Abstract

Background: Health care public reporting (PR) refers to making information about the quality and performance of health care providers available to the public. The primary targeted use of PR is the selection of a health care provider. Previous studies suggest that PR has improved health care quality; however, the overall adoption rate of PR systems remains low. Misalignment between PR information and users' actual needs can explain this gap.

Objective: This study conducts a systematic literature review of PR systems in health care, aiming to explore how data encoding and presentation influence user utilization, with particular attention to the impact of data inconsistencies and inaccuracies on actual use.

Methods: A literature search was conducted on 5 electronic databases (Web of Science, CINAHL, Embase, PsycINFO, and PubMed), focusing on studies providing information in health care from an individual perspective. Subsequently, the quality of the included studies was assessed using the Mixed Methods Appraisal Tool (McGill University). Finally, a total of 25 empirical studies were included in this study.

Results: Among the 25 studies, 40% (10/25) investigated website presentation formats, 20% (5/25) explored dashboard-based data presentation formats in PR systems, 48% (12/25) examined data quality, and 20% (5/25) addressed user heterogeneity. Quantitative methods were used in 80% (20/25) of studies, while qualitative and mixed method designs accounted for 16% (4/25) and 4% (1/25), respectively. Findings suggest that standardized website and dashboard guidelines improve data reliability and user comprehension and that user heterogeneity mediates the effects of structural and process indicators on outcomes. Data collection was completed in February 2025, and the study was projected to be fully completed by September 2025.

Conclusions: This study provides an integrated structure-process-outcome–based framework for PR in health care. By presenting data through dashboards, inconsistencies and inaccuracies in data across different web pages can be mitigated, thereby decreasing conflicting information and improving comprehension in PR systems. Based on the literature findings and identified knowledge gaps, this study also proposes future research directions for online PR.

digital health; public reporting systems; data and information process; health literacy; quality indicators

Introduction

Background

Digital health refers to the development and use of digital technologies to enhance health-related knowledge and practices [1]. It is not only a technological concept but also profoundly shapes how people access health information. For instance, a 2023 report by Digitalis Medical indicates that 7% of all daily Google searches are health-related, equating to approximately 70,000 health care searches every minute [2].

The core function of public reporting (PR) systems is to assist individuals in selecting health care providers and services [3]. Improving the use of the PR system requires understanding how data are encoded and decoded in digital health. This understanding is crucial for individuals who use the PR system to proactively manage their health and engage in recommended behaviors [4].

Previous studies have shown that inconsistencies or errors in PR data can affect trust and reduce users' confidence in the reporting system [5]. Such inconsistencies not only challenge data reliability but also influence how users understand PR information. However, empirical research on these data inconsistencies remains fragmented. For example, some studies suggest that information presentation affects users' actual use of PR systems [6,7]. Moreover, these studies largely remain focused on information presentation formats, while research on

XSL•FO
RenderX

data heterogeneity within systems remains limited, underscoring the complexity of PR data usage.

Patient activation measure (PAM) refers to an individual's knowledge, skills, and confidence essential for managing their own health and health care [8,9]. Although patients show strong interest in accessing PR information to make informed health care decisions, the overall adoption of the PR system remains low, largely due to information presentations that do not match patients' comprehension levels [10-12]. Therefore, exploring data generated in real-world physician-patient co-management contexts may help alleviate data communication challenges and support informed decision-making [13,14].

To address this gap, this study conducts a systematic literature review to provide an overview of current research on PR in digital health information systems. To achieve this objective, we address the following research questions: (1) How do system-level structural indicators influence process indicators, and subsequently influence outcome indicators? and (2) How do decoding errors in PR systems and user-system interactions influence users' information use?

Accordingly, we systematically identified and reviewed 25 empirical studies on information presentation in PR in health care contexts. Drawing upon the structure-process-outcome (SPO) theoretical framework, we categorized and synthesized the structural indicators (website guidelines and dashboard guidelines), process indicators (data quality guidelines and data process criteria), and outcome indicators (user satisfaction and surgical mortality). Meanwhile, we position user heterogeneity as a mediating variable that links process indicators to outcome indicators. Specifically, variations in contextual and individual-level factors (age, gender, political affiliation, employment status, income, and area of residence) can influence the interactions of users' engagement with information.

The remainder of this paper is structured as follows: the "Methods" section describes the methodology for planning and conducting the literature review, focusing on recent research; the "Results" section presents the findings in response to the 2 research questions; and the "Discussion" section discusses the progress and identifies challenges in current literature, concluding with recommendations for future research. Checklist 1 presents the PRISMA-P (Preferred Reporting Items for Systematic Review and Meta-Analysis Protocols) 2020 checklist which outlines recommended items to address in a systematic review protocol. Multimedia Appendix 1 contains the search strategies used in each database. Multimedia Appendix 2 shows the Mixed Methods Appraisal Tool (MMAT; McGill University) quality assessment report. Multimedia Appendix 3 contains the key characteristics of the included studies. Multimedia Appendix 4 includes additional details of the included studies.

Theoretical Background

Overview

The presentation of information in public reports significantly influences user engagement with these systems [15]. To gain an understanding of individual users' attitudes toward the PR system and how this forms health information adoption behavior, it is necessary to explore the information presented in the PR systems. While information is composed of data, the way data is structured determines how information is understood [16]. Based on this premise, this study assesses whether existing PR data align with users' informational needs and examines how such alignment influences users' adoption of PR systems.

PR and Quality Indicators

PR in health care refers to the disclosure of performance-related information about providers, organizations, or systems to the general public. Such information is typically nonanonymous, identifying specific professionals or institutions, thereby enabling direct comparison and accountability [17,18]. By disclosing the performance data, individuals (patients and nonpatients) can choose higher-performing providers and make health plan decisions [17,19].

The assessment of PR systems, rather than direct health care delivery, has increasingly drawn academic attention. Donabedian [20] addresses this issue by conceptualizing health care quality through the SPO framework. In health care, structure indicators refer to the system's resources and organizational arrangements, and process indicators include all service delivery activities such as diagnosis, treatment, nursing, and patient education. Finally, outcome indicators reflect the resulting health effects, including patient health improvements, satisfaction, and mortality rates. By applying the SPO framework in this manner, we shift the focus from assessing health care delivery quality to evaluating how PR system structures and processes influence user outcomes.

In recent times, we have also seen that PR in health care is demanded from the perspective of environmental, social, and governance (ESG) reporting, which involves public disclosure of an organization's performance and its impacts on environmental, social, and governance factors [21]. Currently, PR seems to be moving toward health care processes beyond basic clinical activity, such as PR on clinical trials [22]. In the era of the current artificial intelligence revolution, the impact of artificial intelligence on PR is, of course, an important topic [23,24].

Although defining and measuring quality in health care remains challenging, extensive evidence supports the essential role of the SPO framework in measuring health care quality [20,25]. Within the structural dimension, PR systems are an important component [25]. The health care system is depicted through structural indicators, which in turn influence process indicators, ultimately affecting outcome indicators [20]. PR has to inform its users of all these health care components. Previous research on process indicators in PR primarily focused on operational standardization, consistency, and service standard implementation [15,26]. However, few studies have examined the structural dimension from an individual-system interaction perspective.

At the process level, patient-physician collaboration (PPC) generates substantial user data [27]. During interactions between health care organizations and users, systems serve as supporting tools that can enhance treatment efficiency. The data generated in this process holds significant value for collection and use

XSL•FO
RenderX

[28]. The fine details of PPC, however, remain a difficult item to document in PR.

Existing research has paid insufficient attention to patient-generated data from the PPC process, particularly in the digital era, where the processes of data collection, organization, and use remain inadequate compared to the opportunities that digital data processing could offer. Such gaps may lead to unintended consequences, including users' mistrust of PR systems.

Finally, outcome indicators include subjective or functional metrics, such as in our sample, patient satisfaction and mortality rate [29,30]. Online PR websites enable individuals to interact directly with information, whereas individuals often rely on their own knowledge to evaluate content [17]. In contrast, in offline settings, user interaction is typically mediated by health care institutions, resulting in a more indirect experience [31].

Previous research indicates that attitudes formed through direct experience are more effective in predicting behavior than those formed through indirect experience [32]. However, studies examining interactions between individuals and system information in online environments in a PR context remain relatively limited. Taken together, these gaps highlight the need for a framework that integrates system information processing into the SPO dimensions of PR.

Sociotechnical Theory

According to Bostrom and Heinen [33], sociotechnical theory suggests that information systems should be designed so that the individual and technology operate as an integrated whole. In other words, the design of information systems should not only focus on data collection, processing, and transmission; the interaction between humans and information should also be emphasized. Within the context of PR, this principle is embodied through the interaction between PPC, user heterogeneity, and system-level demand for data reliability and standardization.

The operational goal of any PR system is to serve as a channel through which health care organizations and governments convey PR information to the public. This process enables individuals to filter health care information via the selection pathway and make health care choices suited to their needs [12]. PR information selection is both receptive and selective, and at the system stage, it primarily involves information processing.

In the context of PR, effective information processing is critical because it shapes how users understand and use performance data to make informed decisions. The information processing in PR systems involves a series of systematic steps that transform raw health data into actionable information for diverse stakeholders such as policymakers, providers, and the public [34]. On the PR website, data are symbols that represent the properties of objects and events [35].

