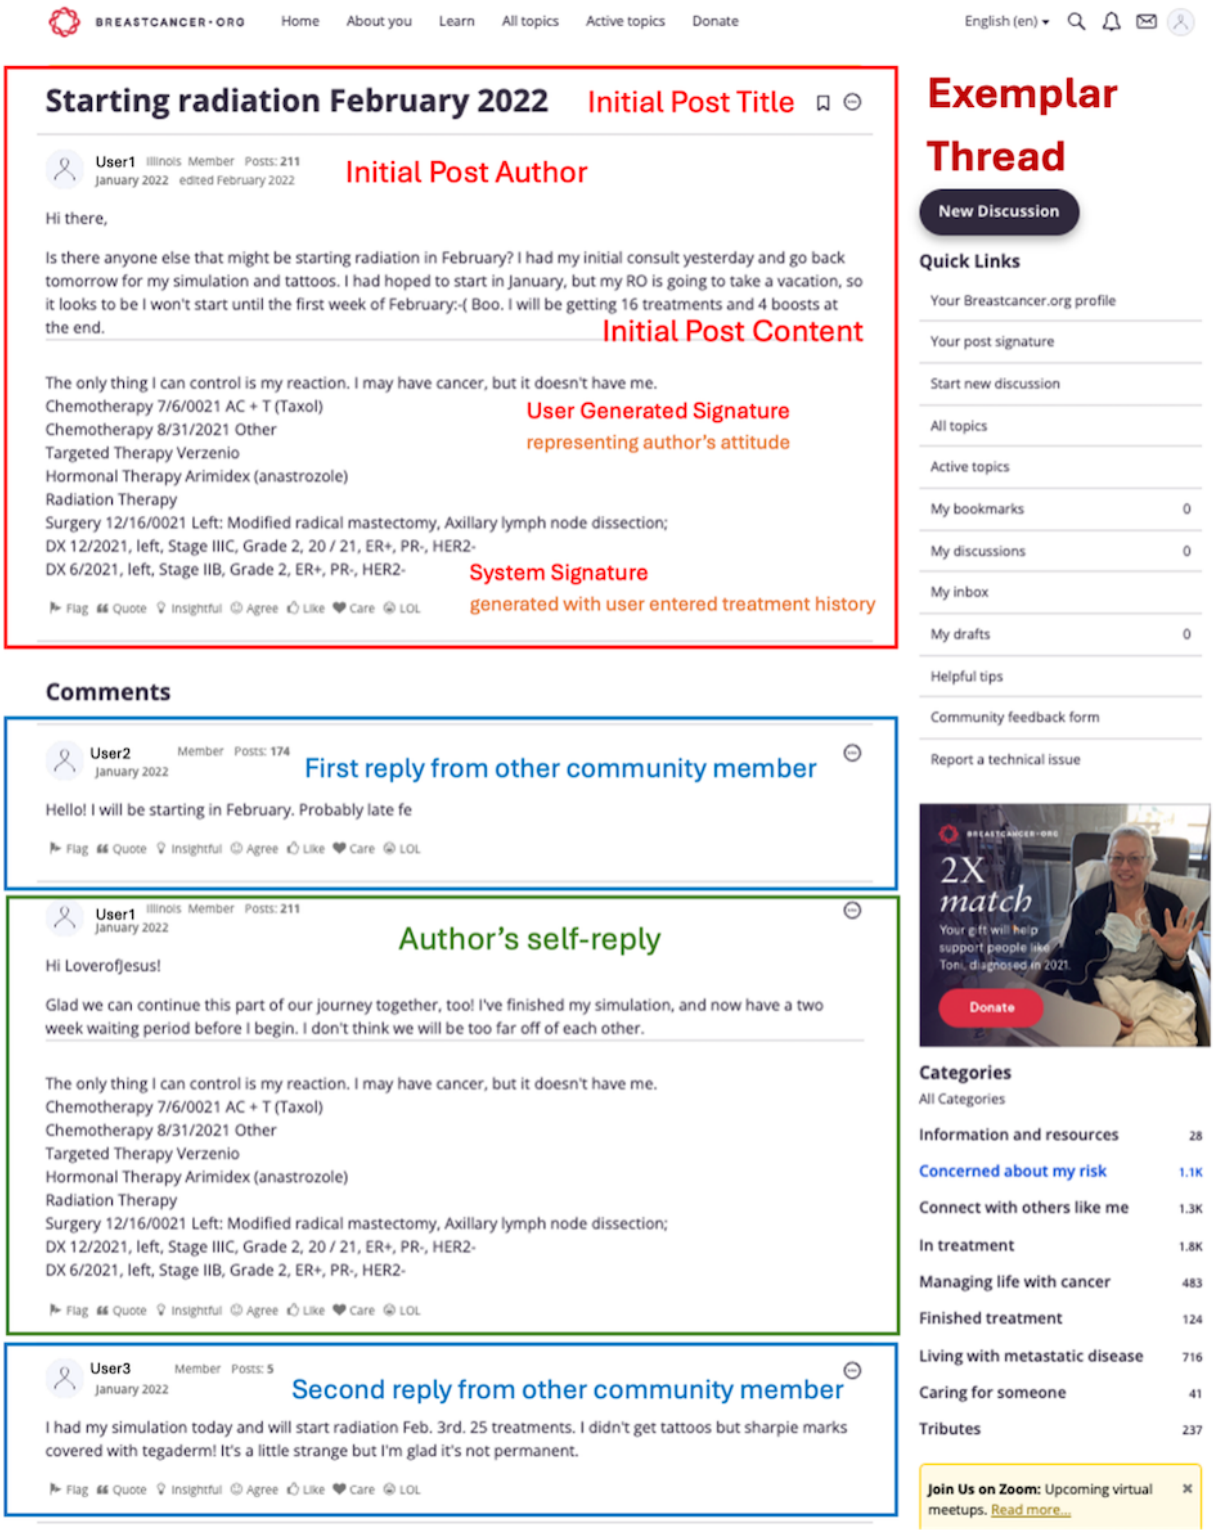
Figure 2 presents the overall process of our study, which includes 4 stages: collecting posts and replies from an OCC (a breast cancer community), extracting emotion scores from initial posts, gauging engagement behaviors by analyzing community responses, and empirically analyzing the effects of different emotions on user response behavior.

Figure 2. The overall approach. BERT: Bidirectional Encoder Representations From Transformers.

Ethical Considerations

Our study uses publicly available data from an online breast cancer community, community.breastcancer.org. The research protocol was reviewed by the Institutional Review Board at Bentley University and was determined to be exempt from further review under the US Department of Health and Human Services regulations for the protection of human research participants (45 CFR 46.102[e][2][ii]), which applies to research involving observation of public behavior where the information recorded does not allow identification of the individuals.

As this study analyzed publicly accessible user-generated content and did not involve direct interaction with participants, informed consent was not required. To protect participant privacy, all data were deidentified before analysis. Usernames and other potentially identifiable information were removed, and findings are reported only in aggregated form to prevent identification of individual users.



Participants did not receive compensation because this study relied solely on publicly available online posts and did not involve recruitment or intervention.

Data Collection

community.breastcancer.org is a prominent OCC for patients with breast cancer and covers a range of topics relevant to breast cancer, and provides a structured platform for patients to interact and exchange information. In this OCC, a patient in need of help typically starts a conversation (a.k.a., thread) by posting a message (a.k.a., initial post). Other members in the community can respond by adding their replies to the same thread. The initial poster may also post self-replies. Following each message (eg, the initial post and the replies) are the authors' signatures. There are 2 types of signatures—user-generated signatures and system signatures. User-generated signatures are customized texts that members choose to display, while system signatures are automatically generated using the member's self-reported diagnosis and treatment history. Figure 3 depicts a thread in community.breastcancer.org.

XSL•FO
RenderX

Figure 3. Exemplar thread from an online breast cancer community.

The forum consists of numerous threads, with each thread comprising an initial post followed by a chronological sequence of replies to that post. One patient may initiate multiple initial posts, and each initial post leads to 1 thread. Our dataset spans from October 21, 2002, to November 19, 2017, containing 101,171 threads initiated by 25,481 patients, with a total of 1,949,894 replies by the time of data collection. For the purposes of this study, we excluded threads with no replies and those whose initial posts were predominantly informational with minimal emotional expression. To identify informational posts and to further ensure that only emotionally expressive content remained, we applied a pretrained BERT (Bidirectional Encoder Representations From Transformers)–based sentiment analysis model, which classified each initial post as positive, negative, or neutral. Only threads whose initial posts were labeled as positive or negative were kept, while threads with neutral sentiment were removed because they contained little or no emotional content. After this screening and sentiment-based

XSL•FO
RenderX

filtering, the final dataset for analysis comprises 23,633 threads initiated by 9137 patients.

Emotion Extraction

We capture both the presence and strength of emotions expressed in the initial posts. We apply the BERT [56] model to extract the 8 emotions and explore their effects on 5 community response categories (detailed description in section Community Response Measurements). As it was impractical to annotate emotions in all 23,633 initial posts manually, we used a machine learning–based approach to extract emotions from the posts. For the 8 emotions, the score for each emotion ranges from 0 to 10, where 0 indicates that the emotion is not expressed in the post, and 10 indicates the highest level of emotional strength. The details of the extraction process are described in Multimedia Appendices 1 and 2, and the distribution of the estimated scores for each emotion is presented in Table 1.

Table 1. Distribution of the predicted emotion scores.

Emotion	Observations	Mean (SD)	Minimum	Maximum
Surprise	23,633	1.66 (0.46)	0.08	2.73
Anticipation	23,633	4.46 (0.86)	0.81	5.69
Joy	23,633	1.78 (1.31)	0.02	5.22
Sadness	23,633	3.28 (1.09)	0.02	4.86
Trust	23,633	3.37 (0.69)	1.83	5.68
Disgust	23,633	2.52 (1.01)	0	3.84
Fear	23,633	3.76 (1.42)	0	5.23
Anger	23,633	1.6 (0.94)	0	3.19

Community Response Measurements

In this study, the unit of analysis is per thread, and we examine community members' responses to the initial post within each thread in 5 categories and summarize them in Table 2.

Table 2. Definition and explanation of community response categories.

Community response category	Definition	Explanation
Responder count	The number of distinct participants, aside from the initial poster, contributing to the thread within 7 days.	A higher number of responders can make the original poster feel that more community members care about them and are interested in the topic. Additionally, increased participants generally demonstrate that the community is active and welcoming.
Reply volume	The number of replies to a thread within 7 days, excluding the original poster's self-replies.	This metric provides the original posters with a sense of the level of interest and attention generated by their initial post. A higher reply volume indicates greater engagement and interest in the topic.
Average reply length	The mean word count in replies, excluding self-replies by the initial poster, over the established time intervals (eg, 7 days).	This metric offers an estimate of the depth and quality of engagement from participants. Longer replies may indicate that participants are deeply engaging with the topic.
Response promptness	The time at which a thread receives a designated number of replies, excluding the initial poster's self-replies. Specifically, it measures the time in seconds taken (in logarithm) for a thread to reach the first 10 replies.	Response promptness reflects how quickly the thread obtains initial responses. For the original posters, a quicker response can indicate immediate interest or urgency regarding their posts. This can be particularly important for time-sensitive topics or when the poster is seeking rapid feedback from the community.
Response relevance	The average topical relevance between the original post and all replies received within 7 days.	This measure evaluates whether community replies meaningfully address the concerns or information expressed in the original post. To compute this score, Sentence-BERT[a] is used to generate embeddings for the original post and for all replies within a fixed time window (eg, 7 days). Semantic similarity (eg, cosine similarity, range from –1 to 1) is calculated for each reply-post pair. The response relevance is then computed as the average similarity of all replies falling within that time period. Higher scores indicate that replies are strongly aligned with the poster's topic, while lower scores suggest off-topic, generic, or mismatched responses.

Empirical Analysis

We use the following ordinary least squares regression model (equation 1) to evaluate the impact of expressed emotion intensity in an initial post on subsequent community responses. The independent variables are the emotion-intensity scores for the 8 primary emotions. The model additionally controls for the medical context described in the post, user attributes, prior user participation behavior, and a range of linguistic and content-based features of the post. The dependent variables, independent variables, and all control variables are summarized in Table 3.

$$\text{CommunityResponses} = \alpha_0 + \alpha_1\text{PostEmotions} + \alpha_2\text{PostHealth} + \alpha_3\text{AuthorHealthHistory} + \alpha_4\text{AuthorCommunityActivity} + \alpha_5\text{PostChar} + \varepsilon \quad (1)$$

Table 3. Summarization of the dependent variable, independent variable, and control variables.

Variables	Description
Dependent variable	
CommunityResponses	In our analysis, we treat each of the 5 categories of community response measures as a dependent variable individually. Thus, we conduct 5 separate analyses on our data: 1 for responder count, 1 for reply volume, 1 for average reply length, 1 for response promptness, and 1 for response relevance.
Independent variable	
PostEmotions	We take the independent variable in the form of scores of the 8 emotion dimensions expressed in the initial post, for example, surprise, anticipation, joy, sadness, trust, disgust, fear, and anger.
Control variables	
PostHealth	PostHealth is a set of features regarding the number of diseases, diagnoses, drugs, examinations, procedures, and symptoms mentioned in the initial post. We used an LLM[a], gpt-3.5-turbo-0125 [57], to identify and count those terms. Multimedia Appendix 3 provides more details about the identification process. These features can indicate the complexity of the patients' conditions expressed in the initial post, which may be related to how other community members respond to the initial post and lead to more targeted, in-depth discussions.
AuthorHealthHistory	AuthorHealthHistory is a group of features containing the initial poster's medical histories, including the number of diagnoses, surgeries, chemotherapy, radiation, target-therapy, and hormonal-therapy the initial poster had before starting this thread. This information is retrieved from the system-generated signature entered by the member. These features indicate the complexity of the patients' overall health conditions, which may affect how community members respond to the author, fostering more specific and detailed discussions.
AuthorCommunityActivity	AuthorCommunityActivity represents the community participation behaviors of the initial post's author, including the number of threads the author has initialized before starting the focal one, and the number of replies the author has written to others (excluding self-replies) before initializing this focal post. The reason for including this control variable is that prior research suggests that user behavior in social communities can be influenced by others' actions and history [43,58,59]. Community members who have seen the author's previous contributions may respond differently based on prior interaction and established reputation within the community.
PostChar	PostChar represents additional characteristics of the initial post, including the number of images in the post, whether the initial poster has signatures, the day of the week the post is created, and other linguistic features, which are extracted using LIWC[b] [60]. Examples of LIWC features include word count of the post, number of "I," "we," and "you" in the post, and number of family, friend, body, money, and death-related words. These features represent the initial post's content and visibility, which further impact how community members interpret and interact with the initial post.

[a]LLC: large language model.

[b]LIWC: linguistic inquiry and word count.

Results

The results of the analysis are presented in Table 4 regarding the effects of the independent variable (ie, the 8 primary emotions) on subsequent community responses across the 5 categories. Multimedia Appendix 4 reports the comprehensive results for other variables included in equation 1. The numbers in the parentheses indicate the SEs. In Table 4, columns 1 and 2 report the impacts of emotions on the responder count and the number of replies, respectively, which show significant similarities across the 2 categories. Emotions such as surprise (P<.001 for responder count and P=.03 for number of replies) and anticipation (P<.001 for both responder count and number of replies) negatively influence the responder count and reply volume, indicating that higher levels (greater intensity) of these emotions in the initial post significantly decrease the number of participants and the number of replies in the thread. Conversely, emotions such as joy (P<.001 for both responder count and number of replies), sadness (P=.003 for responder count and P=.02 for reply volume), trust (P<.001 for responder count and P=.047 for reply volume), fear (P<.001 for responder count and P=.02 for reply volume), and anger (P<.001 for both responder count and reply volume) positively affect the number of responders and replies, with increases in emotional intensity associated with more active participation. Disgust has no significant impact on the responder count but significantly increases the reply volume. Among all emotions, sadness has the most substantial effect, with each unit increase in sadness intensity attracting an average of 1.68 (SD 0.57) additional users to respond with 2.19 (SD 0.87) more replies in the thread.

XSL•FO
RenderX

Column 3 demonstrates that the stronger expressions of anticipation (*P*<.001) and anger (*P*<.001) lead to longer replies, whereas higher-intensity presence of joy (*P*<.001) and sadness (*P*=.02) in the initial post tends to result in shorter replies. Anger and sadness exert the strongest but opposite effects on the average reply length. Column 4 shows that surprise (*P*<.001), anticipation (*P*<.001), and trust (*P*<.001) positively affect response promptness, meaning that greater emotional intensity in these categories delays the time it takes for an initial post to receive a certain number of replies (in this case, 10 replies). In contrast, posts expressing a higher level of intensity in joy (*P*<.001), fear (*P*<.001), and anger (*P*<.001) prompt quicker responses from other community members. Column 5 indicates that, when the original post expresses higher-intensity anticipation (*P*<.001) and fear (*P*=.007), community members are more likely to respond in a way that remains topically consistent with the post. However, greater intensity of joy (*P*<.001) is related to lower topical relevance, which suggests that replies tend to diverge from the original post's content.

Table 4. Empirical results of emotions (independent variables only).[a]

Independent variables	Responder count (1)	Reply volume (2)	Average reply length (3)	Response promptness (4)	Response relevance (5)

To ensure the validity of our findings, we expanded our analysis to include various time windows (1, 2, 3, 10, and 30 days) and to compare the effects of different emotions. The results illustrate that, across all time intervals, sadness predominantly affects responder count, reply volume, and average reply length. Higher-intensity expressions of anger also have a strong impact on average reply length, while increases in anticipation intensity exert the most substantial influence on response promptness and response relevance among all emotions. Joy remains a relatively influential emotion across all 5 response categories. The detailed analysis process is demonstrated in Multimedia Appendix 5.

Discussion

Our findings show that both the type and intensity of emotions expressed in patients' initial posts are associated with different levels of community engagement and different response behaviors in OCCs, and that opposite emotions elicit similar rather than opposing responses, which confirms our hypothesis that the emotions shaping community engagement in OCCs extend beyond a simple positive-negative polarization. Specifically regarding RQ1, higher intensity of joy, sadness, trust, fear, and anger increase responder participation and the volume of reply, while surprise and anticipation decrease them. Sadness has the largest overall effect. Stronger expressions of anticipation and anger lead to longer replies, whereas higher-intensity joy and sadness are associated with shorter replies. Surprise, anticipation, and trust slow response speed, whereas joy, fear, and anger accelerate it. In addition, higher-intensity anticipation and fear increase topical relevance in replies, while joy reduces it. Furthermore, with respect to RQ2, this study also shows that for most opposing emotion pairs (eg, surprise vs anticipation, joy vs sadness, and fear vs anger), their effects on engagement move in parallel rather than in opposing directions. These results indicate that emotional expressions convey situational appraisals (social information) and simultaneously serve as social signals that affect how community members allocate attention, effort, and timing when providing support.

Across the 5 response dimensions, our results show that different emotional expressions influence multiple dimensions of community engagement in distinct ways, for example, whether members respond, when they respond, how much effort they invest, and how relevant their responses are. Certain emotions, including joy, sadness, anticipation, and anger, exert particularly strong effects across responder count, reply volume, reply length, response speed, and topical relevance, although the direction and magnitude of these effects vary by dimension. These findings support RQ1 by demonstrating that emotional expressions do not affect engagement uniformly; instead, different types of emotions guide attention, effort, timing, and content alignment in qualitatively different ways. This pattern is consistent with the EASI framework, which emphasizes that emotions function as social information and social signals that guide observers' interpretations and behavioral decisions.

At the same time, our results indicate that emotional intensity amplifies signaling strength but does not override situational meaning. As emotional expressions are measured as continuous intensity scores, our analysis captures how increasing emotional strength alters engagement behaviors. Higher intensity generally increases the likelihood and scale of community response, but these effects are conditional on emotion type and response dimension. Emotional intensity, therefore, enhances the importance and clarity of emotional signals, which makes situational appraisals more visible to observers, without changing the situational context conveyed by a given emotion. This finding extends prior work that treats emotions categorically or dichotomously by showing that intensity complements, rather than replaces, the informational role of emotion type.

Regarding RQ2, our findings reveal that emotions defined as opposites in Plutchik's framework do not consistently function as opposing social signals and elicit opposite engagement behaviors in OCCs. Instead, for most opposing emotion pairs (eg, surprise vs anticipation, joy vs sadness, and anger vs fear), the impacts on the 5 types of community responses move in parallel rather than opposing directions. A straightforward interpretation might be that opposite emotions receive similar reactions or community engagement because they are expressed with comparable intensity. However, our descriptive statistics do not support this explanation. As shown in our descriptive statistics, opposite emotions differ substantially in both their prevalence and intensity distributions. For example, sadness is expressed more frequently and with higher average intensity than its opposite emotion, joy; likewise, fear and anger also show distinct levels of occurrence and magnitude. As these opposite emotions do not share similar intensity patterns, the parallel effects observed in our models cannot be attributed to intensity alone. Instead, our results suggest that community members respond primarily to the situational context, such as facing uncertainty, confronting threats, or processing important outcomes, conveyed by emotional expressions rather than to emotional valence. For instance, both surprise and anticipation are about patients' reactions to unpredictable situations; both joy and sadness are related to patients' important milestones or accomplished events; both fear and anger are linked to potential threats to patients [50]. When emotions share similar appraisal meanings, they can elicit similar patterns of engagement even

XSL•FO
RenderX

when they are theoretically defined as opposites. In addition, not all opposing emotion pairs behave identically; for example, 2 opposing pairs of emotions, namely surprise vs anticipation, and joy vs sadness, demonstrate completely opposite impacts across all community response categories. For example, initial posts expressing surprise or anticipation tend to receive a delayed and reduced number of replies from fewer responders. In contrast, posts expressing joy or sadness prompt quicker and more numerous replies. These contrasting response patterns may be caused by the situations described in the initial posts, for example, an unpredictable scenario vs a fact. Specifically, when other community members encounter descriptions of unpredictable situations, which are associated with surprise and anticipation, they may need more time to come up with thoughtful responses. In contrast, accomplished facts, which cause gains or losses to patients and further evoke joy or sadness, tend to elicit more immediate and numerous replies as the community members may be clearer about how to react, for example, celebrating successes or providing comfort for difficult issues. These patterns further support the EASI framework by showing that emotional expressions guide observers' interpretations of situational context and appropriate response strategies.

Overall, this study contributes to health care, psychological, and sociological research by clarifying how emotions serve as social information and social signals in high-stress health contexts. First, this study extends the EASI model by showing that emotions defined as opposites do not necessarily function as opposing social signals in OCCs. Opposite emotions can elicit similar engagement behaviors not because they share comparable intensity, but because they convey similar situational context, such as uncertainty, threat, or outcome significance, from the perspective of community members. This finding refines EASI by demonstrating that observers' responses are driven primarily by inferred situational context rather than emotional valence alone. In this sense, emotional expressions help community members infer underlying circumstances and determine appropriate forms of engagement, consistent with prior work showing that post content influences interaction patterns in online health communities [20,61,62]. Second, by modeling emotions as continuous intensity scales, this study provides a more precise account of how emotional communication affects support dynamics in OCCs. By integrating Plutchik's emotion framework with the EASI perspective, we show that these effects are caused by the combination of emotion type and emotional intensity, offering insights beyond what polarity-based sentiment analysis has discovered. Emotional intensity clearly matters, but it is not independent of emotion type or appraisal meaning; instead, it amplifies the signaling strength of emotions and influences participation, effort, timing, and topical relevance in community responses. Third, our findings confirm the key tenets of the EASI model by demonstrating that different emotions expressed in patients' initial posts are associated with distinct patterns of community engagement and response. When different emotions are expressed, community members react differently in terms of whether they respond, how quickly they respond, how much effort they invest, and how closely their replies align with patients' concerns.

Our findings also have practical implications for patients, OCC platforms, and health care practitioners by clarifying how emotional expressions influence the distribution, timing, and nature of peer support in digitally mediated health communities. From the patient's perspective, these findings help set realistic expectations about how OCCs may react and what responses they may receive. Patients may benefit from understanding that variations in response volume, speed, or depth are often a natural outcome of community dynamics rather than a reflection of the importance, legitimacy, or severity of their situation. For example, posts expressing certain emotions (eg, joy, sadness, anger, or anticipation) may be more likely to receive rapid or numerous responses, whereas others may elicit fewer or delayed replies. Increased awareness of these patterns can reduce feelings of neglect, self-blame, or disappointment and help patients interpret their online experiences more constructively. Such awareness may also encourage patients to engage more confidently with peer support resources throughout their cancer journey.

From the OCC platform and community management perspective, the findings provide actionable guidance for improving the effectiveness and equity of social support. OCCs can train moderators to recognize posts that are less likely to attract spontaneous engagement and proactively highlight or promote these posts to the community. More importantly, early prediction of low-engagement posts based on the emotions expressed enables scalable neglect-mitigation strategies. Given the large volume and length of user-generated posts in OCCs, manual monitoring is often infeasible. Emotion-aware models that predict engagement early can help identify posts at risk of being overlooked and support timely intervention. Such systems allow moderators to deploy targeted strategies aligned with the emotions expressed in the posts, such as prioritizing reassurance-oriented responses for posts expressing anticipation, or providing follow-up explanations for posts expressing surprise. By intervening strategically and broadly, OCCs can improve participation, encourage more balanced information exchange, and strengthen inclusive and supportive community environments [5,63,64].

From the health care practitioner's perspective, our findings can inform how clinicians guide patients in using online support resources as part of psychosocial support. By understanding the relationship between emotional expression and community response patterns, health care providers can better prepare patients for their online interactions, help them interpret engagement outcomes, and reduce anxiety associated with delayed or limited responses. Clinicians may incorporate such guidance into consultations to encourage appropriate and beneficial engagement with OCCs.

In addition, health care providers, OCC facilitators, and technical teams can collaborate to develop emotion-aware systems that automatically identify posts expressing heightened distress, uncertainty, or fear. These systems can support early detection and prioritization of patients who may benefit from timely psychosocial support, counseling, or patient navigation services. By complementing existing screening and triage processes, such approaches can enhance care coordination and improve the overall quality of patient support.

XSL•FO
RenderX

This study has limitations. One limitation of this study is that our data come from a single long-standing cancer community with its own communication norms, which limits the generalizability of our findings to other health conditions or support platforms. In addition, emotional expressions in online posts may not fully represent patients' true emotional states. Individuals often moderate, soften, or mask their emotions when communicating in a public forum, which means that the emotional intensity captured in their written posts may underestimate or misrepresent their actual feelings. As our analysis relies on expressed emotion as the independent variable, this moderation can weaken the correspondence between true emotional experience and textual emotional signals, which may potentially weaken the observed relationships between emotional expression and community responses. Furthermore, different community members may interpret the same emotional expression in varied ways based on their personal experiences, coping styles, or communication preferences, which introduces natural variability in how emotions are understood and reacted to within the community.

Future research can improve these limitations in several ways. First, expanding the analysis to other health conditions, support platforms, or culturally diverse communities would help assess the generalizability of these emotional dynamics and reveal whether different patient populations exhibit distinct emotional communication patterns. Second, studies may incorporate complementary qualitative or mixed method approaches to better understand how patients choose to express or withhold emotions in OCCs, and how these choices affect the interpretation and impact of their posts. Third, future work could examine how emotions evolve throughout the entire conversation rather than focusing solely on the initial post, offering deeper insight into the dynamics of emotional exchange and support over time. Fourth, researchers might explore how individual differences influence both emotional expression and community responses, such as for patients with different illness stages, coping strategies, or social support needs. Finally, investigating how emotions and other forms of content (eg, informational requests, narratives, or disclosures) interact to affect peer support could broaden our understanding of the mechanisms underlying engagement in online health communities and inform the design of more responsive and patient-centered support systems.

Abstract

Background: Qualitative thematic analysis is widely used in health research to examine patient experiences and inform the refinement of digital health interventions, but it is time- and labor-intensive. Large language models (LLMs) may help accelerate this process, yet their performance may depend not only on the model itself but also on how the analytic workflow is structured. Current evidence remains limited on how different LLMs perform across multistage thematic analysis workflows and across multiple health-related qualitative datasets.

Objective: This study aimed to evaluate a modular human–artificial intelligence (AI) collaboration pipeline for LLM-assisted thematic analysis and compare how model choice and workflow strategy influence alignment between AI-generated and human-generated themes across 3 qualitative health studies.

Methods: The framework was applied to analyze deidentified semistructured interview transcripts from 3 completed qualitative health studies involving patients with interstitial lung disease, postural orthostatic tachycardia syndrome, and chronic obstructive pulmonary disease. Three LLMs were compared: Gemini (Gemini 3 Pro), ChatGPT (GPT-5.2-thinking), and Opus (version 4.6). The workflow separated analysis into code extraction, code combination, and theme generation, and 5 strategies were tested. AI-generated themes were embedded using sentence-t5-xxl and compared with human-generated themes using cosine similarity after alignment with Hungarian and Greedy matching. Runtime and output-format consistency were also examined.

Results: Output volume differed substantially by model. Gemini generated the fewest codes and themes, while ChatGPT showed a similar but higher output ceiling. Opus produced the largest and most variable codebooks and theme sets. Across the 3 studies, Opus showed the strongest and most consistent alignment with human-generated themes, with the best cosine similarity scores observed in postural orthostatic tachycardia syndrome–direct coding (mean 0.893, SD 0.041), chronic obstructive pulmonary disease–direct grouping (mean 0.891, SD 0.027), and interstitial lung disease–L3 (mean 0.889, SD 0.032). ChatGPT was competitive in selected settings, whereas Gemini generally produced slightly lower similarity scores but had the shortest runtime. ChatGPT and Opus also showed better formatting consistency and workflow usability than Gemini.

Conclusions: A modular human-AI pipeline can support thematic analysis across multiple digital health interview studies, but performance depends strongly on both model choice and workflow design. Opus produced the most consistently human-aligned themes, while Gemini and ChatGPT showed different trade-offs in speed, fidelity, and usability. These findings support the use of LLMs as structured, human-supervised analytic assistants rather than replacements for qualitative researchers.

Introduction

Qualitative methods are widely used in health research to examine patient experiences, identify barriers and facilitators to care, and guide the refinement of clinical and digital health interventions. Among these methods, thematic analysis is especially useful because it provides a flexible yet systematic approach for identifying, organizing, and interpreting patterns of meaning across textual data. Thematic analysis involves systematically identifying patterns in qualitative data through iterative coding and abstraction. For example, in a patient interview, a participant might state, "I get short of breath when walking even short distances, and it makes me anxious to leave the house." A researcher may assign codes such as activity limitation, dyspnea, and anxiety for symptoms. Across multiple interviews, similar codes are grouped and refined into broader themes, such as the impact of symptoms on daily functioning or emotional responses to chronic illness. This process is inherently interpretive and requires balancing detail preservation with conceptual abstraction, making it both time-intensive and dependent on analyst judgment.

Foundational and health-oriented methodological literature emphasizes that rigorous thematic analysis depends on transparency, traceability, and a clear fit between analytic procedures and research aims [1-3]. In multidisciplinary health research teams, structured approaches such as the framework method can further improve consistency and auditability when working with large collections of interview transcripts. At the same time, qualitative analysis remains labor-intensive, requiring repeated transcript review, iterative code development, comparison across cases, and abstraction from codes to higher-level themes. These demands can make rigorous analysis difficult to scale, particularly in digital health research, where interview-based usability and implementation studies often need timely feedback to support intervention refinement. Prior studies of home telemanagement and rehabilitation technologies have further shown that understanding patient experiences, usability concerns, and practical barriers to participation is important for designing patient-centered systems for home use [4-7].

The use of artificial intelligence (AI) to support qualitative data analysis is not entirely new, but the recent emergence of large language models (LLMs) has substantially renewed interest in this area. Recent overviews show that AI-supported qualitative analysis has been applied across inductive and deductive coding, thematic analysis, discourse analysis, and analysis of large text corpora, suggesting that the current LLM wave should be understood as an acceleration of a longer methodological trajectory rather than an entirely new phenomenon [8,9]. What has changed is accessibility: contemporary LLMs can produce fluent codes, summaries, and theme descriptions directly from natural language prompts, making them attractive to researchers. However, this accessibility also raises the risk of superficial or poorly governed use if methodological safeguards are not clearly specified.

Recent literature on LLM-assisted qualitative analysis presents a mixed picture of promise and caution. Recent empirical and methodological studies have examined LLMs for qualitative coding, content analysis, grounded theory, thematic analysis, and thematic summarization in health and social science research [10-26]. These studies suggest that LLMs can support coding, theme generation, and synthesis, particularly when prompts are structured, and outputs are reviewed by human researchers [10-17,21-24,26]. For example, recent work has compared GPT-4 with human researchers in qualitative health care data analysis, evaluated LLMs for thematic summarization in qualitative health research, and tested ChatGPT-based protocols for thematic analysis and grounded theory [12,17,23,24]. At the same time, these studies consistently emphasize the need for human oversight, transparent prompts, validation procedures, and caution when interpreting AI-generated themes [8-12,18-22,25]. Taken together, the literature suggests that LLMs can contribute meaningfully to qualitative workflows, but their usefulness depends heavily on the dataset, task, model, prompt design, and workflow structure.

At the same time, more recent studies also highlight important limitations that are directly relevant to thematic analysis. Sakaguchi and colleagues [18] found that ChatGPT with GPT-4 achieved high agreement with human researchers for more descriptive themes in Japanese interview data, but its performance dropped markedly for themes requiring deeper cultural and emotional interpretation, with some agreement rates around 30%. Wen and colleagues [19] similarly showed that model choice matters: in a real-world charity-sector case study, GPT-4o achieved substantial agreement with human coders in multilabel categorization, whereas GPT-4o-mini showed only moderate agreement and greater instability across runs. These findings reinforce concerns that LLM outputs may be more reliable for surface-level pattern detection than for context-dependent interpretation, especially when cultural nuance, ambiguity, or subtle experiential distinctions are important. More critical methodological discussions have therefore argued that generative AI in qualitative data analysis introduces epistemic risks and should be treated as an assistive, human-supervised analytic tool rather than an autonomous interpreter [20].

Despite this growing literature, several gaps remain. First, many studies evaluate a single model, a single dataset, or a single prompting approach, which makes it difficult to separate model-specific behavior from workflow-specific effects. Second, much of the literature focuses on direct or near end-to-end prompting, with less attention to how multistage workflows may preserve or distort traceability as data move from transcripts to codes and from codes to themes. Third, evaluation practices remain heterogeneous: some studies emphasize feasibility, efficiency, or human comparison, whereas others compare thematic overlap or semantic similarity [13-17,23,25]. Few studies directly compare alternative workflow structures across multiple qualitative health datasets under standardized conditions. These gaps are especially important in health-related qualitative research, where less frequent but clinically meaningful concerns may be lost if models overcompress the data or privilege more common patterns [8,12,18-20,25].

Building on this literature, this study evaluates a modular human-AI collaboration framework for thematic analysis across 3 completed qualitative health studies involving patients with

XSL•FO
RenderX

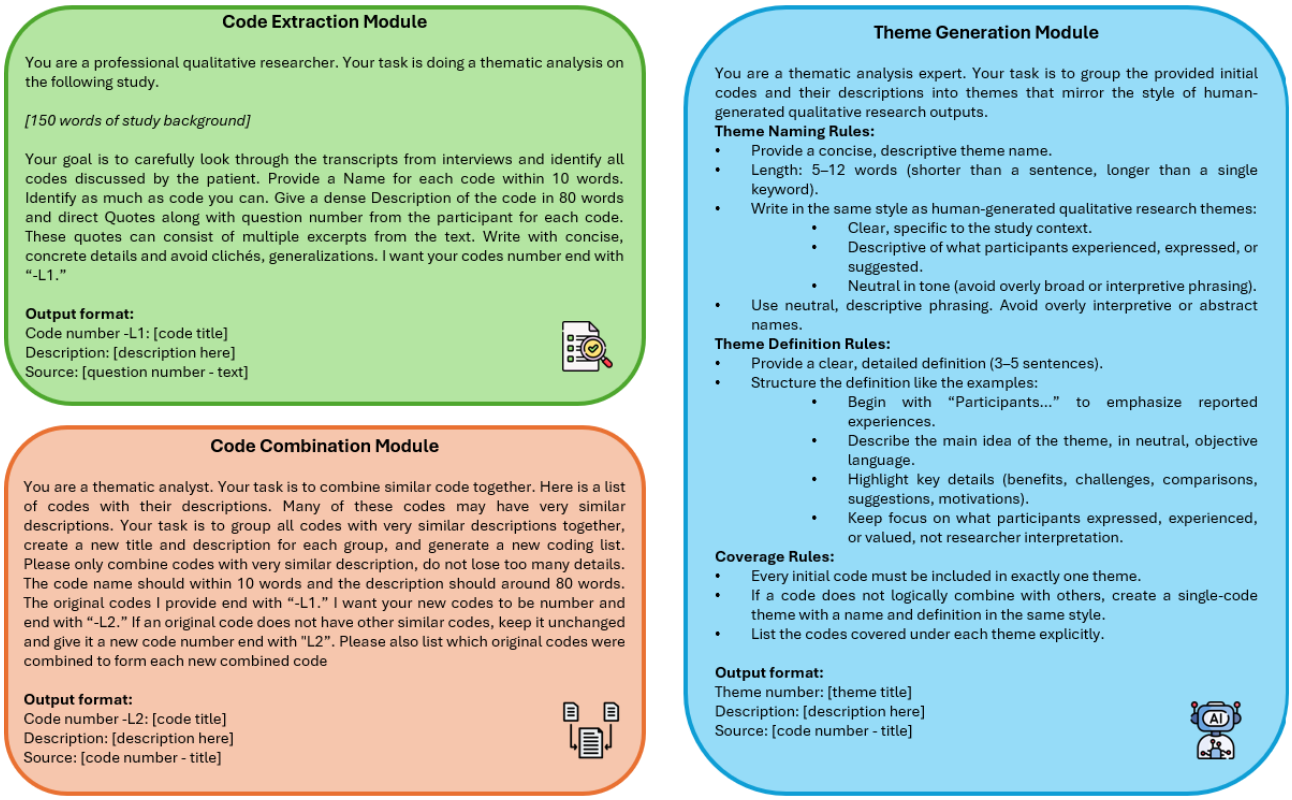
interstitial lung disease (ILD), postural orthostatic tachycardia syndrome (POTS), and chronic obstructive pulmonary disease (COPD) [27-29]. The framework decomposes thematic analysis into 3 discrete subtasks—code extraction, code combination, and theme generation—each conducted in independent LLM sessions to reduce context overload and improve traceability [30]. Using this framework, we compare 3 widely used LLM platforms (ChatGPT, Opus, and Gemini) and 5 workflow strategies, including both hierarchical and direct approaches to code consolidation and theme development [31-33]. AI-generated themes are then benchmarked against human-generated themes from the original studies using embedding-based semantic similarity and systematic alignment. By doing so, this study aims to clarify how model choice and workflow structure influence thematic fidelity, how iterative consolidation affects information retention, and what practical trade-offs emerge when implementing LLM-supported qualitative analysis in digital health research.

Methods

Model Selection

In this study, we selected 3 models from 3 widely used LLM platforms for evaluation and comparison. Specifically, we evaluated ChatGPT with GPT-5.2-thinking (with extended thinking; OpenAI), Opus (version 4.6; Anthropic), and Gemini (Gemini 3 Pro; Google) [31-33]. During the study window, extended thinking modes were available for ChatGPT and Opus but not for Gemini; therefore, each platform was evaluated using the relevant configuration available through its consumer-facing web interface at the time of analysis.

We intentionally used the consumer-facing web interfaces rather than the corresponding application programming interfaces (APIs), and each model-workflow condition was executed once using a standardized prompt and independent conversation, because the goal of this study was to evaluate a practical, researcher-facing workflow under conditions that resemble how many qualitative researchers currently interact with these tools in applied settings, rather than to benchmark API-level performance under fully programmatic control. This choice also allowed direct assessment of operational factors relevant to multistep qualitative analysis, including conversation organization, output exportability, and adherence to structured prompts within the native user interfaces.



All data collection and model interactions were conducted within a fixed study window from February 10, 2026, to March 30, 2026, to provide a temporal anchor for the model versions available at the time of evaluation. To reduce variability related to prior interaction history, all analyses were performed using newly registered accounts with paid personal subscriptions (ChatGPT Plus, Claude Pro, and Gemini Pro). Where available, settings that allow models to reference prior conversations were disabled (eg, “Reference chat history” in ChatGPT). Each analytical subtask was performed in a new, independent conversation so that no model could rely on prior session memory. The same standardized prompts, workflow logic, and transcript inputs were applied across all 3 platforms.

Human-AI Collaboration Framework

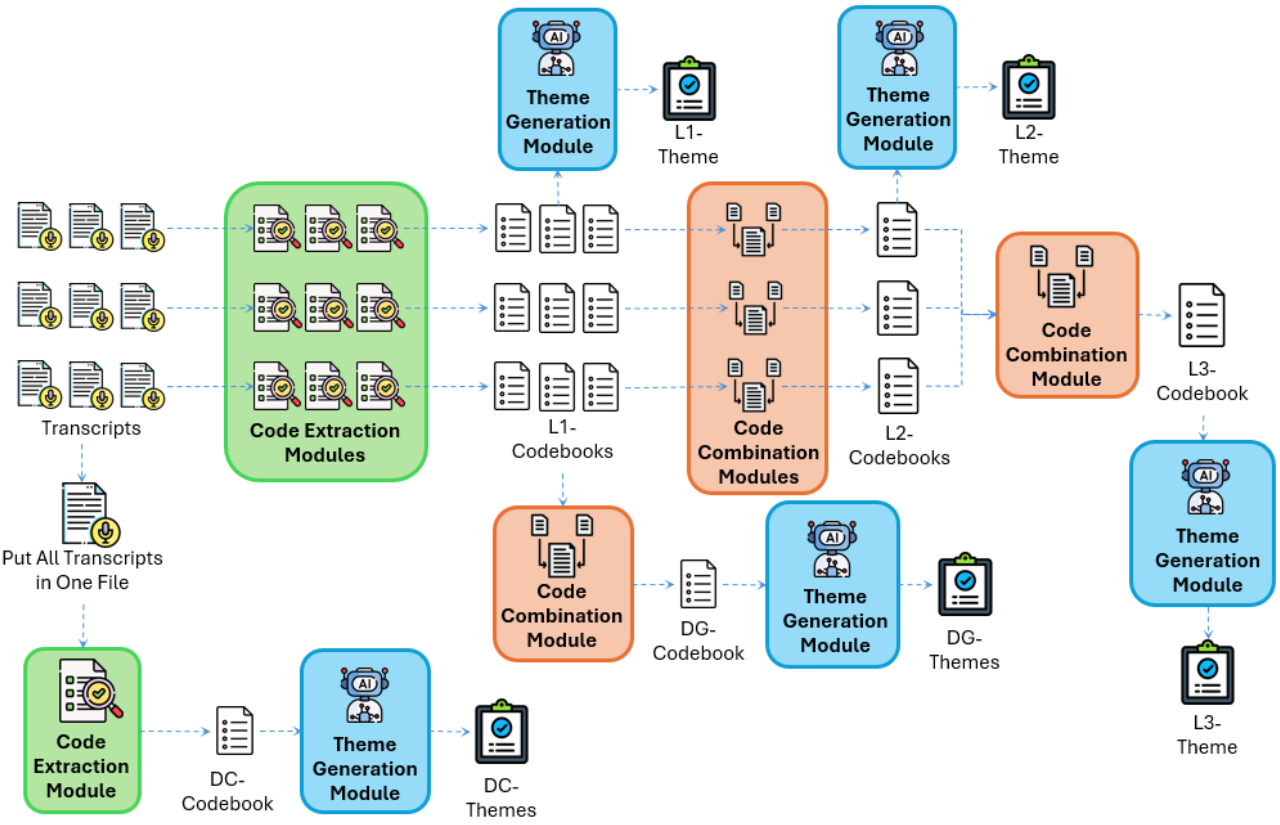
To conduct thematic analysis, we applied a human-AI collaboration framework developed in our prior study [30]. In this framework, the overall analytical workflow is decomposed into a series of discrete, model-specific subtasks, each executed by a specialized LLM module. Each subtask is performed within an independent LLM conversation, and modules do not share memory or contextual knowledge across sessions. This modular architecture reduces per-module complexity, mitigates data loss caused by context-window limitations, lowers computational overhead, and improves the consistency and quality of the generated outputs. The framework consists of 3 specialized modules: a code extraction module, a code combination module, and a theme generation module. Figure 1 shows the prompts for the 3 modules.

XSL•FO
RenderX

Figure 1. Verbatim standardized prompts used for the 3 modules in the modular human–artificial intelligence collaboration pipeline for large language model–assisted thematic analysis. This figure reproduces the exact prompt wording used across all analyses for the code extraction module, code combination module, and theme generation module. The prompts were applied consistently across ChatGPT (GPT-5.2-thinking), Opus (version 4.6), and Gemini (Gemini 3 Pro). The code extraction prompt instructs the model to identify transcript-level qualitative codes, assign concise titles, generate approximately 80-word descriptions, and cite question number–based supporting evidence. The code combination prompt instructs the model to merge semantically overlapping codes while preserving traceability to source code identifiers and standardized formatting. The theme generation prompt instructs the model to group codes into nonoverlapping, human-style qualitative themes with explicit rules for naming, definition structure, coverage, and source attribution.

The code extraction module is responsible for identifying all relevant qualitative codes from an input transcript. A standardized prompt is provided alongside the transcript, instructing the model to identify as many relevant codes as possible, assign each code a concise name limited to 10 words, and produce an approximately 80-word description for each code. The prompt also requires the model to cite the corresponding interview question number as supporting evidence, use clear and concrete language, avoid clichés or vague generalizations, and generate outputs in a predefined standardized format.

The code combination module consolidates overlapping or redundant codes in order to produce a more coherent and streamlined codebook. Using another standardized prompt, the model is instructed to group codes with substantially similar titles and descriptions and generate a new name and definition for each merged group. For codes without close counterparts, the original title and description are retained. To ensure traceability throughout the analysis process, the module records the original code number or numbers associated with each merged group, and the final results are produced in the same prescribed output format.



The theme generation module derives higher-level themes from the consolidated codebook. Its prompt directs the model to cluster codes and their descriptions into themes that reflect conventions commonly used in human-authored qualitative research. Detailed guidelines regarding length constraints, thematic structure, and stylistic requirements are embedded in the prompt to guide the generation process. Each code must be assigned to exactly 1 theme, ensuring complete coverage of the dataset without overlapping. The final output consists of a comprehensive list of themes, with each theme accompanied by a title, a descriptive summary, and the original code numbers associated with the codes it subsumes.

Strategies for Using the Framework

Figure 2 illustrates the workflow of the human-AI collaboration framework. The input for our framework would be a set of transcripts of interviews. Each transcript was uploaded as a .txt file into a new LLM conversation together with the standardized prompt for the code extraction module. Initiating a separate conversation for each transcript ensured that the interview context was preserved while respecting token-length constraints, maintained uniform analytical conditions, and prevented contamination from prior interactions.

XSL•FO
RenderX

Figure 2. Overview of the multistage human–artificial intelligence collaboration pipeline and the 5 workflow strategies evaluated for large language model–assisted thematic analysis across different digital health qualitative interview studies. The framework was applied to deidentified semistructured interview transcripts, all drawn from previously completed telerehabilitation-related studies. The pipeline decomposes thematic analysis into 3 sequential large language model–assisted subtasks performed in independent conversations: code extraction, code combination, and theme generation. In the hierarchical workflows, transcripts are first analyzed individually to produce an L1 codebook, followed by iterative consolidation into an L2 and L3 codebook before theme generation. In the direct workflows, either all transcripts are analyzed together once to produce a DC codebook or the L1-codebook is submitted directly for 1-step consolidation to produce a DG codebook. Each resulting codebook (L1, L2, L3, DC, and DG) is then independently submitted to the theme generation module to produce a corresponding theme set. DC: direct coding; DG: direct grouping; L1: layer 1; L2: layer 2; L3: layer 3.

After code extraction, one researcher (YB) collected the model-generated codes in text files. To reduce manual effort and the risk of identifier transcription errors, a short Python script (Python Software Foundation) was used solely to assign unique identifiers to the collected codes and generate 2 structured text files: a layer 1 (L1) codebook containing the code number, name, and definition for each code, and a quote-trace file containing the code number, code name, and corresponding interview question numbers. This deterministic organizational step did not modify code content, conduct qualitative analysis, or involve programmatic interaction with the LLM platforms, and it could be performed manually if needed.

To reduce redundancy, the code combination module was applied. The L1 codebook was divided into 4 subcodebooks to control the input length for each LLM conversation; each subcodebook contained the codes and descriptions derived from 4 to 5 transcripts. This partition was selected as a practical heuristic to balance input-length constraints and codebook diversity. Specifically, grouping 4-5 transcripts ensured that each subcodebook remained within a manageable size for the consumer-facing web interfaces used in this study, while still preserving sufficient variation in codes to support meaningful consolidation at the L2 stage. This approach allowed iterative merging without exceeding response length limits or overly compressing heterogeneous concepts in a single step.

These 4 subcodebooks were submitted independently to new LLM conversations together with the standardized code combination module prompt. The resulting outputs were then collected and processed to form the layer 2 (L2) codebook. To further consolidate overlapping codes, the L2 codebook was submitted again to the code combination module, producing the layer 3 (L3) codebook. Throughout this iterative consolidation process, parent-layer code numbers were preserved to maintain traceability between newly generated codes and their original source quotes.

In addition to this hierarchical workflow, we evaluated 2 straightforward strategies that did not impose input length controls. In the first approach, all transcripts were merged into a single txt file and submitted directly to the code extraction module, producing a direct coding (DC) codebook. In the second approach, the L1 codebook was submitted directly to the code combination module without dividing it into subcodebooks, producing a direct grouping (DG) codebook. Finally, all 5 resulting codebooks—L1, L2, L3, DG, and DC—were independently submitted to the theme generation module in separate LLM conversations using the same standardized prompt. The themes generated were then used for subsequent

XSL•FO
RenderX

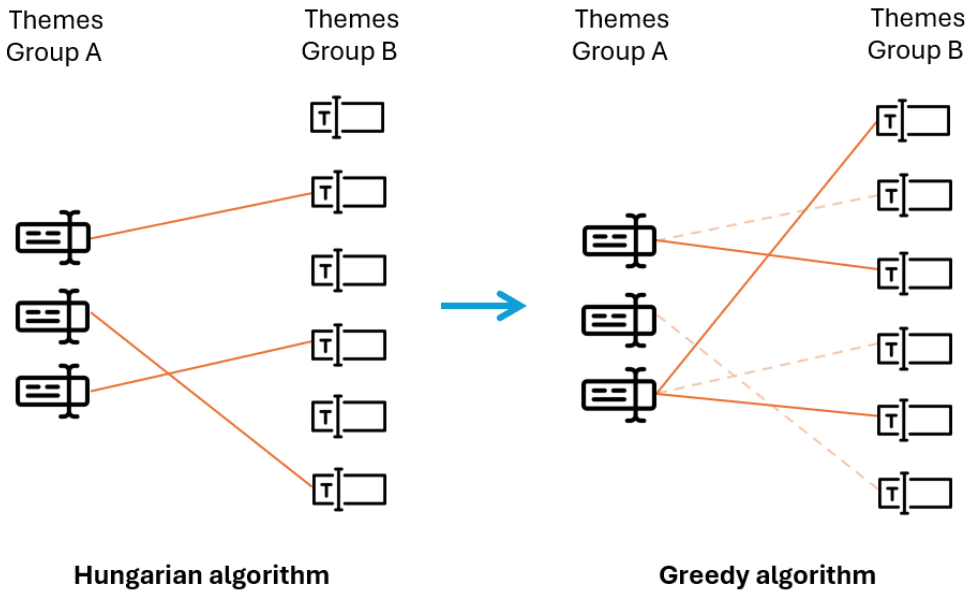
evaluation and comparison across the different analytical strategies.

Semistructured Qualitative Interviews

The semistructured qualitative interviews were collected as part of 3 usability studies using a mixed methods design [27-29]. The studies aimed at assessing usability, attitudes, and acceptance of home-based telerehabilitation systems in patients with 1 of 3 conditions: COPD, POTS, or related dysautonomia, and ILD. All study participants were aged 18 years or older. They also needed the ability to complete study procedures, including usability testing and a semistructured interview. Individuals were excluded if they had medical conditions that could increase risk during the exercise-related usability evaluation, including unstable angina, uncontrolled hypertension, a recent myocardial infarction, pacemaker use, painful or unstable bony metastases, recent skeletal fractures, or any other condition that, in the clinical or research team's judgment, would make participation unsafe. Enrolled participants attended a single, 1-hour, in-person visit. After providing informed consent, research staff demonstrated the telerehabilitation system and supervised a practice session and then administered a sociodemographic questionnaire. Usability testing comprised 3 standardized tasks completed independently: logging into the system, completing a survey, and reviewing and performing an exercise routine. Analyses were stratified by the underlying medical conditions.

After usability testing, participants took part in a semistructured interview with open-ended questions to explore their perceptions of the system and its potential for home-based symptom management. Interviews were transcribed verbatim and deidentified. The qualitative interview data were analyzed using thematic analysis following Braun and Clarke's [1] 6-phase process to organize, identify, and interpret key patterns and themes. The qualitative analysis team comprised a qualitative researcher (Aileen Gabriel) and a clinician-scientist (JF). The disagreements were resolved by a clinical informatician familiar with qualitative analysis. The iterative analysis continued until all codes were finalized and disagreements were reconciled. The research team repeatedly reviewed transcripts to immerse themselves in the data; initial codes were generated inductively through open coding, iteratively refined, and grouped into broader categories to capture patterns across participants. These categories were then synthesized into themes representing key aspects of participant experiences [27-29].

Evaluation



For evaluation, we used the original deidentified interview transcripts and the final human-generated thematic analysis results from the 3 source studies. The ILD dataset included 17 transcripts, for which the human analysis generated 169 codes and 7 themes. The POTS dataset included 15 transcripts, for which the human analysis generated 178 codes and 10 themes. The COPD dataset included 16 transcripts, for which the human analysis generated 261 codes and 6 themes. The original transcripts were submitted as input to the LLM-assisted workflow, and the corresponding human-generated themes served as the reference standard for evaluating framework-derived themes.

All interview transcripts used in this study were deidentified and were not publicly available, published, or released before the present analysis. Therefore, direct exposure of the evaluated models to the source transcripts through publicly accessible training data is unlikely. The code extraction module prompt also included a study background field that was populated separately for each disease cohort. The exact verbatim text used for the ILD, POTS, and COPD datasets is provided in Multimedia Appendix 1.

To quantitatively assess the similarity between human-generated themes and those produced by the LLM, we used the sentence-transformer model sentence-t5-xxl, which has demonstrated strong performance on sentence similarity tasks, to embed the theme texts into a 768-dimensional dense vector space [34]. Because this model has a bounded maximum input length, we verified that all theme texts were below this limit; therefore, no truncation was applied during embedding. The resulting vectors were normalized to remove length bias and ensure that comparisons reflected semantic similarity rather than differences in text magnitude. Cosine similarity was then calculated for each pair of human and LLM theme vectors. Cosine similarity scores range from −1 to +1 and indicate the degree to which 2 texts describe conceptually similar content, with higher values representing greater semantic similarity. In addition, to verify traceability fidelity, we developed a Python script to validate whether each propagated parent-layer code identifier referenced an existing valid code in the immediately preceding codebook layer. The number of themes identified by humans and by the LLM often differed. To compare unequal theme sets while preserving both alignment quality and complete theme coverage, we used a 2-stage matching procedure combining the Hungarian algorithm and a Greedy nearest-neighbor assignment [35,36]. Figure 3 illustrates this alignment process.

XSL•FO
RenderX

Figure 3. Themes alignment procedure is used to compare artificial intelligence (AI)–generated themes with human-generated reference themes across different qualitative health interview studies. This schematic illustrates the 2-step matching approach used after generating themes. First, theme descriptions from the human analysis and from each AI-generated output were embedded into 768-dimensional vector spaces using sentence-t5-xxl, and pairwise cosine similarity was calculated. Because the number of themes differed between the human and AI outputs across models and workflow strategies, the Hungarian algorithm was first applied to create a globally optimal one-to-one alignment between the smaller theme set and a subset of the larger theme set. Any remaining unmatched themes in the larger set were then assigned using a Greedy algorithm to the most similar theme in the smaller set. This combined procedure ensured that all themes were matched while maximizing overall semantic similarity.

First, the Hungarian algorithm was applied to the cosine similarity matrix to identify the globally optimal one-to-one alignment between the smaller theme set and an equally sized subset of the larger theme set, thereby establishing the primary bidirectional correspondences. Using the Hungarian algorithm alone would have excluded the remaining unmatched themes in the larger set from evaluation, which could bias the final similarity upward by omitting surplus themes with lower semantic similarity. Therefore, any remaining unmatched themes in the larger set were subsequently assigned to their most semantically similar theme in the smaller set using a Greedy nearest-neighbor procedure, ensuring that all themes contributed to the evaluation rather than discarding surplus themes. A Greedy-only strategy was not used because it does not enforce a globally optimal one-to-one primary alignment, and some themes in the opposite set may remain without any primary correspondence.

When multiple themes from the larger set mapped to the same theme in the smaller set, the cosine similarity values for those mappings were averaged rather than retaining only the single highest-scoring match. As a result, generating additional themes did not inherently improve the final score; extra weakly aligned themes could reduce the aggregate similarity. Basic statistical measures (average, standard deviation, maximum, median, and minimum) were then calculated for the resulting cosine similarity scores.

Processing time was measured manually using a digital clock or stopwatch. Timing began when the prompt and input file were submitted through the web interface and ended when the model completed its full response. Therefore, the recorded time represents end-user wall-clock processing time, including web interface latency, model response generation, and streaming time, rather than isolated model inference time. For theme generation tasks, processing time was measured 3 times, once for each study dataset. For L1 code extraction, 5 transcripts were randomly selected from the 48 available transcripts, and the corresponding extraction tasks were timed for each model. For the other tasks, processing time was measured across 5 randomly selected observations. Reported values are presented as mean (SD) in seconds.

We also conducted a brief descriptive assessment of output format consistency and workflow management. Format deviations were defined as responses that did not follow the prompt-specified structure and required manual correction before downstream processing, such as missing required fields, inconsistent numbering, omitted source or parent-code identifiers, or unrequested formatting changes. One researcher (YB) reviewed the generated outputs and recorded distinct format patterns. Workflow management was assessed descriptively based on whether the web interface supported project-level organization, easy tracking of multiple conversations, and convenient copying or exporting of outputs. Interrater agreement was not assessed because this was a practical workflow observation rather than a formal usability evaluation.

Ethical Considerations

This study did not involve human participants or the collection of identifiable private information. No patient identifiers were accessed, recorded, or analyzed, and no attempt was made to reidentify individuals. In accordance with JMIR guidelines, this research does not meet the definition of human subjects research and was therefore exempt from institutional review board review and informed consent requirements. The study was conducted in compliance with applicable ethical standards for research

XSL•FO
RenderX

using deidentified secondary data. The qualitative interview protocol was approved by the institutional review board of the University of Utah (protocol IRB_00168937).

Results

For the AI-generated codes and themes, output volume varied substantially by strategy and model (Table 1). Gemini produced the fewest codes, with outputs remaining at approximately 10 codes per conversation, including definitions and traceability information, regardless of whether the task involved code extraction or code combination. ChatGPT showed a similar but higher capped pattern, producing approximately 25 codes per conversation across most tasks, except during the L2-to-L3 code combination step. In contrast, Opus did not exhibit a fixed-count pattern: extracted codes ranged from 15 to 60, and combined codes ranged from 43 to 153. These differences in code volume also shaped theme generation. Gemini produced fewer inputs for theme development and generated only 3-5 themes in several DC and DG settings, whereas Opus produced the largest codebooks and generally yielded the greatest number of themes. Python-based validation identified no invalid or hallucinated propagated code identifiers; all parent-layer code references were valid across models and consolidation stages.

Table 1. Counts of artificial intelligence–generated codes and themes across 3 large language models, 5 workflow strategies, and 3 digital health qualitative interview datasets[a].

Category	ILD[b]			POTS[c]			COPD[d]		
	Gemini	ChatGPT	Opus	Gemini	ChatGPT	Opus	Gemini	ChatGPT	Opus
AI[e]-generated codes, n									
L1[f]	185	314	395	155	303	341	159	295	357
L2[g]	43	114	208	46	118	167	58	128	201

L3	6	17	15	4	10	16	5	13	13
DC	3	7	12	3	8	13	4	9	11
DG	4	9	17	4	7	17	5	14	13

[a]This table presents the numbers of codes and final themes generated by Gemini, ChatGPT, and Opus when the modular human–artificial intelligence thematic analysis pipeline was applied to deidentified semistructured interview transcripts from patients with interstitial lung disease (n=17), postural orthostatic tachycardia syndrome or related dysautonomia (n=15), and chronic obstructive pulmonary disease (n=16). Results are shown for 5 workflow strategies: L1, in which themes were generated from transcript-level extracted codes; L2 and L3, in which themes were generated after successive code combination stages; direct coding, in which combined transcripts were submitted directly for code extraction; and direct grouping, in which the L1 codebook was submitted directly for code consolidation before theme generation.

[b]ILD: interstitial lung disease.

[c]POTS: postural orthostatic tachycardia syndrome.

[d]COPD: chronic obstructive pulmonary disease.

[e]AI: artificial intelligence.

[f]L1: layer 1.

[g]L2: layer 2.

[h]L3: layer 3.

[i]DC: direct coding.

[j]DG: direct grouping.

To examine whether these differences reflected broader output length behavior, we analyzed input and output word counts at each stage (Table 2). Input transcript lengths were comparable across models, but output lengths differed substantially. Gemini and ChatGPT produced relatively stable output lengths across tasks, with limited variation despite large differences in input size. This pattern suggests an effective output ceiling, where response length did not scale proportionally with input length. By contrast, Opus showed a more input-responsive pattern, with output length increasing in high-input settings such as DC and large codebook consolidation. This word count pattern supports the code and theme count findings, suggesting that Gemini and ChatGPT generated relatively bounded outputs, whereas Opus produced more variable and input-dependent results.

XSL•FO
RenderX

Input and output length also influenced the runtime. Table 3 summarizes end-user wall-clock processing time across models and workflow tasks. Gemini generally had the shortest processing time across most stages, while Opus required the longest time in code combination and theme generation tasks. The longer processing times for Opus are consistent with its larger and more variable outputs, which increased both response generation time and the amount of text carried into later workflow stages. Because processing time was measured through consumer-facing web interfaces, these values should be interpreted as practical workflow benchmarks rather than hardware-controlled inference-speed measurements.

Table 2. Input and output word counts across models and workflow stages in the modular human–artificial intelligence thematic analysis pipeline[a].

Task	Gemini word counts, n		ChatGPT word counts, n		Opus word counts, n	
	Input	Output	Input	Output	Input	Output
L1[b] code extraction (n=48 transcripts)	1023 (277)	1174 (281)	1023 (277)	1946 (428)	1023 (277)	2128 (401)
DC[c] code extraction (n=3 datasets)	16,860 (1560)	1749 (232)	16,860 (1560)	2949 (154)	16,860 (1560)	8890 (391)
L1-L2[d] code combination (n=12 subcodebooks)	3119 (551)	1015 (157)	6180 (792)	2754 (731)	6302 (982)	3914 (793)
L2-L3[e] code combination (n=3 datasets)	3579 (345)	1164 (94)	10,310 (599)	5783 (797)	14,735 (1600)	8999 (1036)
L1-DG[f] code combination (n=3 datasets)	12,474 (1257)	1605 (457)	24,720 (842)	2876 (492)	25,210 (2482)	8502 (1711)
L1 theme generation (n=3 datasets)	12,474 (1257)	1210 (258)	24,720 (842)	1800 (70)	25,210 (2482)	3118 (150)
L2 theme generation (n=3 datasets)	3579 (345)	870 (113)	10,310 (599)	1617 (442)	14,735 (1600)	3063 (319)
L3 theme generation (n=3 datasets)	1053 (101)	463 (81)	5479 (771)	1680 (148)	8506 (982)	1839 (192)
DC theme generation (n=3 datasets)	807 (176)	376 (25)	1855 (87)	828 (26)	3747 (478)	1437 (77)
DG theme generation (n=3 datasets)	3	1214 (500)	478 (21)	2404 (492)	958 (205)	7607 (1603)	2271 (167)

[a]Values represent mean (SD) word counts for inputs and generated outputs at each stage for Gemini, ChatGPT, and Opus (Claude), applied to 3 qualitative health interview datasets (ILD, POTS, and COPD). Tasks include L1 code extraction, DC, hierarchical code combination (L1→L2, L2→L3), DG, and theme generation across codebook levels. Input lengths reflect submitted transcripts or codebooks, and outputs include generated codes, definitions, and traceability information. Gemini and ChatGPT showed relatively stable output lengths across tasks, whereas Opus exhibited more input-responsive output scaling.

[b]L1: layer 1.

[c]DC: direct coding.

Table 3. Processing time across models and workflow tasks in the modular human–artificial intelligence thematic analysis pipeline[a].

Task	Gemini (seconds), mean (SD)	ChatGPT (seconds), mean (SD)	Opus (seconds), mean (SD)
Extract codes from 1 transcript (L1[b] extraction)	72 (6)	123 (16)	81 (9)
Combine codes from L1 codes in 4 transcripts (L1-L2[c] combination)	91 (8)	185 (21)	273 (28)
Combine codes from L2 codes (L2-L3[d] combination)	133 (11)	196 (19)	663 (56)
L1 theme generation	145 (13)	168 (16)	488 (42)
L2 theme generation	65 (5)	127 (17)	402 (36)
L3 theme generation	40 (4)	62 (5)	268 (25)

[a]Processing time was measured manually using a digital clock or stopwatch from prompt submission through the web interface to completion of the full model response. Theme generation tasks were measured 3 times, once for each study dataset, whereas all other tasks were measured across 5 observations. These values reflect end-user wall-clock time under consumer-facing web interface conditions and therefore include interface latency, response generation, and streaming time rather than isolated model inference time.

[b]L1: layer 1.

[c]L2: layer 2.

[d]L3: layer 3.

Table 4 shows the cosine similarity between human-generated themes and AI-generated themes under different settings, and Multimedia Appendix 2 visualizes the distribution of similarity scores. Because this study was designed as a descriptive workflow evaluation, the cosine similarity results are reported as descriptive summaries rather than inferential statistical comparisons. Across the 3 studies, Opus showed the strongest and most consistent alignment with human-generated themes, achieving the highest average cosine similarity in nearly all settings. Its scores were generally clustered around 0.88-0.89, with the best performance observed in POTS-DC (mean 0.893, SD 0.041), COPD-DG (mean 0.891, SD 0.027), and ILD-L3 (mean 0.889, SD 0.032). In comparison, ChatGPT showed competitive performance in some settings, particularly ILD-L1 (mean 0.870, SD 0.027), POTS-L2 (mean 0.881, SD 0.052), and COPD-DC (mean 0.872, SD 0.040), but its results were more variable across workflows. Gemini generally produced slightly lower similarity scores than the other 2 models, although it remained competitive in several direct-coding settings, such as ILD-DC (mean 0.866, SD 0.024) and COPD-DC (mean 0.865, SD 0.036). Word count of human-generated and AI-generated themes across models and workflow strategies was similar and lower than the limitation of the embedding models. Values are reported as mean word count with range and number of themes in Multimedia Appendix 3.

Across workflow strategies, no single strategy was universally best for all models, but some patterns were evident. For Opus, L3, DC, and DG consistently yielded the highest similarities, suggesting that either deeper hierarchical consolidation or DC strategies helped produce themes closer to human reference. For ChatGPT, performance was relatively stronger in L1 and L2, indicating that it may perform better with moderate structure rather than extensive consolidation. Gemini showed comparatively stable but less optimal performance, with its best results often appearing in DC or L1 settings. Overall, these findings suggest that model choice had a greater effect on theme similarity than workflow strategy, and that Opus combined with L3, DC, or DG produced the most human-aligned thematic outputs.

To help interpret the cosine similarity scores, Textbox 1 provides a representative example from the POTS dataset. The human-generated theme “biofeedback and self-monitoring” was closely matched with AI-generated themes from all 3 models, with cosine similarity scores of 0.89 for Gemini, 0.94 for ChatGPT, and 0.96 for Opus. These matched themes shared the central concept of using real-time physiological feedback, especially heart rate and oxygen saturation monitoring, to support safe exercise and symptom management. For comparison, the textbox also includes AI-generated themes that were mapped to different human themes in the full alignment but had lower cosine similarity scores when compared with “biofeedback and self-monitoring”. These examples show how scores decreased when the AI-generated theme focused on adjacent but less directly related concepts, such as home-based rehabilitation logistics, onboarding, device accessibility, or equipment constraints.

Table 4. Mean cosine similarity between human-generated themes and artificial intelligence–generated themes across 3 qualitative health interview studies, 5 workflow strategies, and 3 large language models[a].

Study and themes	Gemini, mean (SD)	ChatGPT, mean (SD)	Opus, mean (SD)
ILD[b]			
L1[c]	0.840 (0.024)	0.870 (0.027)	0.884 (0.029)
L2[d]	0.843 (0.027)	0.869 (0.032)	0.868 (0.034)
L3[e]	0.841 (0.035)	0.844 (0.042)	0.889 (0.032)[f]
DC[g]	0.866 (0.024)	0.851 (0.038)	0.882 (0.019)
DG[h]	0.848 (0.031)	0.865 (0.041)	0.882 (0.021)
POTS[i]			
L1	0.874 (0.046)	0.874 (0.038)	0.887 (0.039)
L2	0.856 (0.054)	0.881 (0.052)	0.888 (0.027)
L3	0.841 (0.021)	0.852 (0.050)	0.888 (0.035)
DC	0.859 (0.022)	0.872 (0.045)	0.893 (0.041)[f]
DG	0.859 (0.025)	0.866 (0.026)	0.882 (0.035)
COPD[j]			
L1	0.861 (0.039)	0.861 (0.041)	0.879 (0.041)
L2	0.861 (0.030)	0.852 (0.045)	0.884 (0.028)
L3	0.859 (0.042)	0.869 (0.038)	0.890 (0.031)
DC	0.865 (0.036)	0.872 (0.040)	0.888 (0.028)
DG	0.863 (0.037)	0.844 (0.038)	0.891 (0.027)[f]

[a]This table summarizes semantic alignment between the original human-generated themes and artificial intelligence (AI)–generated themes produced by Gemini, ChatGPT, and Opus when the modular human-AI collaboration pipeline was applied to deidentified interview transcripts from 3 previously completed studies: ILD (17 patients evaluated during a 1-hour in-person feasibility session of a home-based telerehabilitation system, followed by semistructured interviews), POTS (15 patients with dysautonomia or POTS evaluated during a 1-hour in-person telerehabilitation usability session, followed by semistructured interviews), and COPD (16 patients interviewed remotely after completing a 12-month home-based pulmonary telerehabilitation program). Results are shown for 5 workflow strategies: L1, L2, L3, DC, and DG. Theme descriptions were embedded using sentence-t5-xxl, aligned using a combined Hungarian and Greedy matching procedure, and compared using cosine similarity. Higher values indicate greater semantic agreement between AI-generated and human-generated themes.

Textbox 1. A representative example illustrates how cosine similarity scores (CSSs) vary with thematic overlap between human-generated and AI-generated themes. This textbox presents 1 human-generated reference theme from the postural orthostatic tachycardia syndrome telerehabilitation dataset, "biofeedback and self-monitoring", alongside artificial intelligence (AI)–generated themes from Gemini, ChatGPT, and Opus. The first row shows that the AI-generated theme matched to this human theme during the alignment procedure and its CSS. The second row shows an AI-generated theme from each model that was mapped to a different human theme in the full alignment, but was compared with "biofeedback and self-monitoring" to illustrate how similarity scores decrease when thematic overlap is partial or adjacent rather than direct. This example provides an interpretive anchor for understanding the cosine similarity range reported in the quantitative results.

Human theme

- "Biofeedback and self-monitoring": Real-time biofeedback, particularly heart rate and oxygen saturation monitoring, was viewed as essential for exercising safely with postural orthostatic tachycardia syndrome (POTS) symptoms. Participants reported that these features provided reassurance, guided exercise intensity, and helped prevent overexertion, enabling them to exercise independently with confidence. Visual displays, including engaging elements such as the racecar avatar, were appreciated for making monitoring intuitive and motivating. Tracking progress over time further reinforced adherence and a sense of accomplishment. Suggestions for improvement included making data more visible, adding instructional cues, expanding monitoring to blood pressure or symptom logging, and offering alerts to emergency contacts.

Primary matched artificial intelligence–generated themes for this human theme

- Gemini (CSS 0.89): Using Biofeedback and Structure for Safety and Symptom Management: Participants identified real-time physiological biofeedback, particularly heart rate monitoring, as a critical safety tool that transformed abstract sensations into actionable data for self-regulation. The structured nature of the program provided a verified medical framework that alleviated anxiety about overexertion, allowing users to move from avoidance behaviors to active management with confidence. Ultimately, users viewed this combination of biofeedback and guided pacing as a vital strategy for preventing "boom and bust" cycles and managing long-term stamina within the constraints of their condition.
- ChatGPT (CSS 0.94): Biofeedback-led pacing and safeguards address fear of flares: Participants described real-time vitals feedback (especially heart rate and oxygen) as central for pacing and safety during POTS-appropriate exercise. Participants reported using biofeedback to adjust intensity moment-to-moment and to decide when to slow down or stop, and some wanted additional vitals (eg, blood pressure) integrated to match their personal thresholds. Participants also wanted vitals displayed more prominently so that they can check quickly during exertion without competing visual elements. Participants linked these features to concerns about overexertion, symptom worsening, and the need for safeguards that respect "bad day" limitations and flexible intensity.
- Opus (CSS 0.96): Real-Time Physiological Monitoring for Safe Exercise Management: Participants with POTS identified continuous heart rate and oxygen saturation monitoring as medically essential for exercising safely, given the unpredictable cardiovascular responses characteristic of the condition. Real-time biofeedback allowed users to adjust exertion levels and avoid symptom flares from overexertion. Specific design feedback included repositioning the vital signs display for better visibility during active pedaling. Participants also requested the addition of blood pressure monitoring to provide a more complete physiological picture for both self-management and provider review.

Comparison with artificial intelligence–generated themes mapped to another human theme

- Gemini (CSS 0.80): Motivation, Accountability, and Logistical Factors in Home-Based Rehabilitation: Participants emphasized that the home-based model eliminated draining commutes, thereby conserving energy for exercise and democratizing access to care for those with mobility limitations. Engagement was further driven by gamified elements that provided mental distraction from physical exertion, as well as the professional accountability of knowing that a health care provider was monitoring their progress remotely. However, while the convenience was a primary driver for adherence, some participants noted that practical constraints, such as the need for dedicated physical space and equipment setup, presented logistical barriers in smaller living environments.
- ChatGPT (CSS 0.75): Guided Onboarding and Practice Builds Independent System Use: Participants reported that an initial walk-through or practice session was needed to learn how to use the system correctly, even when the interface later felt intuitive. Participants described onboarding as helping them understand where to click, how to start sessions, and how to set up the tablet and connected peripherals. Participants also suggested that future users with less technology experience may need additional support such as tutorial videos or remote guidance to replicate setup and use at home.
- Opus (CSS 0.77): Device Accessibility, Equipment Constraints, and Adoption Barriers: Participants identified practical barriers that could limit system adoption across diverse users and living situations. Requests for smartphone and tablet compatibility reflected the preference for accessing the system on primary daily devices rather than a dedicated computer. Physical space requirements for the recumbent pedal device and associated equipment were seen as potentially prohibitive for those in small living spaces. Cost concerns were raised as a hypothetical barrier given existing medical expenses, and participants noted that individuals with limited technology experience—particularly older adults—would require enhanced onboarding and tutorial support.

Across the full pipeline, ChatGPT and Opus also demonstrated stronger usability and task management support. Both platforms provided project-level conversation grouping, which facilitated tracking and managing the multiple conversations required by the pipeline. Gemini lacked an equivalent project management function; although this did not create a major limitation in our experimental setup (which used a new account with a single project), it may become more consequential in larger or longer-term studies.

Finally, with explicit output format requirements in the prompts, ChatGPT and Opus followed the requested format reliably and could export outputs as .txt files without additional prompting or tuning. Gemini was less consistent in adhering to the specified format: across 48 code extraction conversations, it produced 12 distinct formats; across 15 code combination conversations, it produced 5 formats; and across 15 theme generation conversations, it produced 8 formats. This variability increased downstream preprocessing effort relative to the other 2 models.

Discussion

Principal Findings

This study evaluated a modular human–AI collaboration pipeline for LLM-assisted thematic analysis across 3 qualitative digital health interview datasets and 5 workflow strategies. Overall, the findings show that both model choice and workflow structure shaped thematic outputs, but model choice appeared to have a stronger influence on alignment with human-generated themes. Across ILD, POTS, and COPD, Opus produced the most consistently human-aligned themes, while ChatGPT performed competitively in selected settings, and Gemini showed more constrained but relatively stable performance. These findings suggest that LLM-assisted thematic analysis should not be treated as a single generic capability; rather, performance depends on how a model interacts with specific workflow designs for extraction, consolidation, and theme generation.

A key finding is that Gemini and ChatGPT exhibited constrained output behavior under the evaluated conditions. Both models produced relatively fixed numbers of codes across tasks (approximately 10 for Gemini and approximately 25 for ChatGPT), even when input size and task complexity varied. In qualitative analysis, this matters because thematic fidelity depends on adequately capturing the diversity of participant experiences. When outputs are effectively bounded, there is a risk of undercoding distinct ideas and underrepresenting less frequent but potentially important perspectives. This risk is particularly important in health-related interviews, where less frequent concerns may still be clinically meaningful [18-20].

The word count analysis provides additional evidence supporting this pattern. Despite substantial variation in input length across workflow stages, Gemini and ChatGPT produced outputs with relatively stable lengths, suggesting the presence of an effective output ceiling under the evaluated conditions. In contrast, Opus exhibited more input-responsive behavior, with output length increasing in higher-input settings such as DC and large codebook consolidation. This difference in output length responsiveness is consistent with the observed variation in code and theme counts across models.

At the same time, the findings show that workflow structure can partly compensate for model-specific limitations. For Opus, the hierarchical strategies performed especially well, with L3 producing the highest or near-highest similarity in 2 of the 3 studies, and strong performance was also observed in DC and DG settings. This pattern suggests that Opus was able to absorb longer inputs and iterative consolidation without substantial thematic drift. In practical terms, this is encouraging for larger qualitative projects: a staged workflow that first extracts detailed codes and then merges them iteratively may reduce redundancy while still preserving conceptual distinctions. The strong performance of DC and DG for Opus also indicates that the model can tolerate broader inputs, giving researchers flexibility to choose between hierarchical and direct strategies depending on dataset size, desired granularity, and time constraints.

For ChatGPT, a different pattern emerged. Its performance was relatively stronger in L1 and L2, with less consistent results after deeper consolidation. This suggests that ChatGPT may benefit from moderately structured intermediate representations but lose details when codes are repeatedly merged. One interpretation is that each consolidation step reduces input richness, and because ChatGPT also showed capped output behavior, repeated merging may amplify information loss. In this sense, ChatGPT appears well suited to workflows that preserve more of the original code diversity rather than heavily compressing it. For small- to medium-sized datasets, this may make L1 or L2 especially useful, whereas for larger datasets requiring multiple rounds of consolidation, the trade-off between manageability and thematic detail may become more pronounced.

Gemini showed the lowest overall similarity scores in most settings, but its results were not uniformly weak. In several direct-coding settings, it remained competitive, and its performance was relatively stable across studies. However, Gemini's strong tendency to generate approximately the same number of codes regardless of input size suggests limited responsiveness to transcript complexity. This likely constrained downstream theme generation by reducing the range of available concepts before theming even began. From a practical perspective, Gemini may still be useful when the analytic goal is rapid, high-level summarization rather than detailed qualitative interpretation. Its short outputs and fast runtimes make it efficient, but that efficiency appears to come at the cost of granularity and formatting consistency.

The runtime findings reinforce this interpretation of model behavior. Across the pipeline, processing time was driven less by the nominal task type than by cumulative input and output length. Opus had the longest runtimes because it also generated the most extensive output, which then increased the size of the next-stage inputs. Gemini was consistently the fastest, reflecting its shorter and more compressed responses. This highlights an important trade-off in applied LLM-assisted qualitative research: the most detailed outputs may better preserve thematic nuance, but they also require more time and create heavier downstream processing burdens. Therefore, researchers need to balance fidelity, scalability, and efficiency when selecting a platform and workflow.

Another practical contribution of this study is that it evaluates not only thematic similarity but also the operational usability of the platforms for multistep qualitative work. ChatGPT and Opus more reliably followed the required output structure and supported easier management of multiple conversations through project-level organization. Gemini was less consistent in output format, which increased preprocessing effort. These differences may seem secondary to thematic quality, but they matter in real-world research settings. A workflow that requires dozens of extractions, combinations, and theme generation sessions depends on consistent formatting and manageable conversation organization. Thus, platform usability should be considered alongside analytic performance when choosing tools for LLM-assisted qualitative analysis.

Comparison With Prior Work

Compared with prior literature, this study contributes a more explicitly workflow-centered evaluation. Recent studies have

XSL•FO
RenderX

shown that LLMs can support qualitative coding, content analysis, grounded theory, and thematic summarization, including comparisons between AI-generated and human-generated qualitative analyses [13-17,23-25]. However, many prior studies rely on single-prompt, single-model, or near end-to-end approaches. These approaches can be efficient, but they make it harder to identify where information loss occurs and often provide less traceability across analytic stages. By contrast, our pipeline separates code extraction, code consolidation, and theme generation into independent, standardized steps. This structure makes the analytic process more auditable and allows direct comparison of hierarchical versus direct strategies, aligning with recent recommendations that LLM-supported qualitative analysis should emphasize transparency, reproducibility, validation, and human oversight [8,10-12,20,22,24-26].

This study also adds a reproducible quantitative evaluation layer by comparing AI-generated themes with human-generated themes through embedding-based semantic similarity and systematic alignment. Although semantic similarity cannot fully capture qualitative rigor, it provides a useful comparative signal across models, workflows, and datasets [6,8,20]. In this study, the use of 3 separate health interview datasets strengthens confidence that the observed patterns are not tied to a single sample alone. Across ILD, POTS, and COPD, Opus remained consistently strong, while the relative strengths and weaknesses of ChatGPT and Gemini followed broadly similar patterns. This cross-study consistency suggests that workflow-model interactions may be a meaningful area for future methodological research in LLM-assisted qualitative analysis.

Limitations

Several limitations should be noted. First, all analyses were conducted through consumer-facing web interfaces rather than APIs. Although we used newly registered paid accounts, disabled memory settings where available, and restricted data collection to a fixed study window, web-based platforms may still be affected by unannounced model updates, interface-level output constraints, and uncontrolled generation settings. In addition, the available configurations differed across platforms: ChatGPT and Opus were evaluated with extended thinking modes, whereas Gemini did not offer a comparable extended thinking option during the study window and was evaluated in its available standard configuration. Accordingly, Gemini's shorter outputs and generally lower similarity scores may reflect differences in the available model-interface configuration, in addition to differences in model behavior.

Second, the study used standardized prompts and a modular workflow, which improved consistency across models but may not reflect performance under alternative prompt designs or less structured qualitative analysis workflows. In addition, each model-workflow condition was executed once to mirror practical researcher-facing use, so within-model stochastic variation was not quantified.

Third, the evaluation relied on embedding-based cosine similarity and a 2-stage Hungarian plus Greedy alignment procedure. This approach allowed all themes to be included in the comparison, but it is not equivalent to a formal precision-recall framework and does not fully capture qualitative rigor, interpretive depth, or potential overgeneration effects.

Fourth, this study was descriptive rather than confirmatory. Formal inferential testing was not conducted because theme pair similarity scores were generated through an alignment procedure, were not fully independent, and came from only 3 datasets with 1 run per model-workflow condition. Therefore, differences across models and strategies should be interpreted as descriptive patterns rather than statistically confirmed effects.

Although all LLM interactions were performed through consumer-facing web interfaces, to reduce manual labor and the risk of human error, this implementation used a simple Python-assisted identifier assignment step to organize intermediate outputs, which requires intermediate programmatic data-processing skills.

Finally, the study evaluated only 3 LLMs and included a descriptive assessment of output format consistency and workflow management conducted by one researcher (YB). Future work should include additional proprietary and open-source models, repeated runs, independent workflow assessments, and prespecified statistical analyses across larger and more diverse qualitative datasets.

Future Directions

Future work should validate this framework across larger and more diverse qualitative datasets, disease areas, and methodological traditions. Additional studies should include a broader range of proprietary and open-source LLMs, repeated runs for each model-workflow condition, and API-based implementations with controlled decoding parameters to better assess reproducibility and run-to-run variability. Evaluation should also extend beyond embedding-based semantic similarity by incorporating expert ratings of theme quality, code-level validation linking excerpts to assigned codes, human-human comparison baselines, and measures of thematic coverage, missed concepts, and overgeneration. Future research could further examine how prompt design, transcript partitioning strategies, and human intervention at different stages influence analytic fidelity. These efforts would help clarify which combinations of model choice, workflow design, and human oversight are most appropriate for different qualitative research goals.

Conclusions

This study shows that a modular human-AI pipeline can support thematic analysis across multiple digital health interview studies, but its effectiveness depends strongly on both model choice and workflow design. Opus achieved the most consistent alignment with human-generated themes, while ChatGPT and Gemini showed distinct trade-offs in thematic fidelity, runtime, and usability. These results suggest that LLMs can serve as valuable assistants in qualitative research when embedded within structured, transparent, and human-supervised workflows. Rather than replacing qualitative researchers, LLMs may be most useful as configurable analytic partners whose strengths and limitations must be carefully matched to the goals and scale of the study.

Multimedia Appendix 2
Distribution of cosine similarity scores between human-generated themes and artificial intelligence (AI)–generated themes across 3 large language models, 5 workflow strategies, and 3 digital health qualitative interview studies. This figure visualizes the distribution of semantic similarity scores obtained after aligning AI-generated themes to the human-generated reference themes from 3 previously completed thematic analyses involving patients with interstitial lung disease (n=17), postural orthostatic tachycardia syndrome (n=15), and chronic obstructive pulmonary disease (n=16). For each model (Gemini 3 Pro, GPT-5.2-thinking, and Opus 4.6) and each workflow strategy (layer 1 [L1], layer 2 [L2], layer 3 [L3], direct coding [DC], and direct grouping [DG]), theme descriptions were embedded using sentence-t5-xxl and compared using cosine similarity after Hungarian plus Greedy matching. Higher scores indicate closer semantic alignment between the AI-derived themes and the original human thematic analysis. Across the 3 studies, Opus 4.6 generally showed the highest and most consistent similarity distributions.
[DOCX File , 699 KB - medinform_v14i1e96129_app2.docx]

Multimedia Appendix 3
Word count distribution of human-generated and artificial intelligence (AI)–generated theme summaries across models and workflow strategies. Values are reported as mean word count with range (minimum–maximum) and number of themes (n). Human-generated themes (n=23) were derived from 3 qualitative health interview studies (interstitial lung disease, postural orthostatic tachycardia syndrome, and chronic obstructive pulmonary disease). AI-generated themes were produced by Gemini

Abstract

Background: The Delphi method is widely used to derive expert consensus on complex clinical problems, yet it is slow and resource intensive. Recent advances in large language models and retrieval-augmented generation (RAG) offer the possibility of accelerating consensus while maintaining methodological rigor. Large language models can retrieve and summarize evidence, but they frequently hallucinate and cannot reliably cite sources. At the same time, RNA-based drugs and messenger RNA vaccines are rapidly moving from concept to clinic, generating a pressing need for timely, evidence-based consensus on regulatory, manufacturing, and clinical issues.

Objective: We evaluated whether a modular, RAG-enabled, multi-agent artificial intelligence (AI) pipeline could replicate the post–round 1 behavior of a human reviewer in a Delphi study. The primary objective was to determine whether AI-assisted statement revision could rescue a greater proportion of subthreshold statements and achieve a consensus comparable to that obtained through human revision by round 2.

Methods: A parallel, 2-arm Delphi study was conducted on 28 statements about RNA medicines. In total, 50 international panelists (clinicians, researchers, and patient representatives) were randomized into human (arm A) and AI-assisted (arm B) groups. After round 1, statements below the 75% agreement threshold were revised either manually by human reviewers or by an AI pipeline comprising the following software agents: (1) ReferenceDetector, to identify external citations; (2) Summarizer, to produce structured summaries of supporting PDFs; (3) a hybrid RAG module that combined dense and sparse retrieval with cross-encoder reranking; and (4) Refiner, which generated revised statements, reasoning logs, and explicit citations. Two human reviewers with expertise in Delphi methodology and literature review who had contributed to statement development verified retrieved citations and approved or amended revisions. Agreement rates and vote distributions were compared across arms.

Results: Arm A reached consensus on 71.4% (20/28) of the statements in round 1, whereas arm B reached consensus on 46.4% (13/28). After revision, consensus increased to 92.9% (26/28) of the statements in arm A and 85.7% (24/28) in arm B. The AI arm exhibited a larger mean improvement (absolute difference between rounds 1 and 2=39.3 percentage points) because more statements were initially below the threshold. Nonetheless, the absolute difference between arms after round 2 was modest (7.2 percentage points). AI-assisted revisions were particularly effective for statements far below the threshold, but both arms failed to rescue 2 to 3 statements owing to substantive disagreements.

Conclusions: A modular, citation-anchored AI pipeline can closely approximate human performance in Delphi consensus procedures while substantially reducing manual workload. When paired with human oversight, AI assistance accelerated revision and closed most of the performance gap by the second round. Adoption of AI-assisted workflows could accelerate consensus development on emerging technologies such as RNA therapeutics provided that transparency, rigorous retrieval, and human review are maintained.

KEYWORDS

Delphi method; large language models; retrieval augmented generation; RNA-based therapeutics; consensus; multi agent systems; artificial intelligence; AI

Introduction

The Delphi method is a structured technique for eliciting expert judgment and achieving consensus in complex domains [1]. Its strengths include anonymity of responses, controlled feedback, and the ability to draw on geographically dispersed experts [2]. These advantages make the Delphi method an attractive tool for health science questions for which empirical evidence is scarce. However, narrative reviews have emphasized persistent limitations: Delphi rounds are time-consuming, often taking 2 to 6 months; panelist engagement declines with each round; recruiting and retaining qualified experts is difficult; and the heterogeneity of expert panels, while desirable for breadth of perspective, complicates data collection and consensus formation [2]. A recent scoping review of 287 Delphi studies found substantial heterogeneity in panel composition and modifications to the classic method, making comparisons across studies difficult and underscoring the need for methodological innovation [3].

In parallel, RNA-based therapeutics have moved rapidly from experimental platforms to clinical realities. Successes in developing messenger RNA vaccines against SARS-CoV-2 and respiratory syncytial virus, along with a pipeline of candidates for other infectious diseases, cancers, and rare diseases, have highlighted the flexibility of the platform but also exposed regulatory and societal challenges [4]. Regulatory thinking varies across jurisdictions, and public acceptance—the "social license to operate"—remains critical for uptake [4]. Timely, evidence-based consensus statements can guide regulators, clinicians, and industry on the safe development and deployment of RNA-based products.

Large language models (LLMs) have been applied to medical knowledge retrieval and summarization. Retrieval-augmented generation (RAG) integrates external knowledge into the generative process, enabling LLMs to answer domain-specific questions. In a recent evaluation of 10 LLM-RAG models for preoperative assessment, the GPT-4 RAG model produced answers within 20 seconds and achieved 96.4% accuracy—significantly better than human reviewers (86.6%)—illustrating the potential of RAG to deliver rapid, accurate medical recommendations [5]. However, unaugmented LLMs often hallucinate, generating confident but fabricated statements and failing to provide verifiable citations [6]. These limitations have spurred interest in multi-agent architectures that break down complex tasks into retrieval, synthesis, and verification phases, as well as hybrid retrieval systems combining dense and sparse methods. Hybrid RAG approaches have been shown to improve recall and ranking precision by leveraging both semantic and lexical signals [7,8].

Given the need for timely consensus on RNA therapeutics and the emerging capabilities of LLMs, we designed an artificial intelligence (AI)–assisted Delphi pipeline to mirror the workflow of a human reviewer in the post–round 1 phase. Our main objective was to compare consensus outcomes when subthreshold statements were revised manually vs through an AI pipeline that used RAG and multi-agent modules. We hypothesized that AI assistance would rescue more statements by providing comprehensive evidence summaries and citation-anchored revisions, whereas final consensus rates would approximate those of human reviewers.

Early explorations of AI-facilitated Delphi exercises have highlighted both promise and pitfalls. Nóbrega et al [9] introduced AI Delphi, a machine-machine collaboration between multiple ChatGPT instances to explore future-of-work scenarios; the authors reported that LLMs could accelerate Delphi process execution but cautioned that human foresight remains indispensable. Perez Gálvez et al [10] subsequently proposed a hybrid soft consensus framework that treated generative LLMs as active participants alongside human experts; their experiments showed that LLM-assisted panels can reach agreement faster but emphasized the need for careful governance and transparency. In a controlled chat-based study, Triantafyllopoulos and Kalles [11] evaluated how LLMs facilitate agreement by adapting strategies such as clarification, summarization, and compromise; the authors found that GPT-4 produced consensus proposals more quickly than earlier models and argued for quantitative metrics to assess AI facilitation. Another Delphi-style experiment used LLMs to forecast the evolution of generative AI and reported that AI-mediated rounds captured diverse perspectives and mitigated respondent fatigue, although knowledge cutoffs and model biases remained challenges [12]. More recently, DeLLMphi has extended this line of work by constructing a fully in silico Delphi panel in which multiple "expert" LLMs, each conditioned on different superforecaster examples, iteratively update their forecasts in response to feedback from a mediator LLM. On a subset of the ForecastBench dataset, DeLLMphi outperformed alternative LLM configurations and closed approximately one-quarter of the performance gap between public forecasters and human superforecasters, highlighting the value of diversity, structured mediation, and multi-round interaction in LLM-based Delphi processes [13]. Together, these pilot studies suggest that generative models can enrich group decision-making and speed consensus formation. However, these experiments are conducted in a relatively clean forecasting environment, where questions admit a numerical ground truth and where LLM agents never directly intervene in clinical or regulatory decisions. In contrast, Delphi exercises in health care often address normative statements under weak or fragmented evidence and rely heavily on tacit clinical experience. In such high-stakes settings, fully automated panels may be inappropriate; instead, AI agents are better framed as tools that retrieve and synthesize evidence while human experts retain responsibility for judgment and consensus formation.

Methods

Overview

This study used a parallel 2-arm Delphi design. In total, 50 international panelists—including clinicians, researchers, and representatives of patient organizations—were recruited via professional networks, stratified, and randomized into 2 groups of 25 (50%) participants each to ensure a balanced distribution of professional backgrounds across the 2 arms (arm A: human revision; arm B: AI-assisted revision). Before participation, panelists were informed that the study included both a human revision arm and an AI-assisted revision arm; however, they were not informed of their individual allocation and, therefore, did not know which revision process had been applied to the statements circulated within their arm. Panelists assessed 28 statements concerning the development, studies related to quality, and preclinical aspects and regulatory issues of the classification of RNA-based medicines. Statements were rated on a 5-point Likert scale (1="strongly disagree"; 5="strongly agree"). A consensus threshold was predefined as 75% or more of the panelists selecting "agree" or "strongly agree." Round 1 remained open for 2 weeks. After closure, statements below the threshold entered the revision process. Operational end points such as turnaround time, reviewer workload, and cost were not prospectively measured as the study was designed to compare consensus outcomes after revision between arms. Panelists in both arms evaluated the same set of statements using the same 5-point Likert scale within the same 2-week response window; accordingly, panelist time commitment was intended to be comparable across arms.

The AI pipeline (Figure 1) was designed to replicate five key steps undertaken by human reviewers: (1) analyzing panelist comments to detect requests for clarification or additional evidence, (2) identifying external references suggested by panelists, (3) summarizing supporting PDF documents, (4) retrieving text segments relevant to the statement, and (5) drafting a revised statement with a transparent rationale and explicit citations. Three specialized agents formed the core of the pipeline:

Figure 1. Modular artificial intelligence (AI)–assisted pipeline for revising subthreshold Delphi statements. Human reviewers verify external references and summaries, approve or amend AI-generated revisions, and may request additional iterations. Major failures trigger the return to manual revision. DOI: digital object identifier; RAG: retrieval-augmented generation; w.r.t.: with respect to.

1. ReferenceDetector; this low-temperature agent scanned comments for URLs, digital object identifiers, or explicit article titles and returned a list of candidate references along with a description of context. Detected references were presented to human reviewers for optional inclusion in the source library, ensuring that relevant evidence was considered without blindly trusting the model.
2. Summarizer; for each supporting PDF, a summarization agent generated a concise, structured synopsis at moderate temperature. Summaries were cached for reuse across statements to minimize redundant application programming interface calls and facilitate rapid comprehension. Human reviewers approved summaries before use.
3. Refiner; this agent received the original statement, percentage of agreement, panelist comments, retrieved evidence, and summaries. Operating at low temperature to prioritize accuracy, it drafted a revised statement, produced a change log explaining each modification, and generated a citation map linking edits to specific comments and evidence. The output adhered to a structured schema to facilitate human verification.

To ground revisions in verifiable evidence, the pipeline used a hybrid retrieval module. Text from the supporting PDFs was segmented and indexed using both dense embeddings (all-MiniLM-L6-v2) and sparse BM25 representations.

The retrieval system operated on a static, curated source library composed of the supporting PDF documents available during the Delphi process together with any additional references suggested by panelists and validated by human reviewers before inclusion. The pipeline did not access regulatory databases or bibliographic sources in real time.

XSL•FO
RenderX

For each query (the subthreshold statement), both retrievers returned a fixed number of candidate passages. A cross-encoder (ms-marco-MiniLM-L-6-v2) reranked the combined candidates selecting the most relevant excerpts. During the hybrid fusion step, the final retrieval score was computed as a weighted combination of the individual retrievers, assigning a weight of 0.7 to the dense semantic scores and 0.3 to the sparse lexical (BM25) scores to favor semantic depth while retaining lexical coverage. Hybrid retrieval improves recall and precision compared with either dense or sparse retrieval alone; RAG combines pretrained sequence-to-sequence models with a dense vector index to generate more specific and factual answers [14]. Hybrid systems that fuse sparse BM25 and neural embeddings outperform either method individually in text retrieval tasks [7], and knowledge distillation from cross-encoder rerankers yields dense representations that retain much of the accuracy of cross-encoders while reducing storage requirements; when combined with sparse signals, these distilled embeddings approach cross-encoder performance [8]. In biomedical search, hybrid first-stage retrieval models combining lexical and neural methods consistently surpass purely sparse or purely neural models [15], and hybrid reranking schemes that aggregate similarity scores from dense and sparse retrievers deliver stable improvements over baseline rerankers [16]. We implemented our vector store using the Faiss library, which offers efficient algorithms for searching, clustering, and compressing vector representations [17]. Emerging work explores resource-constrained hybrid retrieval architectures leveraging smaller language models to support RAG on edge devices, although these approaches were not tested in our pipeline [18].

At each stage, oversight was provided by 2 researchers with expertise in Delphi methodology whose familiarity with the topic derived from their involvement in the development of the statements through literature review. They were not panelists. In the AI-assisted arm, their role was limited to verification of retrieved references, summaries, and draft revisions rather than full manual interpretation of panelist comments and complete redrafting of statements. After reference detection and summarization, they confirmed that the references and summaries were appropriate. After retrieval and refinement, they examined the revised statement, change log, and citations. If a revision contained errors or omissions, they could request additional iterations or edit the statement manually. Reviewer time and cost were not prospectively recorded. This human-in-the-loop design aligns with recommendations that LLM outputs be verified and that AI tools augment rather than replace expert judgment [19].

For each statement and round, the percentage of panelists selecting “agree” or “strongly agree” was calculated. Statements were classified as “passed” or “failed” based on the 75% or more threshold. We compared the number and proportion of statements passing in each arm across rounds using descriptive statistics. Because panelists evaluated the same statements across arms, no inferential tests were performed. Improvements were expressed as percentage-point differences between rounds.

Ethical Considerations

This methodological study involved an anonymous expert elicitation through a Delphi consensus procedure to evaluate aggregate statements on RNA-based medicines. Per the guidelines of local and institutional ethics committees regarding noninterventional research, formal ethics approval was not required as the study did not process individual patient health data, collect sensitive personal parameters, or involve clinical interventions on human participants. All participants were international health care experts, clinicians, and organizational representatives who took part voluntarily and were fully informed about the study’s scope, objectives, and data use protocols prior to completing the questionnaires. Completing the online feedback was considered informed consent to the use of aggregated, anonymized responses.

Results

All 50 panelists completed the first round of voting. The human arm (arm A) reached consensus on 71.4% (20/28) of the statements, corresponding to items meeting or exceeding the 75% agreement threshold, whereas the AI-assisted arm (arm B) reached consensus on 46.4% (13/28) of the statements. Mean Likert-scale scores were higher in the human arm (4.24, SD 0.82) than in the AI arm (3.90, SD 0.99), suggesting that participants in arm B were more critical at baseline. As a result, 28.6% (8/28) of the statements from arm A and 53.6% (15/28) of the statements from arm B required revision.

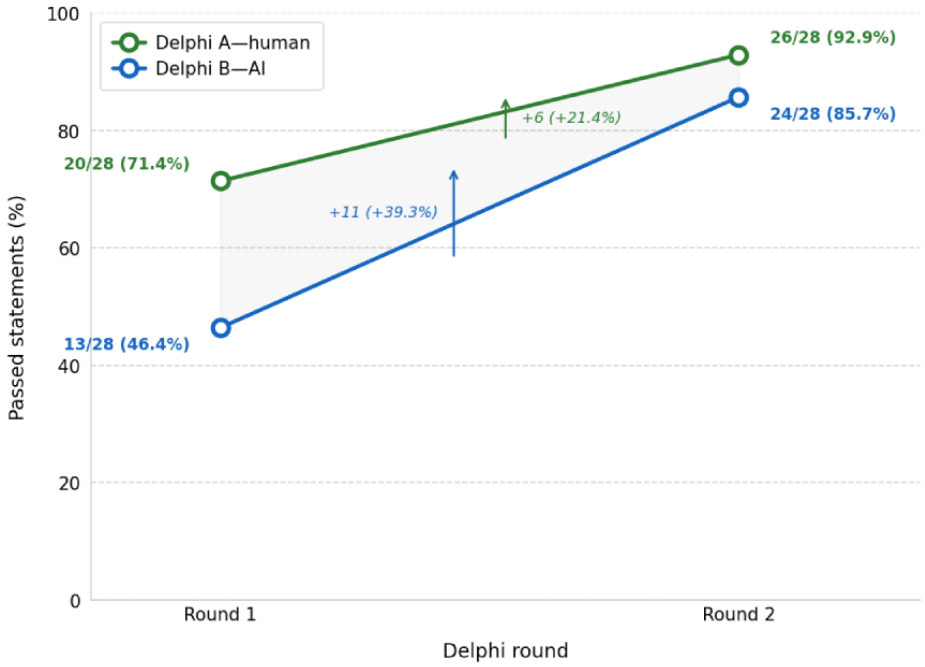
Human reviewers manually read comments, revisited references, and drafted edits. In the AI arm, the pipeline aggregated comments, detected missing references, retrieved relevant evidence, and produced citation-anchored revisions with explicit rationales. Each AI-assisted revision was reviewed before circulation by 2 researchers; they verified retrieved citations and approved or amended the revised text.