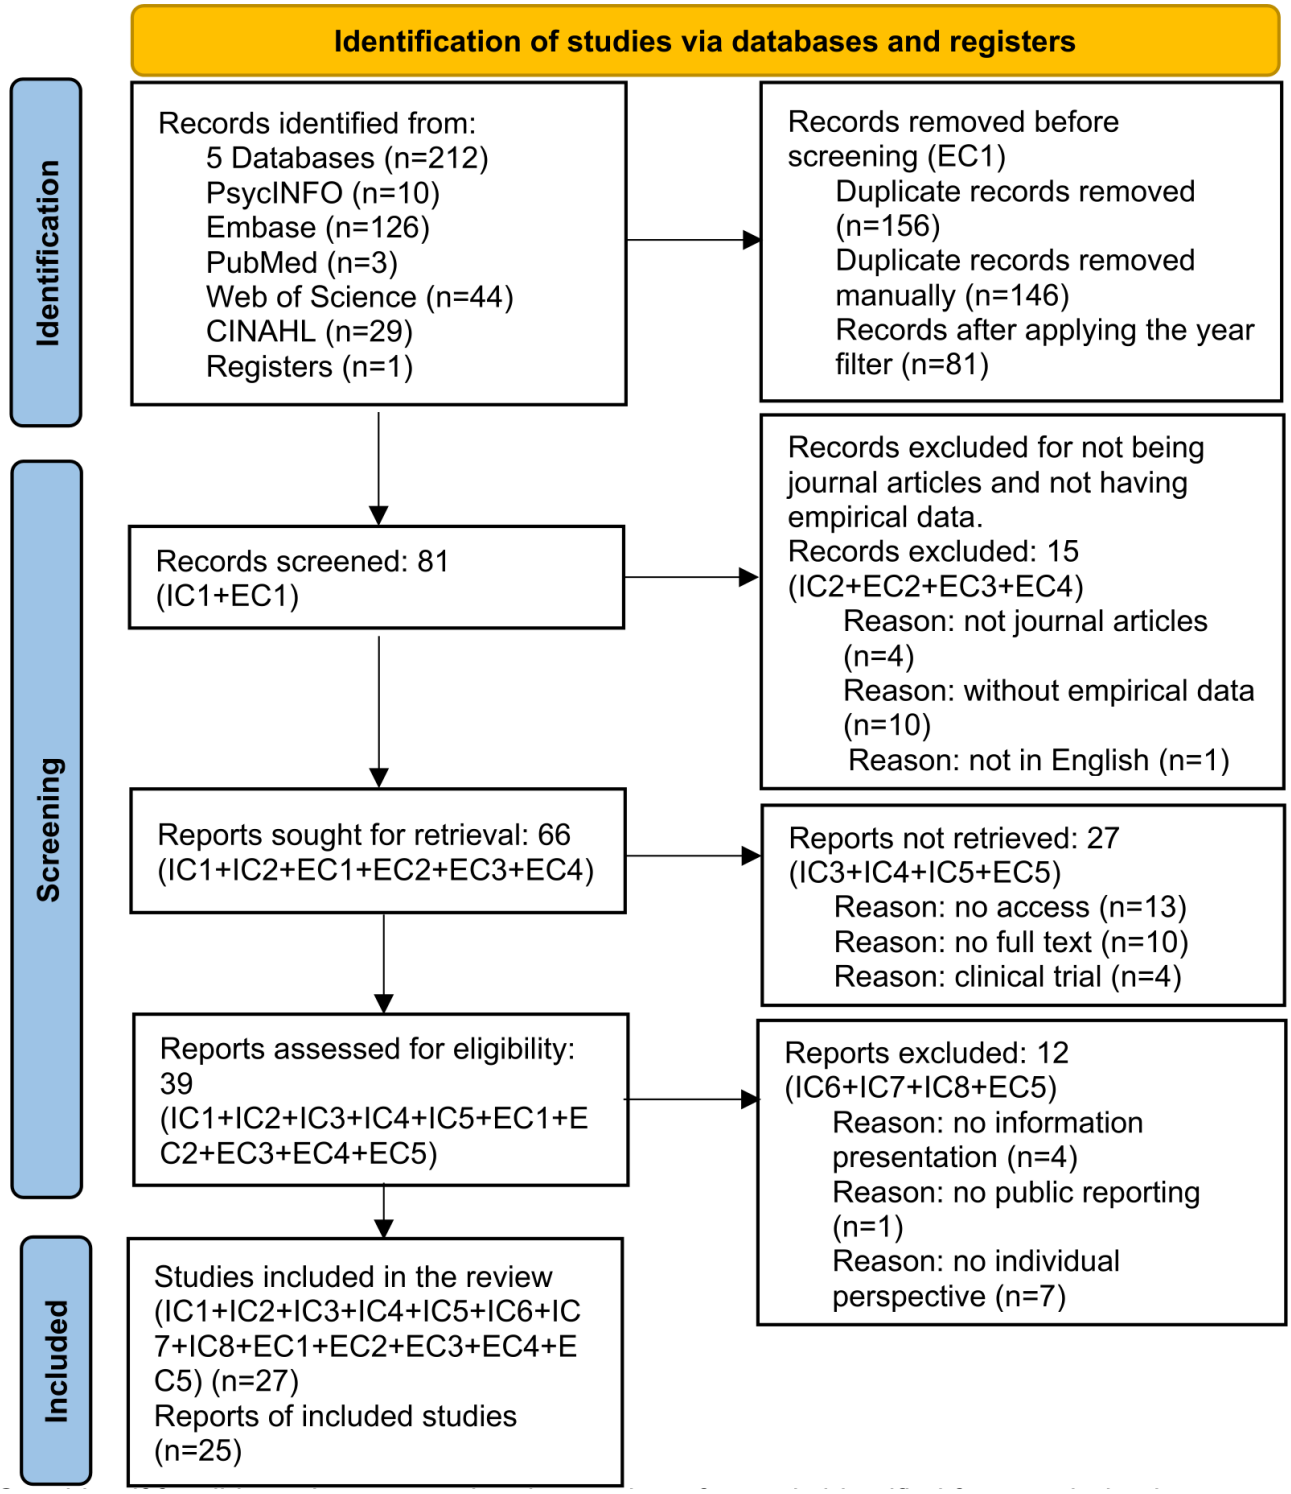
Information consists of processed data, with the processing directed at increasing its usefulness [16]. System information processing involves integrating data from multiple sources into a central database, which is then retrieved and displayed on websites [36]. Regarding quality indicators, many individuals still experience significant analytical challenges, particularly when information is not clearly presented [37]. Thus, it is necessary for the PR system to reduce information asymmetries and empower patients, families, and payers to select high-quality providers [38].

These studies provide insights into the interaction between PR information and individuals, particularly regarding how end users use PR information. Previous research has primarily focused on issues of data inconsistency and low accuracy in PR [39]. However, previous studies have provided insufficient investigation into how data inconsistency issues can be effectively addressed within the field of information systems. Specifically, it is equally important to consider the objective quality of the data, incorporating data guidelines to address data inconsistency.

These findings underscore the critical role of data quality in shaping the adoption of PR systems. However, extant research demonstrates several notable limitations. First, the analytical depth remains constrained. Most studies focus primarily on information presentation as the primary mode of data delivery; however, they often overlook how data processing within systems fundamentally influences website presentation and user interpretation.

Second, investigations in the PR domain have predominantly adopted an awareness-to-behavior framework, emphasizing the role of awareness in guiding user actions [17]. Nevertheless, the complex interrelations between data quality and adoption remain underexplored, resulting in substantive gaps between PR systems and users' actual attitudes. Consequently, there is a pressing need to examine online PR systems through a lens that integrates the system and individuals.

Methods



Overview

A systematic literature review requires clearly defined research questions, a transparent search process, data extraction, and data presentation [17,40]. Typical reviews cover a span of approximately 10 years. In this study, the time frame was set from 2016 to 2025. The rationale for selecting studies after 2015 is that, from this year onward, PR increasingly transitioned to internet-based platforms. The system reached its peak in July 2015, but then declined rapidly and has remained at a relatively low level since [41]. Additionally, the Hospital Consumer Assessment of Healthcare Providers and Systems star ratings system was launched, enhancing patients' visual understanding of hospital quality information [42].

We used the guidelines of Okoli and Schabram [43] and the framework proposed by Webster and Watson [44] to conduct our literature review. This review adopts a structured approach to the literature. As shown in Figure 1, the complete selection and synthesis process is summarized in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of the selection process for public reporting systems retrieved from 5 databases between 2016 and 2025. EC: exclusion criteria; IC: inclusion criteria.

First, when designing the search strategy, efforts were made to capture all studies that met the inclusion criteria [45]. This research aims to explore the presentation of information in PR systems. Therefore, the search term was set to information; meanwhile, the research mainly focuses on PR, and the keyword includes "PR." The search term is provided in Multimedia Appendix 1, and the search date was September 14, 2025.

Second, PR has evolved as an interdisciplinary field, drawing from health policy and behavioral science. Conducting a review can be helpful to fill in the gap of data inconsistency and identify future directions from the information system perspective [46]. Access to these databases was obtained via Volter (Library of the University of Turku), ensuring that the user was logged in to minimize the number of ignored studies due to access issues. The data sources were chosen from Web of Science (multidisciplinary and broad literature search), CINAHL (health and public health information systems), Embase (health and public health information systems), PsycINFO (cognitive science, decision-making, and behavioral economics), and PubMed (biomedicine literature database).

XSL•FO
RenderX

Third, using tools to assess the risk of bias in studies is an important step described in systematic review protocols, as judgments made during this process may influence the analysis and interpretation of the review results [45]. Meanwhile, applying objective and reproducible methods helps ensure the appropriateness and fairness of the study findings [43]. The quality assessment protocol covers study methodology, level of structuring, study outcomes, and research topics. After the deduplication of studies (n=146) in EndNote (Clarivate) combined with manual checking, 81 studies were included in the final scoring pool.

Among the included studies, the methodologies involved both qualitative and quantitative approaches. The scoring table referenced from Hong et al [47] is provided in Multimedia Appendix 2.