An important aspect of the workflow was the “human-in-the-loop” mechanism designed to call an expert reviewer whenever the pipeline suspected that commenters were requesting new references. Across all AI-assisted revisions, the trigger was activated only once. In that instance, a panelist explicitly asked to include an additional reference, and the pipeline correctly flagged the comment. The human reviewer agreed and added the suggested reference, and the new citation was subsequently incorporated into both panels. There were no false-positive triggers (situations where the system called for human review even though no new references were requested) and no false negatives (instances in which a request for a new reference was missed). Once AI-assisted revisions were approved, panelists rarely felt the need to intervene: none of the AI-revised statements were rejected outright for being inaccurate or inconsistent with the literature, and only 4 comments required minor rewording. In 3 of these, the reviewer deleted a sentence beginning with “However,” deeming it unnecessary, and in 1 case, a brief parenthetical statement inserted by the AI was removed. Overall, the minimal editing required suggests that the AI pipeline produced revisions that were coherent, factually grounded, and aligned with panelist expectations.

XSL•FO
RenderX

After the revision phase, consensus improved markedly in both arms. Arm A went from 71.4% (20/28) of the statements passing in round 1 (95% CI 51.3%-86.8%) to 92.9% (26/28) in round 2 (95% CI 76.5%-99.1%), whereas arm B went from 46.4% (13/28; 95% CI 27.5%-66.1%) in round 1 to 85.7% (24/28; 95% CI 67.3%-96.0%) in round 2, closing most of the performance gap and leaving a modest absolute difference of 7.2 percentage points between the 2 arms after round 2. The AI-assisted arm exhibited a 39.3–percentage point increase in pass rate compared with a 21.4-point increase in the human arm, most likely because panelists in arm B were more critical at baseline, resulting in a lower round 1 pass rate and more statements entering revision below the threshold; residual heterogeneity in panel composition may also have contributed. Table 1 summarizes pass and fail counts before and after revision, and detailed statement-level results across both rounds are provided in Multimedia Appendix 1. Figure 2 illustrates the cumulative pass rate across rounds.

Throughout the experiment, the AI pipeline frequently delivered substantial improvements on statements that were far below the consensus threshold. For example, one statement regarding safety monitoring of RNA therapeutics, to which 16 of the 25 arm B panelists responded, increased from 43.8% (7/16) agreement to 75% (12/16) after AI revision, whereas the corresponding statement in the human arm showed little change. Another statement on regulatory harmonization improved by nearly 25 percentage points in the AI arm, reaching consensus alongside the human-revised version. Nevertheless, not all statements benefited equally. A few complex items dealing with long-term regulatory frameworks and public acceptance experienced minor declines after AI revision, underscoring the need for human judgment on nuanced topics. Overall, AI-assisted revisions raised mean Likert-scale scores by roughly half a point.



Despite these gains, a small subset of statements remained below the 75% threshold after round 2—7.1% (2/28) in the human arm and 14.3% (4/28) in the AI arm. These outliers typically addressed contentious or speculative issues for which evidence was limited and on which panelists held divergent views. Panelist comments suggested that further rounds or alternative consensus methods would be required to resolve these disagreements.

Table 1. Pass and fail distribution per arm and round (n=28).

Arm	Round 1 passed, n (%)	Round 1 failed, n (%)	Round 2 passed, n (%)	Round 2 failed, n (%)
Human (arm A)	20 (71.4)	8 (28.6)	26 (92.9)	2 (7.1)
AI[a] assisted (arm B)	13 (46.4)	15 (53.6)	24 (85.7)	4 (14.3)

[a]AI: artificial intelligence.

Figure 2. Cumulative pass rate per round. Labels indicate the number of statements passed and the percentage point increase from the previous round. The artificial intelligence (AI)–assisted arm exhibits a steeper slope owing to a lower starting point, but both arms converge by round 2.

Discussion

Principal Findings

This controlled study demonstrates that a citation-anchored, multi-agent AI pipeline can nearly match human reviewers in rescuing subthreshold Delphi statements. The AI arm started from a lower baseline but achieved consensus on 85.7% (24/28) of the statements after 1 revision cycle, closing most of the gap with the human arm. AI-assisted revisions were particularly effective for statements far below the threshold, suggesting that comprehensive retrieval and structured reasoning can surface evidence and clarify ambiguities that panelists may have overlooked. This is in line with recent AI-assisted post hoc assessment of published expert consensus showing that LLMs may help highlight convergent interpretations and identify statements deserving closer evidentiary review when evidence is limited while not replacing independent expert judgment [20]. Residual differences between arms were modest and may reflect panel heterogeneity rather than intrinsic limitations of the AI.

Our findings align with a growing body of evidence that RAG and hybrid retrieval substantially improve the reliability of LLM outputs. RAG couples a pretrained sequence-to-sequence model with a dense vector index so that the generation step can draw on external documents and, thus, produce more specific and factual answers [14]. Hybrid systems that fuse semantic (dense) and lexical (sparse) signals achieve superior recall and ranking precision compared with either method alone [7,8]. These results informed our design of a dense-sparse retrieval module and cross-encoder reranking.

At the same time, unaugmented LLMs are prone to hallucinations. Adversarial evaluations of GPT-4 and related models report hallucination rates ranging from 50% to 82%, and prompt engineering mitigations reduce hallucinations only modestly [19]. Such vulnerability underscores the need for retrieval mechanisms and human verification. Multi-agent frameworks that break down tasks into retrieval, reasoning, and verification phases are increasingly advocated for to mitigate hallucinations and maintain factuality [6]. Our pipeline embodies this “retrieve-summarize-verify” paradigm: it anchors statements to cited evidence, exposes reasoning steps, and allows human reviewers to approve or amend each stage.

The inclusion of human reviewers is not merely precautionary; it reflects emerging guidance for transparent and accountable AI-assisted scientific writing and health-related AI use. In high-stakes consensus settings, AI can assist with retrieval, summarization, and draft revision, but decisions about the relevance of the retrieved evidence, its interpretation and grading, and the final normative framing of recommendations should remain under human responsibility. Reviewers, therefore, validate extracted references, approve summaries, and ensure that revised statements align with domain knowledge and the intended consensus context. This iterative oversight balances the efficiency gains of automation with the trustworthiness of expert judgment and is better understood as collaborative intelligence than as autonomous AI decision-making [19,21-23].

In the context of consensus methodology, our results corroborate the observation that panel composition profoundly influences consensus outcomes. Heterogeneous panels bring diverse perspectives but make consensus harder to achieve [2]. In our study, the AI arm panelists were more critical at baseline, as reflected by both a lower mean Likert-scale score and a lower proportion of statements meeting the consensus threshold in round 1. This likely resulted in more subthreshold statements entering the revision phase and, consequently, a larger apparent improvement after revision. A further probable explanation is residual heterogeneity in panel composition, which is known to influence Delphi outcomes by shaping how conservatively or permissively statements are judged. When these baseline differences are taken into account, the final consensus rates between arms were nearly identical. Our work, therefore, supports the feasibility of integrating AI tools into Delphi processes while underscoring the continued importance of careful panel selection and human expertise.

This study has several limitations. First, the AI pipeline used a specific LLM and retrieval configuration based on a static, curated knowledge base rather than real-time access to regulatory or bibliographic databases; performance may vary with different models, temperatures, retrieval strategies, or source update policies. While live access might improve the timeliness of revisions by incorporating newly published evidence or updated regulatory documents, the use of a static source library improved reproducibility, traceability, and consistency across statements in this controlled study. Second, operational efficiency was not formally quantified. We did not prospectively measure turnaround time, reviewer workload, personnel cost, or the time required from panelists in each arm. Although panelist participation was designed to be comparable across arms and the AI-assisted workflow shifted expert input from full manual rewriting toward verification and minor postediting, this study cannot make formal claims about time or cost savings. Future studies should prospectively compare time to revision, reviewer effort per statement, and cost-effectiveness between human-only and AI-assisted workflows. Third, the human and AI arms differed in baseline criticality, which partly explains the larger improvement in the AI arm. Fourth, our pipeline used a single model; multi-model ensembles might further reduce variance but would increase computational costs.

Research should extend this evaluation across diverse domains, panel sizes, and consensus thresholds. Comparative studies exploring alternative retrieval strategies, prompt designs, agent configurations, and multi-model ensembles could identify optimal architectures. Formal assessments of time savings, computational costs, and environmental impact will inform the practical viability of AI-augmented consensus workflows. Developing automated metrics for citation fidelity and hallucination detection could enhance trust in AI outputs. Qualitative research into panelists’ perceptions of AI-assisted revisions and their willingness to disclose AI involvement will help refine human-in-the-loop designs and support responsible adoption. In the rapidly evolving field of messenger RNA therapeutics, AI-assisted consensus methods may help regulators and clinicians keep pace with scientific advances.

XSL•FO
RenderX

Conclusions

This study demonstrates that a modular, retrieval-augmented AI pipeline can deliver revision outcomes comparable to those of human reviewers in a Delphi consensus exercise on RNA therapeutics. The pipeline rescued a greater proportion of subthreshold statements by aggregating panelist comments, retrieving relevant evidence, and producing citation-anchored revisions. Human oversight remains essential: experts must verify references, validate summaries, and approve final wording. With appropriate safeguards, AI-augmented workflows can accelerate consensus development in rapidly evolving fields.

Abstract

Background: Pharmacists' prescription review is key to medication safety, but rising numbers of outpatient prescriptions and expanding formularies leave less time per case, increasing error risk. Large language models (LLMs) show promise, yet two barriers hinder routine use: first, most systems rely on cloud-based commercial models, risking data breaches by transmitting protected patient information externally, and second, retrieval-augmented generation (RAG) pipelines used to reduce hallucinations depend on complex text vectorization and vector databases, which hospitals with limited IT resources struggle to build and maintain.

Objective: This study aimed to evaluate the feasibility and usefulness of a locally deployed, knowledge-augmented LLM as a decision-support tool for pharmacist-led outpatient prescription review.

Methods: The open-source Qwen3-14B model was deployed on a hospital intranet server using the Ollama framework. A structured knowledge base derived from drug package inserts served as the principal reference and supported lightweight knowledge augmentation through exact-match injection. A 2-period crossover design was used: 2 pharmacists independently reviewed 213 outpatient prescriptions under both unaided and AI-assisted conditions, yielding paired unaided and collaborative results for each prescription. Plain AI review and knowledge-augmented AI review were also run on the same 213-prescription test set to quantify hallucination rates, and stand-alone AI performance was assessed against the reference standard. The reference standard was established by independent consensus between two supervising pharmacists, with disagreements adjudicated by a deputy chief pharmacist. Accuracy, sensitivity, and specificity were compared between conditions using paired McNemar tests, and review time was compared using the Wilcoxon signed-rank test.

Results: Overall review accuracy was 97.2% (207/213, 95% CI 94.0%-98.7%) in the human-AI collaborative condition vs 82.6% (176/213, 95% CI 77.0%-87.1%) in the pharmacist-alone condition (P<.001). Sensitivity was 98% (61/62) vs 55% (34/62), and the false-negative rate fell from 45% to 2% (P<.001). Specificity did not differ significantly (146/151, 96.7% vs 142/151, 94%; P=.29). Knowledge augmentation reduced the model hallucination rate from 19.7% (42/213 prescriptions) to 4.7% (10/213), an absolute reduction of 15.0 percentage points (relative reduction 76.2%; P<.001). Collaborative review reduced the mean per-prescription review time from 2.33 (SD 0.97) to 1.12 (SD 0.49) minutes (approximately 51.9% reduction; Wilcoxon signed-rank Z=−12.65; P<.001; r=0.87).

Conclusions: A locally deployed, knowledge-augmented LLM used as a pharmacist-supervised prescreening tool was associated with substantially higher accuracy and sensitivity in outpatient retrospective prescription review, while keeping all prescription data within the hospital network. Locally deployed open-source models may offer hospitals a privacy-preserving and practical route to AI-assisted pharmacy decision support.

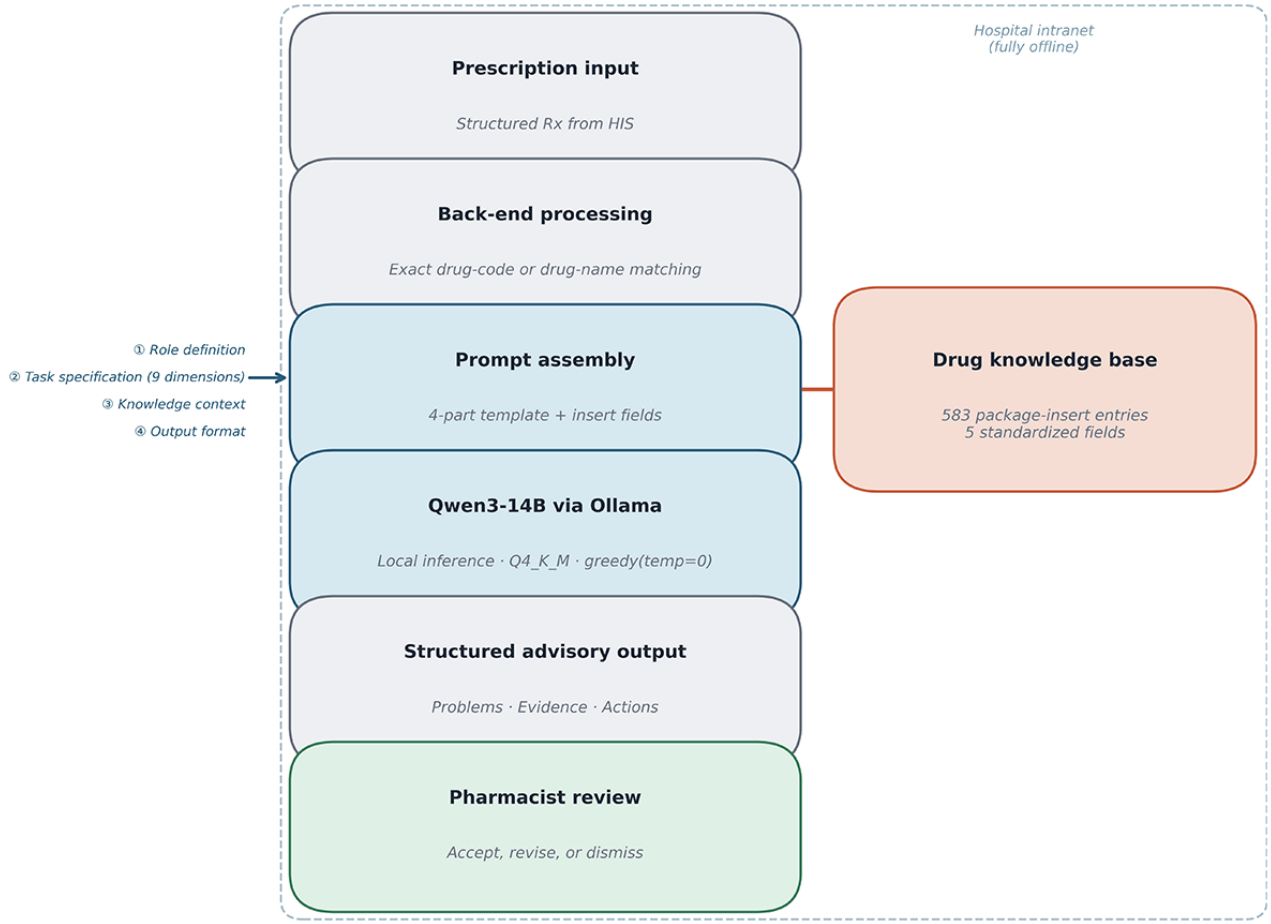
Introduction

Prescription review is fundamental to ensuring medication safety and rational drug use in health care institutions. China's Hospital Prescription Review Management Standards (Trial) designates pharmacists as the primary agents of prescription review across all levels of health care facilities [1]. However, as outpatient prescription volumes and drug formularies steadily expand, pharmacists face growing pressure to evaluate indication appropriateness, dosing, drug interactions, and other factors within limited time, inevitably raising the risk of oversight [2]. Finding effective supportive tools to enhance review quality and efficiency while preserving the pharmacist's central role has therefore become an urgent priority.

Since 2023, large language models (LLMs) have gained considerable traction in health care. Studies have demonstrated that LLMs can effectively encode clinical information and perform comparably to experts on medical question-answering tasks [3,4]. In the domain of medication safety, researchers have explored the capacity of LLMs to correct medication direction errors [5], identify drug-drug interactions [6], and review prescriptions [7]. Despite this progress, LLMs still fall short of matching pharmacist-level expertise. In a prospective crossover study, Ong et al [8] showed that combining LLM-based screening with physician review achieved significantly higher medication error detection rates than either method alone. LLMs thus appear better suited as a complement to clinical practice rather than a replacement.

Despite these advances, two critical gaps remain. First, nearly all existing studies rely on cloud-based platforms. Prescription data inherently contain legally protected patient information (eg, diagnoses and medication histories) that cannot be transmitted through external interfaces without substantial data breach and regulatory risk [9]. Second, the hallucination problem intrinsic to LLMs poses particular dangers in clinical settings [10]. Retrieval-augmented generation (RAG) is the prevailing strategy for mitigating hallucinations [11]; however, conventional RAG pipelines require text vectorization, embedding models, and vector databases, creating a significant technical barrier for health care facilities with limited informatics resources.

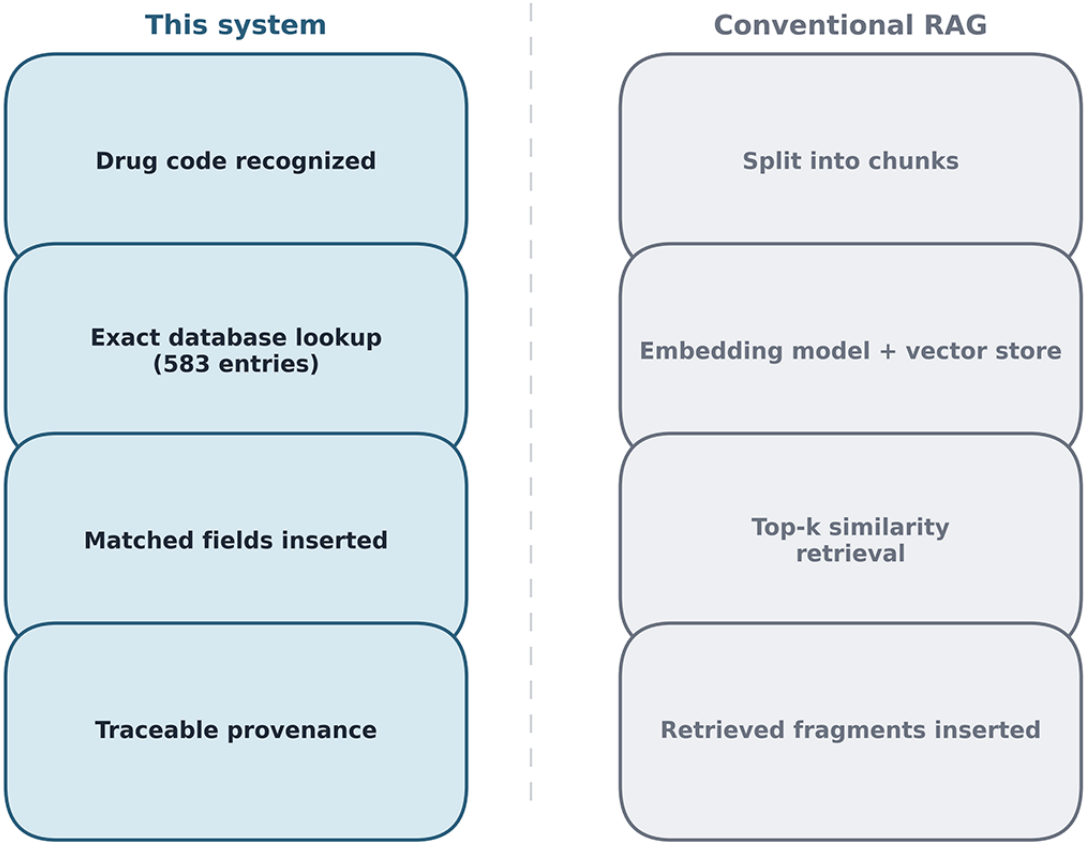
To address these gaps, we deployed the open-source Qwen3-14B model on a hospital intranet server via the Ollama framework and constructed a structured knowledge base from drug package inserts. Instead of the vectorization and semantic retrieval overhead of conventional RAG, we adopted exact-match injection for knowledge augmentation. Importantly, this study was not designed to evaluate stand-alone AI performance. We used a crossover design grounded in routine pharmacy workflows, comparing unaided pharmacist review with AI-assisted pharmacist review and systematically assessing the impact of knowledge augmentation on model hallucinations. This approach preserves regulatory compliance by maintaining pharmacists as the reviewers and reflects realistic implementation conditions. The aim of this study was to determine whether a locally deployed, knowledge-augmented LLM, serving as a pharmacist-supervised prescreening tool, improves accuracy, sensitivity, and efficiency of outpatient prescription review compared with unaided review, and to quantify the degree to which exact-match knowledge augmentation reduces hallucinations. We hypothesized that AI-assisted review would improve accuracy and sensitivity without meaningful loss of specificity, and that knowledge augmentation would substantially lower the hallucination rate relative to unaugmented AI review.



Methods

System Architecture and Knowledge Augmentation

The system adopts a browser or server architecture with a PHP (version 8.2.27; PHP Group) back end communicating with a locally deployed Ollama (version 0.10.1; Ollama Inc) instance serving Qwen3-14B (Alibaba Group; Q4_K_M quantization, greedy decoding, up to 5120 tokens per prescription) on the hospital intranet. All processing remained fully offline. The end-to-end pipeline and its comparison with conventional RAG are illustrated in Figures 1 and 2. Implementation details, including hardware specifications, are provided in Multimedia Appendix 1.



XSL•FO
RenderX

Figure 2. Deterministic exact matching vs conventional retrieval-augmented generation (RAG). Exact matching is traceable, needs no retraining, and removes the semantic mismatch risk of vector retrieval, although it still depends on accurate drug code correspondence; conventional RAG adds infrastructure and carries a risk of semantic mismatch.

Feature	This system	Conventional RAG
Retrieval method	Exact code match	Semantic similarity
Infrastructure	Database only	Embedding model + vector store
Provenance	Fully traceable	Probabilistic
Maintenance	Edit one record	Rebuild index
Mismatch risk	No semantic mismatch	Semantic confusion

Drug knowledge was sourced exclusively from package inserts, which serve as the legally binding reference under Chinese regulations, decomposed into 5 standardized fields (indications, dosage and administration, contraindications, interactions, and special-population precautions) across 583 entries. Upon recognizing a drug code, the system performed deterministic exact matching and injected the corresponding fields into the prompt. This approach avoids the need for an embedding model, vector store, and semantic mismatch risks inherent to conventional RAG; provenance is fully traceable, and updates require only editing a single database record. Because matching is keyed on the drug code rather than on free text, it removes the semantic retrieval errors of vector search, although it still depends on consistent coding; a brand-vs-generic naming difference or a coding inconsistency in the hospital information system could therefore prevent a match. Such cases are handled by the same safeguard applied to unmatched drugs: they are treated as uninjected and flagged for manual review, so a failed match surfaces as an explicit no-injection alert rather than a silent or erroneous injection. Drugs absent from the knowledge base were flagged for manual pharmacist review; all 213 test prescriptions were fully covered. We chose package inserts over subscription compendia such as Micromedex (Merative LP) or UpToDate. Although these compendia offer richer indication and dosage information, they require licensing and external connectivity, which is incompatible with the fully offline, privacy-preserving design at the core of our study.

The prompt comprised 4 components: role definition (advisory tool, not a decision-maker), task specification (9 review dimensions, including indication-diagnosis correlation, dosage, interactions, and special populations), injected package-insert content and review rules, and a structured output format (problem description, supporting evidence, and recommended action). The complete template is provided in Multimedia Appendix 2.

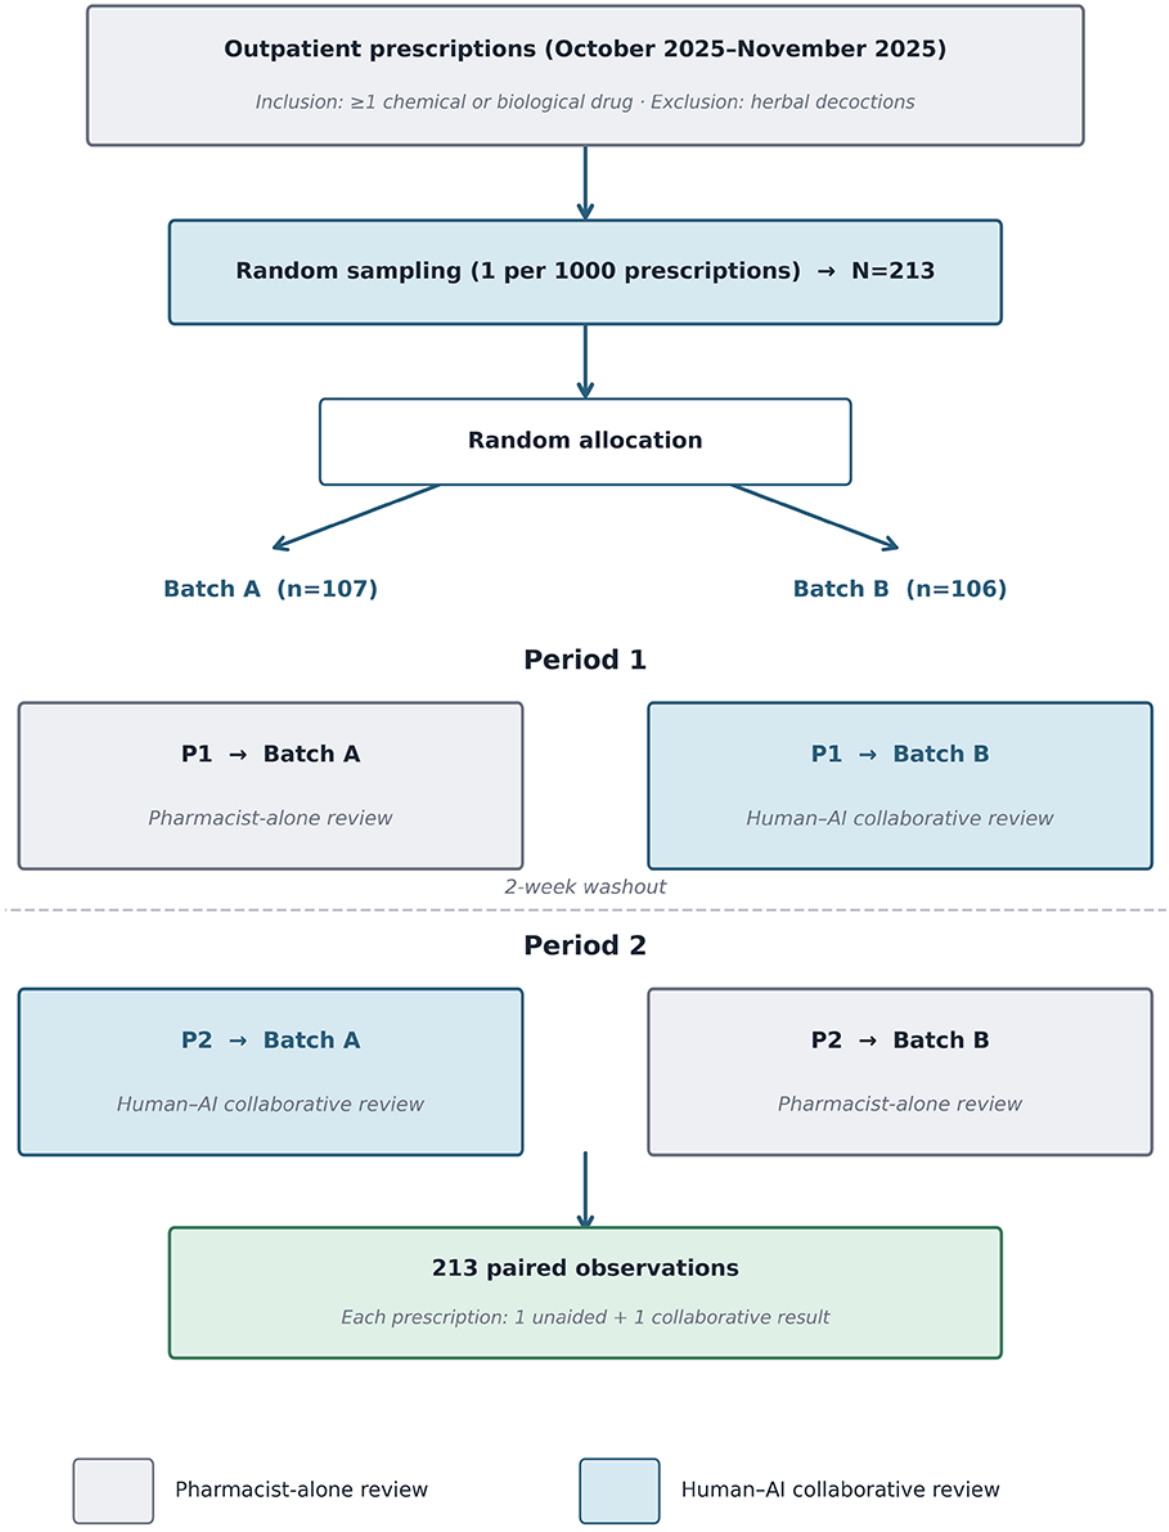
Study Design

Population and Allocation

The population of the study was outpatient prescriptions from a tertiary teaching hospital in October and November 2025. Inclusion criteria were prescriptions with a minimum of 1 chemical or biological pharmaceutical drug. Exclusion criteria were traditional Chinese herbal decoction prescriptions. Following the screening process, 213 prescriptions were randomly sampled at a rate of 0.1%, as specified by the Hospital Prescription Review Management Standards [1].



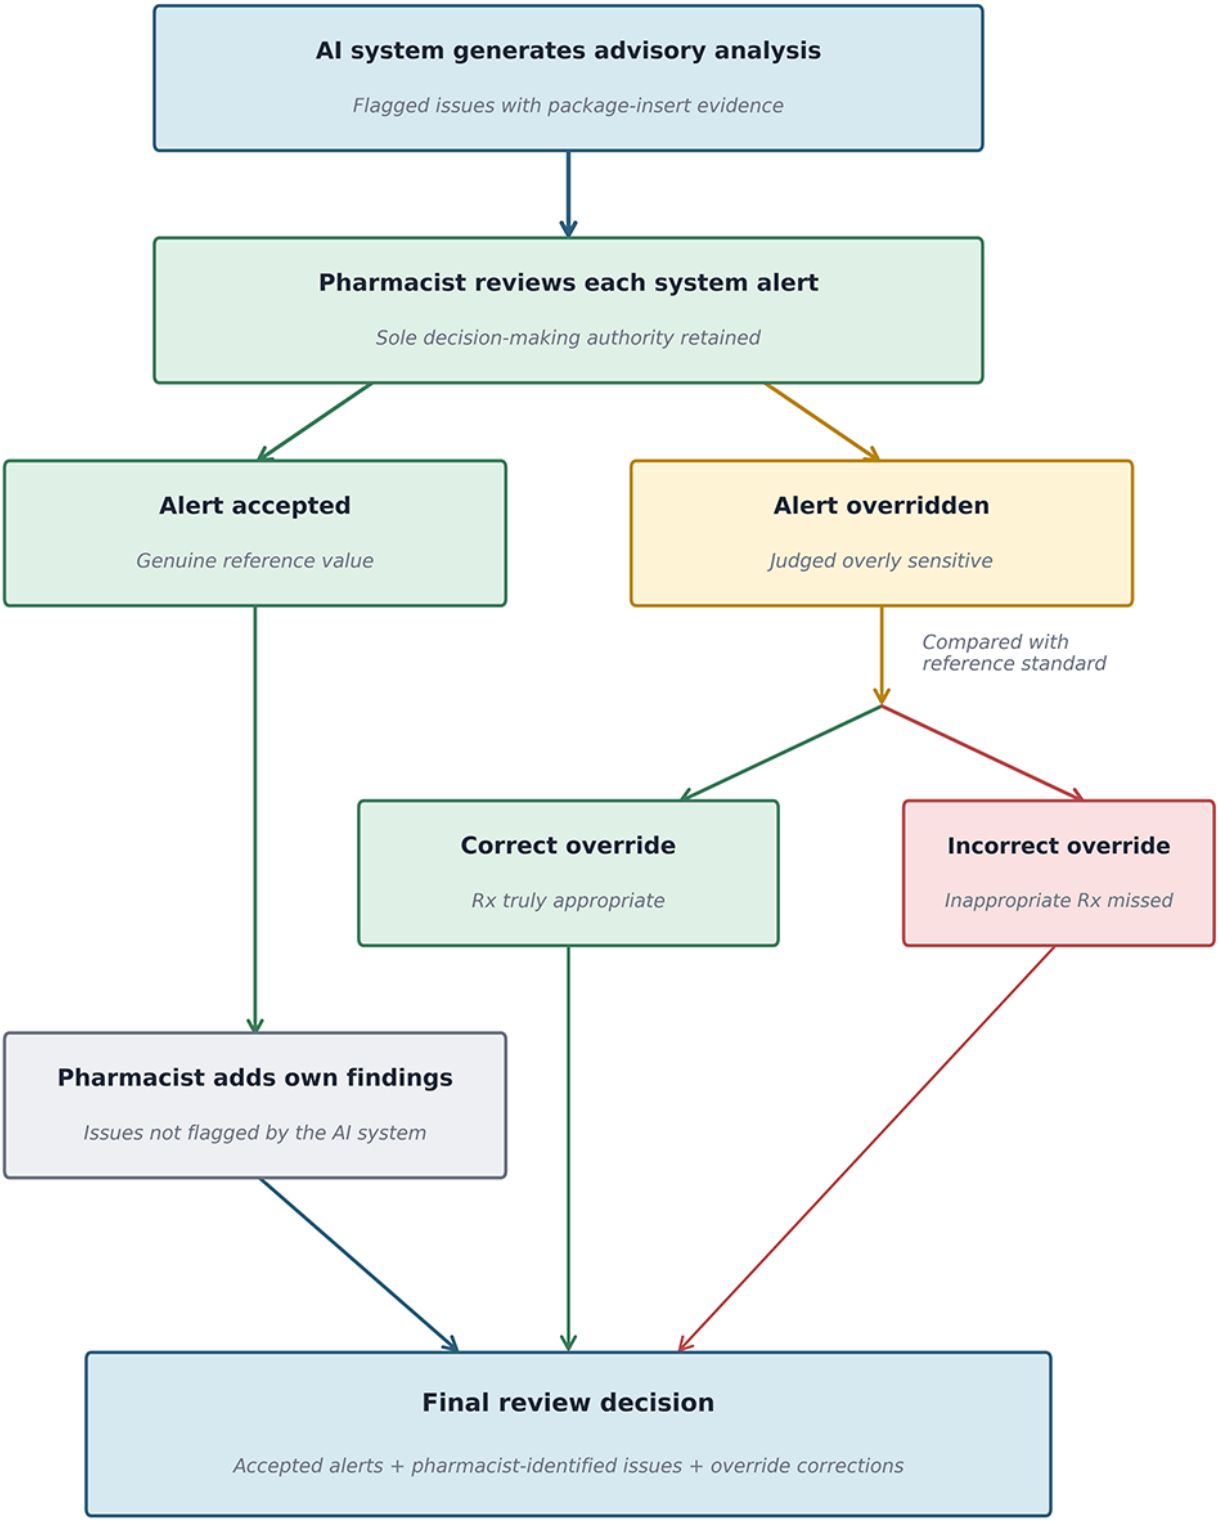
The sample size was fixed by this administrative sampling rule, and no a priori power calculation was performed before the study. We did not conduct a post hoc power analysis, because observed power is a deterministic function of the observed *P* value and adds little information beyond the CIs. Instead, the precision of every estimate is conveyed by its Wilson-score 95% CI, and the fixed sample size is acknowledged as a limitation. As a planning reference only, the sample size formula for the McNemar test described by Lachin [12] indicates that, for a 2-sided α of .05, 80% power, and a between-condition accuracy difference of at least 10 percentage points, about 124 discordant-informative pairs would be required; the 213 paired observations available therefore provided a reasonable basis for the primary comparison. The therapeutic duplication (n=5, 2.3%) and dosage inappropriateness (n=11, 5.2%) subgroups contained too few cases for adequately powered testing and are reported as exploratory.

Crossover Design and Collaborative Workflow

A 2-period crossover design was used (Figure 3). The 213 prescriptions were randomly allocated to batch A (n=107, 50.2%) and batch B (n=106, 49.8%). Two junior pharmacists (P1 and P2; 1-2 years of experience) each performed 1 period of unaided review and 1 period of human-AI collaborative review, counterbalanced across batches with a 2-week washout interval, yielding 213 paired observations (1 unaided and 1 collaborative result per prescription).

XSL•FO
RenderX

Figure 3. Two-period crossover design. Prescriptions were randomly split into 2 batches and counterbalanced across pharmacists and periods, separated by a 2-week washout.



In the collaborative condition (Figure 4), the pharmacist reviewed system-generated alerts, each linked to package-insert evidence, and exercised sole decision-making authority to accept, revise, or dismiss each flag or to add findings not identified by the system. Every alert disposition was recorded as accepted or overridden according to the reviewing pharmacist's judgment. Overridden alerts were subsequently verified against the reference standard and classified as correct or incorrect. The system automatically recorded the review time of each prescription as the wall-clock interval from opening to submission, capturing end-to-end time at the prescription level rather than the drug-item level. Model inference for every prescription in a batch was completed beforehand as an offline preprocessing step, so that pharmacists reviewed previously generated outputs; the recorded review time therefore reflects the pharmacist's interaction with the system and excludes model

XSL•FO
RenderX

inference latency. Per-prescription review time served as the primary efficiency outcome.

Figure 4. Human-AI collaborative workflow. The pharmacist reviewed each system alert, accepting or overriding it, and added any issues not flagged by the system; overridden alerts were compared with the reference standard.

Comparison of AI Review Modes

All 213 prescriptions were additionally processed in 2 stand-alone AI modes, plain (parametric knowledge only) and knowledge-augmented, to quantify the effect of knowledge injection on hallucinations. Hallucination was defined as any assertion contradicting the package insert or established clinical guidance, adjudicated at the prescription level by 2 senior pharmacists (disagreements resolved by a deputy chief pharmacist); Cohen κ quantified interrater reliability. The knowledge-augmented AI's stand-alone diagnostic performance was also evaluated against the reference standard.

XSL•FO
RenderX

Reference Standard

Two supervising pharmacists (>5 years of prescription-review experience), blinded to all experimental outputs, independently assessed all 213 prescriptions; discrepancies were resolved by a deputy chief pharmacist. A sensitivity analysis included all prescriptions flagged by any condition but classified as appropriate by the expert panel for post hoc review (with blinding lifted); verified inappropriate prescriptions were added to an extended reference standard, and all analyses were repeated.

Statistical Analysis

Baseline characteristics of the 213 prescriptions were summarized overall and by crossover sequence (P1 and P2), and between-sequence balance was tested with the Mann-Whitney *U* test for age and drug items per prescription (both nonnormal by the Shapiro-Wilk test) and the Pearson chi-square test for sex and age category.

The primary outcome was overall accuracy (correct classifications divided by total prescriptions); secondary outcomes included sensitivity, specificity, false-positive rate, false-negative rate, and mean review time. Paired conditions were compared with the McNemar test (Yates continuity correction; exact binomial McNemar test for small subgroups). A Mann-Whitney *U* test (with a *P*>.10 threshold) verified batch exchangeability before pooling periods. All proportions are reported with Wilson 95% CIs. No multiplicity correction was applied to exploratory end points. Analyses were performed in Python (version 3.10.2; Python Software Foundation). Additional statistical analysis details are provided in Multimedia Appendix 1.

Ethical Considerations

This retrospective, noninterventional study analyzed existing, deidentified outpatient prescription records, with no contact with patients and no influence on clinical care. It therefore qualified for exemption from ethics committee review and individual informed consent under Article 32 of China's 2023 Measures for Ethical Review of Life Science and Medical Research Involving Humans, and the institutional research-governance office confirmed this exemption (no case number applies, as no review was sought) [13]. Direct identifiers were removed during extraction, and only the fields required for analysis (patient age, sex, diagnosis, drug, dose, route, and frequency) were retained, yielding a dataset from which no individual can be identified. All processing occurred within the hospital intranet on access-controlled servers. No participants were recruited or compensated, and no image or supplementary file contains patient-identifiable information.

Results

Baseline Prescription Characteristics

The 213 prescriptions came from patients aged 1 to 95 years (median 57, IQR 38-69); 110 (51.6%) were female, and the median number of drug items per prescription was 2 (IQR 1-3). Sequences P1 (n=107, 50.2%) and P2 (n=106, 49.8%) were well balanced with respect to age (*P*=.86), age category (*P*=.33), sex (*P*=.73), and drug items per prescription (*P*=.33), supporting pooling across periods (Table 1).

Table 1. Demographic and clinical characteristics of the 213 outpatient prescriptions sampled at a tertiary teaching hospital in China (October 2025-November 2025) for a 2-period crossover study comparing unaided pharmacist review with human-AI collaborative review, overall and by crossover sequence.

Characteristics	Overall (N=213)	Sequence P1 (n=107)	Sequence P2 (n=106)	*P* value
Age (years)				.86[a]
Mean (SD)	53.5 (19.9)	53.0 (21.3)	54.1 (18.5)	
Median (IQR)	57 (38-69)	57 (36-70)	56 (40-68)	
Range	1-95	1-93	13-95	
Age group (years), n (%)				.33[b]
Children (<18)	12 (5.6)	8 (7.5)	4 (3.8)	
Adults (18-59)	106 (49.8)	49 (45.8)	57 (53.8)	
Older adults (≥60)	95 (44.6)	50 (46.7)	45 (42.4)	
Sex, n (%)				.73[b]
Male	103 (48.4)	50 (46.7)	53 (50)	
Female	110 (51.6)	57 (53.3)	53 (50)	
Drug items per prescription				.33[a]
Mean (SD)	2.16 (1.04)	2.07 (0.96)	2.25 (1.11)	
Median (IQR)	2 (1-3)	2 (1-3)	2 (1-3)

Comparison of Review Performance Between Groups

Before pooling the two periods, we examined whether the two prescription batches were comparable across sequences; given the prescription-level paired design, this is a check of batch and sequence comparability rather than a formal person-level carryover test. The Mann-Whitney *U* test, using the per-prescription sum of the two-period outcomes as the test statistic, showed no significant difference between sequences (batch A in period 1: n=107, 50.2%, vs batch B in period 2: n=106, 49.8%; *P*=.37). Because the paired unit was the prescription and the sequences corresponded to the 2 prescription batches, this result indicates that the batches were exchangeable with no detectable sequence-level effect; the 2 periods were therefore pooled for the main analysis.

Independent expert review and adjudication classified 62 (29.1%) of 213 prescriptions as inappropriate: 51 (24.0%) with an inappropriate indication, 11 (5.2%) with an inappropriate dosage, and 5 (2.3%) with therapeutic duplication (67 distinct errors in total, as some prescriptions had >1 problem). No prescription in the test set contained a clinically significant drug-drug interaction, a physicochemical incompatibility, or a confirmed contraindication or special-population error. Consequently, the system performance reported here pertains to indication, dosage, and duplication errors; its proficiency in detecting interactions, incompatibilities, contraindications, and special-population problems could not be validated in this sample, even though each of these dimensions is specified in the prompt (addressed in the Limitations). All subsequent findings are based on this reference standard, with between-condition performance summarized in Table 2.

Table 2. Prescription-review performance of unaided pharmacist review vs human-AI collaborative review on 213 outpatient prescriptions sampled at a tertiary teaching hospital in China (October 2025-November 2025) in a 2-period crossover study, using an independent expert reference standard (62 inappropriate prescriptions)[a].

Groups	Accuracy (%)	Sensitivity (%)	Specificity (%)	False-positive rate (%)	False-negative rate (%)
Pharmacist alone	82.6	55	94	6	45
Human-AI collaborative	97.2	98	96.7	3.3	2
Chi-square test (*df*)	25.71 (1)	25.04 (1)	—[b]	—	25.04 (1)
P value	<.001	<.001	.29	.29	<.001

[a]Comparisons used paired McNemar tests with Yates continuity correction (213 paired observations). For accuracy, there were 33 discordant pairs that were correct only with collaboration and 2 that were correct only when unaided; for sensitivity and the false-negative rate, there were 27 and 0 discordant pairs, respectively. Accuracy denominators were 213; sensitivity, specificity, and the error rates used 62 inappropriate and 151 appropriate prescriptions, respectively.

[b]Specificity and false-positive-rate differences were not significant, and their test statistics are not reported.

Human-AI collaborative review significantly outperformed pharmacist-alone review in both overall accuracy and sensitivity (Table 2). Specificity did not differ between the 2 groups, indicating that AI support did not increase the misclassification of appropriate prescriptions as inappropriate and therefore added no meaningful false-positive risk.

To characterize individual pharmacist differences, Cohen κ was calculated for each pharmacist's unaided review against the reference standard. Because P1 and P2 reviewed different prescription batches, the 2 pharmacists were not directly compared. These values therefore reflect criterion agreement with the reference standard. They do not represent interrater reliability between P1 and P2. P1 yielded κ=0.554 (95% CI 0.360-0.749; observed agreement 84.1%) and P2 yielded κ=0.520 (95% CI 0.284-0.751; observed agreement 81.1%). By the Landis and Koch classification, both fall within the moderate-agreement interval (κ range: 0.41-0.60). The two estimates were close (|Δκ|=0.034), indicating similar criterion agreement, although κ values obtained on nonoverlapping batches cannot establish agreement between the raters themselves. A related caveat concerns the paired analysis: because different reviewers performed the two conditions for any given prescription, the prescription-level differences carry a rater component, which the counterbalanced crossover design balances across conditions at the aggregate level.

Evaluated as a stand-alone classifier against the same reference standard, the knowledge-augmented AI flagged 77 prescriptions and achieved a sensitivity of 100% (62/62; 95% CI 94.2%-100%), a specificity of 90.1% (136/151; 95% CI 84.3%-93.9%), and an accuracy of 93% (198/213; 95% CI 88.7%-95.7%). The AI alone was thus highly sensitive but less specific than the collaborative condition, and its stand-alone accuracy (198/213, 93%) was lower than that achieved by the collaborative workflow (207/213, 97.2%). By retaining almost all the AI's sensitivity while the pharmacist's judgment raised specificity, the collaborative condition attained the highest overall accuracy, illustrating the complementary mechanism underlying the collaborative benefit. The increase in specificity, from 90.1% (136/151) in the stand-alone system to 96.7% (146/151) in the collaborative condition, was driven by pharmacist filtering of the model's false alarms: of the 15 (7%) appropriate prescriptions that the AI overflagged, the pharmacists correctly dismissed 10 (4.7%) and accepted 5 (2.3%), while overriding 1 genuine alert (the single false negative in the collaborative arm).

Detection of Different Problem Types

Subgroup analysis showed that the magnitude of AI-assisted improvement varied by problem type (Table 3). Where sample sizes were adequate, the collaborative group consistently outperformed the pharmacist-alone group. Identification of inappropriate indications rose from 61% (31/51) to 98% (50/51;

XSL•FO
RenderX

P<.001), and identification of inappropriate dosages rose from 46% (5/11) to 100% (11/11; *P*=.03). Both categories rely on relatively objective criteria that can be verified against package inserts or diagnostic information, so the system's knowledge base effectively compensated for gaps in pharmacist recall, yielding the clearest benefit from collaboration. Detection of therapeutic duplication improved from 20% (1/5) to 100% (5/5), but the small sample (N=5) precluded statistical significance (exact McNemar *P*=.13); this result is reported for reference only.

Table 3. Detection rates for each type of prescription problem under unaided pharmacist review and human-AI collaborative review among 213 outpatient prescriptions from a tertiary teaching hospital in China[a].

Problem types	Pharmacist-alone, n (%)	Collaborative, n (%)	McNemar *P* values
Indication inappropriateness (n=51)	31 (61)	50 (98)	<.001
Dosage inappropriateness (n=11)	5 (46)	11 (100)	.03
Therapeutic duplication (n=5)	1 (20)	5 (100)	.13

[a]All subgroup sample sizes were small (n=5-51); exact McNemar tests (binomial exact) were used for paired comparisons. Detection rates were calculated per error: the denominators (n=51, 11, and 5) sum to the 67 distinct errors contained in the 62 inappropriate prescriptions, whereas the performance metrics in Table 2 were calculated per prescription. The collaborative detection counts (50+11+5=66) therefore differ from the 61 true-positive prescriptions implied by Table 2 because some prescriptions carried >1 error.

Effect of Knowledge Augmentation on Model Hallucinations

On the same 213-prescription test set, plain AI review produced 101 marked events, of which 42 were adjudicated as hallucinations affecting 42 distinct prescriptions, a per-prescription hallucination rate of 19.7% (42/213). All 42 hallucinations fell into 3 categories: erroneous dosing advice (45%, 19/42), fabricated drug interactions absent from the package insert (38%, 16/42), and false indications (17%, 7/42). After knowledge augmentation, the system produced 94 marked events with only 10 adjudicated hallucinations across 10 prescriptions (4.7%, 10/213), an absolute reduction of 15.0 percentage points and a relative reduction of 76.2%. Because both modes processed the same 213 prescriptions, the comparison was paired: hallucinations occurred only in plain mode for 33 (15.5%) prescriptions and only in augmented mode for 1 (0.5%), while 9 (4.2%) prescriptions had hallucinations in both modes and 170 (79.8%) had hallucinations in neither mode. The resulting McNemar χ^2_1 was 28.26 (*P*<.001). Among the 10 residual hallucinations in augmented mode, 8 (80%) were drug interaction errors, mostly in complex prescriptions with >2 coprescribed drugs, suggesting the model may still extrapolate beyond injected knowledge when package-insert information for several drugs overlaps.

Interrater reliability of hallucination adjudication was good, with Cohen κ of 0.858 (95% CI 0.756-0.959) for plain mode and 0.810 (95% CI 0.627-0.992) for knowledge-augmented mode, indicating substantial to almost perfect agreement.

Review Efficiency

The pharmacist-alone condition required 496.3 minutes to complete the full batch, whereas the human-AI collaborative condition required 238.6 minutes (N=213 prescriptions), yielding per-prescription review times of 2.33 (SD 0.97; median 1.95, IQR 1.47-2.92) minutes and 1.12 (SD 0.49; median 0.92, IQR 0.70-1.45) minutes, respectively. The mean within-prescription reduction was 1.21 (SD 0.50, 95% CI 1.14-1.28) minutes, representing an approximately 51.9% decrease under the collaborative condition, with shorter times observed in all 213 paired prescriptions. As the paired differences deviated from normality (Shapiro-Wilk *W*=0.91; *P*<.001), the primary comparison used the Wilcoxon signed-rank test, which confirmed significantly shorter review times in the collaborative condition (*Z*=−12.65; *P*<.001; *r*=.87); a paired *t* test produced a consistent result (t_{212}=35.34; *P*<.001; Cohen d_z=2.42, a very large effect).

Two factors likely contributed: the system preselected potentially problematic prescriptions, enabling pharmacists to focus on higher-risk cases, and relevant package-insert information was retrieved automatically, eliminating manual reference lookup. Timing was recorded at the prescription level rather than the individual drug-item level, so the estimates reflect end-to-end review time per prescription.

Pharmacist Acceptance and Feedback on System Suggestions

When working collaboratively, the system sent a warning of a possible problem with 77 prescriptions. The reviewing pharmacist accepted 86% (66/77) of these alerts and overrode the remaining 14% (11/77) as overly sensitive false alarms. Acceptance records the pharmacist's disposition rather than verified clinical validity. As noted previously, 5 (7.6%) of the 66 accepted alerts concerned prescriptions that the reference standard ultimately classified as appropriate. Of the 11 overrides, 10 (90.9%) proved correct on verification against that standard; the single incorrect override produced the only false negative in the collaborative group. During unstructured verbal debriefings after the final review session, both participating pharmacists expressed willingness to use the system in routine practice, remarking that it eased the burden of manual reference lookup and the stress of possible omissions.

Sensitivity Analysis

Some prescriptions flagged by experimental arms had been classified as appropriate under the reference standard. To assess whether such omissions affected the conclusions, these cases were returned to the expert panel for post hoc reevaluation. Three were confirmed as inappropriate and added to an extended reference standard (65 inappropriate prescriptions in total). Because both the pharmacist-alone and human-AI teams had

XSL•FO
RenderX

correctly identified all 3, the discordant-pair structure between groups was unchanged.

Under the expanded standard, the pharmacist-alone group achieved 84% accuracy (95% CI 78.5-88.3) and 57% sensitivity (95% CI 44.8-68.2), while the collaborative group reached 98.6% (95% CI 95.9-99.5) and 98% (95% CI 91.8-99.7), respectively. The McNemar test statistic remained identical to the main analysis (χ^2=25.71; P<.001), confirming that the overall conclusions are robust to minor imperfections in the reference standard.

Discussion

Principal Findings

In this 2-period crossover study, pairing a locally deployed, knowledge-augmented LLM with pharmacist review substantially improved outpatient prescription review. Overall accuracy rose from 82.6% with unaided review to 97.2% with collaborative review, and sensitivity rose from 55% to 98%, while specificity was essentially unchanged; the gain in error detection was therefore not obtained at the cost of additional false alarms. Exact-match knowledge augmentation lowered the model hallucination rate from 19.7% to 4.7%. Collaborative review was also markedly faster, with mean per-prescription review time decreasing from 2.33 (SD 0.97) minutes to 1.12 (SD 0.49) minutes (≈51.9% reduction). Taken together, these findings indicate that a modest, locally hosted open-source model, used as a pharmacist-supervised prescreening tool, can meaningfully strengthen medication safety review without transmitting prescription data outside the hospital network.

Rationale and Significance of Local-Deployment Human-AI Collaboration

Using a crossover design, we compared unaided pharmacist review with review assisted by a locally deployed LLM. The collaborative mode achieved substantially higher accuracy, sensitivity, and efficiency, with the pharmacist retaining decisional authority and the LLM serving as a prescreening agent. This copilot approach is consistent with Ong et al [8], who found that collaborative review outperformed either the model or the clinician alone, although their work relied on cloud-based GPT-4. Our study extends this rationale by relocating deployment from the cloud to the hospital intranet. Because Ollama keeps prescription data within the institutional network, it addresses the data-privacy requirements of Chinese medical facilities [9]. These findings suggest that effective human-AI cooperation in pharmacy need not depend on commercial cloud models, since locally deployed open-source solutions can deliver comparable collaborative benefits while preserving privacy.

Prior literature on LLMs in pharmacy has focused largely on isolated model evaluation, including drug interaction identification [6], benchmarking against clinical pharmacists [7], community pharmacy decision support [14], and real-world drug information accuracy [15]. These studies collectively show that ChatGPT responses are often incomplete or contain errors. Although they delineate the performance boundaries of LLMs, none addresses the more practically meaningful question of whether pharmacist work is improved by LLM assistance. By taking the pharmacist-LLM dyad as the unit of evaluation, our study quantifies net real-world benefit and thereby complements the existing evidence base.

Technical Characteristics of the Knowledge Augmentation Strategy and Its Hallucination-Mitigation Mechanism

Conventional RAG is significantly different from the exact-match injection approach. The clinical decision-support system outlined by Ong et al [8] involves document chunking, vector indexing, and semantic retrieval, a pipeline that incurs substantial development and maintenance costs. We use the unique nature of drug identifiers to minimize knowledge retrieval to an individual deterministic database search and avoid the need for embedding models and vector storage. In prescription review in particular, the query goal is a clear-cut drug name as opposed to free text; exact matching is thus more reliable than fuzzy semantic retrieval and far less prone to noise.

The assessment of hallucination provides additional support regarding the mechanism of the collaboration effect. Knowledge augmentation lowered the hallucination rate from 19.7% to 4.7%, corresponding to a relative reduction of approximately 76.2%, which indicates that exact-match injection meaningfully narrows the model's output space and confers adequate trustworthiness for system-generated suggestions for routine pharmacist consultation. This further supports the finding that the acceptance rate in the collaborative group was 86%: a small hallucination rate is required so that pharmacists could trust and use system outputs effectively. It should also be noted that the evaluation of hallucinations was intended as an explanatory analysis in the current research; that is, it aims to elucidate the technical basis of the benefit of collaboration but not to act as an isolated main end point equivalent to accuracy and sensitivity.

Clinical Effectiveness and Translational Value of the Collaborative Mode

The collaborative mode demonstrated its principal value in sensitivity. The miss rate for inappropriate prescriptions fell from 45% under pharmacist-only review to 2% with AI support. System prescreening reminders served as a safety net for lapses arising from heavy workloads or imperfect recall of drug-specific information during independent review. Specificity remained high in both groups (142/151, 94% vs 146/151, 96.7%) with no statistically significant difference, indicating that AI support added no meaningful false-positive risk. The pharmacists' appraisal of system alerts was nonetheless imperfect: two-thirds of the model's false alarms were correctly dismissed (10/15, 66.7%), while the remaining third (5/15, 33.3%) were accepted. This finding aligns with Ong et al [8], who reported that collaborative review does not increase false positives, and with Singhal et al [3], who showed that LLMs can perform at an expert level when provided with adequate contextual knowledge. Subgroup analysis revealed the greatest gains in knowledge-intensive, rule-based domains such as indication and dosage appropriateness, whereas improvements were smaller for judgments requiring integration of individualized patient information, defining both the current scope of the system and directions for future development.

XSL•FO
RenderX

From a clinical standpoint, raising sensitivity from 55% to 98% carries substantial weight. As a post hoc quality assurance measure, prescription review derives its core value from systematic identification of irrational drug use and the continuous feedback that subsequently shapes prescribing behavior. A high miss rate directly undermines this loop: undetected inappropriate prescriptions never enter quality control, the prescribing physicians receive no corrective feedback, and the same errors tend to recur. Reducing the false-negative rate from 45% to 2% produces a more representative profile of prescribing problems in review outputs, offering a more accurate basis for departmental feedback and behavioral intervention. Over time, improved detection should reinforce a positive review-feedback-improvement cycle and curtail inappropriate prescribing at its source. The benefit is particularly relevant for primary care institutions, where pharmacist staffing is limited and full review coverage is difficult to sustain; the collaborative approach markedly improves efficiency, substantially reduces missed detections, and offers a practical solution for medication safety oversight in such settings.

Limitations

The 213-prescription sample reflected an administrative rule rather than an a priori power calculation; we report Wilson-score 95% CIs so that estimate precision is directly visible. Subgroup intervals are wide, and the therapeutic duplication (n=5, 2.3%) and dosage inappropriateness (n=11, 5.2%) findings should be treated as exploratory pending validation in larger multicenter samples covering uncommon combinations and special populations. Both reviewers were junior pharmacists (1-2 years' experience), so the AI-related gain may be smaller for senior staff and should not be extrapolated across seniority without further study. The 2-period crossover with a 2-week washout balanced period and rater effects but cannot fully exclude asymmetrical learning: knowledge acquired under AI assistance may have raised later unaided performance, biasing the estimated benefit toward the null and rendering the reported improvement, if anything, conservative.

The system itself has intrinsic scope limits. It analyzes each prescription in isolation, with no access to longitudinal data such as prior medications, allergies, or renal and hepatic function; dosage and special-population review were therefore judged only against package-insert dose ranges, indications, and population statements alongside the recorded diagnosis, and cumulative polypharmacy was not evaluated. Some dosing decisions cannot be fully adjudicated without laboratory parameters. The 14-billion-parameter Qwen3 model is less capable than leading proprietary models, which may constrain deep-reasoning tasks; moreover, the model ran under 4 bits (Q4_K_M) quantization, which may modestly reduce reasoning performance or alter hallucination behavior relative to full-precision weights, so the stand-alone results reported here reflect a quantized deployment and may represent a performance floor. Even so, the collaborative gains achieved under local deployment indicate that scale is not the sole determinant of assistive value. Inference took 15 to 30 seconds per prescription on consumer-grade hardware. Because this inference was performed as a batch preprocessing step before the review session, the latency was not included in the recorded per-prescription review time and did not affect the efficiency comparison; it would, however, lengthen overall batch turnaround and could become a bottleneck at very high outpatient volumes, where more capable hardware, batched processing, or parallel inference would be required. Beyond hardware, local deployment carries recurring operating costs that we did not quantify, including server maintenance, electricity, and the staff time needed to keep the package-insert knowledge base current. We also did not perform a formal economic evaluation, which should precede any claim about affordability or cost-effectiveness. The 583-entry knowledge base is a subset of the hospital's formulary; off-base drugs receive no knowledge injection and are routed for manual review, so generalizability depends on continued expansion both locally and at sites with broader formularies. The reference standard classified 29.1% (62/213) of sampled prescriptions as inappropriate, a rate that reflects the 0.1% administrative sampling of a tertiary teaching hospital and may exceed the prevalence in many outpatient or primary care settings. Because positive predictive value falls as prevalence declines, the same model operating at a lower error prevalence would return a larger proportion of false-positive alerts: for the stand-alone system (sensitivity approximately 100%, specificity approximately 90%), illustrative positive predictive value decreases from approximately 80% at the observed prevalence to approximately 53% at a prevalence of 10% and 35% at 5%. A higher false-alarm fraction could aggravate alert fatigue and automation complacency, although the model's high specificity limits the absolute number of false alerts and the human-in-the-loop design allows pharmacists to filter them; characterizing the real-world alert burden will therefore require prospective evaluation across settings with differing baseline error rates.

Measurement issues also apply. The absolute hallucination counts were small (42 plain and 10 augmented), limiting the precision of the type distribution; severity was not graded, and a clinical-significance taxonomy would enable finer comparison of augmentation strategies. Only explicit problem statements were adjudicated, so hallucinations embedded in justifications for prescriptions deemed appropriate were missed, making the per-prescription rate probably conservative. The sample contained no confirmed drug-drug interaction or physicochemical incompatibility error, leaving proficiency in these clinically critical domains unvalidated despite prompt coverage. The post hoc sensitivity analysis was unblinded, introducing some incorporation bias, and is reported only as a robustness check.

Finally, the collaborative efficiency advantage partly reflected preflagging of suspect prescriptions, raising a real risk that busy pharmacists rely on alerts and underscrutinize unflagged orders. Safe deployment therefore requires AI alerts to supplement rather than replace complete pharmacist review, with workflow safeguards, periodic audit of nonflagged prescriptions, and targeted training to manage automation complacency before broader implementation.

XSL•FO
RenderX

Future Directions

Future work should pursue several complementary directions. Domain-specific fine-tuning informed by expert-reviewed prescriptions and pharmacist feedback could further refine accuracy for particular drug classes [16,17]. Deeper integration with the hospital information system would enable automated retrieval of laboratory results, allergy history, and medication history, supporting genuinely patient-level rather than prescription-level analysis. A closed-loop learning mechanism that incorporates pharmacist accept or reject decisions could progressively improve advisory quality. Privacy-preserving, deidentified sharing of knowledge bases and exemplar cases across institutions also warrants exploration. If licensing and offline deployment allow, adding richer resources such as Micromedex or UpToDate to the package-insert knowledge base could broaden indication and dosage coverage.

Conclusions

In this study, the pharmacist was kept at the center of decision-making, and a prescription-review decision-support system was built on the Qwen3-14B LLM, deployed inside the hospital through the Ollama platform together with a structured drug knowledge base. The crossover evaluation showed that AI assistance increased pharmacist review accuracy from 82.6% to 97.2% and sensitivity from 55% to 98% (both $P<.001$), while shortening the per-prescription review time from 2.33 (SD 0.97) to 1.12 (SD 0.49) minutes, an approximately 51.9% reduction (Wilcoxon signed-rank $Z=-12.65$; $P<.001$; $r=0.87$; N=213). Knowledge augmentation reduced the model hallucination rate from 19.7% to 4.7% (relative reduction 76.2%). By keeping all prescription data within the hospital's own network, local deployment offers health care institutions a workable and secure way to integrate AI-driven pharmacy services without stepping outside their existing data-compliance requirements.

Abstract

Background: Patient safety events (PSEs) are preventable incidents that cause, or have the potential to cause, harm to patients during their medical journey. Although incident reporting systems capture large volumes of such events, only a small proportion undergo comprehensive investigation due to the resource-intensive nature of the review process. Patient safety specialists are tasked with triaging PSEs to prioritize high-severity cases that warrant timely institutional investigation; however, the rapidly increasing volume of events has made manual triage increasingly impractical.

Objective: This study aimed to develop and validate ranking-based machine learning models for prioritizing high-severity PSEs and to compare their performance with conventional classification-based models and the reporter-assigned severity baseline.

Methods: A total of 101,239 PSE reports were retrospectively extracted from a large Canadian academic health system between January 2017 and March 2025. Each report included a free-text incident description and a corresponding severity label denoting the level of severity, assigned through an institutional review process. Both feature-based and transformer-based models were developed using ranking and classification frameworks. Model performance was evaluated using ranking metrics, including average precision and normalized discounted cumulative gain (NDCG) at multiple cutoff thresholds (k=10, 20, 50, 100, 200), as well as Precision@k and Recall@k. The best-performing model was further benchmarked against the reporter-assigned severity baseline.

Results: The ranking model, LLAMA3.1-RA, achieved the highest mean average precision of 0.94 (95% CI 0.90-0.98), representing a 22.1% relative improvement over the best classification model (LLAMA3.1-CL: mean 0.77, 95% CI 0.72-0.82; P<.001). LLAMA3.1-RA demonstrated superior performance across 10 of 16 evaluation metrics, with larger relative gains at broader evaluation cutoffs (eg, +12.9% in NDCG@200, +21.1% in Precision@200, and +20.3% in Recall@200). Compared with the reporter-assigned severity baseline, LLAMA3.1-RA achieved significantly higher performance across all 16 metrics, retrieving 83.0% of high-severity PSEs within the top 200 ranked events, compared with 41.0% retrieved under the reporter-assigned severity baseline.

XSL•FO
RenderX

Conclusions: LLAMA3.1-RA demonstrated superior capability in prioritizing high-severity PSEs compared with both classification approaches and the reporter-assigned severity baseline. Integrating this model into triage workflows may offer a scalable and efficient solution for identifying and prioritizing high-severity safety events.

Introduction

Overview

Systematic reporting and analysis of adverse events are essential for improving patient safety in modern health care systems. According to the World Health Organization, adverse events are incidents associated with health care that result in, or have the potential to result in, harm to a patient, many of which are potentially preventable [1,2]. Common examples include medication errors, unsafe surgical procedures, and diagnostic errors [3,4]. In Canada, recent national data indicate that unintended harm occurs in approximately 6% of hospitalizations, corresponding to about 1 in every 17 hospital stays, and that multiple harmful events occur in roughly one-quarter of these cases [5]. Beyond clinical consequences, adverse events also impose substantial economic burdens. The indirect costs of unsafe care were estimated at US $118 trillion globally between 2000 and 2020 [6].

The significant impact of adverse events has led many countries to implement mandatory reporting legislation [7,8]. As of 2021, 9 out of 13 jurisdictions in Canada require health care providers to report adverse events [9]. Systematic reporting enables institutions to detect unsafe practices and implement preventive strategies. Adverse events are typically documented as patient safety event (PSE) reports through institutional incident reporting systems (IRSs) [10,11]. PSE reports typically comprise both unstructured fields—such as narrative descriptions of the incident—and structured fields, including the date, location, event type, and severity of harm [12,13]. The submitted reports are investigated by designated hospital personnel, such as risk managers, patient safety specialists, nurse managers, and physicians, to identify contributing factors and root causes [14-16]. Although these reports offer valuable learning opportunities, their investigation is resource-intensive, demanding substantial time, expert knowledge, and interdepartmental coordination [17]. As a result, only a limited proportion of PSE reports undergo comprehensive investigations [18].

Hospitals prioritize the investigation of high-severity PSEs to optimize the effectiveness of limited resources [18,19]. The prioritization of high-severity PSEs is also driven by legislated investigation requirements, as well as ethical obligations to address patient harm, support affected individuals and families, and prevent recurrence through system-level mitigation [14,20]. Event reporters typically assign a severity rating within the IRS to reflect the perceived seriousness of an event. These ratings inform prioritization decisions for investigation efforts. However, research has shown that severity ratings vary substantially among health care professionals, due to differences in clinical roles and familiarity with the severity taxonomy [21,22]. To address this inconsistency, patient safety specialists frequently conduct retrospective manual reviews of submitted reports to identify high-severity cases that warrant timely investigation [18,23,24]. Although individual reports can be assessed through expert review, the rapidly growing volume of submissions makes the timely screening of every incoming report increasingly resource-intensive. For example, over 4.4 million PSE reports were submitted to the National Reporting and Learning System in England between 2020 and 2022 [25]. This operational challenge underscores the need for scalable triage solutions that can support report prioritization while allowing clinical and patient safety resources to be directed toward investigation and quality improvement initiatives.

Natural language processing (NLP) may help address this need by enabling incident descriptions to be analyzed automatically at scale. Accordingly, recent studies have applied NLP techniques to classify the severity of PSE reports [1,18,26,27]. Ong et al [18] used naïve Bayes and support vector machine (SVM) models for severity classification, while Wang et al [27] investigated convolutional neural networks for predicting severity levels. However, most prior studies have relied on classification-based approaches that focus on maximizing categorical accuracy, which may not fully align with the practical needs of patient safety specialists. In institutional settings, these specialists are responsible for prioritizing high-severity PSEs for investigation under significant time constraints and limited resources. In this context, accurately ranking the most critical events at the top of the review list can more effectively support their workflow and decision-making processes.

Ranking-based approaches explicitly learn the relative ordering of instances according to their importance or relevance, making them particularly suitable for this prioritization task. Instead of assigning each report to a discrete severity level, these methods estimate a continuous severity score and order events from most to least severe. By emphasizing relative priority rather than categorical accuracy, ranking-based models align more closely with the operational needs of patient safety specialists. To our knowledge, no prior studies have systematically evaluated ranking approaches for prioritizing PSEs by severity.

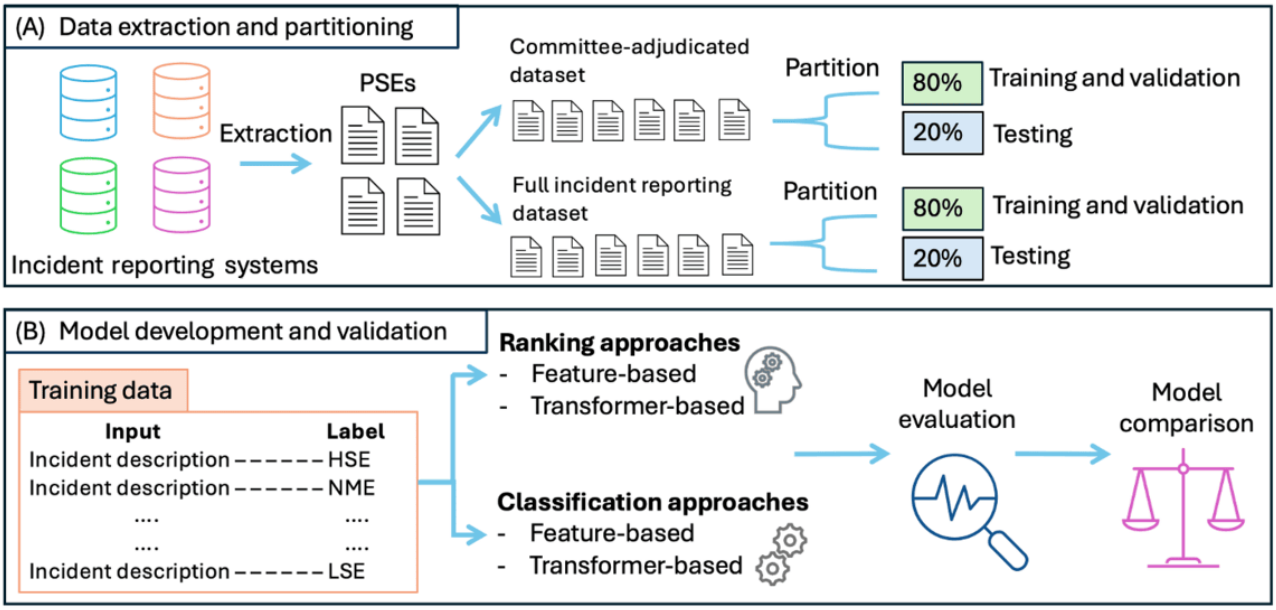
Study Objectives

This study aimed to evaluate the effectiveness of machine learning models for prioritizing high-severity PSEs using retrospectively collected incident reports. We developed both ranking-based and classification-based models and compared

XSL•FO
RenderX

their performance in prioritizing PSEs by severity. The top-performing model was further evaluated against the reporter-assigned severity baseline to assess its potential to improve severity triage practices.

Methods



Ethical Considerations

This study conducted a secondary analysis of deidentified PSE data collected through institutional IRSs for quality and safety improvement. The study protocol was approved by the hospital's research ethics board (REB# 23-5237) and was further reviewed to ensure compliance with jurisdictional privacy legislation and institutional quality assurance policies. Following extraction, all data were fully anonymized in accordance with applicable privacy regulations. Informed consent was not required, as the study involved secondary use of anonymized data. No compensation was applicable for the use of these data. Figures and supplementary materials in this manuscript do not contain any identifiable information regarding individual participants or users.

Study Design

This study aimed to develop and validate machine learning models for prioritizing high-severity PSEs. Figure 1 presents an overview of the study workflow, comprising two phases: (1) data extraction and partitioning and (2) model development and validation.

Figure 1. Overview of the study workflow, including data processing, model development, and validation. HSE: high-severity event; LSE: low-severity event; NME: near-miss event.

Dataset Description

This study used deidentified PSE reports collected from a large academic health system in Eastern Canada. A total of 101,239 reports were extracted from institutional IRSs between January 2017 and March 2025. Each PSE was assigned a severity label to indicate the level of harm associated with the event. The classification includes four categories: (1) high-severity event (HSE), (2) low-severity event (LSE), (3) near-miss event (NME), and (4) no safety-concern event (NSE). HSEs refer to incidents associated with substantial patient harm, including life-threatening outcomes or death. LSEs include incidents with limited or no clinically significant harm. NMEs are incidents that had the potential to cause harm but were prevented before reaching the patient. Nonsafety events refer to reports that do not represent a patient safety issue or do not involve a deviation from standard care processes. To further illustrate how event outcomes and clinical circumstances inform severity determination, Multimedia Appendix 1 provides synthetic examples of PSE reports together with the rationale for their corresponding severity classifications.

Severity labeling followed a 2-stage institutional review process. First, patient safety specialists screened PSE reports submitted through the IRS to identify those with potential for high severity. Reports identified through this initial screening were subsequently reviewed by a multidisciplinary committee of point-of-care clinicians, patient safety specialists, operational leaders, and other domain experts. Based on this review, severity labels were assigned according to established institutional classification practices. Although PSE reports describe events that have already occurred, their screening and escalation are ongoing components of the institutional patient safety workflow. Timely screening is important because the late identification of potentially high-severity cases may impede institutional investigation and appropriate follow-up actions. The proposed approaches are intended to support the initial screening stage by prioritizing incoming reports for specialist review and potential escalation. Final severity determination remains the responsibility of the multidisciplinary committee.

We composed 2 analytic datasets to support complementary but distinct evaluation objectives. Table 1 presents the distribution of PSE reports by severity category across the 2 datasets. The first dataset comprised PSE reports that underwent

XSL•FO
RenderX

multidisciplinary committee review and received severity labels. These expert-adjudicated labels provide a high-quality reference standard and were used to support robust assessment and comparison of model performance. This dataset included 2675 reports, of which 1037 (38.8%) were classified as HSE (panel A in Table 1). Throughout this study, the term PSE refers to any reported safety-related incident that could have resulted, or did result, in unnecessary harm to a patient, whereas HSE, LSE, NME, and NSE denote the severity categories used in the institutional classification system.

The second dataset included all PSE reports submitted to the IRS, encompassing both committee-reviewed reports with severity labels (ie, the entire committee-adjudicated dataset) and reports that were not escalated for committee review and therefore did not receive severity labels. Under current institutional workflows, reports that are not escalated are implicitly treated as lower-priority events and are not subject to formal severity adjudication. For analytical purposes, we assume that these unreviewed reports represent non-HSEs as operationally defined by existing triage practices. This assumption reflects institutional decision-making rather than asserting the absence of patient safety concerns. It enables operationally relevant evaluation in which the model must prioritize a small number of high-severity PSEs for investigation from a large volume of incoming reports, mirroring real-world safety triage conditions. The second dataset comprised 101,239 reports, of which 1037 (1%) were classified as HSEs, reflecting the low prevalence of high-severity cases in routine triage settings (panel B in Table 1).

Table 1. Distribution patient safety event reports by severity labels.

Severity label	Reports, n (%)
Panel A. Committee-adjudicated dataset	
HSE[a]	1037 (38.77)
LSE[b]	830 (31.03)
NME[c]	56 (2.09)

Total	2675 (100)
Panel B. Full incident reporting system dataset	
HSE	1037 (1.00)
LSE	830 (0.82)
NME	56 (0.06)
NSE[e]	99,316 (98.10)
Total	101,239 (100)

[a]HSE: high-severity event.

[b]LSE: low-severity event.

[c]NME: near-miss event.

[d]NSE: no safety-concern event

[e]NSE includes both explicitly classified NSEs and reports not escalated for committee review.

Model Development and Validation

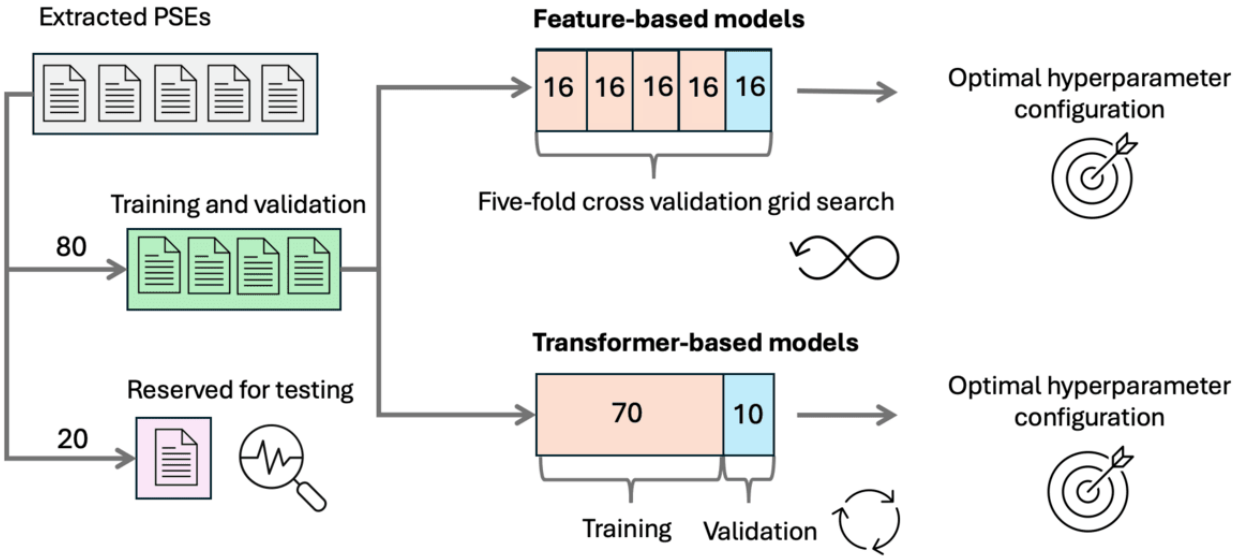
In this study, we developed machine learning models to prioritize high-severity PSEs using both ranking and classification approaches. We used the incident description section of each PSE report as input and the corresponding severity label as the outcome variable, consistent with prior work [18,26,27]. The incident description is a free-text narrative field in which the event reporter documents the circumstances and outcomes associated with the safety event.

Ranking-based models were developed using a learning-to-rank (LTR) framework, which learns to order items based on their relevance or importance and produces a ranked list [28,29]. During the training of LTR models, the assigned labels guide the model in identifying patterns that distinguish higher-priority items from lower-priority items [28,30]. Once trained, the model generates a continuous priority score for each item, which determines its position in the resulting list. LTR differs from conventional classification in both its objective and output. Classification models aim to assign each item to a predefined category [31], whereas LTR models focus on positioning the highest-priority items near the top of a ranked list. Accordingly, classification models are optimized to predict predefined categories. In this study, the classification models predicted all 4 severity categories, and the predicted probability assigned to the HSE class was used as a continuous score to order reports for ranking-based evaluation. As a sensitivity analysis, we also evaluated a binary classification formulation that directly distinguished HSE from non-HSE reports (Multimedia Appendix 2). In contrast, LTR models are trained directly to optimize the relative ordering of items based on predicted priority. Items within the same category may receive different scores, allowing finer prioritization within categories. This distinction is particularly important when it is impractical to review every

XSL•FO
RenderX

available item and attention must be directed toward the highest-priority cases.

In this study, each PSE report represented an item to be ranked, and its institutional severity label indicated its relative priority. Using the incident descriptions, the LTR models learned textual patterns associated with differences in event severity and generated a predicted priority score for each report. The reports were then ordered according to these scores, with high-severity PSEs prioritized for review.



To evaluate the ranking and classification approaches across different model architectures, we implemented both feature-based and transformer-based models. Feature-based models refer to traditional machine learning algorithms that are computationally efficient and frequently serve as baselines in NLP tasks [32,33]. Transformer-based models are deep learning architectures that have achieved state-of-the-art performance in a variety of classification and ranking benchmarks [34-36]. Their effectiveness is attributed to their ability to capture contextual dependencies in text and leverage knowledge from large-scale pretraining.

We trained 2 feature-based models: XGBoost and LightGBM [32,37], both of which are gradient-boosted decision tree algorithms known for their effectiveness in prior ranking applications [29]. To provide comparisons with conventional text classification approaches, we also developed SVM and multinomial naïve Bayes (MNB) classification baselines using bag-of-words (BAG) and term frequency inverse document frequency (TF-IDF) representations. We trained 8 transformer-based models: BERT, ROBERTA, XLM-ROBERTA, BIOBERT, BIOMEDBERT, GATORTRON, LLAMA3.1-8B, and QWEN3-8B [36,38-43]. BERT, ROBERTA, and XLM-ROBERTA were selected due to their widespread adoption and competitive performance across diverse NLP tasks [44-46]. BIOBERT, BIOMEDBERT, and GATORTRON were included for their pretraining on biomedical corpora, optimizing their performance for tasks involving clinical narratives and medical terminology [39-41]. LLAMA3.1-8B was included because it is a widely adopted open-source model that serves as an established benchmark across NLP applications [42]. Qwen3-8B was selected as a more recently developed open-source model representing advances in contemporary large language model architectures [43]. Throughout the manuscript, the suffix “RA” identifies models developed for ranking, whereas “CL” identifies models developed for classification. A complete summary of the evaluated models, abbreviations, and full model names is provided in Multimedia Appendix 3. In addition, for the feature-based models, free-text narratives were converted into structured feature representations before being used as input; these feature-extraction methods are also described in Multimedia Appendix 3.

The model development workflow is illustrated in Figure 2. The dataset was partitioned at the individual-report level, with no report appearing in more than 1 data partition. Patient-level stratification was not performed because the fully deidentified dataset provided under the research ethics board–approved secondary-use protocol did not contain patient identifiers or linkage keys. The dataset was partitioned into 80% for training and validation and 20% for testing, with no overlap between splits. For feature-based models, hyperparameter tuning was conducted using grid search with 5-fold cross-validation [47]. The training and validation data were divided into 5 mutually exclusive folds; for each hyperparameter configuration, models were trained on 4 folds and validated on the fifth, with the process repeated across all 5 folds. The optimal configuration was selected based on the average cross-validated performance, measured by average precision. For transformer-based models, the dataset was partitioned into 70% for training, 10% for validation, and 20% for testing. To ensure comparability, the same testing set used for the feature-based models was retained. Models were trained on the training set, and hyperparameter tuning was conducted on the validation set. A conventional training-validation-test split was used instead of cross-validation due to the substantial computational cost associated with training transformer-based models. A complete list of tuned hyperparameters for both model types is provided in Multimedia Appendix 4.

RenderX

Figure 2. Model development workflow for feature-based and transformer-based models. Numbers indicate the proportion of the dataset allocated to each stage of model training, validation, and testing. PSE: patient safety event.

The distribution of severity labels in the dataset was imbalanced, with some classes underrepresented. The imbalance can negatively impact the performance of classification-based models, particularly for minority classes [48]. For feature-based classifiers, we applied the Synthetic Minority Oversampling Technique (SMOTE) to generate synthetic samples for the underrepresented classes in the training set, thereby addressing class imbalance [49]. SMOTE was applied only to the training set to preserve the original class distribution in the test set and avoid bias in model evaluation. For transformer-based classifiers, we implemented a loss reweighting strategy by assigning higher weights to minority classes in the loss function [48]. This approach penalizes misclassifications of underrepresented classes more heavily, promoting more balanced performance across classes. Within the full IRS dataset, the distribution of severity labels is characterized by extreme class imbalance. To mitigate this imbalance during classifier training, we additionally explored random downsampling of the majority class (ie, NSE). All non-NSE severity reports were retained, while the number of NSEs was varied across a predefined range to construct training sets with differing class imbalance ratios. The downsampling ratio was treated as a hyperparameter and selected based on validation performance. Downsampling was applied exclusively to the training data, and all validation and testing were conducted on datasets reflecting the original class distribution to preserve operationally relevant prevalence. Detailed parameters for SMOTE, random downsampling, and class-weighted loss, together with the numbers of synthetic samples generated and NSE reports removed, and the final model-specific sampling ratios and class weights, are provided in Multimedia Appendix 5. On the other hand, ranking-based models focus on learning the relative ordering of items rather than predicting discrete labels. These models are optimized based on comparisons between items, making them inherently less sensitive to class imbalance [50].

Model Evaluation and Comparison

Model performance was evaluated using established ranking metrics, including average precision, normalized discounted cumulative gain (NDCG) at multiple cutoff thresholds (k=10, 20, 50, 100, 200), as well as precision and recall computed at the same cutoffs. Average precision quantifies the model's ability to rank high-severity PSEs near the top of the list and is calculated as the mean of precision values at each position where a high-severity PSE is retrieved. NDCG measures the quality of a ranked list by accounting for both the severity of the PSEs and their rank positions, offering a comprehensive evaluation of ranking effectiveness [29]. Precision@k denotes the proportion of high-severity PSEs ranked in the top k positions, while recall@k captures the proportion of all high-severity PSEs that appear within the top k. High-severity PSEs were defined as those assigned a severity label of HSE, which necessitates prioritization for institutional investigation. All evaluation metrics range from 0 to 1, with higher values indicating better ranking performance. The mathematical definitions of all evaluation metrics are provided in Multimedia Appendix 6.

During testing, the models were evaluated based on their ability to rank PSE reports according to severity. Specifically, each model generated an ordered list in which reports with higher predicted severity were placed closer to the top, and those with lower predicted severity were placed further down the list. The original HSE, LSE, NME, and NSE labels were retained throughout model testing. We used 2 complementary sets of evaluation metrics. Average precision, Precision@k, and Recall@k used binary relevance to evaluate the study's primary objective of prioritizing HSE reports for institutional investigation. For these metrics only, HSE reports were considered relevant, whereas LSE, NME, and NSE reports were considered nonrelevant. In contrast, NDCG used graded relevance, with HSE, LSE, NME, and NSE assigned decreasing levels of priority, to evaluate the relative ordering of reports across the complete severity spectrum. Together, these metrics

XSL•FO
RenderX

evaluated both HSE prioritization and the preservation of the broader ordering of event severity.

For classification models, PSEs were ranked by their predicted probabilities of receiving a severity label of HSE and evaluated performance using ranking metrics. This approach more effectively captures the model's ability to prioritize high-severity PSEs than conventional classification metrics. For example, patient safety teams may triage the top 50-100 PSEs that are relatively more severe than others. In such contexts, ranking-based evaluation directly assesses the model's ability to order events by clinical urgency, thereby aligning more closely with clinical workflows.

We evaluated all trained models on the internal testing set, which comprised 20% of the total PSEs. The 95% CI was computed using bootstrapping with 2000 random subsamples, drawn with replacement and matched to the testing set's original size, to quantify uncertainty in model performance. We compared the performance of the best-performing ranking and classification models using paired *t* tests. In addition, the top-performing model was compared with the reporter-assigned severity baseline. This baseline was derived from the preliminary severity ratings selected by frontline health care workers when submitting reports to the IRS. These ratings reflect reporters' initial perceptions and are distinct from the gold-standard severity labels subsequently assigned through multidisciplinary committee adjudication. Baseline performance was evaluated by ranking reports according to reporter-assigned severity and comparing the resulting rankings against the reference severity labels using the same ranking metrics applied to the developed models. To obtain a more robust estimate of baseline performance, the baseline rankings were bootstrapped using the same resampling procedure as the model evaluations. Multiple-comparison adjustment was performed using a Bonferroni correction, setting the significance threshold at $P<.001$ (0.05/64) to maintain a family-wise error rate of 0.05 across 64 tests (16 metrics × 4 comparisons).

Results

Performance Comparison of Classification and Ranking Models

Among all ranking models, LLAMA3.1-RA achieved the highest performance based on average precision, while LLAMA3.1-CL demonstrated the best performance among the classification models. Table 2 summarizes the comparative results between these 2 top-performing models, while Figure 3 visualizes their NDCG@k, Precision@k, and Recall@k across the evaluated cutoff values. Average precision was selected as the primary criterion for model selection, as it provides a comprehensive measure of each model's overall ranking capability by jointly accounting for the accuracy and ordering of high-severity PSEs across the ranked list. Detailed performance metrics for all developed models are presented in Multimedia Appendix 7. To provide additional benchmarks against conventional text-classification approaches, SVM and MNB classifiers using BAG and TF-IDF representations were also evaluated, with detailed results presented in Multimedia Appendix 8. Among these traditional baselines, SVM-BAG achieved the highest average precision in the committee-adjudicated dataset (mean 0.62, 95% CI 0.55-0.69), while MNB–TF-IDF achieved the highest average precision in the full IRS dataset (mean 0.49, 95% CI 0.44-0.54). In both evaluation settings, the best-performing traditional baseline achieved lower average precision than LLAMA3.1-CL and LLAMA3.1-RA.

As shown in Table 2 and Figure 3, LLAMA3.1-RA achieved equal or higher mean performance than LLAMA3.1-CL across all 16 evaluation metrics in panel A (committee-adjudicated dataset). LLAMA3.1-RA demonstrated a significantly higher average precision (mean 0.94, 95% CI 0.90-0.98) than LLAMA3.1-CL (mean 0.77, 95% CI 0.72-0.82; $P<.001$), corresponding to a 22.1% relative improvement. Both models achieved perfect performance at the most restrictive cutoffs (NDCG@10-20=1.00; Precision@10-20=1.00), with identical Recall@10 (0.05) and Recall@20 (0.10), indicating comparable ability to identify the most severe events within the top-ranked positions. Performance differences became more pronounced at broader cutoffs. At k=100, LLAMA3.1-RA improved NDCG by 4.3%, precision by 9.1%, and recall by 9.3%. At k=200, relative improvements increased to 12.9% for NDCG, 21.1% for precision, and 20.3% for recall (all $P<.001$). Overall, LLAMA3.1-RA demonstrated statistically significant advantages in 10 of the 16 evaluated metrics, with the largest gains observed at higher cutoffs, reflecting more consistent prioritization of high-severity PSEs across the ranked list. In Panel B (full IRS dataset), the superiority of the ranking model remained consistent despite the substantially lower prevalence of high-severity PSEs. LLAMA3.1-RA achieved a 27.1% relative improvement in average precision (mean 0.89, 95% CI 0.84-0.94 vs mean 0.70, 95% CI 0.64-0.76; $P<.001$). Similar to panel A, substantial gains were observed at broader cutoffs, particularly at k=200, where relative improvements reached 15.9% for NDCG, 24.6% for precision, and 22.2% for recall (all $P<.001$). An aggregate error and model-disagreement analysis was also conducted at the top-200 cutoff to examine HSE reports retrieved by both models, by either model alone, or by neither model, together with the severity-category distribution of the non-HSE reports included within each model's top 200 positions; complete results are provided in Multimedia Appendix 9. Additional ablation analyses examining the effects of training-set size and learning objective on LLAMA3.1 performance are presented in Multimedia Appendix 10. To assess temporal robustness, we additionally evaluated LLAMA3.1-RA using chronological data partitioning, with the earliest 70% of reports used for training, the subsequent 10% for validation, and the most recent 20% for testing. The model maintained strong performance under temporal validation, achieving an average precision of 0.92 and NDCG@200, Precision@200, and Recall@200 values of 0.94, 0.84, and 0.81, respectively. These results indicate that LLAMA3.1-RA maintained broadly stable prioritization performance when trained on earlier reports and evaluated on more recent reports. Complete methods and results are provided in Multimedia Appendix 11.

Figure 3. Performance comparison of the best-performing classification model (LLAMA3.1-CL) and ranking model (LLAMA3.1-RA) across cutoff values (k=10, 20, 50, 100, 200). (A-C) NDCG@k, Precision@k, and Recall@k for the committee-adjudicated dataset. (D-F) The corresponding metrics for the full incident reporting system dataset.

Comparison With the Reporter-Assigned Severity Baseline

Table 3 presents the performance comparison between the best-performing ranking model (LLAMA3.1-RA) and the reporter-assigned severity baseline across both evaluation settings, while Figure 4 visualizes their NDCG@k, Precision@k, and Recall@k across the evaluated cutoff values. In panel A (committee-adjudicated dataset), LLAMA3.1-RA consistently achieved significantly higher mean performance than the baseline across all 16 evaluation metrics (all P<.001). Average precision was substantially higher for LLAMA3.1-RA (mean 0.94, 95% CI 0.90-0.98) compared with the baseline (mean 0.45, 95% CI 0.38-0.52), corresponding to a 108.9% relative improvement. Performance gains were evident even at the most restrictive cutoffs. For example, NDCG@10 and NDCG@20 improved by 31.6% and 37.0%, respectively, while Precision@10 and Precision@20 improved by 49.3% and 66.7%. At k=100, LLAMA3.1-RA demonstrated relative improvements of 58.1% in NDCG, 118.2% in Precision, and 123.8% in Recall. At k=200, improvements remained substantial, reaching 57.4% in NDCG, 104.8% in Precision, and 102.4% in Recall. Notably, the ranking model retrieved 83% of high-severity PSEs within the top 200 positions, compared with 41% under the reporter-assigned severity baseline.

In panel B (full IRS dataset), which reflects real-world class imbalance and operationally representative conditions, the superiority of LLAMA3.1-RA was even more pronounced. Average precision improved from 0.27 (95% CI 0.23-0.31) under the baseline to 0.89 (95% CI 0.84-0.94) with LLAMA3.1-RA, corresponding to a 229.6% relative improvement. Substantial gains were observed across all evaluation cutoffs. At k=100, relative improvements reached 172.2% for NDCG, 239.3% for precision, and 253.8% for recall. At k=200, LLAMA3.1-RA achieved improvements of 187.9% in NDCG, 237.5% in precision, and 266.7% in recall. These results indicate that, under operationally representative conditions with a low prevalence of HSEs, reliance on reporter-assigned severity alone performs markedly worse than the ranking-based approach, whereas LLAMA3.1-RA maintains robust prioritization performance.

Discussion

Overview

Adverse events remain a major threat to patient safety and impose substantial burdens on health care systems worldwide [6]. Although many countries have established mandatory reporting legislation [7-9], only a small proportion of PSEs undergo a comprehensive investigation due to the resource-intensive nature of the review process. Patient safety specialists are therefore responsible for manually triaging reported events to identify high-severity cases that warrant institutional investigation [18,23,24]. However, the rapidly increasing volume of reports, while reflecting ongoing efforts to strengthen reporting and safety culture, has rendered manual triage increasingly challenging [25]. Previous studies have applied NLP techniques to facilitate this process; nevertheless, most have relied on classification-based approaches [18,26,27,51], which may not fully align with the operational needs of patient safety specialists who must efficiently prioritize the most critical events requiring investigation. In contrast, ranking-based approaches learn the relative ordering of safety events by severity, making them particularly well-suited for this prioritization task. By directly optimizing the prioritization step within existing triage workflows, ranking-based models offer a practical and workflow-aligned advancement. To the best of our knowledge, this study is the first to develop and validate ranking-based models for prioritizing high-severity PSEs.

Principal Results

The best-performing ranking model (LLAMA3.1-RA) demonstrated a significant advantage over both classification models and the reporter-assigned severity baseline in prioritizing high-severity PSEs. Compared with the best-performing classification model (LLAMA3.1-CL), LLAMA3.1-RA achieved a 22.1% relative improvement in average precision and significantly outperformed it in 10 of 16 evaluation metrics. Although both models achieved perfect NDCG and precision at the top 10 and top 20 ranked positions, LLAMA3.1-RA showed progressively greater gains at broader cutoffs, with relative improvements of 12.9% in NDCG@200, 21.1% in Precision@200, and 20.3% in Recall@200. These findings indicate that while both models effectively identified the most severe cases, the ranking-based approach maintained superior prioritization as the evaluation range expanded. Importantly, similar patterns were observed in the full IRS dataset (panel B), which reflects real-world class imbalance and operationally representative conditions. Despite the substantially lower prevalence of high-severity PSEs, LLAMA3.1-RA consistently outperformed the classification model across evaluation cutoffs. This consistency across both expert-adjudicated and operationally-representative datasets supports the robustness of the ranking-based approach and underscores its potential applicability within this study setting. Consequently, ranking-based approaches may provide a scalable solution for supporting triage workflows, particularly given the increasing volume of PSE reports in modern health care systems [52-54].

Compared with the reporter-assigned severity baseline, the LLAMA3.1-RA model demonstrated significantly superior capability in prioritizing high-severity PSEs across all 16

XSL•FO
RenderX

evaluation metrics. At the 200-event evaluation cutoff, LLAMA3.1-RA retrieved 83.0% of all high-severity PSEs, whereas the reporter-assigned severity baseline identified only 41.0%, corresponding to a 102.4% relative improvement. This substantial gain highlights the model's ability to consistently detect critical events that may otherwise not be prioritized for timely review. The comparatively lower performance of the baseline likely reflects the inherent limitations of the reporter-assigned severity baseline, which is based on reporters' subjective severity ratings that tend to be inconsistent due to variations in professional role, clinical experience, and familiarity with severity taxonomies [21,55]. Integrating ranking-based models such as LLAMA3.1-RA into institutional triage workflows may therefore enhance the efficiency and accuracy of prioritizing high-severity PSEs, enabling more timely identification and mitigation of such events, facilitating earlier escalation to leadership for timely organizational response, and ultimately strengthening patient safety outcomes.

In this study, the primary objective was to prioritize HSE reports for comprehensive institutional investigation within settings where review capacity is limited. This objective reflects the importance of directing available investigative resources toward events involving substantial patient harm. Alternative formulations may capture different aspects of the patient safety review process. For example, combining HSE and LSE could support the identification of events that reached the patient, while distinguishing escalated from nonescalated reports would model historical escalation decisions under existing institutional workflows. In comparison, the present formulation trains the models using committee-adjudicated severity labels to learn patterns associated with final assessed severity and prioritize incoming reports accordingly. The proposed models are intended to support report prioritization and potential escalation rather than automatically assign final severity labels. Future studies could compare these complementary formulations across different institutional review settings.

Although numerous studies have investigated the application of machine learning models to assist in the severity triage of safety events, few have proposed concrete designs or demonstrated how such technologies can be effectively embedded within clinical workflows [18,26,27,51]. Severity triage is an inherently high-stakes process, as decisions directly influence institutional response and allocation of resources for organizational improvements. Within this context, machine learning models should function as decision-support tools rather than autonomous decision-makers, and final judgment must remain a human decision to ensure ethical appropriateness [56-58]. In this study, the proposed ranking models are intended to support specialists by ordering incoming reports according to predicted severity, thereby facilitating the prioritization of reports for further review within available investigative capacity.

HSE prioritization was selected because HSEs represent the reports of greatest concern for comprehensive institutional investigation, particularly when review capacity is limited. Combining HSE and LSE would treat events involving substantial harm and those involving limited or no clinically significant harm as equally relevant. Moreover, escalation decisions are made during preliminary screening and may not reflect the final severity determined through multidisciplinary committee adjudication. The proposed models are therefore intended to assist the escalation process by ranking incoming reports according to predicted severity, while final escalation and severity determinations remain the responsibility of patient safety specialists and the multidisciplinary committee.

Although the proposed approach demonstrated consistent performance across the 2 evaluation settings, both datasets originated from the same health system. The learned ranking may therefore reflect institution-specific characteristics, including local reporting practices, incident descriptions, severity-assessment procedures, and triage workflows. Differences in these characteristics may influence model performance when applied in other settings. Accordingly, independent external validation is needed to determine the extent to which the proposed approach generalizes beyond the institutional context in which it was developed.

A related consideration in interpreting performance on the full IRS dataset is the operational treatment of reports that were not escalated for committee review. These reports were treated as NSEs because they had been considered lower priority within the existing institutional review workflow. This operational definition enabled evaluation under the class distribution encountered in routine practice; however, nonescalation does not independently confirm the absence of an HSE. Some genuinely severe events may not have been escalated because of incomplete information at submission, differences in reviewers' experience or judgment, inconsistent application of escalation criteria, or human error during initial screening. Accordingly, the full IRS dataset may contain label noise if some nonescalated reports would have been classified as HSEs had they undergone multidisciplinary committee review.

The use of operational escalation status also means that historical triage decisions are incorporated into the supervision and evaluation signals. As a result, the models may learn not only textual patterns associated with adjudicated severity but also patterns reflecting existing institutional reporting and escalation practices. Performance on the full IRS dataset may therefore partly represent the model's ability to reproduce or align with those practices rather than its ability to identify true event severity independently. This distinction is especially important because historical decisions may reflect institution-specific workflows, reporting cultures, resource constraints, and variation in how reports were documented and reviewed. Consequently, results from the full IRS dataset should be interpreted as evidence of performance under the study institution's operational labeling framework, whereas the committee-adjudicated dataset provides the more direct assessment against expert-reviewed severity labels. Future studies could independently review a sample of nonescalated reports to estimate potential misclassification and evaluate whether model-assisted prioritization identifies severe events that were not captured through the historical escalation process.

Limitations

This study has several limitations. First, it was conducted using data from a single academic health system in Canada, which may limit the generalizability of the findings to other

XSL•FO
RenderX

institutional or geographical contexts. Future multicenter studies involving more diverse patient populations and reporting systems are warranted to enhance external validity. Second, the proposed model was evaluated retrospectively, and its prospective performance in real-world clinical settings remains to be determined. Future research should examine the model's implementation feasibility and its influence on triage outcomes in operational environments. Third, the study dataset covered an extended period during which medical technologies, organizational structures, and incident-reporting practices may have evolved. Because the extracted data did not include detailed information regarding the timing or nature of specific technological, organizational, or reporting-system changes, we could not directly determine whether or how these developments influenced report content or writing style. As a related assessment of temporal stability, temporal validation demonstrated that LLAMA3.1-RA maintained broadly stable performance when trained on earlier reports and evaluated on more recent reports. However, this analysis does not directly establish whether the nature or writing of the reports changed over time. Future studies should directly examine changes in report characteristics and documentation practices across successive collection periods. Fourth, this study relied exclusively on IRS data and did not incorporate information from other relevant sources such as electronic medical records, maintenance and facility reports, or audit data, which patient safety specialists often use to validate and contextualize reported events. Future research could examine how similar prioritization approaches might integrate these data sources to complement the proposed AI-assisted triage workflow. Future research could also explore the application of ranking models directly to EMR systems, which may enable earlier identification of high-risk events and reduce reliance on downstream incident reporting workflows. In addition, future studies could analyze system-level and longitudinal trends in safety events to enable further automation and provide deeper insight into the underlying contributors to adverse events. Fifth, this study did not examine patient preferences or perspectives on the use of artificial intelligence to support incident severity prioritization. Future research should explicitly address these dimensions, particularly in relation to ethical, governance, and patient-centered considerations. Finally, although this study evaluated 2 open-source general-purpose large language models within a secure computing environment, it did not assess proprietary API-based models such as ChatGPT because the patient safety data could not be transmitted to external services. Future studies conducted within secure, institutionally governed environments could examine these additional models.

Conclusion

This study developed and validated ranking-based machine learning models to prioritize high-severity PSEs. The proposed LLAMA3.1-RA model outperformed both classification-based models and the reporter-assigned severity baseline, demonstrating superior capability in prioritizing critical events requiring institutional investigation. The proposed ranking approach may support patient safety specialists in prioritizing incoming reports for further review, although prospective evaluation is required to determine its effectiveness within operational triage workflows. Collectively, this model-assisted triage framework offers a scalable and efficient solution for prioritizing high-severity PSEs, with the potential to enhance decision-making accuracy, workflow efficiency, and ultimately strengthen patient safety outcomes.

Abstract

Background: This Is My Story (TIMS) was started by Chaplain Elizabeth Tracey to promote a humanistic approach to medicine. Patients in the TIMS program are the subject of a guided conversation in which a chaplain interviews either the patient or their loved one. They are asked four questions to elicit clinically actionable information that has been shown to improve communication between patients and medical providers, strengthening medical providers’ empathy. The original recorded conversation is edited into a condensed audio file approximately 1 minute and 15 seconds in length and placed in the electronic health record where it is easily accessible by all providers caring for the patient.

Objective: TIMS is active at the Johns Hopkins Hospital and has shown value in assisting with provider empathy and communication. It is unique in using audio recordings to accomplish this purpose. As the program expands, there exists a barrier to adoption due to limited time and resources needed to manually edit audio conversations. To address this, we propose an automated solution using a large language model to create meaningful and concise audio summaries.

Methods: We analyzed 24 TIMS audio interviews and created three edited versions of each: (1) expert-edited, (2) artificial intelligence (AI)–edited using a fully automated large language model pipeline, and (3) novice-edited by two medical students trained by the expert. A second expert, blinded to the editor, rated the audio interviews in a randomized order. This expert scored both the audio quality and content quality of each interview on 5-point Likert scales. We quantified transcript similarity to the expert-edited reference using lexical and semantic similarity metrics and identified omitted content relative to that same expert interview.

Results: Audio quality (flow, pacing, clarity) and content quality (coherence, relevance, nuance) were each rated on 5-point Likert scales. Expert-edited interviews received the highest mean ratings for both audio quality (4.84) and content quality (4.83). Novice-edited scored moderately (3.84 audio, 3.63 content), while AI-edited scored slightly lower (3.49 audio, 3.20 content). Novice and AI edits were rated significantly lower than the expert edits (P<.001), but not significantly different from each other. AI and novice-edited interview transcripts had comparable overlap with the expert reference transcript, while qualitative review found frequent omissions of patient identity, actionable insights, and overall context in both the AI and novice-edited interviews. AI editing was fully automated and significantly reduced the editing time compared to both human editors.

Conclusions: An AI-based editing pipeline can generate TIMS audio summaries with comparable content and audio quality to novice human editors with one hour of training. AI significantly reduces editing time and removes the need for manual training; with further validation, it could offer a solution to scale TIMS to a large range of health care settings.

Introduction

Recent statistics show that health worker burnout is a widespread issue [1]. A 2022 Centers for Disease Control and Prevention report found that 46% of health workers "often" or "very often" felt burned out, increasing from 32% in 2018. Physicians in the United States also report similarly high burnout rates (56% in 2021, 53% in 2022, and 48% in 2023), with an all-time high physician burnout rate of 63% during the pandemic [2,3]. Some reasons for this burnout include excessive work hours, administrative burdens (such as electronic health record documentation), insufficient support staff, and limited organizational and leadership support [4-8]. These chronic stresses impact both patients and clinicians. For example, Andhavarapu et al [9] mentioned that symptoms of depression, anxiety, and posttraumatic stress disorder were reported in 34% of the health care workers surveyed (while 14% reported severe posttraumatic stress disorder), with the highest prevalence among nursing staff (42.8%) and physicians (25.2%). Similarly, the National Academies' 2019 report found that between 35% and 54% of US nurses and physicians and 45% to 60% of medical students and residents experience substantial burnout symptoms throughout their careers [10].

Empathy can serve as a solution, reducing widespread symptoms of burnout while promoting professional fulfillment and strengthening connection with patients [11-14]. Already, health care organizations have recognized the value of empathy and designed personal and patient-centered interventions within their clinical workflows [15]. For example, the This Is My Story (TIMS) program was developed by Chaplain Elizabeth Tracey at the Johns Hopkins Hospital to bring a more patient-centered and empathetic approach to medicine [16]. Patients who participate in the TIMS program take part in a conversation with a chaplain; if the patient is noncommunicative, a chaplain has a conversation with the patient's loved ones. These conversations are guided by four questions: How do you prefer to be addressed? What brings you joy? What does your medical team need to know to care for you best? What brings you peace?

In the words of Dr Charles Cumming, Director Emeritus of Otolaryngology at Johns Hopkins, *"TIMS is about helping us get back to the proper essence of medicine...it's essential to get to know the patient if we're going to be able to help that patient as best we can"* [17]. TIMS conversations have demonstrated clear benefits for clinical communication and empathy, providing an opportunity for meaningful connection with patients to directly target the emotional aspects of burnout [16,18-20]. Past studies by Tracey et al [21] support the positive outcomes the program has had on patients, their families, and the care team. For example, one previous study reported a 74% increase in staff empathy for patients and a 99% improvement in interactions by patients' loved ones with the medical team. Although it has also been shown to be useful in improving staff empathy and reducing distress by 69%, the process of recording and editing conversations can be labor-intensive [21]. By automating the conversation summarization process, these benefits can be made accessible to a wider range of patients and medical institutions.

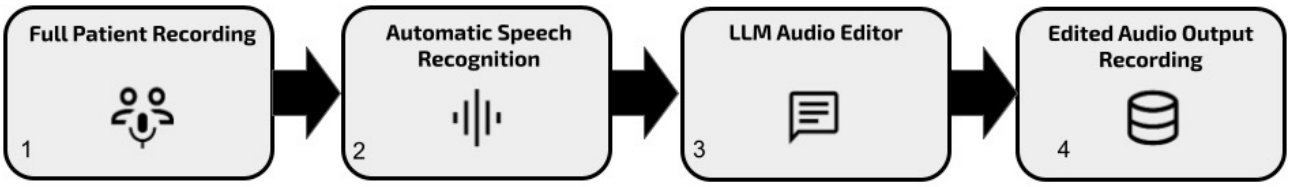
In this study, we propose an automated editing pipeline for TIMS interviews using a large language model (LLM) and evaluate whether artificial intelligence (AI)–edited interviews are a viable alternative to manual editing. Because medical students were frequently trained to edit TIMS interviews during the pandemic, they are a reasonable baseline for comparing performance. We designed our analysis around two key hypotheses: (1) that AI-edited interviews maintain similar quality to expert-edited interviews in both audio and content metrics, and (2) that AI-edited interviews can be produced more quickly than interviews produced by expert or novice editors.

Methods

Study Design

We used a within‐subjects, single‐group design in which our reviewer evaluated interviews across three independent editing conditions (expert, AI, novice). Editors were eligible if they had professional experience interpreting patient–clinician audio interviews. Two chaplains from the Johns Hopkins Hospital took part in the study. The novice editors were two medical students who joined the study team from the Johns Hopkins School of Medicine, each having completed an hour-long training session on audio‐editing with an expert editor (Chaplain Elizabeth Tracey). The two novice editors edited 12 randomly assigned audio interviews, mirroring the normal workflow for the TIMS initiative without the AI tool.

Patient Audio Dataset



We used a retrospective dataset of audio recordings from 24 patients admitted to the Johns Hopkins Neurosciences Critical Care Unit, a tertiary intensive care unit for patients with diseases of the central or peripheral nervous systems, admitted from departments such as neurosurgery, neurology, and others.

AI Editing Pipeline

Audio recordings were first transcribed using Nvidia's Parakeet-TDT 0.6B v2 automatic speech recognition (ASR) model (Figure 1) [22-24]. ChatGPT-4o [25] processed the transcript using a custom prompt. This prompt asked the model to extract only patient statements that provided essential information about their condition, experiences, feelings, or personal identity. It was also directed to exclude any filler or repetitive content and keep humorous or insightful remarks to preserve patient identity and humanity.

XSL•FO
RenderX

Figure 1. Overview of artificial intelligence–automated workflow for summarizing This Is My Story audio interviews. LLM: large language model.

The model was instructed to include the interviewer's four core questions for the TIMS program while excluding interjections or examples provided by the interviewer. Instructions were given to return a processed transcript that the model estimated would take 1.5 minutes during a TIMS interview. The full model prompt is available in Multimedia Appendix 1. The relevant timestamps identified were then used to splice together the final audio file. Examples of cases in which ASR output might have impacted the LLM output are presented in Table S2 in Multimedia Appendix 2. This process was entirely automated and was run on an NVIDIA GeForce RTX 4090 with 24 GB of RAM.

Survey Design

To evaluate both audio quality and content quality for each edited TIMS interview, we created an online questionnaire for our reviewer to complete using a 5-point Likert scale (1=poor, 5=excellent) for each question. The survey included questions grouped into audio (natural flow, pausing/spacing, transitions, pacing, overall listenability of the interview) and content (conversation flow, speaker/topic tracking, patient representation, understanding of patient characteristics, preparation for interaction for patient providers/care team, nuance of the patient's life, relevance of details) quality domains with all details shown in Textbox 1 below. This same survey was used independently for each edited interview for consistent comparison.

Textbox 1. Summary of domain and survey questions following survey administration and data collection.

Audio quality

1. How natural is the conversation flow?
2. How effective are the pauses and spaces between answers?
3. How smooth are the transitions between questions and answers?
4. How does the pacing of the audio feel overall?
5. Overall, how easy is the interview to listen to?
6. Can you understand the flow of the conversation?

Content quality

7. Can you keep track of the speaker and the topic?
8. Is the patient well represented in this conversation?
9. Do you understand the patient's likes/dislikes (proclivities, idiosyncrasies, etc)?
10. Do you feel prepared to interact with the patient in a meaningful way?
11. How well does the conversation capture the depth and nuance of the patient's experience?
12. Does the conversation convey the patient's emotions effectively?
13. How relevant are the details shared during the conversation for understanding the patient's story?
14. How engaging is the conversation in terms of sustaining your interest in the patient's story?

The survey was created and administered using Google Forms. Content experts (ET, JW, CG) provided qualitative feedback on an initial draft of the questions. This feedback focused on improving the clarity and relevance of each item. The questions were then refined based on this input to better capture the intended domains of audio and content quality. It is important to note that because the survey instrument is novel, its reliability and validity have not yet been formally established. The survey asked questions 1, 5, 10, and 11 to gauge general sentiment for the conversation being rated, and more pointed questions to understand where the audios may differ in terms of score (Textbox 1). Since assessing the flow of conversation relies on both audio and content quality, a question about it was used for both parts of the survey. The individual survey responses are available in Figure S1 in Multimedia Appendix 3.

Before rating each edited version, the reviewer listened to the corresponding raw interview as a baseline reference to better understand the context of the interview. Before rating each interview, the reviewer was asked to first listen to two calibration audios—one edited poorly that should score low across all questions, and an expert-edited interview that would score highly. This allowed us to set audio quality expectations for each extreme on the survey. The survey was completed independently for each condition, with the order of the audio

XSL•FO
RenderX

files randomized by condition for each patient to reduce potential order effects.

Editing durations were recorded automatically for the AI pipeline and self‐reported by each novice editor. Expert editing times were not collected due to the limitations of the retrospective dataset.

Content Analysis

For each edited interview, we generated text transcriptions to study the differences in content among the three types of edited interviews. Text transcriptions were created using the Parakeet transcription model. The novice- and AI-edited interviews were compared to the expert edits, and three members of the study team analyzed differences. Types of errors were identified for both AI- and novice-edited conditions across all samples. The most common types of errors were then formalized and described in the results (Table 1). Content similarity between each condition and expert edits was quantitatively measured using ROUGE-L, ROUGE-1, ROUGE-2, bidirectional encoder representations from transformers (BERT), and METEOR on interview transcripts following studies of medical document summarization [26,27]. All metrics measure the similarity of words between summaries and assign a score from 0 to 1, with the ROUGE scores measuring lexical overlap and other scores [28]. METEOR and the BERT scores were used to assess the semantic overlap. Both factor in semantic similarity between words rather than the exact word choice. METEOR also assigns a penalty for differences in phrasing.

Table . Common omissions and inaccurate portrayals by artificial intelligence and novice editors.

Type of error	Artificial intelligence errors	Novice errors
Omission of actionable patient insights	Failure to include specific interests or hobbies of the patient [talking about favorite musical artists bringing her joy]: “She likes Anita Baker, Regina Belle, and Gladys Knight.”	Failure to include information about the patient’s comfort [informing about her medical condition to better care for the patient]: “She has had eczema since she was about three or four, so her skin has to stay moisturized.”
Omission of patient identity and empathy	Failure to include details relevant to understanding the patient’s background [explaining his occupation and hobbies] : “On the church side, he loves to teach. He is a pastor.”	Failure to mention important characteristics about the patient [claiming that her time at Hopkins has made her more independent and resilient]: “She [patient] worked at Johns Hopkins for over 30 years.”
Omission of emotional background	Failure to include framing details relevant for a patient’s background [talking about what brings the patient joy]: “Me [patient’s husband] … We’ve been married 20 years.”	Failure to include details relevant for a patient’s emotional state and anxiety [explaining how he mainly only trusts his partner for everything]: “[He has] a little bit of a trust issue with the medical field.”
Poor narrative fluency	Prompting questions fail to be edited out of the interview: “Introduce yourself and tell me how you’re related to the patient.”	Filler words before prompting questions fail to be edited out of the interview: “That’s great! So, what brings the patient peace?”

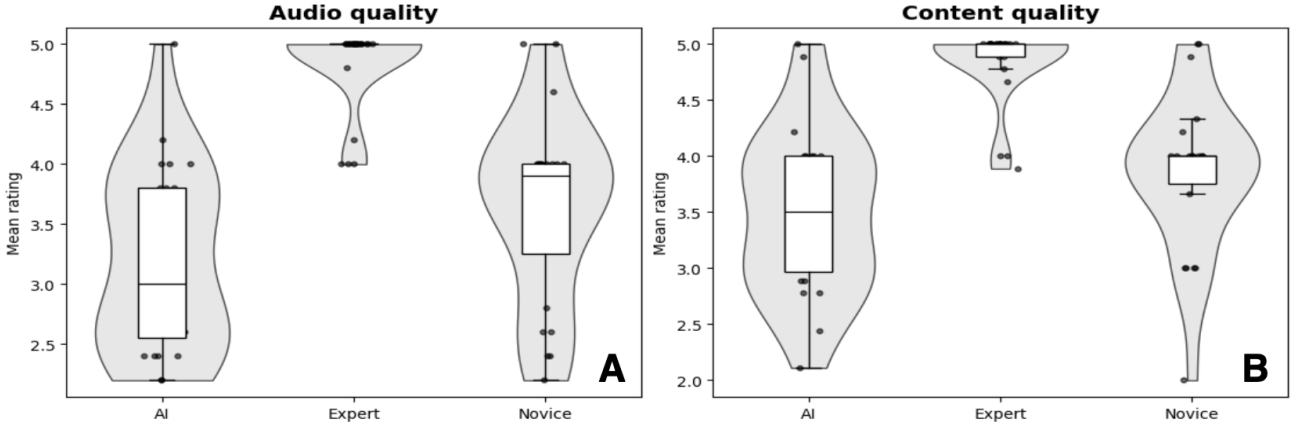
Relationships between audio length and content quality were also explored through simple linear regression of each ROUGE metric on the duration of the original interview (in minutes).

Statistical Analysis

We conducted a Friedman test to compare audio‐quality and content‐quality ratings across conditions, with Bonferroni‐corrected Wilcoxon signed-rank post hoc tests to adjust for multiple comparisons. Editing times were analyzed with an independent‐samples *t* test to test significant differences between the two novice editors. We also examined the relationship between the raw interview length and lexical and semantic score overlap for each editor type using Pearson correlation, testing if each slope differed from zero. We then performed an analysis of covariance with transcript length, editor type, and their interaction term to determine if the slope of the length-overlap relationship differed between AI and novice editors.

Ethical Considerations

Ethical approval was not required for this study as it involved a secondary analysis of anonymized data. The original data collection was conducted under Johns Hopkins institutional review board review and approval of the studies with informed consent obtained from all subjects; the consent allowed for future data use and any participants who declined this future use were not included in this secondary analysis. This study was conducted in accordance with all local, institutional, national, and international regulations on human subject research.



Results

Quantitative Comparison of Editing Quality

Across the three types of editors, the mean audio quality ratings were 3.49 (AI-edited), 3.84 (novice-edited), and 4.84 (expert-edited). Similarly, the mean content quality ratings were 3.20 (AI-edited), 3.63 (novice-edited), and 4.83 (expert-edited). The AI-edited interviews demonstrated a higher variability in the rated content quality compared to the novice-edited interviews (SD 0.73 and SD 0.68, respectively). Both interview types were similarly varied in their audio quality ratings (SD 0.77 and 0.78, respectively). Figure 2 highlights the distributions of content and audio quality ratings across each type of edited interview.

XSL•FO
RenderX

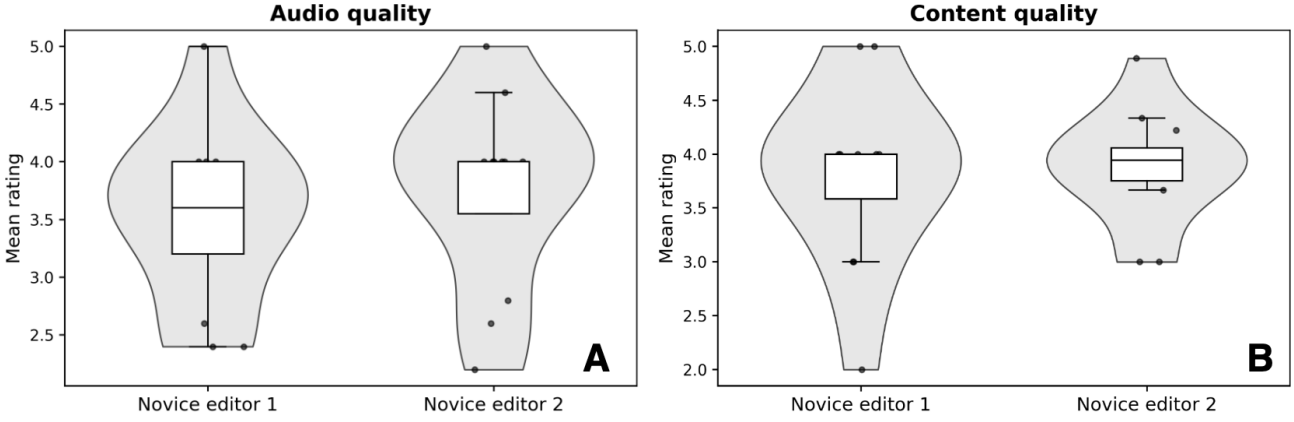


Figure 2. (**A**) A comparison of mean audio quality ratings across the three types of editors aggregated across all 24 audio interviews. (**B**) All editors follow similar trends for the content quality ratings. AI: artificial intelligence.

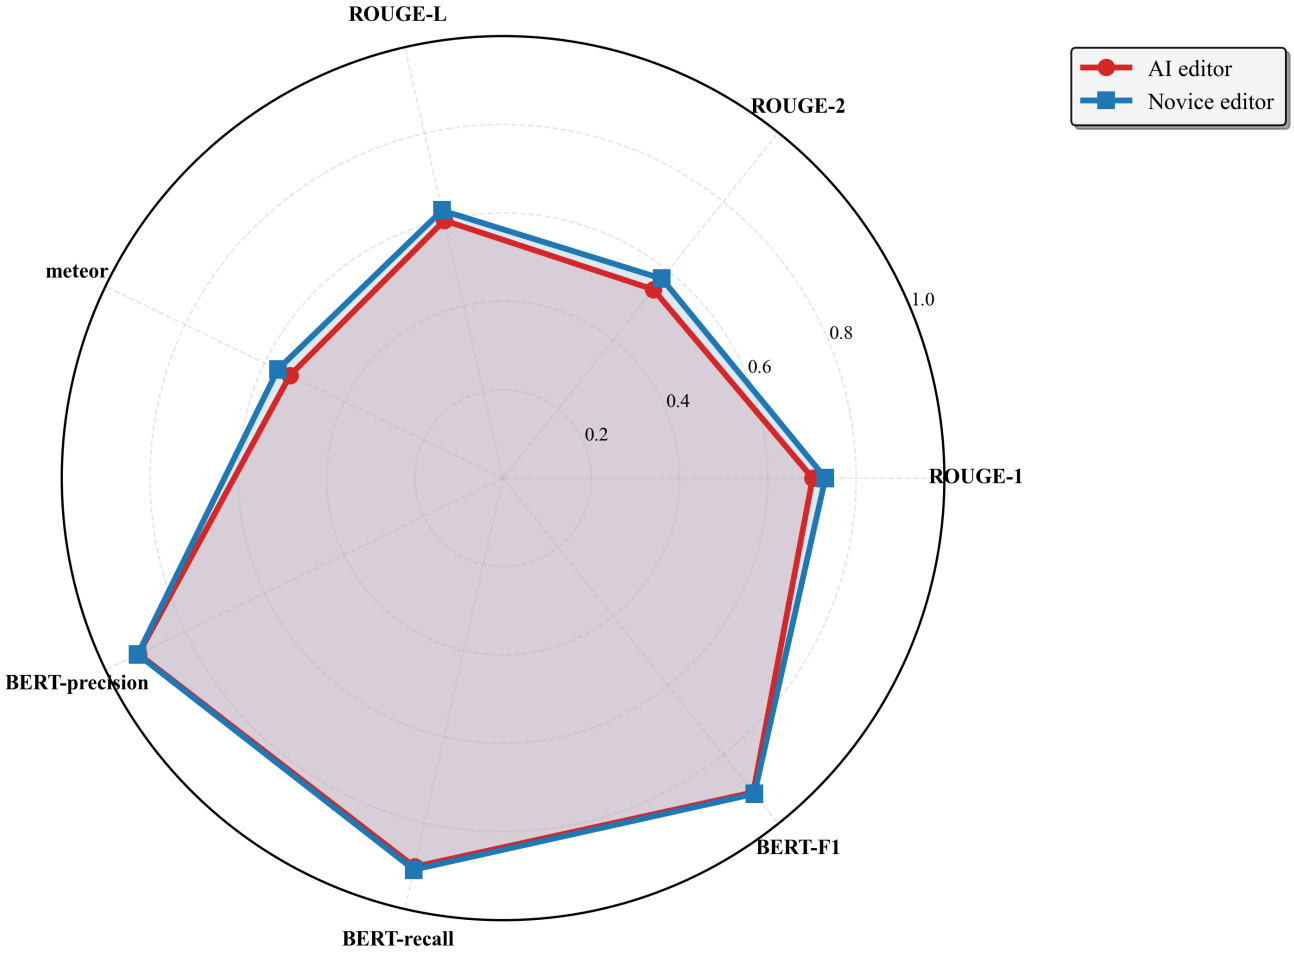
We observed significant differences in audio and content quality between the novice- and expert-edited interviews (P<.001) as well as between the AI- and expert-edited interviews (P<.001). No significant differences were noted between the AI- and novice-edited interviews for either content quality (P=.31) or audio quality (P=.33). A detailed breakdown of the ratings for each individual survey question across all patient interviews can be found in Figure S1 in Multimedia Appendix 3.



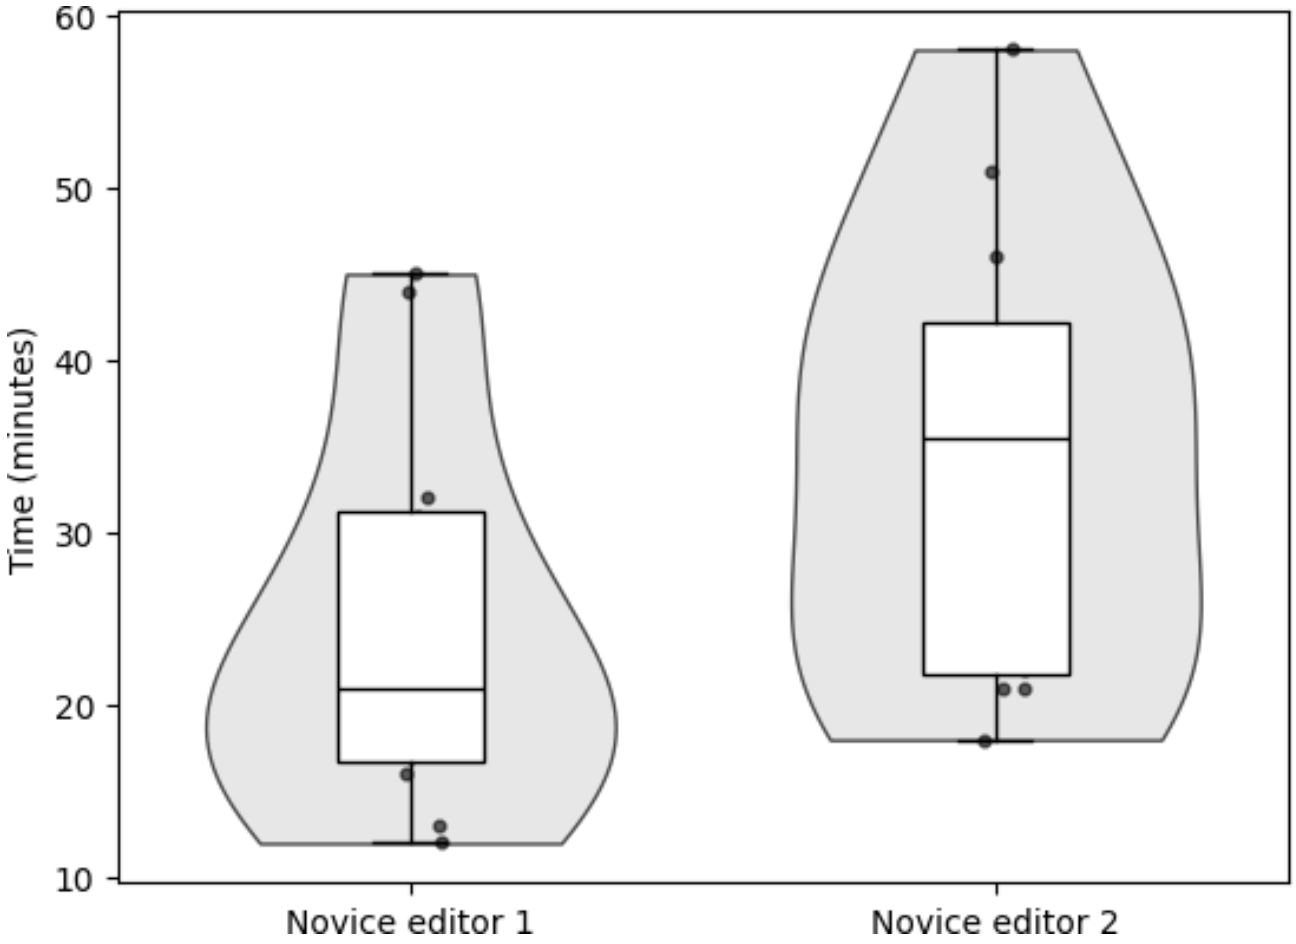
To understand the variability between the novice editors, we broke down the differences in rated audio and content quality in Figure 3. Between the two novice editors, we found that novice editor 1 demonstrated a mean content quality score of 3.81 (SD 0.83) and a mean audio quality score of 3.52 (SD 0.76). The second editor's mean content quality score was measured to be 3.88 (SD 0.52), with a mean audio quality score of 3.75 (SD 0.81). However, neither intragroup difference was significant for both content quality (P>.99) and audio quality (P=.51). Figure 4 shows the mean statistical scores across all audio interviews for both the AI and novice editors.

Figure 3. (**A**) A comparison of mean audio quality ratings between the two novice editors, each of whom edited 12 randomly assigned audio interviews. (**B**) Both editors achieved comparable content quality ratings, but the second novice editor exhibited significantly lower variability. All statistical scores of content similarity highlighted the similarities between the artificial intelligence and novice editors, and we report no statistically significant differences between any metric across both types of editors (P>.05). Detailed scores across each metric are contained in Table S1 in Multimedia Appendix 2.

XSL•FO
RenderX

Figure 4. Mean statistical scores across all 24 audio interviews for both the artificial intelligence and novice editors. AI: artificial intelligence. BERT: bidirectional encoder representations from transformers.

Qualitative Error Analysis



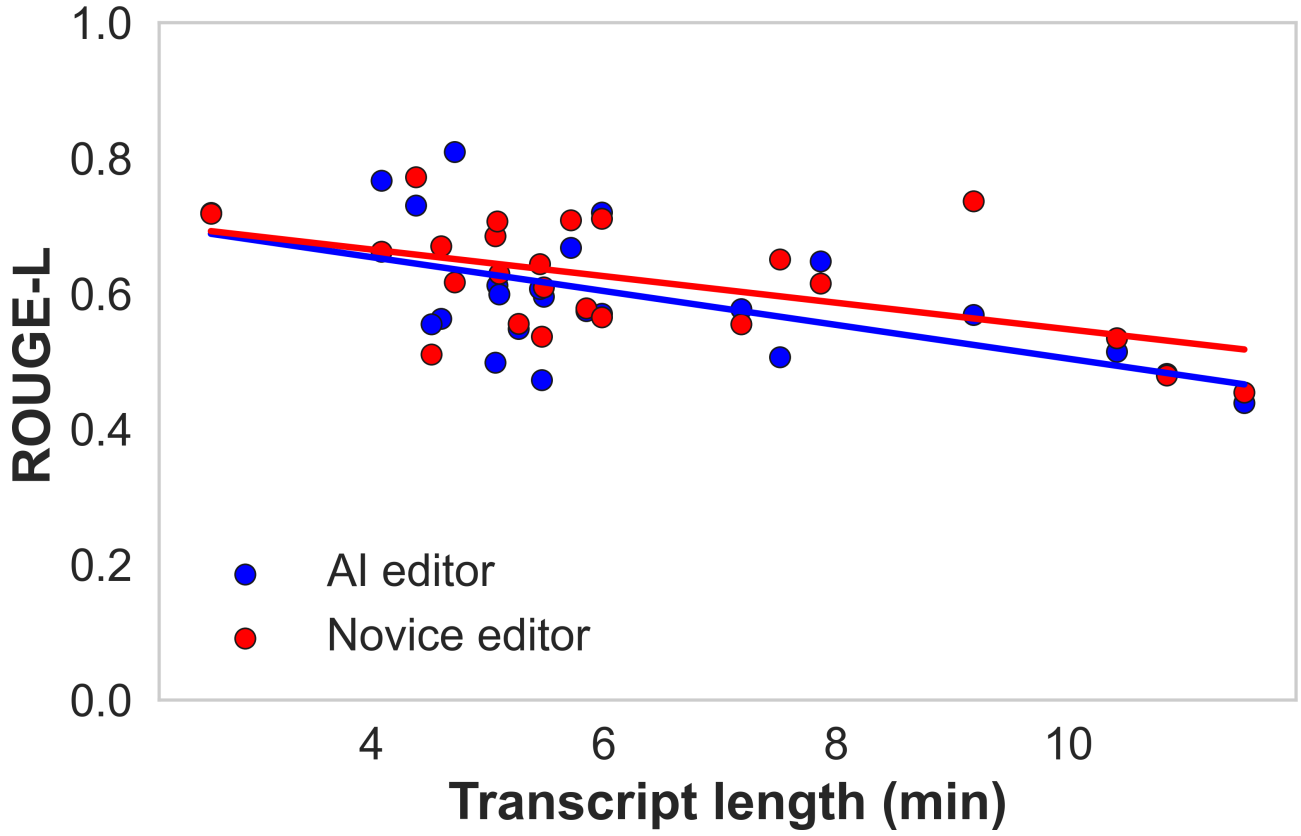
We qualitatively compared the AI- and novice-edited interviews to the expert-edited interviews and found five types of errors repeated across many of the interviews, which are described in Table 1. Many of the errors were similar across the AI- and novice-edited interviews.

Editing Efficiency

On average, each novice editor took 29.54 minutes to edit each interview (SD 12.69 min). However, we report a difference (P=.06) in the time each novice editor takes, with the first editor taking 24.50 minutes (SD 11.18 min) and the second taking 34.58 minutes (SD 13.08 min) to edit each interview. Figure 5 highlights the variability in the time to edit interviews between novice editors. Mean editing times for the expert editor are unavailable as they were not recorded. Based on anecdotal evidence from the expert editor, each audio interview required around 5 to 10 minutes to edit. In contrast to both the expert and novice editors, our automated AI-editing pipeline took less than 10 seconds from ingestion of the raw audio interview to the saving of the edited interview.

XSL•FO
RenderX

Figure 5. Time to edit each interview between each novice editor.



Impact of Interview Length on Editing Quality

We investigated if longer raw audio interviews were associated with changes in the lexical and semantic overlap with the expert reference, as measured by ROUGE-L. For AI-edited interviews, there was a significant negative correlation between transcript length and ROUGE-L scores (r=−0.58, R^2=0.34; Figure 6). This same trend was seen for novice-edited interviews, with a negative correlation (r=−0.52, R^2=0.27). Both slopes were significantly different from zero (P<.05), suggesting longer interviews were associated with lower transcript overlap to expert editor reference for both conditions. Regression plots for ROUGE-1, ROUGE-2, METEOR, and BERT scores showed comparable patterns and are provided in Figure S2 in Multimedia Appendix 3.

XSL•FO
RenderX

Figure 6. Linear regression of the raw transcript length versus ROUGE-L, reflecting the change in lexical similarity to the expert reference with longer interview times.

Discussion

Principal Results

Our study compares the listening experience of patient conversations summarized by an expert editor, a novice editor, and ChatGPT-4o. There was no significant difference in content and audio quality between the AI and novice editors, and both showed varying performance across the samples. Further analysis of the edited transcripts revealed that both of these groups omitted key details. The expert editor had a significantly higher audio and content quality rating than both experimental groups and less variability across samples. Exclusion of natural pauses between phrases and auditory cues to break up conversation led to lower audio quality scores.

Comparison to Prior Work

As burnout remains high among health care workers, TIMS provides an opportunity for meaningful connections with patients to target the emotional aspect of burnout. However, the manpower needed to edit audio is a limiting factor for this program's widespread adoption. Although the audio-editing pipeline introduced was originally developed to expand the TIMS program, these results are also broadly relevant to the use of AI in clinical practice and examine a previously unexplored application of LLMs, specifically editing audio content for a medical context. Previous studies have investigated ChatGPT as a clinical decision-making tool, for taking notes, and analyzing literature [26,28-35]. There have also been studies that demonstrate ChatGPT's capability to elicit empathetic feelings in an emergency setting can even exceed that of clinicians [36-38]. However, the combination of a summarization task to build empathy in a third-party listener has not been investigated. In this study, we aim to evaluate whether an LLM is able to extract emotionally relevant details from a conversation. Additionally, we provide a replicable framework for integrating LLMs in the analysis of patient audio for a broad variety of applications within health care settings. We found that our pipeline faced similar issues raised in previous studies examining ChatGPT's ability to summarize in a medical context. Kernberg et al [39] reported that 58% of structured medical notes from patient-physician interactions omitted important information. A manual analysis of the transcripts revealed that details considered important to a patient's story were also often omitted, highlighting a key disadvantage of LLMs in the literature. ChatGPT also tends to vary widely in the quality of responses across the samples. Although this was a shortcoming observed in the novice editors' performance on audio and content quality (SD 0.68 and SD 0.78), the expert editor's performance was consistent.

In addition to the survey, ROUGE scores (ROUGE-1, ROUGE-2, ROUGE-L) for the novice and AI editors indicated a high level of word overlap with the expert-edited transcript, with no significant differences between the two groups. High (~0.9) BERT scores (BERT-recall, BERT-precision, BERT-F_1) were also reported, indicating a high degree of semantic overlap that was not necessarily reflected in the ROUGE score. As the length of the audios increased, there was a statistically significant negative correlation between interview length and the ROUGE-L score for both AI and novice editors (P<.05), indicating longer interviews tended to have less lexical overlap

XSL•FO
RenderX

with the expert reference. This implies that there might be a length of audio that may not be as suitable for AI editing that will become more apparent as longer audios are recorded. These results from an established tool align with the insights from the survey, suggesting some level of construct validity for the survey questions.

Limitations

There are key limitations beyond the strengths of this study. First, there is no standardized or validated survey instrument available, so the introduction of a novel survey to assess the impact of each audio on a listener was necessary. However, abstract questions concerning "patient representation" or "nuance" are susceptible to subjective interpretation, a weakness that is amplified by our use of a single blinded reviewer. We attempted to standardize these ratings with calibration audios that were developed, but we cannot exclude the possibility that these subjective quality scores were influenced by rater bias. Despite this concern, the consistently high scores awarded to the expert-edited interviews provide some evidence of the survey's validity, as the rater reliably scored the gold-standard interviews. This survey could be adopted in the future by studies to measure the efficacy of interventions to increase empathy in medicine.

Second, the sample size of the study was also relatively limited, with only 24 samples and 1 recruited rater who was surveyed, which makes the results prone to bias. To build on this work, a larger sample size of patient audio interviews and experienced interview raters should be recruited. Previous volunteers of the program were able to receive iterative feedback on their work over long periods, but the novice editors had approximately 1 hour of training in comparison, so their skills were not as developed. Lastly, we were unable to obtain granular editing time measurements from the expert editor as these were retrospectively edited. However, the AI pipeline's completion time of under 10 seconds represents a multiple-orders-of-magnitude improvement in efficiency against any manual editing process.

Future Directions

We have presented the groundwork for an audio transcription and editing pipeline for humanistic patient conversations. Future work should test newer models as they improve, and others that are currently available besides ChatGPT-4o, with the same pipeline. Other strategies to improve performance include fine-tuning the LLM model, using AI agents to summarize the transcript, testing other ASR models, introducing patient-specific contextual metadata, and further prompt engineering to optimize the output. Error propagation was not formally tracked through the entire editing pipeline, but we have hypothesized an association between ASR errors and the final output quality. Future work should investigate these errors.

Conclusions

We conclude that ChatGPT-4o can create summarized audio files with similar audio and content quality to a novice editor in just a fraction of the time. However, the expert editor outperforms the AI editing pipeline and the novice editors on all metrics. After further validation, this tool could be implemented in the TIMS program to reduce workload and overcome adoption barriers.

Acknowledgments

This research has been generously supported with grants from the John Conley Foundation for Ethics and Philosophy in Medicine. We additionally acknowledge support from the Catalyst Award and the Diversity Innovation Grant from Johns Hopkins University. Lastly, we thank the Johns Hopkins Technology Innovation Center for providing access to a protected health information–compliant version of ChatGPT-4o.

Data Availability

The original interview recordings are not publicly available for privacy protection considerations but are available from the corresponding author on reasonable request. The relevant code is provided here [40]. This code corresponds to the automated audio-editing pipeline that processes raw audio, uses ChatGPT-4o to extract key segments, and stitches those selected segments into an AI-edited audio.

Authors' Contributions

All authors contributed to the conceptualization and study design. SR, BB, and ER curated the data and conducted the analysis. ET and JW managed and supervised the project. All authors reviewed and edited the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: In intensive care unit (ICU) settings, structured team-based communication, such as multidisciplinary rounds, handoffs, and goals-of-care discussions, is foundational to high-quality care. However, accurately documenting these complex discussions in the medical record remains a challenge due to time pressures, documentation burdens, and competing clinical demands. Ambient artificial intelligence (AI) scribes, which passively transcribe and summarize spoken interactions, offer a potential solution to assist ICU clinicians with documentation. Yet, little is known about how ICU clinicians perceive the integration of these tools into their high-stakes, collaborative workflows.

Objective: This study explores clinicians' perceptions of integrating ambient AI scribes into structured team-based ICU discussions, including multidisciplinary rounds, handoffs and transitions of care, and goals-of-care discussions, with the broader goal of informing the implementation of these scribes into real-world ICU clinical workflows.

Methods: Interviews and focus groups were conducted with ICU clinicians, including nurses, attendings, trainees (residents/fellows), respiratory therapists, and advanced practice practitioners, who routinely participate in structured ICU discussions. Transcripts were analyzed using grounded theory to identify documentation needs, barriers to documentation, and considerations for the implementation of ambient AI scribes in the ICU setting.

Results: A total of 52 individuals, including 18 ICU attendings, 5 advanced practice practitioners, 10 ICU trainees, 9 ICU nurses, and 10 ICU respiratory therapists, participated. Clinicians emphasized the importance of accurate documentation, but noted persistent barriers such as time constraints, documentation burden, and competing teaching and patient care responsibilities. Clinicians expressed enthusiasm about ambient AI scribes' potential to reduce documentation burden and improve quality, but requested personalization of outputs, robust consent protocols, and transparency around data use. Participants viewed ambient AI scribes as a promising tool to enhance both documentation fidelity and communication quality in ICU settings. Successful implementation may be contingent upon transparent data governance, specialty-specific customization, and sustained efforts to build clinician trust.

Conclusions: ICU clinicians were optimistic about the potential of ambient AI scribes to ease documentation burden and improve the capture of critical clinical discussions, but expressed concerns over transparency regarding data use. Successful implementation may depend on clinician training, customization of output, and transparent institutional policies on data use and consent.

KEYWORDS

ambient artificial intelligence; ambient AI scribes; AI-generated documentation; intensive care unit; ICU documentation; human-computer interaction; quality improvement; transparency and trust in AI

Introduction

In the intensive care unit (ICU), structured team discussions, such as multidisciplinary daily rounds, handoffs and transitions of care, and goals-of-care discussions, are essential for coordinating care and conveying critical information. However, despite their importance, a major limitation of these communication workflows is that what is verbally discussed may not be comprehensively or even formally documented in the electronic health record (EHR) [1,2]. These discussions contain clinically rich information that should be documented with high fidelity, but documenting these discussions is often suboptimal due to a confluence of factors, including the time-intensive and cognitively demanding nature of summarizing complex discussions and balancing documentation with direct patient care and trainee teaching. For example,

XSL•FO
RenderX

multiple studies have highlighted systemic challenges in documenting goals-of-care discussions with sufficient clarity and depth, raising concerns about medico-legal clarity [3-5]. Similar concerns extend to ICU progress notes, where documentation quality may be variable [6-9], and to handoffs and transitions of care, which, despite their clinical significance, are not routinely documented at most institutions. This documentation gap threatens information continuity and patient safety.

Recent advances in large language models and ambient computing have led to the development of ambient artificial intelligence (AI) scribes, which are voice-enabled AI systems that passively listen to clinical conversations and generate draft notes. To date, fully autonomous, EHR-integrated scribes have been used primarily in the ambulatory outpatient setting, with improvements in physician task load, burnout, and usability [10-12]. While prior work has explored the impact of this technology on patient-provider interactions primarily in ambulatory settings, an unexplored opportunity lies in utilizing ambient AI scribes to enhance structured provider-to-provider communication and documentation in ICU settings. With the prevalence of large, multidisciplinary discussions, multiple speakers, and medically complex terminology, the ICU presents unique challenges for deployment and serves as a meaningful testbed for this technology in inpatient workflows. However, there is limited empirical evidence examining ICU teams' perceived need for integrating ambient AI scribes into clinical workflows. Further, the passive capture of team-based conversations introduces complex ethical and operational considerations, particularly given the medico-legal implications of these discussions and the potential for ambient AI scribe systems to hallucinate, generate errors in noisy, multispeaker ICU environments, and exhibit bias. While common mitigation strategies include human-in-the-loop review, the use of structured templates, and chart retrieval, these approaches have not been well studied in inpatient settings, where communication is often provider-to-provider and documentation structures differ substantially from ambulatory care.

In this paper, we present findings from a qualitative study involving semistructured interviews with ICU clinicians across multiple roles. The contributions of our work include (1) insights into ICU clinicians' expectations, concerns, and aspirations regarding the use of ambient AI scribes for documenting common structured, team-based discussions and (2) a set of implementation implications and sociotechnical considerations for safely and meaningfully integrating these tools into inpatient environments. This is an acceptability and integration exploratory study conducted prior to the implementation of an ambient AI scribe in an ICU setting, in order to inform its future use by identifying key factors that may influence adoption. Our work contributes to human-computer interaction (HCI) research on AI in health care by grounding technology implementation and design in the lived experiences of those working on the front lines of care.

Methods

Ethical Considerations

This study was approved as exempt as a quality improvement initiative by the University of California, Los Angeles (UCLA) Office of the Human Research Protection Program (IRB-25 - 0434). The study posed minimal risk, focused on system-level workflow improvements, and did not involve identifiable private information. All participants were informed of the interview purpose, participation was voluntary, verbal consent was obtained, and responses were deidentified for analysis. Appropriate measures were taken to protect participant privacy and confidentiality, and participants were not compensated. The study commenced in April 2025 and ended in July 2025. Semistructured interviews were guided by the RE-AIM/PRISM (Reach, Efficacy, Adoption, Implementation, and Maintenance/Practical, Robust Implementation, and Sustainability Model) framework. Thematic analysis was conducted using both inductive and deductive approaches.

Setting, Study Population, and Recruitment

Given the distinct ways in which different clinicians may engage with an ambient AI scribe in the ICU, a diversity of perspectives was essential for our focus. All clinicians routinely involved in ICU patient care at all UCLA ICUs were eligible to participate, including physicians (attendings, residents, and fellows across disciplines), advanced practice practitioners (APPs), registered nurses, and respiratory therapists (RTs). We specifically sought to recruit providers other than doctors to broaden the perspective. The only exclusion criterion was affiliation with the Quality Improvement team. Individual demographic data (eg, age and sex) were not collected to protect the anonymity of participants in smaller subgroups, such as APPs. Clinicians were recruited via electronic mail messages and announcements at educational conferences. Participants were recruited across both Ronald Reagan UCLA Medical Center and Santa Monica UCLA Medical Center, 2 distinct hospitals within the UCLA Health System.

Interviews and Focus Groups

The decision to interview clinicians individually or in a focus group was dictated by their availability to meet with study personnel. While focus groups were initially prioritized for larger clinician cohorts (eg, residents, ICU attendings, and ICU nurses), these were logistically difficult to conduct, necessitating interviews. For each interview, verbal consent was obtained prior to participation. Semistructured interviews, using an interview guide developed for this study (Multimedia Appendix 1), were conducted by a clinician trained in qualitative research methods, which enhanced contextual relevance and rapport with participants [13]. Reflexivity practices were employed throughout data collection to minimize bias and maintain analytic rigor. To ensure comparability across modes, we used the same semistructured guide in both settings and focused our analysis on participants' experiences and perceptions rather than interactional features of group discussion.

UCLA Health had entered into an enterprise agreement with Nabla, which had been implemented in ambulatory clinics for

XSL•FO
RenderX

over a year but had not yet been deployed in inpatient settings at the time of this study. At the start of the interview, the interviewer provided a live demonstration of the Nabla ambient AI scribe to illustrate how it could be used to assist with drafting a summary of a clinical discussion. This demonstration was intended to establish a consistent baseline of understanding across all participants, enabling them to offer informed perspectives on the potential use of ambient AI scribes for ICU documentation. Participants were asked a series of questions on common ICU structured discussions, using prompts aligned with the interview guide (Multimedia Appendix 1).

Analysis Plan

Qualitative methods were used to explore trust and appropriate use of ambient AI scribes in the ICU [14,15]. Focus groups were facilitated by a trained clinician moderator, and audio recordings were transcribed and deidentified. Transcripts were not returned for member checking due to practical constraints. Sampling was guided by thematic saturation, with a target of 10 to 20 interviews per key clinician group involved in ICU communication. Given the small number of nurse practitioners and physician assistants, we sought to include the full cohort. Data collection continued until no substantively new themes emerged overall. Because some roles were underrepresented, saturation within individual groups cannot be assumed; findings, therefore, reflect cross-cutting rather than role-specific perspectives.

Transcripts were analyzed using a grounded theory approach, allowing themes to emerge from the data [16]. Two authors developed and iteratively refined a codebook (Multimedia Appendix 2), applying constant comparison and recoding transcripts as needed [16]. They independently coded transcripts and met regularly to reconcile differences and reach consensus. This consensus approach was chosen to prioritize depth of interpretation over interrater reliability metrics. Checklist 1 summarizes reporting elements for qualitative informatics studies included in this paper. Coding was facilitated using Atlas.ti (2025 ATLAS.ti Scientific Software Development GmbH).

Results

Clinician Perspectives (Frontline Providers)

From April 2025 to July 2025, we interviewed and conducted focus groups with 52 ICU clinicians (Table 1). Interviews ranged from 14 to 46 minutes in duration, with a median duration of 24 (IQR 17-34) minutes. Two focus groups were conducted with a total of 5 ICU trainees (residents and fellows), 1 focus group with a total of 2 ICU nurses, and 2 focus groups with a total of 4 RTs.

Table . Overview of study participants by role and data collection method.

Participant type	Data type, n	
	Interview	Focus group
Attending ICU[a] physicians[b]	18	0
APPs[c]	5	0
ICU trainees (fellows/residents)	5	5
ICU nurses	7	2
ICU respiratory therapists	6	4
Total	41	11

[a]ICU: intensive care unit.

[b]ICU disciplines represented in interviews were surgical ICU, cardiothoracic ICU, cardiac ICU, medical ICU, neurocritical care ICU, liver ICU, pediatric ICU, and neonatal ICU.

[c]APP: advanced practice practitioner.

All clinician groups emphasized the importance of clear and accurate documentation during structured ICU discussions. There was broad agreement that capturing the content of team-based discussions was critical to safe and effective patient care, and that clinicians wanted these exchanges to be documented well and meaningfully:

> *I personally care a lot about the progress notes and the accuracy and quality of the notes and so I spend quite a bit of time on them on a daily basis when I'm in ICU.* [ICU attending 1]

> *A discussion that I think would benefit from an ambient AI scribe is a goals-of-care conversation. These conversations can get very complex, very long, and sometimes it's really hard to capture all the nuance. It would be helpful if that could be translated into a really high-quality note.* [ICU attending 2]

> *The thing with the handoffs is there's no documentation whatsoever right now. There are a lot of details that you've discussed verbally, but probably should be in a note.* [ICU trainee 1]

Even though structured team discussions were seen as critically important, clinicians identified several barriers and facilitators to documenting them effectively. Chief among these was time pressure, but other factors included patient care and teaching responsibilities, and the cognitive load associated with translating medically complex discussions into a note:

> *Sometimes there's just too much patient care- I frequently do notes at home … on a very busy day,*

XSL•FO
RenderX

> *as much as an hour or more at home.* [ICU attending 3]
>
> *There really is a group discussion … why we're thinking what we're thinking and why we're doing what we're doing … there's definitely things lost in how that gets translated to the progress note.* [ICU nurse 1]
>
> *Those discussions are very rich. They're very comprehensive … But the richness of the discussion frequently does not get translated into a note that I'm writing or sometimes even what the resident writes.* [ICU attending 4]

Clinicians felt that the documentation burden detracted from patient care and trainee education responsibilities:

> *I find it frustrating that writing notes takes so long. And that means there's just less time to actually do bedside teaching, patient updates with family members, and such.* [ICU attending 5]
>
> *The most frustrating thing is that the documentation is important. However, it is not more important than actually being with the patients and doing clinical care. Every minute I spend writing my notes is time that I'm not spending at the bedside.* [ICU attending 6]

From the interview themes, key supporting factors and barriers toward high-quality documentation during structured ICU discussions (Table 2) were identified. For each discussion type, participants described specific factors that either supported or hindered accurate information capture and documentation. We mapped interview responses to these facilitators and barriers to highlight the sociotechnical context in which ambient AI scribe technologies would operate.

We asked participants to share their thoughts on the role that ambient AI scribes might play in their workflows. Overall, clinicians expressed interest that ambient AI scribes could enhance consistency and completeness in documentation and enable more time for resident education and patient care, but did express reservations over issues of consent and concerns for surveillance (Table 3; Textbox 1).

Table . Supporting factors and barriers to effective documentation of structured team-based discussions, with illustrative quotes.

Type of structured discussion	Supporting factors	Barriers
Multidisciplinary ICU[a] rounds	Structured rounding frameworks promote organized, systems-based documentation *"Our rounding discussion is very structured and systems-based; an [ambient AI[b] scribe] could capture that and turn it into a clear assessment and plan."* (ICU attending 7) EHR[c] smartphrases and templates *"The auto-populate stuff is somewhat helpful, but it mainly pulls in objective data. Still, smartphrases and templates let us finish some notes in minutes."* (ICU attending 3) *"You have to like good smartphrases if you want to document well."* (ICU trainee 1) Professional expectation for daily documentation *"It's kind of a painful process for me, but it also helps me to crystallize my thinking and be able to articulate my thoughts. The attending addendum helps me to synthesize in a very clear manner my assessment of the patient overall and the plan going forward."* (ICU attending 4)	Time pressure *"The biggest one is time constraints … you try to do the bare minimum and leave, which then leaves gaps in documentation."* (ICU attending 8) *"Most of the time I go home and I have not been able to complete my ICU notes for the day."* (ICU attending 9) Note-writing interruptions disrupt cognitive flow during writing *"If a patient is crashing, there's no way to get to documentation; most days I'm finishing at home, off the clock."* (ICU attending 10) Competing clinical demands *"You either need to make a decision on whether you're going to be taking care of a patient or focusing on your documentation."* (ICU attending 9) *"I do need to carve out at least an hour, and that means that's just less time to actually do bedside teaching. and patient updates with family members."* (ICU attending 11) Information loss from the discussion *"But even as I'm writing the note and reading through it again, and trying to think- even after I've signed notes sometimes- I'll remember something that I meant to write down or that we talked about and didn't put in the note, and have to go back and change it again."* (ICU attending 5)
Handoffs and transitions of care	OR[d]-to-ICU handoff checklist serves as a strong scaffold for documentation *"The CT[e] and SICU[f] OR-to-ICU handoff is highly structured; with a little training the scribe could create a note for it."* (ICU attending 2)	Handoff documentation is not routinely practiced and may encounter resistance if perceived as adding to clinicians' workload *"We don't currently put handoffs in a note- is the handoff going to take more time if we have to verify a note?"* (ICU attending 4)
Goals-of-care discussions	Documenting changes in a patient's code status is an expected standard of care *"The goals-of-care conversation would be a prime target for the [ambient AI scribe]."* (ICU trainee 2)	Nuanced clinical conversations are often difficult to fully capture in written documentation *"These conversations are really complex. Our ability to write out the nuances of these conversations efficiently and effectively isn't always possible."* (ICU attending 13)

[a]ICU: intensive care unit.

[b]AI: artificial intelligence.

[c]EHR: electronic health record.

[d]OR: operating room.

[e]CT: computed tomography.

[f]SICU: surgical ICU.

XSL•FO

Table . Clinician-identified human factors for ambient artificial intelligence scribe implementation in intensive care unit settings.

Theme	Key insight	Representative quote
Lack of education and training	Clinicians feel unprepared to work with AI[a] technologies	*"AI is coming for all of our futures … we're going to be using AI technology, but no one is teaching us anything about it."* (ICU[b] trainee 3) *"The health literacy or the literacy around AI is so poor right now… there's misinformation and not much familiarity."* (ICU trainee 2)
Need for consent and transparency	Clinicians emphasize the importance of informing the team before using ambient AI scribes	*"It should be like a standard practice- you would say at the beginning: 'We're going to be using the [ambient AI scribe]. Is everyone OK with that?'"* (ICU nurse 3) *"Whoever is using it should notify everybody that it's on and how it's going to be used."* (ICU nurse 4) *"There's consent fatigue … but there's still a need to present it elegantly and transparently."* (ICU trainee 4)
Concern for surveillance and psychological safety	Clinicians voiced concerns about surveillance stemming from a lack of clarity regarding how ambient AI scribe data would be used	*"What's actually being kept? Is it an audio recording, a transcript? Is it a summary? I don't understand what is being kept from the scribe."* (ICU RT[c] 1) *"You're being watched… and that changes your behavior. It's like the panopticon."* (ICU trainee 1) *"Providers should be protected from surveillance."* (ICU trainee 5)
Communication adaptation in response to ambient AI scribe	Staff may shift language to accommodate the ambient AI scribe	*"I think we're going to adapt how we speak during rounds so that the [ambient AI scribe] can do its best job."* (ICU attending 12) *"It will increase professional descriptions and decrease off-the-cuff ridiculous remarks. People actually need to use more formal medical language. Instead of 'AKI[d],' the patient has 'prerenal acute kidney injury.'"* (ICU attending 1) *"People would be more cautious. they might consider their word choice more carefully."* (ICU nurse 5) *"We might structure our communication a little more differently … if we want to make it a very structured note, I bet we would adhere to that even more."* (ICU attending 15) *"It could affect the frankness of how someone describes a case."* (ICU RT 2)
Perceived reduction in cognitive load	Ambient AI scribe may free cognitive resources during rounds	*"It's going to help me just pay attention to the conversation without having to frantically jot down notes at the same time."* (ICU APP[e] 1)
Preference for personalized output and the need for review	Clinicians want editable summaries that are tailored to specific discussions	*"The most important would be accurate transcription … the second most important feature would be that it then organizes that information into some type of paragraph or systems-based note template that I could then review and edit."* (ICU attending 7) *"There's no way I would want it to automatically put in a note without me reviewing it."* (ICU attending 16)

XSL•FO
RenderX

Theme	Key insight	Representative quote
Opportunity to capture structured communication exchanges that are inconsistently or not documented at all	Ambient AI scribes could document key conversations often missed in the chart	"*I do think using it for the goals-of-care conversation would be nice. Sometimes the notes on these discussions are sparse and you don't know why patients went from Full Code to DNR*[f]." (ICU nurse 6) "*I don't think we really know how people are using the OR*[g]*-to-ICU handoff checklist. If you have to place a note now, people will have to use it*." (ICU trainee 2)

[a]AI: artificial intelligence.

[b]ICU: intensive care unit.

[c]RT: respiratory therapist.

[d]AKI: acute kidney injury.

[e]APP: advanced practice practitioner.

[f]DNR: do not resuscitate.

[g]OR: operating room.

Textbox 1. Clinician perspectives on implementing ambient artificial intelligence scribes for documenting structured communication exchanges in the intensive care unit.

In support of ambient artificial intelligence (AI) scribe implementation

"*I think notes are going to be more accurate and more timely or I should say more thorough documentation of the things that we talk about on rounds*." (ICU attending 4)

"*Having an [ambient AI scribe] that's reviewed by a doctor might actually lead to more accurate documentation*." (ICU attending 5)

"*We would also be able to produce an assessment and plan a bit more systematically than we've been doing … for the dual purpose of communicating and educating our trainees and nurses and the [ambient AI scribe]*." (ICU attending 6)

"*Hopefully, if this is done right, you're spending more time with patients, you're spending more time doing care and teaching, you're spending less time billing, coding, and writing notes*." (ICU attending 7)

"*The OR-to-ICU handoff has no documentation currently. This could help*." (ICU attending 9)

"*It's going to help the doctors. Sometimes their notes have too much copy and paste*." (ICU nurse 1)

"*You have to build your relationship. The AI has to learn you and you have to learn the AI*." (ICU attending 16)

Skeptical of ambient AI scribe implementation

"*If it can provide a clear summary with minimal editing- yes I would use it. If not, I probably wouldn't use it*." (ICU attending 17)

"*I would have to edit it … I never trust an AI. How accurate is it?*" (ICU attending 16)

"*You're being watched … when you are being watched, your behavior absolutely changes*." (ICU trainee 6)

"*No one trusts anything anymore… you're still recording verbatim what is being said, even if you generate a summary*." (ICU trainee 1)

"*Not everybody is comfortable being recorded … some people might think it's surveillance*." (ICU nurse 8)

"*I do hope that it is able to recognize people with different accents and different background language. My concern would be that I have an accent and it would pick up my words in a different way*." (ICU attending 18)

"*Sometimes family members are present on rounds … I don't know how they would feel about an ambient AI scribe*." (ICU nurse 4)

"*There's a lot of noise. So I, you know, I could see things being potentially incorrectly transcribed because there's like a lot just, it's just like so much going on*." (ICU attending 15)

> *I think my dream would be that … I use this scribe during rounds. When I am done rounding and seeing my patients, I go back to the computer and I already have a templated progress note draft for me that I make some minor edits to before signing into the medical record.* [ICU attending 1]
>
> *I think recording always affects the freedom of speech … If you feel like you're being watched when you're discussing a patient's care … not everything may come out that freely.* [ICU trainee 1]

Stakeholder Perspectives From ICU Team Members

While our interview guide was developed with the assumption that ambient AI scribes would support ICU attending physician documentation, we also sought to capture perspectives from other ICU team members. These included individuals who regularly participate in structured communication discussions in the ICU, all of whom would be exposed to the presence of

XSL•FO
RenderX

an ambient AI scribe. We conducted role-specific thematic analysis to examine perspectives by clinical role. Representative themes are summarized below:

- ICU trainees (residents and fellows): trainees expressed openness to piloting the tool in ICU workflows. They perceived that AI tools would become increasingly central to their practice and expressed a clear need for training toward AI literacy and integration into clinical education. They expressed concerns over data governance and the potential for trainee surveillance.
- ICU APPs: APPs describe frequent gaps between what is discussed during ICU rounds and what is captured in progress notes, often due to time constraints and rounding fatigue. They viewed ambient AI scribes as a means to allow them to focus on listening instead of documenting during real-time discussions. However, they expressed concerns about overreliance and transcription errors, particularly with soft-spoken or accented speakers, which might require extra correction.
- ICU registered nurses: nurses were generally supportive of the use of ambient AI scribes in physician documentation workflows, particularly if transparency and consent protocols were established. Some also expressed interest in adapting the tool for nursing documentation, such as end-of-shift summaries, provided they had the ability to review and edit the outputs.
- ICU RTs: RTs supported technologies that improve documentation and communication quality. They did not anticipate major workflow disruptions from ambient AI scribes and felt that improved documentation might indirectly enhance interdisciplinary comprehension.

Discussion

Principal Findings

We synthesize these findings to highlight implications for the implementation and policy of ambient AI scribes in inpatient settings. ICU clinicians identified common structured communication discussions, such as daily multidisciplinary rounds, handoffs and transitions of care, and goals-of-care discussions, as high-value opportunities where ambient AI scribes could meaningfully improve documentation. Documentation of these discussions is often compromised in quality or goes undocumented entirely as a result of time constraints, cognitive load, and the demands of direct patient care. Clinicians perceived that this technology might reduce the burden of documentation, allowing teams to focus on the conversation and develop a clearer shared mental model of the patient. This aligns with longstanding insights from HCI, which emphasize the importance of reducing cognitive load and supporting task-focused attention when implementing new technology in high-stakes clinical environments [17].

Ambient AI scribes were viewed not only as tools to reduce documentation burden but also as infrastructure for reinforcing and sustaining real-world standardized communication practices in the ICU [18]. Clinicians perceived that ambient AI scribes might enhance patient safety by documenting critical information that might otherwise be lost, as was notably discussed in the case of handoffs for which no formal documentation exists. Team members believed that capturing undocumented discussions could enable Quality Improvement leaders to measure and monitor real-world handoff practices. This reflects a broader theme in the HCI literature: technology not only can support workflows but also sustain standardized practices over time [19,20]. However, there was recognition that ambient AI scribes would only have an impact in this regard as long as there was institutional commitment to defining and requiring standardized communication and documentation practices that ambient AI scribes can reliably support. Without this foundational structure of expected communication frameworks with their associated required documentation, clinicians felt that ambient AI scribes might not be used for specific discussions that could benefit from documentation, such as handoffs.

A key theme across interviews was clinicians' strong sense of responsibility for the accuracy of ambient AI scribe output, aligning with prior research on trust in automation [21]. Participants emphasized the need to review and edit draft notes before attestation and viewed themselves as the final arbiters of documentation quality. This sense of accountability was a key factor in their willingness to adopt the technology. Few participants expressed concern that clinicians would neglect the task of editing and instead assumed that they would invest the necessary effort to ensure accuracy. They noted that if the draft output required excessive editing, it could add additional work that would undermine the technology's value proposition of saving time. They anticipated that each clinician would develop strategies to balance efficiency and accuracy. These insights suggest that successful adoption depends not only on the system's baseline accuracy but also on clinicians' ability to learn how to work effectively with the technology.

Another theme was the need to tailor ambient AI scribe output to diverse clinical documentation needs, consistent with the HCI concept of technology appropriation and "corealization" [22-24]. Participants felt that output formats must be co-designed with end users and adapted to the clinical context. For example, preferences for documenting daily ICU rounds varied by attending: some favored concise narrative summaries, while others preferred structured formats aligned with service-level templates. Goals-of-care conversations were viewed as best captured in a narrative paragraph that conveyed the rationale behind code status decisions. The OR-to-ICU handoff, which is a highly structured discussion that adheres to site-specific handoff checklists, was desired to be documented in a structured form similar to its associated checklist. Finally, some clinicians wished to co-design the output iteratively as they gained experience with the tool. These findings underscore the importance of participatory design approaches that give clinicians agency in developing how ambient AI-generated documentation is presented [25]. One potential limitation is whether ambient AI scribe vendors can support this functionality; however, as these tools become more prevalent in inpatient settings, close collaboration with vendors will be essential to ensure outputs are appropriately tailored to clinical context. This aligns with core principles of human factors engineering, which emphasize that successful health IT must

XSL•FO
RenderX

fit seamlessly within existing work patterns at the individual, team, and institutional levels [26].

The interest in trialing ambient AI scribes in the ICU was tempered by concerns about the sociotechnical implications of voice-based AI in team-based, high-risk environments, highlighting the need for careful, context-sensitive implementation [27]. Many participants felt that the presence of an ambient AI scribe could alter ICU team communication, although mostly in a positive way. Some clinicians anticipated a need to "narrate" more explicitly, for instance, by speaking directly to the ambient AI scribe, but perceived that this might encourage clearer, more intentional communication, potentially enhancing both the educational value of rounds and the quality of documentation. These themes mirror broader debates in HCI and sociotechnical systems research about how data capture can influence professional behavior [28-30]. Concerns were also raised regarding the transparency of data use and the challenges of obtaining consent within dynamic ICU communication workflows. Given the team-based nature of ICU rounds and other collaborative discussions, clinicians emphasized the importance of ensuring that all participants are aware when an ambient AI scribe is in use. Participants acknowledged that rounding discussions are often interrupted by consulting team members entering and exiting the conversation to provide recommendations or are interrupted by family members who may enter mid-discussion. Some expressed concern about the feasibility of having the ambient AI scribe's end user consistently deliver verbal consent language in such dynamic environments, highlighting the potential need for hardware-based solutions, such as visual indicators, to clearly signal when recording is active. Nevertheless, incorporating standardized consent language into structured discussion workflows, such as verbal announcements at the start of a discussion, was felt to be vital in clarifying the functions of the ambient AI scribe, how its outputs will be used, and what data will be retained. Although participants acknowledged the potential of ambient AI scribes to improve documentation, their use in provider-provider discussions raised concerns about constant job performance surveillance. Participants emphasized that education on data governance will be critical to building trust and positioning these tools as supportive rather than evaluative.

Based on themes garnered from the interviews, a list of implementation considerations for ambient AI scribes in inpatient workflows was generated, as shown in Textbox 2. These considerations were directly informed by the insights and concerns raised by ICU clinicians and represent needs across different roles and use cases. These recommendations aim to serve as a pragmatic guide for health systems that wish to implement pilot testing of ambient AI scribes in inpatient workflows.

Textbox 2. Implementation considerations for integrating ambient artificial intelligence scribes into in-patient clinical workflows.

Context-aware implementation: Identify team-based discussions for which the use of an ambient artificial intelligence (AI) scribe would address a clear documentation need, or where documentation could improve quality and safety.

Customization of scribe output: Co-design with ambient AI scribe vendors to ensure the output conforms with desired formats.

Medico-legal responsibility: Develop institutional guidance on editing and verification workflows, and educate clinicians on their medico-legal responsibility for the accuracy of ambient AI-generated documentation.

Trust, transparency, and data governance: Clearly communicate that ambient AI scribes are intended to support documentation efficiency, with transparent policies on when recording occurs, what is stored, and how data are protected.

Workforce outreach: Demonstration of ambient AI scribe functionality and discussion with team members may foster understanding and comfort.

Multiprovider consent: Establish clear protocols for obtaining consent from all participating providers before initiating ambient AI scribe during team-based discussions.

Training and support: Provide training and support to ensure effective use and foster understanding of AI scribe functionality.

Impact measurement: Define metrics to assess effects on documentation quality, workflow, and safety, supported by ongoing feedback and refinement.

Our study has notable strengths. A key strength of this study is the inclusion of perspectives from a range of ICU stakeholders who would directly engage with an ambient AI scribe. The use of qualitative methodology of a diverse set of ICU team members captured a more holistic view of how ambient AI scribes may impact team dynamics and might alleviate documentation challenges of important team-based discussions, offering insights to guide future implementation and evaluation. Second, several data sources (interviews, focus groups) to support the findings were used.

Limitations

The study has important limitations. First, because ambient AI scribes were not yet in routine clinical use in the inpatient setting, participants' views were based on anticipated rather than observed use. This was intentional, to proactively inform how it would be used in practice, in line with recommendations to embed ethical study into implementation processes [31]. A second limitation of this study is the absence of patient and family perspectives. While this study focused on ICU staff and clinicians to address its specific research aims, patients and families may hold distinct concerns and perspectives that are not captured here and represent an important area for future research. Finally, the live demonstration of the Nabla ambient AI scribe highlighted key functionalities (automatic speech recognition and output formatting options), but participants' responses may have been influenced by priming effects associated with exposure to the demonstration.

Future Directions

Future research should evaluate ambient AI scribe tools in real-world ICU settings using prospective, pragmatic study

XSL•FO
RenderX

designs. Such studies should examine their impact on interprofessional communication quality, how clinical teams communicate in the presence of an ambient AI scribe, documentation completeness, and clinician well-being across professional roles. Relevant metrics may include communication fidelity scoring (eg, the presence of structured discussion elements), professional fulfillment or burnout indices, and provider-level indicators such as EHR audit-log data and time spent in notes. Future work could also focus on the perspectives of family members and patients exposed to an ambient AI scribe during an ICU hospitalization.

Understanding clinicians' perceptions of how new technologies could be used to improve the quality of care delivery, as reported here, is emblematic of the type of investigation needed to make meaningful advances in health care value. The work of sociologists and patient safety experts, such as Dixon-Woods and Bosk, has emphasized the importance of understanding health care culture and the interactions among diverse professionals who must communicate effectively to achieve optimal outcomes [32]. Nowhere is this more evident than in the ICU, where structured team-based discussions are essential but suffer from documentation challenges. Ambient AI scribes may potentially improve how these discussions are captured, but understanding this requires a multidisciplinary approach. As with prior works that have examined structured discussions through collaborative lenses [33], our study aims to extend this tradition by exploring how ambient documentation tools might align with existing team-based communication practices to enhance safety and quality in ICU care delivery.

Conclusion

Ambient AI scribes have emerged as promising tools to alleviate documentation burden, but their integration into high-stakes settings like the ICU demands a deeply human-centered approach. Through interviews with ICU clinicians, we uncovered optimism about the potential of these tools to assist with the documentation of structured team-based communication workflows, but clinicians emphasized the need for transparency in data governance. Our findings highlight the sociotechnical complexities of deploying ambient AI in safety-critical inpatient environments and suggest that success hinges not only on technological performance but also on thoughtful integration into clinical practice, addressing clinician concerns about transparency, trust, and the potential for perceived surveillance. We offer implementation suggestions that prioritize transparency and clinician control, contributing to broader HCI conversations on AI-assisted documentation and human-AI collaboration in health care.

Abstract

Background: Medical ambient artificial intelligence (AI) scribes reduce documentation burden, but the current evidence is almost entirely from English systems. In the Arabic-speaking world, physicians converse mainly in Arabic and write clinical notes in English, adding cognitive burden. Due to scarce corpora in the Arabic language, the development of Arabic-enabled AI speech technologies has been challenging. Here, we address this gap by developing and evaluating a bilingual Arabic-English medical AI scribe.

Objective: This study aims to evaluate the feasibility and performance of a bilingual medical Arabic-English ambient AI scribe, Sahl AI, using a full end-to-end methodology from raw audio to clinical note.

Methods: A prospective, single-arm feasibility pilot study was conducted in 2 stages across outpatient clinics, inpatient services, and primary care clinics within Riyadh First Health Cluster: development and implementation. In stage 1 (development), consultation audios were collected and manually annotated to fine-tune the AI pipeline. Version 1 of Sahl AI underwent feasibility evaluation using a modified 9-item Physician Documentation Quality Instrument (PDQI-9) framework based on Likert-scale ratings. Subsequently, in stage 2 (implementation), the AI pipeline was fine-tuned, and version 2 was evaluated as a real-world deployment in family medicine clinics. Independent reviewers evaluated clinical notes. Physician experience was captured using targeted surveys.

Results: During stage 1, the AI pipeline was fine-tuned, producing version 1 of Sahl AI, which was tested in 64 clinical encounters for technical feasibility. This evaluation yielded a mean modified PQDI-9 score of 42.2 (SD 2.98) out of 45, with the model scoring 4.35 (SD 0.82) out of 5 in the accuracy domain. Following further optimization, version 2 of Sahl AI was evaluated during stage 2, using 55 real-world consultations assessed by 2 independent physician evaluators. Sahl AI achieved mean modified PDQI-9 scores of 42.4 (SD 1.84) out of 45 for Arabic and 37.8 (SD 1.10) out of 40 for English. On the Likert scale, for the accuracy domain, the mean score was 4.53 (SD 0.46) out of 5 for Arabic compared with 4.77 (SD 0.37) out of 5 for English (P=.06). Internal consistency (mean 4.94, SD 0.17) and comprehensibility (mean 4.89, SD 0.21) were the top-rated domains. The targeted survey of a larger cohort of 22 family medicine physicians using Sahl AI showed that most responding physicians agreed that notes were comprehensive and perceived potential time savings and reduced burnout.

Conclusions: Sahl AI, a bilingual Arabic-English medical ambient AI scribe, generates accurate and high-quality notes, and in targeted postimplementation surveys, most physicians agreed that it produced comprehensive notes and perceived potential benefits for time savings and stress or burnout. This provides the first empirical basis for rigorous end-to-end ambient AI scribe evaluation in low-resource languages such as Arabic.

Introduction

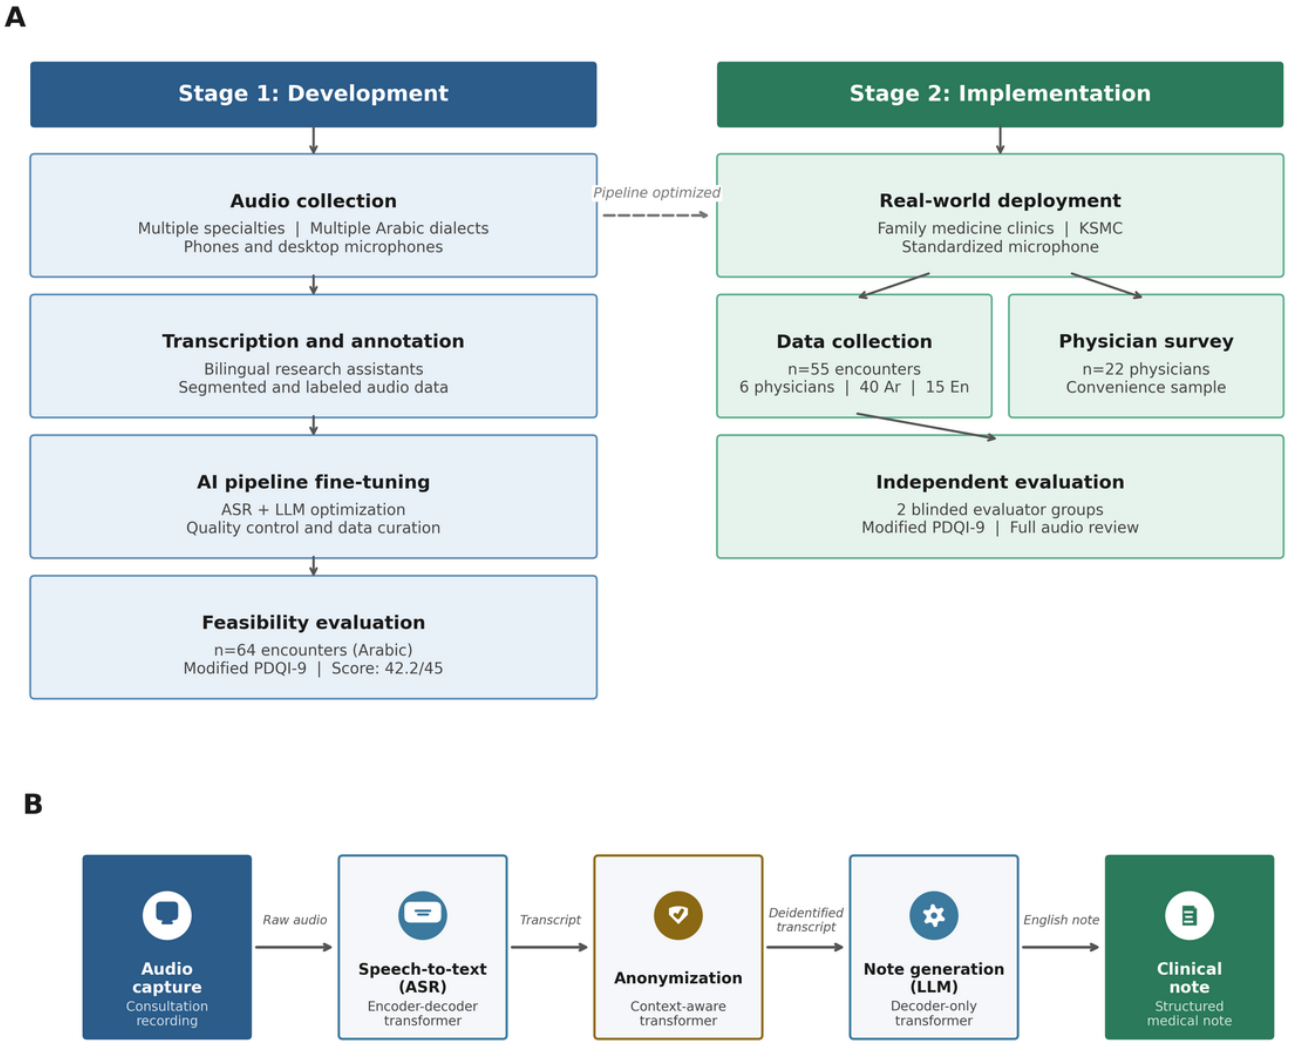
Physicians devote a significant portion of their time to the administrative task of documenting medical encounters with patients [1]. Clinical documentation serves critical functions, including care continuity, quality assurance, and in many jurisdictions, medico-legal protection. It is an essential component for ensuring patient safety and also impacts subsequent tasks, such as submitting insurance claims [2]. The digitization of medical records and the widespread adoption of electronic health record systems have substantially increased the documentation burden on physicians, leading to increased physician burnout [3]. Furthermore, clinical documentation has become a distraction, changing the traditional doctor-patient relationship into a doctor-computer-patient interaction [4].

Clinical documentation is typically completed either during or after patient encounters. Documenting in real time may interrupt the clinical interaction, whereas postvisit documentation may add to physician workload and relies on recall rather than contemporaneous capture. Ambient artificial intelligence (AI) scribes automate clinical note generation and improve the doctor-patient relationship, freeing physicians to focus on personalized care [5,6]. This study evaluates Sahl AI, an AI tool for Arabic and English, using the modified 9-item Physician Documentation Quality Instrument (PDQI-9) tool. This research is unique in its dual-language focus and is particularly relevant in Arabic-speaking countries where clinical encounters are conducted in Arabic, while medical documentation is recorded in English. This supports health care providers who routinely switch between languages during consultations when eliciting patient histories and documenting care.

Arabic is often categorized as a low-resource language in speech technologies due to its complex characteristics. These include its writing system with positional variance and diacritical marks, phonology that features emphatic consonants and vowel length distinctions, and grammar that involves root-based morphology and case-gender agreement. The variability is further compounded by numerous dialects and diglossia, as well as influence from other languages and its significant religious context. This necessitates ongoing translation by the physicians, introducing cognitive strain. Although ambient AI scribes offer a potential solution to mitigate this burden, the effectiveness of bilingual systems in such linguistically complex environments remains insufficiently examined. Therefore, the aim of this study was to develop and assess the feasibility and physician experience of a bilingual Arabic-English medical ambient AI scribe in routine clinical practice.

Methods

Study Design and Objectives



The study was a prospective, single-arm feasibility pilot study evaluating the performance of Sahl AI, a bilingual ambient AI scribe, in routine physician-patient consultations. The primary objectives were to (1) fine-tune an AI pipeline for automated clinical documentation generation and subsequently (2) evaluate the usability of Sahl AI and its impact on the physicians' workflow and the quality of documentation.

Study Setting and Duration

The study was conducted between December 23, 2023, and November 28, 2024, across outpatient clinics, inpatient services, and primary care centers within Riyadh First Health Cluster (Riyadh, Saudi Arabia). The study comprised 2 stages: (1) a development stage, during which data collection and a feasibility evaluation were performed, and (2) an implementation stage, in which the fine-tuned AI pipeline was assessed in a real-world clinical setting (Figure 1A).

XSL•FO
RenderX

Figure 1. (A) Two-stage study design. Stage 1: iterative development including multidialect Arabic audio collection, manual transcription by bilingual research assistants, ASR and LLM fine-tuning, and feasibility evaluation (n=64 encounters; mean 9-item Physician Documentation Quality Instrument [PDQI-9] score: 42.2/45, SD 2.98). Stage 2: real-world implementation at family medicine clinics (King Saud Medical City [KSMC]), with prospective data collection (n=55 encounters; 40 Arabic, 15 English), independent blinded evaluation using the modified PDQI-9, and a parallel physician experience survey (n=22). Dashed arrow indicates pipeline transfer from development to implementation. (B) Artificial intelligence (AI) pipeline architecture: audio capture, encoder-decoder ASR, anonymization via context-aware transformer for personally identifiable information (PII) deidentification, and decoder-only LLM for clinical note generation. ASR: automatic speech recognition; LLM: large language model.

During stage 1, participating specialties included, but were not limited to, general and internal medicine, general surgery, pediatrics, family medicine, obstetrics and gynecology, cardiology, and respiratory medicine. Both new and follow-up patient encounters were included, provided eligibility criteria were met and physicians were able to conveniently record audio conversations during clinical encounters. During stage 2, new patient encounters were sampled during designated family medicine clinic sessions when participating physicians were available. Verbal consent was obtained from patients by the treating physicians and was documented in the clinical notes.

Eligibility Criteria

The inclusion criteria were as follows: patients of all ages and sexes who provided informed consent for the use of Sahl AI during their clinical consultation. For pediatric patients, consent was obtained from a parent or legal guardian.

The exclusion criteria were as follows: patients with cognitive impairment who were unable to provide informed consent.

Collection of Audio Data for Fine-Tuning

During stage 1, audio data were collected to optimize and fine-tune the AI pipeline using Sahl AI's proprietary Data Collection Pipeline. Audio streams from physician-patient conversations were segmented into shorter audio chunks to facilitate accurate labeling. Participating physicians received training on audio recording using various devices and on obtaining informed consent from patients. The recorded audio was securely stored on cloud servers in compliance with the Kingdom of Saudi Arabia's Personal Data Protection Law (PDPL). The audio data were initially retained for 6 months, with the retention period later extended to 1 year following approval of an ethics amendment.

Recordings were collected across multiple clinical specialties during stage 1 using physicians' personal mobile phones as well as desktop microphones, including Anker PowerConf S360 USB Speakerphones and Kaysuda SP300 Bluetooth Speakerphones. A team of bilingual research assistants fluent in Arabic and English reviewed and edited the transcribed audio

XSL•FO
RenderX

segments to ensure high-quality labeled datasets for AI pipeline optimization. The dataset encompassed a wide range of Arabic dialects, including those spoken in Saudi Arabia, Yemen, Egypt, Sudan, the Levant, Kuwait, and North Africa, as well as simplified Arabic spoken by nonnative speakers and diverse English accents. Data scientists subsequently curated the labeled data, excluding poor-quality audio segments identified during review by the research assistants.

The AI pipeline was iteratively tested with internal evaluation metrics before being piloted with physicians during stages 1 and 2 of the study. The pipeline (Figure 1B) comprised multiple components requiring optimization for clinical deployment. In particular, the speech-to-text engine was based on a transformer-based encoder-decoder automatic speech recognition architecture, in which the encoder transforms raw audio signals into high-level semantic representations and the decoder generates the corresponding text transcription. Prior to clinical note generation, transcripts were processed through a deidentification layer that used a context-aware transformer model to detect and redact personally identifiable information. The large language model component was a decoder-only autoregressive transformer trained using causal language modeling.

Fine-tuning focused on improving robustness to spontaneous clinical dialogue, variability in dialects, and background noise commonly encountered in outpatient and inpatient environments. Model training prioritized transcription accuracy for medical conversations. To minimize overfitting and prevent information leakage, training and evaluation datasets were strictly separated.

Feasibility Study

During stage 1, following the fine-tuning and optimization of the AI pipeline, version 1 of Sahl AI was evaluated in a controlled setting to assess feasibility outside of routine clinical practice. This evaluation involved role-plays and mock conversations between physicians, as well as prerecorded simulated physician-patient conversations generated by nonphysicians. These audio recordings were processed by the AI pipeline to generate clinical notes, enabling the assessment of the ambient AI scribe's performance in the Arabic language. Collectively, these activities constituted the feasibility component of the development stage.

Clinical notes were generated in accordance with the documentation requirements of the Central Board for Accreditation of Healthcare Institutions and included standardized headings, such as chief complaint, history of present illness, past medical or surgical history, allergy, medication, social history, family history, physical examination findings, diagnosis, and plan. Participating physicians evaluated the AI-generated clinical notes after completing the role-play scenarios or listening to the prerecorded simulated conversations.

In total, 64 independent assessments were conducted using a modified PDQI-9 (Table 1), a tool that has been previously validated and used in recent evaluations of ambient AI scribes [7,8]. For the purposes of this study, the PDQI-9 tool was adapted to reflect Arabic-language and bilingual audio-to-text workflows. Specifically, the original domains of "up-to-date" and "synthesized" were replaced with "free from hallucination" and "translated accurately to English," respectively. These modified domains have not been formally validated and were used for exploratory assessment only.

XSL•FO
RenderX

Table . Nine-item Physician Documentation Quality Instrument (PDQI-9) tool measuring the quality of the clinical note across 9 dimensions[a].

Domain	Description
Accurate	The note is true. It is free of incorrect information. For example, if the history is about chest pain and the note mentions abdominal pain, then this represents that the note was not accurate.
Thorough	The note is complete and free from omission and documents all of the issues of importance to the patient. For example, if a symptom about visual loss was discussed and was important to the note but not mentioned, then this represents that the note was not thorough.
Useful	The note is extremely relevant, providing valuable information and/or analysis.
Organized	The note is well formed and structured as per CBAHI[b] recommendations in a way that helps the reader understand the patient's clinical course.
Comprehensible	The note is clear, without ambiguity or sections that are difficult to understand.
Succinct	The note is brief, to the point, and without redundancy.
Internally consistent	No part of the note ignores or contradicts any other part. For example, if 1 section of the note mentions that the patient has asthma but another section says no history of asthma, then this is not internally consistent.
Free from hallucination	The note is free of hallucination and only contains information verifiable by the audio conversation. For example, if the note mentions that the patient smokes and drinks alcohol when it was not at all discussed in the note, then this represents hallucination.
Translated accurately to English	The note reflects the Arabic conversation between the physician and the patient accurately in the English language.

[a]Each domain was scored from 1 to 5 (Likert scale), with 1 being "not at all" and 5 being "extremely."

[b]CBAHI: Central Board for Accreditation of Healthcare Institutions.

Real-World Testing

Based on the findings from stage 1, the AI pipeline was further optimized to improve performance prior to real-world deployment. During stage 2, the model was deployed in family medicine clinics for real-world testing involving both new and follow-up patient encounters. From a larger cohort of physicians, 6 physicians who consented to participate received at least 30 minutes of training on the effective use of the software prior to study initiation.

Physician-patient conversations and the corresponding unedited clinical notes generated by Sahl AI were recorded and subsequently evaluated by 2 independent evaluators. Evaluators listened to the complete audio recordings and assessed the associated unedited clinical notes using the modified PDQI-9 tool. To reduce the likelihood of identifying the physician speaker, evaluators were recruited from clinical specialties different from those of the participating physicians; however, complete anonymization could not be guaranteed, as the evaluators were recruited from the same health cluster. Evaluators were blinded to the identities of both patients and physicians. However, as the raw audio was not modified to redact personally identifiable information, complete blinding cannot be assured. Scores from evaluators were averaged prior to calculating the final modified PDQI-9 domain scores.

The evaluation process involved 2 evaluator groups. Evaluator group 1 comprised a single reviewer, while evaluator group 2 consisted of 2 reviewers who divided the assigned clinical notes between them. Each clinical note was reviewed by 2 evaluators—1 from each group. In cases where domain-level scores differed by 2 or more points, both evaluators were asked to rereview the clinical notes and reconcile discrepancies.

To ensure consistency across recordings, a standardized microphone (Kaysuda SP300 Bluetooth Speakerphones) connected to a laptop computer was used for all consultations. Audio recordings were performed by trained research assistants and uploaded directly through the Sahl AI software. Following each consultation, Sahl AI generated a single clinical note immediately using the recorded audio, which was then reviewed in its unedited form by the independent evaluators.

Clinical encounters were categorized as "Arabic" or "English" based on the predominant language of the consultation, as initially determined by research assistants and subsequently confirmed by the evaluators. Code-switched encounters involving substantial use of both languages were classified according to the language comprising the majority (>50%) of clinical content. Regardless of input language, Sahl AI generated all clinical documentation exclusively in English.

Physician Experience

Following real-world deployment in the family medicine department, a targeted physician experience survey was conducted to capture feedback from clinicians with the direct hands-on use of Sahl AI. The survey was completed between 29 July and 28 November 2024 by 22 physicians. Eligibility was limited to physicians who had used the system in at least

XSL•FO
RenderX

3 clinical encounters, ensuring sufficient exposure to evaluate its impact on clinical workflow. Survey items evaluated perceived note comprehensiveness, time savings, ease of use, impact on physician burnout, and impact on clinical workflow using a 5-point Likert scale ranging from strongly agree to strongly disagree. The survey was designed as a descriptive assessment of user experience among active users rather than a population-level evaluation.

Statistical Analysis

During the development stage, individual modified PDQI-9 scores were recorded for each physician's assessment. In contrast, during the implementation stage, the modified PDQI-9 scores were calculated by calculating the mean scores from 2 independent evaluators for each domain and then summing these domain-level means. The overall modified PDQI-9 scores were reported as mean (SD) and were calculated out of a maximum total score of 45 for Arabic conversations and 40 for English conversations, as the "translated accurately to English" domain was not applicable to English consultations. Since the modified PDQI-9 domain scores were ordinal Likert-scale measures and group sizes were unbalanced (40 Arabic vs 15 English consultations), comparisons between Arabic and English groups were conducted using nonparametric Mann-Whitney *U* tests. Differences between evaluator scores were quantified using the mean absolute deviation (MAD), calculated as the average of the absolute differences between paired domain scores. MAD was computed both overall and at the domain level. Descriptive statistics, including means and frequencies, were used to summarize the responses from the physician experience questionnaire.

Ethical Considerations

This study was approved by the institutional review board of King Saud Medical City (protocol H1R1-18-Sep23-01). Verbal informed consent was obtained from all participating patients prior to audio recording and was documented in the medical record. The use of verbal consent was approved by the institutional review board given the minimal-risk nature of the study and the practical limitations of obtaining written consent during routine clinical encounters without disrupting workflow. For pediatric patients, consent was obtained from parents or guardians. All data collection, storage, and analysis procedures were conducted in accordance with confidentiality requirements and complied with the Saudi Data and Artificial Intelligence Authority PDPL [9]. No patient demographic information was collected, and independent evaluators assessed clinical notes without access to any identifying data. Patients did not receive financial compensation for participation, and physicians participated as part of their routine clinical duties.

Results

Feasibility Pilot

During the development stage of the study, feasibility testing was conducted on 64 Arabic-language conversations, with the results summarized in Table 2. The overall mean modified PDQI-9 score across all domains was 42.2 (SD 2.98) out of 45. Clinical notes achieved the highest ratings in the domains of "useful," "organized," and "comprehensible," with mean scores of 4.86 (SD 0.39), 4.87 (SD 0.34), and 4.85 (SD 0.35) out of 5, respectively. The accuracy domain of version 1 of the pipeline was rated 4.35 (SD 0.82) out of 5. Relatively lower scores were observed for the thorough (mean 4.42, SD 0.81) and free from hallucination (mean 4.45, SD 0.85) domains, highlighting areas for further improvement. The identified strengths and limitations informed the subsequent fine-tuning and optimization of the AI pipeline.

Table . Domain-level performance of Sahl AI-generated clinical notes during the development (n=64) and implementation (n=55) stages, assessed using the modified 9-item Physician Documentation Quality Instrument (PDQI-9) tool[a].

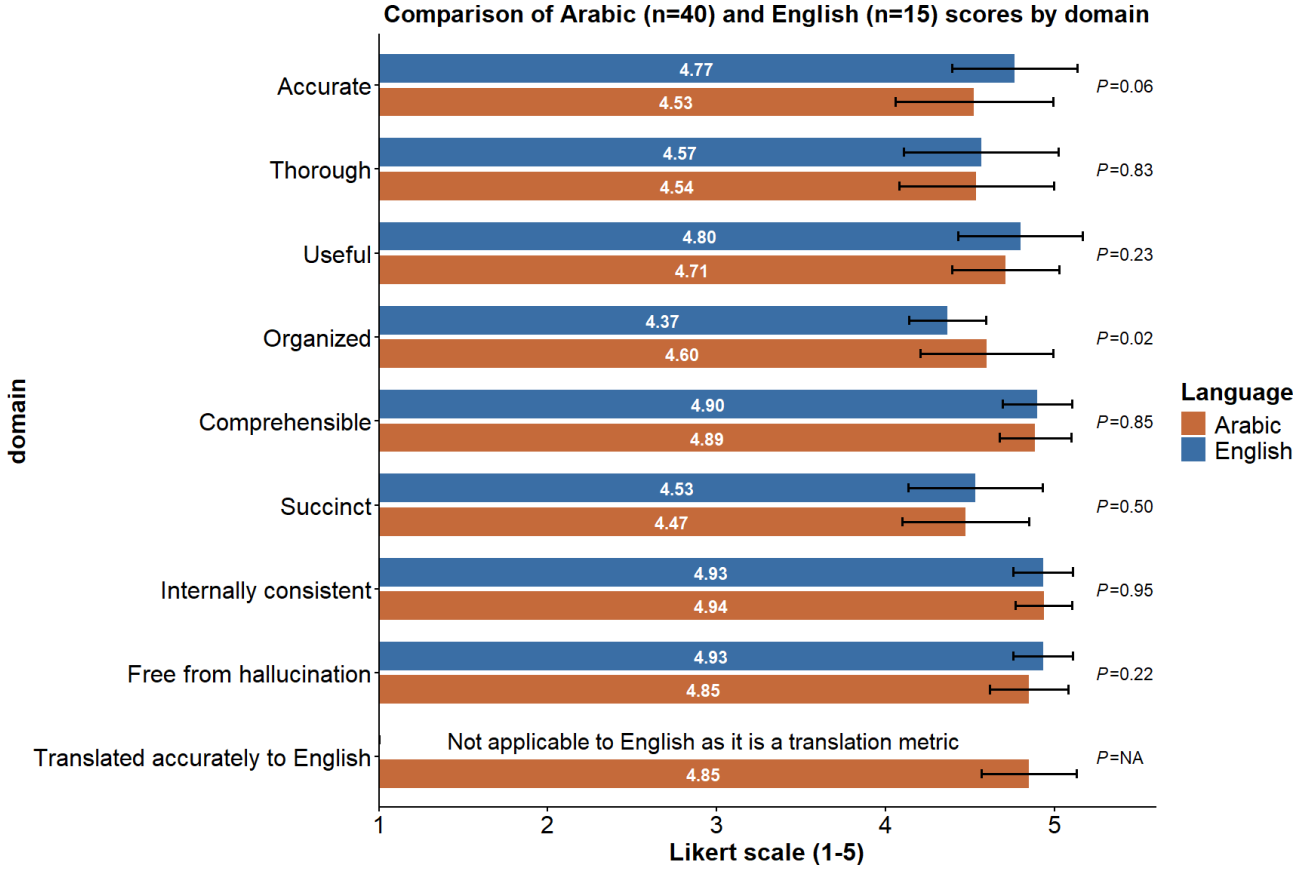
Domain	Development stage[b]		Implementation stage[c]	
	Number of cases	Mean (SD)	Number of cases	Mean (SD)
Accurate	64	4.35 (0.82)	55	4.59 (0.45)
Thorough	64	4.42 (0.81)	55	4.55 (0.45)
Useful	64	4.86 (0.39)	55	4.74 (0.33)
Organized	64	4.87 (0.34)	55	4.54 (0.37)
Comprehensible	64	4.85 (0.35)	55	4.89 (0.21)
Succinct	64	4.84 (0.45)	55	4.49 (0.38)
Internally consistent	64	4.73 (0.60)	55	4.94 (0.17)
Free from hallucination	64	4.45 (0.85)	55	4.87 (0.22)
Translated accurately to English	64	4.79 (0.49)	40	4.85 (0.28)

[a]Values represent mean (SD) Likert-scale scores for each documentation quality domain. The overall mean modified PDQI-9 scores are reported separately for Arabic (out of 45) and English-translated (out of 40) conversations.

[b]Average for development stage: 42.2 (SD 2.98) out of 45.

[c]Average for implementation stage: Arabic: 42.4 (SD 1.84) out of 45; English: 37.8 (SD 1.10) out of 40.

XSL•FO
RenderX



Real-World Implementation

During the implementation stage, real-world testing was conducted in family medicine clinics at King Saud Medical City (Riyadh First Health Cluster). Independent evaluators reviewed 55 new-patient consultations using the modified PDQI-9 tool; 40 consultations involved predominantly Arabic physician-patient conversations, and 15 involved English conversations. The mean modified PDQI-9 score was 42.4 (SD 1.84) out of 45 for Arabic consultations and 37.8 (SD 1.10) out of 40 for English consultations (Table 2).

Across all cases, clinical notes achieved the highest scores in the domains of "internally consistent," "comprehensible," and "free from hallucination" with mean scores of 4.94 (SD 0.17), 4.89 (SD 0.21), and 4.87 (SD 0.22) out of 5, respectively. The mean accuracy domain score for version 2 of the fine-tuned and optimized AI pipeline was 4.59 (SD 0.45) out of 5 across both language groups. Mean scores exceeded 4.5 out of 5 across all domains except for "succinct," which scored 4.49 (SD 0.38), suggesting a tendency toward more verbose clinical notes.

Domain-level scores for Arabic and English encounters were analyzed separately and are presented in Figure 2. A statistically significant difference was observed in the "organized" domain, with higher scores for Arabic compared with English conversations (4.60, SD 0.39 vs 4.37, SD 0.23; P=.02). There was a trend to the English conversations having higher accuracy compared with Arabic conversations (4.77, SD 0.37 vs 4.53, SD 0.46; P=.06). No statistically significant differences were observed across the remaining domains.

Figure 2. Comparison of mean Likert-scale scores for clinical notes generated by Sahl AI, as evaluated by independent reviewers, for Arabic and English conversations across each modified 9-item Physician Documentation Quality Instrument (PDQI-9) domain. Error bars indicate ±1 SD. Between-group differences were assessed using the Mann-Whitney *U* test. NA: not applicable.

Interevaluator Agreement

Interevaluator agreement across modified PDQI-9 domains is presented in Table 3. Overall agreement between evaluator group 1 and evaluator group 2 was high, with a mean absolute deviation of MAD=0.36, indicating close concordance in scoring. Across individual domains, MAD values ranged from 0.13 to 0.66 on a 5-point Likert scale, demonstrating that evaluator ratings typically differed by <1 point. Exact agreement of scores ranged from 34.5% to 87.3%, while agreement within ±1 point on the Likert scale was consistently high across domains (96.4% - 100%).

XSL•FO
RenderX

Table . Interevaluator agreement between evaluator group 1 and evaluator group 2 across modified 9-item Physician Documentation Quality Instrument (PDQI-9) domains[a].

Domain	Number of cases	MAD[b]	Exact agreement (%)	Agreement ±1 (%)	ICC[c]	Cohen kappa
Accurate	55	0.42	60	98.2	0.28	0.28
Thorough	55	0.40	60	100	0.35	0.35
Useful	55	0.35	65.6	100	0.13	0.13
Organized	55	0.60	43.6	96.4	0.12	0.12
Comprehensible	55	0.22	78.2	100	−0.07	−0.06
Succinct	55	0.66	34.5	100	−0.05	−0.05
Internally consistent	55	0.13	87.3	100	0.06	−0.05
Free from hallucination	55	0.26	74.5	100	0.00	0
Translated accurately to English	40	0.20	80	100	0.22	0.22

[a]Agreement is summarized using mean absolute difference, exact agreement (%), and agreement within +1 point on the Likert scale (%), intraclass correlation coefficient (2-way mixed effects, absolute agreement), and weighted Cohen kappa (squared weights).