Screening Process of the Systematic Review

In the screening process, 81 studies were initially included in the research pool. Review or descriptive studies that were not journal publications and did not contain empirical data were excluded. A total of 66 articles were retrieved, and full-text searches were conducted for these studies. During the full-text review, studies without accessible full text and clinical trial papers were excluded. Ultimately, 39 studies were included in the quality assessment.

Some of these studies examined PR systems from an organizational perspective. This study, however, focuses primarily on the individual perspective, specifically the alignment between individual users and the information presented in the PR system. Studies that explored system processes at the organizational level, which do not directly reflect the information presentation encountered by individual users, were excluded. Additionally, since this study focuses on PR systems in the health care domain, studies from non–health care fields were also excluded.

In Figure 1, abbreviated labels are used to represent inclusion criteria (IC) and exclusion criteria (EC).

The selection was conducted independently and double-checked manually. For clarity, the IC correspond to the following criteria: IC1 indicates studies published between 2016 and 2025, IC2 indicates empirical studies, IC3 indicates studies with open access, IC4 indicates studies with full text availability, IC5 indicates studies published after peer review, IC6 indicates studies focused on information presentation, IC7 indicates studies focused on the individual level, and IC8 indicates studies conducted in health care contexts. The EC corresponds to the following criteria: EC1 indicates studies published outside the 2016 to 2025 timeframe, EC2 indicates nonjournal studies, EC3 indicates nonempirical studies, EC4 indicates studies not published in English, and EC5 indicates clinical trials and other studies not focused on PR systems or individual-level information use.

After the initial full‐text screening, 27 studies were eligible for quality appraisal. The methodological quality of the included studies was assessed using the MMAT (2018 version) [47], a validated instrument specifically developed for appraising empirical studies in mixed-study systematic reviews. The MMAT evaluates 5 categories of study designs—qualitative research, randomized controlled trials, nonrandomized quantitative studies, quantitative descriptive studies, and mixed methods studies—each using 5 methodological criteria.

Following MMAT guidance, studies can be classified as low (1‐2 criteria met), moderate (3 criteria met), or high quality (4‐5 criteria met). All assessments were performed independently by the first and third authors, and discrepancies were resolved through discussion. Two studies with MMAT scores of 1/5 and 2/5 were excluded from the analysis, resulting in a final set of 25 studies for article synthesis.

Literature Synthesis

Thematic and Narrative Synthesis

We conducted a thematic synthesis of the included studies to extract key findings, which were then grouped into distinct themes [45]. Within each theme, dimensional indicators were identified and presented using an integration framework to address the first research question. This approach enables the qualitative integration of evidence across studies, highlighting patterns in structure indicators, process indicators, and outcome indicators.

Given the fragmented and broad scope of research in the field of PR, a narrative synthesis approach was adopted [48]. To enhance the transparency and rigor of the synthesis, descriptive statistics were also used to summarize the number of studies within each category and their methodological characteristics.

Regarding the research questions, the theme under the SPO framework is reported quantitatively, whereas subthemes (eg, website, dashboard, and data) are explored using a narrative approach. During synthesis, studies were grouped based on the specific dimensions of the SPO framework and their relevance to the research questions. Furthermore, a subset of studies investigated how structural indicators and process indicators influence the outcome indicators. Examining findings on the same aspects allows them to extend one another, which can be viewed as a form of confirmation [48].

SPO Framework–Based Results Mapping

Each subtheme in the “Results” section corresponds to a specific type of data extracted from the literature: (1) structure (website and dashboard): indicators describing the system design, presentation, and functionality were collected and summarized; (2) process (data quality and data process): studies reporting on data accuracy, completeness, accessibility, and workflow processes were analyzed; (3) outcome (patient satisfaction and surgical mortality): measures were extracted from studies evaluating the effect of PR systems on users’ decision-making, satisfaction, and clinical outcomes; and (4) user heterogeneity: information on demographic characteristics, health literacy, and contextual factors influencing user interaction with PR systems was also extracted and synthesized.

Quality Assurance and Integration

First, we conducted an initial synthesis using thematic analysis, presenting the study results in Multimedia Appendices 3 and 4. Subsequently, 1 author summarized and categorized the included

XSL•FO
RenderX

studies within an integrative framework. Based on this synthesis, an integrative framework was developed to organize the identified themes, which are further elaborated in the "Results" section.

Results

Overview

Among the 25 studies included in this review, 40% (10/25) explored PR from the perspective of information presentation formats, while 20% (5/25) of the studies focused on the dashboard in online PR. Additionally, 48% (12/25) of the studies examined PR systems from the perspective of data presentation, and 20% (5/25) addressed user heterogeneity. Finally, 12% (3/25) of the studies investigated PR from the perspective of patient satisfaction and surgical mortality.

Meanwhile, 80% (20/25) adopted quantitative methods, 16% (4/25) used qualitative designs, and 4% (1/25) used a mixed methods approach. Regarding data sources, 60% (15/25) collected secondary data (eg, web content analyses), while 40% focused on primary data through surveys, interviews, or focus groups. Data collection was conducted between February 2025 and September 2025.

Structure

Website

Among the included studies, 40% (10/25) of the studies examined PR from the perspective of information presentation formats on websites. For instance, studies found that the format of information presentation on PR websites can significantly influence public understanding and trust, policymaking, and pandemic response [49].

Specifically, the findings show that standardized data guidelines help improve the quality of PR websites, including accuracy, completeness, technical elements, design and aesthetics, readability, usability, and accessibility [50]. For example, challenges in information presentation may also result from mismatches between recommended reading levels for patient education materials (typically up to sixth grade) and the actual readability of websites, which seldom meet the needs of most patients [50]. Such mismatches create a gap between the health information users need and what is actually provided. Appropriate readability facilitates comprehension, enabling better disease management and adoption of healthy lifestyles [51].

Moreover, in terms of presentation formats, we found that online ratings may serve as a valuable source of information for both consumers and policymakers [52]. It is worth noting that storytelling techniques that convey narrative trends on dashboards can help users better understand the information presented in PR [53]. Additionally, supplementing this with characteristics of professional care institutions, which are often under-represented, can enhance the comprehensiveness of PR information [54].

Furthermore, the widespread use of aggregated ratings, such as star systems, may further strengthen consumer responses [55]. Interestingly, research has shown that "breadcrumb navigation" (forward-backward topic navigation) helps maintain the continuity of information, enabling users to quickly review previously read content and efficiently locate needed information [50]. Meanwhile, studies indicate that participants accessing "drill-down scores" tend to engage more deeply with the provided data (manifested as increased interactions on the website), but their impact on physician selection is lower than that of participants accessing "roll-up scores" [56].

Additionally, studies have found that over 90% of websites do not include accessibility features for individuals with disabilities, such as hearing, cognitive, neurological, motor, language, or visual impairments [51,57,58]. Therefore, considering accessibility benefits not only for disabled users but also the general population (eg, those using mobile devices, with slow internet, or limited bandwidth), it provides equal access to information for elderly individuals or residents in remote areas [51,57,58].

Dashboard

In our sample, a lot of discussion revolved around dashboards. We see them as a subcategory of web-based information, offering more dynamic and versatile analysis possibilities than static websites.

Overall, 20% (5/25) of studies examined the presentation of information on dashboards. Relevant and high-quality data are crucial for constructing dashboards, and research indicates that data sources are key factors in dashboard development [59,60]. Dashboards are especially useful in presenting epidemic and pandemic trends, such as those of COVID-19 [61], but can also be used in classical resource selection performed by PR users.

In terms of content presentation, dashboards should serve as tools that clearly link current trends with past policy decisions and individual behaviors, thereby enhancing the use of indicators [61]. However, evidence suggests that known and validated presentation techniques were overall underused, especially explanatory narratives [61]. To enhance usability, effective dashboards include: (1) understanding the audience and their information needs; (2) managing the type, quantity, and flow of displayed information; (3) clearly reporting data sources and methods; (4) linking time trends with policy decisions; (5) providing "close-to-home" data; (6) segmenting populations into relevant subgroups; and (7) using storytelling and visual cues [61].

Among these studies, the predominant approach involved data provision (specificity of geographic breakdowns, range of indicators reported, and explanations of data sources or calculations) and advancements enabled by the technologies employed (customization of time trends and interactive or visual chart elements) [53]. Meanwhile, studies also note that the clarity of data sources and methods has improved in dashboard development [53]. Teams differ in how they explore and define the purposes of dashboards. Some view dashboards as tools for presenting raw data to the public, while others attempt to provide explanations through narrative or visualization [59].

Moreover, 8% (2/25) of studies viewed the purpose of dashboards as solely presenting data (raw numbers) for the

XSL•FO
RenderX

public to interpret independently, whereas others sought to provide explanations through narrative or visual methods [53]. Additionally, incorporating storytelling elements and visual cues within dashboards has been shown to enhance users' ability to process information effectively [53]. For example, the development of dashboards that allow users to create profiles and receive personalized scores enables consumers to "see themselves in the data" [62].

Process

Data Quality

Overall, 48% (12/25) of studies examined PR from the perspective of website data. Notably, 32% (8/25) of studies indicated that standardized data guidelines help improve the quality of PR websites [15,45-47,58,59]. Additionally, some research described implementing check types within a data quality framework covering conformance, completeness, and plausibility, including both verification and validation [63].

Data Process

In the context of PPC, the generation of data encompasses multiple sources and activities. By using the data quality framework, data were collected across 4 domains, multiple measures, and time periods to examine access and equity; efficiency and sustainability; quality, safety, and patient orientation; and employee engagement [60].

Among these studies, 28% (7/25) investigated chart information on PR websites. The use of publicly reported data by consumers, policymakers, and researchers has grown substantially [64]. Most websites use charts, graphical elements, and quantitative descriptions as tools to convey differences between hospitals [65]. In addition, some research suggests adding charts to improve navigation [15]. For example, appropriate disease-related images and illustrations help patients better understand the information [50].