[b]MAD: mean absolute deviation.

[c]ICC: intraclass correlation coefficient.

The highest interevaluator agreement was observed for the internally consistent (MAD=0.13; exact agreement 87.3%) and translated accurately to English domains (MAD=0.20; exact agreement 80%). Greater variability was observed in more subjective stylistic domains, including succinct (MAD=0.66; exact agreement 34.5%) and organized (MAD=0.60; exact agreement 43.6%). Despite lower exact agreement in these domains, agreement within ±1 point remained high (≥96.4%), supporting overall consistency between evaluators. To supplement the MAD analysis, the intraclass correlation coefficient (ICC; 2-way mixed effects, absolute agreement) and weighted Cohen kappa were calculated for each domain and are reported in Table 3. However, domain-level ICC and kappa values were markedly attenuated by ceiling effects, as 99% of the individual ratings were 4 or 5 on the Likert scale. Under such restricted variance, these metrics can yield paradoxically low or negative values despite high observed concordance; for example, the succinct and internally consistent domains each achieved 100% agreement within ±1 point yet produced negative ICC and kappa values. Given these distributional constraints, the MAD and percentage agreement metrics provide a more clinically meaningful assessment of interevaluator concordance in this setting.

Physician Experience

Physician experience with Sahl AI was evaluated to assess its perceived impact on routine clinical practice. A larger pool of physicians who may not have contributed to the development or implementation stage but used Sahl AI in their clinical practice was surveyed. In total, 22 physicians responded; however, as the total number of invited physicians was not systematically recorded, a formal response rate cannot be calculated, and these results should be interpreted as descriptive feedback from a convenience sample of unknown proportion. The results are summarized in Table 4. Most responding physicians strongly agreed or agreed across all domains that Sahl AI produced comprehensive notes, produced more complete notes compared with current practice, had the potential to save time and reduce physician burnout, was faster, while having a positive impact on their clinical workflow.

XSL•FO
RenderX

Table . Summarization of the physicians' responses to various statements related to the use of Sahl AI and impact on their clinical practice.

Question	Strongly agree, n (%)	Agree, n (%)	Neither agree nor disagree, n (%)	Disagree, n (%)	Strongly disagree, n (%)
Sahl AI produces comprehensive clinical summaries of the consultations	19 (86.4)	3 (13.6)	0 (0)	0 (0)	0 (0)
I feel that Sahl AI can produce more complete notes compared to current documentation practices	14 (63.6)	6 (27.3)	2 (9.1)	0 (0)	0 (0)
Sahl AI was faster and thus has the potential to save time in documenting comprehensive clinical summaries compared to the present practice	19 (86.4)	2 (9.1)	1 (4.5)	0 (0)	0 (0)
I feel that the use of the tool can help reduce physician stress/burnout	15 (68.2)	6 (27.3)	1 (4.5)	0 (0)	0 (0)
It was easy to use the Sahl AI tool	19 (86.4)	2 (9.1)	0 (0)	1 (4.5)	0 (0)
Sahl AI has the potential to positively affect my clinical workflow	16 (72.7)	4 (18.2)	2 (9.1)	0 (0)	0 (0)

Discussion

Principal Findings

This study demonstrates the feasibility and effectiveness of a bilingual Arabic-English medical ambient AI scribe in generating accurate, thorough, and clinically useful documentation in a real-world clinical setting. The study lays a foundation and benchmark for the successful deployment of medical AI technologies for low-resource languages, such as Arabic, and in the bilingual setting. The positive feedback from surveyed physicians regarding the tool's ease of use, potential for time savings and reducing burnout, producing more complete notes and impact on clinical workflow provides preliminary, descriptive evidence of its value in clinical practice. The results are especially relevant to health care systems in Arabic-speaking settings, where improving documentation efficiency and quality remains a critical operational priority. Furthermore, to our knowledge, this study represents the first end-to-end evaluation of a medical ambient AI scribe spanning audio capture to finalized clinical note generation for the Arabic language, extending beyond prior work that has primarily focused on transcript-to-note pipelines.

Comparison to Prior Work

There is a growing body of research evaluating the performance of ambient AI scribes in the English language, but their performance has not been rigorously assessed in other languages, particularly Arabic, which has multiple dialects and is considered a low-resource language in natural language processing due to a dearth of available datasets. This lack of evaluation poses a significant challenge, as the linguistic and cultural nuances of Arabic necessitate tailored solutions for the successful deployment of medical AI technologies in Arabic-speaking regions. Additionally, challenges in recording medical data, such as ensuring data privacy of health data and compliance with laws, such as PDPL, have contributed to this limitation. This study provides a crucial methodology for the collection of data and the training of ambient AI scribes in any language, especially low-resource languages, such as Arabic, which can help address these gaps and pave the way for the successful deployment of these technologies in diverse linguistic and cultural contexts.

Medical ambient AI scribes have been widely adopted in English-speaking health care settings and are generally reported to generate accurate and comprehensive clinical notes. For example, Tierney et al [7] reported a high documentation quality score of 48 out of 50 using a modified PDQI-9 when evaluating English physician-patient transcripts. In contrast, substantially lower scores have been reported in studies evaluating large language models, such as GPT-4, with PDQI-9 scores of 29.7 out of 45 in 1 study and 25 out of 35 using a modified PDQI-9 in another [10,11]. Kernberg et al [11] further noted that the AI-generated notes frequently omitted clinically important information, introduced hallucinated content, or contained factual inaccuracies and that note generation was not consistently reproducible. More recently, an English-language medical ambient AI scribe incorporating audio input in addition to transcripts was evaluated using a modified PDQI-9 tool, achieving a mean score of 41.9 out of 50 [12].

XSL•FO
RenderX

As a reference benchmark, the original PDQI-9 validation study categorized scores of 26.2 out of 45 as "terrible or bad," compared with scores of 36.6 out of 45 as "good or excellent" [8]. Evidence in non-English and low-resource language settings remains limited. A recent study by Lee et al [13] reported a score of 50.2 out of 65 using a modified PDQI-9 tool for synthetic Arabic transcript-to-note generation. Additional efforts have been reported in other non-English contexts, including Spanish-language AI scribe implementations in surgical outpatient settings [14].

In this study, the total mean score was 42.4 (SD 1.84) out of 45 for Arabic conversations and 37.8 (SD 1.10) out of 40 for English conversations. As in prior studies, the assessment instrument was modified to suit the study context. As these modified domains have not been formally validated, the aggregate scores should be interpreted with caution and are not directly comparable to benchmarks established using the original PDQI-9 instrument. However, unlike previous research that primarily assessed note quality based on written transcripts, this study introduces a novel approach by evaluating notes generated directly from original audio recordings of physician-patient consultations. These audio-derived notes were subsequently reviewed by independent evaluators, offering a more authentic and context-rich basis for assessing note quality. This methodology improves existing studies by considering errors from speech-to-text engines, performing an end-to-end evaluation to better reflect real-world situations rather than considering transcripts as ground truth. By evaluating the entire process from audio input to textual output, the approach ensures that the findings are applicable to everyday use cases, enhancing the robustness and reliability of the results. Although the summary of prior work focuses on PDQI-9 and its derivatives for easier comparison, other studies have utilized Recall-Oriented Understudy for Gisting Evaluation (ROUGE), Bidirectional Encoder Representations from Transformers (BERTScore), Crosslingual Optimized Metric for Evaluation of Translation (COMET), and Sheffield Assessment Instrument for Letters (SAIL), among others, which have not been discussed here.

Surveyed physicians perceived that the tool improved note accuracy and quality compared to the clinical practice of typing notes, resulting in more comprehensive and complete documentation compared to current practice. Most responding physicians perceived that the use of Sahl AI can reduce cognitive overload and save time, resulting in a positive overall impact on their clinical workflow. Such findings have been confirmed by other studies, especially showing that the use of ambient AI scribes leads to time saved and reductions in cognitive burden for physicians [10,15-21]. However, a recent report by the Peterson Health Technology Institute concluded that while AI scribes may reduce clinician burnout, it is unclear whether it actually saves time and leads to financial gains [22]. The report concluded that differences in outcomes were likely due to organization-specific metrics, which had variation in how they were defined and measured. Nevertheless, the result of this study is in line with the growing consensus that AI scribes can enhance physician efficiency by alleviating the cognitive burden associated with comprehensive documentation.

Limitations

This study used a single-arm design without a comparator, as comparative evaluation was outside the scope of this work. The absence of baseline comparisons in Arabic or bilingual settings with physician-authored documentation or generic large language models, both in the literature and in this study, limits the ability to draw conclusions regarding comparative effectiveness. Future studies incorporating head-to-head comparisons are required to establish relative performance.

The sample size was limited due to the practical challenges of collecting real-world audio data, which may affect the interpretability and generalizability of the findings. In addition, physicians used Sahl AI as a stand-alone web app that was not integrated into the electronic medical record. Electronic medical record integration is an important factor in simplifying clinical workflows and has been associated with the improved adoption of ambient AI scribes [21]. Real-world testing was conducted exclusively within the family medicine specialty; therefore, the findings may not generalize to other clinical specialties, and further evaluation across diverse clinical domains is warranted. Furthermore, the independent evaluation was conducted by physicians from the same health cluster; although evaluators were blinded to physician and patient identities, full blinding could not be ensured and may have introduced bias, especially as the raw audio was not modified to redact personal identifiable information.

The study did not include a systematic assessment of medical complexity between Arabic and English encounters, which may influence the interpretation of between-group comparisons. Future studies should capture encounter-level characteristics, such as number of medical entities spoken and number of diagnoses, to assess whether any observed language–based differences may be confounded by case complexity. Additionally, encounters were classified as Arabic or English based on the predominant language, without quantifying the degree of code-switching within individual consultations. This may limit the understanding of the model's performance in heavily code-switched versus predominantly monolingual encounters. Separately, a formal safety audit evaluating the potential clinical impact of documentation inaccuracies was not performed. Incorporating such assessments in future work may further strengthen the evidence base. While the training data included multiple Arabic dialects, performance was not systematically evaluated across specific dialect groups, limiting conclusions regarding dialect-level generalizability.

The physician experience survey was based on a convenience sample of clinicians who had used Sahl AI in at least 3 clinical encounters, which may introduce selection bias toward more engaged users. As the survey was distributed through direct outreach during deployment and the total number of physicians invited was not systematically recorded, a formal response rate could not be calculated. Consequently, the survey findings should be interpreted as descriptive user feedback rather than generalizable estimates of physician satisfaction or adoption. As such, the specific percentages reported from the survey should not be interpreted as representative of the broader physician population.

XSL•FO
RenderX

Since the completion of this study, subsequent iterations of the Sahl AI models have been released with improvements in accuracy and processing speed. Further research is needed to evaluate the clinical impact of Arabic medical ambient AI scribes, including objective measures of time savings, documentation quality compared with standard practice, effects on physician-patient interaction, and downstream operational and revenue-cycle outcomes.

Conclusions

This study highlights the potential of medical ambient AI scribe technology to enhance clinical documentation in both Arabic and English clinical environments. Sahl AI demonstrated the ability to generate high-quality clinical notes, with potential benefits including improved documentation quality, time savings, and reduced cognitive burden for physicians. To support broader adoption, future research should address the limitations identified in this study, including evaluation across diverse clinical settings and patient populations, as well as integration with electronic medical record systems. Importantly, this work provides a foundational framework for the development and training of medical ambient AI scribes in low-resource languages, such as Arabic, while also introducing a robust methodology for assessing the quality of AI-generated clinical documentation.

Acknowledgments

We would like to thank all the research assistants involved in labeling the audio data. Generative AI software (ChatGPT [OpenAI; GPT-5.2]) was used to improve the grammar of the text.

Funding

This study received in-kind support from Riyadh First Health Cluster, which funded the research activity of research assistants involved in data collection and labeling of data.

Data Availability

Aggregated modified 9-item Physician Documentation Quality Instrument scores, interevaluator agreement data, and physician survey responses are available upon request from the corresponding author. However, the raw audio recordings were permanently deleted 1 year after collection in accordance with ethics approval requirements and are no longer available.

Abstract

Background: Health care providers spend an excessive amount of time within electronic medical record (EMR) systems documenting patient encounters, often amounting to hours of work outside of regular office hours. This affects physician productivity and directly contributes to burnout. Artificial intelligence (AI) is becoming more integrated into medical care, including the development of speech recognition and note generation algorithms. Limited studies exist on how these AI tools affect provider satisfaction, work-life balance, and patient satisfaction.

Objective: The aim of this study was to assess the use of ambient AI in medical documentation and its effects on time spent in the EMR and on provider burnout, with a secondary focus on note quality and patient satisfaction.

Methods: This prospective study was conducted at the Hawaii Pacific Health Medical Group to pilot an AI note writer. Abridge was chosen as the AI platform and integrated with the Epic EMR. A goal of 75 providers for a 3-month pilot period was established from December 2024 through February 2025. Surveys were distributed to providers before and during the trial period. Epic Signal and Abridge data were used to correlate provider-perceived outcomes with EMR-recorded outcomes. Users were then divided into groups based on frequency of AI use, with high use defined as ≥60% AI scribe use in patient encounters. The primary outcome was time spent on documentation per appointment.

Results: A total of 80 providers were recruited, with 79 completing the pilot. More than 25,000 notes were generated across 23 specialties. Signal metrics found a 21% decrease in time spent on notes per day (−13.6 minutes) and a 13% decrease in pajama time (−3.6 minutes) among high users. Among 79 providers using ambient AI, 6 (7.6%) reported spending ≥8 hours per week on notes outside of clinic hours, a 76% decrease from 25 (31.6%) providers before the pilot. With ambient AI, 39 (49.4%) physicians reported no burnout symptoms, representing a 22% increase. Provider-perceived workload decreased, and self-reported note quality remained favorable. Providers reported that 84% of notes required edits to less than one-quarter of the note content. Patient experience, as measured by “provider listened to me” scores on patient satisfaction surveys, was not significantly affected by ambient AI use (P=.39).

Conclusions: This ambient AI scribe decreased the time providers spent writing notes in the clinic and decreased time spent in the EMR outside of work hours. There was no significant difference in symptoms of burnout.

(JMIR Med Inform 2026;14:e84104) doi:10.2196/84104

KEYWORDS

ambient artificial intelligence; documentation; burnout; work satisfaction; efficiency; health care technology; artificial intelligence; AI

Introduction

Physician workload and burnout have been directly tied to several factors, with one of the chief factors being time spent documenting in the electronic medical record (EMR) [1]. Burnout has been an increasing problem for physicians, and the EMR is closely tied to this, with 75% of providers identifying the EMR as a contributor to burnout symptoms [2]. This factor has recently become potentially modifiable with the influx of ambient artificial intelligence (AI) scribes in the market. These ambient AI scribes are part of a growing body of AI that uses large language models (LLMs) to train algorithms. LLMs train AI using large volumes of data and typically function to generate outputs (eg, text) in response to prompts, and they have generated much excitement around potential applications in health care [3].

XSL•FO
RenderX

Ambient AI scribes have a goal of reducing physician workload in the EMR while maintaining high standards of robust clinical documentation. Current literature surrounding ambient AI scribes in medical documentation shows that they reduce the amount of time physicians spend writing notes outside of work hours, with a perceived effect on time management [4,5]. The effect size of ambient AI scribe use on time savings and provider satisfaction has been shown to be most prominent among high users; however, the exact definition of a high user is not standardized, ranging from AI scribe use in 60% to 70% of notes across most studies [4,6,7].

AI scribes are being quickly and widely implemented across institutions in the United States; however, data on their outcomes are limited to a few single institutions, with most studies including small numbers of providers and lacking correlation with other important outcomes, including patient experience. There may also exist institutional differences in culture that change the effect of AI scribe implementation, which may only be uncovered with further institutional implementation and review. Additionally, there are many options for ambient AI scribes in the market, and their algorithms and capabilities are evolving rapidly, making the continued reporting of outcomes critical to this growing body of literature. This study sought to define how implementation of the Abridge ambient AI scribe at a single medical group impacted provider time in the EMR and how this technology affected self-reported symptoms of burnout, note quality, and patient satisfaction scores.

Methods

Setting and Selection of Participants

Participants were selected from the Hawaii Pacific Health Medical Group for this pilot program, which was conducted in an ambulatory setting. This medical group provides care across the islands of Hawaii and includes 4 hospitals and 70 clinics located statewide. A minimum participation of 75 providers was determined per agreement between the medical group and Abridge for a 3-month trial period. All selected providers attended an instructional session and completed a prepilot survey before they were allowed to use the AI tool. Any provider not meeting these prerequisites was dropped from the program and replaced by another provider. A total of 80 providers were recruited and met the prerequisites to begin use of the AI tool in November 2024. After a familiarization and onboarding period in November, the 3-month pilot program was conducted from December 1, 2024, through February 28, 2025.

Ethical Considerations

This study (2024-080) was reviewed by Hawaii Pacific Health Research Institute officials and determined to be exempt from the institutional review board's review, as it was determined to fall under a quality improvement initiative. Participants in this study were physicians who volunteered and agreed to participate. Physicians were not required to provide written informed consent to participate. After careful ethics review and consideration by Hawaii Pacific Health, it was decided that use of this ambient AI technology during health care visits would require verbal consent from patients prior to use, and this consent was documented in the encounter note. Patient refusals were not recorded as part of this study. Per the ambient AI company, recordings and transcripts are stored on secure HIPAA (Health Insurance Portability and Accountability Act)−compliant servers for 30 days before deletion. Notes were self-audited by providers prior to submission to the medical record to ensure that there were no inaccuracies generated by the ambient AI scribe in official clinical documentation. The research team deidentified data for distribution and publication.

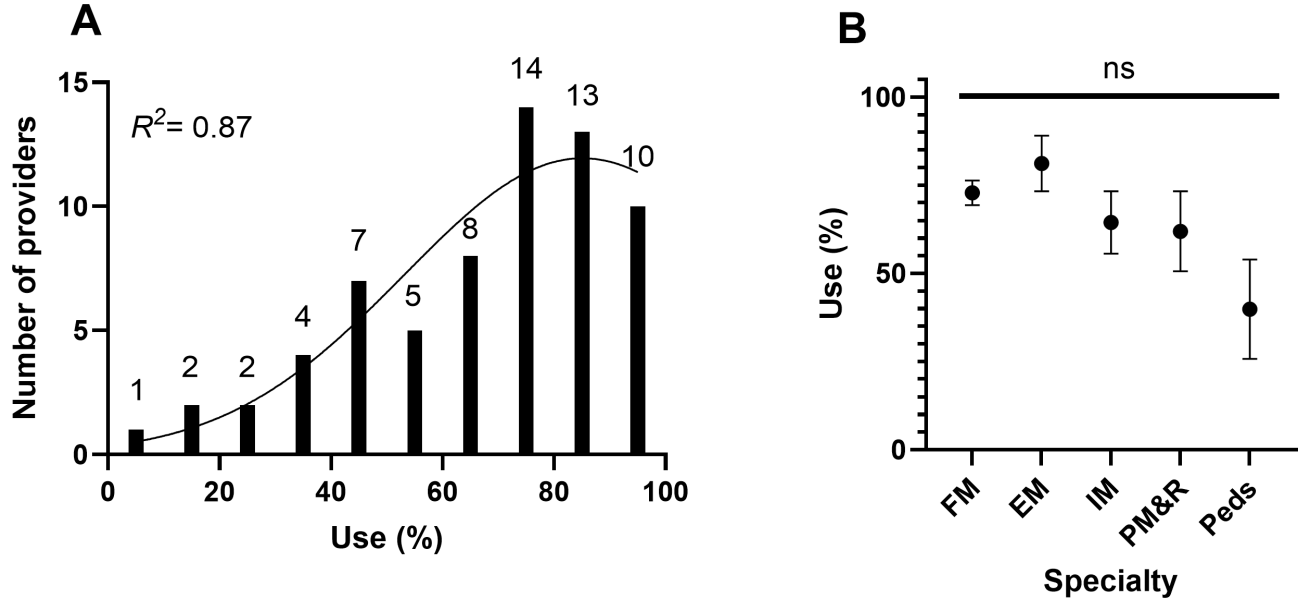
Data Collection

The conceptual framework for this study for data collection and analysis was primarily to evaluate time-saving capability, followed by burnout and workload demands. We sought to measure time savings using self-reported time in the EMR and relate those findings to actual time in the EMR using Epic Signal data. This information was then used to better understand self-reported workload demand and burnout survey results.

Data from the familiarization period were excluded from analysis as providers were added to the pilot and allowed time to learn the AI model. Safety of the AI-generated notes was determined by provider self-auditing of notes and was assessed using 5-point Likert scale responses and free-text responses from providers. To measure provider-perceived effectiveness of the AI tool, another survey with Likert scale scores was sent before and after the pilot (survey example shown in Multimedia Appendix 1). Surveys were not anonymous and were used to match provider responses from prepilot and postpilot results. Questions derived from the National Aeronautics and Space Administration–Task Load Index (NASA-TLX) scale were scored on a 21-point scale (0 - 20). The rest of the survey questions were scored on a 5-point scale, including burnout and perceived ability to provide undivided attention to patients. The survey also included a self-reported measure of time spent in the EMR outside office hours per week, with response options provided in 1-hour intervals ranging from less than 1 hour to more than 10 hours. All providers who were included in the study completed all surveys, totaling 79 surveys for each of the prepilot and postpilot periods. Provider charting metrics, including "pajama time," time in notes per appointment and per day, and number of characters used per note, were collected from Epic Signal. Epic defines pajama time as the average number of minutes per scheduled day spent on charting activities outside of 7 AM to 5:30 PM on weekdays, time outside scheduled hours on weekends, and time on unscheduled holidays. Patient satisfaction data for the proportion of patients responding "Yes, definitely" to the question, "Did this provider listen to you carefully?" on patient satisfaction surveys were collected from optional patient surveys and matched to each provider. Ambient AI scribe use metrics were collected and provided by Abridge. High use was defined as use of the ambient AI scribe on at least 60% of notes, in conformity with previously reported definitions [6]. An example of the survey for the precollection and postcollection periods is included in Multimedia Appendix 1.

Statistical Analyses

For simple outcomes, descriptive statistics were used. For categorical data, including burnout rates, patient satisfaction, and provider-reported work hours outside of normal office hours,



XSL•FO
RenderX

a chi-square test of association was used, and odds ratios (ORs) were calculated to test significant associations. Continuous variables, including Epic Signal metrics for time in notes per appointment, time in notes per day, pajama time, and progress note length, were compared with a paired 2-tailed Student *t* test. Likert scale questions were averaged for each group and compared with a paired 2-tailed Student *t* test, the results of which are displayed with a Gardner-Altman estimation plot to show effect size. To confirm internal consistency of the NASA-TLX data, Cronbach alpha was calculated and found to be 0.77, indicating acceptable internal consistency. A frequency distribution graph was created for all participants and fitted with a Gaussian distribution curve. Goodness of fit was determined by an R^2 value. A graph detailing use by specialty was created by graphing mean use with SE of the mean (SEM) for all specialties with ≥3 participants. Between-group use was then compared using a Brown-Forsythe ANOVA test with a post hoc Dunnett T3 multiple comparison test to compare each group. GraphPad Prism (version 10.6.1; GraphPad) was used for all statistical tests and graph creation.

Results

A total of 80 providers were recruited for this pilot study, and 79 (99%) providers completed the entire 3-month study period. Over this pilot period, more than 25,600 notes were generated and included in the analysis. Of the 79 providers that completed the pilot, 45 (57%) were in the high-user group, maintaining monthly use of Abridge in ≥60% of notes. There were 4 (5%) providers who used the AI on more than 1000 notes, with the highest-volume user generating 1415 notes in an urgent care setting. A total of 23 specialties were represented, with most from primary care, including 24 (30%) providers from family medicine and 12 (15%) from internal medicine. A frequency distribution fitted with a Gaussian curve is shown in Figure 1A, fit with a Gaussian curve. An R^2 goodness-of-fit test for the curve was 0.87, indicating a good fit. Average use by specialty with ≥3 participants was calculated for family medicine (mean 72.85%, SD 16.82%), internal medicine (mean 64.44%, SD 27.94%), emergency medicine (mean 81.16%, SD 19.39%), physical medicine and rehabilitation (mean 61.94%, SD 19.61%), and pediatrics (mean 39.84%, SD 24.39%; Figure 1B). An ANOVA did not find any difference in mean outcomes, and a post hoc multiple comparisons test did not find a significant difference between any groups (*P*=.13).

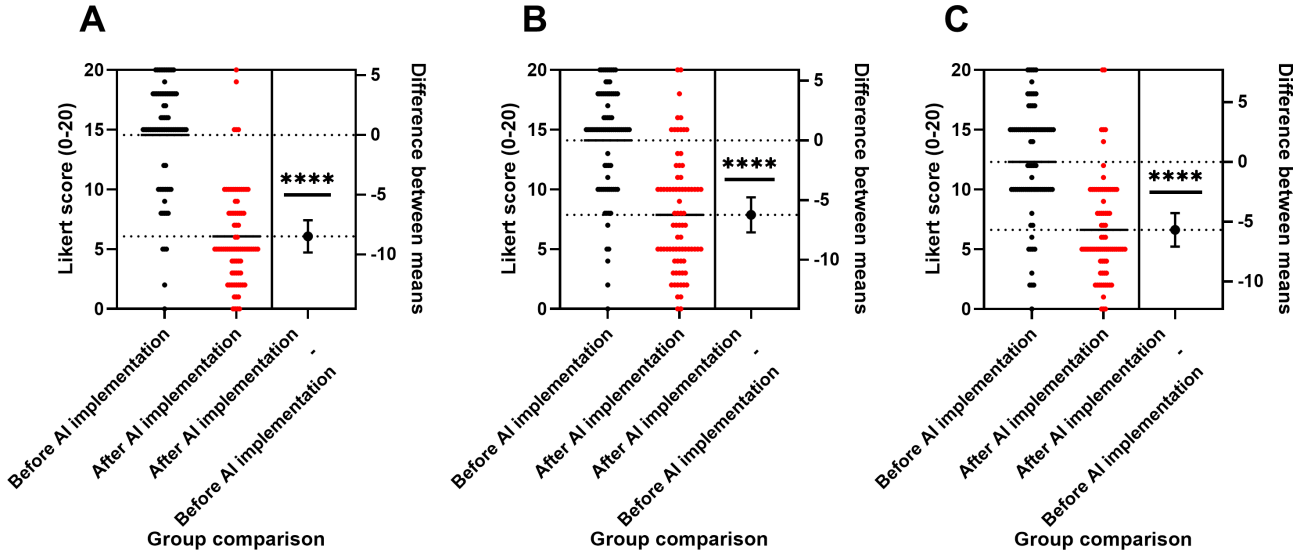


Figure 1. Ambient artificial intelligence scribe use among participating providers. (A) Frequency distribution of use among all pilot users. (B) Use by specialty for specialties with >3 users. EM: emergency medicine; FM: family medicine; IM: internal medicine; ns: no significance; Peds: pediatrics; PM&R: physical medicine and rehabilitation.

Provider-perceived outcomes for workload reduction using the NASA-TLX survey were quantified with pre-AI and post-AI surveys using Likert scale scoring for all 79 participants. A scale of 0 to 20 was used to assess providers' perceptions of mental demand, time demand, and effort. The average score for mental demand decreased by 46% (12.3 pre-AI score to 6.6 post-AI score; *P*<.001), time demand decreased by 58% (14.6 pre-AI score to 6.1 post-AI score; *P*<.001), and effort decreased by 44% (14.1 pre-AI score to 7.9 post-AI score; *P*<.001; Figure 2).

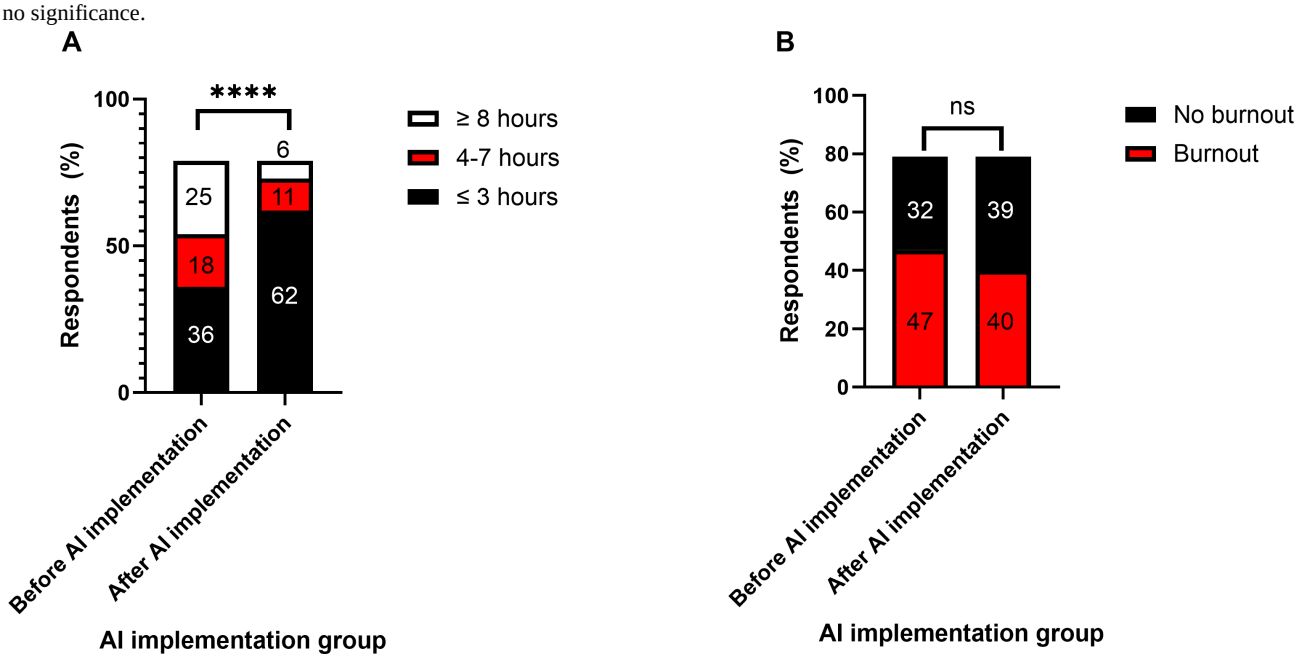

Figure 2. Provider task load questionnaire. In preimplementation and postimplementation surveys, providers were asked questions derived from the validated National Aeronautics and Space Administration–Task Load Index on workload perception. Results were shown for (A) "How rushed are you?" (B) "How hard do you have to work?" and (C) "How mentally demanding is writing notes?" AI: artificial intelligence. ****P<.001.

Provider self-reported symptoms of burnout were tabulated on a 5-point Likert scale, with responses of ≥3 indicating perceived burnout. Reported burnout declined by 15% from 47 (59.5%) to 40 (50.6%) respondents after using Abridge for 3 months; however, the change in proportions was not statistically significant (OR 1.4, 95% CI 0.8-2.7; P=.34; Figure 2). There was a 3% decrease (from n=3, 3.8% providers to n=1, 1.3% provider) in scores of 5, "I feel completely burned out. I am at the point where I may need to seek help." The average Likert score decreased from 2.8 to 2.6, but this difference was not statistically significant (P=.18).

Self-reported time in the EMR outside of clinic hours was also assessed on an hours-per-week basis. In the pre-AI survey, 25 (32%) providers reported working in the EMR outside of the clinic ≥8 hours per week, 18 (23%) worked 4-7 hours per week, and 36 (46%) worked ≤3 hours per week (Figure 3). In the post-AI survey, the number of providers reporting working ≥8 hours per week in the EMR outside clinic hours decreased to 8% (n=6), while those reporting 4 to 7 hours per week decreased to 14% (n=11). A total of 62 (78%) respondents reported spending ≤3 hours in the EMR outside of the clinic per week after implementing the AI tool. The difference between the pre-AI and post-AI groups was statistically significant (P<.001).

Figure 3. Provider self-reported survey responses for (A) time spent in the electronic medical record outside of clinic hours and (B) burnout symptoms before and after implementation of an ambient artificial intelligence (AI) scribe. Absolute values for respondents are placed within the bars. ****P<.001. ns: no significance.

Next, Epic Signal data were used to quantify objective changes in provider note creation and output among high users (AI used on ≥60% of notes). The average time in notes per appointment decreased from 7.14 minutes to 5.63 minutes (21% decrease; P=.005), while the average time in notes per day decreased by 21% (P<.001; Table 1). Pajama time decreased from 27.47

XSL•FO
RenderX

minutes per day on average to 23.89 minutes per day, a 13% decrease that was not significant (*P*=.19). There was an increase in the average number of characters per note by 7%, from 5741 characters to 6121 (*P*=.001).

Table . Epic chart use changes among high users.

Metrics	Baseline, mean (SD)	Pilot period, mean (SD)	Percentage change	95% CI of the difference in means	*P* value
Time in notes per appointment (minutes)	7.14 (3.54)	5.63 (3.50)	−21	−2.07 to −0.37	.005
Time in notes per day (minutes)	66.24 (37.04)	52.63 (31.21)	−21	−18.18 to −8.35	<.001
Pajama time (minutes)	27.47 (35.72)	23.89 (24.96)	−13	−5.77 to 1.20	.19
Progress note length (characters)	5741 (2433)	6121 (2615)	7	234 to 898	.001

Provider satisfaction with note quality was assessed using a 5-point Likert scale survey evaluating accuracy (eg, no hallucinations), thoroughness (eg, no critical omissions), appropriateness of tone, and the proportion of the note that required editing. There were 494 notes that were analyzed for safety by this method. Favorable ratings (responses of 4 or 5) were high with accuracy at 86.6% (n=428), thoroughness at 82.5% (n=408), and appropriate tone at 90.3% (n=446; Table 2). Most of the AI-generated notes required little editing, with providers reporting that 83.6% (n=413) of notes required editing of less than one-quarter of the note, and 21.1% (n=104) of notes did not require any editing by the provider prior to submitting the note to the EMR. Only 13 (2.6%) of notes required editing of at least 75% of the note while 26 (5.3%) required 51%-75% of the note to be edited.

Table . Results of provider self-audited surveys assessing note quality and safety.

Responses	Accuracy, n (%)	Thoroughness, n (%)	Appropriate tone, n (%)
Not at all	12 (2.4)	14 (2.8)	13 (2.6)
(2)	11 (2.2)	13 (2.6)	6 (1.2)
Somewhat	53 (10.7)	68 (13.8)	38 (7.7)
(4)	218 (44.1)	198 (40.1)	149 (30.2)
Extremely	200 (40.5)	201 (40.7)	288 (58.3)

Patient satisfaction scores for “provider listened to me” were collected for each participating provider. A total of 3393 surveys were collected for high users during the prepilot period, and 2796 surveys were collected during the pilot period. Among all providers, the proportion of patients responding “yes, definitely” did not change. Among high users there was a nonsignificant increase in this score from 92.6% to 93.2% (OR 0.91, 95% CI 0.75-1.1; *P*=.36). In the pre-AI and post-AI surveys, there was a 17% increase in the mean Likert score (3.5 to 4.1 out of 5) for providers reporting that they were able to give undivided attention to patients during visits (*P*<.001).

Discussion

Principal Findings

In this pilot study conducted within a single medical group spanning multiple medical centers and clinic sites, we found that physicians who used the ambient AI scribe experienced an average reduction in time spent on notes and in the EMR. Not only did providers perceive improvements in EMR charting time, but they also reported decreased workload pertaining to clinic note-writing responsibilities. Despite these changes, there was no significant change in the distribution of symptoms of burnout by the end of the pilot period. Use among all participants was found to fit a normal Gaussian distribution, and there was no difference in use between specialties. Although high use was encouraged, 57% (45/79) of providers met high-user status.

Although we did find decreases in time spent within the EMR and on writing notes based on Epic Signal data, this time saving was relatively small, averaging only 13.6 minutes saved per day in note writing. This finding differs from the self-reported time spent in the EMR outside of clinic hours, where most providers reported hours of time saved per week after using the ambient AI scribe. This could represent an error in judgment among providers given relative differences in individual interpretation. Interpretation of this discrepancy is further limited by the inclusion of all participating providers in survey analyses, while only high users were included in the analysis of Signal metrics. This may also point to the usefulness of an ambient AI scribe as a mental offloading tool, where, despite less time saved than perceived, there is still a benefit for providers. This coincides with NASA-TLX data, where the validated index for mental workload found significant decreases in perceived workload on average [8].

This reduction in mental workload did not directly translate into reduced burnout, as the change in burnout was not statistically significant. Burnout is not reliably reduced by ambient AI scribes in studies thus far. Our study used a coarse, nonvalidated

XSL•FO
RenderX

measure of burnout, which limits interpretation and is prone to bias. However, ongoing studies seek to use validated burnout metrics and to better understand the relationship between perceived mental workload reduction and burnout outcomes.

Comparison to Prior Literature

Previous literature on ambient AI scribes has been mixed in terms of outcomes and efficacy. The largest study to date, conducted by Kaiser Permanente in California, was published in 2024 and reported the results of a pilot program using Abridge among approximately 1000 providers [4]. Although this study is large, the authors performed analyses on all providers who generated at least 100 notes with the ambient AI scribe and did not stratify results by use status, thereby limiting direct comparison with our data. Despite this limitation in direct comparison, their study also found decreased time spent in the EMR and noted overall favorable remarks from physicians and patients alike.

One major limitation in the literature is the lack of data on long-term use, which these Kaiser Permanente authors recently published in a 1-year follow-up study [9]. The group found 15,700 hours of time saved in clinical documentation for AI scribe users compared to nonusers over the study year, with continued uptake and use, especially among high users, whom they define as the top third of users. Further long-term data collection will be necessary to examine the maintenance of time savings and the potential effects on loss of participants through attrition.

As this scribe is released to more providers, it can be anticipated to aid in increasing provider satisfaction, retention, and longevity, all of which have been declining critically short nationwide [10]. How ambient AI scribes affect burnout is also contested, with some studies finding significant improvements while others, including this study, have found no significant difference [11-14]. Although benefits for burnout remain contested, perceived reductions in workload are consistent across studies and are in agreement with our findings [11,12]. Additionally, subgroup analyses of outcomes for different specialties remain limited, especially outside the realm of primary care [15].

Safety and Patient Experience

A secondary outcome of this study was to determine the safety of this ambient AI scribe to ensure that patients and physicians are protected. Providers considered the ambient AI scribe safe to use for their patients, as long as there was examination of each note prior to submission, because, although infrequent, hallucinations and omissions occurred. Ensuring that notes encompass the critical visit details without omissions or hallucinations is a critical metric for all stakeholders. Our study used provider self-auditing and self-reporting on random notes to examine the safety profile. Independent validation of ambient AI safety is difficult because the underlying development of LLM algorithms is proprietary and varies between products, so we must rely on output metrics. Other studies have attempted to define the safety of these products but largely reach similar conclusions: even when these tools are effective, there are noticeable rates of errors, with the most common being omissions [16-18].

Patient satisfaction is also imperative to assess during this rollout to ensure that the introduction of new technology does not hinder or negatively affect the patient-physician interaction. Our results showed no change in patient satisfaction scores for providers participating in the pilot. Although we found that high users had a nonsignificant increase in the “provider listened to me” score on patient surveys, more data collection over time with longer implementation will be more useful for the interpretation of this effect. Other literature on patient perception of the impact of AI scribes on clinic visits is limited. One study surveying 21 patients at a single clinic found that 71% of patients said they felt they spent more time with their physician, while only one patient said they spent less time [4].

Limitations

There are several limitations to this study. First, we rely, for several metrics, on self-reported survey responses, which are prone to bias. Although we attempted to substantiate some self-reported responses with objective measures, such as time spent in notes outside of work, this could not be accomplished for all metrics. This is particularly true of burnout. Second, self-auditing notes for safety are similarly prone to bias. This form of note evaluation is suboptimal for an in-depth analysis of note-writing capacity for this ambient AI. However, we did not include more thorough objective measures of note-writing analysis as this was not the primary objective of the study, and this area has already been studied for this technology platform [18,19]. Third, despite encouragement to participate, only 45 of the 79 participants met high-user status by using the ambient AI scribe in at least 60% of notes. This decreases the power of the study and points to barriers to uptake that are multifactorial and should be subject to further study.

Future Directions

The findings presented here offer opportunities for further study on ambient AI in the clinical workspace. One opportunity is to expand the cohort to increase the power of the study. By increasing the number of participants, we will also increase the representation of different specialties for subgroup analyses to better understand whether this technology is better suited to specific roles. Expanded power and use of a validated instrument for assessment of burnout will aid in the analysis of the interplay between workload reduction and burnout outcomes [20]. Furthermore, recording and analyzing patient refusals of ambient AI scribe use during encounters, as well as the reasons for those refusals, may elucidate a better understanding of how incorporation and patient education can be improved. Next, further analysis of outcomes by use group (high user vs low user) would improve understanding of the application of this technology and its association with work-life benefit outcomes. Additionally, our providers noted limitations with non-English speaking encounters where there may be an increased occurrence of errors. Noted problems with non-English encounters include the difficulty of the ambient AI scribe picking up contextual exchanges, translating details, and reducing the need for extensive editing in non-English languages. Further study of limitations in these scenarios will aid in improved product

XSL•FO
RenderX

development and application to patient care. Finally, ambient AI scribes represent a rapidly evolving landscape with continuous changes and improvements across platforms and interfaces. These changes are anticipated to enhance usability while improving workflow. For example, queuing orders captured during discussion and recommending appropriate evaluation and management service levels are planned integrations that could improve time-saving capability, reduce mental workload, and mitigate burnout, especially since poor EMR usability has been tied to burnout [10].

Conclusions

This pilot study of 79 providers in a single medical group evaluated the implementation of the Abridge ambient AI scribe and found a decrease in note-writing time in the clinic. There was no significant difference in reported burnout symptoms, although self-reported workload did decrease.

Acknowledgments

The authors thank Hawaii Pacific Health Medical Group's artificial intelligence (AI) working group—Emi Thieme, James Lin, and Eric Chang—for their participation in weekly improvement meetings and contributions to ambient AI implementation. The authors also thank Abridge Inc for providing provider use data and assisting with provider training on the platform.

Funding

No funding was provided for this study. The authors received no compensation from Abridge Inc. JPL and WH participated in the ambient artificial intelligence working group as part of their employment with Hawaii Pacific Health Medical Group and received no special funding for this project.

Abstract

Background: The increasing documentation burden on physicians is a significant contributor to burnout and decreases in care quality. Artificial intelligence (AI) has been proposed as a solution to reduce documentation burden in clinical care, but there are very limited data on its use in the inpatient and intensive care unit (ICU) environments.

Objective: This pilot study aimed to explore the feasibility of using AI-assisted ambient scribes to capture interprofessional ICU rounds and synthesize a singular document to improve documentation efficiency and clinician satisfaction during ICU rounds. In this paper, we showcase our findings from customizing prompts for large language models (LLMs) to generate and evaluate daily progress notes from transcripts of simulated ICU cases.

Methods: This project is divided into 2 phases. In the first phase, a randomly selected transcript of an audio recording of a simulated ICU rounds case was used to iteratively evaluate and improve the prompts for the LLMs. Multiple models (n=5) were used in phase 1, and the best-performing model (M1, based on the highest accuracy) was selected for the next phase. In the subsequent phase, 5 cases were selected and evaluated using the refined prompt and 2 models: M1 from phase 1 and M6, a technological upgrade of M1. Accuracy and error percentages were used as primary metrics. Additionally, error severity and usability were assessed using the Harm scale (adapted for potential harm risk) from the Agency for Healthcare Research and Quality and the 9-item Physician Documentation Quality Instrument, respectively.

Results: Iterative improvements to the prompt increased accuracy and reduced errors during phase 1. In phase 2, M1 and M6 achieved accuracies of 69% and 80%, respectively (P=.04). Overall, errors of omission were most common (mean 15.5%, SEM 2.7%), followed by partial errors (mean 7.2%, SEM 0.92%) and then errors of commission (mean 2.6%, SEM 0.7%). The error severity of both models was low (μ=0.61 vs 0.53; P=.10), with most errors categorized as having potential for no harm to low harm. Both models performed well on the 9-item Physician Documentation Quality Instrument assessment, with the M6 model outperforming the M1 (35.8 vs 38.3; P=.06).

Conclusions: Our findings demonstrate the feasibility of integrating AI-assisted scribes for ICU documentation. Both prompt improvements and technological advancements in LLMs are noted to be helpful. This study lays the groundwork for future research into AI applications in ICU settings, paving the way for broader improvements in health care documentation.

Introduction

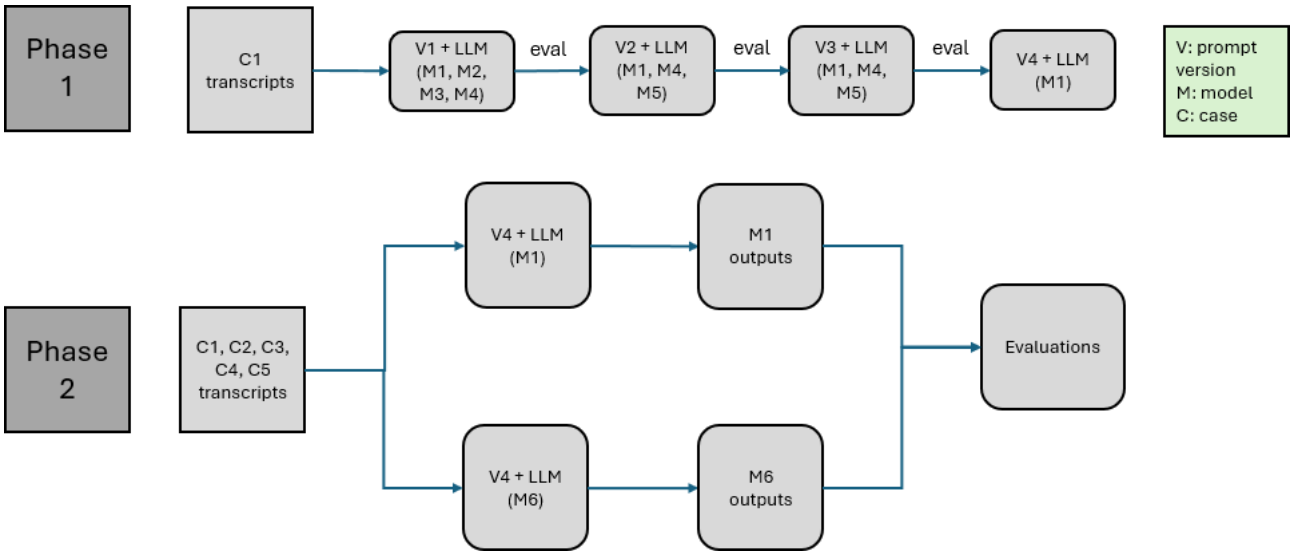
Physicians spend considerable time on documentation, a major risk factor for physician burnout [1]. This can lead to many clinicians leaving health care [2]. Furthermore, documentation burdens decrease patient care quality and increase medical errors [2]. Artificial intelligence (AI) has been proposed as a solution to address these health care challenges, including reducing the documentation burden [3,4]. Reducing clinical documentation should provide clinicians with more time to focus on patient care. This has the potential to improve provider satisfaction,

XSL•FO
RenderX

patient safety, and quality of care while also saving substantial health care costs [4-6].

Recently, there has been a significant increase in the use of AI-assisted scribes in health care, especially in the outpatient setting and in primary care [7-10]. Many vendors have developed different versions of this product [11,12]. There are 2 primary components to the use of AI scribe technology [11]. First, the AI scribes capture ambient sound and generate a transcript, known as automated speech generation. The second component of AI scribes uses large language models (LLMs) to convert transcripts into AI-generated notes. Early results from outpatient implementations demonstrate reductions in documentation time, leading to greater efficiency, decreased physician workload, improved patient engagement, and increased physician satisfaction [7,9,10,13,14].

However, the use of this technology remains underexplored in inpatient and intensive care unit (ICU) settings. To our knowledge, no studies have examined the use of AI scribe technology in the ICU. ICU rounds are significantly different from comparable workflows in other clinical environments [15,16], especially those in the outpatient domain, where 1 clinician typically sees 1 patient in a private room, sometimes accompanied by one or more family members and/or friends. However, in the ICU setting, patient information is discussed during daily rounds [16]. The rounds are usually conducted in an open area outside the patient rooms within the ICUs. ICU rounds typically involve an interdisciplinary team with several members present, including an attending physician, trainees at different levels of graduate medical education, nurses, respiratory therapists, pharmacists, and potentially others, depending on the patient and the ICU staffing model [16]. Finally, in addition to the numerous members within each team, multiple teams frequently conduct rounds in the same clinical environment. Members of one or more teams may speak at the same time. Task and conversation interruptions are also quite common [17-19]. This makes the task of using AI-assisted ambient scribes much more challenging.



We aim to assess the feasibility of AI scribe technology in the ICU. In this pilot study, we assess the feasibility of AI-assisted ambient scribes for capturing interprofessional rounds and synthesizing a singular document. We focused on customizing the prompt for the LLM to generate daily progress notes from transcripts of simulated ICU rounds. The process involved prompt engineering to better align these notes with ICU settings and improve their quality. After optimizing the prompt, we performed early evaluations of the notes using the best-performing model during customization and its upgraded version released during the study.

Methods

Overview

To address the challenge of documentation burden in the ICU setting, we aimed to explore the use of AI-assisted ambient scribes. This project was divided into 2 phases. Phase 1 focused on customizing the prompt for the LLM component of the AI-assisted scribes for ICU rounds, while phase 2 involved evaluating the quality of the generated notes using a customized prompt. Figure 1 illustrates the process map of our project.

Figure 1. Overview of the 2 phases of the study. Phase 1 involved iterative prompt improvements from version 1 to version 4, using the output quality from case 1 and 5 large language models. Phase 2 involved evaluating outputs from 2 models across 5 cases using prompt version 4. C1, C2, C3, C4, C5: case numbers; eval: evaluation; LLM: large language model; M1, M2, M3, M4, M5, M6: model names; V1, V2, V3, V4: prompt versions.

Data

We used software-generated and manually reviewed transcripts of audio recordings from simulated rounds designed by domain experts. The underlying cases were derived from real-world examples. The simulations took place in a real ICU environment to ensure high fidelity. A detailed description of this process can be found in an earlier paper by Bordley et al [20] from our lab.

Phase 1

Overview

In phase 1 of the project, 1 case (C1) was randomly selected to evaluate LLM prompt customization. This case was then run

XSL•FO
RenderX

through 5 different models (M1, M2, M3, M4, M5; descriptions in Multimedia Appendix 1) to generate an ICU progress note. Only models (Claude and Llama family) available through the Health Insurance Portability and Accountability Act (HIPAA)–compliant Amazon Web Services Control Tower at Oregon Health & Science University were used in this study.

Evaluations

In this phase, evaluations were conducted by 2 physicians (RV, SSB) with backgrounds in internal medicine and critical care, serving as clinical subject-matter experts. The case (C1) was broken down into key clinical data elements using the ICU progress note structure as criteria. Daily progress notes are generally divided into different sections using the SOAP (Subjective, Objective, Assessment, and Plan) note structure [21]. Physicians then independently classified these data elements as accurate or erroneous. Errors were classified into 3 subtypes using a previously validated taxonomy [22,23]: error of omission (the element was present in the transcript but absent in the output note), error of commission (the element was absent in the transcript but present in the note), and partial errors (either parts of the element were inaccurate or omitted). The average of the 2 raters was used for final calculations. For quantitative evaluation, the percentages of errors (including subtypes) and accuracy were calculated for each output. For qualitative evaluations, consistent themes were assessed within the errors. The prompt underwent 3 iterative rounds of updates incorporating insights from these evaluations: V1→V2, V2→V3, V3→V4. Table 1 details the changes made to each prompt version, and Multimedia Appendix 1 provides a detailed description of each version of the prompt with Multimedia Appendix 2 provides the exact prompts. Only 1 model was selected to move to phase 2 based on its consistently highest accuracy and the lowest error rate.

XSL•FO
RenderX

Table . Prompt updates.

Prompt version	Update	Rationale
V1	1. Initial draft 2. Introduced a hierarchical framework—main instructions detailing precise tasks, formatting guidelines, followed by a comprehensive medical record format with defined sections. Each section demands detailed extraction and organization from the ICU[a] transcript for clarity, completeness, and actionable continuity of care documentation	The initial prompt was structured based on an ICU documentation template created by team members with domain expertise
V2	1. Assigned role—a prompt engineering method instructing the model to perform explicitly as a clinical documentation assistant. 2. Modularly organized instructions—include an Instructions section guiding the model on medical record structure, tone, style, and content expectations, and a Special Instructions section that refines the model's output by correcting specific behaviors, enforcing completeness, and ensuring inclusion of critical clinical details. 3. Explicit direction for a thorough review of the transcript	Errors of omission were the biggest concern in the first iteration of the prompt involving both Subjective/24-hour events and Plan sections, so explicit language was added to the prompt to ensure completeness
V3	1. Introduced a new Orders & Medications subsection to capture and ensure inclusion of clinical details, such as new or discontinued treatments, that may not explicitly fit within other predefined sections of the medical record. 2. Stronger compliance and review instructions—enhanced the Special Instructions section to ensure detailed content in the Assessment and Plan, requiring each subsection to progress from observation to action, with explicit documentation of current status, identified concerns, and clearly defined intervention plans	Errors of omission, specifically in the Plan section of the note, led us to introduce this new subsection to ensure that the detailed plan is captured in the transcript. In earlier versions, a few outputs already included this subsection, but we decided to make it mandatory
V4	1. Optimized for model-specific behavior: tailored the prompt specifically for the Claude model family by refining language to align with Claude strengths and response patterns, ensuring clearer comprehension and more accurate output generation. 2. Added instructions to refine individual sections—such as relocated guidance for the Orders and Medications from Special Instructions into the <Medical Record Format> section, further classifying it into new and discontinued orders/medications	M1 was selected for subsequent evaluations, so the prompt was optimized to ensure consistency with the M1 family of models. Furthermore, the new subsection of Orders and Medications was broken down for clarity, as the data within this subsection included both instructions for new orders and discontinuation of old orders

[a]ICU: intensive care unit.

Phase 2

Overview

Based on the results of phase 1, using the selection criteria described above, the team decided to proceed with the M1 model for phase 2 of the project. Of note, M5 also performed on par with the M1 model; however, this was discontinued during the study period, resulting in exclusion from phase 2. This phase involved evaluating the M1 model (Claude 3.5 Sonnet) using new simulated cases and prompt version V4. Additionally, a new model, Claude 3.7 Sonnet, became available as a direct upgrade from Claude 3.5 Sonnet. Five cases (C1 from phase 1 and 4 additional randomly selected cases—C2, C3, C4, and C5) were used in this phase of the study to assess whether the prompt generalizes well to other cases and to compare the performance of the new model (M6) with the model (M1) previously selected from phase 1.

XSL•FO
RenderX

Evaluations

Phase 2 evaluations were conducted by 3 physicians (RV, SSB, JAG) with clinical subject-matter expertise. JAG was included to leverage their expertise and provide additional objectivity, since JAG was not involved in developing the prompt, the list of clinical elements, or phase 1 of the evaluations. Similar to phase 1, RV and SSB broke down each case in phase 2 (C1-C5) into key clinical elements using the transcripts as ground truth. Hallucinations, that is, unsupported information noted in each output (M1 and M6 for each case), were added to this list of elements. For each case, there was only 1 list of elements (ie, the same number of total elements) to ensure comparability between the models. RV, SSB, and JAG then classified these elements into 4 categories (omission, commission, partial, correct), similar to phase 1. For quantitative evaluation, the percentages (with the denominator equal to the number of elements in each element list and equal weighting for each element) of errors (including subtypes) and accuracy were calculated for each output. To ensure consistency, interrater reliability was measured using Fleiss' κ score for the preliminary rating. The kappa for the initial classification of errors and correct responses was 0.58 among all 3 raters. Discrepancies were resolved through collaborative review by all 3 raters until consensus was achieved. Errors in the transcripts were not graded as their limited number did not provide meaningful insights into the model's behavior. Examples of transcript errors and model behavior are provided in Table S1 of Multimedia Appendix 1. We have also reported the error percentages for each SOAP category. As in phase 1, qualitative evaluations were performed to identify consistent themes within the errors.

Additionally, the error severity was evaluated separately by all 3 raters using the potential clinical harm of each error. We adapted the previously validated Agency for Healthcare Research and Quality (AHRQ) Harm Scale [23,24] for our study to assess the potential risk of harm associated with each error (Table S2 in Multimedia Appendix 1). Fleiss' κ was calculated to evaluate interrater agreement. The κ for initial severity scoring was 0.91 among the 3 raters. Disagreement was defined as differences of 2 or more points between any 2 raters. Cases with disagreement (scoring differences of 2 or more) were further reconciled by all 3 raters. For all other cases, the average score of the 3 raters was used for analysis. The error severity score was categorized into 3 levels: no harm potential (AHRQ score=0), low harm potential (AHRQ score >0 and <2), and moderate-to-fatal harm potential (AHRQ score ≥2).

Finally, 2 raters (RV, SSB) rated the quality of the notes using the 9-item Physician Documentation Quality Instrument (PDQI-9) [25]. Additionally, note structure was also evaluated by comparing note length with errors and accuracy.

Statistical Analysis

Using the percentages and themes of errors from phase 1 (described above), the prompt underwent 3 rounds of updates: V1→V4. Phase 2 evaluations involved comparing the accuracy and percentage of errors using prompt V4 and models (M1 and M6) across 5 separate cases (C1-C5), as described earlier. A Shapiro-Wilk test was used to check the normality of the data. Boxplots were created to check for outliers. A paired 2-tailed *t* test (data were normally distributed, and there were no outliers) was performed to compare the accuracy and errors (including subtypes) between M1 and M6. Bonferroni correction was applied where applicable for multiple comparisons. To compare the overall (combined M1 and M6) percentage of error subtypes, a Friedman test followed by Bonferroni correction with multiple comparisons was used, as the data were paired. Mean error severity scores were compared between M1 and M6 using a paired 2-tailed *t* test (normally distributed, no outliers). The chi-square test was used to compare the error severity categories between models M1 and M6. Spearman correlation analysis was conducted between accuracy and note length. A Wilcoxon signed-rank test was conducted to compare the average of PDQI-9 scores between M1 and M6 outputs. A *P* value of <.05 was considered statistically significant. All descriptive statistics are quoted as mean/percentages (SEM). All analyses were performed using Python (version 3.12.1). Figures were generated with the Python packages Matplotlib and Seaborn.

Ethical Considerations

The study was deemed exempt by the institutional review board (7551) because only synthetic data were used to develop ICU rounds simulations. The synthetic data were derived from real-world cases covered under Institutional Review Board 9943.

Results

Phase 1

Five separate models were evaluated in this phase of the study with different versions of the prompts (Table 2 and Figure 2). At each stage, team members used a combination of quantitative and qualitative assessments of the errors (Figures 2 and 3 and Table 1) to decide which models would proceed. Most errors were related to omissions, and qualitative assessment revealed which sections and subsections of notes were most affected. These insights guided modifications to the prompts to address those errors. Models M2 and M3 performed poorly and were dropped early. M4 initially performed well but showed inconsistent results and a decline in performance after updates. Both M1 and M5 continued to perform well and responded positively to prompt updates at each stage. The team decided to proceed with M1 for the next phase of testing, as M5 was discontinued later in the study.

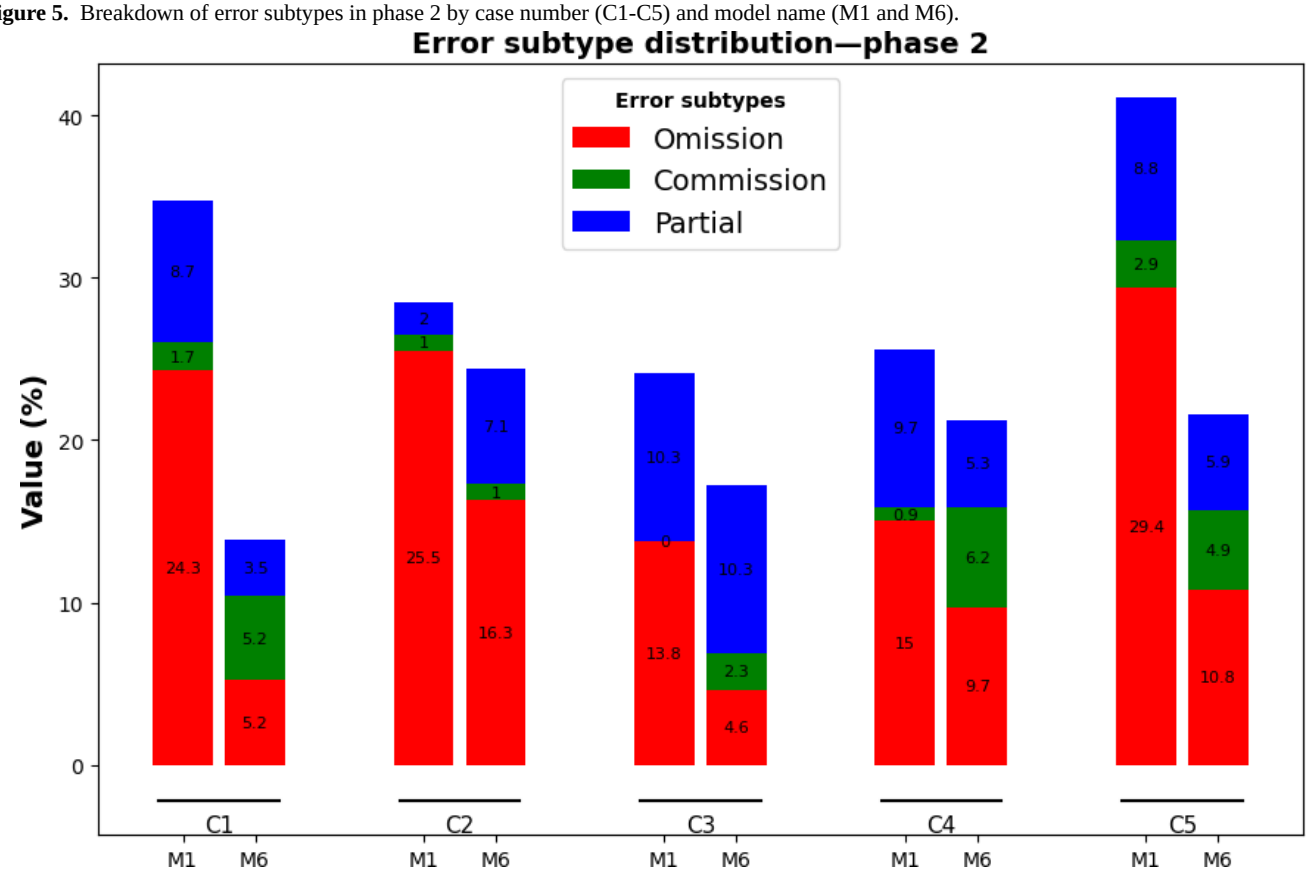
Phase 2

Based on phase 1 results, all phase 2 evaluations proceeded with version 4 of the prompt. Model M1 performed consistently across new cases, with an accuracy of 69.12% (95% CI 69.3% - 77.9%; Table 3 and Figure 4). In comparison, model M6, a direct upgrade of model 1 (Multimedia Appendix 1 for model description), performed better across all 5 cases, achieving an overall accuracy of 80.3% (95% CI 75.2% - 85.5%; *P*=.04).

Table . Phase 2 (prompt version 4): mean (SEM/SD) accuracy and error scores by each model.

Model name (n=5 cases)	Omission (%), mean (SEM/SD)	Commission (%), mean (SEM/SD)	Partial (%), mean (SEM/SD)	Accurate (%), mean (SEM/SD)
M1	21.60 (3.06/6.85)	1.30 (0.48/1.08)	7.90 (1.50/3.36)	69.12 (3.16/7.07)
M6	9.32 (2.12/4.75)	3.92 (0.97/2.18)	6.42 (1.13/2.53)	80.32 (1.85/4.15)

Figure 4. Percentages of accurate responses in phase 2. M1 and M6 represent models used in phase 2. C1-C5 represents 5 cases used in phase 2.



Regarding error subtypes, combined (both M1 and M6) errors of omission were the most common (Figure 5) with an average of 15.5 (SEM 2.7%, 95% CI 9.4% - 21.6%), followed by partial errors at 7.2 (SEM 0.92%, 95% CI 5.1% - 9.3%), with errors of commission being the least common at 2.6 (SEM 0.7%, 95% CI 1.1% - 4.1%). Overall comparison of combined errors was statistically significant (*P*=.001), with subcomparison statistically significant only between omission and commission (adjusted *P*=.02). In terms of absolute counts, the errors of omission occurred at an average of 16 (SEM 2.85) errors per case, while partial errors occurred at 7.3 (SEM 0.89) errors per case, and errors of commission at 2.8 (SEM 0.76) errors per case. Comparison of error subtypes between the 2 models showed that only omission errors (21.60% vs 9.32%; adjusted *P* value =.03) were statistically significantly different between M1 and M6. On a deeper analysis of the errors, we compared which parts of the SOAP note structures contained the most errors. For M1, we observed that 5.08%, 2.75%, 1.95%, and 21.09% of the errors belonged to the Subjective, Objective, Assessment, and Plan categories, respectively. Similarly, for M6, these numbers were noted: 5.06%, 1.24%, 2.63%, and 10.76%, respectively. Further qualitative analysis of errors, with notable examples (Table 4), showed that they were related to historical data, vitals, lab data, imaging results, problems, differentials, and plans. M1 and M6 had similar errors of omission and partial errors, with the primary difference being

XSL•FO
RenderX

quantitative: M6 had a lower proportion, as noted earlier. In contrast, errors of commission varied significantly by models, as noted in the examples in Table 4. Furthermore, most partial errors were omission-related.

Figure 5. Breakdown of error subtypes in phase 2 by case number (C1-C5) and model name (M1 and M6).

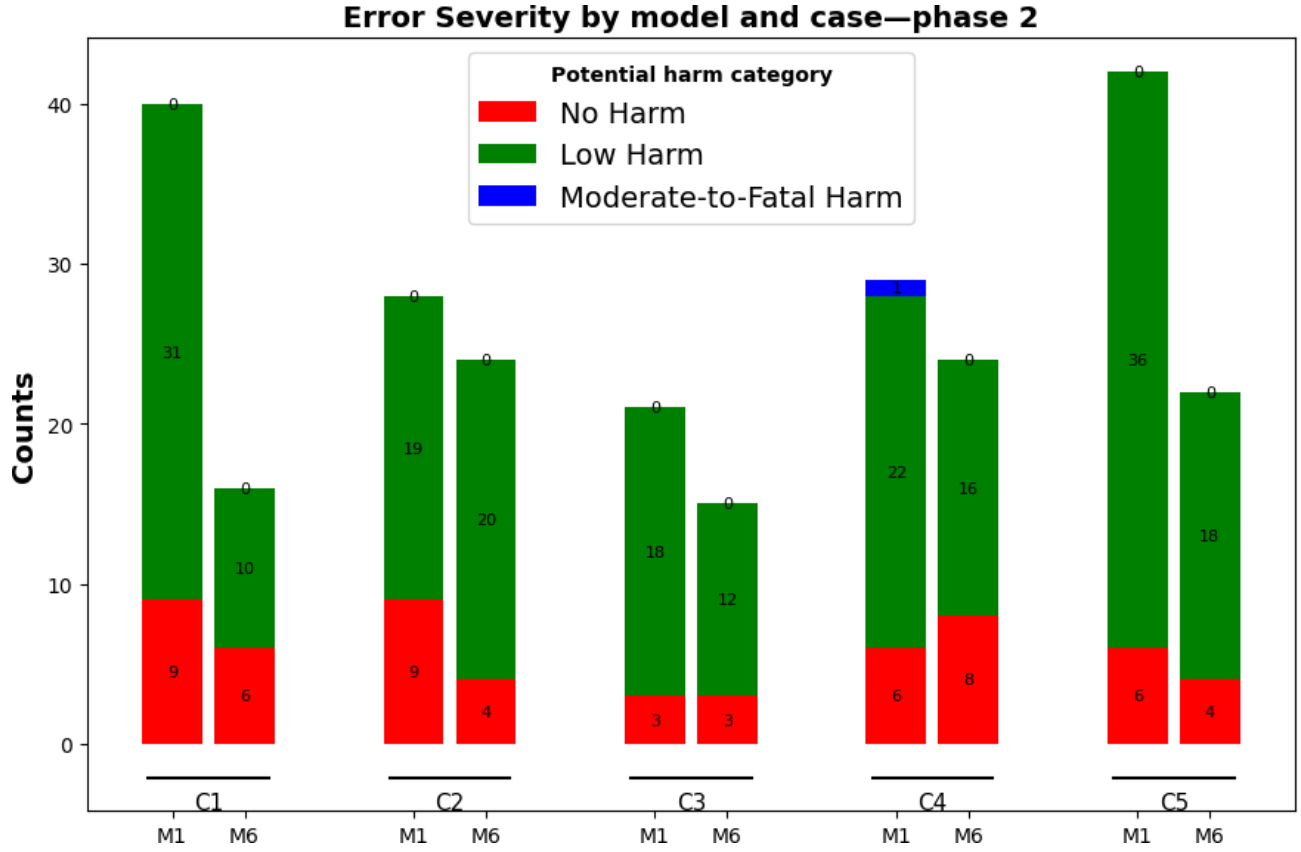
RenderX

Table . Qualitative results of error subtype analysis (phase 2).

Note category	Omission	Commission	Partial
History	1. Nurse's concern for flu isolation (M1, M6) 2. At home, the patient takes oxycodone (M1, M6) 3. Recent intubation for pneumonia, now extubated (M1, M6)	1. None	1. Nurse concern for diminishing urine output and 10 liters positive (10 liters is omitted) (M1) 2. Confirm with the patient if taking Hydrochlorothiazide at home with a plan to start later today after confirming (confirmation with the patient is omitted) (M1, M6)
Exam	1. Surgical site exam reported as "No report on surgical site" in the transcript (M1)	1. None	1. Mean arterial pressure is 79 - 84, systolic 130 s with a blood pressure cuff (systolic reading off the cuff is omitted) (M1)
Lab	1. Glomerular filtration rate =54 (M1) 2. Magnesium was 2 on 2/15 (admission) (M1)	1. None	1. Potassium—3.4, *was 3.1 more recently (recent comparison value is omitted*) (M1) 2. Sodium—stable at 142 (Stable is omitted) (M1)
Imaging	1. "she has a CT chest from 2011, x-ray times two from this admission. no comment about the vertebral bodies." (M1)	1. None	1. Chest X-Ray done while intubated on 2/22—Left lower lobe consolidation (while intubated is omitted) (M1)
Problem	1. "it's become a thing that her pain medication is starting to interfere with the rest of her medical issues as well." (M1) 2. Streptococcal bacteremia (M1)	1. Blood counts are stable (M1) 2. Transcript: "it's become a thing that her pain medication is starting to interfere with the rest of her medical issues as well." Output: "Pain is interfering with overall recovery and may be masking other symptoms." (M6)	1. Blood Pressures (BP) are normal, hold off resuming BP meds (Blood pressures are normal is omitted) (M1) 2. Creatinine is rising by 0.3 in the last 72 hours (last 72 hours is omitted) (M6)
Differential	1. New oversedation due to opioids (M1) 2. Cause of patient's mental status changes—medications (morphine, versed, oxycodone) (M1) 3. Differentials include prerenal/volume overload related (M1)	1. "anemia noted, likely related to critical illness." No discussion of causes of anemia in the transcript (M6) 2. Differentials include infection and ICU[a] stay for confusion. These causes are not discussed in the transcript (M6)	1. Differential Pulmonary Embolism given tachycardia/recent knee surgery (reasoning is omitted) (M1) 2. Stop morphine due to worsening renal function and age (cause is omitted) (M1)
Plan	1. "Continue oxycodone 5 - 10 q4h." (M1, M6) 2. "Repeat Basic Metabolic Panel at 2 PM." (M1) 3. Fluid balance positive, discontinue fluids (M1)	1. "No transfusion indicated at present, given stability." The transcript has no discussion on transfusion. (M6) 2. Code status: "will clarify with the patient." The transcript does not include any discussion of code status. (M6) 3. "Dispo: Continued ICU monitoring" (M1)	1. Start with X-ray lower back for imaging (output just says lower spine imaging—modality is omitted) (M1) 2. Discontinue lacri-lube, mouthwash (Output says—various post-intubation meds) (M1)



[a]ICU: intensive care unit.

The analysis of error severity showed that most errors (n) fell into the no harm or low harm categories (Figure 6). For the moderate-to-fatal harm category, M1 had errors at 0.2 (SEM 0.2) per case, whereas M6 had 0 (SEM 0). Furthermore, within the moderate-to-fatal category, no errors were classified as potentially severe or fatal. M1 had no harm errors at a rate of 6.6 (SEM 1.1) per case, compared to 5.0 (SEM 0.89) per case for M6, while low harm errors occurred at 25.2 (SEM 3.54) per case for M1 and 15.2 (SEM 1.85) per case for M6. The differences in severity between M1 and M6 were not statistically

XSL•FO
RenderX

significant (*P*=.55). Table S2 in Multimedia Appendix 1 provides examples of each harm score category and their descriptions. Finally, the difference in average error severity scores between M1 and M6 (mean 0.61, SEM 0.03 vs mean 0.53, SEM 0.05; *P*=.10) was not statistically significant either.

Figure 6. Breakdown of the error severity (harm potential) in phase 2 by case number (C1-C5) and model name (MA and M6). Error severity categories are defined as follows: (A) no harm: score=0; (B) low harm: score >0 and <2; (C) moderate-to-fatal harm: score ≥2.

In terms of note structure, the average note length for M1 and M6 outputs was 534.6 (SEM 35.7) and 1093.8 (SEM 57.5) words, respectively. Overall, a strong correlation was found between note length (*r*=+0.83; *P*=.003) and accuracy. Furthermore, note length had a very strong statistically significant negative correlation with errors of omission (*r*=−0.83; *P*=.003), and a strong positive correlation, albeit statistically not significant, with errors of commission (*r*=+0.62; *P*=.06). In contrast, there was no correlation with partial errors (*r*=−0.15; *P*=.66). Of note, when evaluated within models, the only significant correlation was between errors of commission and note length, within model M6 (*r*=+0.90; *P*=.04). Finally, in terms of overall readability and usefulness, M6 was better than M1 based on PDQI-9 scores, but the difference was not statistically significant (M1=35.8, SEM 0.78 vs M6=38.3, SEM 0.53; *P*=.06).

Discussion

Principal Findings

This study is the first of its kind to examine the feasibility of using AI-assisted ambient scribe technology in the ICU setting. Our findings show that the LLM component of the AI-assisted ambient scribes can be customized to capture interprofessional ICU rounds and produce a singular document aligned with ICU workflows. While the current literature is limited on the use of AI scribes in the ICU, our results suggest that the use of customized AI-assisted scribes in the ICU setting can generate similar outputs compared to outpatient AI-assisted scribe apps [26-28]. Our results demonstrate that prompt engineering plays a crucial role in improving note quality and customizing them for specific settings and formats. However, the variations observed between different LLMs using the same prompt indicate that technological optimization must address both areas. This aligns with other studies showing high variability in LLM models' performance with identical prompts [29-31]. Our study highlights the need to further investigate the use of AI-assisted scribes in ICU settings and the potential benefits of conducting additional research to validate our findings in a larger, more diverse cohort and to evaluate the accuracy of automated speech recognition components in scribes and their correlation with note errors.

Existing documentation practices are also prone to errors. Data omission is particularly common, with 100% of ICU patient presentations containing at least one omission in 1 study [32]. In at least 1 study, when physician trainees prepared prerounding notes and verbal presentations, 22.9% of the data were missing from written artifacts and 42.4% from the oral presentations [32]. Another study shows laboratory data communication during ICU rounds was similarly problematic, with 96% of patient presentations including at least 1 laboratory misrepresentation and 38.9% of all audited laboratory data being inaccurately communicated [33]. Most of these errors were

XSL•FO
RenderX

omissions rather than incorrect values, and only 7.8% were detected by the rounding team [33]. Our results show the viability of AI-scribe technology for accurately reflecting what is being discussed. However, as noted in these prior studies, interprofessional rounds in ICU settings are far from perfect, underscoring the need for standardization. In our study, we observed that most errors occurred in the Plan section, likely reflecting greater ambiguity in assessment and planning. However, the errors were in the objective or lab data in these prior studies. This further emphasizes the need to standardize verbal presentations; otherwise, we would just be compounding errors. Conversely, AI scribes should create notes that are free of copy-and-paste information, thereby reducing errors related to these mechanisms in the electronic health records [34]. In studies outside ICU settings, prior research has reported error rates ranging from 7% to 21% in clinical documentation, whether derived from dictation software (office notes, discharge summaries, and procedure notes) or patient-reported data (ambulatory notes) [35,36].

Upon closer examination of errors in AI-assisted scribe documentation output, we found that most originated from omissions. Therefore, our main focus in prompt engineering was to reduce missing elements in the generated note. One method to accomplish this was to add a gold-standard template to the prompt. The Plan section was divided into organ-based subsections, which helped identify issues related to specific areas, such as psychiatric problems including delirium and sedation, that were not always captured under the neuro subsection in earlier versions of the prompt. However, by explicitly including subsections for most organ systems in the note template, we observed that models sometimes generated plans for endocrine or hematology-oncology sections even when these were not discussed in the transcript. Although the generated content was not always incorrect or clinically significant, as shown in our qualitative results, for example, “anemia noted” when hemoglobin numbers are in the anemia range, this approach appeared to carry a risk of errors of commission, such as hallucinations or fabrications. Some errors could have a greater clinical impact, including statements such as “cause of anemia” or discussions of “transfusions.” This indicates a trade-off when using a more detailed template in the prompt to better capture data elements. Of course, this trade-off could be eliminated by using strategies to optimize the prompt to reduce errors of commission. This remains an area to be explored in future work.

To enhance completeness and reduce errors of omission, additional prompt engineering procedures included adding “New Orders,” “Discontinued Orders,” and a “Medications” subsection at the end of the note. This resulted in significantly improved performance. Interestingly, the transcripts also included a discussion at the end where the team listed the new and discontinued orders and medications for the day. This presents an opportunity for clinicians to adjust workflows to bring rounds closer to the note templates, thereby further improving transcript and note accuracy. However, future studies should examine the use of the ambient scribe in real-world ICU settings to ensure it does not impose additional tasks or cognitive burdens on the teams. This is especially important, given that the current safeguard against errors in AI scribe notes is manual review by clinicians, which adds an additional burden on clinicians and could lead to automation complacency and/or bias [37-42].

Besides prompt engineering, we found that upgrading LLMs also greatly enhanced performance. Once the prompt was set, using M6 (the larger model) yielded significantly better performance than the earlier version, M1. Part of this difference could be explained by M6’s ability to generate longer notes. We observed a strong overall correlation between note length and accuracy (and errors of omission); however, this correlation is primarily driven by between-model differences rather than a continuous within-model trend. Interestingly, there was a strong positive correlation between note length and overall errors of commission (primarily within model M6), although their impact on accuracy (and total error rate) was not large, as errors of commission constituted a much lower percentage of total errors. This shows a small trade-off between errors of omission and errors of commission depending on the model’s thoroughness or the length of the note. Although longer notes (model-dependent) appear to yield lower error rates, this could affect workflows, further burdening clinicians who would have to manually review longer notes. Ironically, as noted in another study [34], copy-and-pasted information increases the length of the notes, and AI-generated notes, in theory, should not contain copied-and-pasted information. Thus, generating longer notes by AI to reduce omissions might not have as much impact on workflows as anticipated and presents another opportunity for future research. This is evident in the perceived usefulness of these outputs in PDQI-9 scores, where the differences between model outputs are not statistically significant; in fact, the trend favors M6.

Another consideration when using ambient scribes in the ICU is privacy and confidentiality [41,42]. When assessing the feasibility of ambient listening devices in the ICU using the clinical rounds’ structure, which is generally an open environment (as opposed to office-based visits), we need to be mindful that these devices will capture speech from multiple clinicians, families, and ancillary staff. This has implications for consent procedures [41]. For example, would everyone in the ICU have to consent to AI scribes? What about people entering the ICU after rounds have started? Each state’s wiretapping laws may further complicate these regulatory issues [43]. Other regulatory considerations for the use of AI scribes include HIPAA compliance and data security [42], such as where these conversations are stored and for how long. Implementing institutional data governance policies, recording practice protocols, and keeping up with evolving guidance for AI-enabled tools is essential [44].

While the absolute number of individual errors was significant for both models, the severity of these errors was mostly low, categorized as no harm to low harm potential. Additionally, we observed that the error severity scores showed little difference between the 2 models. These results are encouraging, though it is too early to draw definitive conclusions given the small sample size and limited variation in clinical problems in our dataset.

XSL•FO
RenderX

Interestingly, in a few instances, LLMs seemed to extract the correct information from contextual clues, even when errors occurred in the transcripts. This is likely a probabilistic inference based on LLM training data. This could be a strength in ICU or inpatient settings, where open environments and ambient noise can affect transcript quality. However, the autonomous correction of clinical data without flagging it for a human being should be recognized as a potential safety risk. Incorporating safeguards, such as uncertainty signaling or explicit error flagging, could help reduce the cognitive burden of revisions needed after AI scribes generate a note. Since our data lacked sufficient errors in the transcripts to thoroughly analyze model behavior, this remains an area for future research.

Limitations

There are some limitations to our study. First, we did not investigate whether automated speech recognition software impacts transcript quality in ICU settings. While this is important, it was out of scope for this initial pilot to assess the feasibility of customizing the prompt for the ICU-specific setting. We plan to address this in our future work on this project. Second, the small sample size and the use of synthetic cases lacking significant clinical variation might overestimate the accuracy and would limit the generalizability of our findings. We also kept case C1 (used for prompt tuning in the first phase) as a baseline in the second phase for comparison; this could have somewhat inflated the quantitative results, as the prompt was optimized specifically for case 1. Since our synthetic cases were developed from real-world ICU rounds, they partially captured the nonlinear reasoning and diagnostic uncertainty expected in the ICU setting. Additionally, audio simulations were developed using multiple speakers and a simultaneous multiple-team rounding structure, capturing acoustic noise. However, as stated earlier, the goal of this study was to explore the feasibility of our approach in ICU settings. This is early work, and a continuation of our project will build on this. As the inferential statistics are underpowered, our findings should be interpreted as strictly preliminary and hypothesis-generating rather than definitive evidence of performance across ICU populations. Third, we did not perform a head-to-head comparison with standard error rates in ICU notes. The 80% (approximately) accuracy should not be interpreted as evidence of superiority or inferiority relative to current clinical documentation practices. It is a reflection of agreement with the expert-defined content in a controlled environment. The goal of this paper was to assess the minimum safety level before we test this technology in a real-world environment. Fourth, we had only moderate agreement (κ=0.58), reflecting subjectivity in defining errors within the ICU notes. We addressed this by manually reviewing each disagreement together and revising the classification based on the combined consensus, thereby reducing the impact on measurements. This also reflects the inherent complexity of ICU documentation rather than just subjectivity among reviewers. Clinicians often differ in their judgments of the notes' relevance and completeness. These reliability metrics should be interpreted as approximate indicators rather than definitive measures, suggesting the need to improve them in the future as well. Fifth, the evaluators were not blinded, which could have added confirmation bias, especially in subjective metrics such as partial errors (despite reviewing disagreements together) and PDQI-9 scores. Sixth, we used only models (Llama and Claude) available on the HIPAA-compliant Amazon Web Services Control Tower at Oregon Health & Science University. Since we empirically used Claude in phase 2, our results should not be generalized to all other LLMs. We noticed a trend toward larger language models performing better (M6 vs M1); however, it remains unclear whether this holds for other model classes. Future work is needed to evaluate prompt transferability to other LLMs. Seventh, our study did not evaluate whether M6's superior performance was due to inherent improvements in reasoning or simply because its outputs were twice as long as those of M1. There is an apparent trend toward a trade-off between the conciseness and completeness of these AI-generated clinical notes. Future evaluations incorporating normalization strategies, such as accuracy per unit length of the note or trials of different prompts urging smaller models to write longer notes, could be helpful.

Our future goals build upon this work in three key areas: (1) evaluating AI scribes in diverse ICU cases and clinical conditions; (2) assessing the accuracy and quality of speech recognition, transcripts, and notes; and (3) studying the real-world use of ambient AI scribes to understand their impact on workflows and any potential unintended consequences.

Conclusions

In conclusion, we examined the use of AI scribes in the ICU setting. By combining prompt engineering with multiple LLMs, we successfully generated ICU-specific notes with fairly high accuracy. The overall quality and usefulness received high ratings from team members with domain expertise. Analyzing the different types of errors offered valuable insights into areas where efforts could be directed to enhance the quality of these notes. Since AI scribes have seldom been used in ICU environments, our study offers an important starting point and valuable insights for further exploration of this application.

Abstract

Background: Ambient artificial intelligence scribes are increasingly used to reduce clinician burnout and cognitive load, although their impact on documentation time remains inconsistent across studies. Most existing real-world impact studies have been conducted in the United States and rely on electronic health record time stamps, which may not accurately reflect actual documentation time.

Objective: This study aimed to quantify the impact of ambient scribe technology on clinician efficiency and patient engagement in an outpatient setting using direct observational methods and patient surveys.

Methods: We conducted a prospective, within-clinician quality improvement study at a large academic medical center in Singapore from December 2024 to May 2025. Nine clinicians participated in matched observation sessions with and without an in-house ambient scribe tool. Five trained observers used standardized time-motion methodology to capture documentation time, proportion of eye contact, and consultation duration across 169 consultations. Patient surveys were administered following consultations using the ambient scribe. Linear mixed-effects models were used to account for clustering within clinicians.

Results: Ambient scribe use was associated with a 15.0% reduction in documentation time per consultation (mean 5.3, SD 2.7 minutes to 4.5, SD 2.4 minutes; *P*=.04); a 10.6% increase in proportion of eye contact time (mean 69.6%, SD 18.6% to 77.1%, SD 17.7%; *P*=.009); and no significant change in consultation duration (mean 11.5, SD 6.9 minutes vs 10.9, SD 5.6 minutes; *P*=.42) or total cycle time per patient (mean 13.7, SD 7.7 minutes vs 13.2, SD 6.3 minutes; *P*=.57), where total cycle time includes preclerking, consultation, and postconsultation documentation. Effects were consistent across new and follow-up patients. Patient acceptance was favorable: of 39 surveyed patients, 27 (69.2%) agreed that their physician focused on them more during the consultation, and none expressed discomfort with the technology.

Conclusions: This evaluation of ambient scribe use in an Asian health care setting demonstrates that experienced users achieved reduced documentation time and improved patient engagement without affecting consultation duration or total time per patient. The technology was also well accepted by patients. Taken together, these findings suggest that ambient scribes reallocate clinician effort toward patient interaction rather than enabling faster patient turnover, supporting their implementation across diverse health care settings.

Introduction

Ambient scribes use artificial intelligence (AI) to convert verbal clinician-patient interactions into structured clinical documentation. This is one of the fastest-adopted uses of generative AI in health systems worldwide [1].

Recent real-world studies across health systems in the United States demonstrate consistent improvements in clinician well-being and patient interactions with the use of ambient scribes, with studies reporting significant reductions in cognitive load, task burden, and burnout scores alongside enhanced patient experience during consultations [2-7]. However, reported time savings vary considerably between organizations. While some implementations report substantial reductions in documentation time and after-hours charting, others show minimal productivity gains [8,9].

To our knowledge, no comprehensive real-world impact studies have been conducted outside of the United States, leaving questions about the technology's effectiveness in other health care contexts unanswered. Documentation burdens and clinical workflows may differ between countries, potentially affecting the magnitude of time savings and productivity gains achievable through the use of clinical ambient scribes. Additionally, no published studies have evaluated clinical ambient scribe outcomes in multilingual clinical environments despite the prevalence of such settings in many health care systems worldwide. Shah et al [7] have previously highlighted limited functionality with non–English-speaking patients as a specific barrier to ambient scribe adoption. As digital health tools increasingly permeate global health care systems, understanding their implementation in linguistically diverse environments is important for ensuring equitable and effective deployment.

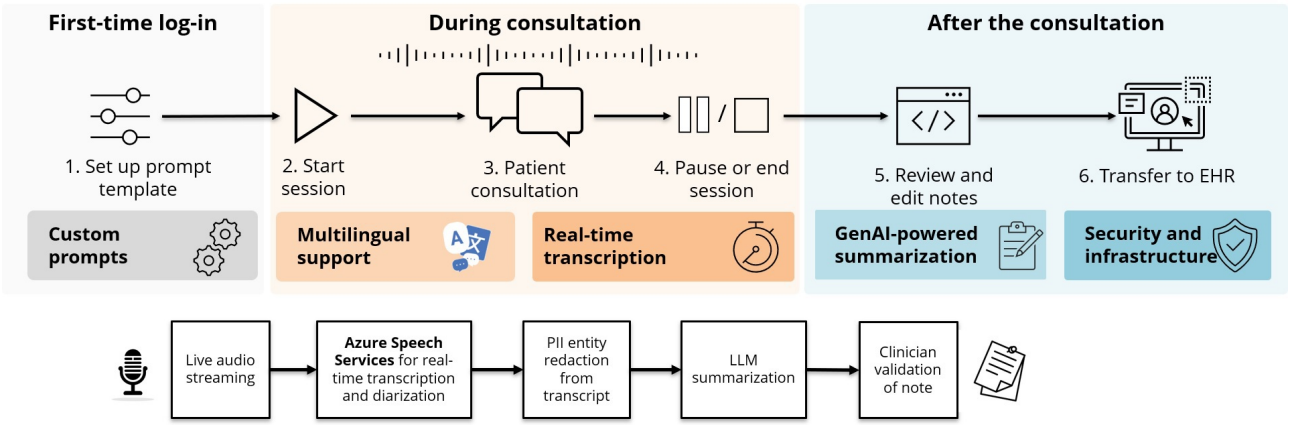
From a methodological perspective, existing studies have relied primarily on electronic health record (EHR) time stamp analysis to measure documentation time and productivity outcomes [4-6,10]. While convenient for large-scale analysis, EHR-based metrics provide only proxy measures that may not accurately reflect the actual time spent on documentation tasks. These metrics often rely on time stamps that capture when a note window is open, which may overestimate documentation time if clinicians multitask or leave notes open [11]. Direct time-motion observation, though more resource intensive, offers superior accuracy in distinguishing active documentation from passive or multitasking periods [12].

To address these evidence gaps, we aimed to determine the effectiveness and acceptability of ambient scribe technology when compared to the standard of care in a multilingual health care setting using direct observational methods.

Methods

Study Design

We conducted a prospective within-clinician observational study to evaluate the real-world clinical impact of an in-house ambient AI scribe in outpatient clinics of Singapore General Hospital, a quaternary referral center with more than 1700 beds that is the largest academic medical center in Singapore [13]. This study was conducted over 5 months between December 27, 2024, and May 30, 2025. It builds on a previous pilot study at the same institution that demonstrated the ambient scribe tool's ability to generate high-quality clinical notes comparable to those written by clinicians [14].



Ambient Scribe Technology

Note Buddy, the ambient scribe tool used in this study, was developed in-house using automatic speech recognition and large language model technology. This tool supports transcription in 5 languages commonly used in Singapore: English, Mandarin, Malay, Tamil, and Cantonese. However, during the study period, only English, Mandarin, and Malay consultations were observed.

Note Buddy can process conversations of up to approximately 96,000 words (based on token limits), identifying speakers and languages at the word level. It leverages GPT-4o's (OpenAI) native multilingual capabilities to process mixed-language transcripts without pretranslation or model fine-tuning. Note Buddy then reformats and summarizes transcripts into clinical consultation notes. On the basis of routine system use, note generation (from end of consultation to completed draft) typically requires 10 to 30 seconds, with duration varying by consultation length and prompt complexity. The system processes audio in real time without storing recordings (Figure 1).

XSL•FO
RenderX

Figure 1. Workflow of Note Buddy use in clinical practice. Users configure prompt templates that specify the structure and formatting of the generated notes. During consultations, the system transcribes clinician-patient interactions in the supported languages. After each consultation, the ambient scribe processes the transcript using the predefined prompt to generate a draft note, which clinicians review, edit if needed, and manually transfer into the electronic health record (EHR). GenAI: generative artificial intelligence; LLM: large language model; PII: personally identifiable information.

Users can customize the generated notes by creating prompt templates specifying note structure and clinical terminology, providing example notes for guidance, or selecting from preconfigured prompts in the prompt library. As the tool was not integrated into the EHR during the study period, clinicians had to manually transfer the AI-generated notes from the ambient scribe into the EHR.

Participants and Setting

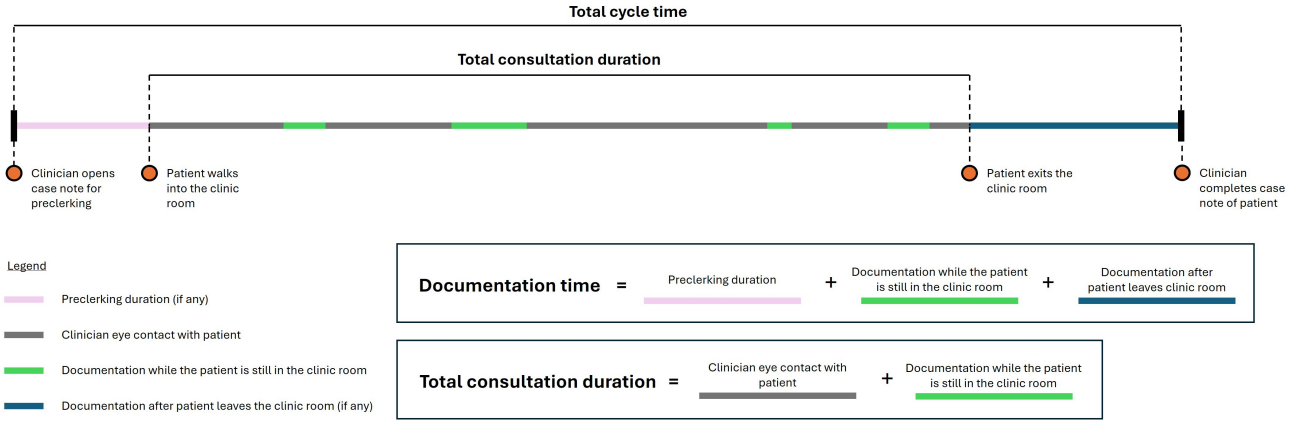
This study was conducted in an outpatient clinic setting where consultations naturally occur in multiple languages according to patient preferences. We recruited clinicians who had generated at least 30 notes using the ambient scribe tool in the 3 months prior to study commencement.

Clinicians unable to participate in 2 consecutive clinic sessions were excluded. Due to the time-intensive nature of direct observation, we intentionally focused on experienced clinician users who had achieved proficiency with the system and were most likely to demonstrate its optimal impact. From 27 eligible clinicians, 9 (33.3%) were selected through convenience sampling based on scheduling feasibility and observer availability.

Each clinician selected 2 clinic sessions for observation: one session using the ambient scribe tool and one using standard documentation methods. Clinicians were asked to select sessions with a similar patient case mix and clinic characteristics. Standard documentation methods consisted of manual typing, with some clinicians potentially using built-in EHR features such as smart phrases. The use of such features was not systematically recorded. Each clinician decided whether to use the ambient scribe tool in the first or second observed session; this was not randomized.

The interval between the 2 clinic sessions was kept within 2 weeks to minimize changes in practice patterns over time. Scheduled appointments remained unchanged to reflect the natural distribution of new and follow-up patients in the real-world setting. The total number of patients per clinic session ranged from 8 to 15.

Data Collection: Observation Methodology



Five observers carried out the observations, with each observer consistently assigned to the same clinician across both clinic sessions. All observations were conducted in person, with the observer present in the consultation room during scribe and nonscribe sessions.

All 5 observers participated in a joint training session to minimize interobserver variability. This included instruction on using a macro-enabled Microsoft Excel worksheet for time-motion data collection. The session concluded with group practice on mock consultations until a consensus was reached on measurement definitions and recording techniques.

Using the standardized macro-enabled Microsoft Excel worksheet, observers recorded real-time data on 3 key metrics and 1 derived metric. Consultation duration was calculated as the time between patient entry and exit from the consultation room. Proportion of eye contact was defined as the percentage of the consultation duration for which the clinician was looking directly at the patient. Documentation time was measured as the total time that the clinician interacted with the computer across all phases of the patient encounter: preclerking (if any), during the consultation, and immediately after the consultation, as illustrated in Figure 2.

XSL•FO
RenderX

Figure 2. Schematic representation of time components measured in the observational time-motion study. Documentation time is the time taken for documentation performed before, during, or immediately after the consultation, defined as the total time the clinician interacted with the computer. Consultation duration is the time between patient entry and exit from the consultation room. Total cycle time is derived from the start of preclerking (if any) to completion of documentation. All time points were recorded in real time by trained observers using a standardized macro-enabled Microsoft Excel worksheet.

Total cycle time was calculated as a derived metric from preclerking start (if any) to documentation completion, as illustrated in Figure 2. This represents the complete time investment per patient encounter and directly reflects potential impact on clinic throughput.

As this ambient scribe was designed for real-time documentation, observers recorded documentation completed within the observation window, which required clinicians to finish notes during or immediately after consultations rather than deferring to later periods. In the sessions with ambient scribe use, documentation time included the time spent reviewing, editing, and manually transferring AI-generated notes into the EHR, as well as the time taken for the ambient scribe to generate the note. Observers did not separately track the time spent on each component.

Data Collection: Sample Size Explanation

Due to the resource-intensive nature of direct observation and the pragmatic evaluation design, we determined the sample size based on clinician availability and feasibility constraints rather than formal power calculations. A post hoc approximation using 2-tailed paired *t* test assumptions (effect size=0.5; α=.05; power=0.95) indicated a minimum of 54 consultations per group (total 108 consultations). This simplified calculation does not account for the clustering of consultations within clinicians, which is addressed by our mixed-effects models. It serves as a conservative proxy given the complexity of power calculations for such models. Our final sample of 169 consultations exceeded this threshold.

Patient Surveys

Patient surveys were conducted to evaluate patient perspectives on ambient scribe use. Four of the 9 participating clinicians were selected through convenience sampling for patient surveys based on surveyor availability and clinician consent. Surveys were conducted across selected clinic sessions, resulting in partial overlap with time-motion observations, although the 2 data collection activities were conducted independently. Surveys were administered verbally by independent surveyors from the Office of Patient Experience immediately following consultations in which the ambient scribe tool was used. The survey assessed 4 domains: perceived quality of the clinical encounter, clinician's attentiveness and engagement, comfort level with AI-assisted documentation, and likelihood of recommending the technology for other clinical encounters. Patients were excluded from surveys if they declined participation or were deemed clinically unsuitable by their physician, for example, due to having just received a poor prognosis.

Statistical Analysis

We used descriptive statistics to summarize the characteristics of participating clinicians and consultation sessions. We applied the Pearson chi-square test to assess whether the distribution of new vs follow-up patients differed between consultations conducted with and without the ambient scribe tool. Linear mixed-effects models were used to account for clustering of consultations within individual clinicians and unequal numbers of observations per clinician. These models included random intercepts for individual clinicians to control for baseline differences in practice patterns and fixed effects for ambient scribe use and patient type (new vs follow-up consultation). Statistical significance was set at P<.05, and all analyses were conducted using SPSS Statistics (version 26.0; IBM Corp).

This manuscript was prepared using the SQUIRE (Standards for Quality Improvement Reporting Excellence) reporting guidelines.

Ethical Considerations

This study evaluated process metrics of an existing ambient scribe tool without collecting identifiable patient data or implementing clinical interventions. In accordance with institutional governance policies, the study was determined to constitute a quality improvement initiative and, therefore, did not require formal institutional review board approval (SingHealth Policy for Governance on Data Use [Non-Research]; document no. SHS-DDS-DAG-1002 [internal policy document]). For routine clinical use of the ambient scribe, explicit patient consent was not required based on institutional guidance as the system functions solely as a documentation support tool and does not store audio recordings. No audio recordings, transcripts, or personally identifiable information

XSL•FO
RenderX

were retained for evaluation purposes, and analyses were limited to deidentified workflow and time-motion metrics. Verbal consent was obtained from patients participating in anonymous satisfaction surveys. Participation was voluntary, and no financial or material compensation was provided to clinicians or patients.

Results

Sample Characteristics

Nine clinicians participated in this study, representing 7 different specialties (Table 1). They had a mean of 20.8 (SD 7.8) years in practice. Each clinician completed matched observation sessions with and without ambient scribe use. Of the 9 clinicians, 4 completed their first observed session using the ambient scribe, and 5 completed their first session without it, resulting in an approximately even distribution of session order. In this study, all clinicians used their own preconfigured prompts and did not make any further modifications to the prompts.

Table . Characteristics of participating clinicians in the observational study of ambient scribe use (n=9).

Characteristics	Values
Duration in practice (y), mean (SD)	20.8 (7.8)
Observed consultations per clinician, mean (SD)	18.8 (6.5)
Clinicians per specialty, n	
Respiratory medicine	2
Endocrinology	2
Gastroenterology	1
Neurology	1
Rehabilitation medicine	1
Neonatology	1
General surgery	1

As shown in Table 2, a total of 169 consultations were observed across the study period: 78 (46.2%) conducted with the ambient scribe and 91 (53.8%) conducted without it. The unequal distribution reflected natural variation in scheduled appointments and patient attendance across the matched clinic sessions. Of these 169 consultations, 54 (32.0%) involved new patients, and 115 (68.0%) were follow-up appointments. Of the 78 consultations with ambient scribe use, 63 (80.8%) were in English, 14 (17.9%) were in Mandarin, and 1 (1.3%) was in Malay.

Table . Distribution of patient types (new vs follow-up) among consultations conducted with and without the artificial intelligence (AI) scribe. The proportions of patient types were similar across groups, with no statistically significant difference in distribution.

Patient type	Overall (n=169), n (%)	Without AI scribe use (n=91), n (%)	With AI scribe use (n=78), n (%)	*P* value[a]
New patients	54 (32.0)	28 (30.8)	26 (33.3)	.72
Follow-up patients	115 (68.0)	63 (69.2)	52 (66.7)	.72

[a]Chi-square test comparing distribution between groups.

Given the potential for variation in individual clinician response, we examined unadjusted clinician-level changes comparing sessions with and without ambient scribe use (Figure 3). Substantial heterogeneity was observed: 7 of 9 clinicians demonstrated reductions in documentation time (7.9% - 34.6%), 6 of 9 had shorter consultation durations (4.3% - 42.2%), and 8 of 9 showed increased eye contact (4.2% - 35.8%).

XSL•FO
RenderX

Figure 3. Unadjusted clinician-level outcome changes with artificial intelligence (AI) scribe use. Each dot represents the percentage change for an individual clinician comparing sessions with and without AI scribe use. The dashed line indicates no change (0%).

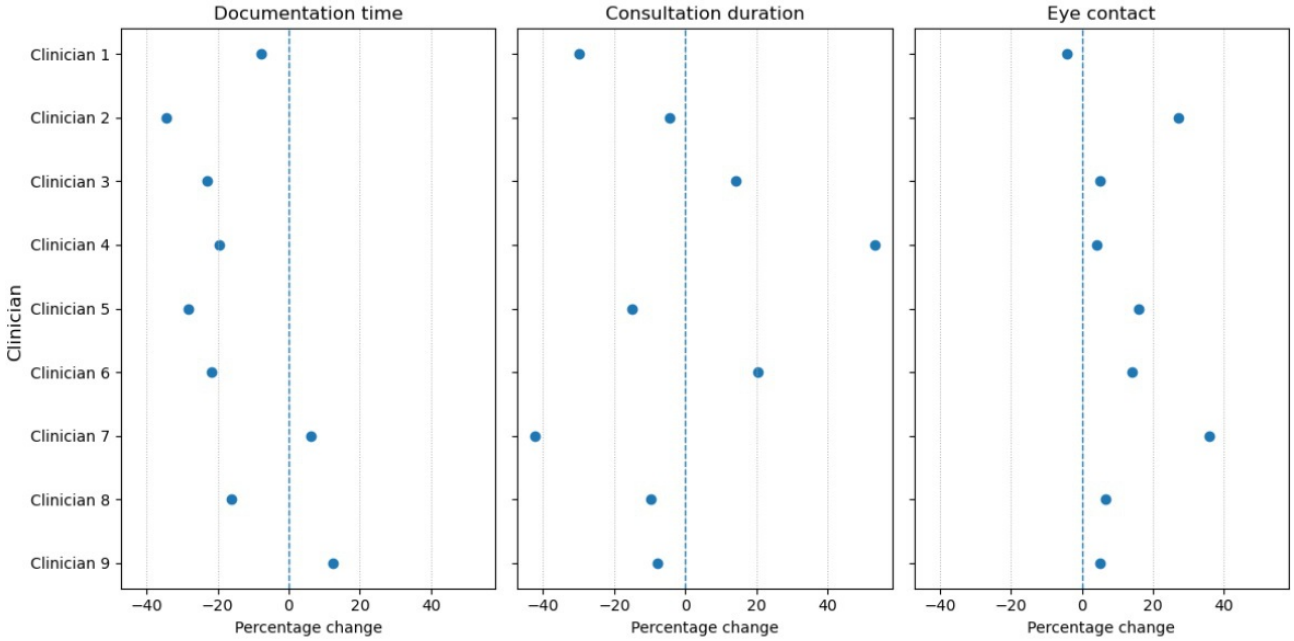


Table 3 summarizes the outcomes associated with the use of ambient scribes. Use of the tool was associated with 15.0% less time spent on documentation (from mean 5.3, SD 2.7 minutes to mean 4.5, SD 2.4 minutes per consultation; *P*=.04). The proportion of eye contact was 10.6% higher with ambient scribe use compared with standard documentation (from mean 69.6%, SD 18.6% to mean 77.1%, SD 17.7% of consultation duration; *P*=.009). Consultation duration was similar between conditions (mean 11.5, SD 6.9 minutes vs mean 10.9, SD 5.6 minutes; *P*=.42), and total cycle time per patient also did not differ significantly (mean 13.7, SD 7.7 minutes vs mean 13.2, SD 6.3 minutes; *P*=.57). The ambient scribe effects were consistent across new and follow-up patients for both documentation time and eye contact (interaction *P* values of .79 and .35, respectively), indicating uniform benefits across different consultation types.

Table . Comparison of outcomes between consultations conducted with and without artificial intelligence (AI) scribe use. Adjusted differences were calculated using linear mixed-effects models accounting for clinician-level clustering.

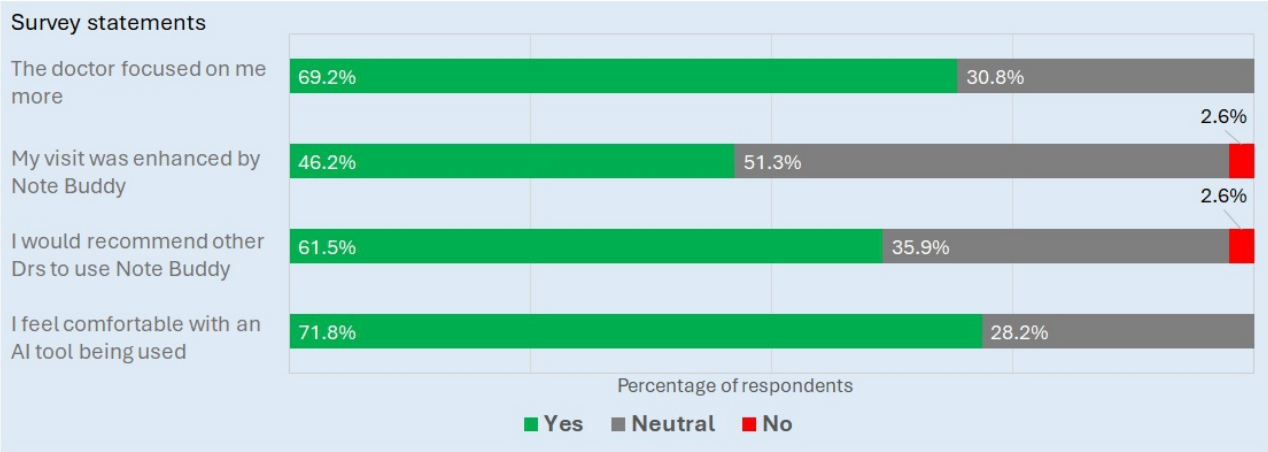
Outcome	Without AI scribe use (unadjusted), mean (SD)	With AI scribe use (unadjusted), mean (SD)	Adjusted difference (95% CI)	Change (%)	*P* value
Documentation time per consultation (min)	5.3 (2.7)	4.5 (2.4)	−0.8 (−1.5 to –0.05)	−15.0	.04
Proportion of eye contact time (%)	69.6 (18.6)	77.1 (17.7)	+7.4 (1.9 to 13.0)	10.6	.009
Consultation duration (min)	11.5 (6.9)	10.9 (5.6)	−0.7 (−2.6 to 1.1)	−6.1	.42
Total cycle time (min)	13.7 (7.7)	13.2 (6.3)	−0.6 (−2.6 to 1.4)	−4.4	.57

Crude independent-sample *t* tests treating all consultations as independent observations yielded similar effect sizes for eye contact (+7.5%; *P*=.008) and consultation duration (–0.67 minutes; *P*=.50). However, the reduction in documentation time reached statistical significance only in the adjusted mixed-effects analysis (crude: −0.74 minutes and *P*=.07; adjusted: –0.8 minutes and *P*=.04). This highlights the importance of accounting for clinician-level clustering.

Secondary Outcomes: Patient Experience

Patient surveys were conducted across 4 clinic sessions involving 4 of the 9 participating clinicians. Of 45 eligible patients in these sessions, 39 (86.7%) completed the surveys; 6 (13.3%) declined participation or were deemed unsuitable by their physician. Of the 39 surveyed patients, 18 (46.2%) were also included in the time-motion observations.

Age demographics are shown in Table 4, with 41.0% (16/39) of the patients aged 65 years and above. Survey language preferences were English (31/39, 79.5%), Mandarin and Chinese dialects (7/39, 17.9%), and Malay (1/39, 2.6%). Survey responses were collapsed into 3 analytic categories (“yes,” “neutral,” and “no”) based on evaluative meaning. Positive responses were coded as “yes,” neutral or indeterminate responses were coded as “neutral,” and negative responses were coded as “no.” The complete survey instrument is detailed in Multimedia Appendix 1.



XSL•FO
RenderX

Table . Age distribution of patients who completed surveys about ambient scribe use during consultations.

Age group (y)	Patients (n=39), n (%)
0 - 19	1 (2.6)
20 - 29	3 (7.7)
30 - 39	7 (17.9)
40 - 49	5 (12.8)
50 - 64	7 (17.9)
≥65	16 (41.0)

Overall, patient acceptance of the AI tool was favorable (Figure 4), with 69.2% (27/39) agreeing that their physician focused on them more during the consultation and 61.5% (24/39) expressing willingness to recommend the technology for use by other physicians. While some patients (20/39, 51.3%) gave neutral responses and 2.6% (1/39) reported that the ambient scribe did not enhance their visit, none expressed discomfort with its use.

Figure 4. Patient perceptions of ambient artificial intelligence (AI) scribe use (Note Buddy). Postconsultation patient surveys assessed perceived clinician attentiveness, consultation experience, comfort with AI-assisted documentation, and willingness to recommend the technology. Responses were collapsed into "yes," "neutral," and "no" categories for presentation.

Analysis of the overlapping subset of patients who were both surveyed and included in time-motion observations (18/39, 46.2%) showed internal consistency between objective measurements and patient perceptions: 61.1% (11/18) of these patients reported that their physician focused on them more during the consultation, whereas measured eye contact was 15.2% higher compared to the same clinicians' sessions without the ambient scribe (mean 72.7%, SD 15.9% vs mean 63.1%, SD 16.9%; *P*=.07). This directional alignment between objective and subjective measures supports the validity of both metrics.

To assess potential selection bias in the patient survey data, we examined whether the effect of the ambient scribe differed between clinicians whose patients were surveyed and those whose patients were not. After adjusting for patient type (new vs follow-up), there was no evidence of a differential effect for either documentation time (interaction *P*=.71) or proportion of eye contact (interaction *P*=.62). These findings suggest that the patient survey results are representative of the broader clinician cohort.

Discussion

Principal Findings

To our knowledge, this is the first study of the real-world impact of an ambient scribe conducted in Asia. Use of an in-house ambient scribe tool was associated with reduced documentation time and increased eye contact, whereas consultation duration remained unchanged. This suggests that clinicians redirected time from clerical tasks toward patient engagement rather than shortening consultations. The overlap between surveyed patients and time-motion observations (18/39, 46.2% of patients) provides supportive internal consistency, with patients who experienced objectively measured increases in eye contact also reporting improved clinician attentiveness.

Allowing clinicians to choose in which clinic session to use the ambient scribe instead of randomizing may have introduced selection bias. However, patient mix and volume were comparable between the scribe and nonscribe sessions (ratio of new to follow-up patients: *P*=.72; patient volume per session: mean 9.0, SD 3.4 with scribe use vs mean 9.8, SD 4.1 without scribe use; *P*=.44), suggesting that any such bias was minimal.

Our findings align with those of recent US studies showing that time savings tend to be modest. Documentation time was estimated to have been reduced by 0.8 minutes (95% CI −1.5 to −0.05; *P*=.04) in the intervention group. Although the upper confidence limit approached zero, indicating potential sensitivity to individual outliers, our observed reduction of 0.8 minutes per consultation is consistent with that observed in prior observational studies. These include findings from Sutter Health

XSL•FO
RenderX

(drop from 6.2 to 5.3 minutes) [6], The Permanente Medical Group (0.4-minute reduction) [15], and Stanford Health Care (0.57-minute reduction) [10], as well as recent randomized controlled trials reporting similar results [4,16]. Additionally, our study uniquely demonstrates improved patient engagement through increased eye contact, which we were able to quantify because we used direct observation rather than EHR-based metrics.

Unsurprisingly, this real-world evaluation demonstrated heterogeneity in individual-level effects between clinicians. However, our mixed-effects model was specifically designed to account for this individual variation while estimating the overall treatment effect, which remained statistically significant despite the heterogeneity. This within-clinician comparison design controlled for individual clinician variability and practice patterns that could confound results. Although our linear mixed-effects model relied on only 9 clinician clusters, which can affect the reliability of variance estimates and increase the risk of type 1 errors in mixed-model analyses, this design allowed us to isolate the specific effects of ambient scribe implementation while accounting for the natural variation in consultation styles and documentation practices across specialists.

Our findings also demonstrate that benefits observed in Western health care systems can be realized in a different cultural and linguistic context. Of the 78 consultations that used the ambient scribe, 63 (80.8%) were conducted in English, 14 (17.9%) were conducted in Mandarin, and 1 (1.3%) was conducted in Malay, highlighting the tool's utility in multilingual environments. The favorable patient responses observed, particularly among older adults, who comprised 41% (16/39) of survey respondents, provide reassuring evidence of acceptance across age groups.

The reproducibility of modest time savings across studies—including our observed 0.8-minute reduction—raises important questions about clinical meaningfulness at the individual clinician and health system levels. Notably, our finding that consultation duration remained unchanged despite reduced documentation time indicates that the time savings did not result in shorter patient encounters. Furthermore, our finding that total cycle time also remained unchanged demonstrates that ambient scribes should not be expected to increase clinic throughput or patient volume at the system level. Recent randomized controlled studies suggest that the primary value of this technology lies in reducing clinician burnout [4,16]. Our results complement this by demonstrating measurable improvements in patient engagement through increased eye contact and positive patient survey responses. Taken together, these findings suggest that ambient scribes should be viewed primarily as quality-of-care interventions that shift clinician attention from clerical tasks to patient interaction rather than as productivity tools [15,17].

Limitations

This study has several limitations. First, the sample was limited to 9 clinicians in specialist outpatient clinics due to the resource-intensive nature of direct observation, which restricts generalizability to other specialties and primary care settings. We focused on experienced ambient scribe users to reflect real-world use patterns as prior research shows that regular users account for 89% of system activations [18]. This means that our findings reflect optimal rather than average implementation outcomes and cannot predict outcomes during initial adoption or among infrequent users. Because our clinicians were both experienced scribe users and relatively senior (mean 20.8, SD 7.8 years of practice), we cannot determine whether the observed benefits reflect scribe proficiency or preexisting EHR documentation efficiency. If our senior clinicians had already optimized their workflows through customized EHR templates and shortcuts, the observed time savings may underestimate the potential benefits for less efficient documenters. Conversely, new users may experience a learning curve that could temporarily reduce initial gains.

Second, the ambient scribe tool required manual transfer of notes into the EHR, which likely underestimates potential time savings compared to fully integrated systems and limits direct comparability with studies of integrated solutions.

Third, several potential biases may have influenced our findings. Clinicians self-selected the sessions in which they used the ambient scribe, introducing the possibility of selection bias. Observer expectancy and Hawthorne effects [19] may have influenced clinician behavior or the measurement of eye contact as observers and clinicians could not be blinded. Interrater reliability could not be assessed because multiple observers in the consultation room would have been intrusive; however, each clinician was consistently observed by the same individual across both conditions to minimize observer-related variability. Patient survey responses may have also been subject to social desirability bias as patients may have been reluctant to express negative views about the technology when surveyed immediately following their consultation within the clinical facility despite the use of independent surveyors. As the ambient scribe tool was developed in-house, some degree of institutional bias is possible, although objective measurement methods were used to minimize this risk.

Finally, this study did not specifically assess whether note accuracy was preserved in the context of the observed reductions in documentation time; nonetheless, the tool's clinical fidelity had been reported in a previous study [14]. The predominance of English-language consultations (63/78, 80.8%) limits conclusions about multilingual performance. Clinicians used different prompts, including customized ones, and we did not systematically analyze variation in prompt length or complexity. Such prompt variability may have influenced the time taken for the ambient scribe to generate a note and represents a potential confounder.

Future Directions

The observed heterogeneity in individual-level effect sizes in this real-world study highlights that the potential benefits of ambient scribe adoption may not be uniform even in experienced users. Future studies should evaluate the impact of ambient scribe technology across a broader range of clinicians and practice environments to identify which user profiles benefit the most and which may require additional support. Qualitative research into factors affecting adoption and sustained use will be important for ensuring long-term effectiveness and

XSL•FO
RenderX

scalability. Future work should systematically evaluate how prompt design—including specialty-specific or individualized prompts—affects the quality of AI-generated documentation and the time required for clinician review and editing. While our study suggested effectiveness in a multilingual patient population, most consultations (63/78, 80.8%) were conducted in English. Further work is needed to assess whether the same benefits are observed in non–English-language consultations as language may influence both scribe performance and outcomes.

Conclusions

This quality improvement study found that ambient scribe use among experienced users was associated with modest reductions in documentation time and improved patient engagement, with high patient acceptance. These findings quantify the impact of ambient scribes in a real-world outpatient setting using direct observational methods. Our findings demonstrate that these benefits can be achieved through in-house–developed solutions, offering health care systems an alternative to commercial products in cases in which data privacy, cost, or localization are key concerns.

Abstract

Background: Physicians routinely document specifics of patient encounters in clinic visit notes, a critical but potentially time-consuming task. Ambient listening artificial intelligence (AI) technology is being integrated into clinical workflows to reduce documentation burden by creating draft visit notes. While this technology is promising, it is not perfect, and the potential for patient harm needs to be understood and mitigated. We developed and piloted an efficient, standardized approach to evaluating AI-generated notes for safety concerns in ambulatory care visits.

Objective: The objective of this quality improvement project was to develop and pilot an efficient, standardized, and scalable approach to evaluating AI-generated notes for safety concerns in ambulatory care visits.

Methods: During a 2-month pilot (July to August 2024), 31 physicians across multiple specialties used an ambient listening AI scribe to assist with the creation of 7545 clinic notes. A novel survey instrument was developed to assess note quality, focusing on 4 error types: accidental inclusions, accidental omissions, hallucinations, and bias. Physicians evaluated 356 (4.7%) AI-generated notes. Where an error was present, physicians rated its severity based on its potential to cause patient harm if it was not corrected, on a 0 to 5 scale. Additionally, a vendor-reported metric on the percentage of note content edited by physicians was analyzed.

Results: Of the 356 evaluated notes, accidental omissions were the most frequent error (n=64, 18%), followed by hallucinations (n=41, 11.5%), and accidental inclusions (n=33, 9.3%). Bias was rare (n=4, 1.1%). Most (119/142, 83.8%) errors were rated as mild to moderate (severity 1 - 3), with only 19 (5.3%) notes containing errors rated as posing serious or imminent risk (severity 4 - 5). Editing metrics across all AI-created notes showed a median of 9.0% (IQR 2.5%-21.9%) of AI-generated words were changed, with 14.9% (143/960) of notes left entirely unedited. Physician editing practices varied widely, with average percentages of AI-generated words changed ranging from 1.9% to 69.3% (median 9.0%, IQR 2.5%-21.9%).

Conclusions: AI-generated clinical notes were generally of high quality, with 94.7% (337/356) free from significant errors. However, because a small number contained errors that carried the risk of serious harm if not corrected, careful clinician review of notes remains imperative. Prior to deploying an AI scribe, organizations should pilot the technology and include an efficient review process to understand the nature and type of errors common at their organization. This pilot provides a scalable model for other health systems seeking to implement AI scribe technology responsibly.

Introduction

Generative artificial intelligence (AI) is infiltrating and transforming many aspects of medicine, with specific emphasis on clinician-based tasks such as note creation and after-visit summaries, drafting responses to patient messages, and summarizing patient charts—all of which could reduce the clinical workload [1]. The specific uptake of AI scribes for note creation has some of the highest rates of implementation in the United States. These AI scribes use ambient listening generative AI technology to generate draft notes [2,3], capturing patient-physician conversations during encounters and converting them to documentation that is reviewed, modified, and approved by the physician. To date, the literature related to AI scribes has signaled improvements in time per note for physicians, with a potential for reducing workload and burnout [4,5].

While capitalizing on the potential benefits of AI scribes, the potential for patient harm also needs to be understood and mitigated. Generative AI is not perfect, and errors embedded in a patient's medical record could impact care [6]. Indeed, concerns have been raised about the use of generative AI to create physician responses to patient inquiries [7], and more broadly, there is a need for rigorous validation of large language models in clinical practice [8]. Real-world validation of generative AI is essential to avoiding patient harm [4], but efficient assessment tools that capture the most critical errors are not yet widely available.

Therefore, as part of a quality improvement pilot program using an ambient listening AI scribe to assist in preparing clinic visit notes, the University of California, Davis Health (UCDH) developed a novel survey instrument to assess the quality of AI-generated notes and identify errors with potential to impact patient care and outcomes. The overall goal of the quality assessment was to ensure patient safety prior to widespread deployment of the AI scribe, with the following specific objectives: develop an efficient, scalable, and standardized approach to assess the quality of AI scribe–generated clinical visit notes; identify the type and frequency of errors introduced by the AI scribe; quantify the severity of different errors and potential for patient harm, and develop a long-term monitoring approach.

Methods

Study Design

The UCDH system is an academic medical center with a 653-bed teaching hospital and the only level I adult and pediatric trauma center in inland Northern California, serving a 33-county region of about 6 million residents with more than 1.9 million patient encounters annually. UCDH conducted an ambulatory care pilot program evaluating use of an AI scribe tool to assist with preparation of clinic visit notes. The pilot program ran for 2 months (July to August 2024), during which the physicians in the pilot had the option of using the ambient listening tool. We first summarized the total number of notes created by the AI scribe technology during the pilot period, overall and by physician, followed by a secondary subanalysis of AI scribe note quality.

Ethical Considerations

This study was determined by the University of California, Davis institutional review board to not be human subjects research and therefore was exempt from review (2367684 - 1). Because this study was exempt from review and patient information was aggregated, study-specific informed consent and privacy protections were not necessary. Physicians were not compensated for participating in the pilot program.

Note Quality Assessment

All physicians in the pilot agreed to assess the quality of draft notes produced by the AI scribe technology using a novel standardized assessment instrument for a subset of their clinic encounters. To minimize assessment burden, physicians were asked to evaluate 10 draft notes on 2 different days during a 3-week period. This number was selected to represent most notes in their outpatient practice on these selected days, and each clinician received regular reminders during the pilot to complete their assessments. Note types included history and physical notes and progress notes; note type was not captured as part of the assessment.

Detailed quality ratings by physicians in the pilot were captured using a novel standardized assessment instrument accessible via an online Qualtrics (Qualtrics, LLC) survey (Figure S1 in Multimedia Appendix 1). The survey was developed in collaboration with our institution's AI Oversight Committee and included four components of quality deemed most relevant to patient safety, specifically whether the AI scribe note had the following: (1) accidental inclusions, (2) accidental omissions, (3) hallucinations, or (4) bias in the draft language (Textbox 1). These components were informed by the Physician Documentation Quality Instrument (PDQI-9) and known deficiencies in AI and large language model summarization tools [9,10]. On the survey, physicians reported if any of these types of errors were present. If so, the physician rated the severity of the error on a scale of 0 to 5, with 0 representing negligible risk to the patient, physician, or health system and 5 representing potential for serious and imminent risk of harm. Within this guidance, severity ratings were based on individual physicians' clinical judgment in the context of the visit. Table 1 provides examples of errors reported for each severity rating level.

XSL•FO
RenderX

Textbox 1. Components of note quality assessment.

Accidental inclusion

- Does the draft note contain inaccurate, real information discussed in the visit that was accidentally included or misattributed by the AI?

Accidental omission

- Does the draft omit information that you would have included in the note if you had written/dictated it without the AI?

Hallucination

- Does the draft note contain inaccurate, undiscussed, hallucinated information that was made up by the AI?

Bias

- Does the note appear to either include or omit information that might increase the risk that vulnerable populations/protected classes of patients are treated unfairly?

Table . Examples of errors in artificial intelligence (AI)–generated notes at each severity rating level.

Severity rating	Examples of AI documentation mistakes
0	• Misattributed a medication dosage statement to the parent, although it was part of the clinician's discussion of risks and benefits • Inserted advice on substance abuse that the clinician did not discuss
1	• Included irrelevant details (eg, ability to use computer) • Attributed a medication side effect comment to the patient when it was stated by the clinician • Missed noting supplement use and risk-benefit discussion • Missed noting spine clinic appointment (instead wrote referral would be placed)
2	• Electrocardiogram results reported as echocardiogram results • Incorrect timeline for COVID-19 exposure • Ovarian adenoma incorrectly documented rather than ovarian thecoma or fibroma • Medication instructions simplified incorrectly ("take for one month" instead of conditional continuation) • Anxiety medication documented for the patient instead of the spouse • Misinterpretation of recommended blood test timing ("have blood drawn in 1 week" instead of 1 week before follow-up)
3	• Included history of osteoporosis without supporting evidence • Attributed discontinuation of a medication stopped years ago to one stopped yesterday • Incorrectly stated that the patient was on methadone • Missed discussion on home safety and assisted living recommendation • Added the phrase "increase dose if symptoms improve," which was contrary to the documented treatment plan
4	• Incorrectly added directive to start aspirin for ankle pain, which was not the proposed plan • Incorrectly stated that the patient has diabetes • Did not include the patient's discussion of weight loss, fatigue, and medication change • Improper medication dose documented in plan
5	• Attributed a history provided by the patient to an incorrect diagnosis • Incorrectly stated that the patient should continue current metformin dosing • Did not document computed tomography scan discussed by the clinician

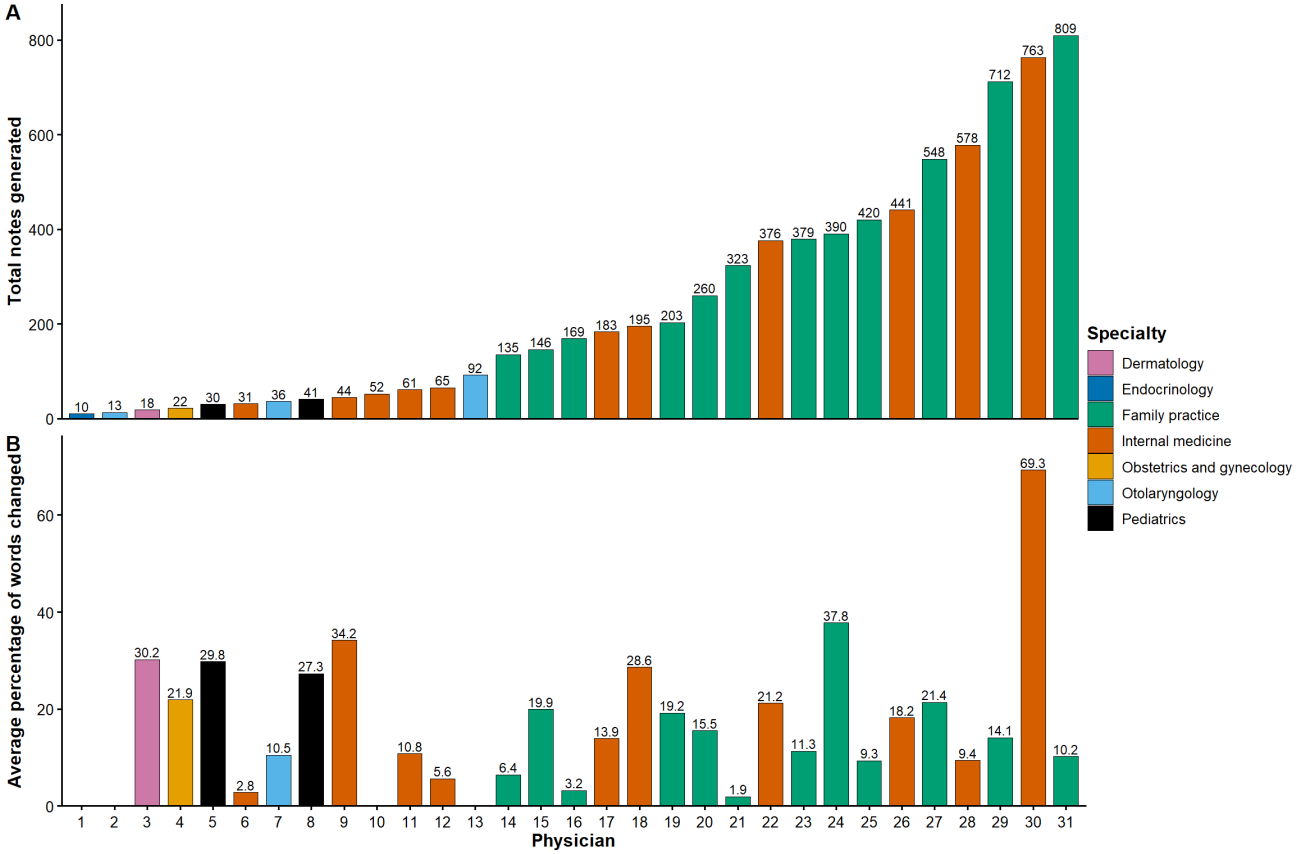
Using these surveys, we summarized the proportion of each error type during the pilot. Furthermore, we calculated a quality score as follows. For each component of quality, a score ranging from 0 to 1 was calculated as 1 – (0.2 × severity) such that higher severity errors resulted in higher point deductions. The overall quality score was then calculated as the sum of the 4

XSL•FO
RenderX

component scores, yielding a score ranging from 0 (lowest quality) to 4 (highest quality). We also linked these quality ratings to patient characteristics for each note to report on the patient distribution in the sample.

The time between the clinic visit and the quality assessment review was calculated as the difference between the time that the AI scribe recording ended and when the physician started to review the note. Data for the quality assessment were collected separately from the AI scribe recording time data, which came from the vendor. We were not able to link the quality assessments and AI scribe data for 9 visits, and recording times were not available for 4 of the assessed notes.

For each note, the vendor calculated a measure of the percentage of the note that was retained, calculated as 1 – (number of word-level edits / number of words in the final completed note). Word-level edits are defined as additions, substitutions, and deletions. The vendor provided the average percentage retained for each physician during the pilot period. Due to technical issues, this measure could only be obtained at the note level from the vendor for 960 notes. We converted the percentage retained metric to the percentage of words changed.



Results

A total of 31 physicians volunteered for the pilot program. Specialties of physicians in the pilot program included family practice (n=12, 38.7%); internal medicine (n=11, 35.5%); otolaryngology (n=3, 9.7%); pediatrics (n=2, 6.5%); and dermatology, obstetrics and gynecology, and endocrinology (n=1 each, 3.2%).

Quality Assessment

Over the pilot period, a total of 7545 notes were generated using the AI scribe by the 31 physicians in the pilot program. There was substantial variability in the number of notes generated across physicians, with a median (IQR) of 169.0 (42.5-384.5) notes, ranging from 10 to 809 (Figure 1).

Figure 1. (A) Total number of notes generated during pilot period by each physician and (B) average percentage of words changed in artificial intelligence (AI) scribe–generated notes by each physician. Due to technical issues, the percentage of words changed was not recorded for some physicians.

Physicians evaluated the quality of 356 (4.7%) of 7545 notes, with a median number of notes evaluated by a physician of 11.0 (IQR 8.5-13.0). Family medicine and internal medicine physicians evaluated most of the notes, 182 (51.1%) and 115 (32.3%), respectively, as these specialties comprised three-quarters (23/31, 74.2%) of the participating physicians. Entering these data for the quality assessments into Qualtrics required a median of only 38.0 (IQR 18.0-96.2) seconds. Physicians usually conducted the quality assessments on the same day as the clinic visit, yielding a median time between the clinic visit and the quality assessment of 3.9 (IQR 1.6-21.1) hours. Among these 356 notes that were scored by physicians, aggregated patient characteristics are summarized in Table S1 in Multimedia Appendix 2, demonstrating a wide representation among patients seen in the health care system.

Error Frequency and Severity

Among the 356 notes, accidental omissions were the most prevalent quality concern, occurring in 18% (n=64) of the notes, followed by hallucinations (n=41, 11.5%) and accidental inclusions (n=33, 9.3%; Table 2). Bias was only reported in 4

XSL•FO
RenderX

notes (1.1%). In general, quality concerns tied to omissions, hallucinations, or accidental inclusions were rated as mild to moderate (severity ratings of 1 - 3). Severity scores of 4 to 5, representing potentially serious or imminent risk of harm if draft errors were not corrected by clinicians, were infrequent—with only 7 (2%) draft notes in this range for accidental omissions, 9 (2.5%) for hallucinations, 5 (1.4%) for accidental inclusions, and 2 (0.6%) for bias.

Finally, the combined note quality score (accounting for severity) was high, with a median quality score of 4.0 (IQR 3.8-4.0). Two-thirds (n=242, 68%) of the notes received a score of 4.0, indicating no quality concerns. A small number of notes (n=11, 3.1%) had an overall score less than 3. Note quality was similar across the specialties (Table 3; Table S2 in Multimedia Appendix 1).

Table . Summary of concern severity ratings for quality assessments of visit notes (N=356).

Severity score	Inclusion, n (%)	Omission, n (%)	Hallucination, n (%)	Bias, n (%)
5 (severe)	1 (0.3)	3 (0.8)	3 (0.8)	—[a]
4	4 (1.1)	4 (1.1)	6 (1.7)	2 (0.6)
3	9 (2.5)	12 (3.4)	14 (3.9)	1 (0.3)
2	7 (2.0)	17 (4.8)	10 (2.8)	—
1	12 (3.4)	28 (7.9)	8 (2.2)	1 (0.3)
0 (no concerns)	323 (90.7)	292 (82.0)	315 (88.5)	352 (98.9)

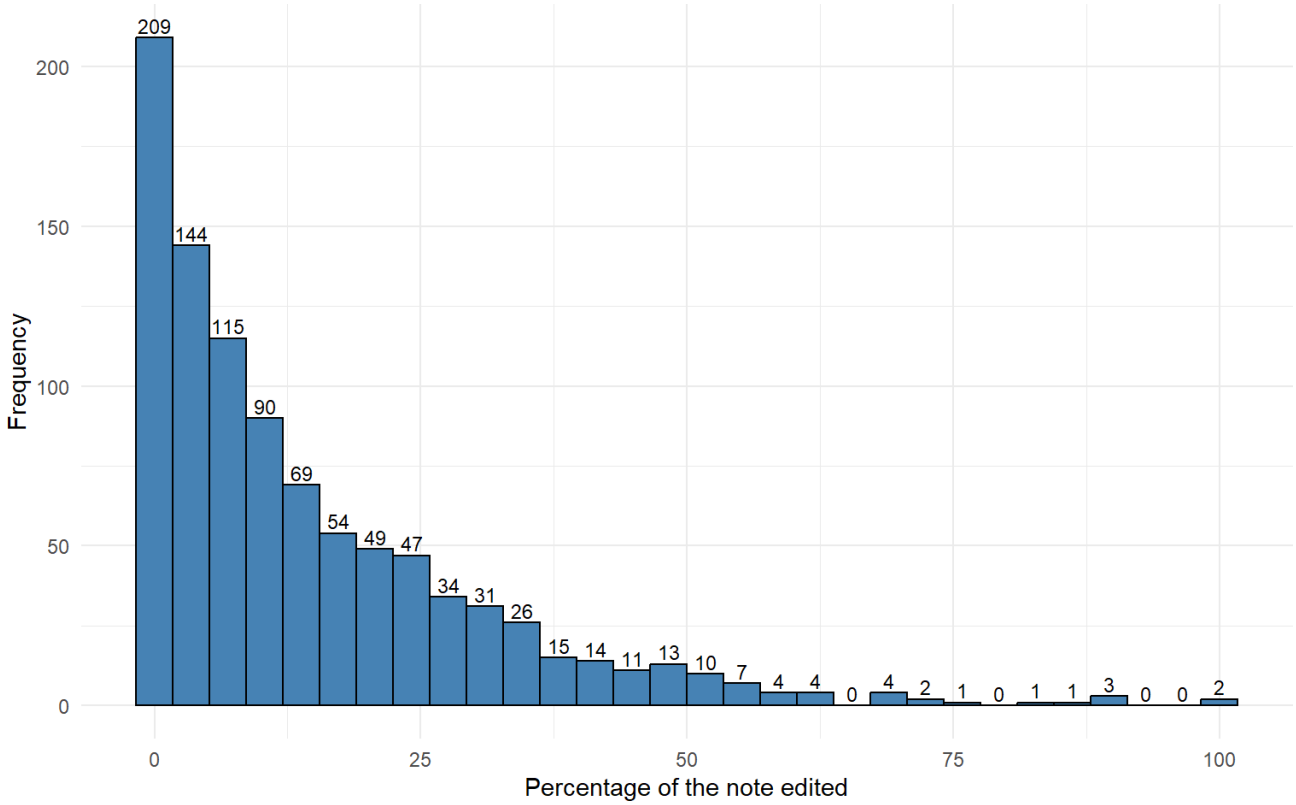
[a]No notes were identified with bias with this severity score.

Table . Summaries of total scores from the note quality assessments and the percentage of each note edited, as reported by the vendor, by specialty.

Specialty[a]	Total score (n=356)		Percentage edited (n=960)	
	Notes, n (%)	Median (IQR; range)	Notes, n (%)[b]	Median (IQR; range)
Dermatology	11 (3.1)	4.00 (3.50-4.00; 2.60 - 4.00)	0 (0)	—[c]
Family practice	182 (51.1)	4.00 (3.80-4.00; 1.80 - 4.00)	571 (59.5)	8.3 (2.4-17.3; 0.0 - 63.5)
Internal medicine	115 (32.3)	4.00 (3.60-4.00; 1.40 - 4.00)	364 (37.9)	9.5 (2.1-25.5; 0.0 - 100.0)
Obstetrics and gynecology	4 (1.1)	4.00 (3.80-4.00; 3.20 - 4.00)	0 (0)	—
Otolaryngology	26 (7.3)	4.00 (4.00-4.00; 4.00 - 4.00)	21 (2.2)	34.4 (21.2-46.8; 8.9 - 91.2)
Pediatrics	18 (5.1)	3.80 (3.45-4.00; 3.00 - 4.00)	4 (0.4)	22.4 (16.2-33.0; 10.7 - 51.7)

[a]No quality assessments were conducted by the endocrinologist.

[b]Due to technical difficulties with the data from the vendor, the percentage edited was only obtained at the note level for a portion of all notes and was not available for any notes for dermatology, obstetrics and gynecology, or endocrinology.



[c]Percentage edited was not available for any artificial intelligence–generated notes for this specialty.

Percentage Edited

Of the 7545 AI-created notes, the vendor metric of percentage of words retained was reported for 960 (12.7%) notes. Most of the AI-drafted note content was left unedited by physicians, with a median 9.0% (IQR 2.5%-21.9%; Figure 2) of AI-generated words changed. Notably, 14.9% (143/960) of the AI-generated notes were not edited at all. Individual editing practices varied substantially by physician, with the average percentage of words changed by physician ranging from 1.9% to 69.3% (Figure 1). At the note level, the percentage edited was similar for family practice (median 8.3%, IQR 2.4%-17.3%) and internal medicine (median 9.5%, IQR 2.1%-25.5%) but higher for otolaryngology (median 34.4%, IQR 21.2%-46.8%) and pediatrics (median 22.4%, IQR 16.2%-33.0%; Table 3).

XSL•FO
RenderX

Figure 2. Distribution of percentage of words changed in artificial intelligence–generated clinic visit notes. The x-axis indicates the percentage of the note that was changed, and the y-axis indicates the number of notes with that level of editing.

Discussion

Consistent with other studies, we found that most (337/356, 94.7%) AI scribe platform–generated notes were of high quality and free from significant errors [11,12]. However, accidental omissions were relatively common, identified in 18% (64/356) of the notes evaluated. Most errors were rated as low risk for patient harm; however, 5.3% (19/356) of AI-drafted notes contained an error deemed to pose a risk of serious harm if left uncorrected. Thus, careful clinician review of notes remains imperative.

Because we prioritized patient safety and specifically focused on identifying errors or bias in AI-generated notes, our evaluation tool to capture physician ratings was very brief, allowing rapid assessment of a large number of notes. This contrasts with the longer PDQI-9 instrument that evaluates overall document quality. Natural language processing metrics have also been used to evaluate note quality in previous studies [13], but these metrics do not explicitly identify deviations that could impact patient safety. Our note quality assessment approach is therefore unique in rating the severity of risk posed to patients if the error is not corrected.

Several limitations were encountered in implementing and evaluating this program. First, this was a pilot program, and clinicians volunteered as early adopters of AI scribe technology within the health care system. Second, although the assessment rubric was short, most physicians in the pilot assessed fewer than the requested 20 notes, despite repeated outreach from the project team. Thus, our method of including participants in the pilot and their differential response rates could have biased our results. Third, because physicians reviewed notes from their own clinic visits, identification and rating of the severity of the errors could be biased due to the physician's individual perspective as well as the passage of time between the visit and note review. However, physicians tended to review notes the same day as the clinic visit, which would reduce recall bias. Finally, to achieve the objectives of our quality improvement project, we did not seek to develop a rigorously validated instrument. Severity ratings were subjective, based on individual physician's clinical judgment within the context of a particular patient, such that scores could vary among institutions and clinical departments, thus requiring local calibration. Future studies and improvements could include rigorous development of the instrument through multiple reviewer assessments of AI-generated notes relative to recorded transcripts, standardization of severity ratings, and external validation.

In the future, ongoing monitoring of the quality of AI-generated notes will be important to identify changes in the underlying algorithm or practices that could degrade note quality. While our assessment tool is time efficient, it still requires human review, which might impede its use for long-term monitoring. Importantly, we combined direct physicians' ratings with vendor-reported metrics that are more easily obtainable, specifically the percentage of each note that was edited, as a secondary indicator of note quality. Using direct feedback and reporting from end users as well as automatically generated information from platforms will be important for a long-term monitoring approach. Given the occurrence of errors in AI-generated notes, monitoring trends, both in the percentage of notes that are heavily edited or notes that are not edited, will facilitate early identification of changes in physician vigilance

XSL•FO
RenderX

in note review. Finally, as our health care system moves toward broader implementation of an AI scribe platform, we are investigating the standardization of quality monitoring by correlating vendor metrics with physician ratings. Given that physician behavior can change over time when adopting AI tools into routine practice, and the performance of the tools themselves may drift, our health system has prioritized long-term monitoring of quality and safety.

In summary, we have outlined a pilot program that might be a generalizable model for other health care systems. Our focused priorities on quality and safety of AI-generated notes, while also maintaining feasibility in the evaluation, were essential for piloting and will likely remain so for broad-scale implementation. Furthermore, we continually engage with the AI vendor to inform their automated metrics that align with our ongoing evaluation priorities. Moving forward, we also plan to implement these approaches and our findings into clinician training in the use of AI technology. With the promise of AI, particularly tools aimed at reducing physician workload and burnout, there is a pathway for rapid deployment while maintaining high standards of patient care.

Abstract

Background: Most US health systems operate on a local or regional scale and face substantial financial and staffing pressures, which are intensified by challenges related to physician satisfaction and difficulties in recruitment and retention. Ambient artificial intelligence (AI) documentation solutions have the potential to reduce burdens and improve satisfaction, but vendor selection is often undermined by cognitive biases, unvalidated marketing claims, and limited real-world testing.

Objective: To address this, McLeod Health developed and implemented an objective, multiphase approach to evaluate and adopt an ambient AI solution across its multihospital system.

Methods: Our evaluation process began in spring 2024 with 4 leading vendors tested through live clinical simulations using 15 complex outpatient scripts, with organizational leaders serving as standardized patients. Ambient patient encounters were captured in real time, and AI-generated notes were scored by physicians, revenue cycle experts, and nonclinical reviewers for accuracy, billing quality, and readability. The top 2 vendors advanced to demonstrations of Epic workflow integration, with physician usability feedback guiding the final selection. In the third phase, the chosen vendor underwent a 90-day pilot across 5 ambulatory specialties beginning in October 2024, followed by system-wide implementation in January 2025. Key performance indicators included documentation time, coding, and financial trends, as well as patient and provider satisfaction. All statistical comparisons were 2-sided using a 95% CI.

Results: The 3-phase evaluation process resulted in careful vendor selection. The pilot showed a 35.4% decrease in pajama time (P=.054, trend toward significance) and a 28.3% decrease in time in notes (n=23; P<.001). Coding patterns shifted toward higher-complexity visits, with a 3.8% increase in level 4 established patient visits (P=.05), and established patient volumes increased by 8.5%, which was associated with a projected revenue gain of US $2629 per provider per month. Patient satisfaction improved significantly across multiple domains, with large gains in listening, trust, communication, and treatment information (all P<.001). These gains exceeded those of prior system-wide patient satisfaction initiatives. System-wide rollout has achieved 81% adoption, with more than 150,000 notes generated.

Conclusions: Our structured, multiphase evaluation process minimized vendor influence and cognitive bias during selection, validated results through real-world clinical testing, and enabled a system-wide rollout. This approach offers a practical framework for nonacademic health systems to objectively assess, implement, and scale ambient AI solutions while preserving fairness, transparency, and measurable value.

KEYWORDS

artificial intelligence; AI; clinical documentation; health system implementation; workflow integration; physician burnout

Introduction

Background

Most health systems in the United States are nonacademic, operate on a local or regional scale, and face far greater pressures to deliver care than well-resourced academic medical centers (AMCs) or private multistate conglomerates. These pressures are especially acute in rural and critical access hospitals, where thin margins and physician burnout make recruitment and retention difficult. Of the 639 health systems across the country, 84% (n=537) operate in a single state with 399 beds, 2 hospitals, and 339 physicians; most are nonteaching hospitals and have a median net hospital revenue of US $2 billion [1].

Ambient artificial intelligence (AI) solutions have the potential to reduce documentation burden, improve physician and patient satisfaction, and increase revenue capture—all of which are

XSL•FO
RenderX

critical to the sustainability of health systems delivering most US health care [2-5]. However, nonacademic health systems typically lack the resources of AMCs or large private systems to evaluate how these technologies will perform in their environments [6,7]. The literature calling for more research, especially on the economic and system-level burden of this technology, has gained momentum [8]. Selecting and integrating ambient AI solutions into daily clinical workflows is complex and highly vulnerable to cognitive bias during the selection process [9,10]. Moreover, despite frameworks for assessing ambient AI tool quality and examples of system-wide adoption by large conglomerates, there is no standardized process for the majority of health systems to systematically evaluate, pilot, and scale these solutions [7,11,12].

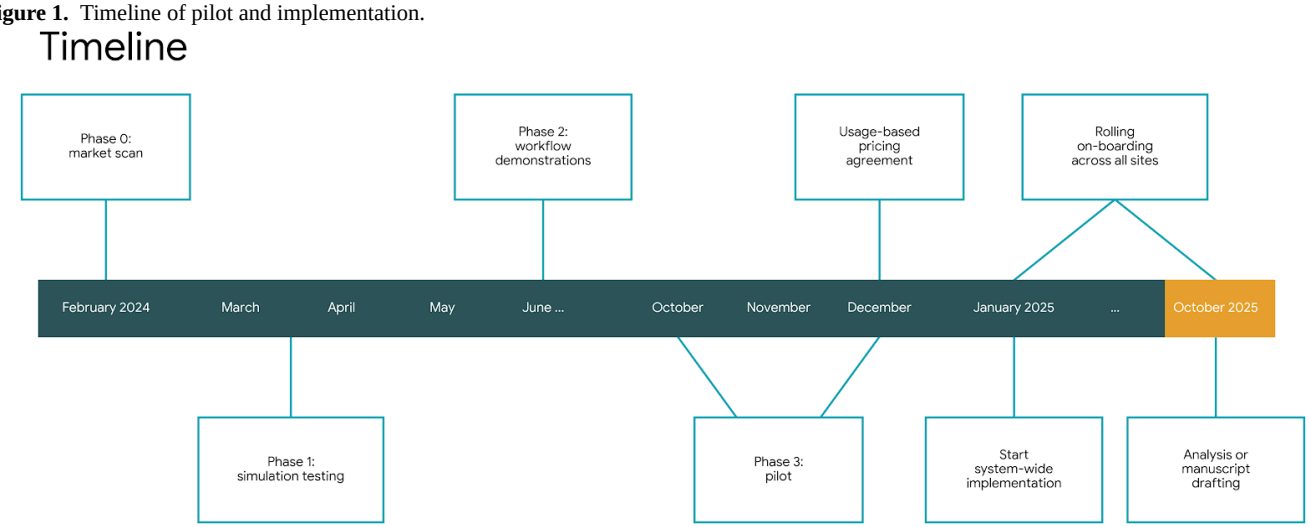
McLeod Health is a nonprofit, nonacademic health system comprising 7 hospitals and more than 1200 providers serving 18 counties in North and South Carolina. While larger than the median US health system, McLeod operates without the dedicated research infrastructure, centralized innovation programs, or academic funding streams typical of major AMCs. Its scale and decentralized clinical operations place it within a broad group of mid-sized, community-based systems that must balance technology adoption with financial stewardship, clinician workload, and operational constraints.

This paper describes the objective, multiphase approach we used at McLeod Health to select and implement an ambient AI solution. McLeod Health reflects the structure and constraints of nonacademic regional health systems across the country more so than AMCs, which have reported much of the current ambient implementation experience, making our experience broadly relevant. By detailing our evaluation process and outcomes, we offer practical lessons that can guide other nonacademic health systems in adopting and scaling ambient AI technologies.

The Main Objective

The purpose of this project was to create and implement a structured, multiphase process for selecting an ambient AI solution that minimized vendor influence and cognitive bias in vendor selection, relied on real-world clinical testing, and measured outcomes across key domains: documentation efficiency, physician satisfaction, patient satisfaction, and financial return on investment.

Methods



The Team

All phases of this project were conducted across the McLeod system. The initiative was led by the chief medical informatics officer and supported by a broad leadership team that included system and regional chief medical officers, ambulatory practice leadership (senior vice president, chief medical officer, chief operating officer, and advanced practice providers), the chief information officer, and IT leadership, the directors of revenue integrity, patient satisfaction, marketing, clinical informatics, the hospital chief of staff, multiple physician champions, and nursing leadership. This multidisciplinary and interprofessional structure ensured that evaluation, selection, and implementation decisions reflected the perspectives of clinical, operational, financial, and informatics stakeholders across the health system.

The Evaluation

We developed a systematic, multiphase approach to objectively evaluate vendor performance, usability, and integration in a large nonacademic health system. The design began in February 2024 (phase 0), with phases 1 and 2 conducted from March through June 2024. A 90-day pilot (phase 3) began in October 2024 (Figure 1).

Figure 1. Timeline of pilot and implementation.

Phase 0: Market Scan

We identified potential vendors by reviewing "Ambient Speech" listings on KLAS and "Digitally Assisted Provider Documentation" vendors on the AVIA marketplace, both of which are trusted by the health care executive community as unbiased sources of data on the industry [13,14]. Vendors were excluded if they raised concerns regarding data security, financial stability, or scalability. Preference was given to those with product roadmaps extending beyond documentation to broader workflow enhancements. Four vendors met these criteria and advanced to phase 1.

XSL•FO
RenderX

Phase 1: Simulation Testing

Four vendors participated in a live patient simulation at McLeod Health. We anticipated that 3 main groups of clinicians would most likely benefit from ambient AI in practice: generalists, medical specialists, and surgical specialists. We selected these 3 specialties because they represent the breadth of medical practice and carry a high documentation burden with cognitively complex visit types, making them the most likely to realize meaningful benefits from ambient documentation. To represent these categories, we selected family medicine, cardiology, and general surgery. In collaboration with a revenue cycle expert, we developed the 5 most common patient encounters for each specialty, creating 15 standardized scripts. The cases incorporated real-world challenges such as difficult accents, contradictory family input, and interruptions to mimic the complexity of clinical practice.

Clinical staff and hospital leadership served as actors portraying patients. They were trained using scripts and could modify their cases to add variability and realism. Three McLeod physicians, representing family medicine, cardiology, and general surgery, conducted the simulated encounters. Each physician reviewed the cases in advance and carried out 5 simulated patient visits.

Simulations took place over several hours on 2 days in a large conference room to ensure transparency. Vendors sat in the front row and were required to record the encounters in real time using their solutions. They submitted the resulting notes immediately to the chief medical informatics officer without any opportunity for edits. Three vendors participated in person, while the fourth was evaluated separately using recordings of the cases. Notes were formatted as plain text and labeled only with the scenario patient name and number. Vendor identity was removed before distribution to the evaluators. Evaluators scored notes independently and remained unaware of which vendor generated each set throughout the review process.

A panel of 25 evaluators attended the sessions. The group included representatives from operations, clinical practice, revenue cycle, and patient satisfaction. Evaluators received the notes at the end of the week and were blinded to the vendors. They were instructed to review the notes, rank vendors based on quality, and disregard any marketing information they had received. Rankings were submitted individually, and evaluators did not have access to each other's scores. Points were assigned as follows: 3 points for the first choice, 2 points for the second choice, and 1 point for the third choice. Results were tabulated and presented to health system leadership for review.

Phase 2: Workflow Demonstrations

The 2 top-ranked vendors from Phase 1 advanced to the second phase. Each vendor was required to demonstrate how its solution would integrate with Epic in a simulated clinical encounter. The demonstration included coding support and real-time note generation for a predetermined complex outpatient case. The chief medical informatics officer acted as the simulated patient to ensure a standardized clinical encounter across both vendor demonstration days. Vendors functioned as the clinician in real time, conducting the interview and demonstrating how documentation would flow into Epic.

Approximately 30 physicians from across the health system participated as observers. They represented nearly all major specialties, except for psychiatry and pediatrics, as well as some smaller subspecialties. After the demonstrations, the physicians were asked to vote for 1 vendor, and to ensure fairness, only physicians who attended both demonstrations were permitted to vote. Their assessments were based on acceptability, workflow fit, and the potential impact on daily practice. At the same time, clinical informatics and IT security teams independently assessed each vendor. They examined the technology stack, implementation roadmap, and data safety, along with each vendor's capabilities beyond documentation.

When the results were collated, both physicians and technical reviewers reached the same conclusion. One vendor's product clearly outperformed the other, receiving overwhelming support from the physician observers and positive assessments from the informatics and information technology teams. The health system leadership had initially planned to conduct a side-by-side trial in phase 3. However, given the consistent findings, the leadership team canceled this planned trial and advanced the preferred vendor to the pilot phase.

Phase 3: Pilot Testing

The third phase was a 90-day pilot across multiple ambulatory specialties, including obstetrics and gynecology, orthopedic surgery, oncology, primary care, and emergency medicine. The health system initially purchased 500 licenses. To manage costs and ensure consistent use, participation was limited to physicians within the top 30% for documentation efficiency who were not already using human scribes. This selection intentionally favored experienced users to establish a reliable baseline and maximize the likelihood of measurable outcomes. Health system leadership emphasized that any efficiency gains should be applied to reducing after-hours documentation rather than increasing patient volume, to avoid exacerbating physician burnout.

Our primary objective in phase 3 was to assess the clinical effectiveness of the tool rather than its adoption. We assumed that if the solution delivered meaningful value, adoption would follow. In addition to pilot physicians, licenses were made available to selected administrative and inpatient clinicians for organizational visibility; however, these individuals were not intended to be part of the pilot cohort and were not included in outcome analyses. Our evaluation focused on ambulatory clinicians who incorporated the tool into routine outpatient practice. To avoid dilution effects, we required more than 20% utilization across encounters, 3 months of baseline data, and at least 1 month of active use. This approach allowed us to evaluate performance among clinicians who meaningfully integrated the technology into their workflow.

Key performance indicators included documentation efficiency, financial impact, and both provider and patient satisfaction. Adoption was defined as completing onboarding and actively using the solution to generate notes at 30 days and again at 5 to 8 weeks after onboarding. Measured documentation metrics included time spent documenting after work hours ("pajama time"), average time in notes per encounter, and the same-day note closure rate using Epic Signal data and established definitions.

XSL•FO
RenderX

Financial impact was modeled by evaluating coding distributions for established patients before and after implementation. Coding charges were based on the evaluation and management codes documented by each provider before and after the start of the pilot. Encounters were grouped by evaluation and management level, and published Centers for Medicare and Medicaid Services reimbursement values were applied to estimate potential changes in revenue [15]. This analysis was limited to established patients, where documentation-related shifts in coding were expected to be most evident. This analysis was also part of the standard evaluation process between McLeod and the vendor and was reviewed collaboratively on a regular basis. There were no usage fees during the pilot. A co-author (DS) independently verified and corroborated all vendor-supplied data through direct extraction of Epic Signal documentation metrics, along with charges, revenue value units, and scheduling data from the electronic health record (EHR). No discrepancies were identified.

Patient satisfaction was assessed using National Research Corporation Health survey questions for each provider over 8 months before and after the pilot (Table 1). The baseline period was February 2024 through September 2024; the pilot period was October 2024 through December 2024; the postpilot period was January 2025 through August 2025. This is a standardized process for the institution, consisting of 3 attempts to contact patients, with 24 hours between attempts: first by SMS text messaging, second by email, and third by interactive voice response phone call. Scores for the Patient Experience survey are calculated as "Percent Positive." This is determined by dividing the number of patient responses in the "Top Box" by the total number of surveys administered per time period. Responses in the Top Box were defined as "Yes, definitely" (from the options "No," "Yes, somewhat," "Yes, mostly," and "Yes, definitely") and ratings of 9 or 10 on a scale from 0 ("lowest") to 10 ("highest"). This methodology represents a standard approach for assessing patient experience scores over time. Scores were compared with the same provider's results from the prior year in a matched-pair analysis. In addition, providers completed a 7-question survey 1 month after the pilot to assess their ability to schedule more patients, their average time spent writing notes, and their overall satisfaction with the solution. For all comparative analyses, statistical tests were 2-sided.

To determine success in phase 3, we used a pragmatic risk and benefit assessment rather than fixed quantitative benchmarks. We weighed direct vendor costs and internal support requirements against provider-reported usability and perceived reduction in documentation burden. The pilot was considered successful when clinical value and provider acceptance justified the financial and operational investment.

Table . National Research Corporation (NRC) survey questions to assess patient satisfaction.

Abbreviation	Full survey question	Answer options
Provider listened	Did this provider listen carefully to you?	• "No" • "Yes, somewhat" • "Yes, mostly" • "Yes, definitely"
Rating of provider	Using any number from 0 to 10, where 0 is the worst provider possible and 10 is the best provider possible, what number would you use to rate this provider?	• 0 ("Worst provider") to 10 ("Best provider")
Trust provider w/ care	Did you trust this provider with your care?	• "No" • "Yes, somewhat" • "Yes, mostly" • "Yes, definitely"
NPS[a]: provider would recommend	How likely would you be to recommend this provider to your family and friends?	• 0 ("Not at all likely") to 10 ("Extremely likely")
Got enough information re: treatment	Did this provider give you enough information about your health and treatment?	• "No" • "Yes, somewhat" • "Yes, mostly" • "Yes, definitely"
Knew what to do if questions	Did you know what to do if you had more questions after your visit?	• "No" • "Yes, somewhat" • "Yes, mostly" • "Yes, definitely"

[a]NPS: net promoter score.

Ethical Considerations

This project was reviewed by the McLeod Health Institutional Review Board and formally determined not to constitute human subjects research per 45 CFR 46.102 [16]. It was characterized as a quality assessment and quality improvement initiative. A formal institutional review board review was not required.

XSL•FO
RenderX

Results

Phase 1

All 25 evaluators submitted note quality rankings within 2 weeks, producing a 100 percent response rate. Of these, 17 submitted complete 3-choice rankings, while 8 submitted a first-place preference only. Based on 45 notes, the overall scores were: vendor 1 with 57 points (45.2% of the vote), vendor 2 with 44 points (34.9%), and vendor 3 with 25 points (19.8%). When the physician subgroup rankings were reviewed, they mirrored the overall results, with vendor 1 receiving 45.8%, vendor 2 receiving 37.5%, and vendor 3 receiving 16.7%. The fourth vendor's notes were reviewed but excluded from further analysis due to noncompetitive pricing and contractual infeasibility.

Phase 2

Physician evaluations and independent technical reviews by the informatics and IT security teams reached the same conclusion. Nearly 20 physicians who observed both demonstrations overwhelmingly preferred vendor 2, with a 90 percent favorability rating compared to vendor 1. Technical reviewers also favored vendor 2, citing a more advanced technology stack and broader functionality beyond documentation, including conversational command capabilities within the EHR, specialty-specific chart summarization, and voice-guided billing and coding assistance. Although vendor 1 received higher note quality scores in phase 1, vendor 2 was rated higher in phase 2 because these additional capabilities were viewed as strategically important for workflow integration and long-term scalability. Based on the alignment between physician and technical reviewers, health system leadership determined that a side-by-side trial was unnecessary and advanced vendor 2 to the pilot phase.

Phase 3

During the 3-month pilot, 49 clinicians were onboarded in 2 cohorts. The adoption rate during the pilot was 79.6% (n=39). Based on the previously described analysis criteria, data from 23 providers were analyzed. The specialty breakdown was as follows: family medicine (n=12, 52.2%), orthopedics (n=5, 21.7%), oncology (n=4, 17.4%), and emergency medicine or urgent care (n=2, 8.7%). Of the analyzed providers, 70% were physicians (DO or MD), and 30% were advanced practice providers (physician assistant, nurse practitioner, and advanced practice registered nurse). Participants from obstetrics and gynecology did not meet the inclusion criteria for analysis.

Documentation efficiency improved substantially. Pajama time decreased by 35.4% per provider per 4-week period, with a trend toward significance (P=.054). Time spent on notes decreased by 28.3% (P<.001), saving 3.6 hours per provider per month, or 83 hours across the group. Same-day note closure did not change significantly.

Coding patterns shifted toward higher complexity for established patients. Level 3 visits decreased by 2.4% (P=.17), level 4 visits increased by 3.8% (P=.05), and level 5 visits decreased slightly by 0.4% (P=.66). These coding shifts alone produced an estimated average gain of US $379 per provider per month (Table 2). When combined with the 8.5% increase in established patient volume, the overall average projected revenue gain was US $2629 per provider per month, representing the total estimated impact of both coding complexity shifts and volume increases (Figure 2). All percentage change results are based on unrounded raw medians. We cannot exclude seasonal variation as a contributing factor, as a concurrent control group was not available. The pilot results were presented to senior leadership and contributed to the decision to scale the solution system-wide.

XSL•FO
RenderX

Median patient satisfaction scores were compared between the 8-month baseline period (February 2024 to September 2024) and the 8-month postpilot period (January 2025 to August 2025) for 21 of 23 providers based on data availability. Scores increased significantly, reflecting sustained improvement that extended well beyond the initial 90-day pilot window. Median scores increased from baseline for: "Provider listened" (8.4 points; $P<.001$), "Trust in provider" (7.5 points; $P<.001$), "Knew what to do if they had questions" (8.8 points; $P<.001$), and "Received enough information regarding treatment" (10.4 points; $P<.001$; Figure 3). Ratings for "Provider would recommend," and overall provider rating remained high without significant change (1.6 points; $P=.09$ and 0.7 points; $P=.28$, respectively). The median response rate was 32.7% across the entire period (n=1377 responses per month, or n=66 per provider). The median response rate was not statistically different before and during the pilot (34.1% vs 33.8%; $P=.23$), and during and after the pilot (33.8% vs 32.9%; $P=.81$) for the 21 providers.

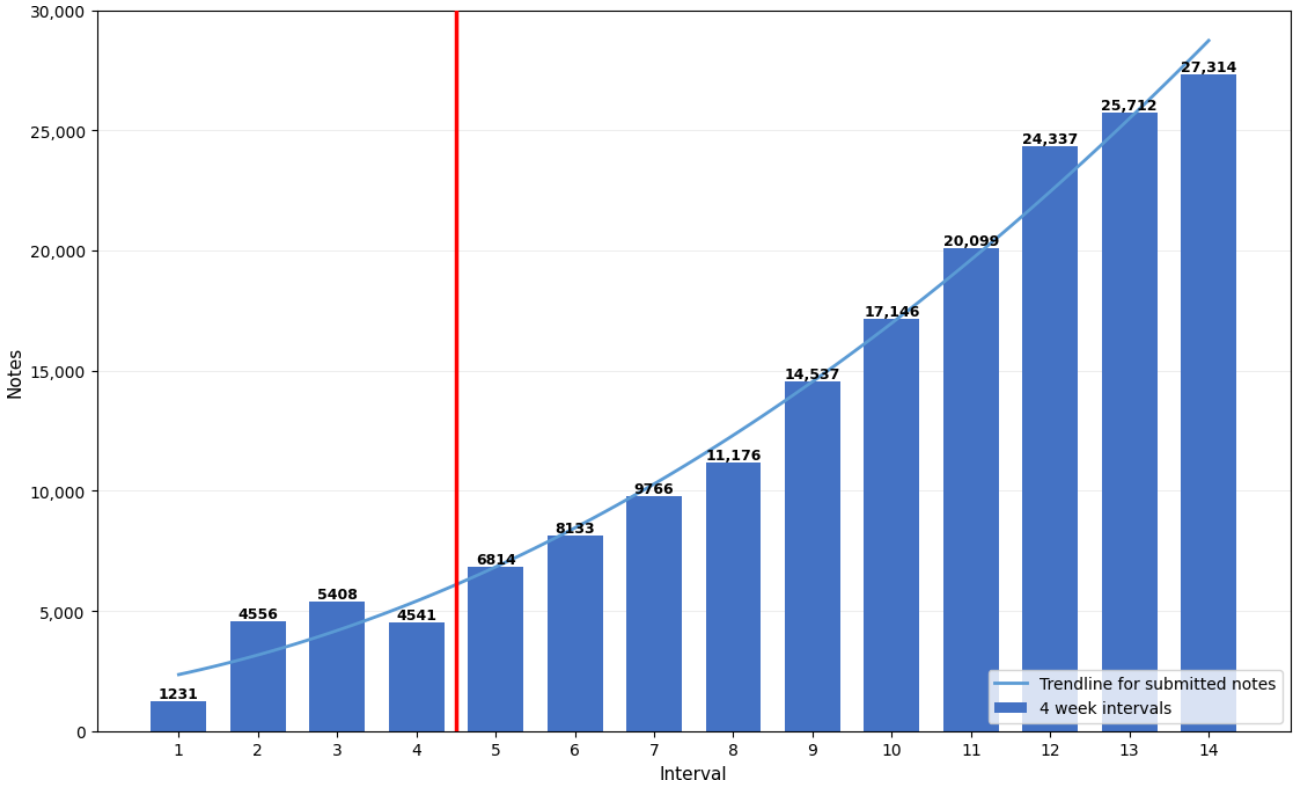
Provider experience was assessed with a survey administered 1 month after the pilot. Eighteen physicians responded (36.7% response rate, n=49). Half reported being able to schedule or see more patients per shift, and 89% reported spending 5 minutes or less per note. The median satisfaction score was 8 out of 10, accuracy was 7.5, and all respondents rated their likelihood of recommending the solution to a colleague as 10 out of 10.

The pilot met our criteria for success, and the hospital leadership decided to proceed with a larger-scale rollout.

Figure 3. Patient satisfaction survey results for the pilot at McLeod Health (n=21, median response rate of 32.7% or 1377 responses per month, courtesy of ©NRC Health. (2026). *Experience improvement database- medical practice*. February 2024- August 2025. [Dataset] NRC Health [17]; NPS: net promoter score.

System-Wide Implementation Progress

Interest in the ambient AI solution grew quickly during the pilot as physicians and staff observed improvements in efficiency, provider well-being, patient satisfaction, and financial performance. This demand created pressure to expand access beyond the pilot group. To address cost concerns and support broader use, health system leadership negotiated a new financial model with the vendor that shifted to usage-based pricing with a capped monthly rate. This structure reduced the risk of unused licenses and aligned incentives between the health system and the vendor.



XSL•FO
RenderX

Once the new model was in place, preliminary results were shared in a system-wide letter with approximately 675 ambulatory clinicians. Access was then expanded to all interested physicians and advanced practice providers who were not using human scribes, regardless of their efficiency. To meet anticipated demand, the health system purchased additional licenses to further expand access to inpatient teams.

Onboarding is occurring in phases to support workflow adaptation. The decentralized nature of McLeod's clinics and facilities has made communication challenging, so leadership launched an educational campaign that included physician testimonial videos highlighting early successes. In March 2025, self-onboarding was introduced to simplify adoption further.

Since the system-wide implementation began in January 2025, 250 providers have been onboarded in phases, achieving an adoption rate of 81%. Collectively, these providers have generated nearly 150,000 notes using the ambient AI solution (Figure 4). Analysis is in progress, but early indications are consistent with the results of the pilot, demonstrating improved documentation time and coding shifts.

Figure 4. Note volumes in 4-week intervals since the start of the pilot at McLeod Health (red line indicates the transition from pilot to system-wide rollout with usage-based pricing).

Discussion

Principal Findings

Our multiphase evaluation and implementation yielded substantial gains in documentation efficiency, clinician and patient satisfaction, and financial performance, while also generating practical lessons for nonacademic health systems.

While frameworks that assess the quality of various ambient AI tools have been published, we have not found any systematic frameworks designed to guide nonacademic health systems in selecting ambient AI vendors for implementation. We initially assumed that a well-established vendor would best meet our needs. However, our objective evaluation revealed that a lesser-known vendor outperformed a prominent competitor in real-world clinical testing. This demonstrated the importance of a transparent selection process that minimizes bias, secures clinician buy-in, and focuses on actual performance under realistic conditions. In our experience, high-stakes technology decisions in health care are inherently vulnerable to conformity bias, particularly when vendors benefit from strong market visibility or widespread peer adoption. Although we did not directly measure cognitive bias, the evaluation framework was intentionally designed to reduce susceptibility to reputation or consensus-driven selection. Predefined criteria, parallel vendor testing, independent technical and clinical assessments, and reliance on objective workflow metrics were used to anchor decision-making in observed performance rather than sales presentations or peer adoption patterns. This data-driven selection approach may help other health systems, particularly those with limited financial margins, reduce costly misalignment between vendor claims and operational realities.

The benefits of ambient AI extend beyond documentation efficiency alone [4,18-20]. We identified several additional benefits that have not been well-quantified in the medical literature on ambient AI. In our setting, time in notes decreased significantly, established patient volume increased, and coding shifts toward higher complexity were associated with an estimated $2629 per provider per month. Additionally, while this data was part of the standard evaluation process between McLeod and the vendor, to ensure the accuracy of these results, we performed an independent review of the raw data from the

XSL•FO
RenderX

electronic record and charges filed during this period and found that the trends remained consistent with these results. After the system-wide rollout, we observed continued and persistent improvements in these operational and financial metrics for high users. For small and mid-sized systems with narrow operating margins, these findings, if replicated in broader provider populations, strengthen the case for investment in ambient AI. Patient satisfaction also improved across multiple metrics in ways that far exceeded prior system-wide initiatives. Though we recognize that correlation does not prove causation and that other secular trends we did not assess could have influenced our findings, the results align with published literature demonstrating improvements in patient satisfaction after the implementation of ambient AI technology [21]. Plausible mechanisms for improvement include focused attention with less keyboard time and a lower perception of distractibility. These gains have also been sustained for months after the pilot, providing longer-term data that remains scarce in the literature.

Our implementation strategy shaped outcomes in unexpected ways. During the pilot, we targeted the top 30 % of providers by efficiency to maximize early adoption and financial return. This conservative approach was driven by concerns over license costs under a subscription model. While the strategy reduced financial risk, it likely underestimated the potential benefits for providers with heavier documentation burdens. However, it remains unclear whether baseline documentation efficiency meaningfully influences adoption patterns or sustained usage, and this question warrants further investigation [22]. We were surprised to see the high levels of adoption in the pilot, but this rate has stayed consistent over the year since system-wide implementation, suggesting that our initial rate was not an overestimate. Negotiating a usage-based pricing model has allowed us to expand access more broadly, aligning vendor and system interests. There is no published evidence identifying which clinicians or specialties benefit most from ambient AI, a gap that should guide future research and implementation strategies.

Scaling across a decentralized health system posed challenges. With numerous clinics and specialty practices spread over a large geographic area, the dissemination of information and consistent adoption strategies were difficult. This experience highlights a structural challenge faced by many nonacademic systems [7]. The primary barrier was not the technology but resistance to changing established documentation habits. Similar to prior transitions from typed documentation to speech recognition, skepticism persisted until clinicians experienced meaningful efficiency gains firsthand. Peer influence proved more effective than formal training. Physicians who demonstrated measurable reductions in documentation time and after-hours work gradually became informal champions, helping normalize adoption across clinics. To support this, we developed an onboarding website with workflow resources and created 12 testimonial videos highlighting early physician experiences. These efforts helped sustain engagement across the organization. This experience may be informative for other health systems implementing ambient technology.

Comparisons With Prior Work

Our results are consistent with several recent publications and particularly add to the literature for nonacademic health systems. An analysis of five ACMs found that the adoption of ambient AI tools was associated with decreases in total time spent in the EHR and time spent documenting (13.4 and 16.0 min, respectively) [23]. While these are not the same measures that we used, they represent the same trend across documentation efficiency measures. Their effects varied by user type with primary care specialties, users with adoption rates of more than 50%, as well as advanced practice clinicians and female clinicians, showing more gains than others. This corroborates our experience that adoption and value vary across a number of factors that have not yet been studied. Two separate analyses at major ACMs found that ambient AI adoption was associated with a modest increase in relative value units [24,25]. This again reflects the trend seen in our data. A randomized clinical trial comparing different ambient AI tools at an ACM found that clinicians had meaningfully different experiences across tools. This suggests that tool selection should be evaluated at the health system level, as we demonstrate in this paper [26].

Limitations

First, the limitations of our project include its single-system design, small pilot, lack of control for seasonality or case mix, and absence of a validated burnout assessment. Second, in phase 2, the chief medical information officer served as the simulated patient to ensure a standardized clinical encounter across both vendor demonstrations. Vendor selection was ultimately determined by independent physician voting and technical team assessments conducted without the chief medical information officer's influence; however, this could have led to some unmeasured bias. Third, in phase 3, we prioritized analysis of providers most likely to demonstrate measurable benefit, and therefore, 16 of 39 active participants were subsequently excluded for not meeting minimum usage thresholds. The final cohort of 23 providers in the pilot represents high-adopting clinicians, and the observed efficiency and financial gains may not generalize to providers with heavier documentation burdens, lower baseline efficiency, or more modest adoption patterns. Fourth, we also did not conduct any internal audits or compliance reviews beyond standard processes during the pilot window. Fifth, for the financial analysis, we were conservative in assessing gains due to increases in volume and complexity of established patients and did not account for gains from new patient volume or complexity due to concern for potential confounders. Additionally, we did not conduct a total cost of ownership analysis, and while there were no usage costs during the pilot, we also did not include cost savings on unused subscriptions from using a usage-based pricing model that was implemented during the system-wide rollout.

Recommendations

For the next steps, broader studies across multiple sites and specialties are needed to evaluate generalizability and to capture additional benefits, such as improved *International Classification of Diseases, Tenth Revision* (*ICD-10*) coding, hierarchical condition category capture, or closure of care gaps. Clinician satisfaction, coding changes, and burnout should also

XSL•FO
RenderX

be tracked over time, as sustained access to ambient AI may reduce attrition and recruitment costs. Patient satisfaction gains, particularly improvements in trust and communication, may also yield indirect financial benefits through value-based care contracts and organizational reputation. Finally, while overall satisfaction was high and reflected in the strong net promoter scores and positive qualitative feedback, clinicians identified areas for improvement in the ambient AI solution, such as enhanced specialty-specific customization, stronger inpatient functionality, and improved adaptability to individual documentation styles. Addressing these needs will be essential for long-term engagement. Despite these challenges, our findings suggest that ambient AI can meaningfully improve efficiency, satisfaction, and financial outcomes in nonacademic health systems.

Conclusions

In summary, this structured, multiphase framework minimized vendor influence and cognitive bias in the selection process, validated performance through objective clinical testing in a pilot, and guided a successful system-wide rollout at McLeod Health. Our experience demonstrates that nonacademic health systems can select and adopt ambient AI successfully using a transparent, evidence-based process that does not require major academic resources. When effectively integrated, ambient AI can reduce documentation burden, improve satisfaction for both providers and patients, and deliver measurable financial returns, which may be meaningful for other nonacademic health systems across the country.

Acknowledgments

The authors thank National Research Corporation Health for sharing their analyses of patient satisfaction metrics for the McLeod Health clinicians participating in the pilot. Figure 3 was reproduced with permission from National Research Corporation Health. The authors thank the staff at Suki for providing summary extracts used in the coding and financial analyses, which the authors independently verified using internal electronic health record and revenue data. No artificial intelligence tools were used in the creation of this manuscript at any point.

Funding

No external funding was received for the conduct of this study.

Data Availability

All data used in this study are proprietary to McLeod Health and the National Research Corporation Health. To request access, please contact the corresponding author.

Abstract

Background: There is significant potential for ambient scribe technology to enhance health care productivity, with a growing range of applications being developed and implemented internationally. Strong organizational drivers to improve efficiency, coupled with the technology's potential to help address clinician burnout, are accelerating interest and adoption. However, limited attention has been paid to the integration of such systems within electronic health records and unintended consequences, as stakeholders navigate their implementation and integration into clinical practice.

Objective: This study therefore aimed to explore the processes involved in implementing and adopting ambient scribe technology across diverse health care settings.

Methods: We conducted a real-time, longitudinal qualitative evaluation of a pilot implementation of an integrated ambient scribe system across National Health Service primary care and secondary hospital settings within a care system in the Midlands region of England. Data collection involved in-depth one-to-one interviews conducted in several phases: an initial scoping study to identify key interests and stakeholders for inclusion, followed by an implementation study with participants involved in the pilot. We also conducted 16 hours of nonparticipant observations of consultations. The implementation study gathered data at 2 time points, before implementation and 3 to 4 weeks after, to capture experiences, changes, and emerging impacts over time.

Results: We collected data from 45 individuals. Use cases varied across settings and shaped how ambient scribe systems were deployed. Differences between general practice and secondary care in documentation purpose, format, and workflow created challenges for developing and validating templates, though the technology showed flexibility across contexts. Automated note-taking often improved patient interaction but required clinicians to adjust how they spoke to ensure the technology captured their reasoning. Outputs were sometimes generic, reinforcing defensive documentation and reducing personal tone or contextual recall. Integration pathways carried distinct trade-offs: stand-alone systems (which were used by many stakeholders in our study) were easier to adopt but offered limited long-term benefits, while integrated systems required greater effort and standardization, yet promised improved efficiency and safety.

Conclusions: The ambient scribe market remains immature and volatile, creating strategic uncertainty for health systems. Careful procurement approaches are needed to balance the risks and benefits of integrated versus stand-alone systems, while aligning user demand with organizational needs for integration.

KEYWORDS

ambient scribes; note-taking; sociotechnical; qualitative; process evaluation; integration; health care

Introduction

With aging populations and rising prevalence of long-term conditions and patient complexity, health care systems are under growing pressure to improve the efficiency of care delivery [1,2]. Ambient artificial intelligence (AI) scribes offer substantial potential to enhance organizational efficiency, alleviate health care professional burnout associated with electronic data entry, and improve the quality of patient-provider relationships [3,4]. These tools do not merely transcribe speech, but they can also produce various kinds of summaries (eg, for patient letters, referrals, and discharge letters). If they are

XSL•FO
RenderX

integrated, they can also populate electronic health records (EHRs). See Table 1 for definitions.

Table . Definitions of terms.

Term	Definition
Ambient voice technology (AVT)	Infrastructure (eg, microphones, voice detection, and speaker diarization) that detects, separates, and prepares speech streams for processing.
Machine learning	Data-driven methods in which models learn mappings from data, including supervised, unsupervised, and reinforcement learning.
Natural language processing (NLP)	Branch of artificial intelligence concerned with the computational processing of human language in text form; used to transform transcripts into structured notes.
Large language model (LLM)	Neural language model trained on large corpora that transforms consultation transcripts into summaries and structured electronic health record (EHR) notes.
Digital scribe	System that records consultations and uses automatic speech recognition (ASR) and NLP models to extract or summarize relevant clinical information.
Ambient artificial intelligence scribe (ambient scribe)	System that records consultations using AVT, ASR, and LLMs to extract clinical information, generate summaries, and populate EHRs.

Clinicians currently spend a considerable amount of time on tasks such as note-taking during consultations, updating EHRs after consultations, and generating summary reports (eg, to facilitate referral or discharge letters) [5]. The effort of data capture for EHRs, compounded by their complexity and uneven usability, has consistently been found to be a contributing factor to stress and burnout [6-8]. By automating note generation, ambient scribes have the potential to reduce data entry work and improve job satisfaction [9,10]. They can also facilitate generating summary reports for various purposes, including referrals and discharge letters, thereby speeding up reporting [11].

Emerging evidence on the benefits of ambient scribes through improvements in efficiency and patient-provider relationships is also encouraging. For example, a 5-week trial with a diversity of clinicians (mainly family medicine) in Pennsylvania found that ambient scribe use was associated with a 30% reduction in daily after-hours work and 20.4% less time spent on notes during consultations (from 10.3 to 8.2 minutes; $P<.001$) [9]. Similarly, a prospective study across a range of clinical settings (mainly primary care) at Stanford Health found that ambient scribe users spent less total daily time (19.95 minutes) and after-hours time (5.17 minutes) maintaining EHRs [10]. In the United Kingdom, a multisite study on ambient scribe use conducted across hospital, primary, and mental health settings reported a 28% increase in time spent on direct patient care during consultations as well as an 8.2% reduction in consultation length (from 18.4 minutes at baseline to 16.9 minutes) [12,13].

These early benefits have attracted numerous vendors, many of whom are aggressively marketing products directly to clinicians, for example, by offering free use to build support ahead of expected procurement. However, there has been an increasing consideration of potential risks and unintended consequences associated with ambient scribes [14]. This pattern reflects a familiar dynamic, akin to the Gartner “hype cycle” [15], in which initial enthusiasm and inflated expectations are followed by a period of disappointment before a more balanced understanding of real-world benefits and limitations emerges.

Growing concerns about potential risks have prompted calls for stronger regulation and oversight [16-19]. For example, one key motivation for integrating ambient scribes is to enhance the accuracy of clinical records [20], which are often compromised by errors such as incompleteness, inaccuracy, and inconsistency [21,22], all of which can lead to patient harm [23]. However, emerging evidence suggests that ambient scribes may introduce new types of documentation errors (eg, hallucinations and omissions) that also have the potential to lead to considerable patient harm [24,25]. Furthermore, some clinicians report that notes generated by ambient scribes can be of lower quality than those composed by humans, often using simplistic language and lacking clarity or detail [9,26]. Consequently, some clinicians still spend considerable time editing generated notes [9,27].

Unintended consequences often emerge only during real-world use, as adopters and implementers integrate technological functionality into routine practice within their specific settings [28]. Ambient scribe technology is advancing rapidly, driven both by improvements in core technologies and by their adaptation to specific health care processes over time. In parallel, the outcomes we achieve with these tools are also evolving, as organizations gain experience, develop new skills, and optimize their use.

This evolution presents challenges for traditional evaluation strategies, such as randomized controlled trials of standardized interventions. Consequently, there is a growing need for rapid, real-time assessment and learning to appropriately balance benefits and risks [29].

Overall, existing evaluations of ambient scribes have predominantly focused on short-term pilot implementations, efficiency metrics, and clinician satisfaction outcomes. There has also to date been limited attention to unintended

XSL•FO
RenderX

organizational and workflow consequences and integration challenges within existing EHR ecosystems.

We therefore here aimed to explore the processes involved in implementing and adopting an ambient scribe intended to be integrated within existing EHRs across diverse primary and secondary health care settings spanning 2 English counties.

Methods

Design

We conducted a real-time longitudinal qualitative evaluation of a pilot implementation of an integrated ambient scribe system in a range of National Health Service (NHS) primary care and secondary hospital-based settings within a care system in the Midlands region of England. The organization launched the pilot between May and September 2025 to explore the potential benefits of scribe technology integrated directly with EHRs. This came at a time when many clinicians were informally using nonintegrated tools and manually copying and pasting outputs into the EHR, creating workflow and safety risks. The evaluation was undertaken between January and October 2025.

Ethical Considerations

Ethics approval was granted by the Health and Sciences Research Ethics Panel, University of Worcester (reference HS24250031-R). Participants received an information sheet and consent form in advance of the interview, which was arranged at a time convenient for the participant. Participants did not receive any financial compensation or other reimbursement for their participation in this study. They were free to withdraw at any time, and all provided written informed consent to participate before the interview was conducted. All identifiable information was removed from the interview recordings and transcripts, and findings were collated and summarized to protect participants' identities.

Study Setting

The care system we studied is responsible for coordinating health and social care across 2 Midlands counties in England. It brings together the NHS, local government, community health providers, and voluntary organizations to plan and deliver services jointly and to improve the overall quality and efficiency of care for the local population. Study settings included rural communities, market towns, and 2 outpatient clinical specialties in a city hospital based in a predominantly rural county. The vendor granted pilot sites a limited number of temporary licenses for the ambient scribe for the study period. A second ambient scribe system was being piloted at the same time in secondary care outpatient settings. This was not the primary focus of this evaluation, but participants reported on its use, so it emerged as an important aspect of the study. Some clinicians involved in this study had used, or previously had experience with, both systems. No other ambient scribe system was in use among the participating primary care staff. However, all described themselves as confident technology users who were open to the potential of AI. They also noted that their colleagues and peers had reported using ambient scribes with varying degrees of success. The role of the ambient scribe in the clinical interaction is described in Textbox 1.

Textbox 1. The role of the ambient scribe in the clinical interaction.

Across study sites, ambient scribing systems were used in 2 configurations: an integrated system embedded within the electronic health record (EHR) and accessed via the clinician's desktop computer and a stand-alone system accessed via a mobile phone, requiring manual copying of information into the EHR. Despite these technical differences, the implications for patient-clinician interaction were broadly similar.

At the start of the consultation, clinicians typically greeted the patient and then sought explicit consent to use the ambient scribe. If consent was granted, the clinician activated the recording function. Clinicians then switched the recording function off when the patient had left the room or paused recording to seek consent from the following patient before switching the recording system back on. During the consultation, clinicians generally refrained from typing and instead focused on interacting with the patient, while ensuring that the computer or phone was positioned close enough to capture the conversation. At the conclusion of the clinical encounter, the clinician deactivated the scribe and reviewed the generated output. This review process involved checking accuracy, making corrections where necessary, and, in the case of the stand-alone system, manually copying and pasting relevant information into the patient's electronic record.

Sampling and Recruitment

The study used 2 complementary sampling strategies associated with 2 different parts of the study.

The first scoping phase involved qualitative, semistructured interviews with a range of professional stakeholders, including vendors, managers, and clinicians who were involved in developing the strategy and were among the early users of ambient scribes. Stakeholders were identified either by the project management team or through recommendations from those initially interviewed, as we expanded the sample through snowball methodology. Each potential participant was independently contacted by a member of the research team (KC), who invited them to participate and provided a participant information pack and consent form. This purposive sample was designed to capture diverse perspectives from individuals involved in the strategic development and decision-making surrounding the use of ambient scribes in both primary and secondary care. It also informed the topic guides of the implementation study. Recruitment for this phase concluded when the interviewers (KC and RW) determined that a sufficiently varied and representative group of stakeholders had been included, reflecting a broad range of experience, knowledge, and roles. Three participants were interviewed twice, once at the beginning and again at the end of the study, to explore evolving insights and lessons learned over time.

The second part of the study focused on user experiences. We invited all clinicians and medical secretarial staff in both primary and secondary care who were participating in the pilot to take part in evaluation interviews. Two members of the research team (CR and JH) were provided with participants' email addresses and workplace details by the pilot project management

XSL•FO
RenderX

team and contacted them directly to invite participation. Each was provided with a participant information sheet and consent form. No interviews or observation sessions were conducted until participants had given written consent and confirmed that they had read the information sheet.

Data Collection

Data collection consisted of two phases: (1) stakeholder mapping and scoping interviews before the pilot and (2) an implementation study of the pilot, involving baseline and follow-up data collection (Table 2).

Table . Overview of data collection activities.

Phase of the work	Data collection method	Participants	Location
Stakeholder mapping and scoping	Semistructured interviews with stakeholders to identify interests, needs, expectations, and insights for the evaluation.	Key stakeholders identified through gatekeeper recommendations, including staff and ambient scribe vendors involved in management, procurement, or decision-making.	Online
Stakeholder mapping and scoping	Review of relevant documents provided by stakeholders (eg, business cases, strategies, meeting minutes, and development plans).	Key stakeholders identified through gatekeeper recommendations, including staff and ambient scribe vendors involved in management, procurement, or decision-making.	Not applicable
Baseline data collection from pilot sites	Semistructured qualitative interviews and real-time observations exploring current use, workplace processes, expectations, concerns, and barriers.	Primary and secondary care teams involved in the pilot; clinicians and medical secretarial staff.	Regional sites; interviews online or onsite; observations onsite
Follow-up data collection from pilot sites	Semistructured interviews to explore implementation and adoption experiences and follow up on baseline topics.	Participants from baseline plus additional clinicians or medical secretarial staff involved in the pilot.	Online or onsite (clinical workplace)

Stakeholders and users of the ambient scribe system under study were interviewed before the pilot began (baseline), and participants in the implementation study were followed up 4 to 5 weeks later. Observational data were also collected by the research team at a subset of implementation sites during baseline and follow-up phases to support understanding of the context and approaches to clinical note-taking across these settings, both with and without the use of ambient scribes. Observations took place during clinical consultations and were nonparticipant in nature (conducted by CR and JH). They involved researchers noting down details surrounding location, setting, equipment, participants, activities, and researcher impressions.

Interviews were conducted either over Microsoft Teams or in a private space at the participant's workplace. Topic guides for the interviews were developed collaboratively through discussion with the research team and the pilot management team (Table 3). They were informed by prior literature on digital health implementation and sociotechnical systems and structured around key domains of the technology-people-organization-macroenvironment (TPOM) framework [30]. These included technological properties (eg, usability), social dimensions (eg, integration with work practices), organizational dimensions (eg, governance), and system-level influences (eg, policy and markets). Initial versions of the guides were used in early interviews and iteratively refined as data collection progressed to incorporate emerging issues and improve clarity. The guides were also reviewed and discussed within the research team throughout the study to ensure conceptual relevance, consistency across settings, and alignment with the study aims. Participants in the implementation group were interviewed by either JH or CR. In some cases, interviews were conducted with multiple participants together, as requested by those taking part.

XSL•FO

Table . Topic guides interviews.

Theme	Scoping interviews	Baseline pilot site interviews	Follow-up pilot site interviews
Current environment	Current use of ambient AI[a] tools; user groups; perceived benefits; settings where tools may be useful; potential resistance and reasons; expected outcomes and how to measure them	Current note-taking processes without AI; awareness of documentation practices	—[b]
Implementation	Perceived challenges to adoption; setting-specific issues; mitigation strategies; preparatory work; identification of champions; potential unintended consequences; patient perspectives	Experiences of ambient AI use; impact on care, workflows, and systems; integration with existing systems; unintended impacts	General experience of using [SYSTEM]
Expectations	Expected use of ambient AI in the organization; potential benefits; anticipated challenges; mitigation strategies	Expectations of [SYSTEM] in the pilot site; perceived usefulness; concerns	Comparisons between expectations and actual experience
Documentation time	—	—	Time spent documenting before and after using [SYSTEM]; reasons for changes; impact on referral processes; use of time saved
Interactions	—	—	Changes in interactions with service users and staff
Workplace impact	—	Experiences of system integration; impact on care provision and workflows; unintended impacts	Impact on care provision, workflows, and system integration
Challenges	Perceived risks and concerns about adoption	Concerns arising during early use	Ongoing concerns following implementation
Uptake and attitudes	—	—	Views on wider rollout; changes in perceptions following pilot
Recommendations	—	—	Recommendations for implementation in other settings

[a]AI: artificial intelligence.

[b]Not available.

All interviews were audio-recorded and transcribed using AI software (Teams or Word Dictate), with transcripts subsequently checked and corrected for accuracy by the research team (JH and CR) against the original audio recordings. Two clinicians who were unavailable for a follow-up interview provided their responses in written form, submitted to the evaluation team either by email or via a colleague during their own interview. We collected data until no significantly new themes were emerging in the concurrent data analysis (the point at which we achieved thematic saturation). Regular team discussions helped to facilitate this.

Data Analysis

Transcripts and observation notes were anonymized and coded by the research team (KC, RW, JH, and CR) using NVivo (Lumivero; KC and RW) and Microsoft Excel codebooks (JH and CR). The datasets were analyzed using a mixture of inductive and deductive approaches using thematic analysis to identify recurring patterns and themes across sites and participants. We used the TPOM framework to code the transcripts and to identify to what extent the results aligned with the existing literature on complex digitalization initiatives in health service settings [30].

Emerging findings were discussed among the full research team during regular project meetings, and an analysis workshop involving KC, LMS, RW, JH, and CR was held at the end of the study to synthesize insights from all datasets and develop an overarching thematic narrative. This workshop focused on exploring novel themes that did not fit in with the framework and tensions across TPOM categories. It provided an opportunity to review findings collaboratively and reflect on the implementation journey and lessons learned.

Results

Overview

We collected interview data from 45 individuals and 16 hours of observations across 4 locations, including 2 primary care and 2 hospital settings (Tables 4 and 5). In total, 3 of the observations had both baseline and follow-up data, while 1 did not have a follow-up because the system was not regularly used in that setting at the time.

[b]Participants involved in pilot implementation sites.

Table . Overview of observations.

Location	Setting	Context	Baseline data collection	Follow-up data collection
Location 1	General practice (large)	Nonmetropolitan English district (population ~57,400)	2 clinics (2 hours; 5 consultations)	Not assessed
Location 2	Adult diabetes clinic	Rural English county (population ~60,475)	1 clinic (2 hours; 4 consultations)	1 clinic (2 hours; 4 consultations)
Location 3	Pediatric clinic	Rural English county (population ~60,475)	1 clinic (2 hours; 3 consultations)	1 clinic (2 hours; 5 consultations)
Location 4	General practice (small)	Rural English town (population ~4700)	1 clinic (3 hours; 3 consultations)	1 clinic (3 hours; 5 consultations)

The study involved several different user groups, including individuals who worked only with the stand-alone system, those who used only the integrated system, and those who had access to both. Participants demonstrated flexibility and enthusiasm toward piloting new ambient scribes throughout the evaluation, despite some challenges encountered. Many described their acceptance that this technology remains in its infancy in terms of clinical utility but acknowledged that there is significant potential for the future.

> *I'm sure there will come a time when AI, because the whole job of AI is to make the life of humans easier, not harder. And on this occasion this software made my life harder rather than easier, but I'm sure there will come a time.* [GP]

At baseline, clinicians also expressed confidence in their general ability to work with new IT systems. However, during the implementation study, some clinicians experienced difficulties using specific functions within the ambient scribe, such as letter generation, and a few discontinued using the system after encountering technical issues.

Variations Across User Profiles and Contexts

Clear differences emerged between user profiles. Stakeholders' attitudes toward and experiences with ambient scribe technology

XSL•FO
RenderX

varied considerably according to a range of contextual and individual factors. These included clinical setting, specialty, and professional role, as well as the nature and complexity of consultations. Differences in software maturity, customization options, experience and familiarity with particular systems, cognitive processing styles, duration of use, and overall technological confidence also influenced how stakeholders perceived and engaged with ambient scribe solutions.

Clinicians and medical secretarial users who had prior experience with the stand-alone ambient scribe generally preferred it to the integrated solution when comparing the 2. In contrast, users who adopted the integrated system during the pilot tended to be more optimistic about its potential, although some primary care staff discontinued use before the end of the study. This discontinuation was largely attributed to the system's limited functionality, textual inaccuracies, and difficulties modifying prompts and templates. Such changes on the integrated system required supplier validation and testing, leading to delays and additional demands on users' already limited time. Many clinicians reported spending substantial time between consultations, filtering out extraneous detail from the AI-generated consultation summaries, restructuring summaries, and adding in additional information that the AI-generated summary had missed. This included medication dosages or pertinent aspects of patient history (medical or nonmedical) or information that was not verbalized but required for notes (eg, prescription numbers and reimbursement codes). Lack of information in the system increased the burden of configuring notes, as relevant information had to be cut and pasted into the EHR, and was difficult to substantially reconfigure within the ambient scribe itself. Configuration was undertaken both by clinicians after consultation and secretarial staff, with time spent on these configuration activities found to offset the productivity gains the system was intended to deliver.

> *It takes you 5 minutes to read through what happened in the last consultation, when it would normally take me in 20 seconds because I would just have looked at my brief notes.* [GP]

These initial setup costs could potentially be outweighed by longer-term benefits; however, the short duration of the pilot and small number of participants prevented assessment of such effects. Respondents reported only modest efficiency improvements from using the integrated system and found it difficult to quantify time or effort saved due to other confounding factors. While none of the participants supported a full roll-out of the integrated ambient scribe system at this stage, most maintained a cautiously optimistic outlook about its future potential.

> *Yeah, it did save a bit of time, yeah. But not lots. That was frustrating because I could see that it could save time, but yeah, we just haven't got to that point where it was good enough.* [Secondary care clinician]

Key Themes Emerging Across Stakeholders and Settings

Overview

Several cross-cutting themes emerged across the respondent group (Textbox 2, Figure 1, and Multimedia Appendix 1). These are discussed below in detail in turn.

XSL•FO
RenderX

Textbox 2. Themes emerging from the analysis.

Variation in use cases strongly influenced how the systems were deployed in practice

- Use cases varied substantially between general practice and secondary care
- The purpose of the generated letters and reports differed by setting and care pathway
- The wide range of clinical needs and pathways presented a challenge for developing and validating variants (templates and prompts) for specific users or uses
- Summary and documentation practices differed across settings and between individual practitioners
- Ambient scribe technology is flexible, allowing use cases to be extended

Unintended consequences emerging within direct care activities

- Enhanced patient interaction from automating note-taking
- To get the ambient scribe to capture their thinking, clinicians learned to adopt different ways of speaking during the consultation
- Effects on reporting—generic style with loss of personal tone and individual clinical report preferences
- Supported, and in some cases increased, tendencies toward defensive documentation
- Risk of more mechanistic communication
- Reduced immersion when reviewing summaries (ie, summaries not taking clinicians back to the context they were created in)

Pathways to integration and their associated risk-benefit profiles

- The stand-alone system had lower adoption and learning costs than the integrated system
- Integration required significant development effort but held out greater promise for improved long-term efficiency and safety
- Integration required standardization and stabilization that was in tension with the diversity of use cases and pathways, and required strategies for addressing diverse contexts including more mature products that could cater for managed diversity through configuration rather than customization
- Tension between standardization, configuration, and customization
- Vendors require more sophisticated strategies to address diverse contexts

Procurement models and pathways to sustainable delivery within a volatile market environment

- Highly dynamic and varied market landscape
- Market immaturity creating strategic uncertainty
- Increasing user-driven procurement dynamics
- Heterogeneous implementation of diverse tools likely
- Risks associated with aggressive sales tactics
- Strategic choices for health systems

Figure 1. Thematic map of emerging themes and subthemes.

XSL•FO
RenderX

Variation in Use Cases Strongly Influenced How the Systems Were Deployed in Practice

Variation in Use Cases Between General Practice and Secondary Care

Use cases for ambient scribe technology differed markedly across care environments. General practice and secondary care exhibited distinct workflows, and significant variation was also evident between secondary care specialties such as pediatrics and diabetes. The purpose and structure of letters and reports generated through the system varied by care pathway and clinical setting, which further shaped how the technology was applied. For instance, general practitioners (GPs) needed to tackle a large range of requirements for referrals to different services, while secondary care consultations were more focused.

These diverse requirements created challenges for standardized system functionality when integrating ambient technology outputs with standardized systems like EHRs. Adapting a single solution to reliably support multiple, highly variable pathways introduced substantial cost and complexity. Medical secretaries continued to play a critical role in managing correspondence and ensuring quality. Documentation practices also differed. GPs were typically accustomed to taking real-time notes directly into their electronic patient record systems during their typically brief patient consultations, and most had developed strong manual note-taking skills, with a focus on accuracy and brevity.

> *Time taken to make notes and dictate letters minimal and smooth process.* [Researcher notes, primary care, baseline observation, location 1]

Prior Experience With Ambient Scribe Tools

Though very confident with technology and learning new systems, most participants lacked prior experience with ambient scribe tools. As a result of high adoption costs and marginal benefit over existing practice, they experienced little incentive to transfer. More secondary care clinicians had prior experience with ambient scribes, though not all did, and hospital clinicians generally sought to capture greater detail when documenting consultations than in routine primary care.

> *The process of dictating a letter is the process of thinking about the facts, reading the facts, remembering the case, and then distilling that into a narrative [...] there is a process of filtering it all through your brain and then hitting the paper ...* [Secondary care clinician]

> *Less experienced colleagues will just write loads, and they'll wind up with paragraphs of information. And then people who are a bit longer in the tooth will say, you know, "saw patient, patient is fine," just a very little, just a couple of lines.* [GP]

Evolving Use Cases

There was also a recognized risk that use cases would evolve over time, with users and organizations finding new ways to use ambient scribe functionality as well as with improving the performance of increasingly mature solutions. This dynamism added another layer of uncertainty for procurement, coordinated roll-out and optimization, and long-term sustainability of system design.

Unintended Consequences Emerging Within Direct Care Activities

Perceived Benefits of Ambient Scribes

Respondents identified several themes related to the impact of ambient scribe technology on the consultation encounter, including the cognitive and interpersonal aspects. Many noted positive effects, including enhanced patient engagement, improved eye contact, reduced mental and physical distraction, and increased transparency during clinical interactions.

Changes in Consultation Styles

A range of subtle changes in consultation style and reporting practices were also observed. We briefly summarize these changes here, but addressing these systematically would require a different kind of (larger scale, longer term) study. At baseline, several GPs and secondary care consultants referenced their need to document consultations with accuracy and sufficient detail to provide medico-legal protection in the event of a case being raised. At follow-up, several of these practitioners reported that they felt a benefit of the ambient scribe was its capacity to capture detail that supported this defensive note-taking. Some clinicians reported that ambient scribe–generated notes frequently contained inaccuracies. To improve the accuracy of documentation, they described modifying their communication style to be more structured and explicit during consultations. Some expressed concerns that they might be talking in a somewhat exaggerated or artificial way ("like a parrot") to ensure that the ambient scribe accurately picked up their words. Similarly, concerns were raised about how well the clinician's "authentic voice" was sustained within written records:

> *I tried to make it very clear, as if there was a ghost in the room, that this is what I'm doing now [...] Yeah, it made me become a bit more robotic ...* [GP]

> *Clinician is speaking to both ambient scribe and patient somewhat mechanically at times.* [Researcher notes, hospital outpatients, location 2]

Adverse Consequences for Documentation

Some participants also noted that the system struggled to capture the clinical reasoning behind their questions. Several clinicians reported adapting their communication style during consultations to make their thought processes clearer—both for the scribe and for the patient. Respondents noted that using the ambient scribe required them to verbalize their observations more explicitly during the consultation to ensure that emerging clinical assessments were captured accurately by the system. Views on this requirement varied. Some clinicians felt that articulating their reasoning aloud reinforced good consultation practice and clinical clarity, while others experienced it as disruptive, altering how they naturally communicated with patients. We also observed variation in clinicians' acceptance of the generated consultation summaries. Some were satisfied with the writing style, particularly valuing the system's ability to produce summaries tailored to different levels of medical literacy. Others,

XSL•FO
RenderX

however, felt that the output did not align with their preferred documentation style and required additional editing.

When reviewing generated summaries, a few users found that subsequent reading of the automated summaries—unlike their own notes and summaries—did not prompt recall of the earlier patient consultation and diagnosis and so would likely be less facilitative for later consultations.