Meanwhile, the trend toward simplified composite rating systems may be reasonable to improve consumer responses to PR [55]. Previous research identified seven key elements that enhance user understanding [7]. The elements include unmarked bar charts, bar charts with simple symbols, bar charts with traffic light indicators, bar charts with thumbs-up symbols, provider rankings based on performance, clearly indicating whether higher values represent better performance, and implying quality levels through performance ranges without explicitly marking scale directions [7].

Furthermore, the transparent communication of standardized databases provides a crucial supplement to the missing components commonly observed in observational research [63]. This transparency can enhance the effectiveness of PR tools, as consumers may question the reliability of the quality information provided and consequently avoid using report cards [66].

Within the PPC process, presenting data in a structured format on dashboards can facilitate clear communication between health care providers and patients [67]. Meanwhile, PR websites can also serve as supplementary materials recommended by physicians, thereby reducing the need for face-to-face education and consultation [50].

Moderating Variable

User Heterogeneity

Overall, 20% (5/25) of the studies examined user heterogeneity, suggesting that themes such as simplicity, trust, collaboration, software and data integration, and adaptability have facilitated the development of PR systems [67]. However, the use of identical data across different websites may result in confusion or even contradictions regarding the same provider [15].

Moreover, research has highlighted that improvements in data timeliness, the level of detail available, and the categorization of comparable population groups can enhance the quality and effectiveness of PR [60]. For instance, individuals with higher health literacy tend to spend more time reviewing PR information than those with lower health literacy [68].

Individual Characteristics and Contextual Factors

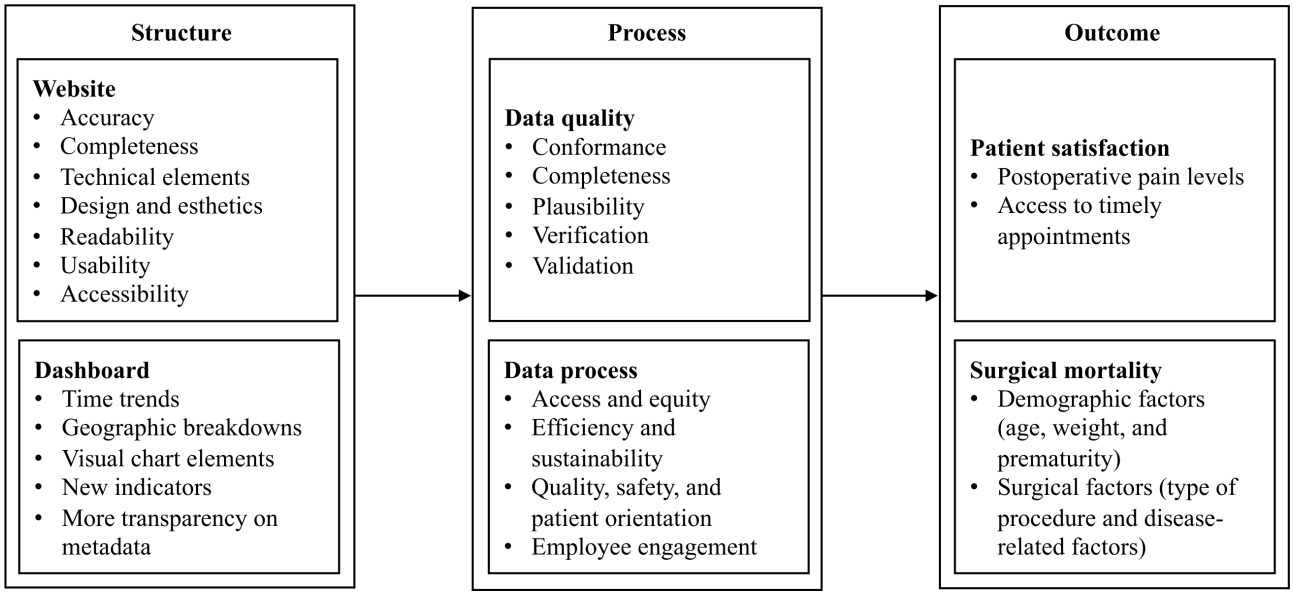
Similarly, individual characteristics and contextual factors, such as age, political orientation, employment status, income level, and residential area, significantly influence users' adoption of PR information [38]. Younger adults are generally more likely than older adults to trust information from all sources [38]. In addition, political orientation, employment status, income level, and residential location are correlated with trust in medical quality information from companies, government agencies, or family and social network sources [38]. Collectively, these findings indicate that both individual characteristics and contextual factors are critical determinants of the perception of PR information.

Outcome

Patient Satisfaction

Overall, although patients generally prefer to obtain health information from medical professionals, the media remains an important source of information [69]. Within the PPC process, patient satisfaction primarily depends on the quality of care and service delivery. Specifically, patient satisfaction appears to depend largely on postoperative pain levels and access to timely appointments [70].

Surgical Mortality



In addition, studies have pointed out that the variables influencing patient risk levels in surgical mortality include demographic factors such as age, weight, and prematurity, surgical factors such as the type of procedure, as well as disease-related factors [71].

A Framework to Understand the PR Quality Indicators in Health Care

The framework used in this study is based on the Donabedian quality model [20]. As shown in Figure 2, the system constitutes a key component of structural indicators [20]. User heterogeneity functions as a mediating mechanism linking the structural indicators and process indicators to outcome indicators. Specifically, the structural indicators and process indicators features of PR systems jointly shape users' perception of the information [38].

XSL•FO
RenderX

Figure 2. Integrative structure-process-outcome (SPO) framework for public reporting systems in health care.

The presentation format of PR websites refers to the channel through which users directly interact with the displayed content of the PR systems. Adherence to the website quality dimension and the dashboard quality dimension in the presentation format facilitates users' understanding of the system in a structured context.

Previous studies have indicated that data inconsistencies negatively affect the actual use of the system, thereby influencing users' adoption of the system [72]. The reviewed study indicates that the dashboards present data that have been processed and integrated within the underlying data architecture, resulting in higher accuracy and consistency. This, in turn, helps users use information that is more reliable and precise.

While structural indicators define the foundational quality of PR websites, process indicators determine how these systems function and generate reliable data. In terms of process indicators, data quality encompasses conformance, completeness, plausibility, verification, and validity. Data processes include accessibility and equity, efficiency and sustainability, quality, safety, patient-centered orientation, as well as employee engagement.

Building on the research gap regarding data inconsistency in existing PR, this study examines the dimensional indicators of data generated within process metrics. Standardizing data generated through PPC processes facilitates process-level data handling, thereby supporting the further use of the data. This aligns with prior findings from reviewed studies indicating that standardized data guidelines help users make better-informed health decisions [51].

User heterogeneity consists of individual characteristics and contextual design features [37]. Prior research suggests that dashboard design often fails to account for distinct user groups, leading to limited engagement [59]. Integrating contextual factors, health literacy levels, and individual characteristics into the design of PR systems allows for a more targeted presentation of information, thereby enhancing user comprehension and decision-making [37,59,68].

Previous research has shown that demographic variations influence information perception [73]. In line with this evidence, the reviewed studies identify multiple factors associated with users' interactions with PR systems, including age, gender, political orientation, employment status, and region of residence. Beyond demographic variations, health literacy and contextual design features jointly shape how users interpret and use PR data [37].

The reviewed studies have demonstrated that audiovisual and narrative information can positively influence satisfaction measures; contextual features such as storytelling techniques, interactivity, and visual chart elements enhance user understanding [37]. Health literacy plays a critical role in users' ability to interpret PR data. The reviewed studies found that individuals with higher health literacy are better able to comprehend PR information, which may explain their longer visual attention to such content [68]. This suggests that health literacy influences both the depth and quality of patient engagement in PPC processes. To address this, design features such as explanatory narratives [59], temporal trends and interactive functions [57], and appropriate visual chart elements can assist users with varying levels of health literacy in better understanding PR information [68].

This study further notes that within PR, patient satisfaction is primarily affected by postoperative pain levels (higher pain correlates with lower satisfaction) and access to timely appointments [70], consistent with previous findings linking health status to user satisfaction. Meanwhile, demographic factors (age, weight, and prematurity) and surgical factors (type of procedure and disease-related factors) influence surgical mortality [71].

By mapping the reviewed studies to the SPO framework, we illustrate that system data are no longer confined solely to structural indicators; they also play a role in process and outcome indicators. Accordingly, this study identifies website guidelines and dashboard guidelines under structural indicators, data quality and data processes under process indicators, and patient satisfaction and surgical mortality under outcome

XSL•FO
RenderX

indicators. Furthermore, the underlying database sources are displayed within dashboards, helping to address inconsistencies between databases across different systems.

Discussion

Principal Findings

Health technology assessment ensures that medical innovations genuinely improve patient outcomes rather than merely increasing the burden [74]. In this literature review, we synthesized the findings of 25 empirical studies by categorizing them under structural indicators, process indicators, and outcome indicators [20]. Our main findings indicate that structural indicators (website and dashboard guidelines) and process indicators (data quality and data processes) jointly influence user outcomes, such as satisfaction and surgical mortality, with user heterogeneity mediating these effects.

This study adopts a dual perspective of the individual and the system in selection pathways to systematically examine the mechanisms through which information presentation and user interaction operate within PR systems [19]. Existing literature indicates that the presentation of information within information systems not only supports patients in selecting health care providers and using report cards [68] but also influences the quality of user decision-making [55]. Consistent with prior research, the mode of information presentation, the level of aggregation, and report personalization significantly affect the extent of user engagement in decision-making [7,62]. However, this study finds that the operability and data-display characteristics of dashboards play a unique role in supporting individualized decisions [53,61] and that the supplementation of online information can enhance users' understanding of the data [51]. Additionally, the personal and contextual characteristics of health care information sources affect users' adoption in PR systems [37].