> *So, you know, I have a narrative to share and that narrative I won't physically remember. I need to be triggered by the letter so I don't know if the AI generated letter will do that.* [Secondary care clinician]

Pathways to Integration and Their Associated Risk-Benefit Profiles

Significant Integration Work

Integration of the ambient scribe technology required substantial effort by the vendor and health professionals. Significant preparatory work was necessary to develop and validate templates and prompts, followed by continuous refinement through user feedback. Aligning the solution with existing organizational information infrastructures introduced unanticipated challenges. Integration work encompassed not only the electronic patient record but also documented management middleware, patient communication tools, electronic notes, and discharge summary systems. The lack of standardization across hospital service order processes and referral systems (varying between specialisms and clinics) amplified the complexity of achieving reliable integration. This was a particular challenge within primary care, where secretarial staff navigate referrals to many different external services with specific templates and documentation requirements. Primary care staff were also concerned that medical documentation included the correct terms and details required for quality and outcomes framework (a system used in UK general practice to reward GP surgeries for delivering high-quality care) coding, a feature likely to be key for wider adoption of such systems into primary care.

> *There could be [50 types of forms] if we were to count every single one, for the different conditions, types of referrals, everything. Every different part of the body, for cancer, it's got a different form [...] It would really help in that sense if it could summarise the notes and then fill in the form.* [Medical secretary, primary care]

Variations in Distribution of Set-Up Effort, Adoption Costs, and Benefits of Use

The distribution of set-up effort, adoption costs, and use benefits also differed sharply between integrated and stand-alone systems. Stand-alone solutions delivered immediate, user-level gains by automating discrete tasks, although this placed responsibility for workflow alignment on the individual to check and paste summaries into reports and letters.

> *Clinician manually copies and pastes medical history, current medications and test results from [electronic health record system] into the ambient scribe record. This is due to non-integration of the two systems.* [Researcher notes, hospital outpatients, baseline observation, location 2]

In contrast, integrated systems offered the prospect of longer-term organizational efficiencies but required substantial upfront investment and broader transformation. The short duration of the pilot meant that these longer-term benefits could not yet be observed, and respondents overall reported no material time savings during the study period.

> *It's [integrated system] going to take ... at least three months to set up, test, embed ... whereas if it's not integrated, you could set that up quite quickly. Obviously in the long term ... it is much more beneficial to have an integrated AI ... integration is more complicated, and it takes longer ... So if you want a quick win, you're not going to integrate, but your long-term strategy would be that you would integrate your AI, but it takes longer.* [Manager]

Balancing Standardization With Configuration and Customization

A recurring issue involved balancing standardization with configuration and customization. Users appreciated the flexibility to tailor templates in the stand-alone system, whereas the standardized templates required for integration were perceived as restrictive. Vendor validation and approval processes for modifications in the integrated system added further delays because templates had to function consistently across multiple settings. Provider organizations therefore needed to strike a careful compromise that protected interoperability without undermining user engagement and adoption.

> *... where there was a bit of a bottleneck was the prompt ... It's the prompt that tells you that tells the machine what to put on the page and the clinicians kept wanting to tweak their own prompts, while the [provider organisation] said 'no, you're not allowed to do that because we haven't signed off on what you're putting in your letters from this AI tool'. So, I think the clinicians were getting frustrated quite a bit. They have to like go through us to make those little changes, so we can reuse some prompts, but generally each specialty is gonna require different information in a letter.* [Supplier]

Vendors may need to develop more advanced strategies to respond effectively and efficiently to diverse clinical contexts and requirements. A model of channeled customization was viewed as a promising approach, involving a curated library of validated templates with controlled scope for local adaptation through configuration (change within predetermined parameters) rather than customization. This approach would help cater for user or use diversity in a managed way while avoiding the extremes of overstandardization or of complete variability, offering users a structured but flexible set of options to support documentation practices.

> *What ideally you would probably want is to have some agreed templates for specialties or disciplines with a level of local editability that would appease clinician requirements. So, you kind of want it on two levels.*

XSL•FO
RenderX

> *You want to have ... the [provider organisation] going ... we're going to have two templates for each specialty, for example, or three templates for each specialty. And within that we'll give the clinicians this much editability to hone those templates for the requirements of specialist clinics.* [Manager]

Procurement Models and Pathways to Sustainable Delivery Within a Volatile Market Environment

Highly Dynamic and Varied Market Landscape

The market for ambient scribe technologies is highly dynamic and diverse. It currently comprises a mix of numerous recent start-ups and more established systems that have benefited from longer periods of optimization. Solutions are evolving rapidly, with continuous improvements in performance and integration capabilities.

> *... that's like, Whack-A-Mole to me, that we'll just spend our entire lives just trying to work out who's coming to market. And they're literally coming up out of the woodwork, like, Whack-A-Mole. You know, every day I hear of two or three extra.* [Manager]

Market Immaturity Creating Strategic Uncertainty

This immaturity in the market contributes to strategic uncertainty for adopting organizations. Many are hesitant to lock themselves into a single solution because technology continues to change at a pace. Integrated products are especially affected, since they entail more complex implementation and higher switching costs. As a result, procurement processes must become more agile, and deployment strategies need to support coordinated upgrades and structured sharing of local learning across sites.

Increasing User-Driven Procurement Dynamics

Procurement is also increasingly being driven by users rather than by organizations. Vendors frequently target individual clinicians or clinical teams directly, sometimes offering free access to encourage familiarity, dependency, and local adoption. This creates challenges related to oversight, information governance, and regulatory compliance, particularly when solutions are introduced outside formal organizational pathways. In April 2025, during the study period, NHS England issued a mandate that any ambient scribe performing summarization in clinical practice should be classified as a Medicines and Healthcare products Regulatory Agency Class 1 Medical Device, reflecting growing concerns about governance and patient safety. Several clinicians reported using tools acquired for their private practice.

> *... it feels a bit on this one like national playing catch up, whereas in other scenarios historically it would be a ... plan, a policy, it would be issued out and you'd be told, you know, you've got to be doing it by next date and you might not have thought about it yourself yet. So, this definitely feels the inverse of what we would normally see.* [Manager]

Given these dynamics, a patchwork of heterogeneous implementations across services, specialties, and regions appears likely. Aggressive sales approaches that bypass organizational governance risk further fragmenting decision-making and complicating future rationalization efforts. Health systems will therefore need to consider whether to permit a hybrid environment that accommodates multiple solutions or pursue more standardized adoption of a single product. Each of these strategic choices presents distinct implications for procurement policy, long-term interoperability, and regulatory management.

> *... there is a load of challenges around regional procurement because actually they've got so many organisations in place. It's how do you satisfy everybody's needs and in theory the needs should be the same. But actually, I think they're subtly different, particularly when it comes to if you want it to be integrated with your with your EPR [Electronic Patient Record]. I think the suppliers will say they can do it and then the reality will be that they can't. So yeah, or they'll be able to do it for some and not others. So, I do think there's going to be some challenges within that ...* [Manager]

Discussion

Summary of Main Findings

We found overall enthusiasm for ambient scribes, but they were used very differently across health care settings, reflecting diverse clinical workflows and documentation practices. While the technology showed flexibility and promise, it also introduced unintended consequences, from changes in clinician communication styles to more generic reporting and defensive documentation. Integrated systems offered greater long-term benefits compared to stand-alone solutions but required significant effort and careful balancing between standardization and local adaptation.

Overall, this work shows that despite strong enthusiasm and rapid uptake, the deployment of ambient scribes is still at an early stage, and the technology has not reached maturity. Risks and benefits remain uncertain, and effective implementation will require careful planning, iterative learning, and attention to evolving market and system conditions.

Strengths and Limitations

It is still very early in the evaluation of ambient scribe technologies, but this work contributes to the emerging evidence base. Our study examined real-world adoption processes across different systems and service settings, providing high ecological validity. However, we focused primarily on a single integrated system, while many users had also experience of using a second stand-alone ambient scribe. This may have led to carryover effects from prior learning and direct comparisons with the alternative solution. It may also reflect the features of the system in question and limit generalizability to other integrated systems. Future studies should therefore aim at more direct comparisons between integrated and stand-alone systems, ideally across a range of institutional contexts, as our findings may lack generalizability.

Clinicians in this study were generally confident users of new technology, which supported strong engagement in data collection activities and excellent follow-up response rates. Future evaluations would benefit from involving staff and

XSL•FO
RenderX

organizations who are not natural early adopters or who hold significant reservations about ambient scribes. Understanding the needs and behaviors of different user and organizational profiles will be essential for preparing the wider workforce and for designing effective protocols and training packages that accommodate a diverse range of staff. Mitigating against this early adopter bias will also be crucial in identifying adoption challenges and unintended consequences.

The short time frame of this evaluation and the implementation were clear limitations, but it reflects the rapid, real-world deployment of ambient scribe solutions across services. Further research is needed to understand long-term integration with different EHRs. Longitudinal studies are particularly important, as many unintended consequences, workflow adaptations, and adoption patterns may only become visible over the medium to long term, including impacts on clinical follow-up, decision-making, burnout, workload, and patient satisfaction.

We initially aimed to estimate time spent on key activities before and after scribe deployment to understand efficiency impacts. However, participants found it difficult to provide reliable time estimates, and these were self-reported and subjective. While our work provides valuable insights into how staff felt about their experience with ambient scribes, future work must strike a balance between the cost and complexity of rigorous time-and-motion studies (which will inevitably vary across contexts) and the use of simpler, less robust self-reported indicators that are easier to collect and still valuable for informing business cases in rapidly evolving environments.

Integration of Findings With the Existing Literature

Research on ambient scribes has so far focused predominantly on their impact on clinician efficiency and burnout related to administrative workload [1-4,31]. Our study contributes to this growing evidence base in several important ways.

First, we found that early-stage adoption appears to yield at best moderate improvements in efficiency. These benefits vary substantially across settings, systems, and individual users. While many existing studies report considerable gains in efficiency, workload reduction, and burnout mitigation [9-14,32-35], our findings highlight the need for a more nuanced understanding. Efficiency benefits cannot be generalized without examining contextual factors such as organizational workflows, user characteristics, and how these evolve over time.

Second, our study draws attention to emerging unintended consequences—an area that has received considerably less scrutiny than exploration of impacts [14]. Consistent with previous work [11,13], clinicians described several positive consultation effects, including improved eye contact and reduced cognitive load during consultations. However, we also observed notable shifts in consultation dynamics. Clinicians reported modifying their communication style to “speak to the scribe,” verbalizing thoughts they would not normally articulate during a natural patient interaction. In addition, ambient scribes were found to affect cognitive processes related to note-taking, potentially hindering information retrieval. These issues warrant a more detailed, longitudinal investigation to understand how ambient scribes may reshape clinical work, patient relationships, administrative routines, and documentation practices over time [36,37]. This will also require attention to how the patient voice and even the patient record may be reshaped through algorithmic summarization and template alignment. AI-driven structuring may privilege biomedical categories over experiential accounts, risking narrative elements (which are often crucial in relation to patient experience) to be neglected in structured outputs [38]. In doing so, ambient scribes may subtly reconfigure what counts as clinically relevant, although this may not be in the best interest of the patient and their care.

Finally, our study provides insight into the differing implementation and adoption pathways associated with stand-alone versus integrated ambient scribe systems, including the benefits, trade-offs, and affordances of each. Previous research has not explicitly examined these distinctions; yet, they are likely to become increasingly significant. In the long term, benefit profiles will depend heavily on the quality of integration between ambient scribes and EHRs; in the short term, strong bottom-up user demand is likely to drive adoption patterns [12,13,32,34,39]. Organizations, particularly those without active engagement from their primary EHR provider, may face difficult decisions around standardization, governance, and procurement. These tensions reflect broader debates within medical informatics regarding standardization versus local customization [40]. What is distinctive in the case of ambient scribes is the strong user pull driving ground-level uptake, which is challenging organizational structures to keep pace with oversight and regulation.

Recommendations for Policy and Practice

Different clinical pathways operate on varying timescales, so strategies must balance short-term usability with long-term integration goals. Stand-alone systems can deliver quick wins for clinicians, while integration remains essential for future interoperability and organizational efficiency. Organizations should avoid entering overly long contracts or buying licenses for all users upfront, instead adopting a measured, flexible approach that allows learning and adaptation as the market evolves.

Early procurement should focus on short-term, limited licenses with a structured rollout, embedding process improvements and evaluating outcomes before committing to wider deployment. This will help to ensure resources are targeted where benefits are likely and support evidence-based decision-making. Evaluation findings should inform procurement, though this remains challenging in a context of rapid, bottom-up adoption and changing vendor landscapes.

Initial deployments should target clearly defined use cases, recognizing that the same technology may be applied differently across clinical settings. Shared learning between sites and vendors will help develop common standards and governance processes, particularly for managing changes to prompts or templates. Maintaining a human-in-the-loop approach is essential to ensure safety and clinical accountability, as there are still many risks associated with unintended consequences of systems (eg, impacts on interactions, hallucinations, and cognitive processing) and significant variations across contexts of use. These often only become apparent once systems are

XSL•FO
RenderX

deployed in real-world contexts of use, highlighting the importance of concurrent monitoring.

As adoption progresses, incremental, opt-in deployment is preferable to large, mandated rollouts, allowing systems to mature while minimizing risk. Ongoing workforce education and engagement, delivered by local champions within clinical environments, will be key to building confidence, addressing concerns, and ensuring responsible use of ambient scribe technologies.

We summarize wider policy implications emerging from these dynamics in Textbox 3.

Textbox 3. Summary of policy implications emerging from this work.

Strategies must balance short-term local usability and benefits with wider long-term integration and interoperability goals within and across organizations.

There is a need to develop novel procurement strategies that avoid vendor lock-in and allow local experimentation and flexibility in line with evolving markets. These should consider different pathways including stand-alone and integrated systems.

Clearly defined use cases of procurement and roll-out can serve as exemplars or blueprints for wider learning across organizational settings. Identifying lessons learned will be particularly important. These need to be used to incrementally build on local lessons before wider roll-out.

Clarifying governance and accountability implications as well as workforce education will be crucial for the safe implementation and adoption of ambient scribes.

Future research must play a key role in informing these efforts. For example, longitudinal effects of ambient scribes on clinical workflows and documentation practices are currently not known and need to be explored over time, identifying and mitigating emerging risks for patient safety before adverse effects occur. There is further a need to conduct comparative studies between integrated EHR-embedded systems and stand-alone tools to better understand the different pathways and risk-benefit profiles over time. Other areas to explore include impacts on clinician burnout, cognitive demands, documentation practices, and changes in patient-provider interactions and relationships.

Conclusions

The deployment of ambient scribe technologies remains at an early stage, characterized by strong enthusiasm and rapid experimentation. However, this enthusiasm must be balanced with careful attention to safety, quality, and potential unintended consequences. These systems are likely to evolve substantially as integration with different EHR platforms progresses, offering the prospect of significant long-term benefits for clinical efficiency and documentation quality.

At the same time, it is important to remain mindful of broader system-level effects. Evaluation should extend beyond measuring improvements in individual productivity to include impacts on teamwork, communication, workplace tasks, and roles and organizational dynamics, ensuring that innovation enhances, not fragments, health care delivery.

Abstract

Background: Clinical documentation demands a significant share of surgeons' time and can contribute to documentation-related burden and burnout. While electronic health records (EHRs) offer accessibility and completeness, they also impose a substantial documentation burden. Ambient AI scribe solutions aim to reduce this burden by capturing patient-clinician dialogue in real time to automate clinical documentation. However, their specific impact on surgical practice remains under-studied.

Objective: We aimed to evaluate surgeons' perceptions of documentation efficiency, documentation timeliness, and burnout following implementation of an ambient AI documentation tool within the EHR during outpatient clinical encounters.

Methods: We conducted a single-center cross-sectional survey of all surgical faculty members at a tertiary care academic institution 3 months after institutional implementation of the ambient AI-powered clinical documentation tool Dragon Ambient Experience (DAX) Copilot. A total of 368 faculty surgeons representing 12 surgical subspecialties were invited to participate. Participants were asked to retrospectively assess their baseline perceptions of documentation burden and subsequently report perceived changes following DAX Copilot implementation using standardized Likert-scale survey items. Descriptive analyses were performed among active DAX Copilot users. Open-ended responses were analyzed using practical thematic analysis.

Results: The survey was completed by 28.5% (105/368) of the invited surgeons, with 38.1% (40/105) of participants reporting active DAX Copilot use. Overall, 77.5% (31/40) of users reported some or significant improvement in perceived documentation efficiency. Of those who reported a negative or neutral baseline perception of documentation time, 75.8% (25/33) reported an improved perception of efficiency following implementation of the ambient AI tool, whereas 85.7% (6/7) of surgeons with positive baseline perceptions of documentation time also reported further improvement. Improvements in perceived documentation timeliness were reported by 70.4% (19/27) of surgeons who previously reported negative or neutral baseline perceptions of timeliness and 76.9% (10/13) of surgeons with positive baseline perceptions. Additionally, 72.5% (29/40) of respondents reported enhanced documentation accuracy, detail, and consistency after DAX Copilot implementation. Improvements in self-reported burnout levels were reported less frequently, with 59.0% (23/39) of respondents reporting some or significant improvement, including 63.0% (17/27) with negative or neutral baseline perceptions of burnout. Qualitative feedback highlighted perceived improvements in documentation quality while also identifying current limitations of the technology, including challenges related to EHR integration, device compatibility, and customization.

Conclusions: In this single-center survey of surgeons using DAX Copilot in their outpatient clinical practice, use of ambient AI scribe technology was associated with improved perceptions of documentation efficiency and timeliness. These findings suggest that ambient AI tools may improve surgeons' perceived documentation experience in outpatient surgical care.

Introduction

Clinical documentation, while essential, has become an increasing source of strain for physicians, particularly with the rise and rapid expansion of electronic health records (EHRs) over the past few decades. Increased time expenditure on documentation has been shown to increase the odds of burnout among health care providers, which in turn has been linked to worse patient outcomes and increased medical errors [1-3]. For surgeons specifically, reported burnout rates range from 30% to 45%, with commonly cited contributing factors including limited control over time, challenges with work-life balance, and documentation burden [4,5]. The literature has demonstrated inefficiencies in the documentation process and massive time investments requiring up to 73.3 twenty-four–hour days of total annual documentation time among a group of surgeons within a trauma setting [6]. In one study of surgical residents specifically, survey participants reported spending at least 30% of their 80-hour work week using the EHR [7]. As concerns regarding surgeon shortages and workforce attrition continue to grow, interventions that reduce administrative burden may play an increasingly important role not only in supporting physician well-being but also in promoting workforce sustainability, retention, and long-term access to surgical care.

Emerging technologies such as ambient AI scribes offer promising strategies to reduce documentation burden that traditional approaches such as medical scribes, workflow modifications, educational initiatives, technological upgrades, and clinical documentation specialists have only partially addressed [8,9]. Ambient AI agents listen to clinician-patient conversations and use generative AI to draft notes as a digital scribe. Early evaluations of ambient AI documentation technologies have demonstrated improvements in documentation efficiency, reductions in documentation and after-hours EHR time, and favorable clinician perceptions across ambulatory practice settings [10-15]. For primary care providers specifically, documentation time was reduced by 28.8% [16]. In addition to improved time to documentation completion, ambient AI has been shown to decrease burnout rates across clinicians in select studies [17]. In one analysis performed in 2025, the proportion of clinicians reporting burnout decreased from 52.6% to 30.7% over a 42-day study period. Furthermore, users of ambient AI noted higher rates of documentation-related well-being [10,15]. However, evidence has been mixed across the literature regarding burnout reduction, with an additional study of 110 primary care providers showing no change in burnout scores after implementation [16].

Despite promising data from primary care and other ambulatory specialties, evidence evaluating ambient AI documentation technologies specifically in surgical practice remains limited. Although recent studies have included surgeons within broader ambulatory clinical cohorts, few investigations have focused specifically on surgeons across multiple surgical subspecialties, and relatively little is known about surgeons' perceptions of ambient AI documentation technologies [18-21]. Furthermore, surgical outpatient encounters differ structurally from those in previously studied specialties as they are often centered on consultation, procedure planning, and operative decision-making, with documentation requirements encompassing informed consent, perioperative planning, and multidisciplinary coordination. Billing for outpatient surgical encounters also differs greatly from that for most nonprocedural specialties as it is typically dependent upon medical decision-making being adequately documented rather than on a time-based billing model. Consequently, the extent to which the benefits of these technologies observed in broader ambulatory populations translate to outpatient surgical practice remains uncertain. An ambient AI-powered clinical documentation tool, Dragon Ambient Experience (DAX) Copilot, embedded within the EHR was implemented at our institution and made available to all surgeons for their outpatient clinical encounters. We sought to understand whether the implementation of ambient AI for surgeons would improve perceived documentation efficiency and burnout.

Methods

Overview

We evaluated the early implementation of DAX Copilot across surgical subspecialties through a cross-sectional survey of all surgical faculty members at Vanderbilt University Medical Center. A total of 368 faculty surgeons representing 12 surgical subspecialties were identified and invited to participate. Surgical trainees, including residents and fellows, were not eligible for use during the initial rollout of the AI scribe and were therefore not included in the present study. Surgical subspecialties included cardiac surgery, otolaryngology, neurological surgery, ophthalmology, oral and maxillofacial surgery, orthopedics, pediatric surgery, plastic surgery, general surgery (including trauma, colorectal surgery, minimally invasive surgery, liver or kidney transplant, surgical oncology, and other related areas), thoracic surgery, urology, and vascular surgery.

To ensure successful adoption, surgeons received comprehensive onboarding and training in the months prior to DAX Copilot integration into outpatient workflows on January 15, 2025. Prior to full deployment, surgeons completed onboarding that included self-service training materials, in-person and virtual guided sessions, and one-to-one support as needed to ensure familiarity with the mobile EHR app, patient consent workflow, and the editing of AI-generated notes. DAX Copilot is a HIPAA (Health Insurance Portability and Accountability Act)-compliant generative clinical voice technology facilitated by AI and owned by Nuance Communications, a Microsoft company. This emergent health technology is meant to reduce the administrative burden on health care providers by using a large language model to document and transcribe patient-provider interactions in real time. DAX Copilot is integrated into the EHR and uses conversational generative AI to automatically and instantaneously draft clinical notes after a patient visit. With patient consent, clinicians can initiate recording of the clinical encounter through the mobile EHR app on their personal iOS devices. DAX Copilot passively captures the clinician-patient conversation in real time. Upon completion of the visit, the audio recording is securely uploaded to a cloud-based service, where it is transcribed and transformed into a draft clinical note. The draft note is then returned to the EHR for clinician review

XSL•FO
RenderX

and editing, after which the finalized note is saved directly into the patient's chart. Adoption of the technology was voluntary, and surgeons were permitted to use their own discretion regarding whether to incorporate DAX Copilot into their clinical workflow.

Outcome Assessment

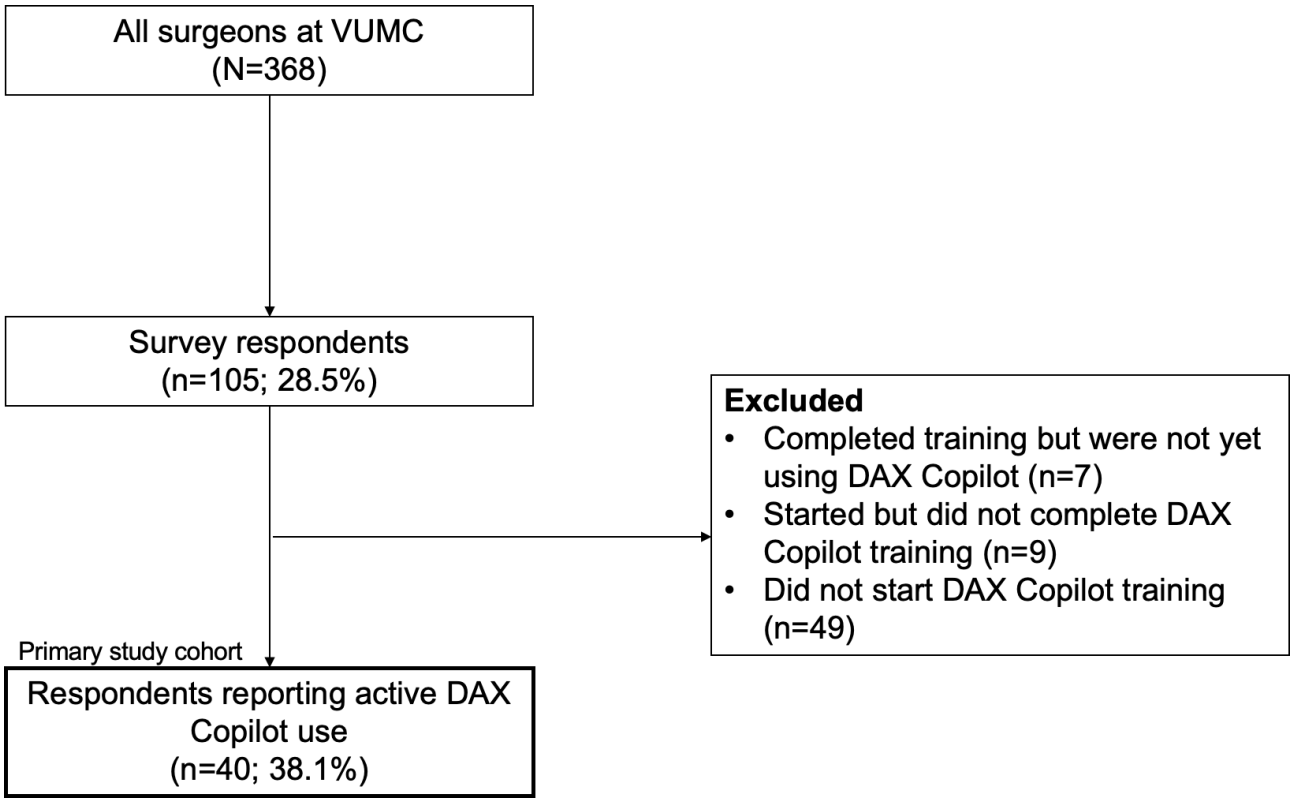
We assessed surgeons' experiences with DAX Copilot 3 months after implementation throughout April 2025 by distributing a REDCap survey (Vanderbilt University) to all surgical faculty, with a focus on burnout and documentation practices. The survey collected qualitative and quantitative data regarding surgeons' experiences with the AI tool. Assessed domains included perceived burnout, time spent on documentation, and timeliness of documentation before and after implementation. Because the survey was administered only after DAX Copilot implementation, respondents were first asked to retrospectively assess their baseline perceptions prior to implementation and were then asked to evaluate the perceived impact of DAX Copilot on each domain. Responses to both retrospective baseline and postimplementation questions were captured using standardized 5-point Likert scales. Additional postimplementation questions evaluated surgeons' perceptions of patient care, along with a single composite item assessing the perceived impact of DAX Copilot on documentation accuracy, detail, and consistency. While the survey items were not derived from formally validated assessment instruments, they were informed by prior literature evaluating health care provider burnout and documentation burden. An optional open-ended survey question was included to allow respondents to provide additional feedback regarding their experience with DAX Copilot, including perceived benefits, limitations, or implementation challenges not fully captured by the structured survey items. Open-ended responses were analyzed using practical thematic analysis. The first author (SL) independently reviewed all responses, identified recurring themes, and grouped the feedback into categories reflecting perceived benefits and opportunities for improvement. Themes were reviewed by a second author (JRR) for accuracy assurance; however, independent coding and formal assessment of interrater reliability were not performed. Representative quotations were selected to illustrate the themes that were identified.

Ethical Considerations

This study was reviewed and approved by the Vanderbilt University Medical Center Institutional Review Board (250238). This study was determined to meet all applicable ethical requirements for research involving human participants. Participation was voluntary. An electronic informed consent statement was presented at the beginning of the survey, and participants indicated their consent by proceeding to the survey. Participants could discontinue participation at any time without penalty.

Data Analysis

We analyzed surgeons' perceptions of documentation before and after DAX Copilot implementation using descriptive statistics. Baseline characteristics were compared between active DAX users and nonusers. Categorical variables were compared using the Pearson chi-square test or Fisher exact test when expected cell counts were small. Statistical significance was defined as $P<.05$. Responses to 5-point Likert-scale questions were dichotomized for descriptive analyses. For baseline assessments, responses of "none" or "slight" for perceived burnout, "minimal" or "low" for perceived time spent on documentation, and "optimal" or "good" for perceived documentation timeliness were classified as positive baseline perceptions. All remaining responses were classified as negative or neutral baseline perceptions. For postimplementation assessments, responses indicating "significant" or "some" improvement were classified as a positive change, whereas all other responses were classified as no improvement or worsening. Analyses of survey items with missing data were based on available responses. Results are presented as frequencies and percentages for the overall cohort and stratified by baseline perception where applicable. Analyses were performed using R (version 4.5.2; R Foundation for Statistical Computing) [22].



Results

Survey responses from a diverse range of surgical subspecialties revealed early adoption patterns and demographic trends among DAX Copilot users. Of the 368 surgical faculty members surveyed, 105 (28.5%) completed the questionnaire. At the time of the survey, 3 months after DAX Copilot implementation, 38.1% (40/105) of the respondents reported actively using the tool (Figure 1).

These 40 surgeons represented 9 distinct surgical subspecialties. Most (24/40, 60%) were male. Nearly one-quarter (9/40, 22.5%) had fewer than 5 years of practice experience, with the remainder distributed relatively evenly across longer practice durations (Table 1).

Figure 1. Cohort selection diagram for a single-center cross-sectional survey evaluating surgeons' perceptions of the ambient AI documentation tool Dragon Ambient Experience (DAX) Copilot at Vanderbilt University Medical Center (VUMC) 3 months after implementation. Of 368 eligible surgeons invited to participate, 105 completed the survey. Respondents who were not actively using DAX Copilot or who had not yet started or completed training were excluded, yielding a final analytic cohort of 40 active DAX Copilot users.

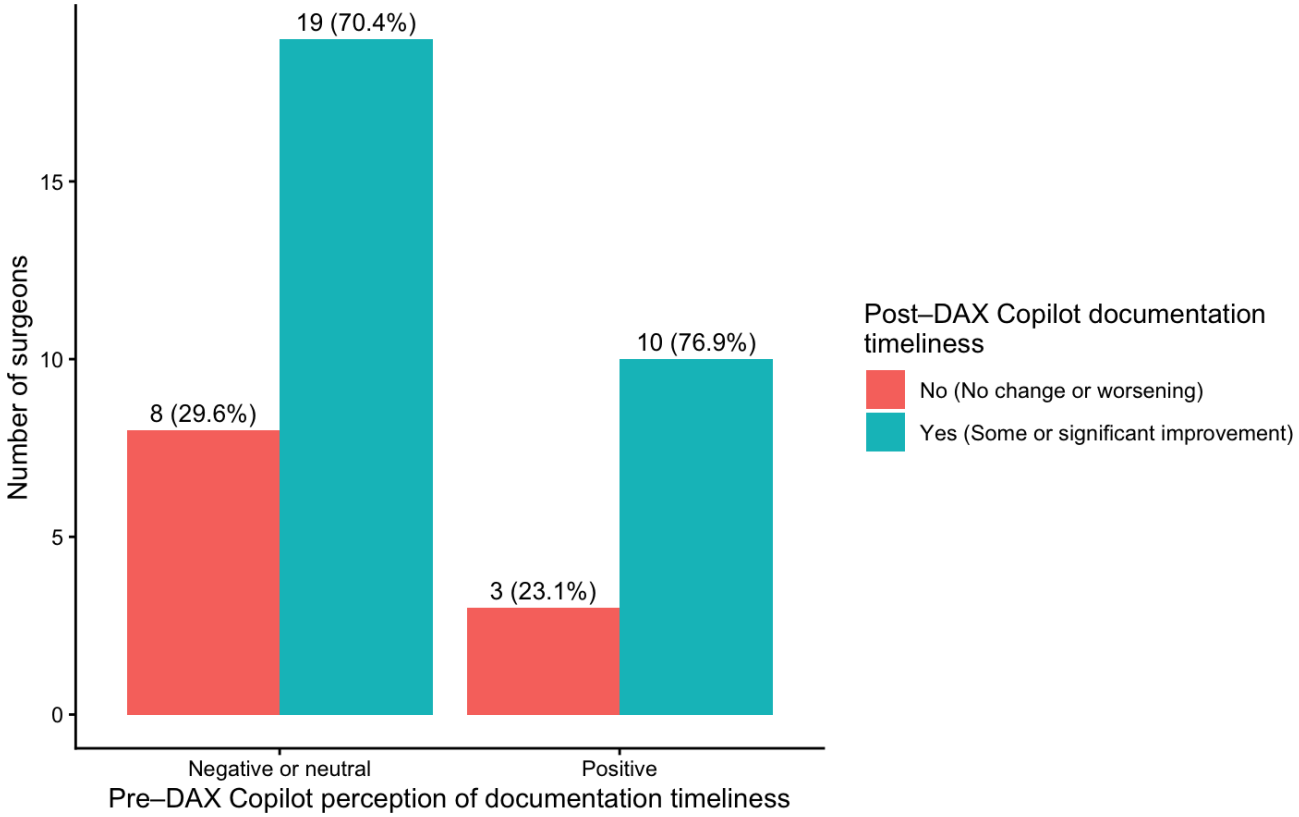
[a]Trauma, colorectal surgery, minimally invasive surgery, liver and kidney transplant, surgical oncology, and other adult general surgery specialties not listed separately (eg, acute care surgery and surgery critical care).

All 40 DAX Copilot users provided responses to each baseline survey item. Following DAX Copilot implementation, 77.5% (31/40) of surgeons reported some or significant improvement in perceived documentation efficiency irrespective of their baseline perceptions of documentation time. Among those with negative or neutral baseline perceptions (n=33), 75.8% (25/33) reported an improved perception of efficiency after DAX Copilot implementation, and among those with positive baseline perceptions (n=7), 85.7% (6/7) reported additional efficiency gains (Figure 2).

Figure 2. Reported improvement in perceived documentation efficiency following Dragon Ambient Experience (DAX) Copilot implementation according to baseline perceived documentation time. Baseline documentation time perceptions were characterized as negative or neutral ("excessive," "high," or "moderate" response options) or positive ("low" or "minimal" response options). Post–DAX Copilot documentation efficiency was characterized as either no change or worsening or some or significant improvement. Bars represent the number of respondents, with percentages reflecting the proportion of respondents within each baseline perception group.



Perceived documentation timeliness also improved after implementation. Among surgeons with negative or neutral perceptions of their documentation timeliness before DAX Copilot adoption (n=27), 70.4% (19/27) reported improvements in perceived timeliness after adopting DAX Copilot. Similarly, among those with positive baseline impressions (n=13), 76.9% (10/13) reported further improvements in timeliness (Figure 3).

When surgeons were asked specifically about their experience following use of DAX Copilot, 72.5% (29/40) reported that their perceived documentation accuracy, detail, and consistency had improved or significantly improved. Improvement in burnout was reported less frequently, with 59.0% (23/39) of respondents reporting some or significant improvement (n=1 missing response from a surgeon with a neutral baseline burnout perception). Among surgeons with negative or neutral baseline perceptions of burnout (n=27), 63.0% (17/27) reported some or significant improvement after adopting DAX Copilot.

RenderX

Figure 3. Reported improvement in perceived documentation timeliness following Dragon Ambient Experience (DAX) Copilot implementation according to baseline perceived documentation timeliness. Baseline perceptions of documentation timeliness were characterized as negative or neutral ("poor," "marginal," or "satisfactory" response options) or positive ("good" or "optimal" response options). Post–DAX Copilot documentation timeliness was characterized as either no change or worsening or some or significant improvement. Bars represent the number of respondents, with percentages reflecting the proportion of respondents within each baseline perception group.

Open-ended survey responses from all 105 responding surgeons, including those who had and had not used DAX Copilot, offered additional insights into DAX Copilot's utility and opportunities for refinement (Table 2).

Surgeons reported faster note completion and improved capture of complex discussions or detailed patient histories, enabling greater focus on the patient during encounters. These benefits were most apparent during new or complex visits. However, several recurring workflow challenges emerged. Respondents noted limited EHR integration, which prevented the automated insertion of laboratory or imaging results. They also reported challenges with the use of "dot" or "smartphrases" within the Epic EHR, mechanisms that note writers often use to aid with efficiency. Others noted poor performance for follow-up visits or carried-forward notes due to the inability to automatically incorporate information from prior patient encounters. Additional concerns included accuracy limitations and the learning curve inherent to any significant technological change. Adoption was further constrained by DAX Copilot's current iOS-only compatibility, which excluded Android users. Despite these limitations, many surgeons still recognized the technology's potential and indicated that they planned to continue using it.

XSL•FO

Table . Surgeons' responses regarding the utility of Dragon Ambient Experience Copilot.

Theme	Representative surgeon comments
Perceived benefits of ambient AI	
Improved documentation efficiency	"Still do a fair amount of editing but saves a lot of time." [User]
Improved patient engagement during visits	"Does free me up to speak to the patient without jotting down notes." [User]
Reduced cognitive load, particularly for new or complex patients	"I can focus on the patient. It really acts as an information storage mechanism so I don't have to remember specifics of the history and exam afterward." [User]
Timelier documentation completion	"DAX certainly provides more timely documentation and closing of encounters." [User]
Anticipated long-term potential	"I think in the long run this will be a very helpful technology." [User]
Challenges and barriers to implementation	
Limited EHR[a] integration	"If I reference a lab result or a CT scan for the patient, instead of 'typing/generating' text around that, it would be more beneficial for DAX to find the lab or imaging result in the EHR and copy/paste it into the note automatically." [User]
Limited ability to customize or format progress notes	"Difficult to incorporate sections into carried forward notes and can't customize how information is organized." [User]
Accuracy limitations	"Doesn't capture many critical elements to optimize billing and often misinterprets correct operation." [User]
Training and implementation barriers	"Many of us would like to use but do not want to impede workflow while trying to integrate this tool." [Nonuser]
Technology access limitations	"I understand that DAX is not available for Android based devices (I do not use Apple/iPhone) so it may be some time before it works into my current workflow." [Nonuser]

[a]EHR: electronic health record.

Discussion

Principal Findings

In this study, we evaluated the early impact of an ambient AI technology integrated within the EHR (DAX Copilot) on perceived documentation efficiency and burnout among surgeons in their outpatient clinical encounters. Our findings suggest that ambient AI may improve surgeons' perceptions of documentation processes in these settings. Overall, the implementation of DAX Copilot was associated with perceived improvements in documentation timeliness and overall efficiency, suggesting that ambient AI tools may help reduce perceived documentation burden among surgeons.

Comparison to Prior Work

These results build on a growing body of literature demonstrating that ambient AI documentation technologies may reduce documentation burden across ambulatory practice settings. Early prospective studies on the impact of ambient AI have shown that health care providers spend less time on documentation and after-hours EHR work and that ambient AI reduces total EHR time following implementation [15,16]. More recently, a multicenter quality improvement study by Olson et al [14] reported improvements in clinician burnout, note-related cognitive task load, and time spent documenting following the adoption of ambient AI. Our findings are consistent with those of these prior reports while extending the literature by specifically evaluating surgeons across a broad range of surgical subspecialties and demonstrating perceived improvements regardless of baseline documentation perceptions. Notably, our study found that DAX Copilot improved perceived documentation efficiency and timeliness among surgeons regardless of whether their baseline perceptions of documentation were positive or negative. These findings suggest that the advantages of DAX Copilot extend beyond individuals who initially viewed documentation as inefficient, underscoring its potential as a beneficial tool that may improve documentation workflow for a broad range of users.

Open-ended user feedback revealed both enthusiasm for AI-assisted documentation and critical barriers to full integration and usability. The reported improvements in documentation quality and completeness, particularly for new or complex patients, suggest that surgeons perceived DAX Copilot as a facilitator for comprehensive documentation without compromising on the amount of information that is captured during the clinical encounter. Conversely, the limitations raised by surgeons, including limited EHR integration, suboptimal performance for follow-up visits, and restricted device compatibility, reflect key workflow barriers that must be addressed to expand the usability and maximize the value of AI-assisted transcription tools. Nonetheless, the willingness of surgeons to continue using DAX Copilot despite these challenges indicates that users perceived meaningful value in the technology and were receptive to integrating it into their clinical workflow as it continues to evolve.

XSL•FO
RenderX

Perceived improvements in burnout were reported by most respondents but occurred less frequently than improvements in documentation efficiency and timeliness. Prior evidence of burnout reduction with ambient AI use has been mixed [14,16]. Our findings suggest that while improvements in documentation may contribute to reduced burnout for some surgeons, clinical documentation likely represents only one of several factors that contribute to overall surgeon burnout.

Despite these potential benefits, important ethical and privacy considerations remain. Because these systems rely on audio capture of clinical encounters, concerns may arise regarding sensitive conversations, patient privacy, and data security. Although DAX Copilot is a HIPAA-compliant platform with enterprise-level security safeguards and encrypted EHR integration, the risk of unauthorized access or data breaches cannot be entirely eliminated. As adoption of ambient AI technologies expands, ongoing attention to patient communication, institutional oversight, and privacy safeguards will be essential to ensure responsible integration into clinical practice.

Our early-stage evaluation offers valuable insights while highlighting the need for larger studies and longer-term follow-up to assess how ambient AI technology may influence surgeon workflow. To our knowledge, this study is among the first to examine surgeons' perceptions of ambient AI technology in outpatient surgical practice among multiple surgical subspecialties and one of the first to examine perceived improvements according to baseline documentation perceptions. We queried surgeons across a broad range of surgical subspecialties and systematically assessed their perceptions using standardized Likert-scale measures, providing an early characterization of surgeon perceptions during the initial adoption of this technology.

Limitations

Several limitations should be acknowledged when interpreting these findings. First, while the survey response rate was moderate at 28.5% (105/368), only 40 respondents reported actively using the software and were included in the final analysis. It is thus possible that the views of all surgeons and surgical subspecialties were not fully represented by this sample. The potential for nonresponse bias should also be considered as surgeons who elected to complete the survey or actively adopted DAX Copilot may have differed systematically from nonrespondents in their documentation burden, attitudes toward ambient AI technology, or willingness to incorporate new technologies into clinical practice. Additionally, the modest sample size limits the precision and generalizability of our findings. Future multicenter studies including larger cohorts of surgeons across diverse surgical subspecialties will help improve the representativeness of these findings.

Second, this study was designed to evaluate surgeons' early experiences during the initial implementation of DAX Copilot using a single postimplementation survey. Respondents retrospectively assessed their baseline perceptions before reporting perceived improvement following DAX Copilot implementation. Consequently, the findings may have been influenced by recall bias and response shift bias, where users who adopted the technology may have retrospectively perceived their preimplementation documentation burden more negatively, potentially resulting in an overestimation of the perceived magnitude of improvement. In addition, surgeons reporting slight or no baseline burnout had limited opportunity to report further improvement, introducing a potential floor effect that should be considered when interpreting the observed proportion of respondents reporting improvements in burnout. Future prospective longitudinal studies incorporating preimplementation baseline assessments will help better characterize the impact of ambient AI documentation technologies over time.

Third, although the survey items used in this study were informed by prior literature evaluating health care provider burnout and documentation burden, they were not formally validated, which may limit reliability and comparability across studies. Likert-scale responses were also dichotomized for descriptive analyses, reducing response granularity.

Fourth, the qualitative component of this study was intended to provide contextual insights into surgeons' experiences with DAX Copilot. Although the identified themes were reviewed by a second author for accuracy assurance, the initial thematic analysis was conducted by a single reviewer without independent coding or formal assessment of interrater reliability. As a result, the qualitative findings may be subject to interpretive bias and should be considered exploratory.

Fifth, because this was an observational study conducted during the early implementation of DAX Copilot, we cannot exclude the possibility that concurrent changes in clinical workflows, EHR functionality, or other software enhancements influenced surgeons' perceptions of documentation burden and efficiency. Accordingly, the observed perceptions of improvement cannot be attributed solely to DAX Copilot.

Finally, perceived utility may differ between early and late adopters of this technology or may evolve as familiarity with the technology increases over time. Notably, while DAX Copilot was only available in outpatient clinical encounters during the initial rollout phase, it is now being adopted gradually in the inpatient environment, where documentation burden persists. As adoption expands across surgical areas, specialties, and clinical settings, the perceived utility of ambient AI technologies and their potential impact on burnout may become more apparent.

Future Directions

Future studies should prospectively evaluate ambient AI technologies using longitudinal study designs that combine clinician-reported outcomes with objective measures of documentation burden and efficiency to better characterize the impact of these technologies on documentation workflows and burnout over time. Although recent multicenter studies have demonstrated improvements in documentation burden and clinician well-being across diverse ambulatory practice settings, additional research focused on surgeons across surgical subspecialties and practice settings will help clarify the generalizability of these findings within surgical practice specifically. In addition, further research evaluating how the

XSL•FO
RenderX

perceived utility of ambient AI technologies evolves with increasing user familiarity and broader implementation across outpatient and inpatient surgical settings will help clarify their long-term role in surgical documentation.

Conclusions

In this single-center survey of surgeons using DAX Copilot in their outpatient clinical practice, use of ambient AI scribe technology was associated with perceived improvements in documentation efficiency and timeliness. These findings suggest that ambient AI documentation technology may improve surgeons' perceived documentation experience in outpatient surgical settings.

Abstract

Background: Clinicians spend a substantial share of their working hours on documentation, contributing to workflow inefficiencies, reduced patient-facing time, and increased burnout. Artificial intelligence (AI) medical scribes have emerged as a promising solution to reduce this burden, yet real-world evidence remains limited and heterogeneous, and data from European health systems are especially scarce. This evaluation combines 2 complementary data sources: objective editing metadata from 236,153 notes generated by 1295 clinicians, describing operational editing behavior within the AI medical scribe, and paired self-reported survey responses from 177 fully onboarded clinicians, capturing perceived change in documentation time and clinician experience.

Objective: This study aimed to evaluate the association of an AI medical scribe on documentation time and clinician experience.

Methods: This observational real-world evaluation was conducted between April 26, 2024, and October 27, 2025, using retrospective paired ratings. The study was carried out across multiple specialties in primary, secondary, and hospital care within Capio Ramsay Santé, a large integrated health care provider operating in Sweden. Eligibility was limited to fully onboarded users, defined as clinicians who had used the scribe for at least 3 months, created more than 100 notes, generated at least 1 document or certificate, and used the conversational edit (“Add or adjust”) feature at least once.

Results: Following the introduction of the AI medical scribe, the estimated time spent on documentation per note was lower than before (4.72 vs 6.69 minutes; −29%, $P<.001$). On a 5-point Likert scale, ratings for the ability to work without stress related to administrative tasks were higher after introduction than before (mean 3.14 vs 2.41; $P<.001$; median change 0 points, 95% CI 0–1), as were ratings for perceived presence with patients (mean 4.33 vs 3.73; $P<.001$; median change 0 points, 95% CI 0–1). The median editing time was 93 seconds, and it did not decrease significantly over continued use.

Conclusions: Among sustained, fully onboarded adopters in a European health care system, use of an AI medical scribe was associated with reductions in self-reported documentation time, administrative stress, and increase of presence with patients, consistent with findings from prior US-based studies. Because the survey cohort represents a highly selected subgroup of users who adopted and continued using the tool mainly in general practice, these associations may not generalize to clinicians who discontinued use or never fully adopted the scribe, and the generalizability across specialties remains unverified. The single-arm observational design and reliance on retrospective self-report are important considerations when interpreting these associations. A limitation of this analysis is that 138,196 notes were excluded because their recorded editing time was 0; these notes may have been used as generated, used as a starting point and later modified in the medical record system, or discarded, which limits the operational interpretation of the editing-time findings.

Introduction

Integrating artificial intelligence (AI) into health care has created substantial opportunities to not only improve clinical efficiency but also enhance patient care and increase clinicians' professional satisfaction. One of the most compelling possibilities lies in reducing clinicians' documentation burden. Although electronic health records (EHRs) have contributed to improved health outcomes [1] and reduced medical errors [2], they have also become a dominant part of clinicians' workdays and are linked to diminished job satisfaction and increased burnout [3-5]. Research consistently shows that clinicians spend up to half of their working hours on computers, primarily performing documentation tasks [6-9], while less than 30% of time is devoted to direct patient care [10]. In this context, ambient large language model–based AI medical scribes able to transcribe clinician-patient interactions and generate structured draft notes have emerged as a promising and scalable means to substantially reduce documentation load. Thereby, they may be able to free time, improve workflow, support better patient care, improve quality of notes, and ultimately strengthen clinician well-being across specialties and care settings [11-16].

Evidence on the effectiveness of AI-assisted clinical documentation remains limited, heterogeneous, and in part contradictory. Early large-scale deployments, primarily in North America, suggest that AI medical scribes can reduce time spent on documentation, decrease after-hours EHR work, and improve elements of clinician-patient interaction [12-14,16,17]. However, reported benefits vary markedly across clinical specialties, workflows, and implementation strategies, emphasizing the need for context-specific evaluation [12,14]. Conversely, some studies have found no measurable improvements in efficiency, in terms of either time savings or economic outcomes [18]. Complicating matters further, the underlying technology is evolving at a rapid pace, making it challenging to draw stable conclusions about current real-world performance. Despite these uncertainties, health care organizations are making adoption decisions now, and AI medical scribe systems are already in use in nearly all major US health systems [19]. This rapidly evolving landscape underscores the importance of rigorous, context-sensitive evaluation of their effectiveness.

European health systems operate within regulatory and operational conditions that may substantially influence the performance and adoption of AI medical scribe technology [20,21]. Unlike AI medical scribes deployed in the United States, which are generally not classified as medical devices, the tool used in this study is a class I medical device under the EU Medical Device Regulation [21]. This classification imposes specific regulatory obligations that directly shape the product's design and postmarket behavior.

The AI medical scribe is designed and deployed in compliance with EU Medical Device Regulation and ISO 14971, incorporating formal risk assessment, defined intended use, and documented mitigation strategies that create user-facing safeguards uncommon in unregulated tools. Clinicians cannot transfer AI-generated notes to the medical record without a mandatory review period, and input of large unreviewed text blocks is restricted. Site managers can monitor edit and transfer rates to ensure appropriate use. The system uses natively multilingual large language models for transcription and note structuring, supporting consultations in over 50 languages, including Swedish, without intermediate translation, and monthly audits monitor hallucinations and omissions. Data governance complies with GDPR (General Data Protection Regulation) and national legislation. All processing occurs on EU-based infrastructure, and audio is streamed in real time without persistent storage, ensuring patient privacy.

Combined with Europe's heterogeneous EHR landscape and multilingual clinical environment, these factors create a context that differs markedly from non-EU settings [22]. Evidence from European countries remains especially limited [23,24], despite their high digital maturity and increasing interest in reducing administrative burden and improving clinician experience through advanced automation.

The aim of this study is to evaluate the association of a fully deployed AI medical scribe on clinical documentation time and clinician experience in primary and secondary care (including hospital care) across multiple specialties. Together, these outcomes provide a comprehensive assessment of the effectiveness and usability of AI-scribe technology in Europe during large-scale implementation in routine clinical practice.

Methods

Ethical Considerations

The study does not constitute human participants research, as it involved analysis of deidentified, aggregated survey data for which ethical approval is not required. Clinician survey respondents were informed in writing about the purpose of the study, the voluntary nature of participation, the pseudonymized handling of their responses, and their right to withdraw, and they consented to participation by submitting the survey. No patients were enrolled, contacted, or asked to consent, as no patient-level data were collected or processed explicitly for the purposes of this retrospective study. In routine clinical use, patients are informed at the start of the consultation that an AI-based documentation tool will transcribe the conversation in real time to support note generation, that no audio is stored, and that they may decline without any effect on their care. Verbal consent is obtained before the scribe is activated, and written information about the tool is available on request.

This study analyzed clinician survey responses and operational note metadata; no patient-level data were collected or processed explicitly for the purposes of this retrospective study. Under the Swedish Ethical Review Act (Lag 2003:460 om etikprövning av forskning som avser människor), ethical review board approval is required for research involving the processing of sensitive personal data as defined in Article 9 of the General Data Protection Regulation, or physical interventions on research subjects. As the study involved only professional experience ratings and pseudonymized usage metadata, with no sensitive personal data categories processed, it fell outside the scope of the Act. Survey participation was voluntary, and respondents were informed of the study's purpose. Capio Ramsay Santé

XSL•FO
RenderX

acted as data controller. Capio administered the clinician survey and held the operational usage data from participating units. Metadata exported from the vendor's system included only the variables required for the preregistered analyses (time stamps, counts, and contextual descriptors). Linkage between survey responses and usage statistics was performed under Capio's organizational data governance policies. The researchers conducting the final statistical analysis received only pseudonymized, prelinked datasets and had no access to respondent identities at any stage. Pseudonymization was performed before any data were transferred to the analytic environment, and the key was held by the data controller; the analyst (VV) therefore had no opportunity to view identifiable data at any point.

Inclusion and exclusion criteria for both the note-level analysis and the survey cohort were prespecified by the academic coinvestigators (ES and VV) and were not modified by vendor-affiliated authors during analysis. Raw prelinkage data were accessible only to Capio data governance staff and to vendor engineers under contractual obligations; the analytic dataset shared with the research team was pseudonymized and prelinked. All statistical analyses were performed by VV, who has no vendor affiliation and received no compensation for this work.

Participants, Setting, and Exposure

This observational study was conducted between April 26, 2024, and October 27, 2025, in health care facilities run by Capio—part of Ramsay Santé. The study uses 2 data sources. First, metadata was gathered from all participating units which implemented the same Conformité Européenne–marked AI medical scribe (Tandem AI Medical Scribe, version 1.0 - 1.1; Tandem Health AB). Second, a survey was conducted among fully onboarded professionals to gather subjective assessments on the use of the scribe. Survey responses were linked to exported metadata on secure infrastructure under organizational data governance policies. Metadata export from the vendor's system included only the elements required for the preregistered analyses (time stamps, counts, and contextual descriptors) and did not contain any personal data of the participants.

The study adhered to the SQUIRE (Standards for Quality Improvement Reporting Excellence) guideline and was preregistered on the Open Science Framework on October 7, 2025. The preregistration was filed on October 7, 2025, approximately 3 weeks before the closing of the data collection window (October 27, 2025), and is therefore effectively retrospective with respect to the note-level metadata, which was continuously accumulating from April 2024 onward. The survey component, however, which is the source of the primary outcome (paired recall of documentation time and the Likert ratings), was dispatched to participants after the preregistration date and was therefore prospectively registered. Three additional analyses were added to the original preregistered plan: a linear mixed-effects model, regression models examining predictors of perceived change, and an inverse-probability-weighted (IPW) nonresponse sensitivity analysis. These were incorporated to strengthen the quality and interpretability of the findings and should be considered exploratory rather than confirmatory. No descriptive or inferential analyses of the accumulated metadata had been inspected by the analyst prior to drafting these additions; only the predefined primary and secondary outcomes had been examined.

Primary outcome was defined as change in self-reported time used to complete a typical clinical note with and without the scribe. Self-reported paired recall was chosen as the primary outcome because it was the only metric for which a comparative preimplementation baseline could be constructed: objective within-tool editing time captures only activity inside the AI medical scribe interface (ie, the time the clinician spent editing the draft note within the Tandem application before transferring it to the EHR) and cannot represent the full documentation workflow clinicians performed before its introduction (eg, free-text typing, EHR navigation, and dictation). Objective measurement of absolute time spent on documentation is notoriously difficult in health care settings, where clinicians' work is highly fragmented and frequently interrupted, and prior studies have reported substantial limitations and methodological failures in attempts to capture it directly [16]. Paired recall, although subject to well-documented overestimation of absolute time, correlates moderately with observed time and is widely used as a pragmatic surrogate in large-scale clinician workflow research [25-27]. We acknowledge that this places a subjective measure at the center of the efficiency analysis, a limitation discussed further in the Discussion section, and therefore reports objective editing time alongside the primary outcome as a complementary operational metric. Secondary outcomes were change in responses to questions "I can work without feeling stressed by administrative tasks" and "I feel fully present with the patient during the consultation" in a 5-point Likert scale. Additional outcomes were yes/no responses to questions related to user satisfaction–related statements.

The exposure consisted of routine use of the AI medical scribe within the health care provider's clinical operations following standard implementation. The AI medical scribe used in the study generates a draft patient record note based on the clinical encounter, which the user can edit, by typing, dictating, or by providing natural language verbal instructions, before final approval. The workflow is essentially the same in both the desktop and mobile interfaces. Deployment included a structured onboarding program delivered by clinician-informed customer success staff from the vendor: an initial 2-hour foundational session covering system introduction, first note generation, and transfer of the note to the EHR, followed by two 1-hour reinforcement sessions at approximately 4 and 8 weeks to review advanced features and address local workflow needs.

Additionally, the health care provider held a 1-hour session with management and senior clinicians focusing on responsible change management, as well as a separate 1-hour course for all end users focusing on how to use the system responsibly and safely with patients in clinical practice. Adoption at each site was then supported by designated superusers, while the centralized IT organization ensured installation, integration, and basic operability across all participating clinics.

XSL•FO
RenderX

Survey

The survey was sent to all fully onboarded clinicians by email with 2 additional reminders when necessary. The inclusion criteria were (1) using the scribe for ≥3 months, (2) creating >100 notes with the scribe, (3) generating at least 1 document or certificate, and (4) using the conversational edit ("Add or adjust") feature at least once. The survey was developed specifically for this evaluation, with some clinician Likert items adapted from a patient survey by Mishra et al [28]. The complete survey is presented in Multimedia Appendix 1.

Time was assessed as the self-reported estimated number of minutes required to complete a typical clinical note with and without the scribe. The survey also included paired 5-point Likert scale items to measure perceived administrative burden ("I can work without feeling stressed by administrative tasks") and clinician presence ("I feel fully present with the patient during the consultation") with and without the scribe. Additional survey items were yes/no responses to questions related to user satisfaction–related statements "Tandem is easy to use," "I want to continue using Tandem," and "Would you recommend Tandem to colleagues in your or other organizations?"

Note Metadata

Each note contained pseudonymized linking to the professional for whom the note was generated as well as the clinical site. Recorded edit time per note was estimated from the automatically generated metadata and was defined as the difference between the first and the last time stamps (YYYY-MM-DD HH:MM:SS.mmm) at which the user inputted a keyboard edit or used dictation or conversational edit mode to insert or remove any character from the generated note.

Collected variables and definitions are specified in Textbox 1.

Textbox 1. Variables and definitions.

- Profession: Each note is associated with a unique clinician user account. Clinicians access the artificial intelligence medical scribe using strong electronic identification (a health care professional smart card or a government-issued electronic ID application linked to their national personal identity number), which ensures that each account corresponds to a specific licensed individual. For each note, the clinician's profession was taken from the account-level role metadata and treated as the note-level profession variable. Notes generated by users with a tagged profession of "clinic admin" or "medical secretary" were considered nonclinical activity and were excluded from the analytic cohort.
- Visit type: The visit type was derived from the template used when generating the note. Clinicians actively choose a note template at the start of documentation, and templates are designed and maintained by the health care provider and vendor's operations team, who know for which clinical context each template is intended. Each distinct template name was thus mapped to 1 of 4 encounter categories: physical (in-person visits and procedures), digital (remote written or online contacts), telephone, or admin or other, with unmatched templates falling into the admin or other category.
- Platform: Clinicians could log in either via a native desktop application or via a web browser on their desktop computer, or on their mobile devices. The platform could thus capture what access method was associated with each note, enabling categorization to desktop or mobile access.

Statistical Analysis

All statistical analyses were performed in R (version 4.3.3; R Foundation for Statistical Computing). Two complementary datasets were analyzed: (1) note-level editing metadata and (2) clinician-level survey responses describing use of the AI-assisted documentation system. Editing time was defined as the interval between the first and last recorded input event (keyboard edit, dictation, or conversational edit) on a given note, without exclusion of idle time; that is, periods of inactivity within an open editing session are included in the measured duration. This definition captures only activity within the AI medical scribe interface. In contrast, clinician-reported documentation time was intended to reflect all tasks performed within the EHR for a single patient encounter, including activities outside the AI medical scribe interface.

Editing durations displayed a pronounced right-skew with extreme values attributable to system artifacts (eg, notes left open for prolonged periods). To mitigate undue influence of these outliers, we applied a 3-hour cutoff, excluding notes with edit durations >10,800 seconds. We also excluded notes with no recorded edits from the primary analysis. As a sensitivity analysis, notes without recorded edits were assigned an editing time of zero seconds to evaluate the potential impact of excluding these notes. Edit times were further log-transformed to stabilize variance and reduce skewness. To examine within-user changes in editing time, we compared each user's first 2 months of recorded note activity with the remainder of the study period.

To evaluate factors associated with editing duration at the note level, we fit a linear mixed-effects model with log-transformed edit time as the dependent variable. Fixed effects included visit type, profession, clinic type, and interaction platform. Clinic type was operationalized as a categorical variable distinguishing primary care from specialist outpatient units within the Capio network.

A random intercept for clinician was included to account for within-clinician correlation arising from repeated notes. Model assumptions were assessed visually via Q-Q plots of residuals and residual-versus-fitted plots. This graphical evaluation indicated modest deviations from normality in the tails, which is expected with large-scale operational data but did not materially affect inference.

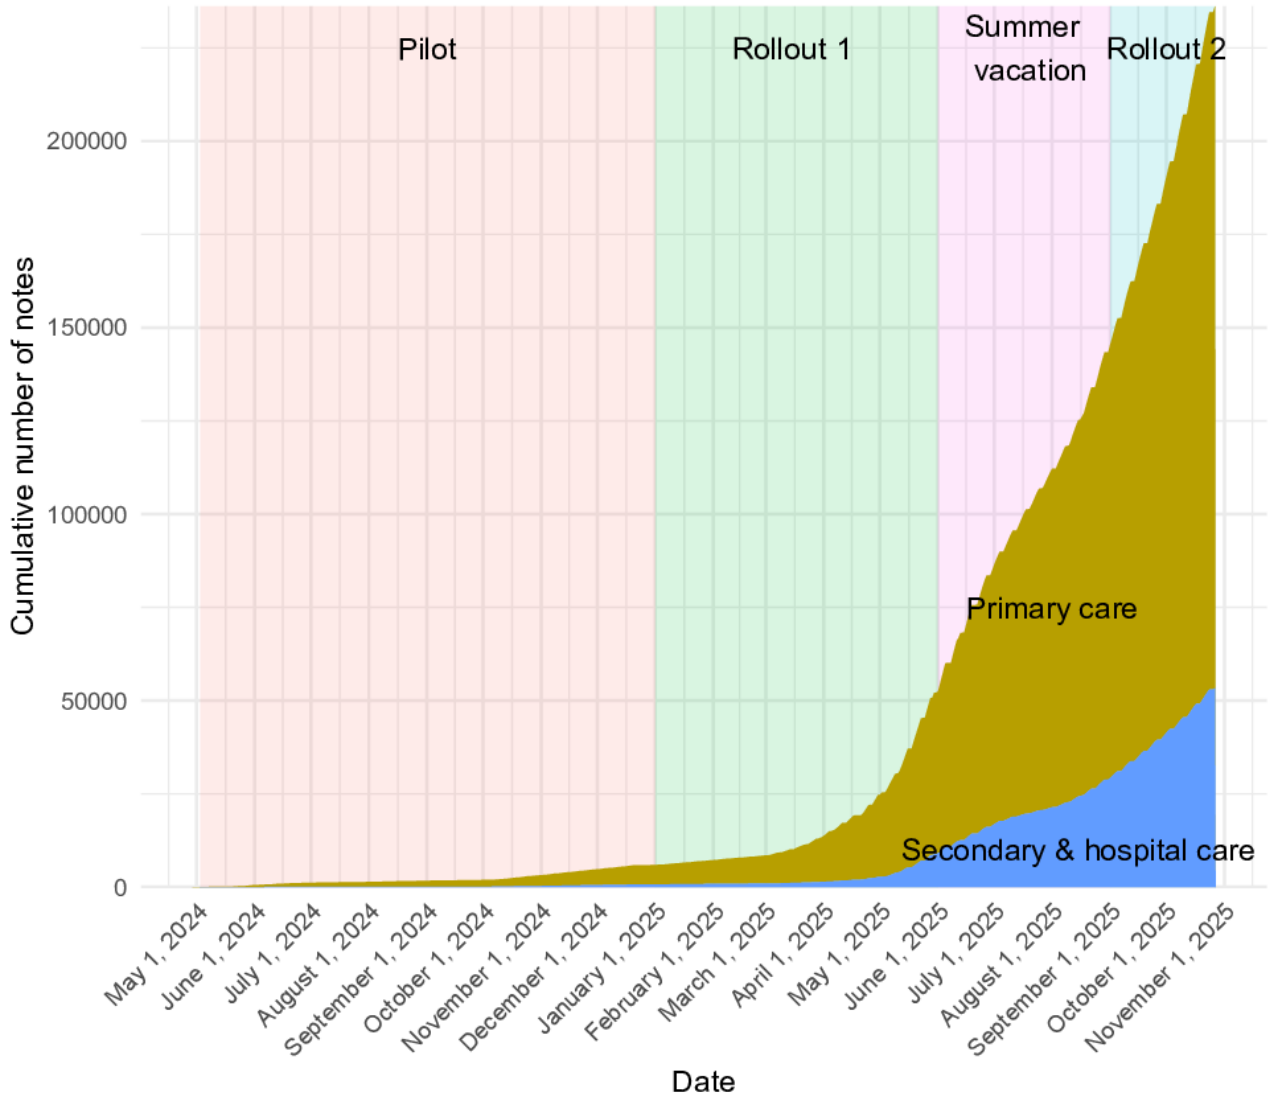
Since Likert-type responses and recall measures were not normally distributed, paired Wilcoxon signed-rank tests were used to compare editing time recall (before vs after), perceived stress (without vs with AI medical scribe), and perceived presence (without vs with AI assistance). To examine whether objective editing behavior was associated with subjective experience, we fitted clinician-level linear regression models with change in perceived stress, change in perceived presence, or change in perceived documentation time as the outcome. The objective editing time predictor was the clinician-level median

XSL•FO
RenderX

editing time across edited notes after artifact filtering, expressed in seconds. Median rather than mean editing time was used to reduce the influence of extreme editing durations. Perceived ease of use ("Tandem is easy to use," yes/no) was included as a binary predictor. Although note-level edit times were log-transformed in the mixed-effects model because of their right-skewed distribution, the clinician-level regression models used raw clinician-level median seconds to retain direct interpretability. Change scores were calculated as the paired within-clinician difference between the postimplementation rating and the recalled preimplementation rating, so the regression coefficient should be interpreted as the change in the outcome per unit change in the predictor at the clinician level. In addition to objective editing time, perceived ease of use ("Tandem is easy to use," yes/no) was included as a binary predictor in the regression models examining associations with self-reported outcomes. Because the regression analyses modeled clinician-level change scores, these variables were treated as approximately continuous and analyzed using linear regression. Also, as survey outcomes were measured at the clinician level, note-level editing metrics were aggregated to clinician-level summaries prior to analysis. For each clinician, we calculated the median editing time across all notes generated during the observation period after artifact filtering. These clinician-level editing time summaries were then linked to survey responses using the pseudonymized clinician identifier. Regression analyses therefore examined associations between clinician-level editing behavior and clinician-level changes in perceived outcomes. For completeness, sensitivity analyses using median edit times instead of mean log-edit times produced consistent conclusions. For yes/no survey items, the proportion answering "yes" was calculated, and 95% CIs were obtained using the exact binomial method.

To assess the potential impact of survey nonresponse bias, inverse probability weighting was applied in sensitivity analyses. A logistic regression model estimated the probability of survey response using clinician-level metadata variables (profession, clinic type, note volume, editing time, and implementation timing). Stabilized weights derived from the predicted probabilities were used in weighted linear regression models examining associations between objective editing time, perceived ease of use, and clinician-reported outcomes. Extreme weights were truncated at the 1st and 99th percentiles.

Results



Overview

The original dataset contained metadata from 376,596 clinical notes. The most active user had generated 2474 clinical notes. After the filtering and removal of artifacts the final dataset contained 236,153 unique notes across 1295 participants. We excluded 138,196 notes with no recorded edits and 2247 notes with editing times exceeding 3 hours. The exclusion of unedited notes was prespecified to ensure that the primary efficiency outcome reflected active documentation work rather than draft generation events that may or may not have entered the clinical record. Although the system tracks note-level transfer events to the EHR for operational monitoring by site managers, these transfer status data were not made available to the research team at the individual note level. This reflected a scope-of-extraction decision at the time of analysis rather than a contractual or GDPR-related restriction, and the linkage of transfer status to editing metadata is technically recoverable in future work. Furthermore, EHR log data were not accessible to the researchers. As a result, it could not be determined with certainty whether unedited notes were accepted as generated, discarded, or modified within the EHR after transfer. The cumulative number of notes and implementation periods are presented in Figure 1.

The 3 most common professions were general practitioners (861/1295, 66.5%), physiotherapists (79/1295, 6.1%), and orthopedic surgeons (63/1295, 4.9%). The remaining 22.5% (292/1295) of participants represented a wide variety of professions including various medical specialties, nurses, dentists, and optometrists (Multimedia Appendix 2). A total of 1302 clinicians had generated at least 1 note in the system; after exclusion of 7 nonclinical accounts (clinic admin and medical secretary), the analytic cohort comprised 1295 clinicians, of which 517 met survey inclusion criteria, and of which 451 were surveyed. Of the 451 surveyed, 177 (39.2% response rate among those invited; 34.2% of the 517 eligible users) clinicians responded, who together created 67,679 notes. Due to missing data, 322 nonresponders and 152 responders were available for the IPW analysis (Multimedia Appendix 3). The survey was distributed to a purposive sample covering the organization's main clinical settings (primary care, secondary outpatient care, and hospital-based care), while the 66 clinicians outside this sampling frame worked in smaller specialist units. This scope applies only to the survey component, as the objective usage metrics were derived from the full eligible user population. A comparison between notes generated by responders and nonresponders is shown in Multimedia Appendix 4.

Metadata-Related Results

The median editing time was 93 seconds, whereas mean editing time was 226 seconds after applying the designated artifact cutoff of 3 hours, indicating a highly skewed distribution (Multimedia Appendix 5). The median remained stable in the sensitivity analysis: in the full dataset of generated notes, the median was 94 seconds, and with a 30-minute cutoff, the median was 87 seconds. When notes were stratified into those generated within the first 2 months of use versus those generated thereafter, the median editing times were 84.0 seconds and 84.5 seconds, respectively, suggesting that no substantial learning curve was observed (Figure 2). In a sensitivity analysis including notes without recorded edits as zero-second editing events, the overall median editing time decreased substantially but the comparison between early and later usage periods remained similar (20 seconds vs 22 seconds). The proportion of notes without recorded edits was also comparable between periods (42.4% vs 41.2%).

The effects of visit type and platform on editing time were studied using a linear mixed-effects model, as presented in Table 1. Differences between professions and clinic types were minimal and statistically nonsignificant and were therefore excluded from the final model. Descriptive analysis comparing characteristics of notes with versus without edits is presented in Multimedia Appendix 6.

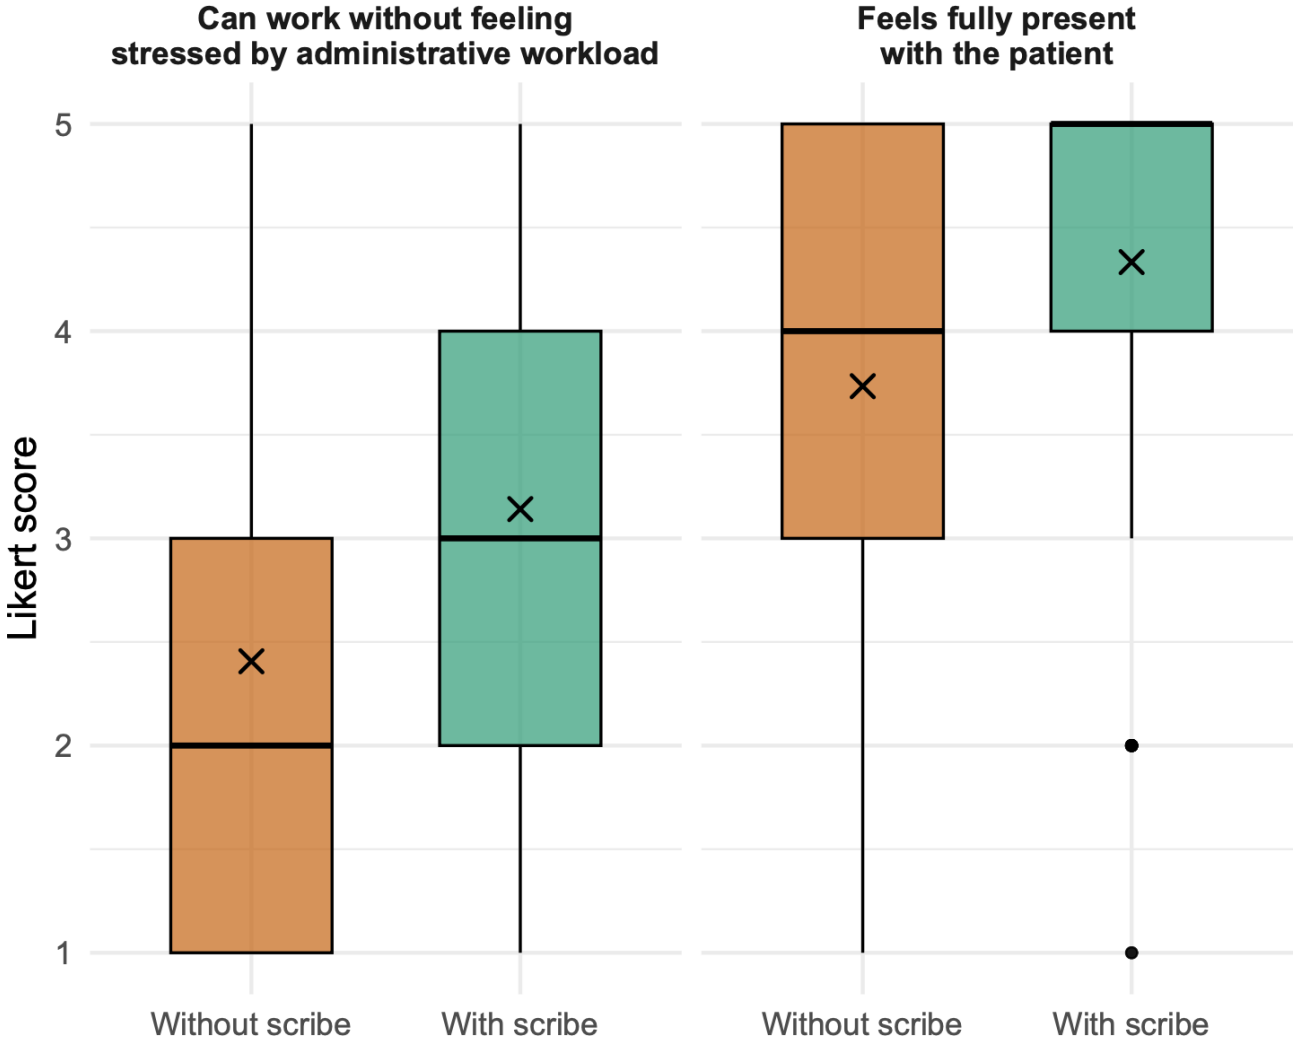
Survey-Related Results

In the predefined primary outcome, estimated time spent on documentation was lower after the introduction of the AI medical scribe than before (6.69 vs 4.72 minutes, *P*<.001; Figure 3), corresponding to a paired decrease of a median of 2 minutes per note (95% CI 1 - 2 minutes). On a 5-point Likert scale (Figure 4), mean ability to work without stress related to administrative tasks was higher after the introduction than before (2.41 vs 3.14; *P*<.001), although the median change was 0 points (95% CI 0 - 1). Similarly, mean perceived presence with patients was higher after the introduction than before (3.73 vs 4.33; *P*<.001), with a median change of 0 points (95% CI 0 - 1). Because the median change was 0 for both Likert outcomes, the statistically significant shifts reflect a consistent directional shift among a subset of respondents rather than a uniform change across the cohort; the Wilcoxon signed-rank test detects such shifts even when the median paired difference is zero. The Likert shift distributions are shown in Multimedia Appendix 5.



In the survey items indicating yes/no answer, 80.2% (142/177) (95% CI 73.6% - 86.0%) said that the scribe was an improvement for their profession, 91.0% (161/177) (95% CI 86.1% - 95.1%) found it easy to use, 91.5% (162/177) (95% CI 86.1% - 95.1%) wished to continue using the scribe, and 84.2% (149/177) (95% CI 78.1% - 89.6%) would recommend colleagues at other clinics to start using the scribe.

Figure 3. Self-estimated time to complete a single clinical note with and without the artificial intelligence (AI) medical scribe, alongside the objectively measured median editing time for each clinician. The 2 metrics capture different scopes of work: self-reported documentation time is intended to reflect all tasks the clinician associates with completing a note in the electronic health record for a single encounter (including activities outside the AI medical scribe interface, such as navigation, prescriptions, and referrals), whereas objectively measured editing time reflects only activity within the AI medical scribe workflow between the first and last recorded input event. X denotes the mean. Orange indicates no scribe, green indicates with scribe, and blue indicates median editing time.

RenderX

Figure 4. Likert scale answers to questions assessing ability to work without stress from administrative tasks and feel fully present with the patient with and without the artificial intelligence medical scribe. X denotes the mean of the answers. Orange indicates without scribe and green indicates with scribe.

Three linear regression models examined whether objectively measured clinician-level median note-editing time and perceived ease of use predicted self-reported changes in documentation time, administrative stress, and patient presence. Lower objective editing time was significantly associated with reduced administrative stress (β=−0.003, 95% CI −0.005 to −0.001; *P*=.01), but it did not significantly predict perceived documentation time (β=0.006, 95% CI 0.000-0.012; *P*=.06) or presence with patients (β=−0.001, 95% CI −0.002 to 0.001; *P*=.52).

In contrast, perceived ease of use was a significant predictor in all models: higher ease-of-use ratings were associated with reduced administrative stress (β=1.796, 95% CI 1.043-2.549; *P*<.001), increased patient presence (β=1.199, 95% CI 0.578-1.821; *P*<.001), and lower perceived documentation time (β=−4.144, 95% CI −6.156 to −2.132; *P*<.001). The magnitude of the ease-of-use coefficient for perceived documentation time (β≈−4.1) reflects the wide scale of the recall-time outcome (minutes per note) rather than an unusually large standardized effect. These ease-of-use estimates should be interpreted with caution: 91.5% (162/177) of the respondents rated the scribe as easy to use, so the reference group consisted of only a small subgroup (approximately 15 respondents). Results from IPW models were similar to those from the primary analyses, suggesting that nonresponse bias did not materially affect the observed associations (Table 2).

XSL•FO
RenderX

Table . Linear regression models (unweighted vs IPW[a]-weighted) for changes in ability to work without stress of administrative tasks, presence with patients, and perceived time used for documentation[b].

Outcome	Predictor	Unweighted β (95% CI)	IPW[a]-weighted β (95% CI)	Unweighted *P* value	IPW-weighted *P* value
Δ Stress	Median edit time (seconds)	−0.003 (−0.005 to −0.001)	−0.003 (−0.006 to −0.001)	.01	.01
	Perceived ease of use (yes vs no)[c]	1.796 (1.043 to 2.549)	1.62 (0.85 to 2.389)	<.001	<.001
Δ Presence	Median edit time (seconds)	−0.001 (−0.002 to 0.001)	0 (−0.002 to 0.002)	.52	.69
	Perceived ease of use (yes vs no)[c]	1.199 (0.578 to 1.821)	0.971 (0.331 to 1.611)	<.001	.003
Change in perceived documentation time (minutes)	Median edit time (seconds)	0.006 (0 to 0.012)	0.006 (−0.001 to 0.012)	.06	.07
	Perceived ease of use (yes vs no)[c]	−4.144 (−6.156 to −2.132)	−4.149 (−6.149 to −2.15)	<.001	<.001

[a]IPW: inverse-probability-weighting based on a response propensity model.

[b]Coefficients are shown as β (95% CI). The unweighted model used all responders while the IPW model used a subset of the participants for which all necessary data were available (see Multimedia Appendix 7 for comparison and details).

[c]The reference group for "perceived ease of use" consisted of only approximately 15 respondents who rated the scribe as not easy to use; estimates from this small subgroup should be interpreted with caution, as the linear regression model is highly sensitive to outliers within such a small reference group, which might skew the magnitude of the reported coefficient.

Discussion

Principal Findings

Previous studies have demonstrated that AI medical scribes can reduce perceived documentation time as well as stress, thereby potentially lowering the risk of burnout among clinicians [15,16,29]. However, these findings have almost exclusively originated from the United States, whose health care system differs substantially from European systems in terms of organization, financing, and clinical workflows [12-16]. In our study, we showed that, in a European context, the use of an AI medical scribe was similarly associated with reduced physician-reported stress and a decrease in self-reported time spent on documentation.

Our findings on perceived time savings are consistent with the majority of published studies. However, not all studies have been able to demonstrate a reduction in documentation time [18]. In most prior work, time has been assessed subjectively, as in our study, but objective time measurements reported in some studies also support the observation that AI medical scribes can reduce the time burden of documentation [14,16]. However, due to inherent study design limitations, neither our study nor similar studies in this field can establish causality [29].

Previous studies have additionally reported differences between professional groups in the time spent in clinical documentation [7]. In contrast, we did not detect meaningful differences between professions in our analysis, suggesting that the potential advantages of AI medical scribe use may generalize across clinician groups in this setting.

Second, Liu et al [18] observed that the extent of clinicians' use of an AI medical scribe influenced the magnitude of benefit they derived in their daily work. In contrast, in our study we did not observe any substantive change in editing time between the initial phase of use and subsequent periods. This may suggest that efficiency gains, at least with respect to note editing time, are attained relatively early, remain comparatively stable over time, and are indicative of a technology that is readily usable and intuitive without a substantial learning period. Alternative interpretations should, however, be acknowledged. Users completed approximately 5 hours of structured onboarding before the observation window began, so the flat trajectory is equally consistent with a ceiling effect in which most efficiency gains were realized during training prior to measurement. We also note that editing time alone may not capture other dimensions of learning such as improved note quality, reduced cognitive effort, or more effective use of advanced features, which could continue to evolve after editing time has stabilized.

In our study, the time required to edit notes generated by the AI medical scribe was relatively short, with a median of 93 seconds. This may partly reflect the structured onboarding provided to users (approximately 5 hours), which could have increased familiarity with the interface and editing workflow. Notably, a subset of editing episodes extended over several hours. Because editing time was defined as the interval between the first and last recorded edit, periods of inactivity were not separable from active editing. Prolonged intervals may therefore reflect a common workflow in which the editing window is left open and the note is finalized later, rather than sustained continuous editing. A significant number of notes were not edited at all (approximately 42% of all generated notes), and the fate of this group has important but opposing implications

XSL•FO
RenderX

for interpretation. Onboarding follow-ups with users suggested at least three distinct patterns: (1) notes accepted as generated and transferred directly to the EHR, which would imply very high draft quality and any efficiency benefit captured in our primary analysis; (2) notes transferred to the EHR and then edited within the EHR rather than in the AI medical scribe interface, which would represent unmeasured documentation work and could overstate the observed efficiency gain; and (3) notes abandoned entirely and rewritten from scratch, which would imply overestimated usefulness. Because transfer status and posttransfer edits in the EHR were not available to the research team, we cannot quantify the relative prevalence of these patterns, and the direction of any net bias is therefore uncertain. Lukac et al [16] have recently reported a comparable inability to verify posttransfer edits in the EHR in a randomized trial of an ambient AI scribe and noted that this constraint limits inference about true documentation savings.

Both visit type (in-person, digital, and telephone) and editing platform (desktop vs mobile) were associated with variation in editing time. Remote encounters resulted in approximately 62% and 55% less editing time for digital and telephone contacts, respectively. On mobile platforms, editing times were roughly double those on the desktop platform. Editing on a desktop interface was also linked to greater editing efficiency. Although the workflow is essentially identical across platforms, we hypothesize that this difference reflects input modality constraints. Touch screen keyboards, limited screen real estate, and the lack of multiwindow navigation likely slow text editing, review of longer passages, and cross-referencing on mobile compared with desktop. Mobile use may also occur predominantly in less ergonomic contexts, such as between visits or at the bedside. Given that improved documentation efficiency is one of the main drivers for adopting AI medical scribes, these findings highlight the importance of careful selection and optimization of the user interface. Without attention to workflow design and platform choice, the full potential benefits of the technology may not be realized in routine clinical practice.

Interestingly, physicians' self-reported documentation time was substantially longer than the measured note editing time. This suggests that, within the time they attribute to "documentation," clinicians are also performing other tasks, such as writing prescriptions or referrals requiring navigation in the EHR. The estimated time is, however, broadly in line with a previous study [12]. Conversely, prior work indicates that although health care professionals systematically overestimate the time spent on documentation, often by as much as 2-fold [25], there remains a moderate correlation between actual and estimated time, supporting the use of clinician self-reports as a pragmatic surrogate measure in large-scale process improvement and research [26,27]. This recall bias is also a potential limitation in our study. In addition, the survey item asked clinicians how many minutes they spend finalizing a typical clinical note, while we interpret this self-reported time as encompassing the full documentation workflow (including navigation, prescriptions, and referrals). If respondents understood the question more narrowly, the estimates may under- or overstate the broader time impact, underscoring the need for additional metrics that capture the full scope of clinical documentation work. The significant number of notes excluded from the analysis due to no editing likely had varying fates such as used as is without editing, transferred and edited in the medical record system, or were disregarded.

One important dimension of effectiveness is health care professionals' experience, which is particularly critical in the context of worsening shortages and increasing burnouts of medical personnel [30,31]. The urgency of addressing clinician well-being is also reflected at the policy level: for example, the National Academy of Medicine convened a meeting in December 2024 to examine the potential for AI to improve health worker well-being, including reducing burnout [32]. This growing international interest highlights how AI-based tools, such as AI medical scribes, are increasingly viewed not only as instruments for improving efficiency but also as potential levers to mitigate the psychological burden of clinical work.

In our study, the reduction in stress was associated both with the perceived ease of use of the AI medical scribe and with shorter editing time for the generated notes. Although these findings could partly be explained by simpler clinical cases requiring less editing, the existing literature does not support the point of view [13,33], and they may reflect a benefit attributable to automation, associated with a reduced self-assessed workload. This suggests that, beyond potential gains in efficiency, AI medical scribes may contribute meaningfully to improving clinicians' day-to-day work experience, which is a key outcome in its own right. This interpretation is in line with previous studies reporting that AI medical scribes can reduce clinicians' cognitive load and, consequently, alleviate stress and the risk of burnout [15].

Strengths and Limitations

The main strength of this study is the large number of medical notes analyzed, which likely provides a reliable representation of current editing times in routine clinical practice. Additionally, we excluded the 138,196 notes with no recorded edits to avoid reporting overly positive or potentially misleading results. If a clinician did not use the generated note or modified it later within the EHR system, actions not captured in our dataset, retaining these notes could have artificially inflated efficiency estimates. Some of the excluded notes were likely used as generated, but we were unable to reliably distinguish these cases.

However, we were unable to determine whether the edits made by professionals were clinically necessary for medical quality or patient safety, or whether they primarily reflected stylistic preferences, tone adjustments, or other experiential aspects of documentation. Previous research has, however, demonstrated quite equal quality of doctor and AI-generated medical documentation [34]. The most important limitations relate to the study design. Although this was a mixed methods study, the survey component was not controlled: it was administered only once and did not include a comparison group. Although response propensity weighting suggested that nonresponse bias was unlikely to substantially influence the results, residual bias from unmeasured factors cannot be excluded. In addition, the survey sample consisted of users who had accumulated sufficient use of the AI medical scribe, specifically, fully onboarded clinicians

XSL•FO
RenderX

who had used the tool for at least 3 months, generated more than 100 notes, and used the advanced conversational edit feature, which likely overrepresents professionals who were more satisfied or at least willing to continue using the tool. Users who discontinued use early or struggled with adoption were therefore likely excluded, introducing potential survivor bias and limiting the generalizability of the findings to the broader clinician population. Also, since the ease-of-use variable was highly skewed toward positive responses, its estimates should be interpreted cautiously as reflecting differences between a relatively small subgroup of respondents reporting lower usability. Because the reference group consisted of only approximately 15 respondents, the linear regression model is highly sensitive to outliers within this extremely small subgroup, which might skew the magnitude of the reported estimate. We were unable to reliably assess whether perceived time savings varied by clinicians' prior documentation method (eg, typing, dictation, and human scribe), as several subgroups were too small to yield stable estimates, leaving potential heterogeneity across baseline workflows unresolved. Also, the survey responders were predominantly composed of general practitioners and, therefore, the survey results cannot readily be generalized across specialties based on these data. Furthermore, the primary survey item asked clinicians how many minutes they spend finalizing a typical clinical note, which is narrower than the broader documentation time construct discussed throughout this manuscript; respondents may not have considered tasks such as EHR navigation, prescription writing, or referral management when answering this prompt, and the magnitude of any time savings beyond note finalization therefore cannot be quantified from these data.

As in almost all prior work in this area, time savings could not be quantified fully objectively. Both self-reported documentation time and editing time are subject to multiple sources of error reported also in previous studies [16]. However, because a comparative baseline reflecting preimplementation workflow could be constructed only for the self-reported time measure, it was selected as the primary outcome variable. The editing time has several potential sources of error. While current software allows relatively precise estimation of time spent using the AI medical scribe (eg, editing time), no baseline time measurements of documentation without the tool were available. Editing time data are consistent with AI medical scribe technology being able to support efficient documentation, but it does not on its own provide an absolute estimate of time saved. Moreover, this study evaluated editing duration, self-reported user experience, and adoption patterns, but it did not assess note accuracy, error types, clinical quality, or patient safety outcomes; comprehensive evaluation of these dimensions would require further research, including systematic chart review, safety event monitoring, and assessment by downstream clinicians of the clinical usability of the generated notes. To more robustly assess effectiveness, future studies should incorporate objectively measured baseline and follow-up documentation times, include the full spectrum of users (including those who discontinue or are dissatisfied), and evaluate patient experience, ideally within a randomized controlled study design.

Conclusions

Our findings suggest that the perceived time savings and reductions in cognitive load and stress reported in previous US-based studies may also be achievable within a European health care system using an AI medical scribe. These results reflect the experience of sustained, fully onboarded adopters mainly in general practice and may not generalize to the broader clinician population, particularly those who discontinued use or never fully adopted the tool. The single-arm observational design and reliance on retrospective self-report are important considerations when interpreting these associations.

Acknowledgments

Generative artificial intelligence (AI) (ChatGPT and OpenAI) was used solely for language editing and improvement of grammar and clarity. No AI tools were used for data analysis, interpretation, or generation of scientific content. The authors reviewed and approved all final content and take full responsibility for the manuscript.

Funding

This study was initiated as a cooperation of Tandem Health and Capio Ramsay Santé. The company had no role in the statistical analysis, interpretation of results, or decision to submit; these were performed independently by the academic coinvestigators.

Data Availability

Aggregated results supporting the findings of this study are presented in the paper and in the accompanying multimedia appendix files. The underlying pseudonymized note-level metadata and individual survey responses are held by Capio Ramsay Santé and Tandem Health under organizational data governance and GDPR obligations and cannot be shared publicly. Deidentified, aggregated data supporting the regression models and sensitivity analyses are available from the corresponding author upon reasonable request, subject to the data controller's approval and execution of an appropriate data use agreement.

Abstract

Background: Clinicians spend a lot of time on electronic health record (EHR) documentation, often at the expense of direct patient interaction. Ambient listening technology uses AI to passively record and summarize clinical encounters. Although early studies are promising, there is limited evidence on system performance in complex, non-English settings.

Objective: This study aimed to compare the documentation performance of 3 commercially available ambient listening systems in simulated Dutch-language outpatient consultations by assessing note completeness, correctness, and conciseness under predefined linguistic and interactional challenges.

Methods: Standardized audio recordings of 10 scripted physician-patient interactions across 2 specialties were used. Scenarios included multispeaker dynamics (patient companion), conversational disruptions (nurse interruption), evasive patient communication, and a regional dialect (Gronings). Three ambient listening providers (provider 1, provider 2, and provider 3) processed the audio files. Generated notes were divided into 4 note sections: patient history, physical examination, diagnostic impression, and treatment plan. For each system output, each note section was scored for completeness, conciseness, and correctness using a 5-point ordinal scale against physician-developed reference summaries. In total, 8 clinicians participated in scoring: 4 junior clinicians evaluated all outputs, and 4 senior clinicians each reviewed a subset of scenarios. Analyses were based on 351 rater-averaged section-domain scores. Interrater agreement was assessed using Gwet agreement coefficient 2 (Gwet AC-2). System-level technical characteristics were assessed alongside clinical performance to aid interpretation of between-provider differences.

Results: Across 351 rater-averaged section-domain scores on a 5-point scale, overall interrater agreement was high (Gwet AC-2=0.827). Provider-level mean scores ranged from 3.82 to 4.26 (4.26, SD 0.73 for provider 3, 4.00, SD 0.90 for provider 2, and 3.82, SD 1.07 for provider 1). Mean scores were higher in otolaryngology than in surgical oncology (4.36, SD 0.56 vs 3.68, SD 1.10). Across scoring domains, correctness received the highest mean score (4.21, SD 0.98), while completeness received the lowest (3.81, SD 0.90). Variation in mean scores was observed across script scenarios. Dialect-containing scenarios had the lowest mean score overall (3.77, SD 1.21), although this pattern was not uniform across specialties and systems. Median summary generation times ranged from 13.5 seconds (IQR 12-15; provider 3) to 22.0 seconds (IQR 18-24; provider 2).

XSL•FO
RenderX

Conclusions: Ambient listening systems demonstrated generally strong performance in this simulated Dutch-language evaluation, including under several common conversational challenges. However, mean scores varied across scripted scenarios, with lower scores observed in some dialect-containing and otherwise challenging interactions. Future deployment studies must prioritize linguistic equity, real-world validation of efficiency gains, and evaluation of both clinician and patient perceptions to understand how these systems influence consultation dynamics and care delivery across diverse patient populations.

KEYWORDS

large language models; generative artificial intelligence; generative AI; ambient listening; electronic health records; artificial intelligence adoption; AI adoption

Introduction

Clinical documentation during patient encounters remains a significant challenge. Physicians often face a trade-off between documenting in real time, which may undermine face-to-face interaction, and postponing documentation, which leads to working in "pajama time" and delayed record completion. Studies have shown that physicians may spend nearly half of their workday interacting with the electronic health record (EHR), sometimes leaving only 27% for direct patient care. This administrative burden is strongly associated with reduced job satisfaction and increased burnout [1-6].

The consequences extend beyond clinicians. When attention is directed toward a computer screen rather than the patient, consultations may feel less personal [7]. Reduced eye contact and increased cognitive load during documentation have been shown to affect trust, communication quality, and patient satisfaction [8,9].

Ambient listening technology has emerged as a potential solution. These systems passively capture physician-patient conversations and use AI to transcribe and summarize encounters directly into structured clinical notes. Early evaluations suggest reductions in documentation burden, after-hours charting, and clerical workload [10-17]. However, evidence for patient-related benefits remains limited and heterogeneous [18]. Importantly, most existing evaluations have been conducted in English-language settings [19].

Less is known about how these systems perform in other languages when consultations include multiple speakers, conversational interruptions, indirect or evasive patient communication, and regional dialect use.

Our study evaluates the performance of 3 ambient listening systems in scripted Dutch-language consultations before clinical deployment. Because ambient listening systems differ substantially in architecture and integration, we additionally examined key technical characteristics to support the interpretation of performance differences and real-world adoption decisions. The scenarios incorporated interactional challenges, including multispeaker dialogue, conversational disruption, evasive communication, and the use of a regional dialect (Gronings), to assess the linguistic and contextual robustness of these systems. By exploring these dimensions, our study contributes novel insights into the linguistic and contextual adaptability of ambient AI documentation tools and their potential applicability in diverse real-world health care settings.

Methods

Scripted Audio Design

The study used audio recordings of scripted physician-patient interactions in 2 clinical domains: otolaryngology and surgical oncology. These domains were selected to include both relatively routine outpatient consultations and more complex oncological conversations at a high-volume oncological center, while keeping the pilot evaluation feasible. All scripts were written by physicians but were fully fictional, incorporating invented names, clinical cases, and dialogues. A total of 10 distinct scripts were developed, each involving up to 4 roles: physician, patient, patient companion, and nurse. Departmental staff volunteered to perform these roles and provided informed consent for the recording, storage, and use of their audio data. A total of 4 unique speakers participated in the recordings, including 2 clinicians and 2 nonclinicians. Within a given script, each speaker performed only 1 role, and there was a maximum of 4 roles per script. All speakers were fluent in Dutch. For the dialect-specific scenario, the participant voicing the Gronings-speaking patient was familiar with this dialect through their regional background. We aimed to reflect a realistic mix of speaker roles and consultation dynamics that may occur in outpatient practice. The scripts were shared with participating staff in advance to allow them to become familiar with the content. Immediately prior to recording, participants reviewed the scripts again. During recording, the interactions were primarily script-based rather than fully improvised; however, participants were encouraged to deliver the dialogue naturally, and small variations, such as filler words, minor phrasing adjustments, and limited natural overlap where consistent with the script, were allowed where appropriate. No substantial deviations from the scripted content were made.

Script Design and Structure

Two sets of 5 scripts were created: set 1 for otolaryngology and set 2 for surgical oncology, numbered 1.1 to 1.5 and 2.1 to 2.5, respectively (Multimedia Appendices 1 and 2). The scripts were constructed to reflect different consultation dynamics that may occur during routine clinical encounters. These interactional challenges were selected to introduce variation and to represent situations encountered in outpatient practice that may affect ambient listening performance. The aim was to evaluate system performance not only in straightforward consultations but also

XSL•FO
RenderX

in conversational circumstances that may be more challenging for transcription and summarization. Each script type represented a distinct interactional scenario:

- Baseline scripts (1.1 and 2.1): standard Dutch consultations, including patient history, physical examination, diagnostic impression, and treatment plan, without interruptions or additional speakers
- Companion-influenced scripts (1.2 and 2.2): consultations in which a patient companion actively participated in the dialogue
- Disrupted scripts (1.3 and 2.3): consultations interrupted by a nurse entering the room, resulting in conversational disruption and early termination
- Evasive patient scripts (1.4 and 2.4): consultations in which the patient frequently digressed or provided irrelevant information
- Dialect-specific scripts (1.5 and 2.5): consultations conducted in Gronings, a regional Dutch dialect. This scenario was included because regional language variation is relevant in our clinical setting in the north of the Netherlands. It was designed to explore whether such variation influenced ambient listening performance and to ensure that the evaluation reflected speech variation that may be encountered in routine care at our institution rather than standardized Dutch alone. No predefined list of anticipated problematic words or phrases was specified in advance.

English translations of the baseline otolaryngology and surgical oncology scripts are provided in Multimedia Appendix 3.

Ambient Listening Providers

Ambient listening providers were recruited via an open call to companies collaborating with our hospital. All interested providers were invited to participate. Three providers participated in the evaluation: Autoscriber (Autoscriber BV; provider 1), Juvoly powered by Tandem (Tandem Health; provider 2), and OurMind (OurMind BV; provider 3). In this manuscript, "provider" refers to the company providing the ambient listening tool, whereas "clinician" or "physician" refers to the health care professional evaluating the outputs. Throughout the remainder of the manuscript, the providers are referred to as provider 1, provider 2, and provider 3 to maintain consistency across the Results section, Tables, and Figure. Providers were informed about the general testing process but were not given access to the script content. They received a high-level outline of the expected summary structure: patient history, physical examination, diagnostic impression, and treatment plan.

Recording and Playback Protocol

Recordings were conducted at the University Medical Center Groningen in a private, soundproof room using a Windows-based laptop. This was a soundproof meeting room, rather than a studio environment. During recordings, the microphone was positioned centrally between the physician and the patient-side speakers. Audio recordings were stored on a secure institutional research drive.

Playback conditions were identical for all providers: recordings were played from the same Microsoft PC (Microsoft Corp) connected to a Logitech external speaker (Logitech International SA). At the start of each session, the provider's ambient listening system was activated through its standard interface, and generated summaries were saved for evaluation. During testing, audio files were played locally on the research computer while the ambient listening providers captured the sound through their standard audio input. The providers did not store any audio data.

Reference Standard

For benchmarking, 2 physician-authors (AHH and RCS) developed reference summaries a priori for each specialty. Reference summaries were initially drafted separately and then iteratively merged through review of commented versions until a final agreed version was reached. Within each specialty, the baseline, companion-influenced, evasive, and dialect scenarios shared the same underlying consultation content and therefore used the same reference summary structure. The disrupted scenario was intentionally shortened and therefore required a separate reference summary. The reference summaries defined the key expected elements for each scenario, namely the core clinically relevant content expected in the note according to the common outpatient note format used in our hospital: patient history, physical examination, diagnostic impression, and treatment plan. In the disrupted scenarios, elements that were not reached during the consultation were intentionally not included in the reference summary. The reference summaries were used to standardize rater comparisons across providers. The reference summaries were not shared with the providers.

Evaluation Framework

Each generated summary was divided into 4 clinical note sections: patient history (including presenting complaint), physical examination, diagnostic impression, and treatment plan. These sections were chosen because they represent common and clinically meaningful components of outpatient documentation in both otolaryngology and surgical oncology and broadly reflect how notes are structured in the EHR in these specialties at our institution. Each section was evaluated on 3 domains: completeness, correctness, and conciseness, using a 5-point ordinal scale and compared with the reference summary [20]. On the 5-point ordinal scale, a score of 1 indicated no usable output or severely inadequate content, while a score of 5 indicated near-complete, accurate, and concise documentation.

Four junior clinicians evaluated all outputs. Each scenario was additionally reviewed by 1 senior clinician with at least 5 years of clinical experience, ensuring senior clinical oversight of the specialty-specific content.

For analysis, the unit of observation was the section-domain score aggregated across raters. For each provider output, ratings from the available reviewers were averaged for each note section and evaluation domain. In 1 disrupted script (2.3), the physical examination was intentionally omitted and therefore not scored. Consequently, rather than the theoretical 360 section-domain evaluations (10 scenarios×3 providers×4 sections×3 domains), a total of 351 aggregated scores were obtained. These aggregated

XSL•FO
RenderX

section-domain scores formed the basis for all subsequent analyses.

Technical Characteristics

In addition to documentation quality, each provider's technical characteristics were assessed, including processing speed, system requirements, integration capability, data security and privacy compliance, model architecture, and template customization options.

Statistical Analysis

Descriptive statistics were used to summarize case characteristics, clinician rating scores, and provider processing times. Because summary quality scores were recorded on a 5-point Likert scale, they were treated as ordinal. Interrater reliability was quantified using Gwet agreement coefficient 2 (Gwet AC-2) with quadratic weights rather than intraclass correlation coefficients, and agreement estimates are reported with 95% CIs.

For descriptive comparison across providers, specialties, domains, and note sections, rating scores are presented as means with SDs and medians with IQRs. Processing times were summarized using means with SDs and medians with IQRs; medians were emphasized due to right-skewed distributions and the presence of outliers. No inferential statistical comparisons between providers were performed, given the comparative and predeployment nature of this evaluation.