Regarding consistency, most studies emphasize the importance of PR dashboards for user decision-making [67], while user health literacy and individual characteristics modulate actual information use [68]. This study further highlights that the standardized design of data and websites can enhance decision-making effectiveness [60]. Unified dashboard guidelines, along with aggregation and search functionalities, can reduce information conflicts and increase user comprehension and trust [59,68].

In terms of heterogeneity, studies have examined the impact of different information types (eg, online reviews, report cards, and dashboards during the pandemic) and diverse user groups (classified by age and health status) on decision-making [54]. Specifically, users differ in their focus on data operability versus information sources [37,61]. Common challenges in PR include missing information, delayed updates, complex formats, lack of standardization, and limited accessibility for users with low health literacy [51,68].

Regarding the user selection pathway, the system is considered a critical avenue for decision-making. Dashboards can mitigate existing issues in PR, such as missing data, delayed updates, and information confusion. As Donabedian [20] noted, while quality indicators are difficult to measure, their establishment contributes to improving actual health care quality. Standardized data guidelines and structured information presentation can support more effective decisions within structural and process indicators, while reducing information asymmetry and enhancing the quality of health services [55].

In summary, by referencing different PR scenarios and information types, this study proposes practical system optimization recommendations and categorizes differences among user groups as user-consciousness heterogeneity, which serves as a moderating variable. It emphasizes the role of standardized guidelines in facilitating the flow of information.

Future Research Agenda

Overview

In the era of digital health, the adoption of PR has evolved. From the perspective of availability, it is possible to examine the innovativeness of technologies in shaping users' perceptions of what they can accomplish [75]. Information systems, as a critical component of structural indicators [20], also play a significant role in enhancing patient awareness [15]. Based on the classification of diverse user groups and the multiple roles involved in the PPC process, incorporating dashboards and other visualization tools into system design can facilitate the adoption of PR information.

Based on the analysis of the studies included in this review, the public's understanding and use of PR remain at a preliminary stage across different population groups [76,77]. To advance the practical use of PR information, future studies should adopt diverse methodological and theoretical approaches to explore how enhancing awareness can foster trust between health care organizations and various demographic groups. Research on this topic should be further expanded along four key dimensions: conceptual understanding, thematic exploration, methodological innovation, and technological development.

Conceptual Agenda

User attitudes are fundamental determinants of behavioral intentions and actual behaviors [17]. Underlying these attitudes are user cognitions, particularly awareness and understanding, which align with levels 1 and 2 of the PAM. While existing research highlights the role of health literacy in PR and its connection to PAM, little attention has been paid to its functional and interactive dimensions [78].

Although system design and information presentation can foster awareness and literacy, the conceptual link between the two remains underexplored. From a systems perspective, perception marks the initial awareness stage; subsequent information processing drives decision-making and system adoption. Information framing, as shown in media studies, shapes comprehension and interpretation [79]. Empirical evidence shows that most patients remain at level 1 of PAM [10]. Enhancing health literacy may help users progress from basic awareness to initial engagement.

XSL•FO
RenderX

Thematic Agenda

This study notes that participants with more severe health conditions tend to seek care more frequently than healthier individuals, making the process of choosing a physician particularly important for them. Notably, significant differences in decision quality are observed among these participants [56]. Previous research on the design of PR websites has largely focused on conditions such as hypertension, diabetes, and infectious diseases [15]. The future PR system should pay greater attention to the needs of patients with complex conditions, such as those with multiple comorbidities.

Moreover, this study points out that contextual factors, health literacy, and individual characteristics affect an individual's adoption. Future research should explore how individuals' emotional states and literacy capacities interact with and interpret PR information. For instance, Shaller [80] proposed a context-based consumer choice framework that emphasizes the integration of users' decision contexts, emotional states, and literacy capacities.

Methodological Agenda

Primary data collection was primarily used in surveys, experiments, and semistructured interviews, whereas qualitative approaches, such as interviews, focus groups, and thematic content analysis, remained less common. Mixed method studies were rare, typically combining expert evaluation with descriptive and thematic analyses.

Methodologically combining natural language processing, causal inference, and experimental designs could advance the understanding of how system-level indicators interact with user heterogeneity, health literacy, and decision-making behaviors in the PR system.

Technological Agenda

In health care organizations, the PPC extends beyond physicians and patients to include family members, friends, caregivers, and other stakeholders. Future system designs that integrate and accommodate these multiple roles could enhance communication between actual users and the system.

Previous studies have indicated that patients with poorer health conditions exhibit more pronounced differences in decision-making [56]. Population segmentation can be categorized into low-health-demand, multiple comorbidities, medically complex, and frail groups [77]. Future research could explore the heterogeneity of responses across these groups in relation to information presentation. For example, web design could incorporate switchable versions to accommodate the health information needs of patients with different health conditions.

Limitations

First, this study retrieved literature through keyword searches within selected databases. This approach may have limited the scope of study selection and potentially excluded relevant studies from other databases.

Second, this study explored PR systems from the perspective of individuals in health care. Even though employees act as individual users of the PR system, broadening the search term to include employees of health care organizations in their dual roles can bring new insights. It can be helpful to explore the interaction between employees in the organization and individuals within the sociotechnical theory. Additionally, given that qualitative research methods are interpretive, potential subjective biases may exist when evaluating study findings.

Conclusions

This study provides the following contributions to the existing literature. First, we synthesized within the SPO framework. By systematically analyzing current research on the use of PR information presentation, this study provides an overview of the website and dashboard dimensions in the structure indicators, data quality and data process in the process indicators, and patient satisfaction and surgical mortality in the outcome indicators. Moreover, this study contributes to the literature by identifying contextual factors, such as health literacy, individual characteristics, political affiliation, employment status, income, and area of residence that influence users' perceptions.

Second, this study builds a connection between data appearing during PPC and the PR systems in the structure quality dimension. Finally, this research outlines future research directions from conceptual, methodological, thematic, and information system perspectives. These insights provide valuable guidance for advancing research in this field, bridging existing gaps, and improving the overall quality of academic inquiry.

Acknowledgments

The authors thank Professor Hongxiu Li for her guidance in conceptualizing the study and providing comments on the manuscript. We also acknowledge the librarians at the University of Turku for their assistance with refining the search strategies. Finally, the authors are grateful to the anonymous reviewers for their comments on the conceptual framing and comments regarding the search strategy.

Funding

LD was financially supported by the Chinese Scholarship Council (grant 202306770017). The funder had no role in the study design, data collection, analysis, interpretation, or manuscript writing.

Data Availability

All extracted data, coding notes, and synthesis outputs generated in this study are publicly available in the Open Science Framework repository at [81]. This includes structured data files (ciw/ris/nbib). Access is unrestricted. Researchers can download and use these materials for noncommercial purposes. During the preparation of this manuscript, generative artificial intelligence (AI; ChatGPT) was used solely for translation and language polishing purposes. All outputs generated by the AI were carefully reviewed and verified by the authors to ensure accuracy and appropriateness. The AI was not involved in study design, data collection, analysis, interpretation, or in writing the scientific content of the manuscript.

Abstract

Background: Kidney transplant recipients require lifelong self-management and follow-up care to maintain allograft function. Mobile health (mHealth) effectively improves self-management behaviors and clinical indicators, consequently enhancing nursing care quality. However, these apps commonly face challenges, including low adoption rates and high discontinuation. Although researchers have explored associated facilitators and barriers from various perspectives, a systematic review of these influencing factors is lacking.

Objective: The objective of this study was to systematically review the influencing factors of mHealth apps in kidney transplant care and to provide evidence for developing targeted interventions.

Methods: The systematic review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, and the protocol was registered in PROSPERO (International Prospective Register of Systematic Reviews, CRD420251091361). PubMed, Web of Science, Embase, MEDLINE, and Chinese databases, including China National Knowledge Infrastructure, Wanfang Data, China Science and Technology Journal Database, and SinoMed, were searched from inception to March 2025. The Mixed Methods Appraisal Tool was used for quality assessment given its suitability for appraising diverse study designs. Influencing factors were identified and coded according to the Consolidated Framework for Implementation Research due to its utility in systematically identifying multilevel implementation factors.

Results: A total of 19 studies (all English-language publications) were included, comprising 9 qualitative studies, 5 mixed methods studies, and 5 quantitative studies, involving 1265 kidney transplant recipients and 34 health care providers. A total of 16 facilitators and 14 barriers were identified and categorized into 5 domains: intervention characteristics, outer setting, inner setting, characteristics of individuals, and process.

Conclusions: The use of mHealth apps in kidney transplant care is influenced by multidimensional factors, with intervention characteristics constituting the most prominent domain, while the outer setting and process domains are relatively underrepresented. Future research should investigate these influencing factors and implement multidimensional strategies to optimize mHealth apps in kidney transplant care.

Introduction

Kidney transplantation is currently the most effective treatment for end-stage renal disease, effectively alleviating clinical symptoms and prolonging patient survival [1,2]. Research indicates that the 1-year survival rate for kidney transplant recipients has reached 97.8%, with the 5-year survival rate at 88.1% and the 10-year survival rate at approximately 60% [2]. However, due to the risks of graft rejection and long-term immunosuppressant use, kidney transplant recipients require lifelong self-management and follow-up care to maintain allograft function [3].

XSL•FO
RenderX

The World Health Organization defines mobile health (mHealth) as "medical and public health practice supported by mobile devices, including mobile phones, patient monitoring devices, personal digital assistants, and other wireless technologies" [4]. Currently, mHealth has been applied across multiple domains of kidney transplant care, including medication adherence reminders [5], weight management [6], and postoperative self-monitoring [7]. Studies demonstrate that mHealth interventions can effectively enhance self-management behaviors, improve treatment compliance, optimize clinical outcomes, and elevate nursing care quality [8-10]. Additionally, mHealth apps can reduce transportation costs and time burdens for recipients, mitigate disease exposure risks, and decrease nosocomial infection rates [11,12]. Nevertheless, challenges persist, including low software adoption rates, high discontinuation rates, and short user retention periods [13]. Existing research has explored facilitators and barriers from the perspectives of device functionality, user experience, and management protocols [11,14,15], yet it lacks a comprehensive synthesis of these influencing factors.

The Consolidated Framework for Implementation Research (CFIR) was developed by Damschroder et al [16]. As a widely recognized and extensively cited framework in implementation science, it is applicable to all implementation stages, including preimplementation, active implementation, and sustainability [17]. This theoretical framework encompasses 5 domains (intervention characteristics, outer setting, inner setting, characteristics of individuals, and process) and 39 underlying constructs. It enables systematic identification of multidimensional and multilevel influences during intervention implementation processes. Guided by the CFIR framework, this study aims to systematically evaluate the influencing factors of mHealth apps in kidney transplant care, identify key facilitators and barriers, and provide evidence-based recommendations for developing targeted intervention strategies.

Methods

Search Strategy

A comprehensive computerized search was conducted across 8 English and Chinese databases: PubMed, Web of Science, Embase, MEDLINE, China National Knowledge Infrastructure, Wanfang Data, China Science and Technology Journal Database, and SinoMed, covering literature from inception to March 2025. The search focused on identifying influencing factors of mHealth apps in kidney transplant care. Search terms were structured using a combination of Medical Subject Headings and keywords. English search terms: “kidney transplant* OR renal transplant* OR kidney graft* OR renal graft* OR kidney allograft* OR renal allograft* OR transplanted kidney OR kidney homotransplantation* OR renal homotransplantation*,” “tele?medicine OR telemedicine OR mobile health OR m?Health OR mHealth OR tele?health OR telehealth OR e?Health OR eHealth OR tele?rehabilitation OR telerehabilitation OR tele?monitoring OR telemonitoring OR video?conferencing OR videoconferencing OR online OR technolog* OR mobile information technolog* OR electronic OR digital OR Internet-based OR app* OR mobile app* OR software OR wearable electronic device* OR WeChat OR platform* OR smartphone*,” “motivator* OR motivation* OR enabler* OR promote OR drive OR encourage OR facilitator* OR barrier* OR obstacle* OR challenge* OR difficult* OR issue* OR influencing factor* OR impact factor* OR relative factor* OR experience* OR perception* OR opinion* OR feeling* OR need* OR attitude*.” The search strategy was adjusted according to different databases. Key adaptations included the use of database-specific subject headings (eg, Medical Subject Headings in PubMed, Emtree in Embase) and adjustments in field tags (eg, [Title/Abstract] in PubMed; ab, kw, ti in Embase). Taking the PubMed database as an example, the search query is provided in Multimedia Appendix 1. To ensure comprehensive reporting, the PRISMA checklist is provided in Checklist 1.

Inclusion and Exclusion Criteria

Inclusion criteria:

1. Study subjects: kidney transplant recipients and stakeholders involved in mHealth apps (eg, health care providers, caregivers);
2. Study content: facilitators, barriers, or influencing factors related to the application of mHealth, with mHealth functions relevant to transplant care;
3. Study design: qualitative, quantitative, or mixed methods studies.

Exclusion criteria:

1. Conference abstracts, unpublished data, or inaccessible full texts;
2. Secondary literature (reviews, systematic reviews) or duplicate publications;
3. Non-Chinese or non-English publications.

Literature Screening and Data Extraction

Two researchers trained in evidence-based nursing systematically and independently conducted the screening process using predefined protocols. Duplicates were removed using NoteExpress 3.8 software. Initial exclusion was performed through title and abstract screening, followed by full-text assessment. Discrepancies were resolved through consultation with a third researcher.

Data extraction was independently performed by 2 researchers. To ensure accuracy and completeness, all extracted data were cross-checked against the original full-text articles by a third researcher. Any disagreements or uncertainties were resolved through team discussion. The data extraction form was independently developed by the researchers, subsequently refined through research team discussions, and ultimately finalized for implementation. Extracted data included authors, publication year, country, study design, sample size, study population, sampling method, data collection methods or tools, names and functions of mHealth apps, and Mixed Methods Appraisal Tool (MMAT) rating.

Quality Assessment

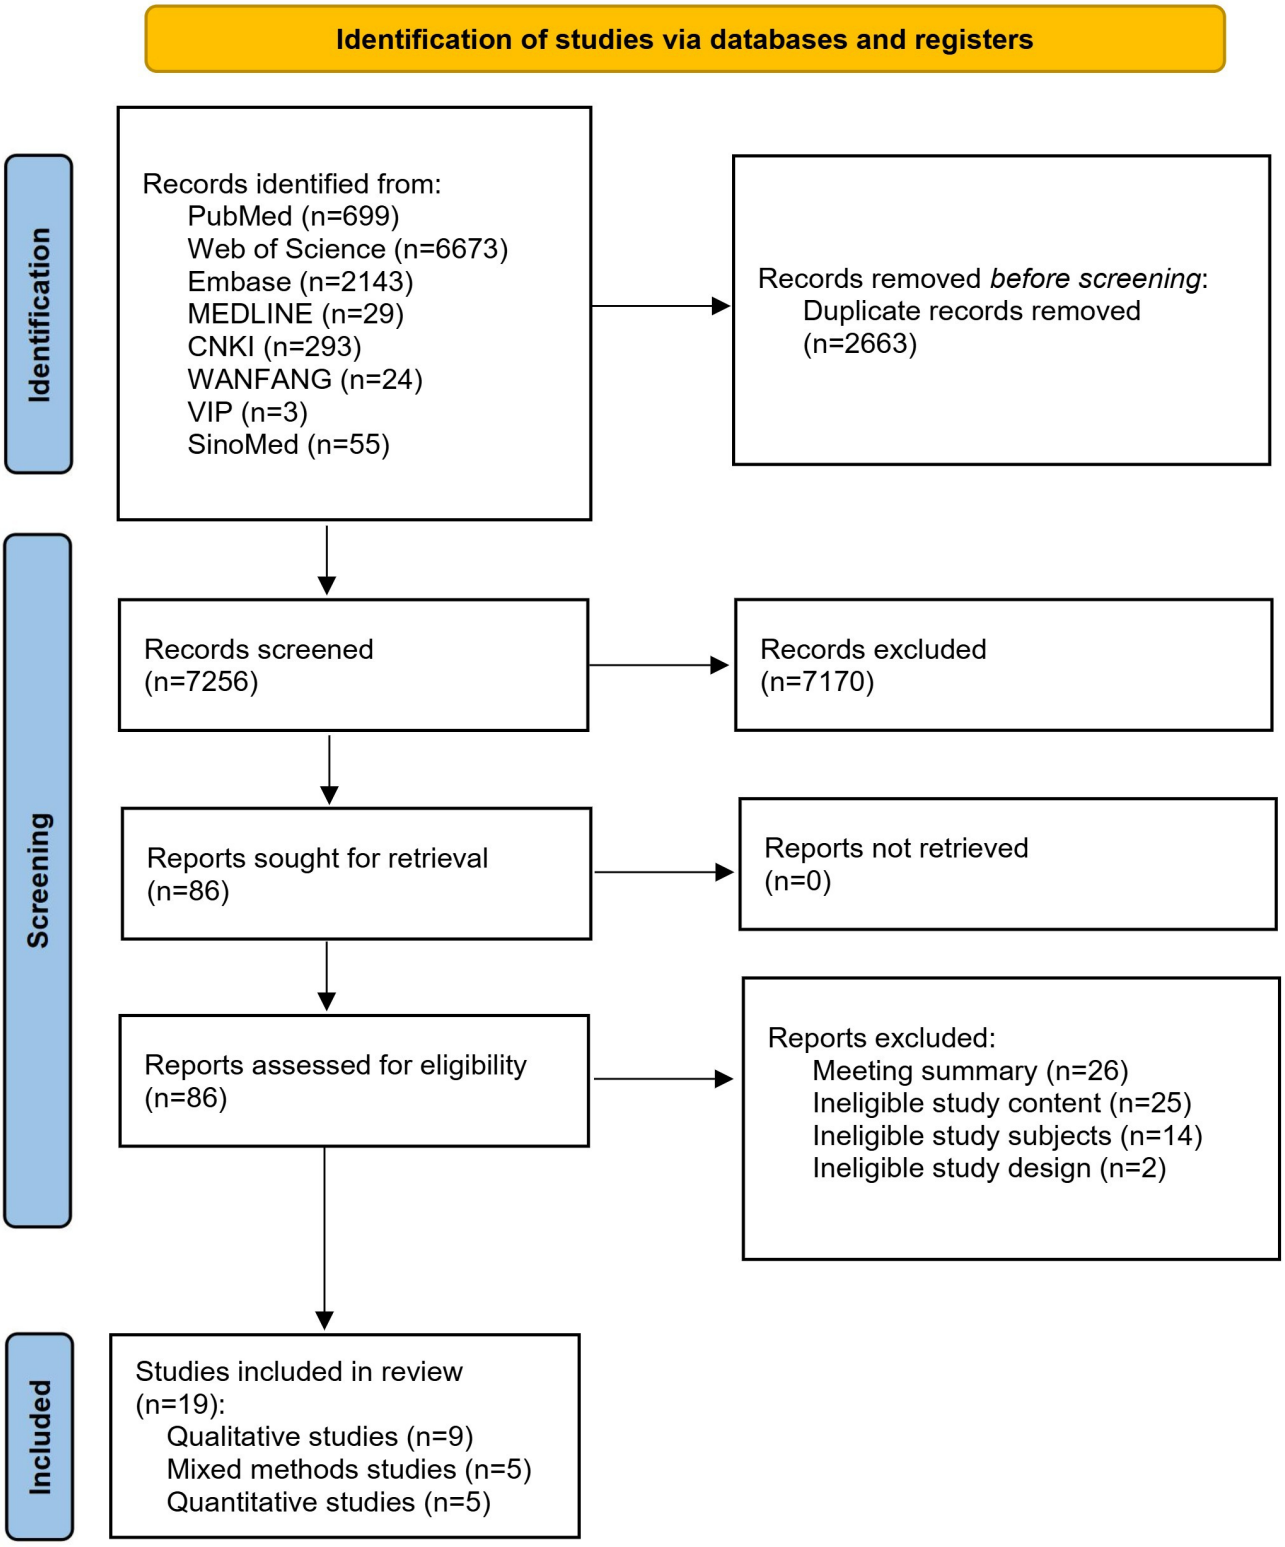
Given the heterogeneity of study designs, 2 researchers independently evaluated the methodological quality of included studies using the MMAT, 2018 edition [18]. Discrepancies were