All domains and note sections were weighted equally. Analyses were conducted using R (version 4.5.1; R Foundation for Statistical Computing) and Stata (version 18.0; StataCorp LLC).

Ethical Considerations

This study was conducted under the EPICAI (Implementation of generative artificial intelligence in Epic—a scientific analysis of risks and benefits) research protocol (UMCG RR 19035; METc 2024/098), which was reviewed by the Medical Ethics Review Board of the University Medical Center Groningen. The board determined that the protocol did not constitute research with human subjects as defined by the Dutch Medical Research Involving Human Subjects Act (WMO) and therefore did not require full ethical review or approval. All clinical encounters were simulated using entirely fictional patient scenarios; no actual patients, patient data, or EHR data were involved. Colleagues participated as actors and provided informed consent for audio recording and subsequent processing of the recordings for research purposes. Recordings were stored on the institution's secure research drive with access restricted to authorized research personnel. Participants received no additional compensation for participation; participation occurred during working hours.

Results

Provider-, Section-, and Domain-Specific Scores

Each provider-generated note contained structured note sections (patient history, physical examination, diagnostic impression, and treatment plan) derived from the recorded consultation. Each section was independently scored on 3 domains (completeness, conciseness, and correctness). Across 351 rater-averaged section-domain scores, provider-level means were 4.26, SD 0.73 for provider 3, 4.00, SD 0.90 for provider 2, and 3.82, SD 1.07 for provider 1 (Table 1). Averaged across scenarios, mean scores were higher in otolaryngology than in surgical oncology (4.36, SD 0.56 vs 3.68, SD 1.10). Section-specific means showed limited overall spread: 4.13, SD 0.72 for treatment plan, 4.11, SD 1.12 for diagnostic impression, 3.97, SD 1.09 for physical examination, and 3.90, SD 0.69 for patient history. Across domains, correctness scored highest, followed by conciseness, and completeness scored lowest (4.21, SD 0.98, 4.07, SD 0.86, and 3.81, SD 0.90, respectively). Averaged across specialties, scenario means ranged from 3.77, SD 1.21 for script 5 to 4.18, SD 0.73 for script 4, with intermediate values for scripts 1 to 3 (3.98, SD 0.91, 4.09, SD 0.88, and 4.14, SD 0.77 respectively). As shown in Figure 1, this pattern was consistent across providers, with lower mean scores observed for dialect-specific scenarios than other scenario types. Scenario 5 (dialect) showed the lowest mean and the highest variability.

Table 2 illustrates how differences in provider performance translated into clinically relevant variation in the generated treatment plans. Provider 1 achieved the highest mean score by covering the key diagnostic, surgical, and care coordination elements specified in the a priori reference plan, including staging imaging, operative planning, and oncology nursing follow-up. Provider 3 documented appropriate staging and operative planning but did not mention complication counseling and oncology nurse assignment, contributing to a modestly lower score. Provider 2 documented surgical planning but did not capture essential staging imaging elements, and reviewers rated the plan lower.

Detailed section-level scores for each provider across all script scenarios and both specialties are provided in Multimedia Appendices 1 and 2.

Table 1. Descriptive summary of rater-averaged section-domain scores by provider, specialty, note section, domain, and script[a].

Categories and subgroups[b]	Observations, n	Score, mean (SD)	Score, median (IQR)
Provider			
Provider 1	117	3.82 (1.07)	4.20 (3.40-4.60)
Provider 2	117	4.00 (0.90)	4.20 (3.60-4.60)
Provider 3	117	4.26 (0.73)	4.40 (4.00-4.80)
Specialty			
Otolaryngology	180	4.36 (0.56)	4.40 (4.20-4.80)
Surgical oncology	171	3.68 (1.10)	4.00 (3.20-4.60)
Note section			
Patient history	90	3.90 (0.69)	4.00 (3.40-4.40)
Physical examination	81	3.97 (1.09)	4.40 (3.80-4.60)
Diagnostic impression	90	4.11 (1.12)	4.40 (4.00-4.80)
Treatment plan	90	4.13 (0.72)	4.30 (3.80-4.80)
Domain			
Completeness	117	3.81 (0.90)	4.00 (3.40-4.40)
Correctness	117	4.21 (0.98)	4.60 (4.00-4.80)
Conciseness	117	4.07 (0.86)	4.20 (3.80-4.60)
Script number			
1	72	3.98 (0.91)	4.20 (3.60-4.60)
2	72	4.09 (0.88)	4.40 (3.90-4.60)
3	63	4.14 (0.77)	4.20 (3.80-4.80)
4	72	4.18 (0.73)	4.40 (3.80-4.80)
5	72	3.77 (1.21)	4.20 (3.20-4.60)

[a]Scores were rated on a 5-point ordinal scale, with higher scores indicating better performance. Values are based on rater-averaged section-domain scores and are presented as mean (SD) and median (IQR). n indicates the number of rater-averaged section-domain scores.

[b]The physical examination section was omitted in surgical oncology, script 2.3; therefore, fewer ratings contributed to the surgical oncology specialty summary, physical examination note section summary, and script 3 summary.

Figure 1. Provider performance across scenario types. Bars represent mean rater-averaged section-domain scores on a 5-point scale for each provider across scenario types. For each scenario type, scores were averaged across the corresponding otolaryngology and surgical oncology scripts and across evaluated note sections and domains. Specialty-specific results are shown in Multimedia Appendices 1 and 2.

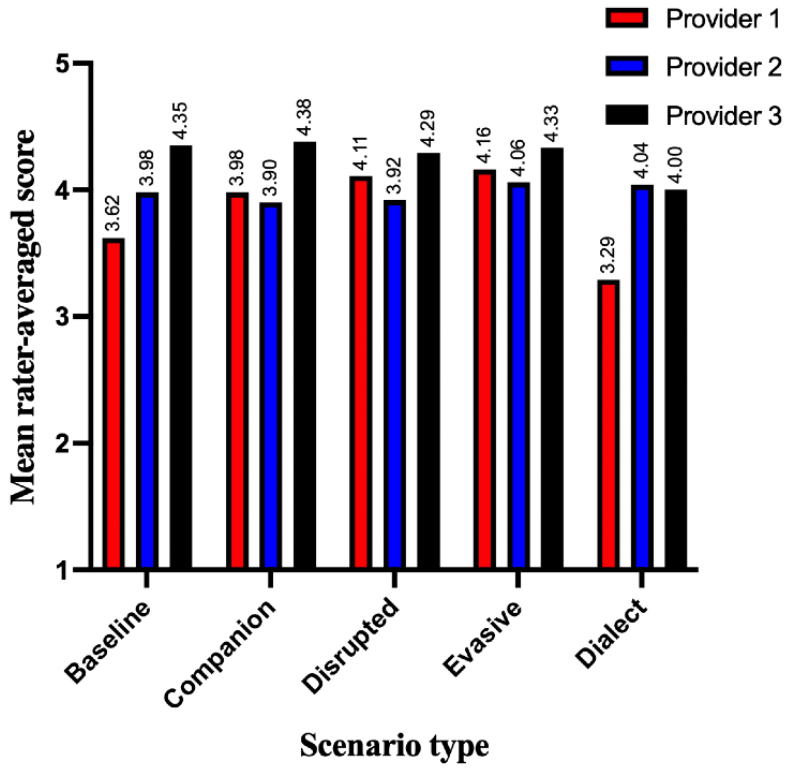

Table 2. Example comparison of treatment plans generated by 3 ambient listening systems for script 2.4 (surgical oncology; evasive patient), presented as an English translation. Scores are based on rater-averaged evaluations of completeness, correctness, and conciseness relative to the clinician-developed reference plan and are reported on a 5-point scale[a].

Providers	Treatment plan (English translation)	Rater-averaged treatment plan score
Provider 1	• CTb scan of the abdomen and chest MRIc of the pelvis for preoperative screening • Planned sigmoid resection • Consideration of chemotherapy depending on disease stage and findings • Smoking cessation if applicable • Healthy diet • Moderate-intensity physical activity • Contact with oncology nurse specialist	4.4
Provider 2	• Colectomy with primary anastomosis within 2 weeks • Possible chemotherapy depending on disease stage and lymph node status • Smoking cessation • Healthy diet • Moderate-intensity physical activity • Preoperative screening	3.0
Provider 3	• CT scan of the abdomen and chest to assess for metastases • MRI of the pelvis to evaluate local tumor extension • Planned sigmoid resection with primary anastomosis • Preoperative screening to assess surgical fitness • Consideration of chemotherapy based on imaging and surgical findings	4.1

[a]All systems were evaluated using the same recorded audio file. For this illustrative treatment plan section, ratings from the available reviewers were averaged within each evaluation domain; the displayed score summarizes the resulting rater-averaged section-domain scores across completeness, correctness, and conciseness. The a priori reference management plan specified the following expected elements: scheduling CT of the chest or abdomen and MRI of the pelvis, discussion of results at a multidisciplinary tumor board, scheduling sigmoid resection with complications discussed, consideration of chemotherapy depending on imaging and operative findings, and assignment of an oncology nurse specialist.

[b]CT: computed tomography.

[c]MRI: magnetic resonance imaging.

Provider Performance Across Scenario Types

Bars represent mean rater-averaged section-domain scores on a 5-point scale for each provider across scenario types. For each scenario type, scores were averaged across the corresponding otolaryngology and surgical oncology scripts and across evaluated note sections and domains. Specialty-specific results are shown in Multimedia Appendices 1 and 2.

To complement the quantitative ratings and the illustrative example in Table 2, we descriptively reviewed recurrent qualitative error patterns across system outputs. These included omissions of clinically relevant information, loss of specificity, hallucinations, misinterpretations, unnecessary information, redundancy, and overelaboration. Representative examples are summarized in Table 3.

Table 3. Recurrent qualitative error categories observed across summaries, with illustrative examples.

Domains and error categories	Examples
Completeness	
Omission of timing	"Follow-up" instead of "Follow-up in 6 weeks"
Omission of key clinical content	Missing relevant negatives, medication, physical examination, diagnostic impression, oncology nurse involvement, or multidisciplinary oncology discussion
Omission of conditionality	Chemotherapy without "depending on scan and operative findings"
Omission of laterality	Dix-Hallpike without "right-sided"
Correctness	
Hallucination	Not observed
Loss of medical terminology	"Had the tonsils taken out" instead of "tonsillectomy"
Misinterpretation	"Adenocarcinoma in the caecum" instead of sigmoid
Conciseness	
Unnecessary information	Irrelevant remarks about football club membership or global problems
Redundancy	Repeated information across headings, for example, smoking, alcohol, and drug use in both social history and intoxications
Overelaboration	Detailed description of benign paroxysmal positional dizziness pathophysiology

Interrater Agreement

Overall agreement (Gwet AC-2 score) across 8 raters was 0.83 (95% CI 0.81-0.85), indicating good to very good concordance. Agreement among juniors alone was similar (Gwet AC-2=0.83, 95% CI 0.81-0.85). For combinations of the junior raters with a single senior rater, Gwet AC-2 ranged from 0.80 to 0.85 across seniors. By domain, agreement was highest for correctness (Gwet AC-2=0.86, 95% CI 0.82-0.90), followed by conciseness (0.85, 95% CI 0.81-0.88) and completeness (0.78, 95% CI 0.74-0.81). By section, agreement was highest for diagnostic impression (0.88, 95% CI 0.85-0.92), followed by physical examination (0.84, 95% CI 0.80-0.87), treatment plan (0.82, 95% CI 0.77-0.87), and patient history (0.78, 95% CI 0.73-0.83). Detailed interrater agreement estimates stratified by rater group, scoring domain, and note section are provided in Multimedia Appendix 4.

Generation Time (Seconds)

Across scripts, summaries were typically produced within 10 to 36 seconds, with a small number of outliers. Mean generation times by provider were 15.6, SD 7.4 seconds for provider 3, 26.9, SD 18.0 seconds for provider 2, and 63.3, SD 106.4 seconds for provider 1 (overall mean 35.3, SD 63.7 seconds). Two provider 1 scripts (1.4 and 2.4) and 1 provider 2 script (2.5) exceeded 1 minute (Table 4). Median generation times were 13.5 seconds (IQR 12-15) for provider 3, 22.0 seconds (IQR 18-24) for provider 2, and 17.5 seconds (IQR 12-30) for provider 1, with an overall median of 17.5 seconds (IQR 13-23).

RenderX

Table 4. Processing time for AI-generated summaries across scenarios and providers[a].

Scripts	Provider 1, processing time (seconds)	Provider 2, processing time (seconds)	Provider 3, processing time (seconds)
1.1 Otolaryngology—baseline	6	29	36
1.2 Otolaryngology—companion	12	18	14
1.3 Otolaryngology—disrupted	12	24	16
1.4 Otolaryngology—evasive	332	19	15
1.5 Otolaryngology—dialect	20	23	15
2.1 Surgical oncology—baseline	15	18	12
2.2 Surgical oncology—companion	30	17	12
2.3 Surgical oncology—disrupted	23	23	10
2.4 Surgical oncology—evasive	171	21	13
2.5 Surgical oncology—dialect	12	77	13

[a]Processing time was defined as the interval from initiating summary generation ("generate summary") to receipt of the finalized AI-generated summary.

Overview of Provider Performance and Technical Characteristics

Beyond processing speed and clinical performance, the evaluated transcription software systems exhibited differences in their underlying architecture. All 3 systems had minimal and identical system requirements, needing only a browser, microphone, and internet connection for operation. However, meaningful distinctions were observed in processing speed, model training background, and template customization options. Provider 3 demonstrated the fastest processing time, whereas provider 2 showed slower generation times. Differences were also observed in the reported language model architecture. Provider 2 reported a Dutch-language speech-to-text model, whereas provider 3 used an English-language model with Dutch compatibility within a multilayer pipeline. Provider 1 also used a Dutch-language speech-to-text engine, and no translation step was reported. Template customization was possible in all systems, although the reported flexibility differed at the provider, institutional, departmental, and clinician levels. Reported security and compliance characteristics were broadly similar in that all systems were described as General Data Protection Regulation (GDPR)–compliant and Nederlandse Norm (NEN; Dutch Standard) 7510/ISO 27001–aligned, but additional certifications varied among providers. In the present study, no audio data were stored by the providers. These evaluation results and provider-reported technical characteristics are summarized in Table 5.

XSL•FO
RenderX

Table 5. Evaluation results and provider-reported specifications of the 3 ambient listening providers[a].

Features	Provider 1	Provider 2	Provider 3
Part 1: evaluation results (December 2024)			
Overall rater-averaged section-domain score (5-point), mean (SD)	3.82 (1.07)	4.00 (0.90)	4.26 (0.73)
Processing time (seconds), median (IQR)	17.5 (12-30)	22.0 (18-24)	13.5 (12-15)
Part 2: provider-reported specifications (May 2026)			
Integration with Epic	Yes	Yes	Yes
System requirements	Browser, microphone, and internet	Browser, microphone, and internet	Browser, microphone, and internet
Security, compliance, and certification	ISO 27001, NEN[b] 7510, GDPR[c]-compliant, and QMS[d] based on ISO 13485	ISO 27001, ISO 13485, ISO 42001, ISO 14001, NEN 7510, GDPR-compliant, and MDR[e] class IIa certified	ISO 27001, NEN 7510, and GDPR-compliant
Language model	Dutch-language speech-to-text engine (no translation step reported)	Dutch-language speech-to-text model	English-language model with Dutch compatibility, used within a multilayer pipeline
Template support and customization	Fully customizable; template builder available; custom templates available at institutional, departmental, and clinician levels	Customizable up to the clinician level, with support before, during, and after implementation; template builder and template library available	Customizable at provider, institutional, and clinician level; community template library planned

[a]Evaluation results reflect the provider versions tested in December 2024. Provider-reported specifications reflect information verified by the providers in May 2026 and may not fully correspond to the configurations evaluated in December 2024. Overall mean scores are based on rater-averaged section-domain observations across all scenarios, note sections, and evaluation domains, with higher scores indicating better performance. Processing time is reported as the median time from initiating summary generation to receipt of the finalized AI-generated summary.

[b]NEN: Nederlandse Norm (Dutch Standard).

[c]GDPR: General Data Protection Regulation.

[d]QMS: quality management system.

[e]MDR: Medical Device Regulation.

Discussion

Principal Findings

Ambient listening systems are increasingly proposed to reduce documentation burden and support clinicians in high-volume, digitally intensive care environments [21,22]. Although early evaluations suggest potential efficiency and workflow benefits, evidence remains limited regarding system performance outside English-speaking settings and during consultations involving complex interactional dynamics [14].

This study evaluated 3 ambient documentation systems in Dutch-language consultations that incorporated multiple speakers, conversational disruption, evasive dialogue, and regional dialect use. All systems were able to generate clinically usable draft summaries across most scenarios, demonstrating that ambient listening technology can function effectively beyond English-language environments. Variation in mean scores was observed across scenarios and specialties, with dialect scenarios generally associated with lower scores and greater variability.

Importantly, these outputs are intended to support clinicians and require human review. Although overall mean scores were high, the observed variability indicates that some summaries were substantially weaker, which may translate into a greater editing burden in practice and highlights the need for appropriate implementation safeguards. In practice, this implies multiple behavioral adjustments for clinicians: careful review of generated documentation and more explicit verbalization of examination findings and clinical reasoning during the encounter, as ambient listening systems rely entirely on spoken dialogue to produce their summaries.

Direct comparison with prior studies is limited because evaluation instruments and scoring methods differ widely across the ambient documentation literature. A recent scoping review highlighted the lack of standardized metrics used to evaluate ambient clinical documentation systems and emphasized the need for more structured evaluation approaches [19]. In this context, our findings align with broader evidence showing that ambient systems can produce usable draft documentation while remaining sensitive to linguistic variation and conversational complexity.

Dialect-containing scenarios tended to receive lower ratings in our dataset, although this pattern was not uniform across specialties and providers. The lower scores observed in these scenarios may indicate that regional language variation can influence ambient listening performance in our setting, but this finding should be interpreted cautiously. Differences may also

XSL•FO
RenderX

have been shaped by specialty-specific script content or other contextual features of the scenarios.

Taken together, these findings provide insight into how ambient listening systems behave under varied consultation dynamics in a predeployment setting.

Strengths

A key strength of this study is the direct, side-by-side comparison of multiple commercial ambient documentation systems using identical audio input and standardized evaluation criteria. Evaluation across 2 specialties and varied consultation dynamics further strengthens the relevance of the findings. High interrater agreement supports the robustness of the assessment framework.

Limitations

This study used scripted consultations, which cannot fully replicate the unpredictability of live clinical encounters. Although the recordings were performed by clinicians and delivered naturally where possible, they remained primarily script-based and may not have fully captured features of spontaneous speech. Playback also took place under controlled acoustic conditions in a soundproof meeting room. Although this supported standardized side-by-side comparison across systems, and the scripted scenarios incorporated realistic interactional challenges such as interruptions and multispeaker dialogue, it does not fully capture the acoustic complexity of routine clinical care, including background noise, room acoustics, microphone positioning, and unstructured workflow interruptions. The simulated design also involved a limited number of speakers and therefore may not reflect the full range of speaker variation encountered in routine clinical practice. Evaluation of documentation quality also involves subjective judgment, despite strong interrater reliability. In addition, only 1 regional dialect was evaluated, and multilingual consultations were not included. Finally, as a simulated predeployment evaluation, this study does not assess actual workflow impact or clinician time savings.

Future Directions

Future research should focus on real-world deployment studies in routine clinical practice, where both objective outcomes (such as actual documentation time and editing burden) and subjective outcomes (such as clinician experience and patient perceptions) can be assessed. Expanding evaluations to multilingual consultations and a broader range of dialects is essential to ensure equitable performance across diverse patient populations. In parallel, ethical and legal considerations, including transparency, patient consent, and responsibility for documentation errors, must be addressed as these systems move toward wider clinical adoption.

Conclusions

In summary, this study shows that ambient listening systems can achieve strong performance in non-English clinical settings, even under conversationally complex conditions. Although linguistic variation remains a key challenge, the ability of multiple systems to produce clinically acceptable documentation suggests the potential for broader international adoption. Continued evaluation in real-world, linguistically diverse environments will be essential for safe and effective implementation.

Acknowledgments

The authors thank Stijn Kusters and Gerhard Bultema for their support with the technical integration of the ambient listening systems and for contributing as voice actors in the simulated clinical scenarios. The authors also thank Katerina Kagialari and Nettuno Nadalini for their contributions. The authors declare that ChatGPT (GPT-5.2, GPT-5.3, GPT-5.4, and GPT-5.5; OpenAI) was used to support minor revisions for clarity and readability of the manuscript text. All outputs were critically reviewed, revised, and approved by the authors prior to submission.

Funding

No financial support or grants were received from any public, commercial, or not-for-profit entities for the research, authorship, or publication of this article.

Data Availability

The datasets generated and analyzed during this study are not publicly available due to contractual restrictions with commercial system providers and institutional data governance policies. Deidentified rating data and aggregated performance metrics may be made available by the corresponding author upon reasonable request and subject to institutional approval.

Abstract

Background: Medical record quality is a key focus of health care quality management. Traditional manual medical record quality control (QC) suffers from low efficiency, inability to achieve full-sample coverage, and poor consistency. Existing intelligent QC systems have significant deficiencies in real-time intervention and quantitative assessment of application effects.

Objective: This study aimed to describe the design and development of the medical record quality control system (MRQCS) and to retrospectively evaluate its associations with medical record defect detection, medical record quality, and interreviewer consistency using 7-year longitudinal final-stage QC records (2019-2025).

Methods: MRQCS implements a 2-level QC process for clinicians: nonblocking real-time prompting during documentation and blocking validation upon medical record completion. For QC reviewers, it provides AI-assisted defect detection and a 1-click write-back function. QC records from January 2019 to December 2025 were analyzed as 84 monthly discharge cohorts (43,324 sampled admissions), using interrupted time series (ITS) segmented regression with breakpoints aligned to the first discharge cohorts affected by each intervention (December 2020, July 2023, and May 2025). A stable-rule-set analysis was performed for genuine quality improvement. Linear mixed-effects modeling with intraclass correlation coefficients (ICC) was applied to assess reviewer consistency, alongside multiple sensitivity analyses.

Results: By 2025, the MRQCS QC rule library expanded from 41 rules initially to 597 rules. The sampled-case defect rate increased sharply after the January 2021 launch (trend change +0.06, 95% CI 0.03-0.08, P<.001), and rrates based on the 41 stable rules present in every year rose from 16.7% (880/5256) in 2021 to 50.9% (3662/7190) in 2023, indicating that most of the increase reflected improved system sensitivity. The high-risk case rate declined significantly after July 2023 (trend change –0.09, 95% CI –0.15 to –0.02, P=.007), and the residual defect rate showed an immediate decline at the May 2025 breakpoint (level change –0.44, 95% CI –0.85 to –0.03, P=.03). The AI-assisted write-back rate exceeded 97% after August 2023 and declined to 84%-87% after the May 2025 discharge blocking intervention (level change –2.14, 95% CI –3.08 to –1.21, P<.001), suggesting that clinicians corrected an increasing proportion of defects. Reviewer-level defect rates were far more homogeneous in the AI-assisted period (coefficient of variation [CV] 26.8% vs 115.7%), with reviewer identity accounting for a smaller share of the total variance (ICC 0.317 vs 0.782), indicating greater interreviewer consistency. Consistency of the high-risk defect rate showed the same pattern (CV 31.3% vs 135.3%; ICC 0.053 vs 0.541).

Conclusions: Through the collaborative model of 2-level real-time QC and AI-assisted final-stage QC, MRQCS was associated with improved defect detection, reduction of documentation defects, and substantially greater interreviewer consistency; the discharge-time blocking intervention further reduced the residual defect rate. These findings provide a practical reference for the construction of medical record quality management systems.

KEYWORDS

medical record quality control; real-time prompt; block validation; defect detection; rule engine; AI-assisted quality control; interreviewer consistency

Introduction

Medical record quality control (QC) is a critical component of hospital health care quality management. The completeness, standardization, and accuracy of medical records are important indicators for measuring health care quality and management levels [1]. Numerous clinical studies use medical record documentation as the core data source for information extraction and predictive analysis [2-9], such as extracting subphenotypes of critical limb ischemia cases through improved natural language processing [2], predicting fall risk [3] and mortality [6] in older adult patients using clinical records, and identifying treatment-emergent adverse events [9]. Medical record quality directly determines the accuracy of research results and the scientific validity of clinical decision-making.

With the popularization of electronic health record (EHR) systems and the advancement of structured medical records, medical record quality has improved to some extent [10-14]. However, medical institutions both domestically and internationally still face issues with inconsistent medical record quality: a 2019 study on rural medical institutions in China showed serious deficiencies in basic diagnostic and treatment information in outpatient medical records [15]; a 2022 study at 2 Dutch medical centers indicated that even with standardized documentation, medical record quality remained at a low level [13], highlighting the urgent need for medical record quality improvement in health care institutions.

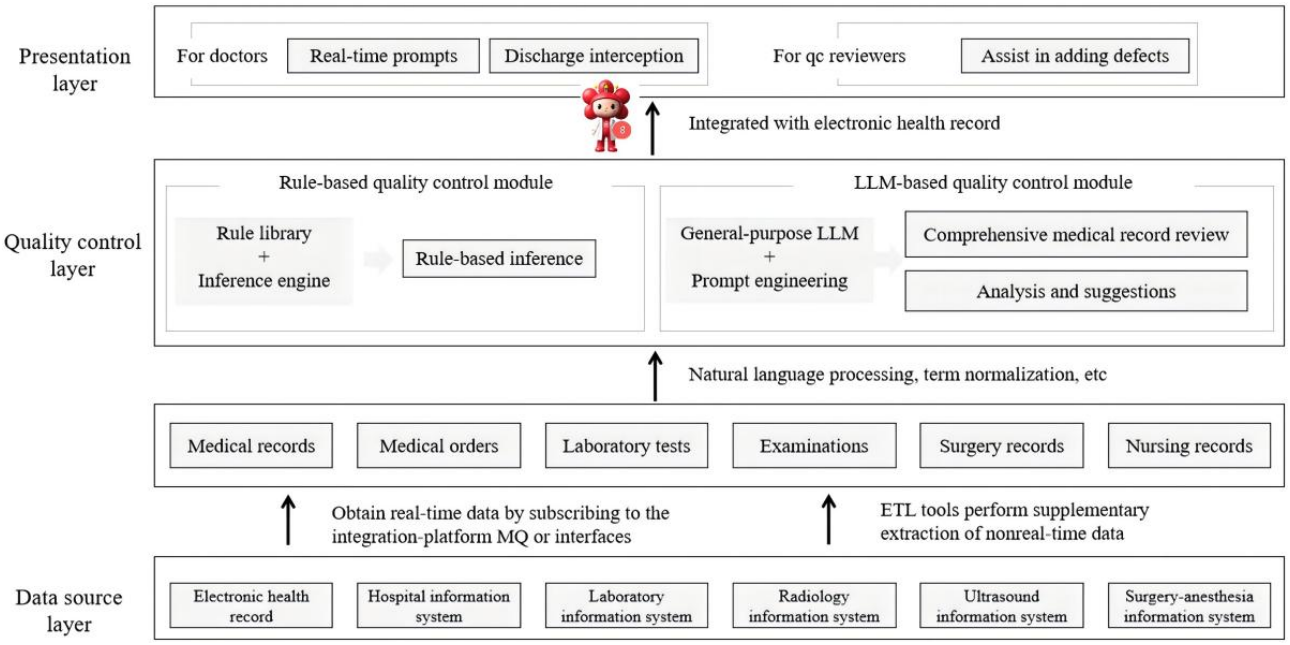
Quality assessment is the foundation of medical record quality improvement. Existing assessment tools such as QNOTE [16] and the Physician Documentation Quality Instrument [17,18] all rely on manual evaluation, which is labor-intensive and cannot achieve real-time assessment. Traditional manual QC adopts methods such as process control, 3-level QC, and 2-level random blind review, which are limited to sampling inspection and cannot achieve full-sample validation, consuming considerable time and effort. The development of AI and big data technologies has promoted research on AI-assisted medical record content QC [19,20]. Related systems achieve full-sample automatic QC through natural language processing for medical record structuring combined with authoritative standards for rule library construction. However, significant shortcomings remain: QC interventions are mostly triggered at scheduled times or specific nodes without achieving true real-time capability [19]; application effect assessments lack specificity and do not adequately reflect the system's defect detection capabilities [20]; quantitative research on interreviewer consistency has not been conducted; QC result notification mechanisms are unclear, with excessive prompts interfering with clinical work and insufficient prompts leading to delayed defect handling.

In recent years, large language models (LLMs) such as ChatGPT (OpenAI) and DeepSeek (Hangzhou DeepSeek Artificial Intelligence Basic Technology Research Co Ltd) have shown promising applications in the health care field [21-23], with advantages in semantic understanding and complex defect identification that can provide new technical support for medical record QC. To address the above challenges, this study designed and developed a medical record quality control system (MRQCS) primarily based on rule engines and supplemented by LLMs and deeply integrated with clinical workflows, achieving nonblocking real-time prompts and blocking validation (defined as a mandatory validation step that prevents submission until flagged issues are deleted or resolved) for clinicians and AI-assisted defect detection with 1-click write-back for QC reviewers.

The objective of this study was to describe the design and development of MRQCS for clinicians and QC reviewers and to retrospectively evaluate its associations with medical record defect detection, medical record quality, and interreviewer consistency using 7 years of longitudinal final-stage QC records (2019-2025).

Methods

Study Design and Setting



This was a single-center, retrospective longitudinal evaluation of MRQCS implemented at a tertiary hospital in Beijing, China. The study evaluated the associations of MRQCS with defect detection, medical record quality, and interreviewer consistency. The system integrates multisource structured and unstructured in-hospital data; it provides real-time prompts and blocking validation for clinicians and offers AI-assisted defect detection and 1-click write-back for final QC reviewers. This evaluation included all final QC records of patients discharged between January 2019 and December 2025, with patient discharge month set as the temporal analysis unit, since QC is conducted on medical records after patient discharge.

System Architecture and Workflow

The MRQCS proposed in this study adopts a 4-tier hierarchical architecture. From bottom to top, it consists of the data source layer, data collection layer, QC layer, and presentation layer, as shown in Figure 1.

XSL•FO
RenderX

Figure 1. Four-tier architecture of MRQCS. ETL: extract, transform, load; LLM: large language model; MQ: message queue; MRQCS: medical record quality control system; QC: quality control.

Data Source Layer

As the fundamental data foundation of the entire system, the data source layer connects to multiple core hospital business information systems, including the EHR system, hospital information system, laboratory information system, radiology information system, etc. This layer provides multidimensional raw clinical data, serving as the data source for upstream data collection modules.

Data Collection Layer

The data collection layer is responsible for acquiring and processing multisource clinical data. It captures real-time streaming clinical data by subscribing to message queues of the hospital integration platform or via application programming interfaces. Meanwhile, extract, transform, load (ETL) tools are used to supplement the extraction of historical and offline nonreal-time data, balancing the timeliness and completeness of data acquisition. This layer processes both structured data (eg, laboratory reports, nursing vital signs, and physician order entries) and unstructured data (eg, textual diagnostic content in examination reports). The system leverages a BiLSTM-CRF (bidirectional long short-term memory–conditional random field) model [24-26] combined with domain-specific business rules for natural language processing. Raw collected data go through processing workflows, including word segmentation and term normalization, to complete text cleansing and medical term standardization. The processed data are then forwarded to the QC layer for subsequent analysis.

QC Layer

Overview

As the core operational processing unit of the system, the QC layer consists of 2 submodules: the rule-based QC module and the LLM-based QC module.

Rule-Based QC Module

This module comprises a rule library and a rule-based inference engine. The rule library is built in accordance with national industry standards, including the Specification for Medical Record Documentation and the Quality Scoring Standard for Inpatient Medical Records, as well as the hospital's internal medical record quality management regulations. QC rules are formulated and reviewed collaboratively by the hospital's medical affairs department and medical record quality experts. The quality assessment covers 25 types of medical documents categorized into 8 main groups: progress notes, discharge or death records, admission notes, other medical records, medical record front page (the standardized summary form of each inpatient record, which serves as the primary data source for diagnosis-related groups [DRGs]–based payment and hospital performance evaluation in China), perioperative records, physician order sheets, and informed consent forms. Evaluation dimensions include document completeness, cross-source data consistency, and documentation timeliness. The rule library supports multiattribute configuration to define deduction items, risk levels (low, moderate, and high), and interception flags. Interception flags adjust the execution intensity of QC workflows to enable differentiated QC strategies: for example, missing surgical informed consent is configured as an interception rule, while nonstandard progress note documentation is set as a general alert rule. By conducting logical matching between case data and the predefined rule library, the inference engine identifies defects in medical records and returns standardized QC outputs through application interfaces. The returned outputs contain defect details, deduction scores, and risk levels, providing support for front-end QC alerts and defect resolution.

LLM-Based QC Module

This module is built on the on-premises LLMs DeepSeek-R1 and Qwen3-235B-A22B and is entirely deployed within the

XSL•FO
RenderX

hospital's secure internal network to ensure data privacy and compliance with the institution's information security policies. Qwen3 is used as the default model to balance response latency and computational cost. Before clinical data is fed into the LLM, patient-identifiable information is removed, with only the clinical content required for analytical tasks retained. This module implements 2 core functions. **First, the Medical Record Review function** analyzes completed medical documents via prompt engineering and clinical context; it can identify potential medical record defects that are not captured by the rule library, such as missing key laboratory and examination findings in discharge summaries. The relevant prompts for this function are provided in Multimedia Appendix 1**. Second, the analysis and suggestions function** generates targeted revision suggestions based on the medical record context for defects detected by the rule-based module to assist clinicians in revising medical records, and the corresponding prompts for this function are also included in Multimedia Appendix 2. Limited by the concurrency capacity of locally deployed large models, LLM-based QC functions require manual triggering by clinicians. Outputs are returned approximately 1 second after activation, and fully automatic real-time concurrent QC is not currently supported.

Presentation Layer

Overview

The presentation layer supports result visualization and human-computer interaction. Through deep integration with the EHR system, it delivers differentiated QC services to both clinicians and QC reviewers.

Integration With the EHR

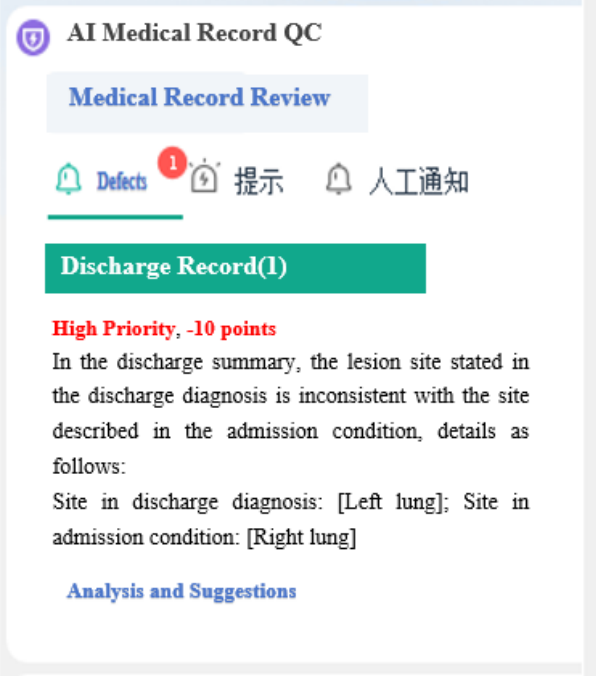
The MRQCS achieves seamless end-to-end integration with the EHR system without disrupting routine clinical workflows. Key integration points are outlined in the following paragraphs.

Regarding the EHR startup, when the EHR system launches, the MRQCS activates automatically and appears as a floating widget in the bottom-right corner of the EHR interface. It does not occupy primary screen space and leaves normal clinical documentation operations unaffected.

Regarding medical record saving, when clinicians save or submit medical records within the EHR, data is asynchronously pushed to the MRQCS. The MRQCS performs multidimensional quality assessment using the associated clinical datasets and refreshes QC outputs asynchronously without interrupting ongoing documentation work.

Regarding the medical record completion, after a patient is discharged, clinicians trigger the "complete medical record" function within the EHR, which invokes interception validation from the MRQCS. If any interception rule is violated, a pop-up window displaying defect details will appear within the EHR, and clinicians must resolve or delete all intercepted defects before they can submit the record. A 5-second time-out mechanism is also implemented: if the MRQCS malfunctions, the EHR will continue its workflow to maintain clinical continuity.

Regarding the final-stage QC, QC reviewers retrieve records pending quality assessment through the EHR-embedded QC module. The MRQCS dynamically visualizes deduction scores and defect distribution for the retrieved records. When accessing the details of an individual record, reviewers can view all detected defects and write validated defects into the defect database with a single click.



Two-Tier Prompt Mechanism for Clinical End Users

Stage 1: Nonblocking Real-Time Prompting During Documentation

When medical records are saved to the EHR, the floating MRQCS widget in the bottom-right corner displays the number of detected defects. Clicking the widget displays detailed defect information, including defect descriptions, deduction values, and risk levels (Figure 2). This notification workflow does not disrupt normal EHR operations. After clinicians revise and resave the documents, QC outputs are refreshed to form a closed-loop workflow covering documentation, quality review, and revision. A supplementary LLM-based review function is also available: after opening a target document, clinicians can activate the medical record review function, which identifies latent defects missed by rule-based checks and provides supporting rationales and revision guidance. For specific defects identified by rule-based QC, the analysis and suggestion function generates customized modification recommendations for the document.

XSL•FO
RenderX

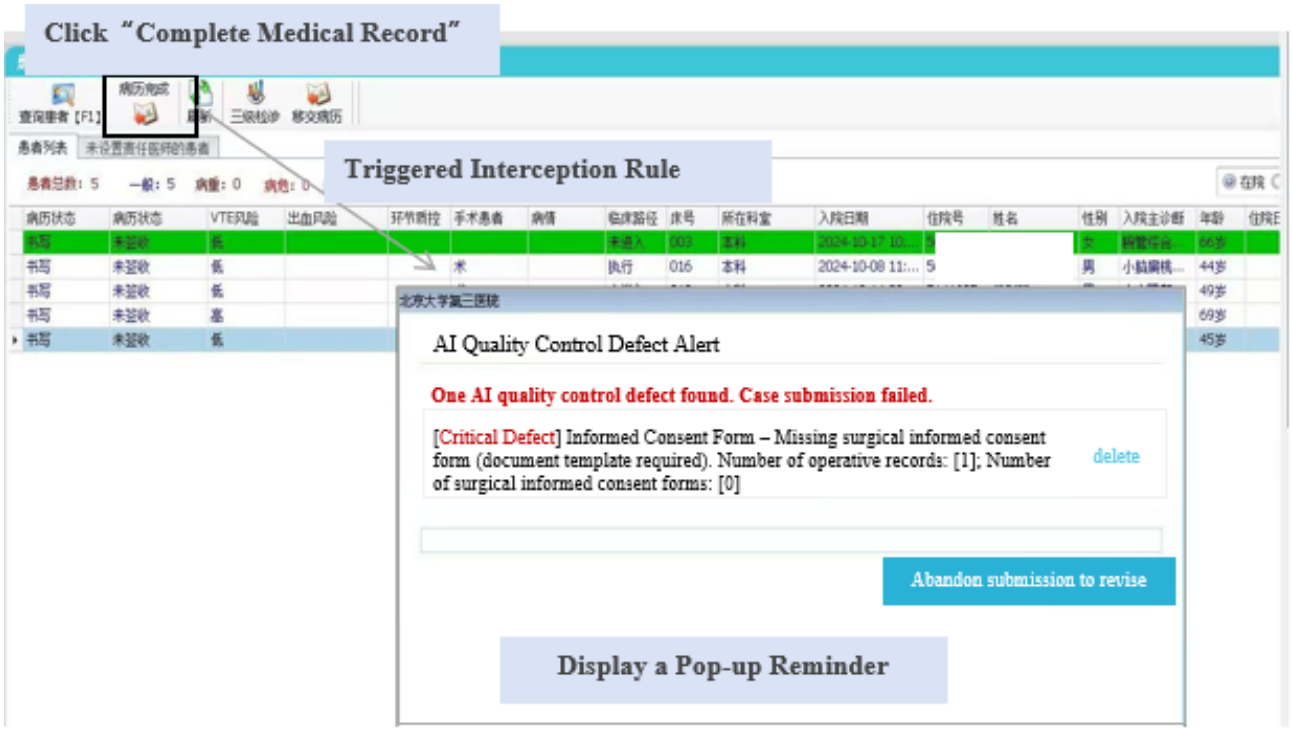


Figure 2. Real-time defect alerts during medical record documentation. QC: quality control.

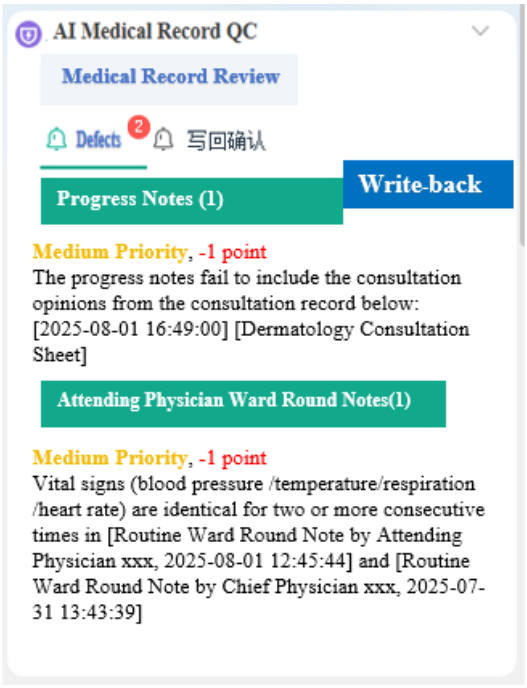
Stage 2: Blocking Validation Upon Medical Record Completion

After a patient is discharged, mandatory blocking validation is triggered when clinicians initiate the "complete medical record" action. If interception rules are violated (eg, missing surgical informed consent documents), a mandatory pop-up window will appear in the EHR, requiring clinicians to revise the relevant documents. Manual removal of false-positive defects is also supported. This process is shown in Figure 3.

Figure 3. Blocking validation pop-up upon medical record completion.



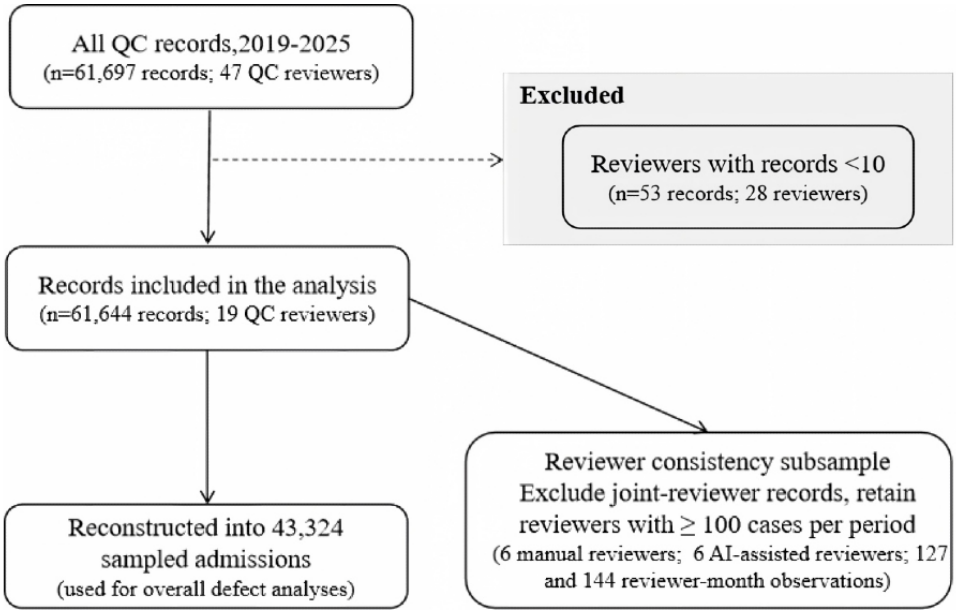
AI-Assisted Defect Addition for the QC Reviewers

For monthly retrospective record audits, high defect scores exported from MRQCS are combined with randomly sampled cases and assigned to quality reviewers. When reviewers confirm the system-identified true-positive defects, they can use the "write-back" function to directly import validated defects to the QC database (Figure 4). False-positive results can be deleted manually. Reviewers may also manually add new defects missed by the system, enabling complementary collaboration between AI-assisted QC and manual record review.

XSL•FO
RenderX

Figure 4. AI-assisted defect addition for the QC reviewers. QC: quality control.

Data Source and Study Population



This evaluation included all QC records of patients discharged between January 2019 and December 2025 stored in the MRQCS QC database. Each record corresponds to 1 QC entry for 1 inpatient admission: defect cases have 1 record per detected defect, while defect-free sampled cases are represented by a single record with empty defect fields. After deidentification, 61,697 QC records from 47 QC reviewers were retrieved; 53 records from 28 reviewers with fewer than 10 records were excluded, leaving 61,644 records from 19 reviewers for analysis. The included records were reconstructed into case-level observations, and the final analytic sample covered 43,324 inpatient admissions (defined by the unique combination of patient identifier and discharge date-time) that received monthly sampling QC during the study period (Table 1). Discharge date-times span January 2019 to December 2025 with no missing values, forming 84 monthly discharge cohorts. For the reviewer consistency analysis, joint-reviewer cases (case defects attributed to more than 1 reviewer) were further excluded, and only reviewers with a substantial workload (≥100 cases reviewed within each study period) were retained (6 reviewers in each of the manual and AI-assisted periods, with 127 and 144 reviewer-month observations, respectively; Figure 5). Table 1 summarizes the annual numbers of sampled cases, defect cases, high-risk cases, defect records, and AI-assisted write-back records across the 7-year study period.

Table 1. Annual summary of sampled cases, defect cases, high-risk cases, defect records, and AI-assisted write-back volume, 2019-2025.

Year	Sampled cases, n	Defect cases, n (%)	High-risk cases, n (%)	Defect records, n	AI-assisted write-back, n
2019	6491	1327 (20.4)	74 (1.14)	1706	0
2020	4888	995 (20.4)	114 (2.33)	1239	0
2021	5256	1123 (21.4)	134 (2.55)	1594	198
2022	5875	2400 (40.9)	276 (4.70)	4477	1149
2023	7190	4229 (58.8)	514 (7.15)	9735	7814
2024	6290	3877 (61.6)	619 (9.84)	7566	7432
2025	7334	4401 (60.0)	326 (4.45)	8955	8221
Total	43,324	18,352 (42.36)	2057 (4.75)	35,272	24,814

RenderX

Figure 5. Participant flow diagram of quality control records, 2019-2025. QC: quality control.

Sampling Procedure and Case Definitions

Monthly sampling QC was conducted by trained QC reviewers. Before system deployment, reviewers manually selected cases stratified by department for verification. After MRQCS implementation, the Medical Affairs Department assigned review tasks by combining high-deduction records exported from MRQCS with randomly sampled admissions. It should be noted that our dataset lacks metadata to distinguish between records from high-deduction lists and those from pure random sampling, which may introduce residual selection bias between the preimplementation and postimplementation periods. A case is classified as a defect case if it contains at least one defect record and as a defect-free sampled case if the admission is represented by a single record with empty defect fields. A high-risk case is defined as any case with at least one defect score ≥ 10. The AI field indicates whether a defect was added via the AI-assisted write-back workflow (1=AI-assisted, 0=manually added; empty for defect-free sampled cases).

Intervention Timeline

MRQCS was rolled out in phases. In January 2021, its real-time clinical QC and final-stage QC assistance functions were launched, with 41 predefined rules configured. In June 2021, the Medical Affairs Department recommended the system to reviewers, and it was approved as an auxiliary tool. In August 2023, with 335 rules in total, final-stage QC transitioned to the mode of "AI pre-verification as primary, manual review as supplementary." A discharge-blocking function with 597 rules was deployed in May 2025. Final QC was typically conducted around 1 month after patient discharge (eg, QC for discharge cases from August is performed at the end of September to early October), so each intervention was assigned to the first discharge cohort affected by the corresponding measure. However, the discharge-blocking function operates in real time. Accordingly, the month when the function was activated was defined as the intervention time point: December 2020 (B1), July 2023 (B2), and May 2025 (B3).

Outcome Measures

Four monthly outcome indicators were analyzed as follows: (1) sampled-case defect rate (number of defect cases / number of sampled cases × 100%), (2) high-risk case rate (number of cases with at least one defect score ≥ 10 / the number of sampled cases × 100%), (3) average number of defects per sampled case, and (4) AI-assisted defect write-back rate (number of AI-assisted defect records / the total number of defect records × 100%), which reflects the proportion of documented defects entered via the AI-assisted workflow. We additionally examined the type-specific detection rate across 8 document categories.

Statistical Analysis

We conducted the primary analysis using interrupted time series (ITS) segmented regression on data from 84 monthly discharge cohorts. For the defect rate, high-risk rate, and AI write-back rate, we fitted quasi-binomial logistic regression models (on the logit scale) with the number of sampled cases set as the binomial denominator; for the mean defect count, we fitted a Poisson model with a log link. Each model included a continuous time term, 3 level-change indicators (D), and 3 trend-change terms (T) corresponding to the 3 breakpoints: December 2020, July 2023, and May 2025. All models were estimated with heteroskedasticity-robust SEs. We computed counterfactual predictions on the logit scale by extending prebreakpoint trends, then transformed these predictions back to the probability scale to compare observed rates with the values expected if none of the interventions had been implemented. To distinguish improved detection capability from genuine quality improvement, we repeated the ITS analysis on a stable rule set consisting of the 41 defect codes that appeared in every year from 2019 to 2025. Finally, we assessed residual autocorrelation using the Durbin-Watson statistic and the Ljung-Box test.

We evaluated reviewer consistency after excluding joint-reviewer records and restricting the analysis to reviewers who reviewed at least 100 cases in each study period, which retained 6 reviewers in both the manual review period and the

XSL•FO
RenderX

AI-assisted review period. For each period, we fitted a linear mixed-effects model with a random reviewer intercept (adjusted for time) to the reviewer-month mean defect counts and high-risk defect rates (defined as cases with at least one defect score ≥ 10). We calculated the intraclass correlation coefficient (ICC) as the ratio of reviewer variance to total variance and tested reviewer effects using likelihood-ratio tests. We additionally summarized between-reviewer dispersion with the coefficient of variation (CV) of reviewer-level defect rates.

Sensitivity analyses involved shifting each breakpoint by ±1 and ±2 months, excluding 2020 (the COVID-19 pandemic period), adding a placebo breakpoint set at January 2020, and testing an alternative high-risk threshold of 5. For the reviewer consistency analysis, we additionally tested alternative workload thresholds (≥50, ≥200, and ≥500 cases per period). All statistical tests were 2-sided, with the significance level set at 0.05. All analyses were performed in Python (version 3.12, Python Software Foundation) using the Statsmodels (version 0.15), SciPy, and pandas libraries.

Ethical Considerations

This retrospective study was approved by the Medical Science Research Ethics Committee of Peking University Third Hospital (IRB00006761-M20250619). It did not involve the collection of personal privacy data, strictly adhering to the Declaration of Helsinki. Given the retrospective nature of the study and the use of deidentified data, the requirement for informed consent was waived.

Reporting Guideline

This study was reported in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) statement for observational studies, and the completed STROBE checklist is provided in Multimedia Appendix 3.

Results

ITS Analyses

Table 2 presents the ITS regression coefficients for all outcomes on the logit scale, using quasi-binomial logistic models with heteroskedasticity-robust SEs. Outcome Y3 was fitted with a Poisson model with a log link. All *P* values are 2-sided, where "—" indicates the result is not estimable. Since the AI-assisted write-back rate was 0 before January 2021, the model for Y4 was fitted using data from January 2021 onward.

Overall Defect Rate (Y1)

Table 2 and Figure 6 show that the overall sampled-case defect rate remained stable before 2021 (time trend 0.00, 95% CI –0.01 to 0.02, *P*=.59), and increased sharply after the launch in January 2021 (trend change 0.06, 95% CI 0.03-0.08, *P*<.001). This was followed by a further level increase at the July 2023 breakpoint (level change 0.50, 95% CI 0.02-0.97, *P*=.04), alongside a subsequent declining trend (trend change –0.07, 95% CI –0.10 to –0.04, *P*<.001). At the May 2025 breakpoint, the defect rate saw a significant immediate decline (level change –0.44, 95% CI –0.85 to –0.03, *P*=.03), followed by an upward trend (trend change 0.10, 95% CI 0.05-0.14, *P*<.001). Counterfactual analysis estimated that, in absolute percentage-point terms, the sampled-case defect rate was 0.44 higher by August 2023 and 0.38 higher by December 2025 compared with the no-intervention counterfactual (Figure 6). This finding is consistent with a substantial expansion of the system detection capacity.

XSL•FO
RenderX

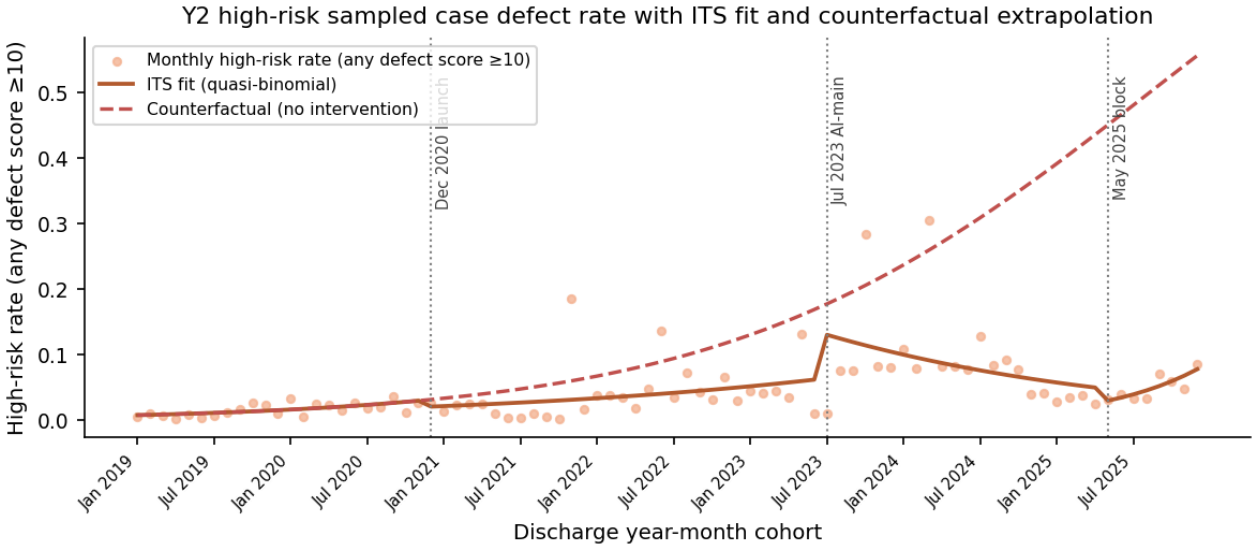

Figure 6. Monthly sampled-case defect rate with ITS fitting, breakpoints (December 2020, July 2023, May 2025), and counterfactual extrapolation assuming no interventions. ITS: interrupted time series.

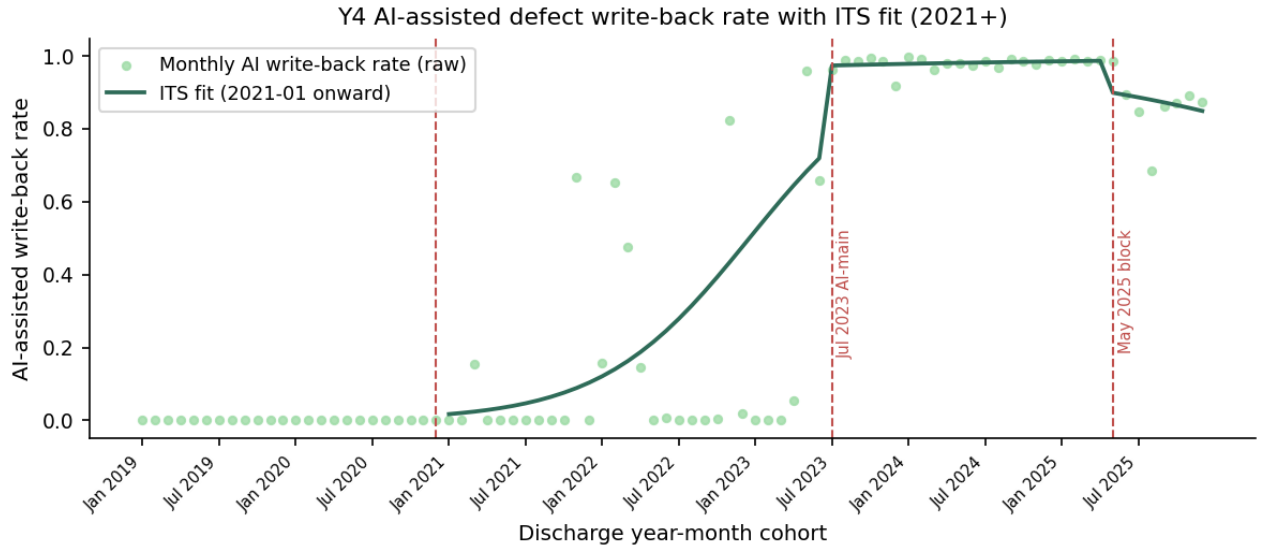
High-Risk Case Rate (Y2)

Table 2 and Figure 7 show that the high-risk case rate increased steadily before 2023 (time trend 0.06, 95% CI 0.03-0.09, *P*<.001) and declined significantly after the July 2023 breakpoint (trend change –0.09, 95% CI –0.15 to –0.02, *P*=.007), with a further level reduction at the May 2025 breakpoint (–0.48, 95% CI –1.03 to 0.07; *P*=.09) and a strong upward trend thereafter (trend change 0.19, 95% CI 0.12-0.26, *P*<.001). Counterfactual analysis estimated that, compared with the preintervention trend, the high-risk case rate was 0.42 lower by May 2025 and 0.48 lower by December 2025, indicating a genuine reduction of high-risk defects.

Figure 7. Monthly high-risk case rate (proportion with 1 defect score ≥ 10) with ITS fit and counterfactual extrapolation assuming no interventions. ITS: interrupted time series.



AI-Assisted Defect Write-Back Rate (Y4)

Table 2 and Figure 8 show that the AI-assisted write-back rate was 0% in 2019-2020 and increased after the system launch, reaching a plateau above 97% after the August 2023 shift to AI-primary review (level change 2.50, 95% CI 0.39-4.61, *P*=.02). After the May 2025 discharge blocking intervention, the write-back rate declined significantly (level change –2.14, 95% CI –3.08 to –1.21, *P*<.001), stabilizing at 84%-87%. This is consistent with the trend that clinicians correct an increasing proportion of defects during hospitalization through real-time prompts and blocking validation (Figure 8).

XSL•FO
RenderX

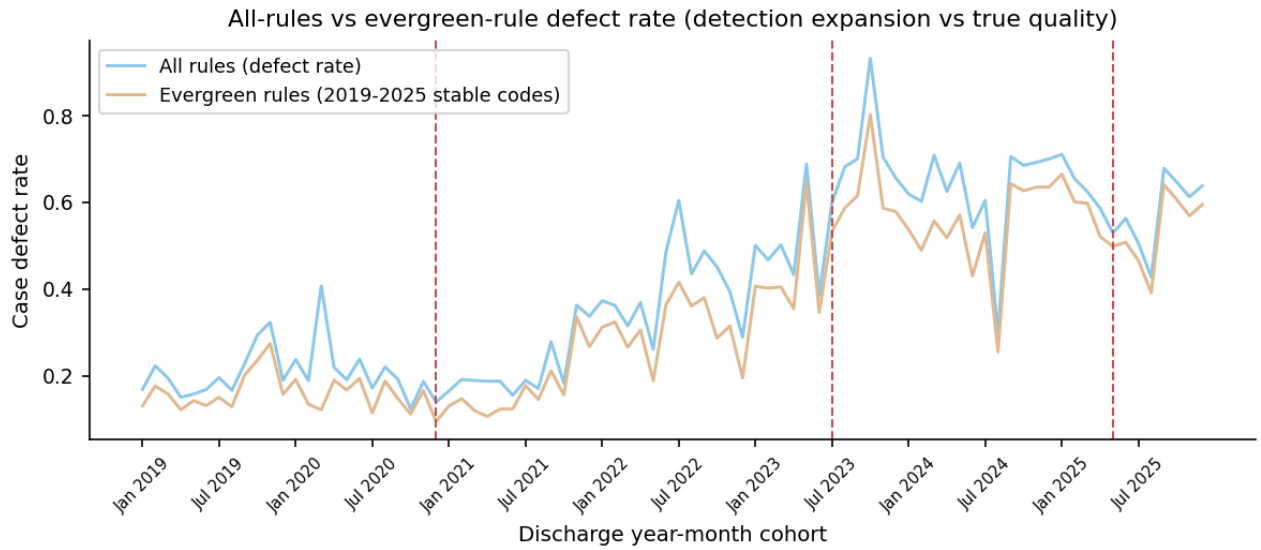


Figure 8. Monthly AI-assisted defect write-back rate with ITS fit (January 2021 onward). ITS: interrupted time series.

Stable-Rule-Set Analysis

To distinguish improved detection from genuine quality improvement, we repeated the ITS analysis for the 41 defect codes included in every year from 2019 to 2025, holding the rule set constant (Figure 9 and Table 2). The stable-rule defect rate rose from 16.7% (880/5256) in 2021 to 50.9% (3662/7190) in 2023, and declined significantly after July 2023 (trend change –0.06, 95% CI –0.09 to –0.03, *P*<.001) and in May 2025 (level change –0.40, 95% CI –0.79 to –0.02, *P*=.04). Since the rule set was fixed, the increase before 2023 reflects higher detection intensity associated with AI-assisted review, while the subsequent decline indicates genuine quality improvement across stable dimensions. The gap between the all-rules curve and the stable-rules curve remained modest (5%-8% in 2023-2025). At the case level, the stable rules alone identified 86.1% (3338/3877) to 92.8% (4086/4401) of all defective cases, which indicates that rule library expansion added only a limited number of new defective cases. Therefore, the overall increase in defect rate was driven predominantly by improved detection sensitivity rather than rule growth. At the record level, however, rules not present in every year accounted for 16.3% (1464/8955) to 27.2% (2646/9735) of defect records during 2023-2025, indicating that newly added rules contributed additional defect types within already-flagged cases.

Figure 9. Monthly defect rates based on the full rule set vs the stable 41-code rule set.

Mean Number of Defects per Case (Y3)

The mean number of defects per sampled case increased after January 2021 (trend change 0.07, 95% CI 0.01-0.13, *P*=.02), declined after July 2023 (trend change –0.07, 95% CI –0.12 to –0.01, *P*=.02), and showed a significant immediate reduction in May 2025 (level change –0.34, 95% CI –0.60 to –0.07, *P*=.01) followed by a subsequent upward trend (trend change 0.05, 95% CI 0.02-0.08, *P*=.002).

XSL•FO
RenderX

Reviewer Consistency

To limit the influence of reviewers with negligible workloads on consistency estimates, we restricted the analysis to reviewers who completed at least 100 reviews within each period after excluding joint-reviewer records. This left 6 reviewers in each period: there were 127 reviewer-month observations in the manual period and 144 in the AI-assisted period; reviewers completed a median of 1926 cases (IQR 813-2997) in the manual period and 2,255 cases (IQR 2229-2297) in the AI-assisted period. Reviewer-level defect rates varied widely in the manual period (mean 0.56, SD 0.64, CV 115.7%), but were far more homogeneous in the AI-assisted period (mean 1.22, SD 0.33, CV 26.8%). In linear mixed-effects models with a random reviewer intercept, adjusted for time, reviewer identity accounted for 78.2% of the total variance in the manual period (ICC 0.782; reviewer variance 0.244 vs residual variance 0.068; likelihood-ratio test $P<.001$), but only 31.7% in the AI-assisted period (ICC 0.317; reviewer variance 0.100 vs residual variance 0.215; $P<.001$; Table 3). The period-by-time interaction was not statistically significant ($P=.28$), confirming that the reduction in reviewer identity variance was not attributable to differential time trends between the 2 periods; systematic differences between reviewers were thus substantially smaller when AI assistance was the primary workflow.

Table 3. Reviewer consistency for the overall and high-risk defect rates by period.

Outcome and period	Reviewers, n	Observations, n	Rate, mean (SD)	CV[a], %	ICC[b]	Reviewer effect LRT[c] *P* value
Overall defect rate						
Manual (2019-2020)	6	127	0.56 (0.64)	115.7	0.782	<.001
AI-assisted (2024-2025)	6	144	1.22 (0.33)	26.8	0.317	<.001
High-risk defect rate						
Manual (2019-2020)	6	127	0.034 (0.046)	135.3	0.541	<.001
AI-assisted (2024-2025)	6	144	0.070 (0.022)	31.3	0.053	.26

[a]CV: coefficient of variation.

[b]ICC: intraclass correlation coefficient.

[c]LRT: likelihood-ratio test.

Consistency of the high-risk defect rate showed a similar pattern (Table 3): reviewer-level rates ranged from 0.13% to 12.07% in the manual period (mean 3.4%, SD 4.6%, CV 135.3%), but converged to the range of 2.9%-8.8% in the AI-assisted period (mean 7%, SD 2.2%, CV 31.3%). The ICC declined from 0.541 (reviewer variance 0.0185 vs residual variance 0.0157; likelihood-ratio test $P<.001$) to 0.053 (reviewer variance 0.0003 vs residual variance 0.0057; $P=.26$), which indicates that when AI assistance is adopted as the primary workflow, systematic differences between reviewers in detecting high-risk defects are no longer detectable.

Document-Type-Specific Detection Rates

Comparisons across document types are purely descriptive. Because aggregated document-type rates do not include individual-level case identifiers, formal hypothesis testing and normality-based selection between parametric and nonparametric statistical tests could not be performed. Table 4 presents defect detection rates for the 8 document types in 2019-2020 vs 2024-2025. Detection rates rose considerably for progress notes (+597.9%), discharge or death records (+516.1%), admission records (+280.5%), and medical record front pages (+278.7%), while the rate for other records dropped by 85.8%. The decrease in detection rates for certain document types under AI-assisted review can be explained by 3 categories of defects. First, complex semantic and logical defects, such as unclear stratification of the present illness history or disordered narrative chronology, were detected less often. This is because the current rule library can only identify explicit logical errors (eg, “the duration of time-related items in the present illness history exceeds the patient's age”) and has limited coverage of underlying semantic issues. Second, defects without corresponding QC rules, such as missing assessment forms in other records, cannot be automatically recognized, as they have not been added to the rule library, resulting in a clear drop in detection. Third, simple omission defects, such as blank or incorrect entries in the drug allergy field, can be corrected in real time by clinicians during documentation when prompted by AI. Additionally, analysis of defects manually added by QC reviewers in 2025 showed that all of these defects belonged to types not covered by the MRQCS rule library, which confirms that there are still blind spots in current defect detection and the rule library needs further improvement.

XSL•FO
RenderX

Table 4. Defect detection rates by document type before (2019-2020) and after (2024-2025) AI assistance.

Document type	Before (2019-2020, %)	After (2024-2025, %)	Relative change (%)
Admission records	9.4	35.8	+280.5
Discharge or death records	1.7	10.7	+516.1
Medical record front pages	2.3	8.9	+278.7
Informed consent forms	1.0	0.7	–33.1
Other records	0.3	0.0	–85.8
Perioperative records	2.8	8.1	+190.6
Physician orders	0.0	0.1	+101.7
Progress notes	8.2	57.0	+597.9

Sensitivity Analyses

The results of the ITS analysis remained robust across all sensitivity analyses (Table 5): shifting the July 2023 breakpoint by ±1 or ±2 months produced level changes between 0.19 and 0.52, and slope changes between –0.057 and –0.088, all with the same direction of effect. Excluding data from 2020 (the COVID-19 pandemic period) generated consistent estimates of 0.50 for the level change and –0.072 for slope change. Setting a placebo breakpoint at January 2020 detected no significant effect (*P*=.98), which supports that the observed effect is not spurious. In addition, using an alternative high-risk threshold of 5 still yielded consistent conclusions. The Durbin-Watson statistic was 1.89, and the Ljung-Box test was not statistically significant (*P*=.35), indicating no substantial residual autocorrelation.

Table 5. Sensitivity analyses for the interrupted time series model of the defect rate (July 2023 breakpoint estimates).

Scenario	Level change at B2 (β)	Slope change at B2 (β)
Breakpoints –2 months	+0.39	–0.057
Breakpoints –1 month	+0.19	–0.058
Breakpoints +1 month	+0.52	–0.083
Breakpoints +2 months	+0.42	–0.088
Excluding 2020	+0.50	–0.072
Placebo breakpoint, January 2020	+0.01[a]	—[b]
High-risk threshold 5	+0.76	–0.084

[a]*P*=.98.

[b]Not available.

For reviewer consistency, sensitivity analyses using alternative workload thresholds (≥50, ≥200, and ≥500 cases per period) yielded consistent conclusions (Table 6): the AI-assisted ICC remained stable at 0.317, the manual ICC ranged from 0.549 (≥200 cases, 5 reviewers) to 0.782 (≥50-100 cases, 6 reviewers), and in all scenarios the AI-assisted period showed a smaller reviewer variance share and lower reviewer-level CV, indicating that the conclusion of greater interreviewer consistency with AI assistance was robust to the workload threshold.

Table 6. Sensitivity analysis of the ICCa to the reviewer workload threshold.

Threshold (cases per period)	Manual period: reviewers, n	Manual period: ICC	AI-assisted period: reviewers, n	AI-assisted period: ICC
≥50	6	0.782	6	0.317
≥100 (main analysis)	6	0.782	6	0.317
≥200	5	0.549	6	0.317
≥500	5	0.549	6	0.317

[a]ICC: intraclass correlation coefficient.

Discussion

Principal Findings

Based on the complete 84-month time series from 2019 to 2025, this study found that the deployment of MRQCS was associated with a significant expansion of defect detection, a clear reduction in high-risk documentation defects after July 2023, an immediate drop in the residual defect rate after the May 2025 discharge blocking intervention, and considerably higher interreviewer consistency during the AI-assisted period (reviewer-level CV

XSL•FO
RenderX

26.8% vs 115.7%; ICC 0.317 vs 0.782). Through the stable-rule-set analysis, we successfully distinguished detection expansion from actual quality improvement. These findings directly meet the 2 primary objectives of this study: describing the development and implementation of the system and retrospectively evaluating the system's associations with defect detection, documentation quality, and interreviewer consistency.

Interpretation and Comparison With the Literature

Compared with the scheduled or node-based QC systems described in the literature [19], the most distinctive feature of MRQCS is its in-process intervention capability: it delivers nonblocking real-time prompts to clinicians while they are writing medical records and enforces blocking validation when records are completed. This allows defects to be intercepted before they are added to the permanent medical record, rather than being detected days or weeks afterward. Meanwhile, the system maintains the efficiency of clinical workflow through asynchronous, nonblocking notifications and a 5-second time-out mechanism, which guarantees the continuity of clinical work even when the system malfunctions.

Regarding the quantitative evaluation of system effects, most existing studies on earlier AI-based MRQCSs either lacked rigorous effect assessments or only reported results with limited specificity [20]. By contrast, this study used a complete 7-year, 84-month time series and an ITS design with breakpoints aligned to the intervention timing. It applied counterfactual prediction, adopted a stable-rule-set analysis to distinguish improved detection capability from true quality improvement, and used linear mixed-effects models with ICCs to quantify interreviewer consistency.

Limitations

This study has several limitations. First, because the dataset did not retain a sampling-source indicator (random sample vs high-deduction list), residual selection differences between study periods cannot be completely ruled out, though the stable-rule-set analysis and the high-risk defect rate help partially address this concern. Second, the accuracy of MRQCS defect detection was not directly evaluated; instead, the AI-assisted defect write-back rate was used to indirectly reflect system usability. This is because the manpower cost of a full manual review of all records is prohibitively high, and the process by which reviewers add defects via the system already includes a manual verification step that can, to a certain extent, reflect the accuracy of system detection. Third, the reviewer cohorts in the manual period and the AI-assisted period were not identical, and reviewers did not assess overlapping sets of medical records across the 2 periods. Despite mixed-effect adjustment and ICC quantification, observed changes in interreviewer consistency may still be confounded by differences in reviewer training, case-mix composition, and institutional QC policy updates. Fourth, due to the retrospective study design, confounding factors could not be fully controlled. Fifth, LLM-assisted QC has not yet realized automatic triggering, primarily due to constraints on system execution efficiency and hardware resource consumption; currently, it only serves as a supplementary function that is manually triggered by clinicians.

Based on the limitations outlined above, our future work will focus on three aspects: (1) further improving the comprehensiveness of the rule library to enhance the system's defect detection capability; (2) leveraging LLMs and model fine-tuning to explore their detection performance for long-tail defects and defects with complex semantics [27-29], with a particular focus on improving the model's response speed and detection precision; and (3) continuously tracking the number of medical record QC defects to provide more robust evidence for system optimization, clinical management, and the improvement of overall medical record quality.

Conclusions and Implications

Using the complete 84-month time series of QC records spanning from 2019 to 2025, this study demonstrates that the deployment of a real-time AI-assisted MRQCS is associated with multiple notable improvements: a significant expansion in defect detection capability, a genuine reduction in high-risk documentation defects, higher interreviewer consistency during the AI-assisted period, and an immediate drop in the residual defect rate after the discharge blocking intervention implemented in May 2025. Beyond the scope of this single hospital, this study provides a replicable model for integrating rule-based and AI-assisted QC into clinical documentation workflows. In this model, real-time, full-sample in-process QC complements traditional post-hoc sampling QC, while graded interventions, including non-blocking prompts and discharge blocking, can be rolled out incrementally, with measurable effects at each stage. Future research should incorporate blinded reference-standard evaluation of detection accuracy, direct measurement of system efficiency, and multicenter validation.

Abstract

Background: Patient-generated health data (PGHD) can enhance patient-centered care by improving disease awareness and preparedness for clinical encounters. However, automated incorporation of PGHD into electronic medical records (EMRs), which is a prerequisite for broader clinical implementation, remains technically and administratively challenging.

Objective: This study describes the development of *Miri-Alimi*, a PGHD collection platform that delivers mobile social networking service–based previsit questionnaires with automated transfer of structured patient responses into the EMR, and evaluates patient participation, EMR documentation quality, and user satisfaction in a cardiology outpatient clinic.

Methods: This single-center observational study was conducted between August and November 2024 and included 751 consecutive cardiology outpatients, comprising 282 first-visit patients and 469 patients attending follow-up visits for heart failure. All eligible patients received a previsit electronic questionnaire link via KakaoTalk or multimedia messaging service prior to their scheduled visit. The primary outcomes were the overall survey response rate among all enrolled patients and EMR documentation completeness among follow-up patients with heart failure. Documentation quality was evaluated based on 3 prespecified parameters relevant to routine heart failure care—dyspnea, peripheral edema, and medication adherence status—and was quantified using an EMR completeness score ranging from 0 to 3. Secondary outcomes included patient and provider satisfaction assessed using postvisit 5-point Likert-scale surveys. Firth penalized logistic regression was used to evaluate the association between survey response status and EMR completeness, with adjustment for age and sex.

Results: The response rate was 38.5% (289/751), including 48.9% (138/282) of new patients and 32.2% (151/469) of follow-up patients with heart failure. Responders were younger than nonresponders (mean 62.0, SD 15.7 years vs mean 69.8, SD 12.5 years; P<.001). Among the follow-up patients with heart failure, EMR completeness was higher among responders (median score 3, IQR 3 - 3) than among nonresponders (median score 0, IQR 0 - 1; P<.001). Patient satisfaction was high: 82.9% (63/76) to 92.1% (70/76) agreed that the system was appropriate, easy to use, and helpful, and 78.9% (60/76) completed the survey in <10 minutes. Both cardiologists and 7 of the 8 participating nurses supported continued use of the system, citing workflow efficiency gains.

Conclusions: Miri-Alimi enabled patient-friendly PGHD collection without requiring log-ins or a dedicated app and demonstrated direct transfer of patient responses into the EMR. Its use was associated with effective transfer and structured integration of PGHD into the EMR, as well as high satisfaction among survey respondents and participating staff. Further studies should evaluate sustainability and associations with long-term clinical outcomes across diverse care settings.

Introduction

The burden of cardiovascular diseases on the Korean health care system has steadily increased, with chronic cardiac conditions such as heart failure significantly contributing to this burden. Cardiovascular mortality in South Korea reached 123 per 100,000 persons in 2018, and hospitalizations due to circulatory system diseases increased by approximately 3.7-fold from 169,000 in 2002 to 630,000 in 2018 [1]. Furthermore, heart failure prevalence increased from 0.77% in 2002 to 2.53% in 2020 [2]. Patients with cardiovascular diseases commonly have multiple comorbidities, and this is particularly evident among patients with heart failure; for instance, 78.7% of patients with heart failure also had hypertension, 58.8% also had diabetes mellitus, and 15.8% also had chronic kidney disease [2].

Clinicians face ongoing challenges in managing patients with complex medical histories, such as the thorough collection and documentation of patient data, while considering diverse comorbidities. Effective management of chronic conditions requires continuous monitoring rather than intermittent isolated interventions [3]. Additionally, substantial discrepancies exist between the patient- and physician-based recognition of symptoms in routine clinical practice, potentially hindering precise assessment and appropriate clinical decision-making [4].

Many medical institutions have adopted electronic patient-reported outcomes (ePROs) to address these issues. A patient-reported outcome refers to any report on a patient's health condition directly provided by the patient, thus shifting clinical consultations toward patient-centered care [5,6]. In a nonrandomized controlled study, Rocque et al [7] demonstrated that the implementation of an electronic patient-reported outcome–based remote symptom monitoring program in routine cancer care was associated with significantly lower hospitalization rates compared with historical controls, with a 19% reduction at 3 months (risk ratio 0.81; 95% CI, 0.73 - 0.91) and a 13% reduction at 6 months (risk ratio 0.87; 95% CI, 0.80 - 0.96). Patient-reported outcomes are typically collected through clinician-initiated tools embedded within health care systems, whereas patient-generated health data (PGHD) are produced outside clinical encounters using widely accessible commercial platforms such as mobile apps and wearable devices. PGHD are distinguished by 2 key characteristics: data capture is primarily patient driven rather than provider directed, and decisions regarding data sharing and distribution are controlled by patients, encompassing self-measured physiological and behavioral data collected through home devices, mobile apps, or wearable technologies [8,9]. PGHD enrich clinical information by providing personalized and contextual insights and promoting self-care practices among patients [10]. In oncology, PGHD supports survivorship care by fostering patients' autonomy, improving health outcomes, and contributing to population-level health [11]. When designing ePRO systems, investigators decide whether patient-reported outcome measures should be collected directly within participating health systems or integrated from external platforms into individual electronic records, a choice that carries important implications for clinical usability and future research [12]. Despite the widely acknowledged significance of EHR integration, prior studies indicate that approximately 70% of PGHD implementations lack effective EHR linkage, which underscores the need for more streamlined mechanisms for data incorporation in future applications, particularly in cardiology clinics [13,14].

In response, we developed "Miri-Alimi," a mobile previsit questionnaire system delivered via social messaging platforms commonly used in South Korea. Designed to lower digital barriers and facilitate integration with a hospital's in-house automated electronic medical record (EMR) system, Miri-Alimi aims to enhance outpatient documentation, improve patient-clinician communication, and streamline clinical workflows. This study evaluated the implementation of Miri-Alimi in a cardiology outpatient clinic by assessing the participation rates, completeness of EMR documentation, and satisfaction among patients and health care providers.

Methods

Study Design and Population

This single-center prospective study was conducted at the outpatient cardiology clinic of a tertiary hospital. The digital service Miri-Alimi was developed through collaboration of a multidisciplinary team including clinical staff, medical record specialists, a digital engineering team, and 2 external technology companies responsible for message delivery and PGHD integration into EMRs (Figure 1). Miri-Alimi was officially launched following a 3-month pilot phase to enhance system reliability, user convenience, and readability.

XSL•FO
RenderX

Figure 1. Multidisciplinary team–based development of Miri-Alimi, including clinical staff (questionnaire development, chart review, and efficiency evaluation), medical record specialists (target patient selection and EMR formatting), 2 external tech companies (system development and data transfer), and the digital engineering team (EMR management). EMR: electronic medical record.

A multidisciplinary team was composed of clinical staff who were in charge of developing questionnaires, reviewing patient charts, and evaluating the efficiency of Miri-Alimi; medical record specialists who were in charge of selecting target patients and formatting questionnaire results into electronic medical record; 2 external tech companies (Lemon Healthcare and LC Tech) who built and managed the mobile questionnaire system and were in charge of the transfer of survey data into the EMR; and the digital engineering team who managed errors in running the survey.

Patients were enrolled between August and November 2024 and categorized into 2 groups: new patients with cardiovascular disease (first-time visits for various cardiovascular conditions) and repeat patients with heart failure (follow-up visits for existing patients with heart failure). The eligibility criteria included an age of ≥18 years and the capability to use a mobile phone with messaging features. Patients without access to a mobile phone or those who were unable to complete the survey because of severe visual or cognitive impairment were excluded.

During the study period, 751 patients, comprising 282 new patients with cardiovascular disease and 469 repeat patients with heart failure, received invitations to use Miri-Alimi. Invitations were sent before each scheduled outpatient visit.

Ethical Considerations

Ethical approval for human subject research was obtained from the Institutional Review Board of Korea University Guro Hospital (approval 2024GR0221). All participants provided informed consent electronically prior to participation. The consent included authorization for the collection of personal

XSL•FO
RenderX

identifiers, medical information, and survey responses, as well as permission for secondary analysis without the need for additional consent. No financial or nonfinancial incentives were provided for participation.

All data exported from the Miri-Alimi platform were anonymized prior to analysis to protect participant confidentiality. Survey results were not accessible to patients through the mobile system after submission; access was restricted to authorized clinicians during face-to-face consultations or through formal, in-person medical record requests verified by hospital staff.

Patient authentication was conducted using birthdate verification, which was chosen to lower digital barriers and improve accessibility for patients, particularly older adults or those with limited digital literacy.

Patient responses were initially stored on Lemon Healthcare's external cloud server and subsequently transferred in real time to the hospital's designated external server, hosted by Naver Cloud (NAVER Corp), which maintains multiple security certifications. In compliance with the Korean Personal Information Protection Act (PIPA), all data outsourcing and cloud storage processes adhered to legal and regulatory requirements.

In accordance with Article 26 of PIPA, a formal data processing agreement was established, clearly specifying the purpose of data outsourcing, restrictions on further processing, technical and administrative safeguards, and the designation of Lemon Healthcare and Naver Cloud as authorized data processors.

Additionally, pursuant to Article 29, appropriate technical and managerial measures were implemented to ensure the protection of personal information. All server-client communications were encrypted using Secure Sockets Layer (SSL) and hypertext transfer protocol secure (HTTPS) protocols. User sessions were protected through JSON Web Token (JWT) authentication, with automatic termination after 30 minutes of inactivity or upon survey completion. Furthermore, an administrative dashboard enabled authorized clinical staff to monitor the delivery status of survey invitations, track real-time response completion, and review system-generated analytics to support quality control and data integrity throughout the study.

Previsit Questionnaire Development

A multidisciplinary team of cardiologists, cardiovascular nurses, and medical information specialists created a Korean-language electronic questionnaire optimized for outpatient cardiovascular care. Questionnaire development proceeded through several multidisciplinary meetings, during which items were iteratively refined to minimize discrepancies in symptom interpretation between patients and clinicians and to ensure compatibility with outpatient workflows, particularly for heart failure care. A key design objective was the seamless transfer of patient-entered data into EMR fields aligned with established scales, including the New York Heart Association (NYHA) functional classification and Canadian Cardiovascular Society (CCS) angina grading. For example, a patient response of "I experience shortness of breath or fatigue during ordinary activities such as walking on level ground" was automatically mapped to NYHA class III within the EMR. This automated semantic mapping promotes objective and consistent documentation of symptom severity and facilitates longitudinal monitoring of clinical status. Survey-derived NYHA class was automatically populated in the EMR and could be modified by clinicians during the encounter. Two versions of the questionnaire were developed (Textboxes 1 and 2) for 2 patient groups. The questionnaire for new patients was designed to systematically assess cardiovascular symptoms and to obtain detailed medical histories. The questionnaire for follow-up patients with heart failure was designed to capture essential clinical information regarding patient status, including general health condition, symptom severity, medication adherence, and use of medications prescribed outside the clinic.

Textbox 1. The content of questionnaire for first-visit patients.

- Symptoms and severity: dyspnea, chest pain, palpitations, syncope
- Comorbidities: hypertension, diabetes mellitus, dyslipidemia, coronary artery disease, arrhythmia, stroke
- Lifestyle and social history: drinking, smoking, exercise, occupation
- Family history
- Problems or questions for medical staff

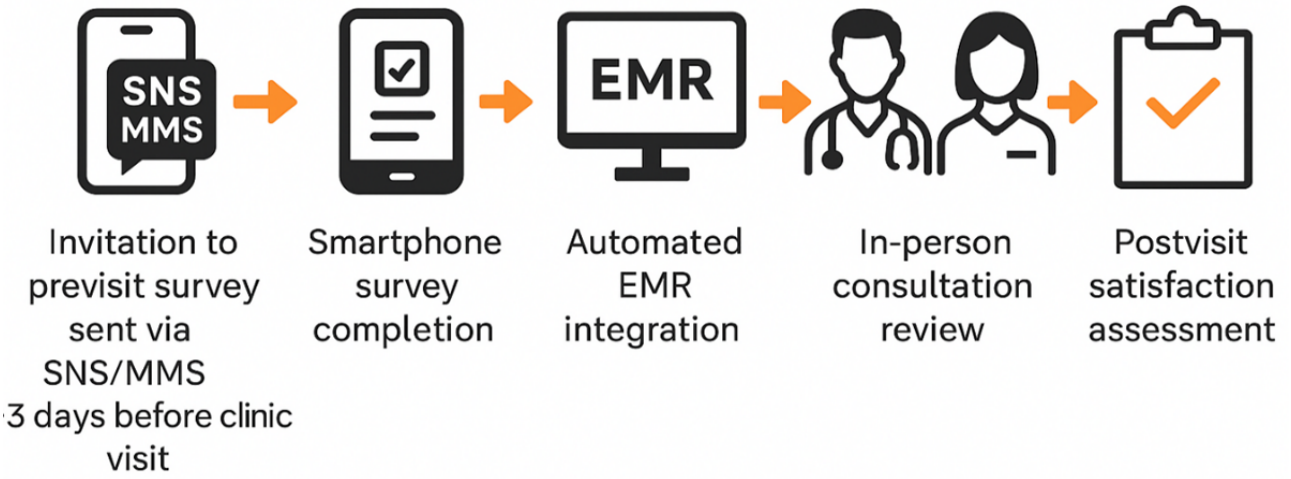
Textbox 2. The content of questionnaire for follow-up patients with heart failure.

- General health rating (0-10)
- Symptoms and severity: dyspnea, chest pain, palpitation, dizziness, syncope
- Signs of decompensation: peripheral edema, weight change compared to last visit
- Medication from external providers
- Medication adherence assessment (≥80% doses taken) and barriers
- Home-measured vital signs (blood pressure and heart rate) and weight
- Dyspnea, chronic fatigue, and peripheral edema assessed (0-10)
- Problems or questions for medical staff

XSL•FO
RenderX

In the new patient questionnaire, thirteen stem questions (with conditional subitems) gathered baseline data on (1) cardiac symptoms, (2) past medical history and comorbidities, (3) social history, and (4) family history of cardiovascular disease.

In the heart failure follow-up questionnaire, seventeen stem questions were supplemented with validated scoring scales and interval changes and adherence were monitored. Patients (1) rated global health status, (2) graded dyspnea and chest pain, (3) reported changes in dyspnea since the previous visit, (4) reported peripheral edema or weight gain >3 kg, (5) detailed medication adherence (≥80% of prescribed doses taken) and listed drugs prescribed outside of the institution, and (6) entered home-measured vital signs and body weight.



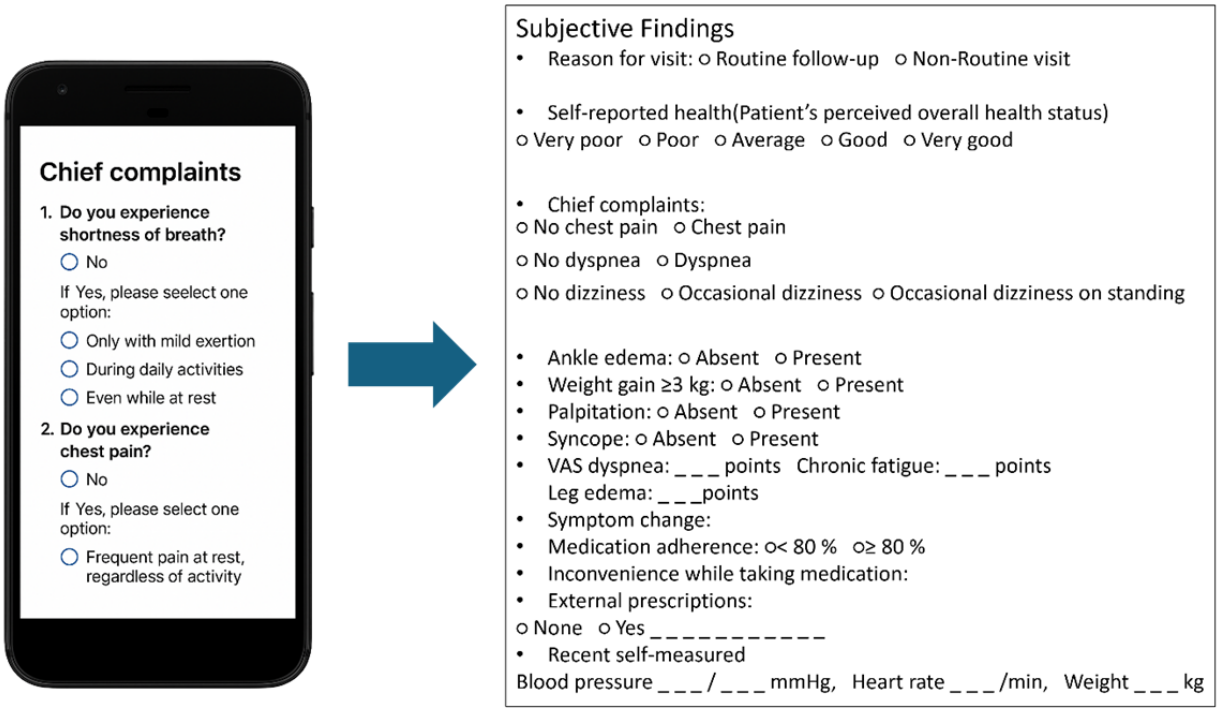
Both instruments relied primarily on fixed-choice items, and the follow-up questionnaire included 6 short-answer fields. Each questionnaire ended with a free-text section on patient-identified concerns.

Delivery of the Previsit Questionnaire

The Miri-Alimi platform was integrated into the hospital's appointment scheduling system, enabling automated distribution of previsit surveys. Considering South Korea's high smartphone penetration rate of 95.1% in 2024 [15], a personalized URL linking directly to the survey was delivered via KakaoTalk (versions 10.9.0 to 11.3.0; Kakao Corp), a messaging platform used by 98.9% of Korean mobile users [16], 3 days before the scheduled outpatient appointment. For patients without access to KakaoTalk, survey invitations were alternatively dispatched through multimedia messaging service (MMS).

The survey was designed for ease of access, requiring neither the installation of an app nor user authentication through username and password. Instead, identity verification was conducted by matching patient-entered birthdates with EMRs. Patients provided informed consent electronically regarding the collection and use of personal information for research purposes before proceeding with the survey. The survey URL remained accessible until the time of consultation, allowing patients to complete the questionnaire in the clinic waiting area if necessary. An automated reminder was dispatched 1 day before the appointment for those with incomplete responses. Each patient received only 1 questionnaire prior to their index visit during the study period (Figure 2).

Figure 2. Workflow of this study EMR: electronic medical record; MMS: multimedia messaging service; SNS: social networking service.



The survey used a responsive HTML-based interface compatible with both desktop and mobile devices. Upon accessing the URL, patients encountered a dashboard displaying assigned surveys, which could be edited until the scheduled consultation. The survey used mandatory response fields to minimize missing data. Additionally, conditional branching logic was used to enhance the relevance and efficiency of the survey flow. Completed survey responses were transferred directly to the institution-specific EMR of Korea University Medical Center via Lemon Healthcare's proprietary Quick Application Programming Interface (API) Builder, enabling immediate clinical use.

Data Collection and EMR Integration

The completed survey responses were automatically transmitted to the hospital's EMR system. Each survey item was mapped to a corresponding field in a structured clinical note, enabling standardized documentation. For example, self-reported symptom severity and general health status were incorporated into the review of systems section (Figure 3). At the time of the visit, the clinicians reviewed the patients' responses transferred to electronic charts. If a patient did not complete the survey prior to the appointment, no previsit entry was generated, and routine in-person medical history interviews were conducted.

XSL•FO
RenderX

Clinic Visit Workflow and Postvisit Surveys

During clinical consultations, physicians were encouraged to incorporate the information provided by patients through Miri-Alimi into their evaluations. After consultation, patients who responded to the survey received a postvisit satisfaction survey delivered through the same messaging system.

The patient satisfaction survey comprised 15 items. Among these, 13 items related to appropriateness, acceptability, and satisfaction were rated on a 5-point Likert scale (1=strongly disagree, 5=strongly agree). Of these, 2 items assessed the appropriateness of the PGHD collection method and number of survey questions. Three items evaluated acceptability: ease of understanding the questions, difficulty in providing responses, and overall usability of the system. Eight items measured satisfaction with the perceived usefulness of Miri-Alimi. Two items were open-ended; the first assessed the time required to complete the survey and the second allowed patients to provide feedback in a free-text space with unlimited word count.

Separately, all participating clinical staff (n=10; 2 cardiologists and 8 nurses) were invited to complete a provider survey after the study period. The staff questionnaire comprised 15 items for cardiologists and 8 items for nurses. These surveys included 13 and 6 Likert-scale items assessing system acceptability and satisfaction, respectively, 1 item evaluating perceived changes in consultation time, and 1 open-ended item for additional comments.

Outcome Measures

The primary outcomes were the rates of previsit survey responses and EMR data completion. The response rate was defined as the proportion of eligible clinic visits for which the patient submitted a previsit questionnaire. The rates were calculated separately for new patients and for those with follow-up visits for heart failure.

Data completeness was evaluated using a predefined EMR completeness score applied to follow-up visits for heart failure. Follow-up patients with heart failure formed a clinically homogeneous population, which permitted prior specification of disease-specific documentation elements. Based on consensus between 2 participating cardiologists, 3 core documentation parameters relevant to routine heart failure care were selected: dyspnea status, presence of peripheral edema, and medication adherence status. Each parameter received 1 point when the corresponding information was explicitly documented in the EMR clinical note, either through automated transfer of questionnaire responses for responders or through routine clinician documentation for nonresponders. For medication adherence, documentation was considered complete when the clinical note explicitly indicated whether adherence was above or below the 80% threshold. The total EMR completeness score ranged from 0 to 3, with higher scores indicating more complete structured clinical documentation.

Completeness scores among responders were derived automatically from structured data generated by the previsit questionnaire. In contrast, completeness scores for nonresponders were determined through a comprehensive manual review of the EMRs performed by the study investigators. For nonresponders, a point was assigned only when the relevant parameter itself was explicitly documented.

All relevant components of the EMR were reviewed, including structured symptom fields, free-text clinical notes, and prescription records. Free-text entries that lacked explicit clinical definition or standardized symptom descriptors, including nonspecific phrases such as “so-so” or “no interval change,” that suggested overall stability or interval status were not

XSL•FO
RenderX

regarded as valid documentation of heart failure–related symptoms. To minimize subjective interpretation by chart reviewers and to ensure methodological consistency, such entries were assigned a completeness score of 0.

Secondary outcomes included measures of the utility of the ePRO system, specifically the proportion of follow-up patients with heart failure who reported taking medications prescribed outside the heart failure clinic and the acquisition rate of free-text entries describing those medications. Additional secondary outcomes included patient satisfaction (defined as the proportion of respondents who agreed or strongly agreed with positive statements), provider satisfaction, and the perceived impact on clinical workflow.

As an exploratory workflow-related measure collected separately from the Miri-Alimi platform, consultation time was estimated using EMR time stamps. Specifically, the attending physician was asked to perform an initial save of the EMR at the start of the outpatient encounter and a final save at the end of the consultation, and the interval between these 2 time points was used as a proxy for consultation duration. Consultation time was not a prespecified study end point. However, because objective time stamp data had been collected for a subset of visits, these data were analyzed exploratorily to complement provider-reported assessments of workflow efficiency.

Data Analysis

Analyses were conducted using R software (version 4.4.2; R Foundation for Statistical Computing). Response rates and item-specific satisfaction rates were calculated for both the patient and provider postvisit surveys. Free-text responses were qualitatively analyzed to identify recurring themes.

Because this study was designed as a real-world implementation study, no a priori sample size calculation was performed. The study population therefore consisted of a sample of all eligible consecutive patients during the prespecified study period.

Descriptive statistics were used to summarize the patient demographics, clinical characteristics, and survey responses. Continuous variables are presented as means with SDs or medians with IQRs and were compared using 2-tailed *t* tests or Wilcoxon rank sum tests, as appropriate. Categorical variables are reported as frequencies and percentages and were compared using the chi-square test or Fisher exact test. Statistical tests were 2-tailed, with the significance level set at $P<.05$.

Exploratory analyses of consultation time were performed only for visits with available time stamp data. Given the substantial and differential missingness in consultation time data, formal statistical testing was not performed. Additional subgroup analyses were performed separately for first-visit patients and follow-up patients with heart failure. Given the substantial proportion of missing time stamp data, particularly among nonresponders, these analyses were considered exploratory and were interpreted with caution.

Differences in EMR completeness between responders and nonresponders were evaluated using Firth penalized logistic regression because the distribution of EMR completeness scores demonstrated substantial separation. Two prespecified binary outcomes were examined: complete documentation (score 3 vs scores 0‐2) in the primary analysis and higher documentation completeness (scores ≥2 vs scores 0‐1) in the supplementary analysis. To account for potential demographic confounding, particularly age-related differences in digital health engagement, both age and sex were included in the adjusted models.

Results

Patient Participation and Characteristics

Of the 751 patients invited, 289 (38.5%) responded to the previsit questionnaire (Figure 4 and Multimedia Appendices 1 and 2). The response rates were 48.9% (138/282) among new patients and 32.2% (151/469) among follow-up patients with heart failure. The proportion of women was slightly higher among responders (147/289, 50.9%) than among nonresponders (194/462, 42%; $P=.020$). Moreover, responders were significantly younger than nonresponders (mean 62.0, SD 15.7 years vs mean 69.8, SD 12.5 years; $P<.001$; Table 1). Age distribution analysis showed lower response rates among patients aged ≥70 years, who constituted 56.7% (262/462) of nonresponders versus 30.4% (88/289) of responders (Figure 5). Patient participation was robust, with consistently high response rates exceeding 90% for all multiple-choice items. Nonconditional short-answer items achieved response rates exceeding 50%, while lower response rates were observed for items intended to be answered only when applicable (Table S2 in Multimedia Appendix 3).

Figure 5. Histogram of age distribution among patients who completed the previsit survey (response=1) vs those who did not (response=0).

EMR Documentation Completeness

Among the 469 follow-up patients with heart failure, the completeness of the EMR documentation was significantly greater among those who completed the previsit survey. Responders (n=151) had a median EMR score of 3 (IQR 3 - 3), reflecting complete documentation of dyspnea, peripheral edema, and medication adherence. In contrast, nonresponders (n=318) had a median EMR score of 0 (IQR 0 - 1; *P*<.001), with only 28% (89/318) having any of the 3 parameters recorded (Table 2). The distribution of EMR completeness scores showed sparse outcome strata with quasi-complete separation (Figure 6).

Descriptive Results of ePRO-Based Medication Reporting

Among 151 follow-up patients with heart failure who completed the previsit survey, 89.4% (135/151) responded to the question regarding the use of medications prescribed outside the heart failure clinic. Of these respondents, 53.3% (72/135) reported taking at least 1 medication not prescribed by the heart failure clinic. Of those reporting externally prescribed medications, 80.6% (58/72) provided specific medication details through the free-text input field (Table 3).

Table . Descriptive results of ePRO[a]-based medication reporting among follow-up patients with heart failure.

	Participants, n/N (%)
Response to question on medications prescribed outside the heart failure clinic	135/151 (89.4)
Reported use of medications prescribed outside the heart failure clinic	72/135 (53.3)
Completion of free-text medication entry among those reporting externally prescribed medications	58/72 (80.6)

[a]ePRO: electronic patient-reported outcome

Patient Satisfaction

Of the 289 patients who completed the previsit questionnaire, 26.3% (76/289) participated in the postvisit satisfaction survey (Table 4 and Multimedia Appendices 1 and 2). The mean age of these respondents was 61.6 (SD 14.3) years; 42.1% (32/76) of the patients were women, and 42.1% (32/76) were new patients. Most respondents (60/76, 78.9%) reported that they completed the previsit survey within 10 minutes, with the majority (72/76, 94.7%) reporting that they completed it within 20 minutes (Table 5).

Table . Postvisit satisfaction survey.

	Participants, n/N (%)
Participation rate	76/289 (26.3)
First-visit patients	32/76 (42.1)
Follow-up patients	44/76 (57.9)
Women	32/76 (42.1)

Table . Reported time required for previsit survey.

Time required for previsit survey, minutes	Participants, n (%)		
	Combined (n=76)	New patients (n=32)	Follow-up patients (n=44)
<10	60 (78.9)	23 (71.9)	37 (84.1)
10 - 20	12 (15.8)	7 (21.9)	5 (11.4)
20 - 30	2 (2.6)	1 (3.1)	1 (2.3)
>30	2 (2.6)	1 (3.1)	1 (2.3)

All 76 patients completed the 15-item satisfaction survey (Table S3 in Multimedia Appendix 3), and their satisfaction responses were overwhelmingly positive. Agreement rates for the 13 key items ranged from 82.9% (63/76) to 92.1% (70/76), each surpassing 70% (χ^2_1=4.8 - 17.7, all P<.028 after false discovery rate adjustment). Item means were between 4.09 and 4.30 on the 5-point Likert scale, all exceeding the neutral midpoint of 3 (t_{75}=12.4 - 16.4, P<.001 with Bonferroni correction; Cohen d=1.5 - 1.9), which confirms pronounced patient satisfaction with Miri-Alimi.