XSL•FO
RenderX

resolved through consensus discussions with a third researcher. The MMAT was developed by a research team at McGill University, Canada, in 2006 and updated in 2018 [18]. It is designed to appraise the quality of qualitative, quantitative, and mixed methods research studies. The tool comprises 2 screening questions and 15 appraisal criteria. After addressing the 2 screening questions, the appropriate study category is selected for appraisal. Qualitative and quantitative studies require the evaluation of 5 criteria each. Each item was rated as "Yes," "No," or "Unclear." A rating of 5***** or 100% indicates fulfillment of all quality criteria, 4**** or 80% indicates fulfillment of 80% of the criteria, and so forth. For mixed methods studies, all 15 criteria (instead of 5) must be appraised. The overall quality rating adheres to the principle that the quality of the whole is determined by its weakest component.

Data Synthesis

This study conducted data analysis anchored in the 5 domains of the CFIR [16] and adhered to the Joanna Briggs Institute guidelines [19] for mixed methods systematic reviews. The analytical process involved: (1) integrating findings from distinct research methodologies separately; (2) translating quantitatively synthesized results into qualitative narratives and merging them with qualitatively synthesized evidence; and (3) finally establishing integration categories, inducing thematic patterns, and deriving consolidated outcomes.



Results

Literature Search Results

A total of 9919 relevant studies were retrieved from the databases. After removing duplicates, 7256 studies remained. Following preliminary screening, 86 studies were retained. Ultimately, 19 studies were included after full-text review. The literature selection process and the list of included studies are presented in Figure 1 and Table 1, respectively.

[a]The Mixed Methods Appraisal Tool (MMAT) uses the following rating system: 5***** indicates full compliance with 100% of the quality assessment criteria, 4**** corresponds to meeting 80% of the criteria, 3*** signifies adherence to 60%, 2** represents 40%, and 1* denotes meeting 20% of the standards.

Characteristics of the Included Studies

All included studies were published in English, with publication years spanning from 2009 to 2025. These studies originated from 8 countries, with the United States contributing the highest number of publications [11,14,26,28,30,33,35]. The research designs comprised 9 qualitative studies, 5 mixed methods studies, and 5 quantitative studies. The study populations included 1265 kidney transplant recipients and 34 health care professionals. The basic characteristics of the included studies are summarized in Table 1.

Quality Assessment of the Included Studies

A total of 9 qualitative studies exhibited high overall quality, each scoring 5*****. Among the 5 quantitative studies, 1 [14] did not clearly describe whether the sampling method was appropriate for addressing the research questions, another [14] failed to specify the representativeness of the sample relative to the target population, 1 [30] lacked clarity on the risk of nonresponse bias, 1 [26] did not explicitly address confounding factors in the study design or analysis, and 1 [31] did not confirm whether interventions were implemented as intended during the research period. The 5 mixed methods studies demonstrated lower overall quality: 4 studies [21,23,25,35] did not justify the rationale for adopting a mixed methods design to address the research questions, 4 [21,23,25,35] inadequately explained the integration of qualitative and quantitative results, 4 [21,23,25,35] insufficiently addressed discrepancies or heterogeneity between quantitative and qualitative findings, and 3 [21,25,35] failed to cohesively integrate distinct components of their research. The MMAT scores for all included studies are presented in Table 1.

Factors Influencing the Application of mHealth in Kidney Transplant Care

This study identified 16 facilitators and 14 barriers influencing the application of mHealth in kidney transplant care. Based on the CFIR, both facilitators and barriers were categorized into 5 domains, as detailed in Table 2.

XSL•FO
RenderX

Table . Factors influencing the application of mHealth in kidney transplant care.

Category	Facilitators	Barriers
Intervention characteristics	Evidence strength and quality: • Authoritative content [21,22] Relative advantage: • Convenience and flexibility (time-, effort-, and cost-saving) [11,21,22,24,27,29,35] • Reduced infection risk [11,22,24,31] • Improved comfort [11] Design quality and packaging: • User-friendly design (easy to understand, operate, and humane) [22,28,29,35] • Personalized design [15,22,28]	Evidence strength and quality: • Lack of authoritative content [34] Complexity: • Communication/interaction limitations [11,20,22,24,27] • Privacy/security risks [22,23] • Negative online content [22] Design quality and packaging: • Poor design (complex operation, unclear content, inappropriate sizing) [15,21,25,26,28,30,34,35]
Outer setting	Patient needs and resources: • No additional costs [33]	Patient needs and resources: • External environmental interference [23,24] • Extra costs [30]
Inner setting	Networks and communications: • Professional support [23,32] • Peer support [15,20,21]	Structural characteristics: • Unstable network/equipment [24] Networks and communications: • Lack of multidisciplinary team support [24] Compatibility: • Time conflicts [20] • Conflicts with user habits [25,35]
Characteristics of individuals	Knowledge and beliefs about the intervention: • mHealth literacy [14,21] Self-efficacy: • Self-efficacy [23,32] Individual identification with organization: • Perceived benefits [20,21,29,31,34] Other personal attributes: • Intrinsic motivation (curiosity, altruism, responsibility) [20,23,26,29] • Demographics (race) [33]	Knowledge and beliefs about the intervention: • Lack of mHealth literacy [21,22,24,30] Other personal attributes: • Poor physical condition [24,30]
Process	Engaging: • Training on device functions [15,30] • Executing: SMS/email reminders [15]	Engaging: • Lack of training on device functions [27]

Facilitators

Intervention Characteristics

Intervention characteristics are critical predictors of the successful application of interventions. The authoritative content of mHealth platforms can effectively alleviate user concerns and enhance their confidence in using these tools (“These sorts of webpages would need to carry some sort of certification so that we, the individuals, know we are getting professional advice as opposed to some blogger.” [21]). Compared to traditional face-to-face care models, mHealth offers advantages such as convenience and flexibility ("Now [with telehealth] it’s very convenient for me because I can even take calls while I’m working in the office or whether I’m home.” [24]; “I think video visits might actually help with compliance, especially for socioeconomically disadvantaged or older patients that don’t drive.” [11]), reduced infection risks (“I prefer [eHealth], I’m so scared of COVID. I don’t want to get sick, so I’m happy to do the online, video calls and things like that.” [22]), and enhanced comfort ("I was comfortable sharing personal information since, like I said, I’m in my own house. So, it’s easier to actually sometimes talk to the doctor when you’re at home.” [11]). These advantages serve as key motivators for users to persist with mHealth. Additionally, some users emphasized that designs featuring clear language (“Level of language, get the language to a layperson’s point of view. Doctors would understand what it was and so would the person who is reading it… [or else] they would go away from it.” [22]), ease of use (“You know, it’s user-friendly, going to it isn’t complicated. […] It’s pretty easy to figure out. […] You quickly get the hang of it.” [29]), human-centered care ("The nurse came across as very professional […] as someone who cares about your health […] Me, I found her to be warm. Even though it was a video, it’s. it’s not. it can seem a little cold, but it’s someone who’s talking to us, deep down.” [29]), and personalization (“If something was going wrong, yes, rather

XSL•FO
RenderX

than just getting an automatic message that was just saying 'keep going for your goals!' and you're like 'well I haven't been on 3 weeks'. I would prefer something more personable." [15]) would make mobile devices more appealing.

Outer Setting

Users' needs and resource accessibility are critical external factors determining the adoption of mHealth. If mHealth solutions require no additional financial burden on users, their willingness to adopt is significantly enhanced (79% of users endorsed this view [15]).

Inner Setting

Multidisciplinary collaboration and communication are central to the successful application of mHealth. Regular communication and professional guidance from health care providers motivate patients to adhere to care plans ("I think, um, it will be helpful [for my adherence] because I spoke to my physio quite a bit. She used to call me and, um, she would—I'd tell her sometimes—and she'd be like, you know what, you know keep busy, do this and do that and stuff like that. She would give me advice." [23]). Some patients highlighted that sharing experiences and emotional support with peers fosters a sense of connection, alleviates loneliness, and strengthens their resolve to persist ("When I had a question, I could send a text and they [peers] responded right away, right away. So it was really good, you know." [20]; "Being together, that always motivates more than when we're alone." [20]).