Among 76 participants, 92.1% (n=70) agreed that KakaoTalk or text messages were a suitable notification method, and 88.2% (n=67) found the number of questions appropriate. In terms of acceptability, 89.5% (68/76) reported that the questions were easy to understand, 86.8% (66/76) were able to complete the survey without assistance, and 85.5% (65/76) found it overall easy to use. Regarding perceived usefulness, 86.8% (66/76) to 89.5% (68/76) agreed that the survey was helpful in preparing for the visit and in communicating symptoms and history, while 82.9% (63/76) to 84.2% (64/76) found it beneficial for clinicians' understanding and overall care (Table S3 in Multimedia Appendix 3). Overall satisfaction was reported by 85.5% (65/76), with 92.1% (70/76) expressing willingness to continue using the system and 84.2% (64/76) indicating they would recommend it to others.

Provider Feedback

Feedback from ten clinical staff members (2 cardiologists and 8 nurses) supported the system's utility. Nurse respondents (n=8) reported high agreement (88%) across domains, including question appropriateness, clinical utility, workflow efficiency,

XSL•FO
RenderX

and satisfaction with continued use (Table 6). Aligning with Miri-Alimi's goal of streamlining outpatient workflow, nurses reported that the system facilitated patient assessment and reduced both previsit preparation and in-clinic encounter times by allowing them to focus on key information rather than conducting an extensive history. Both cardiologists (n=2) endorsed the integration of Miri-Alimi into the clinical workflow and noted improvements in documentation and patient engagement, although only 1 reported a perceived reduction in in-clinic history-taking items (Table S5 in Multimedia Appendix 3).

Table . Postvisit satisfaction survey results of nurses (n=8).

Category	Item	Participants who agreed or strongly agreed, n (%)
Appropriateness	Appropriateness of number and types of questions	7 (87.5)
Clinical utility	Helpfulness of patient self-reporting in identifying patients	7 (87.5)
	Easier patient management compared to without Miri-Alimi	7 (87.5)
Workflow	Reduction in previsit preparation time	7 (87.5)
	Reduction in patient encounter time	7 (87.5)
Overall satisfaction	Overall satisfaction with care using Miri-Alimi	7 (87.5)
	Agreement on continued use and expansion of Miri-Alimi	7 (87.5)

Exploratory Objective Consultation Time Data

Objective consultation time data were collected separately from the Miri-Alimi platform by measuring the interval between the physician's initial EMR save at the start of the encounter and the final save at the end of the visit. However, these data were incomplete because of transmission errors and missed final saves during routine care. Of the 751 enrolled patients, consultation time data were available for 400 patients (Multimedia Appendix 4). Consultation time data were available for 208 of 289 (72%) responders and 192 of 462 (41.6%) nonresponders, respectively.

In the overall cohort with available time stamp data, consultation time, measured in seconds, was descriptively longer among responders than among nonresponders (median 292, IQR 207-410 seconds vs median 250, IQR 182-358 seconds). In -subgroup analyses, consultation time did not show a clear descriptive difference between responders and nonresponders among follow-up patients with heart failure (100/151, 66.2% vs 119/318, 37.4%; median 294, IQR 218-380 seconds vs median 276, IQR 186-362 seconds). In contrast, among first-visit patients, consultation time was descriptively longer for responders than for nonresponders (108/138, 78.3% vs 73/144, 50.7%; median 288, IQR 201-456 seconds vs median 216, IQR 179-333 seconds). However, these comparisons are descriptive only and do not imply statistical significance due to substantial and differential missingness in time stamp data.

Firth Penalized Logistic Regression

In the Firth penalized logistic regression, survey response status was strongly associated with complete EMR documentation after adjustment for age and sex (adjusted odds ratio [OR] 3611.09, 95% CI 497.9 - 459754.6; P<.001). In the sensitivity analysis using a less stringent threshold of EMR completeness (score ≥2 vs scores 0 - 1), the association remained significant (adjusted OR 368.89, 95% CI 157.6 - 1010.9; P<.001). Sex and age were not significantly associated with either outcome.

Discussion

Main Findings and Comparison With Prior Work

This nonrandomized service implementation study suggests that Miri-Alimi, a mobile-based previsit questionnaire system, is feasible for implementation in routine cardiology practice and was acceptable among responding patients and participating health care providers. The system improved the structured documentation of essential clinical data relevant to patient status assessment. In addition, PGHD collection and use were associated with favorable satisfaction among postvisit survey respondents.

However, previous studies investigating whether PGHD collection enhances clinical outcomes beyond satisfaction have yielded inconsistent results. Sandhu et al [17] observed no significant changes in heart failure quality of life scores, despite patients reporting that clinicians had an improved understanding of their symptoms. In contrast, Yamashita et al [18], in a randomized study, found significant enhancements in patient satisfaction and the quality of information provided by clinicians when using ePROs compared to traditional methods. These benefits were attributed primarily to more frequent patient follow-ups. Furthermore, Sandhu et al [17] highlighted that automated clinician alerts for clinically meaningful symptom deterioration could enhance the effectiveness of routine PGHD monitoring. Collectively, these insights emphasize that collecting PGHD data alone is insufficient and that timely reviews and responsive clinical actions are critical.

To facilitate wider adoption of PGHD collection and use in clinical settings, the process of notifying patients to submit PGHD and authenticating users to access PGHD platforms must

XSL•FO
RenderX

be simplified. Traditionally, PGHD collection has relied on patient portals or dedicated apps, with notifications delivered via portal messages, emails, text messages, or in-clinic tablets [19,20]. Log-in requirements or app installations were identified in 16 of the 17 comparable programs reviewed by Austin et al [13], likely contributing to limited adoption. Prior studies reported low completion rates (6% - 10%) for email- or text-delivered portal surveys and moderate completion rates (up to 52%) for in-clinic tablet deployments, although these required human assistance (Table 7) [21-23]. While Yedulla et al [21] achieved higher completion rates (email: 52%, portal: 49%, control: 30%), their cohort was relatively young (mean age: 56 years) and restricted to participants with dual digital credentials, potentially excluding older adults and individuals with limited digital literacy. Consequently, selecting simple and widely accessible methods for patient invitation and authentication is essential to minimize biases related to age and digital barriers and promote broader patient engagement.

[a]PGHD: patient-generated health data.

[b]EMR: electronic medical record.

[c]Not applicable.

[d]SNS: social networking service.

[e]MMS: multimedia messaging service.

[f]USA: United States.

Another major challenge in PGHD use is seamless EMR integration. Accessing separate PGHD platforms and manually organizing and inputting data increase the workload of clinicians [19]. Austin et al [13] reported that manual transcription of PGHD was necessary in 35% of the programs reviewed. Reading et al [27] further highlighted the substantial need for the electronic integration of PGHD into existing clinical systems. Even in US clinics where EMR systems automatically upload PGHD, patient log-ins via embedded portals remain necessary [24,25]. Similarly, a recent Korean prototype collected PGHD in a standalone system without EMR integration (Table 7) [26]. Thus, achieving both simplified patient access and seamless EMR integration remains challenging. The Miri-Alimi system addresses these issues through direct EMR integration, thereby significantly reducing the clinician burden.

Strengths and Limitations

Miri-Alimi distinguishes itself by addressing the major challenges in PGHD collection through a collaborative, multidisciplinary approach. First, it facilitates high patient participation by eliminating complex portal access procedures and distributing survey links via widely used messaging platforms (KakaoTalk and MMS). Leveraging this approach, Miri-Alimi achieved an overall response rate of 38%, substantially outperforming email-based portals.

Second, iterative pilot testing enabled the development of comprehensive yet user-friendly questionnaires tailored specifically for patients with cardiovascular diseases. These questionnaires were rigorously evaluated by a multidisciplinary team to ensure that the patients could complete them independently. Consequently, over 80% of respondents reported satisfaction with the questionnaire delivery method, question quantity, and ease of understanding. Incorporating standardized symptom scales (NYHA and CCS) enabled patients to effectively quantify symptom severity. Responders had significantly improved documentation of symptoms such as dyspnea, edema, and medication adherence in the EMR compared with nonresponders, demonstrating Miri-Alimi's ability to accurately capture clinically relevant data, thus reducing information loss and discrepancies between patient and clinician perceptions.

Third, Miri-Alimi significantly reduced the workload of the medical staff by eliminating the barriers associated with accessing separate PGHD platforms and manually entering data into EMRs. It streamlined the clinical workflow by enabling patients to document their medical histories prior to visits, enhancing clinicians' understanding, and improving patient-clinician communication.

Another strength of this study is the potential generalizability of the proposed PGHD-EHR integration framework. Survey responses were linked to the hospital EHR through a patient identifier–based matching process, without requiring modification of the core clinical system. Many hospitals already operate automated MMS- or SNS-based outpatient notification systems. Use of these existing communication channels, together with a PGHD platform that supports identifier-based linkage and standardized data export, allows the proposed workflow to be implemented across heterogeneous EHR environments with minimal structural change.

Nonetheless, this study has several limitations. First, it was conducted at a single tertiary hospital in South Korea using

XSL•FO
RenderX

Korean-language questionnaires and communication tools tailored to the local health care context. Accordingly, the generalizability of the findings to other countries or health care systems may be limited.

Second, the primary outcome of documentation completeness was evaluated only in follow-up patients with heart failure, a clinically homogeneous subgroup in which disease-specific documentation elements could be prespecified and assessed consistently. This design substantially narrows the scope of the study's conclusions, as the core metric of success was validated only within this specific subgroup rather than across the broader cardiovascular outpatient population, including patients with newly diagnosed cardiovascular disease. Moreover, the very large ORs and wide CIs indicate substantial imbalance in score distributions between groups. These estimates therefore support the direction of the association but not its precise magnitude.

Third, the system specifically targeted smartphone users, thereby excluding individuals with physical or cognitive impairments that limited completion of mobile questionnaires, as well as those lacking smartphones or internet access. Although the platform was intentionally designed to minimize digital barriers by allowing access through simple invitation links without log-in or app installation, important disparities in participation persisted. Responders were significantly younger than nonresponders, and response rates were notably lower among patients aged 70 years and older. These findings suggest that even simplified mobile-based PGHD systems may underrepresent elderly patients and exacerbate disparities in care. This concern is particularly important in heart failure clinics, where older adults constitute a large proportion of the patient population and frequently carry the highest disease burden. Accordingly, mobile PGHD platforms may serve as useful adjunctive tools in clinical practice; however, careful attention to patients who may be marginalized in the clinical setting should continue to be maintained during in-person care. Moreover, this study is subject to residual confounding due to unmeasured variables relevant to digital health interventions. Factors such as socioeconomic status, digital literacy, educational attainment, and baseline health status were not captured in the analysis and may have independently influenced both the likelihood of questionnaire completion and the extent and quality of mobile documentation.

Fourth, the absence of prior sample size calculation is an important limitation of this study. The sample comprised all eligible consecutive patients willing to participate during the study period, and the final sample size was therefore determined pragmatically rather than statistically.

Fifth, the use of birthdate-only verification constitutes a significant security vulnerability. Because access to the PGHD portal required only the patient-specific invitation link and the patient's birthdate, any individual who obtained both could theoretically submit inaccurate or false patient-reported information into the EMR. Although clinicians reviewed the structured PGHD responses during the outpatient encounter and could revise the medical record after consultation when necessary to better reflect the patient's actual condition, this review process does not mitigate the fundamental vulnerability of the authentication design. Accordingly, future implementations will require stronger security measures that reduce the risk of unauthorized access or inaccurate data entry.

Sixth, the automatic mapping of patient-reported symptoms to NYHA functional class without initial clinician adjudication may introduce misclassification and potential anchoring bias relative to clinician-determined functional assessment. Although survey response options were developed through iterative discussions among cardiologists and medical information specialists to translate NYHA functional classes into patient-friendly language, discrepancies between survey-derived and clinically adjudicated NYHA classification may still occur.

Seventh, another methodological limitation concerns the primary outcome of EMR completeness. The completeness score compared 2 inherently different documentation processes: automatically structured EMR fields among responders versus routine clinician documentation among nonresponders. Because the intervention directly transferred prespecified questionnaire items into the EMR, the completeness metric likely favored structured documentation. Therefore, the higher EMR completeness observed among responders should be interpreted primarily as improved structured capture and transfer of patient-reported information, rather than as proof that the intervention improved the overall quality of clinical care.

Eighth, a limitation pertains to the dichotomization of the ordinal EMR completeness score in the regression analysis. To evaluate the association between survey response and EMR completeness, Firth penalized logistic regression was used to address quasi-complete separation. In this context, the original ordinal EMR completeness score of 0 to 3 was dichotomized into ≥2 versus 0 to 1. Although this approach facilitated model convergence, it may have led to loss of information and reduced statistical efficiency, thereby limiting the ability to detect graded differences across levels of documentation completeness.

Ninth, an additional limitation relates to the objective assessment of workflow efficiency. Although consultation time data were collected for a subset of visits, these data were incompletely captured and were susceptible to operational error. Consultation duration was defined as the interval between the physician's initial and final EMR entries, a measure inherently dependent on clinician behavior and therefore prone to substantial missingness. Missing time stamp data were differentially distributed between responders and nonresponders and were influenced by workflow-related factors, suggesting a missing-not-at-random mechanism. Consequently, the observed differences in median consultation time between groups may not reflect clinically meaningful differences in real-world practice, and this study does not establish whether the use of Miri-Alimi altered overall consultation duration. Furthermore, because only total consultation time was available, the study could not evaluate how time was distributed within the clinical encounter. Accordingly, any interpretation that time saved from routine history taking was reallocated to other components of the visit, such as addressing patient concerns or performing physical examination, remains hypothetical and was not directly assessed. Therefore, all analyses of consultation time should be considered exploratory and hypothesis generating.

XSL•FO
RenderX

Tenth, the operational value of PGHD-supported care should not be defined solely by whether the overall visit becomes shorter. Even if previsit PGHD reduces time spent on routine history taking, the time saved may instead be redirected toward clarification of patient concerns and more focused clinician-patient communication. In this context, longer consultation time among responders may reflect redistribution of clinical attention rather than inefficiency. Future studies should therefore incorporate prospectively defined and automatically captured workflow metrics, including time spent on routine history taking, total encounter duration, and postvisit charting burden, to better quantify the operational impact of PGHD-enabled care.

Eleventh, the number of participating clinicians was small, which limited the statistical power for analyses of provider satisfaction. Larger, multicenter studies involving more diverse clinical staff will be required to validate these findings.

Furthermore, although the Miri-Alimi questionnaires were developed through expert consensus and iterative multidisciplinary pilot testing, the instruments did not undergo formal psychometric validation. Specifically, internal consistency, content and construct validity, criterion validity, and test-retest reliability were not formally evaluated. Accordingly, this study should be interpreted primarily as a feasibility and implementation study of a PGHD-integrated questionnaire system rather than as a formal validation study of a patient-reported outcome instrument.

Additionally, medication adherence was assessed using a single, nonvalidated binary item. Given that medication adherence is a multidimensional construct encompassing both intentional and unintentional nonadherence, use of validated or prescription-based measures (eg, guideline adherence indices) would have enabled more detailed characterization of adherence patterns, including reasons for missed or discontinued medications.

Moreover, the patient-reported external medication feature did not fully realize its intended clinical utility for medication reconciliation. Among patients who reported taking medications prescribed outside the heart failure clinic, 81% provided additional details through the free-text field. However, these entries often relied on nonspecific terminology rather than precise drug or ingredient names. Consequently, although the responses were useful for identifying the presence of externally prescribed medications and for capturing clinically relevant categories that could affect decision-making, such as newly added medications and the use of anticoagulants, antiplatelet agents, and diuretics, they were insufficient for accurate medication-level reconciliation. This feature should therefore be regarded as providing partial contextual support rather than comprehensive reconciliation. To overcome this limitation, system enhancements incorporating linkage with national health insurance claims–based drug utilization review (DUR) data are currently under development and may allow more accurate integration of externally prescribed medication information into the EMR.

Furthermore, the limited number of patients (n=76) and clinical staff participating in the postvisit surveys may constrain the representativeness of the study population and introduce potential selection bias. The small number of participating clinicians also limited the statistical power of analyses related to provider satisfaction. These results should be interpreted as descriptive perceptions from a highly selected subgroup rather than as definitive evidence of overall system acceptability. These limitations reflect the study design, which evaluated a single outpatient encounter at a single cardiovascular center and therefore did not permit assessment of longitudinal participation or sustained use of the Miri-Alimi system. As the project is extended over time and expanded to include multiple centers, increased patient enrollment and broader staff participation may mitigate these limitations and enhance external validity.

Finally, another important limitation is that the study did not evaluate actual changes in patient management or clinical outcomes. Although key parameters relevant to patient status were successfully captured through the PGHD platform and incorporated into the EMR, the downstream impact on clinical care was not examined. We did not assess whether these data prompted timely medication adjustments, escalation of care, or other management decisions. In addition, clinical end points such as hospital readmission, emergency department use, and survival were not evaluated. Therefore, this study demonstrates the successful documentation and EMR integration of selected PGHD but does not establish whether such integration translates into improved clinical outcomes. Future studies are warranted to determine whether EMR integration of these PGHD leads to more timely therapeutic adjustment, fewer hospital readmissions, or lower cardiovascular mortality across diverse care settings.

Conclusion

Miri-Alimi, a mobile-based platform designed to collect PGHD and integrate the data directly into the EMR, demonstrated feasibility and acceptability in routine cardiology outpatient practice. By leveraging widely used messaging services and eliminating barriers such as log-in or app installation, the system achieved patient participation of 38.5% (289/751). In follow-up patients with heart failure, documentation of key clinical parameters—dyspnea, peripheral edema, and medication adherence—was significantly more complete among responders (median score 3, IQR 3 - 3) than among nonresponders (median score 0, IQR 0 - 1; P<.001). Among patients who completed both the previsit questionnaire and the postvisit satisfaction survey, 82.9% (63/76) to 92.1% (70/76) agreed that the system was appropriate, user-friendly, and beneficial to their care experience. In addition, both participating cardiologists and 7 of 8 participating nurses endorsed continued use of the system, noting perceived improvements in workflow efficiency.

Acknowledgments

Miri-Alimi was developed by a multidisciplinary team under the project titled "Establishment of a Pre-Visit Survey System for Heart Failure Patients at Korea University Guro Hospital" in collaboration with Lemon HealthCare and LC Tech. The authors wish to express their sincere gratitude to the in-hospital medical record specialists, who identified the eligible patient cohort and maintained the registry of consenting participants; the Digital Engineering Team, which implemented the architecture for importing patient-generated health data into the electronic medical record; Lemon Healthcare, which developed the survey interface and dispatched invitations through the Miri-Alimi platform; and LC Tech, which operated the interface and transmitted patient-generated health data to the hospital information system. We acknowledge the use of artificial intelligence (ChatGPT-o3 and ChatGPT-4.5 from OpenAI, 2025) for English language editing and for generating images that illustrate the multidisciplinary development of Miri-Alimi (Figure 1) and its workflow (Figure 2).

Figures 1 and 2 were created using the DALL·E image generation tool (OpenAI) based on author-provided prompts. Figure 1 was generated on July 15, 2025, to depict the collaborative development process of the Miri-Alimi system, with a prompt requesting removal of the background while retaining the central smartphone labeled “Miri-Alimi” and 4 inward-pointing arrows from "Clinical staff," "Medical record specialists," "Digital engineering team," and "External technology companies," respectively. Figure 2 was generated on July 17, 2025, to illustrate the study workflow using a flat-style, transparent-background infographic showing five horizontally arranged steps with equal-length orange arrows: (1) invitation to the previsit survey sent via social networking service (SNS)/multimedia messaging service

(MMS) 3 days before the clinic visit, (2) smartphone survey completion, (3) automated electronic medical record (EMR) integration, (4) in-person consultation review, and (5) postvisit satisfaction assessment.

Funding

This project was funded by the Health X-Challenge Seoul program and jointly organized by Novartis Korea, Seoul Biohub (Korea Institute of Science and Technology), and the Seoul Metropolitan Government.

Data Availability

Deidentified previsit and postvisit survey datasets for first-visit patients and follow-up patients with heart failure are available in Multimedia Appendix 1 and Multimedia Appendix 2, respectively.

Authors' Contributions

EJK and SKL conceptualized and designed the study and jointly led the multidisciplinary team. Both authors implemented the Miri-Alimi system in their outpatient cardiology clinics. EJK served as the project director and coordinated communication among internal team members and external stakeholders. SKL conducted pilot tests involving patient invitation processes and was responsible for developing patient-friendly, cardiology-specific previsit survey sets. JSJ organized and analyzed preliminary data derived from patient and staff responses and conducted comprehensive literature reviews. EJC performed detailed data analysis. EJC was the primary author of the manuscript.

Conflicts of Interest

This study was supported by the Health X-Challenge Seoul program, a digital health care innovation initiative jointly organized by Novartis Korea, Seoul Biohub (under the Korea Institute of Science and Technology), and the Seoul Metropolitan Government to promote innovations in digital health care. Although Novartis Korea participated as a co-organizer of the program, this study did not involve or evaluate any pharmaceutical products, including heart failure therapies marketed by Novartis.

Abstract

Background: A 2019 French national online survey explored activity limitations and participation restrictions among children and youth with disabilities for which innovative solutions could help.

Objective: The primary aim of this study was to use text mining analysis to complement previous human-led qualitative research and to uncover actionable additional knowledge related to difficult life situations that innovative solutions could help address and to compare the perspectives of children and youth with disabilities, relatives, and professionals.

Methods: This study was part of *Innovation for Participation*, a cross-sectional online survey, including (1) closed questions about sociodemographic characteristics, (2) closed questions about life situations that induced difficulties, and (3) open questions to explore these situations in greater depth. This study used a text mining approach designed for French data to analyze answers to open-ended questions about difficulties and desired innovative solutions. The analysis process included (1) data cleansing; (2) computing and analyzing the word frequency in the answers and their cooccurrence; (3) clustering answers using K-means algorithms; (4) analyzing the cluster words to define a title for each one and identify answers that are consistent with cluster titles, thereafter defined as well-classified; and (5) evaluating internal consistency defined as the ratio of well-classified answers to the total number of answers.

Results: In total, 1055 responses were received, and 962 (91.2%) were included, representing 2018 open-ended answers to questions about difficult life situations for which innovative solutions could be useful. Frequency analysis highlighted the desire for action and autonomy by children and youth with disabilities and their relatives (“do” in first position, closely followed by “by themselves” in third position). “Disability” was frequently used by professionals (third position) but did not figure among the 20 most frequently used terms by other respondents. Cooccurrences with “do” revealed a deep interest in “doing sports.” Answers were gathered into 14 clusters, ranging in size from 9 to 681 answers; 5 underwent a second clustering step. Internal consistency ranged from 42% to 100%. Finally, 8 clusters were related to the difficulties linked to a desire for autonomy, and 4 highlighted difficulties related to actions within a group or community. Some clusters reinforced domains that emerged in the human-led analysis.

Conclusions: Analysis of 2018 open-ended answers using a text mining approach designed for French data revealed that solutions are required to facilitate autonomy and the ability to “do it by myself (or themselves),” as well as integration into group and community life. Complementary to previous human-led analysis, the results reinforced the need for solutions to facilitate mobility, transport, and sports. They additionally highlighted differences in vocabulary used between the 3 respondent groups, suggesting that professionals may need to consider the language they use when communicating with individuals and relatives.

Introduction

Children and youth with disabilities may encounter activity limitations and participation restrictions [1-3]. These limitations affect children and youth across a broad spectrum of conditions, including physical and motor disabilities, neurodevelopmental conditions (eg, autism spectrum disorder, attention deficit hyperactivity disorder), mental and cognitive disabilities, and sensory impairments. Some difficulties may be overcome using assistive devices and technology [2,4], as defined by the International Classification of Functioning, Disability and Health [5] as any product, instrument, equipment, or technology adapted or specially designed for improving the functioning of a person with a disability. Technological advances have created new opportunities for children and youth with disabilities. Recent literature evidence confirms the potential for assistive technologies whatever the participation domain (eg, school [6,7], leisure, and play [8]) and the origin or type of disabilities (mental or cognitive [9], sensory [6], physical and motor [10], and multiple disabilities [11]) and, more generally, the need for further research and development in these domains. Major challenges remain in the use of technology, including improving access [2,12] and improving design to facilitate adoption [13]. New innovative solutions are still needed when there is no existing satisfying solution [13,14]. As challenges vary considerably in nature and severity across the disability spectrum and therefore developing inclusive technologies that meet the needs of as many varied conditions as possible, a comprehensive understanding of technology needs for new solutions requires engaging all disability types rather than focusing on a single condition.

The user's opinion is essential in the development of assistive technologies to ensure their relevance [15]. Engaging users (ie, children and youth with disabilities, relatives, and all the professionals involved with children and youth with disabilities in the health care system, at school, and in free-time activities) helps to build a comprehensive picture of their needs [16,17]. Therefore, we developed the "Innovation for Participation" survey to identify activity limitations and participation restrictions for which assistive products and technologies may be useful [18]. The survey was addressed to children and youth with disabilities, relatives, and professionals involved with children and youth with disabilities. Collecting open-ended (and unstructured) opinions may enrich closed-ended answers to questionnaires by allowing participants to freely share their vision; this approach can enable a better and deeper understanding of individuals' needs [19,20]. Therefore, open-ended questions asked survey participants to describe the difficult life situations mentioned in the closed-ended questions and the desired solutions. In a prior study [18], we analyzed the answers using adapted human-led qualitative methods [21,22]. The results showed that difficulties were frequently highlighted in the closed questions and described in detail in the open questions related to participation in recreational activities, leaving the house and using transport, participating in a group, and getting ready for the day. Transversal explanations for difficulties were provided spontaneously (eg, lack of accessibility and mobility). Solutions proposed included personal assistive devices to facilitate home life, high-tech devices, devices to compensate for impaired body functions, and adapting the familiar environment and daily activities. Few public solutions were proposed. The necessity of human assistance in daily life was emphasized [18].

A recent systematic review showed that methods for analyzing large qualitative datasets still rely on traditional qualitative analyses, such as thematic and content analysis [23]. However, pioneering studies have shown that combining these analyses with text mining can enrich qualitative text analyses [24]. A combined approach may reveal findings not identified by qualitative or text mining analysis alone, thus providing multiple lenses to deepen understanding of text data [25-31].

Techniques such as word frequency analysis can identify the priorities of different groups [32-35] and help to make their voices heard [36]. Classification sorts text data into predefined categories, whereas clustering may facilitate concept emergence by grouping similar answers rather than isolated terms [37,38]. Thus, actionable knowledge may be uncovered without a priori assumptions. For example, a clustering analysis of tweets expressing opinions on vaccination was used to draft a proposal for health policy improvements to enhance vaccination promotion [25]. Similar analyses were applied to prioritize and adapt rare disease associations' priorities based on user feedback by comparing the relative frequency of words in associations' priority reference documents with posts on patient Facebook groups [32]. Cooccurrence analysis was used to facilitate communication between patients and health professionals about musculoskeletal disorders, highlighting differences in the concepts used by these groups [36]. Topic modeling of YouTube video posts provided insights into the use of virtual reality tools to raise awareness of Alzheimer disease and related dementia in the general population [38].

Our overall aim was to highlight the insights and experiences of children and youth with disabilities, relatives, and professionals involved with children and youth with disabilities, regarding the real-world challenges they encounter for which a technical solution could be useful. Our objective was to complement a previous human-led qualitative research and to uncover actionable additional knowledge related to difficult life situations for which innovative solutions could be useful [18,25]. Our goals were as follows:

1. To discover actionable knowledge related to difficult life situations for which innovative solutions could be useful,

XSL•FO
RenderX

as a complement to findings from the human-led qualitative analysis conducted on the data from this survey
2. To compare the perspectives of children and youth with disabilities, relatives, and professionals involved with children and youth with disabilities. To this end, we analyzed the text data from the "Innovation for Participation" survey [18] using French-language text mining techniques.

Our work was driven by 2 leading hypotheses. The first was that user needs exploration using text mining would enrich our understanding of survey answers by uncovering actionable knowledge, complementing human-led qualitative analysis [18]. The second posited that text mining would effectively reveal user needs while considering the diverse perspectives of people with disabilities, relatives, and professionals. The main challenge of this work was that it was based on a French-language survey for which no language-adapted analytical framework was available.

Methods

Ethical Considerations

The study was conducted in compliance with current French regulation (Loi Jardé 2012 - 300) [39-41]. It was not within the scope of research involving human subjects; therefore, French law does not require ethical approval for such research protocols [42,43].

Innovation for Participation Survey

This cross-sectional study was part of "Innovation for Participation," a national survey aimed at identifying the most frequent activity limitations and participation restrictions for which assistive products and technologies may be useful. It was promoted through the European Academy of Childhood Disability, especially during the 2019 conference, whose leading theme was "Innovation for Participation," and through the French-Speaking Society for Studies and Research on Disabilities (in French: Société Francophone d'Etudes et de Recherche sur les Handicaps [SFERHE]). It adopted a convergent parallel mixed methods design. An online open survey was developed following the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) [44] guidelines and disseminated to associations, personal, and professional networks in France between March and December 2019 using convenience and snowball sampling methods [18]. The study is reported according to the STROBE (Strengthening the Reporting of Observational studies in Epidemiology) guidelines [45].

Study Population and Selection Criteria

Overview

Three versions were developed to gather the opinions of the included populations, with the aim of providing the broadest possible picture of the lives of children and youth with disabilities:

- Children and youth with disabilities: young individuals with childhood-onset disabilities capable of self-reporting, spanning ages up to 30 years, regardless of the underlying etiology or severity of their impairment (including cognitive, mental, physical, sensory, or multiple disabilities)
- Relatives: family members, legal guardians, or close friends of a child or youth with disabilities
- Professionals: health care, educational, rehabilitation, and leisure or sports professionals actively involved in the care, education, or support of this population.

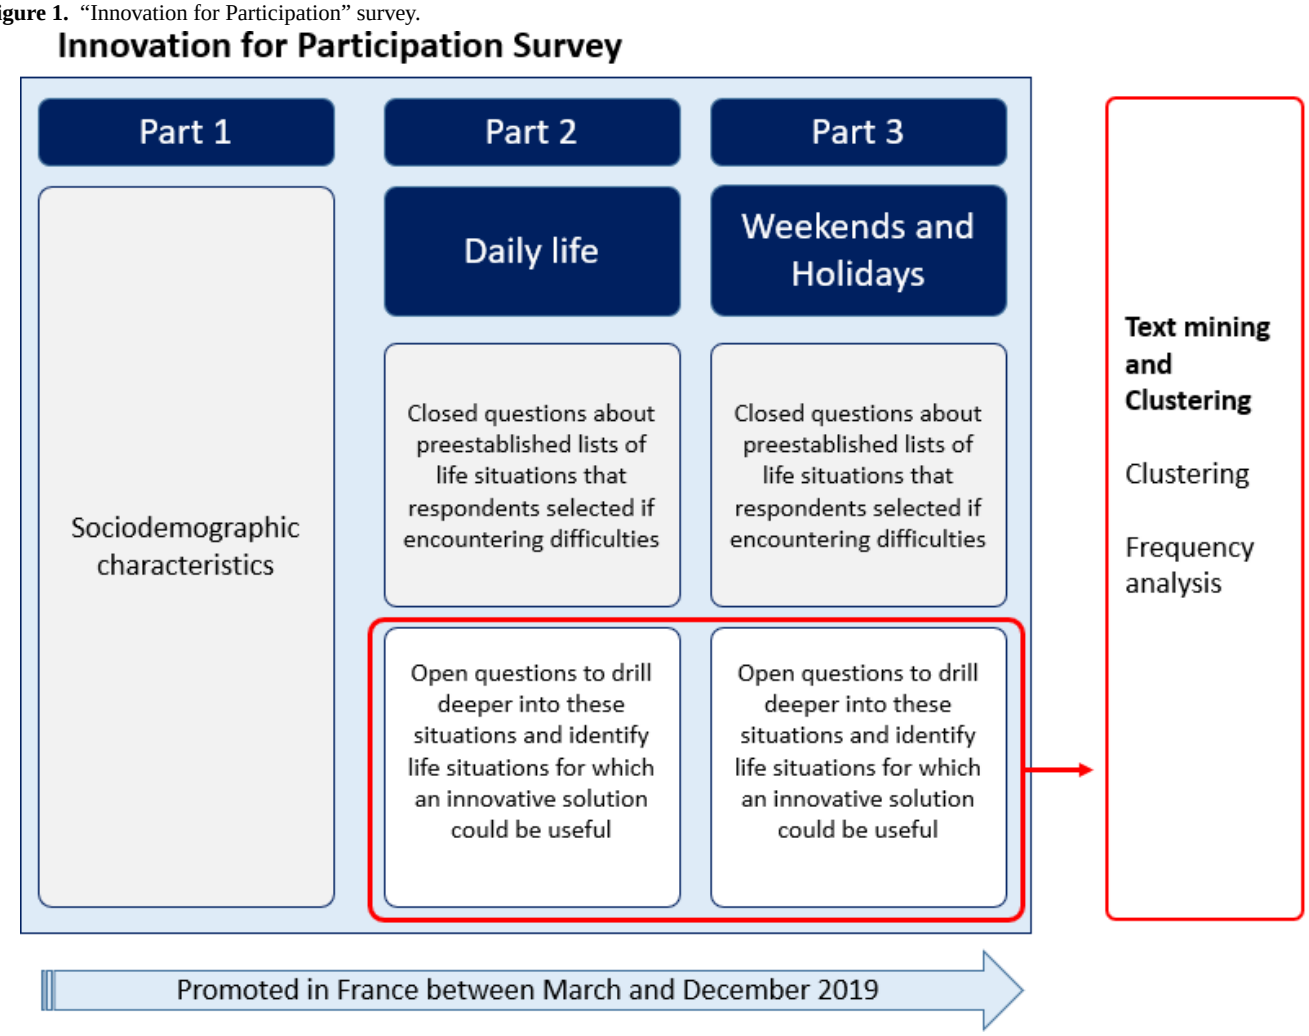
Inclusion Criteria

To be included in the text mining analysis, respondents were required to (1) reside in France at the time of data collection, (2) provide a nonvoid response, and (3) be 30 years of age or younger for the child or youth with disabilities cohort to minimize retrospective memory bias.

Exclusion Criteria

Responses were systematically excluded if they were geographical outliers living outside of France, exact technical duplicate entries, completely void responses, or adults with childhood-onset disabilities who were older than 30 years.

These 3 versions can be found online [46-48].



Survey Description

The survey included closed and open questions to obtain complementary data on the topic. The closed questions aimed to identify the most frequent life situations for children and youth with disabilities for which a product or technology could be useful for daily life, weekends, or holidays, and the open questions explored these situations in greater depth by asking respondents to describe their personal experiences, to characterize those situations, and to identify desired solutions (Figure 1). The answers to the 4 open-ended questions were analyzed in the study presented here.

The study design, including complementary details about materials and methods, has been described and published elsewhere [18].

XSL•FO
RenderX

Figure 1. "Innovation for Participation" survey.

Text Mining Process

To identify priorities for innovation needs and to compare the perspectives of children and youth with disabilities, relatives, and professionals, we carried out a frequency analysis of the data collected. We then conducted a clustering analysis to uncover actionable knowledge from the unstructured data without relying on predefined categories. The study was conducted in 3 stages.

Stage 1: Preprocessing and Dataset Cleansing

The answers to the open questions were stored in Microsoft Excel files. As the open questions were not mandatory, void answers were removed.

To ensure accurate text mining analysis, the data underwent initial cleansing. This process involved several key steps: first, all uppercase and accented characters were replaced with lowercase and unaccented characters because omitting accents is a common error among French speakers in writing. Next, numbers and punctuation marks were eliminated. Sentences were tokenized into individual words, then lemmatized to group different inflections under a single root form, allowing for words such as "adapt" and "adapting" to be recognized as the same. More accurately, lemmatization, rather than stemming, was applied using morphological analysis to reduce each word to its dictionary base form rather than simply truncating endings; this approach better preserves semantic accuracy in French, a morphologically rich language. Finally, common stop words (ie, words that occur so frequently that they offer little value for indexing or research purposes) were removed. Although there is no universal list of stop words, existing French-language lists were used and refined with guidance from domain experts.

Stage 2: Clustering

Clustering aims at grouping similar answers into a predetermined number of clusters. As the aim was to discover actionable knowledge, clustering was performed on the entire set of answers, including the 3 respondent groups. First, embedding was performed using the numeric TF-IDF (Term Frequency–Inverse Document Frequency) vectorizer. TF-IDF is a statistical measure that weights each word (a.k.a. unigram) in proportion to how often it appears in a given response relative to how common it is across all responses, thereby highlighting words that are distinctive and informative for that response rather than merely frequent everywhere. To quantify this relationship, the TF-IDF weight of a term t within a specific document d is calculated using the following formula:

$$W_{t,d} = tf_{t,d} \times \log \frac{N}{df_t}$$

where $W_{t,d}$ is the total weight assigned to the word; $tf_{t,d}$ represents the term frequency (TF) or how many times the word appears in this specific document; N is the total number of

XSL•FO
RenderX

documents in the entire collection analyzed (in this research, the answers to the survey); dft being the document frequency or how many different documents contain the specific word *W*; log (N/dft) represents the inverse document frequency (IDF) and is the "scaling factor" that shrinks the value of common words.

TF-IDF is an embedder that converts each sentence into a vector of numbers, accounting for the occurrence of each term in each answer. As the TF-IDF representation operates at the level of individual words, it captures word-level patterns but does not directly model multiword expressions or sentence-level syntax; this is a known limitation of the approach, discussed further in the *Limitations* section. Semantic algorithms perform relatively well in English, but few are usable in French. Therefore, a numeric embedder was preferred to ensure robustness. Moreover, numeric algorithms group answers by similarities in sentence structures and/or frequent words and word associations, rather than primarily by meaning [37], as is done in qualitative analysis. Therefore, they may help to uncover actionable knowledge. The k-means algorithm was then used to group sentences into k clusters by minimizing intracluster Euclidean distance while maximizing intercluster separation, thereby enabling each word to be interpreted in the context it shares with other words [25,49]. The number of clusters (N) was determined using the Ray-Turi method and index [50]. This method identifies the optimal number of clusters k by minimizing within-cluster compactness while maximizing intercluster separation. When the first minimization was reached, the output consisted of N clusters of vectors and the representative words for each cluster. At this stage, k-means was run with k varying from 2 to 30. For clusters with more than 100 terms, a second clustering step was performed, forming cluster subgroups.

A group of 3 experts (a physician, a health data scientist or medical informaticist, and a biomedical engineer) independently analyzed representative terms and defined a title for each cluster, then met to reach consensus. The obtained clustering was then independently analyzed by 2 researchers (JMG and MB), who annotated each answer for each cluster according to its correspondence (1) or not (0) to the cluster title. When a discrepancy arose between the first 2 researchers, a third researcher (AB) provided his annotation. The internal consistency, defined as the ratio of well-classified answers to the total number of answers, was then calculated. When a second clustering step was performed, the internal consistency was calculated on the subgroups. To verify interoperator consistency, Cohen κ was calculated between the 2 researchers' annotations. For each cluster, if κ was lower than 0.80, the following process was conducted:

- Knowing that divergences in the calculated internal consistency may be partly due to difficulties in labeling, when the percentage of differently classified answers was above 30%, a new title was proposed, and each researcher performed a new independent classification. Internal consistency was recalculated, and κ was checked again to determine whether the process could proceed to the next step.
- If the title was consensual, discussions were engaged between the 2 researchers on the divergent annotations to reach a consensus (defined by κ values above 0.8) for each item.

Stage 3: Frequency Analysis

The obtained text data were 3 corpora of answers. Therefore, frequency analysis was conducted by respondent category using a TF-IDF function to avoid overemphasizing specific terms, as this function weights the frequency of each word based on its occurrence in a single answer relative to its occurrence in the corpus of answers.

An additional function was developed to study word cooccurrence by identifying words frequently associated with a given word in the corpus of answers.

Results

Survey Population Characteristics

We received 1005 answers. We excluded answers from respondents who did not live in France (n=32, 3.2%), duplicates (n=4, 0.4%), void answers (n=14, 1.4%), and those from adults with childhood-onset disabilities over 30 years of age (n=53, 5.3%; to avoid memory bias).

Of the 962 included answers, 92 (9.6%) were from children and youth with disabilities (mean age 17.1, SD 5.7 y), 493 (51.2%) were from relatives (mean age 46.6, SD 11.5 y; 378/493, 77.5% were the mother), and 377 (39.2%) were from professionals (mean age 41.3, SD 11.1 y). In total, 764 (79.4%) respondents were women, and 13 (92.9%) of 14 French regions were represented. Regarding the children and youth with disabilities, 81.5% (75/92) had a physical impairment, and 54.3% (50/92) had a nervous system disease; regarding the relatives, 81.5% (402/493) of the people with disabilities they were relatives of had a physical disability, 69.8% (344/493) had a mental disability, 66.3% (327/493) had a cognitive disability, and 36.7% (181/493) had a nervous system disease. Regarding the professionals, 30.8% (116/377) were rehabilitation professionals (not including physicians), 20.4% (77/377) were physicians, and 12.5% (47/377) were education professionals. A detailed description of the population had been previously published [18]. A total of 2018 open question answers about difficult life solutions for which a technical solution could be useful were analyzed automatically.

Cluster Analysis

We conducted a clustering analysis of the answers about difficult life situations for which an innovative solution could be useful.

Table 1 presents the themes of the 14 clusters, their sizes, and internal consistencies. The cluster size varied from 9 to 681 answers. Five clusters (clusters 1 to 5 in Table 1), whose sizes were above a hundred answers, underwent a second step of clustering. Internal consistency varied from 42% to 100%. After reaching consensus, all κ values were above 0.85.

Table . Clustering analysis.

Main cluster and subcluster	Cluster theme	Internal consistency, % (n/N)
1		
1.1	To be able to[a]	91 (298/328)
1.2	Possibility through adapting[a]	58 (103/178)
1.3	Activities specific to children	48 (57/116)
1.4	Difficult situation in a given/specified location	59 (19/32)
1.5	Warmth and sociability[b]	54 (7/13)
1.6	Organization and scheduling	78 (7/9)
1.7	Behavioral disorders and mental disability	60 (3/5)
2		
2.1	To be able to do in daily life[a]	72 (114/158)
2.2	Difficulties with independence, need for support[a]	68 (50/73)
2.3	Friendship and social relations[b]	51 (19/37)
2.4	Children and youth relationships[b]	53 (18/34)
3		
3.1	Sports and activities	84 (109/130)
3.2	Impediments	83 (52/63)
4		
4.1	To be able to do (within a group or with help)[a,b]	80 (66/83)
4.2	Being able to do things “by myself”[a]	87 (55/63)
5		
5.1	Daily life, help and adaptation[a]	91 (68/75)
5.2	Travel issues, including technical aids and means	73 (51/70)
6	Action in the community[b]	66 (47/71)
7	Cluster of “doing,” everyday action	63 (36/57)
8	Unhappiness	54 (25/46)
9	Learning and autonomy[a]	42 (18/43)
10	Needed or proposed solution	70 (21/30)
11	Technological tools	58 (7/12)
12	Fine motor skills and communication	64 (7/11)
13	Marginal answers	100 (32/32)

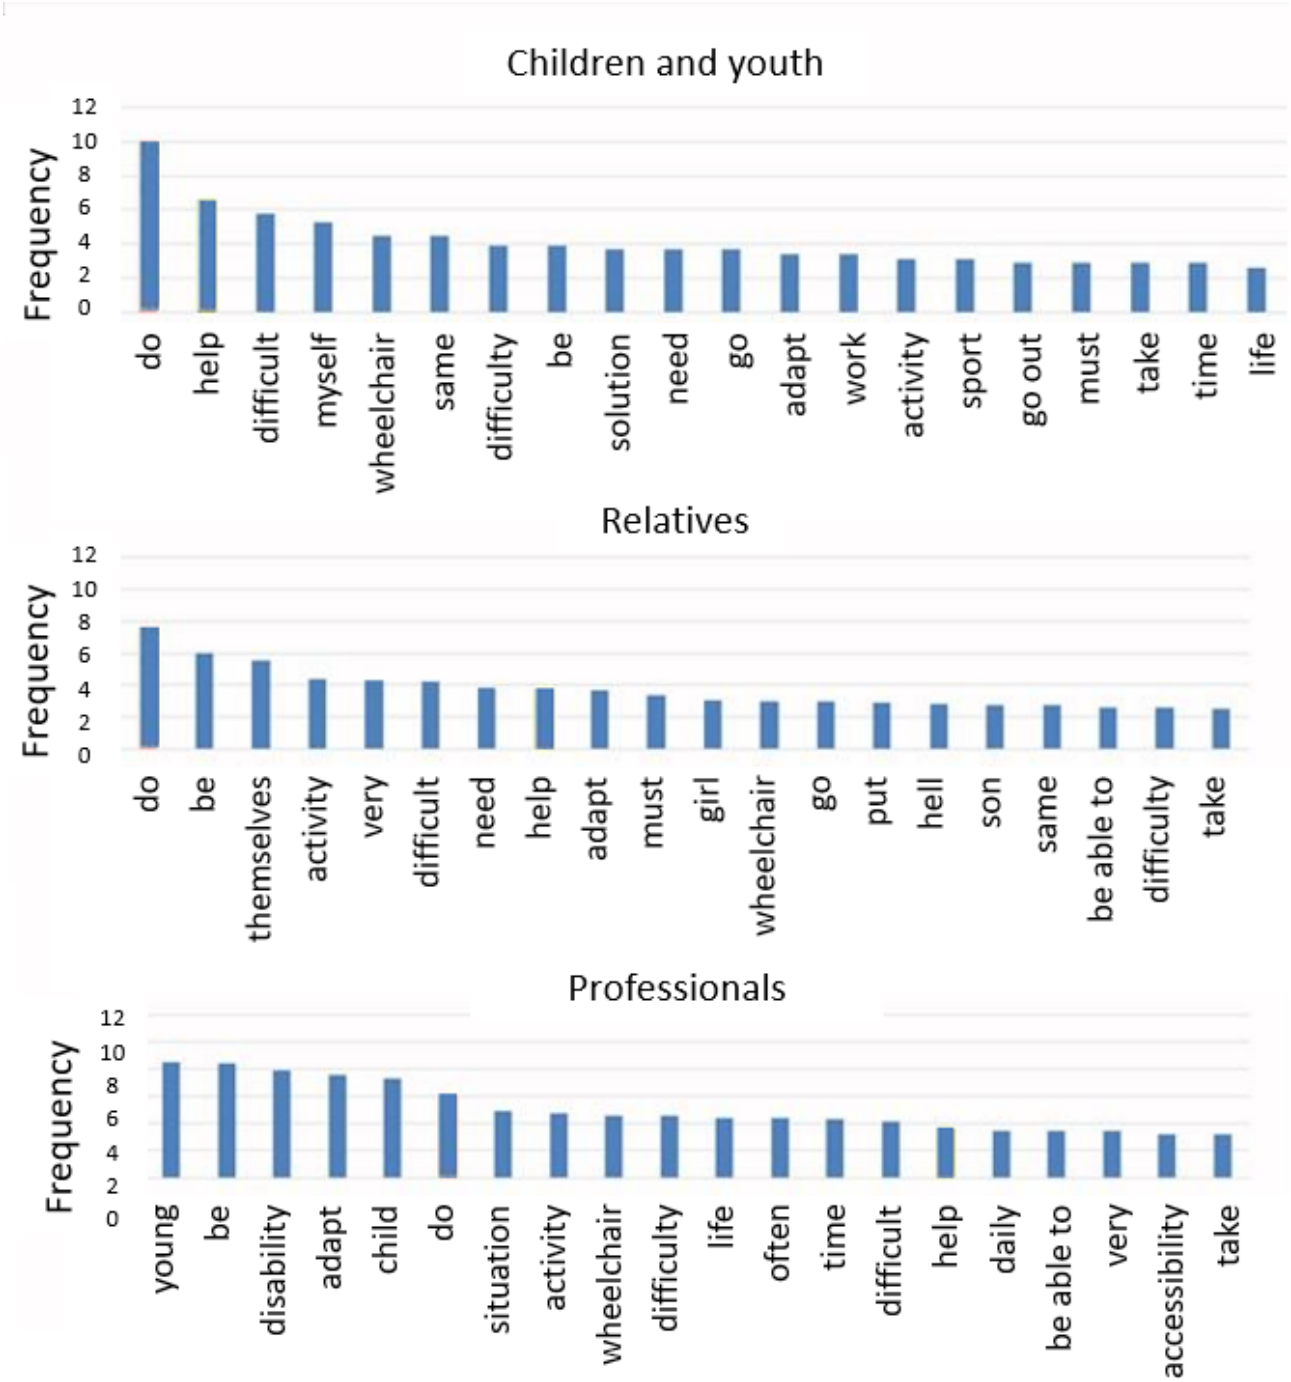
[a]Clusters related to autonomy and desire for independence.

[b]Clusters referring to action within a group or community.

Cluster titles were defined by the 3 experts involved in the annotation process based on the dominant themes each identified as relevant, informed by their professional backgrounds and individual interpretations of the participants’ answers, and then an additional consensus decision was made, looking at the clinical, informational, and engineering understanding of each title that can allow sharing the results with decision-makers and solution developers.

Eight clusters highlighted difficulties related to autonomy and desire for independence*:* “To be able to,” “Possibility through adapting,” “To be able to do in daily life,” “Difficulties with independence, need for support,” “To be able to do (within a group or with a help),” “Being able to do things by myself,” “Daily life, help and adaptations,” and “Learning and autonomy.”

Four clusters highlighted difficulties related to actions within a group/community*:* “Warmth and sociability,” “Friendship and social relations,” “Children and youth relationships,” and “Actions in the community.”



XSL•FO
RenderX

Some clusters reinforced areas that emerged in the qualitative analysis, such as “Travel issues, including technical aids and means,” “Technological tools,” and “Sports and activities.”

Frequency Analysis

Figure 2 shows the frequency analysis of words for the 3 respondent groups. The most frequent occurrences differed across the groups. The term “do” was largely used by children and youth with disabilities and relatives (first position for both), closely followed by “myself/themselves” (respectively in fourth and third positions), underlying the need for technical solutions to facilitate autonomy. Other frequently used words were “help” (second position) and “difficult” (third position) for children and youth and “be” (second position) and “activity” for relatives. “Disability” was frequently used by professionals (third position) but did not figure among the 20 most frequently used terms by children and youth with disabilities and relatives. “Be” (second position) and “adapt” (fourth position) were also frequently used by professionals, whereas “do” appeared only in the sixth position.

Figure 2. The first 20 most frequently quoted words by children and youth with disabilities, relatives, and professionals.

The most frequent cooccurrence for the term “do” was “sport.” The most frequent cooccurrence for the term “help” was “human.”

It should be noted that high-frequency general terms such as “do,” “help,” and “be” are context dependent and can carry varied meanings across responses; for instance (examples from the responses): “doing sports,“doing pauses,” and “manage to

XSL•FO
RenderX

do"; or "help my daughter to overcome her fear of water," "human help," and "adapted housing with human help"; "getting their school supplies out and doing homework without being helped by a parent," "be frustrated," and "be able to do."

Illustrative Quotes From Participant Responses

To illustrate how these terms were used in context, to clarify the conceptual distinctions between thematically similar clusters, and ground the analysis in the participants' own words, response examples are presented in Table 2.

XSL•FO
RenderX

Table . Examples of participants' answers to the survey according to the cluster they are related to.

Main cluster and subcluster	Theme	Examples[a]
1		
1.1	To be able to	• To have an assistive robot for daily living that can anticipate and meet my needs as soon as I require help, so that I no longer have to rely entirely on my mother.[b] • Difficult travel/mobility has significant consequences on social ties, access to leisure, education, and employment.[c] • During a city center trip with four children in wheelchairs, we encountered bus transit issues; we were only allowed to board with two children. We had checked with the company beforehand, but they never mentioned a two-wheelchair maximum limit. While the company offers special assistance transport for disabilities, the application process is overly complicated, requiring an MDPH certificate proving a disability rating of over 80%.[d]
1.2	Possibility through adapting	• Navigating outdoors or indoors (needing more effective navigation systems, particularly via GPS); computing/reading such as text-to-speech systems and Braille displays exist, but because current Braille displays only feature a single line, a multi-line display capable of rendering graphics (eg, on an A4-sized surface) would be incredibly useful.[b]
1.3	Activities specific to children	• "Inappropriate games in the school playground: skipping ropes, elastic bands, and balls. Nothing but "physical" games.[b]" • To design engaging games tailored for children with disabilities that able-bodied children would also want to play.[c] • Accessibility in schools and educational facilities is not always guaranteed, and access to adaptive sports still needs to be developed across many disciplines[d]
1.4	Difficult situation in a given/specified location	• When visiting certain public spaces or shops downtown, there are very few access ramps, leaving parts of the town completely inaccessible to people with disabilities.[b] • Confined spaces, such as hotel rooms, where there is excessive noise (music, loud machinery, or maintenance tools).[c] • An indoor play center similar to Jim and Jump, but larger, more accessible, better suited, and catering to ages 0 to 20, as there is a severe lack of leisure facilities for people with disabilities.[c]
1.5	Warmth and sociability	• To develop and foster social relationships for people with disabilities.[d]
1.6	Organization and scheduling	• Creating a schedule using pictograms/establishing a routine for announcing daily schedules.[d]

XSL•FO
RenderX

Main cluster and subcluster	Theme	Examples[a]
1.7	Behavioral disorders and mental disability	• Bringing in qualified external experts to explain behavioral disorders to care teams.[d]
2		
2.1	To be able to do in daily life	• I have to exert deliberate effort for every single everyday task. For you, picking up a bottle of water is simple; for me, I have to focus on whether it's empty or full and break the action down into smaller steps just to manage it, and this applies to everything. Eating, moving around, working... Because it's a constant struggle, I get fatigued very easily.[b] • You constantly have to find someone to open doors to the buildings where tenants live; nothing is automated or accessible.[d]
2.2	Difficulties with independence, need for support	• The hardest part for me is going shopping on my own, withdrawing cash... and dealing with accessibility issues around town.[b] • The terrain is too rugged to navigate unaided; operating the Joelette wheelchair requires at least two assistants.[d]
2.3	Friendship and social relations	• His friends' houses are rarely accessible.[c] • My son finds it hard to break out of his daily routine; the moment we do, it becomes incredibly difficult to bathe, feed, or put him to bed. Consequently, it's highly challenging (if not impossible) for us to go away for the weekend or spend an evening at a friend's house.[c]
2.4	Children and youth relationships	• Due to her hemiparesis, she is not yet able to get dressed on her own. Although she is eager to join a club despite her young age, she feels different from her peers and has chosen to step back.[c] • He asks to invite friends over, but when they arrive, he seems happy yet unable to actually play with them; he just shares his snack, and we end up having to supervise both children.[c]
3		

XSL•FO
RenderX

Main cluster and subcluster	Theme	Examples[a]
3.1	Sports and activities	• Adapting the PS4 controller. Not being able to use it means I can't play video games with my friends at the youth center.[b] • As an adaptive physical activity teacher, I reach out to as many organizations as possible to ensure sports are integrated into school programs. The challenges we still face involve facility accessibility and a lack of understanding among support staff. We constantly have to justify why regular physical activity is beneficial for these children; it is an uphill battle. Furthermore, financial support for adaptive sports equipment should be automatic, as the support network in this area is currently underdeveloped.[d] • Designing a finger prosthesis with a specific orientation that reduces instrument weight (for agenesis); creating arm protection sleeves and jacket fastenings to keep the upper limb from swinging unprompted (for fencing with brachial plexus palsy).[d]
3.2	Impediments and barriers	• It is difficult to find accessible holiday destinations.[b] • Difficulty navigating the city and ongoing accessibility issues.[d]
4		
4.1	To be able to do (within a group or with help)	Typing a text on a smartphone with one hand. Cutting a piece of meat. Playing team sports...[b] • I have previously organized a play session in a park for a 4-year-old alongside other children.[d] • Ultimately, it all comes down to how well parents can tolerate the judgment and stares of others! Going for a walk or doing activities with a child who is different can provoke uncomfortable reactions or outright judgment.[d]
4.2	Being able to do things "by myself"	• Having to wait a long time to use the restroom until a professional is available to help.[b] • He is completely dependent on others. He loves going out into nature, meeting people, and listening to music, but he cannot do any of it on his own.[c] • She cannot climb play structures with ropes and ladders by herself.[c]
5		

XSL•FO
RenderX

Main cluster and subcluster	Theme	Examples[a]
5.1	Daily life, help, and adaptation	• For every single aspect of daily life, you have to constantly encourage, guide, and supervise.[c] • There are no suitable adult changing facilities in public spaces.[c]
5.2	Travel issues, including technical aids and means	• Navigating uneven terrain in a standard wheelchair, or flying when a person cannot sit upright (a major obstacle for families with relatives abroad, especially nowadays when air travel is so common). We need an airline-approved, highly portable system (like a specialized harness or a mechanism to secure the seat shell of an adaptive stroller).[d]
6	Action in the community	• Creating/adapting board games.[c] • Yes, for dancing, she absolutely loves it. We engineered a custom harness that allows her to dance standing up rather than always being confined to her seat.[c]
7	Cluster of “doing,” everyday action	• Styling my hair into a ponytail; washing myself; raising my arm.[b] • Tying shoelaces; holding a knife and fork.[c] • Going grocery shopping.[c]
8	Unhappiness	• Severe frustration surrounding sexuality and intimacy[b] • Sleep disrupted by chronic back pain.[b]
9	Learning and autonomy	• Training programs for local stakeholders and community members.[d] • Educational and instructional support provided by trained staff.[d]
10	Needed or proposed solutions	• I haven’t found any viable, long-term solutions. Just a few basic tools, like visual aids.[b] • Correct equipment installation and assistive switches/contactors.[d]
11	Technological tools	• Robotic tools and artificial intelligence.[d] • Human dependence on IT tools and robotics.[d]
12	Fine motor skills and communication	• Implementing the Makaton vocabulary system.[c] • Hand-writing text.[b]

[a]Translations from French into English.

[b]A response from a child or youth with disabilities.

[c]A response from a relative.

[d]A response from a professional.

While several clusters share an autonomy theme, they differ in their perspectives. Cluster 2.1 includes broad, general daily life activities, whereas cluster 4.2 encompasses expressions of an explicit, first-person desire for independence, and self-empowerment. Cluster 7 comprises concrete and highly localized motor and routine acts of execution. Similarly, community clusters (1.5, 2.3, 2.4, and 6) vary in relational scope,

XSL•FO
RenderX

ranging from specific peer friendships to broader social integration.

Discussion

Principal Findings

Text mining has indicated the significant role of autonomy and the theme of "doing it by myself." This theme appears to be enriched through computational analysis compared to prior human-led qualitative analysis. This point suggests that both approaches can and are complementing one another. Thus, our study suggests that there is a need for innovative solutions that can facilitate autonomy and the ability to do things independently and facilitate integration into groups and community life.

The findings underscore the importance and the need of developing solutions addressing mobility, travel, and sports needs [18]. Additionally, the analysis also revealed differences in language across the 3 respondent groups. "Do" and "by myself" ranked among the 5 most frequent words for children and youth with disabilities and relatives. "Disability" was among the most frequent words used by professionals but was not among the 20 most frequent words used by the other respondent categories (eg, children and youth with disabilities and relatives).

Actionable Knowledge Uncovered by Text Mining Analysis

The need for solutions promoting autonomy and self-empowerment was highlighted by both the frequency and clustering analyses, echoing previous work in the literature on the role of autonomy in parental well-being [51] and the importance of evaluating the impact of assistive devices on autonomy [52]. Additionally, frequency analysis revealed that autonomy and self-empowerment were frequently mentioned by children and youth with disabilities and relatives but less frequently by professionals. In contrast, professionals more frequently mentioned the concept of adaptation ("adapt") than the concept of action ("do"). First, these text mining results highlighted a desire for autonomy, a theme less prominently amplified in the human-led qualitative analysis, which the text mining approach detected through a computational and less expectation-biased analytical lens [18]. Interestingly, a comparison of human-led and large language model (LLM)–assisted approaches to analyzing the narratives of people with cancer also found that text mining analysis highlighted the active role of patients, with ChatGPT-4o emphasizing patients' proactive use of digital platforms to gather medical information and manage appointments [29]. Human coders—who were here researchers and physicians—may have their own biases. Humans are inevitably influenced by personal perspectives and theoretical frameworks [29]. Therefore, our results reinforced the complementarity between human-led qualitative analysis and text mining to uncover the desire for autonomy and the ability to "do it by myself." Second, these results demonstrated the importance of taking into account the points of view of various stakeholders to build as complete a picture of needs as possible, as previously reported [16,17,52]. This type of approach may also help professionals adjust their proposals to children and youth with disabilities' and relatives' concerns [36].

Regarding patients' preferences for the way physicians communicate with them, it has been shown that they prefer their physicians to avoid medical jargon [53]. Interestingly, it appears that even a common language term such as "disability" was frequently used by the professionals but not by the children and youth with disabilities or the relatives. On the contrary, children and youth with disabilities and relatives emphasize action-oriented language such as "do." These results suggest that children and youth with disabilities and their relatives prioritize action. This should be taken into account by health professionals in the process of shared decision-making with their patients. Furthermore, based on these results, further studies could evaluate the preferences of children and youth with disabilities and relatives about words they want to be chosen or avoided by their professionals when evaluating a life situation, similar to a study that specifically evaluated person-first and identity-first language preferences for various chronic conditions [54].

The emergence of multiple clusters that share an action-oriented or autonomy-related theme allowed to approach the subject from different perspectives and therefore to deepen overall understanding of these topics. While cluster 2.1 ("To be able to do in daily life"), cluster 4.2 ("Being able to do things by myself"), and cluster 7 ("doing, everyday action") all center on autonomy, they shed light on the subject from a different angle. Cluster 2.1 included broad, general daily life tasks and situational activities across a wide spectrum of daily functions. Cluster 4.2 encompassed expressions of an explicit, first-person desire for independence and self-empowerment. Cluster 7 comprised concrete motor and routine acts of execution characterized by concrete everyday verbs and actions such as "to wash" or "shoelace." Recognizing these distinctions prevents the oversimplification of "autonomy" into a single homogeneous concept, highlighting instead that user needs span from physical task execution to overarching psychological independence. However, this did not rule out some overlap between clusters; some responses classified under a given theme might also have corresponded to another theme within the same group (autonomy related or action related).

The need for solutions to facilitate integration into community life was also revealed by the clustering analysis. Several clusters reinforced this point, offering insights that deepened understanding of this need. The parents of children with a disability often face difficulties in their social interactions [55]. Our results suggested technical solutions could alleviate some of those difficulties and facilitate broader integration into community life. This aligns with the findings of a scoping review showing that technical issues for robots that constitute promising opportunities for inclusive classrooms should be overcome for their effective use [7]. Our results suggest that similar needs and opportunities to those raised in the school context are relevant across a wider range of social contexts.

Reinforcement of Knowledge From Qualitative Analysis

Comparison of the results of the text mining analysis with those of the human-led qualitative analysis of answers to the open questions [18] confirmed and reinforced the need for innovative solutions to overcome difficulties in the following domains: mobility and accessibility (reinforced by the clustering analysis), sports (reinforced by the clustering analysis, frequency analysis, and analysis of cooccurrence), and high-technology devices (reinforced by the clustering analysis). The frequent association of the terms "help" and "human" echoed the previously highlighted need for solutions to support relatives. This cooccurrence reinforces an important conceptual point: assistive technologies are not intended to replace human assistance but to complement and facilitate it. The aspiration for autonomy expressed by participants coexists with an acknowledgment of the continuing value of human support, as a balance between "high-tech" and "high-touch" care that should guide both the design of assistive technologies and their integration into the daily lives of individuals with disabilities and their families.

Limitations

This study has several limitations. First, it was based on an online survey; therefore, internet access was required to respond. This may have induced a selection bias. However, an online survey allows a large range of people to respond. More than 1000 answers were obtained; however, some respondents did not complete the optional open questions. Therefore, analysis by respondents' categories was possible for the frequency analysis but not the clustering.

Internal consistency was insufficient for exhaustive classification of each answer, but enabled 40% to 100% of consistent answers to be grouped, allowing meaningful knowledge to emerge. Therefore, the clustering analysis effectively reinforced some findings highlighted by the human-led qualitative analysis and uncovered new findings, rather than exhaustively classifying answers. The difficulty of classifying items into strict emerging themes has recently been highlighted by Prescott et al [28] in a study comparing human-led and LLM-based analyses of English text messages. They evaluated theme overlap between both methods at approximately 70%. However, intercoder reliability between LLM and humans, operationalized as the number of agreements in coding divided by the sum of agreements and disagreements in coding, varied between ~40% to 50% and thus showed results comparable to ours.

Some specific issues may also make it difficult to achieve higher internal consistency. This may be first linked to the few existing developments in clustering the French language. Furthermore, some answers included explanations of multiple topics within a single response, resulting in overlap. This could be resolved by manually splitting answers that cover different topics before the analysis; however, that is a time-consuming process. Additionally, because TF-IDF operates at the individual word level (ie, unigrams), multiword expressions and frequent collocations (eg, "do sports," "go outside") are not captured as meaningful units; this may limit the model's ability to reflect the full semantic content of participants' responses. Incorporating bigram or trigram features in future analyses or using algorithms such as Word2Vec [56] or topic modeling [38] could address this limitation and may also improve the internal consistency of clusters with higher thematic overlap, such as cluster 9 "learning and autonomy." To improve data gathering in the future, the online survey materials could be adapted to include the option of describing issues across different fields; this was not available with the free tool we used. Furthermore, differences in internal consistency across researchers may be partly explained by subjectivity induced by background differences. However, the different backgrounds may help to reach a consensus and avoid bias.

Future Work

Clustering may be facilitated by automated indexing using existing ontologies [57-59]. The International Classification of Functioning, Disability, and Health (ICF) framework [5] could be considered for this purpose; however, the ICF is a conceptual and technical description of daily life and participation. As such, the use of ICF terminology may not correctly label the everyday language of nonprofessional respondents, whose opinions are crucial in this context. This issue is recurrent in health care data, which are often heterogeneous. Integrating various ontologies into models to combine data across different technical contexts, levels of language, and levels of data structuration [60] remains a challenge, even for English-language data. One group [60] annotated a corpus and created dictionaries to analyze Chinese posts on a questions and answers forum about rehabilitation issues using BERT-BiGRU-attention models. The posts included questions from patients and answers from physicians, and therefore, data with different levels of language and technicity, although the questions and answers were strongly contextually linked [60]. The analysis led to the creation of a relationship dictionary of diseases and their corresponding symptoms. Our results could also be used to enrich existing ontologies [61] to facilitate the integration of heterogeneous data on daily life and participation. This enrichment would support text data analysis across different levels of technicity and incorporate the perspectives of diverse stakeholders, such as health care professionals, education professionals, relatives, and children and youth with disabilities.

The next step to enhance clustering performance could involve integrating LLMs into the process [62,63]; however, these models may reproduce bias from their training data [30]. Therefore, care must be taken when applying LLMs to heterogeneous datasets—including answers from individuals with disabilities, relatives, and professionals—to ensure that the model is not biased toward a particular linguistic or technical level. More broadly, the use of LLMs in qualitative health research raises ethical questions regarding algorithmic bias and representational fairness. LLMs trained predominantly on majority-language, able-bodied corpora risk underrepresenting the voices of individuals with disabilities and may reproduce institutional framings of disability that diverge from the action-oriented language used by children and youth with disabilities and relatives in this study. Transparency in model selection, systematic evaluation of outputs for differential performance across participant groups, and human oversight at the interpretation stage are therefore essential safeguards for any future LLM-assisted analysis of this type of dataset.

From an application perspective, such an approach may help prioritize the development of assistive technologies for people with disabilities. However, the perceived limited market for assistive products and technologies results in high selling prices due to development costs. Development needs should be organized by user profile rather than by the same expressed need. Clustering development needs could support the identification of opportunities to extend an existing solution to a related need, regardless of its original domain, or to highlight needs that represent a sufficiently large market for new solution development. For this aim, such an analysis may be repeated at regular intervals, in France, as well as in other countries with different public health policies.

Conclusions

Analysis of 2018 open-ended answers using a text mining approach designed for French data on needs in terms of activity limitations and participation restrictions for which assistive products and technology may be useful for children and youth with disabilities revealed that solutions are required to facilitate autonomy and the ability to "do it myself (or themselves)" as well as integration into group and community life. The results reinforced the need for solutions to facilitate mobility, travel, and sports, as highlighted by the human-led qualitative analysis. Combining text mining analysis with human-led qualitative analysis may help prioritize solution development by identifying recurrent needs. The text mining analysis also highlighted differences in language use across the 3 respondent groups, demonstrating the importance of questioning all stakeholders to build a comprehensive picture, and suggesting that professionals should consider the terms they use with children and youth with disabilities and relatives.

Acknowledgments

We are grateful to all the people who contributed to the development and refinement of the survey and helped distribute it and to all participants who took the time to respond. We thank the SFERHE (French-Speaking Society for Studies and Research on Disabilities [in French: Société Francophone d'Etudes et de Recherche sur les Handicaps]), the General Management of the European Academy of Childhood Disability (EACD), and the EACD 2019 organizing and scientific committees for support in survey diffusion. We thank Johanna Robertson for contributing to the proofreading process. The authors declare they did not use generative artificial intelligence in the research. The authors declare that they used Grammarly as a generative artificial intelligence in the writing process for proofreading.

Funding

No financial support or grants were received from any public, commercial, or not-for-profit entities for the research, authorship, or publication of this article.

(JMIR Med Inform 2026;14:e99873) doi:10.2196/99873

In "Automated ICD-10–Anchored Classification of Primary Care Text Data: Development and Evaluation of a Custom Multilabel Classifier" [1], the authors made one correction.

Authors OS and VvW are senior authors, but attribution of their joint contribution was missing in the metadata and the Acknowledgments.

An asterisk has been added to both author names, and the following footnote has been added to the metadata:

> **these authors contributed equally*

Furthermore, the following sentence has been added to the Acknowledgments section to clarify the senior authorship:

> *OS and VvW share joint senior authorship of this work.*

The correction will appear in the online version of the paper on the JMIR Publications website, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Abstract

(JMIR Med Inform 2026;14:e92491) doi:10.2196/92491

In “Comprehensive Pediatric Health Risk Stratification Using an AI-Driven Framework in Children Aged 2 to 8 Years: Design and Validation Study” [1], the authors noted two errors.

The author list has been corrected from the following:

Zhihe Mao, PhD; Jundan Chen, PhD

The author list now reads:

Jundan Chen, PhD; Zhihe Mao, BA

Author ZM’s contact information has been corrected to the following:

Phone: 86 13789072016

Fax: 86 07367283047

The correction will appear in the online version of the paper on the JMIR Publications website, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

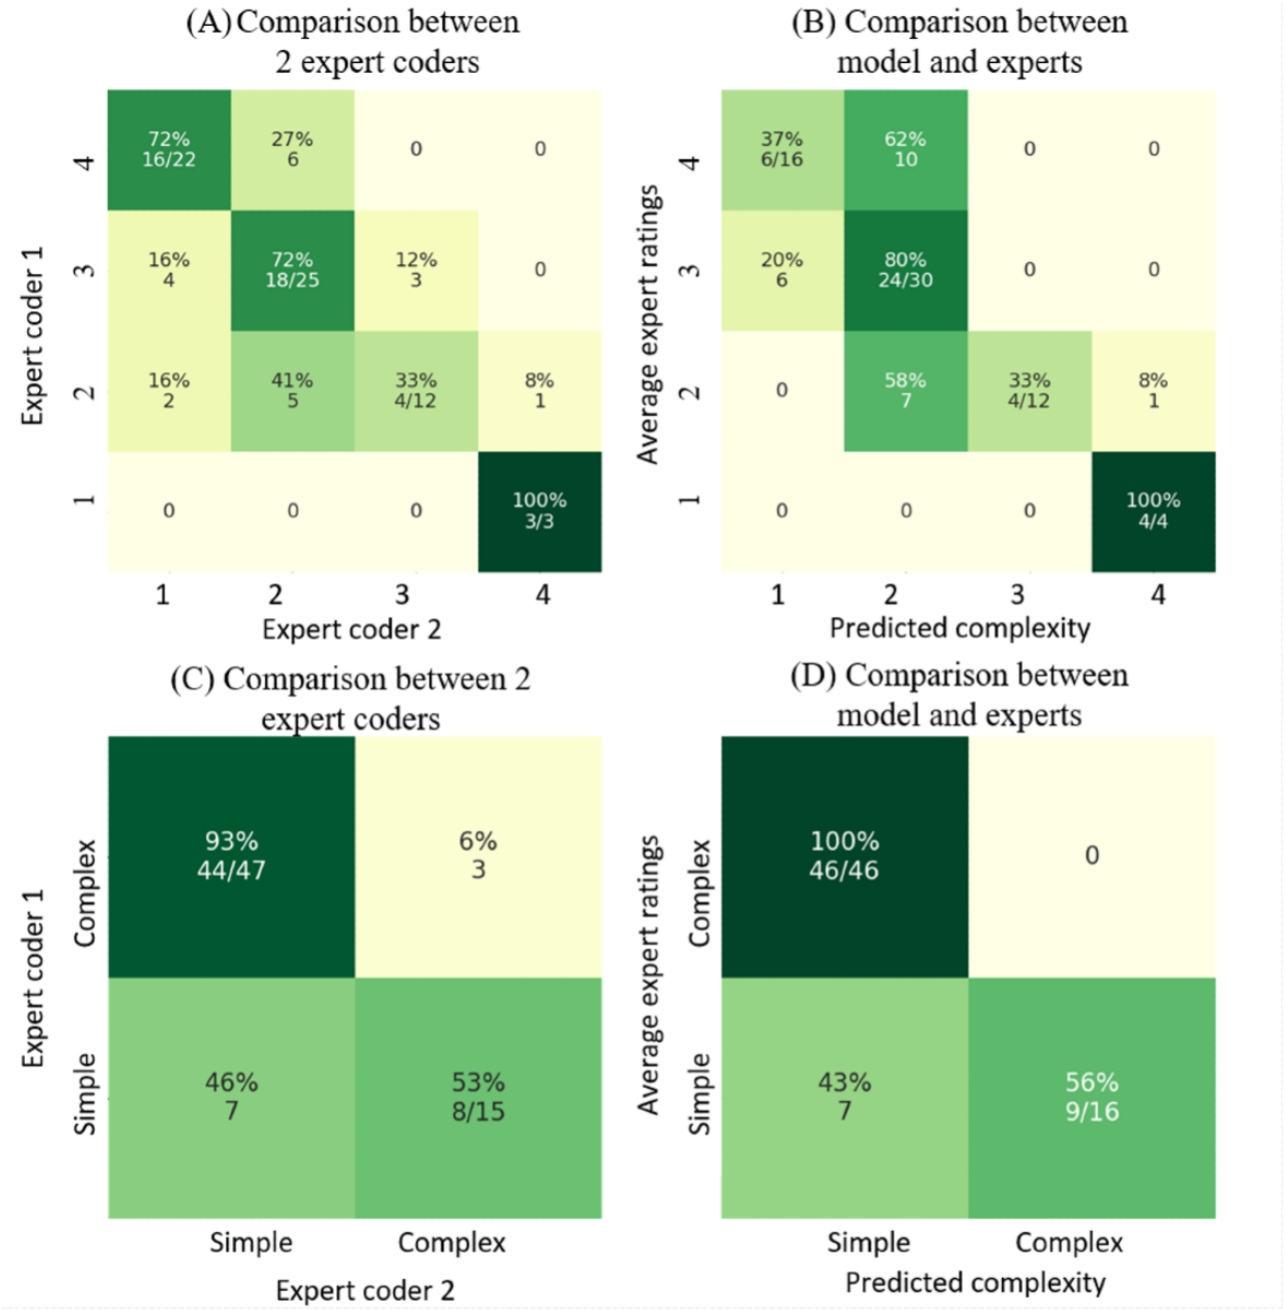
Correction of: https://medinform.jmir.org/2023/1/e38150



(JMIR Med Inform 2026;14:e94047) doi:10.2196/94047

In “An End-to-End Natural Language Processing Application for Prediction of Medical Case Coding Complexity: Algorithm Development and Validation” [1] the authors made two corrections. The y-axis labels in Figures 9 and 10 were misprinted and did not correspond to the intended values shown in the original submission. The underlying data and conclusions of the paper remained unchanged.

The first figure originally appeared as follows (Figure 1):

XSL•FO
RenderX

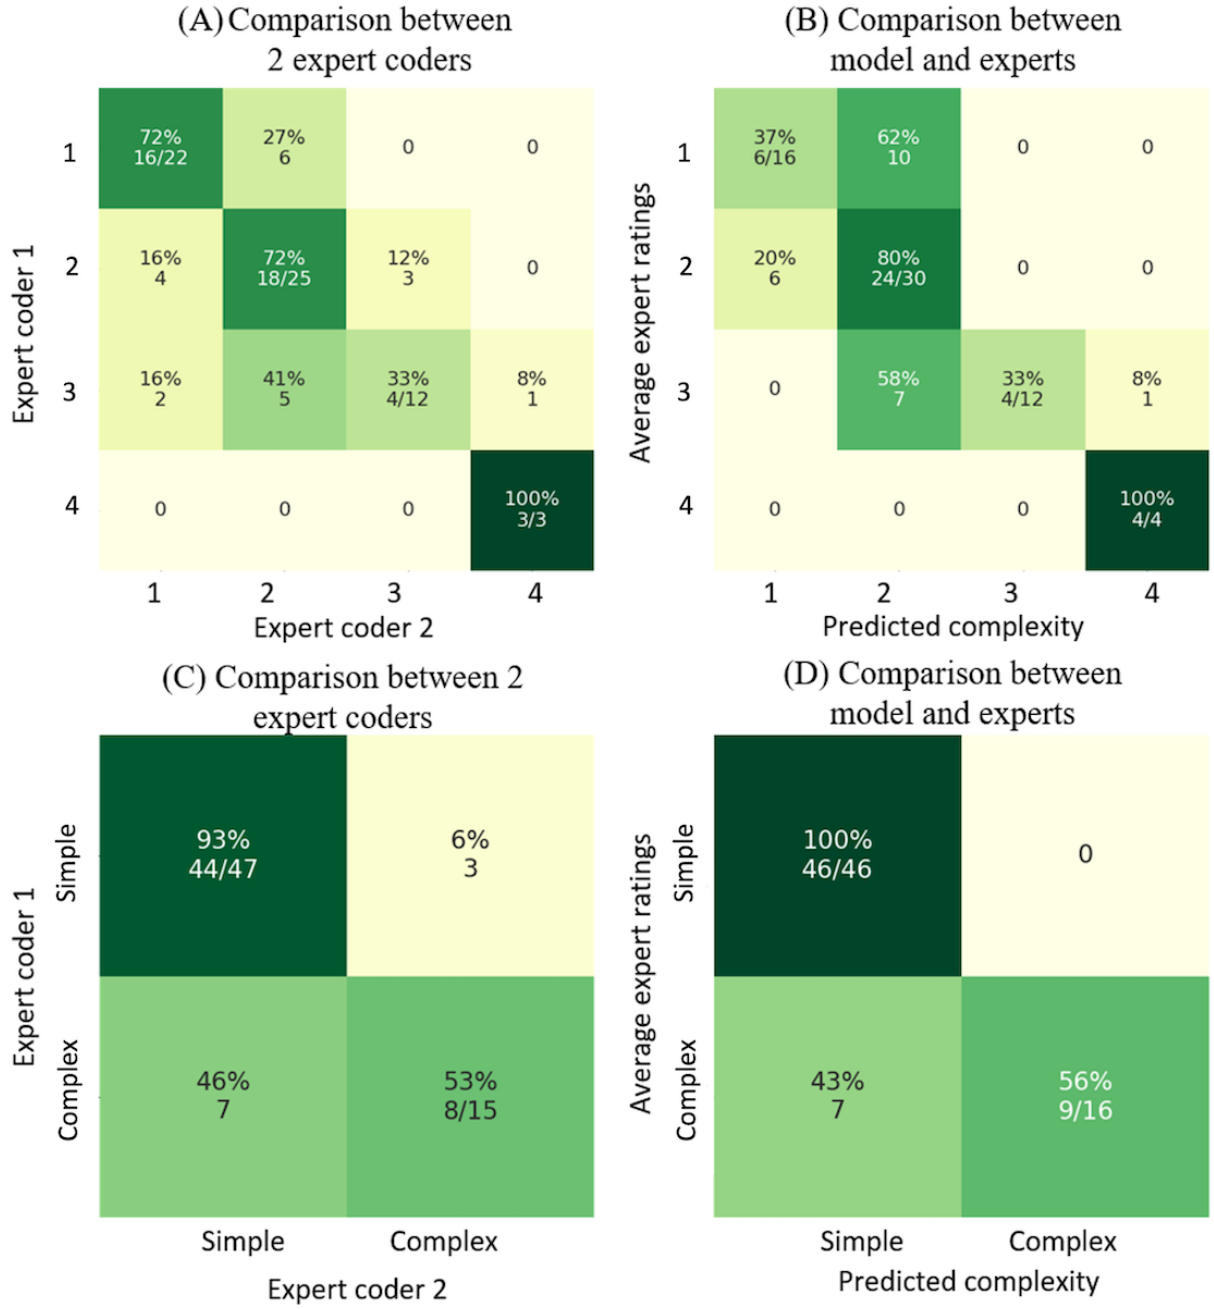


Figure 1. Original Figure 9, (A) The complexity rating comparison between 2 expert coders on the gold-standard set. (B) The comparison between the validation model's predictions and average expert ratings on the gold-standard set. (C) The comparison between 2 expert coders' ratings on the gold-standard set when grouping into simple (complexity 1 and 2) and complex (complexity 3 and 4) cases. (D) The comparison between average expert ratings and the validation model's predictions on the gold-standard set when grouping into simple and complex cases. The average expert ratings are rounded up to the next largest integer.

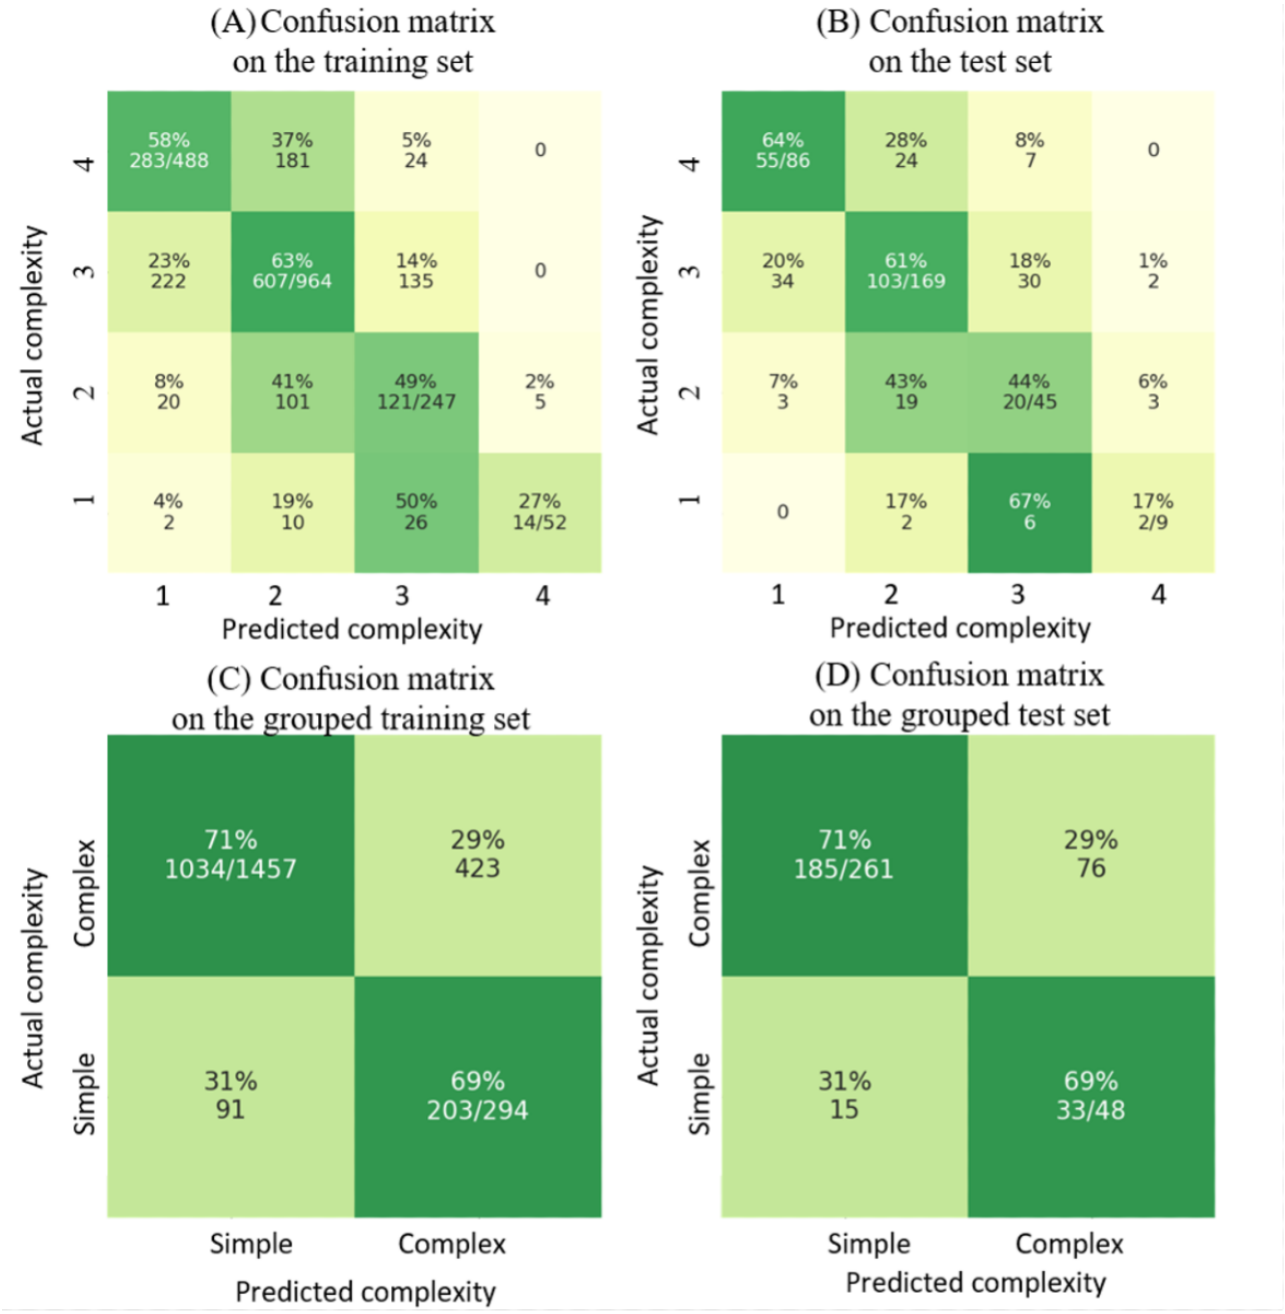
This figure has been revised to the following (Figure 2):

XSL•FO
RenderX

Figure 2. Revised Figure 9, (A) The complexity rating comparison between 2 expert coders on the gold-standard set. (B) The comparison between the validation model's predictions and average expert ratings on the gold-standard set. (C) The comparison between 2 expert coders' ratings on the gold-standard set when grouping into simple (complexity 1 and 2) and complex (complexity 3 and 4) cases. (D) The comparison between average expert ratings and the validation model's predictions on the gold-standard set when grouping into simple and complex cases. The average expert ratings are rounded up to the next largest integer.



The y-axis labels in Figure 9 (A, B) were presented in reverse order. In the original published version, the labels appeared as 4, 3, 2, 1 from top to bottom, whereas they should read 1, 2, 3, 4 from top to bottom. The y-axis labels in Figure 9 (C, D) were presented in reverse order. In the original published version, the labels appeared as "Complex, Simple" from top to bottom, whereas they should read "Simple, Complex" from top to bottom. The underlying data and conclusions of the paper remained unchanged; however, the labeling error may cause confusion for readers.

The second figure originally appeared as (Figure 3):

XSL•FO
RenderX

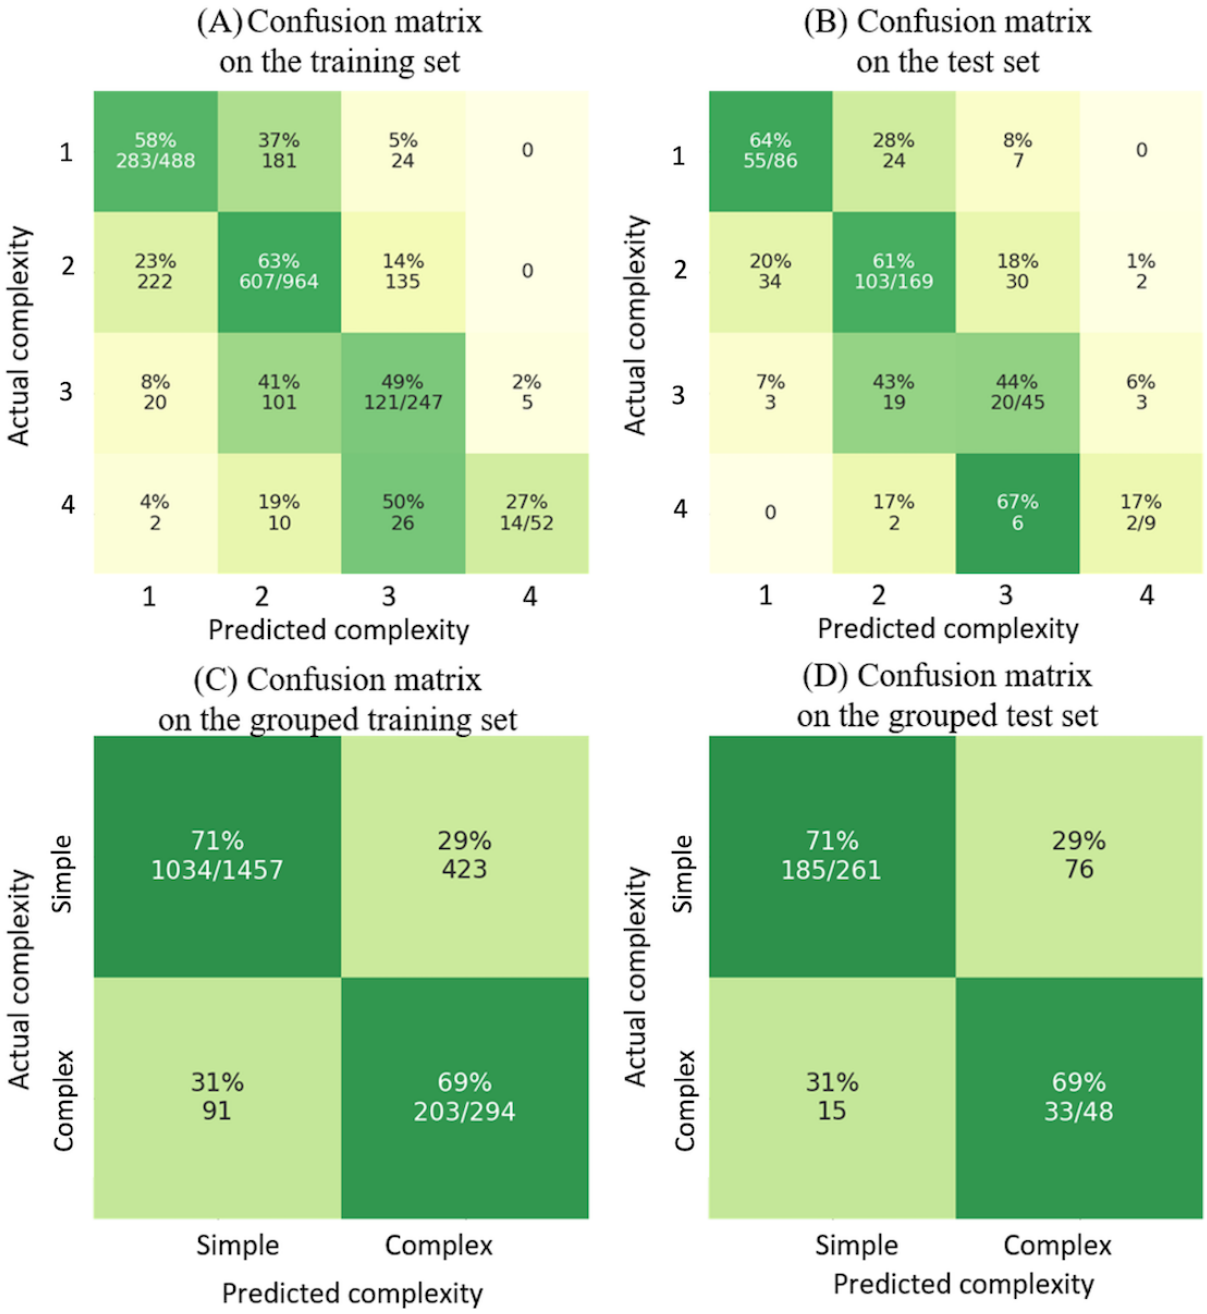


Figure 3. Original Figure 10, (A) and (B) The main model's performance on the training set (1751 cases) and the test set (309 cases). (C) and (D) The main model's performance on the grouped training set (1457 cases as simple and 294 cases as complex) and the test set (261 cases as simple and 48 cases as complex).

This figure has been revised to the following (Figure 4):

XSL•FO
RenderX

Figure 4. Revised Figure 10, (A) and (B) The main model's performance on the training set (1751 cases) and the test set (309 cases). (C) and (D) The main model's performance on the grouped training set (1457 cases as simple and 294 cases as complex) and the test set (261 cases as simple and 48 cases as complex).

The y-axis labels in Figure 10 (A, B) were presented in reverse order. In the published version, the labels appeared as 4, 3, 2, 1 from top to bottom, whereas they should read 1, 2, 3, 4 from top to bottom. The y-axis labels in Figure 10 (C, D) were presented in reverse order. In the published version, the labels appeared as "Complex, Simple" from top to bottom, whereas they should read "Simple, Complex" from top to bottom. The underlying data and conclusions of the paper remained unchanged; however, the labeling error may cause confusion for readers.

The correction will appear in the online version of the paper on the JMIR Publications website, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to thos

(JMIR Med Inform 2026;14:e96740) doi:10.2196/96740

In "Complete Blood Count–Derived Inflammation Indices to Predict 3-Year All-Cause Mortality in Patients With Diabetes and Acute Myocardial Infarction in Critical Care: Retrospective Cohort Study With Single-Center External Validation" [1], the authors made one correction.

In the originally published manuscript, the affiliation for all authors was listed as:

> *Zhongnan Hospital of Wuhan University, Wuhan, China*

The affiliation has been revised and now includes two departments, as follows:

> *Tong Zhou[1], MS; Kun Yang[2], PhD; Ying Yang[1], PhD; Song-Mei Liu[1], Prof Dr*
>
> *[1]Department of Clinical Laboratory, Center for Gene Diagnosis and Program of Clinical Laboratory, Zhongnan Hospital of Wuhan University, Wuhan, Hubei, China*
>
> *[2]Department of Pharmaceutical Sciences, Zhongnan Hospital of Wuhan University, Wuhan, Hubei, China*

The correction will appear in the online version of the paper on the JMIR Publications website, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

In "Enterocutaneous Fistula–Associated Sepsis and Mortality: Development and Validation of a Multimodal Artificial Intelligence Prediction Model" [1], the authors noted one error.

The affiliation has been revised from the following:

> *1. Department of Emergency Medicine, Biomedical InnovationCenter, The Sixth Affiliated Hospital of Sun Yat-sen University, Sun Yat-sen University, Guangzhou, Guangdong, China*

The affiliation has been split into two separate affiliations, as follows:

> *1. Department of Emergency Medicine, The Sixth Affiliated Hospital of Sun Yat-sen University, Guangzhou, China*
>
> *2. Biomedical Innovation Center, The Sixth Affiliated Hospital, Sun Yat-sen University, Guangzhou, China*

The correction will appear in the online version of the paper on the JMIR Publications website, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

(JMIR Med Inform 2026;14:e109596) doi:10.2196/109596

In “Clinical Evaluation of a Real-Time Wearable System for Monitoring In-Hospital Ambulatory Patients With COVID-19: Retrospective Data Study” [1], the authors have requested that the two authors listed first—SV and CR—be recognized as joint first authors with equal contribution. This was indicated in the original submitted metadata but removed during publisher processing.

The metadata has been amended to include an asterisk after both SV’s and CR’s names, indicating equal contributions.

The author list has been revised from the following:

> *Sarah Vollam[1,2], PhD; Cristian Roman[2,3], PhD; Mauro Santos[3], DPhil; Marco Pimentel[3], DPhil; Oliver Redfern[1], PhD; Lionel Tarassenko[2,3], DPhil; Peter Watkinson[1,2,4], MD*

The author list now reads:

> *Sarah Vollam[1,2*], PhD; Cristian Roman[2,3*], PhD; Mauro Santos[3], DPhil; Marco Pimentel[3], DPhil; Oliver Redfern[1], PhD; Lionel Tarassenko[2,3], DPhil; Peter Watkinson[1,2,4], MD*
>
> **these authors contributed equally*

The correction will appear in the online version of the paper on the JMIR Publications website together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Correction of: https://medinform.jmir.org/2026/1/e78117

(JMIR Med Inform 2026;14:e107705) doi:10.2196/107705

Following the publication of "Enhanced Prediction of Atrial Fibrillation in Patients With Ischemic Stroke Through Electronic Medical Records and Text Mining: Algorithm Development and Validation" [1], concerns were raised regarding potential conflicts of interest between reviewers Szu-Yin Lin and Pei-Ju Lee and the authors. These concerns included prior co-publication with members of the author list. These conflicts were not disclosed to the JMIR Publications Editorial Office as per journal policy.

This article has been subsequently reassessed by the editor in chief, who determined that the content of these reviews did not unduly influence the decision to accept the article. The decision to accept the submission was based primarily on the editor in chief's contemporary appraisal of the manuscript.

As such, the JMIR Publications Editorial Office issues this corrigendum to update the Conflicts of Interest statement from the following:

> *None declared.*

The Conflicts of Interest statement now reads:

> *Reviewers Szu-Yin Lin and Pei-Ju Lee were found to have undisclosed conflicts of interest with members of the author list under the terms of JMIR Publications policy. The editor in chief determined that the content of the reviews did not unduly influence the decision to accept the article. The decision to accept the submission was based primarily on the editor in chief's contemporary appraisal of the manuscript.*

We regret that these issues were not identified before publication.

The correction will appear in the online version of the paper on the JMIR Publications website together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Corrigenda and Addenda

Correction: Exploring the Potential of Claude 3 Opus in Renal Pathological Diagnosis: Performance Evaluation

JMIR Publications Editorial Office

Related Article:

Correction of: https://medinform.jmir.org/2024/1/e65033

(JMIR Med Inform 2026;14:e88845) doi:10.2196/88845

Following the publication of "Exploring the Potential of Claude 3 Opus in Renal Pathological Diagnosis: Performance Evaluation" [1], concerns were raised regarding a potential conflict of interest between reviewer X Liu and members of the author list. After review, it was determined that the authors and the reviewer were both affiliated with Sichuan University West China Hospital. This conflict of interest was not disclosed to the editorial office as per journal policy.

This article has been subsequently reassessed by the *JMIR Medical Informatics* editor in chief, who determined that the content of this review did not unduly influence the decision to accept the article. The decision to accept the submission was based primarily on the remaining reviewers' comments and the previous editor in chief's contemporary appraisal of the manuscript.

As such, the JMIR Publications Editorial Office issues this corrigendum to update the Conflicts of Interest statement as follows:

> *Reviewer X Liu was found to have undisclosed conflicts of interest with members of the author list under the terms of JMIR Publications policy. The editor in chief determined that the content of the reviews did not unduly influence the decision to accept the article. The decision to accept the submission was based primarily on the remaining reviewers' comments and the editor in chief's contemporary appraisal of the manuscript.*

We regret that these issues were not identified before publication.

The correction will appear in the online version of the paper on the JMIR Publications website together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

The JMIR Publications Editorial Office is retracting the article:

> *Application of an Isolated Word Speech Recognition System in the Field of Mental Health Consultation: Development and Usability Study [1]*

This action is being taken due to identified concerns regarding potential manipulation of the submission process, the integrity of the peer review process, and the relevance of several references.

The concerns with this publication were identified during an investigation of a series of articles with related concerns. Author Weifeng Fu was contacted and offered an opportunity to comment on these findings and the proposed retraction but did not respond to any attempts at communication.

The JMIR Publications Editorial Office is retracting the article:

> *Application of a Mathematical Model in Determining the Spread of the Rabies Virus: Simulation Study [1]*

This action is being taken due to identified concerns regarding potential manipulation of the submission process and authorship, the integrity of the peer review process, and the relevance of several references.

The concerns with this publication were identified during an investigation of a series of articles with related concerns. In response to our request for comment, author Yihao Huang indicated that the identified references were cited in a broader methodological context on computational modeling. However, as these references supported statements related to the history and transmission of rabies, the JMIR Publications Editorial Office determined that this response did not fully resolve the concerns regarding the initial use of these references in the published article.

Yihao Huang disagreed with the retraction. Author Mingtao Li did not reply directly and could not be reached regarding the decision to retract the article.

The JMIR Publications Editorial Office is retracting the article:

> *Optimization of Precontrol Methods and Analysis of a Dynamic Model for Brucellosis: Model Development and Validation [1]*

This action is being taken due to identified concerns regarding potential manipulation of the submission process, the integrity of the peer review process, and the relevance of several references.

The concerns with this publication were identified during an investigation of a series of articles with related concerns. In response to our request for comment, author Yihao Huang indicated that the identified references were cited in a broader methodological context and that multiple references may not have been the most appropriate for statements relating to brucellosis transmission or infection. The JMIR Publications Editorial Office determined that the author's response did not fully resolve the concerns regarding the initial use of these references in the published article.

Yihao Huang disagreed with the decision to retract the article. Author Mingtao Li did not reply directly and could not be reached regarding the decision to retract the article.

The JMIR Publications Editorial Office is retracting the article:

> *Application of Intelligent Computer-Assisted Taylor 3D External Fixation in the Treatment of Tibiofibular Fracture: Retrospective Case Study [1]*

This action is being taken due to identified concerns regarding potential manipulation of the submission process and authorship, the integrity of the peer review process, and the source of the study's ethics approval.

The concerns with this publication were identified during an investigation of a series of articles with related concerns. The authors were contacted and offered an opportunity to comment on these findings and the proposed retraction but did not respond to any attempts at communication.

The JMIR Publications Editorial Office is retracting the article "A Deep Neural Network for Estimating Low-Density Lipoprotein Cholesterol From Electronic Health Records: Real-Time Routine Clinical Application" [1] due to concerns regarding third-party involvement in the submission and the integrity of the peer review process.

The authors stated that the absence of disclosure regarding a previous copublication with reviewer T Lee in accordance with JMIR Publications policy was an inadvertent omission.

However, the Editorial Office and editor in chief determined that there is sufficient evidence indicating that both the submission process and peer review process for this article were compromised.

The authors did not respond to the decision to retract the article.