Characteristics of Individuals

Individual characteristics are pivotal factors influencing the adoption of mHealth. An individual's mHealth literacy directly impacts the effectiveness of mHealth use. Those with higher mHealth literacy exhibit stronger technical proficiency, information evaluation skills, and greater acceptance of mHealth ("Factors associated with mHealth use include higher eHEALS scores and higher education, with odds ratios [ORs] of 1.21, 95% CI 1.06 - 1.38 and 7.78, 95% CI 2.19 - 27.7, respectively." [21]). Self-efficacy reinforces individuals' confidence in using mHealth ("I was just [pause] following the program through. Um, but that was just my personal thing, just because I have—you know—I have the knowledge and the confidence to do my own thing." [23]). Some patients noted that using mHealth offers benefits such as enhanced self-management ("Patient portal containing access to all of the above suggestions in one unified system, where my blood results, education, and app monitoring can all be tracked by myself at a click of a button. This will ultimately increase self-management among patients and allow for more detailed 'healthier life' conversations with health professionals." [21]) and disease-related knowledge ("All important things are included [in this platform]: where I have to take precautions, what I need to do. Everything is well explained." [34]). Intrinsic motivations such as curiosity ("It was out of curiosity. I'm naturally curious. So I really wanted to see how far it went..." [29]), altruism ("Well, I did it for you… it was to help you out, because you help me in a way. Your aim… the reason that you're doing this, I imagine, is to help me." [29]), and a sense of responsibility ("So, my point there is in terms of being accountable to something. Even though it's not a human being, you are being accountable to a system…" [23]) drive patients to persist. Additionally, race influences attitudes toward mHealth ("Black individuals exhibited more positive attitudes than White individuals [mean 4.25, SD 0.88 vs mean 3.76, SD 1.07; *P*=.02]." [33]).

Process

Supportive strategies during the implementation process are critical factors for ensuring the sustainability of mHealth interventions. Participants emphasized that receiving training prior to using mHealth builds operational confidence and foundational knowledge, reducing adherence decline or misuse caused by technical unfamiliarity ("I think the first steps you need it face-to-face to start with… then you can do it on your own at home." [15]). Additionally, reminder features in devices play a role in encouraging adherence ("If there's a 12-week program, what would be useful would be a text reminder or an email reminder." [15]).

Barriers

Intervention Characteristics

Inherent limitations of mHealth may hinder its application. When mHealth platforms provide content lacking official certification or conflicting with clinical recommendations, patients may question its reliability ("My doctor advised taking tacrolimus between meals, but the platform instructed me to take it 1 h before or 1.5 - 2 h after meals." [34]). User-unfriendly designs, such as overly lengthy interfaces ("Instead of scrolling through all the different things because that's [the excessively long pages] what drives me crazy with apps." [28]) or bulky devices ("The mobile health device [MEMS] is too large to carry around or travel with." [35]), foster resistance and reduce willingness to continue use. The virtual nature of mHealth limits nonverbal interaction ("I like face - to - face because my doctor tells me if he thinks that I'm putting on weight or I'm not doing the right thing." [24]; "Telehealth can't take your blood pressure… and they can't take a look at your wound or check you or examine you or weigh you. Sitting down, I could have gained 25 kg, but no one would know." [22]). Participants also expressed concerns about privacy breaches ("Hearing about hackers, and you don't want your records and things like that when you subscribe to these sites and things. You're putting yourself at risk and your whole medical history at risk. There are things in my medical history that I don't want people to know." [22]). Additionally, exposure to negative online content during use imposed psychological burdens ("Sometimes it got a bit depressing… it was like really a bit of a mental burden as well, just like constantly getting notifications about this message and that message and someone dying. Sometimes when you're in a difficult headspace, it can be really hard to be confronted with that." [22]).

Outer Setting

The inability of external resources to meet user needs can hinder the application of mHealth. The use of mHealth may be interfered with by external environments, thereby negatively impacting its effectiveness ("Because I think face - to - face, you're in the room, you're kind of in the moment, with

XSL•FO
RenderX

telehealth, you can get distracted. You can get a bit confused" [24]; "If you're doing telehealth, then you might miss something like the dog barking in the background or the kids screaming." [24]). Additionally, participants noted that additional costs associated with mHealth reduce willingness to use such services, as these expenses impose financial burdens [30].

Inner Setting

Structural barriers within mHealth systems represent core constraints affecting their application. Participants reported that unstable network equipment compromises their user experience ("Like when the internet's down, when it's slow, which it is often at my place. Even my phones aren't that good. The landline, even… [Whether I can use mHealth normally] just depends on if everything's working." [24]). Compared to traditional face-to-face clinical models, mHealth struggles to ensure patients receive simultaneous support from multidisciplinary teams ("When I do telehealth, you become sort of like missing out on all the other aspects of allied health." [24]; "Nurses are a part of my training team as a nephrologist, and I feel that connect with the nurses is completely cut off [with telehealth]." [24]). Some mHealth services require advance appointments, yet users often fail to attend due to personal scheduling conflicts ("The schedule was a problem, it [mHealth] just didn't work for me at all." [20]). Additionally, some participants expressed difficulty adapting to new self-management models via mHealth due to entrenched habits (eg, medication or exercise routines) ("When the situation differs from my routine, it [mHealth] gets in the way and is hard to accommodate." [35]).

Characteristics of Individuals

User characteristics directly influence the effectiveness of mHealth adoption. For users with limited mHealth literacy, such as older adults or those with lower education levels, technical challenges encountered during mHealth use often lead to abandonment of the technology ("Not being a tech-savvy person, I find trying to navigate and download apps very stressful." [21]; "The problem is that when you get older, it's harder for you to understand and pick up if you are not constantly on the computer. I don't use it much." [22]). Additionally, users' physical conditions impact mHealth utilization, with patients reporting that visual impairments and limited hand dexterity hinder their engagement with mHealth platforms [30].

Process

Insufficient training on mHealth use results in ongoing challenges for users during later implementation ("I would say it is incredibly complex in the sense that when the doctor says it, it sounds logical and totally correct, but when you come home, then what? Because then if I make a slight deviation, is it the same, or is it a new situation?" [27]).

Discussion

Principal Findings

An important finding of this review is that, despite the comprehensive 5-domain analytical structure offered by CFIR, a notable imbalance exists in the focus of existing research. Influencing factors are predominantly concentrated within the domains of intervention characteristics, characteristics of individuals, and the inner setting. In contrast, factors related to the outer setting and process domains, such as policy support and stakeholder collaboration, remain significantly underrepresented.

This pattern may be explained by 2 primary reasons. First, the majority of included primary studies focused on technology acceptance and user experience. Their participants were predominantly kidney transplant recipients, who are generally not in a position to provide in-depth perspectives on macrolevel issues such as health care policies, regional resource distribution, or multistakeholder coordination. Second, evidence concerning the complex factors of the outer setting and process is more likely to reside in what is known as "grey literature," including project evaluation reports, dissertations, or specific policy studies, which was not captured by our predefined academic database search.

Optimizing mHealth Design and Performance to Enhance User Experience

The findings of this study indicate that the application of mHealth is closely tied to its inherent characteristics. The domain of intervention characteristics contains the highest number of influencing factors, which aligns with prior studies [36]. For successful integration into the workflow, the intervention needs to align with the prevailing value system of key stakeholders.

After enduring the hardships of dialysis, most kidney transplant recipients highly value their transplanted kidney and exhibit heightened caution in health management [37]. The authoritative nature of mHealth content helps build trust in the platform and strengthens users' confidence. Studies [38,39] reveal that approximately 30% of kidney disease–related apps on the market lack clinically validated content, posing risks such as incorrect medication advice or deviations from the latest guidelines, which significantly undermine patient trust and hinder sustained use. Therefore, mHealth development should be grounded in evidence-based medicine and clinical guidelines, with regular updates. Prior to releasing content, experts in kidney transplantation should review materials to ensure scientific rigor. The design and performance of mHealth directly impact user experience. Kidney transplant recipients vary widely in age, educational background, and health literacy. With global population aging, the proportion of older recipients is rising [40,41]. Older users may struggle with complex medical terminology or operational workflows due to cognitive decline or limited technical adaptability. Thus, mHealth design should prioritize accessibility, using plain language and intuitive interfaces to lower barriers and improve acceptance. Kidney transplant recipients commonly face psychological challenges such as anxiety and depression [42]. Research [43] shows that integrating emotional support features into mHealth can alleviate patient anxiety and enhance long-term engagement. Additionally, lifelong self-management is essential for recipients. If apps lack personalized feedback, users may abandon them due to perceived low value. To address this, personalized features such as achievement badges to motivate

XSL•FO
RenderX

users or tailored notifications to boost engagement could be incorporated.

mHealth is a double-edged sword. While offering advantages such as convenience, flexibility, and reduced infection risks, it also has limitations, including security risks, hindered clinician-patient interaction, and exposure to negative content, which diminish user willingness to adopt it. Studies [44,45] highlight widespread patient concerns about data security in mHealth, particularly for long-term conditions such as kidney transplantation, where sensitivity to privacy breaches is heightened [46]. Thus, health care providers should strengthen awareness of data protection and regularly debug and update software to prevent cyberattacks. Beyond safeguarding privacy, stakeholders could enhance user experience by improving content moderation and integrating wearable devices to mitigate mHealth's shortcomings.

Strengthening Multidimensional Support Systems to Improve Resource Accessibility

The findings of this study reveal that the adoption of mHealth is influenced by multiple internal and external factors. Additionally, outer setting factors are relatively few among all influencing factors. This aligns with a prior scoping review by Rangachari et al [47].

Peer, professional, and multidisciplinary team support significantly impact kidney transplant recipients' engagement with mHealth, suggesting that health care providers should establish multidimensional support strategies. Peer support fosters emotional resonance and experience sharing among patients with similar backgrounds, reducing loneliness and enhancing willingness to use mHealth. Therefore, integrating peer communication modules into mHealth platforms is recommended; however, medical advice or medication sharing should be explicitly prohibited to ensure compliance. Guidance and feedback from health care professionals can alleviate patients' technological apprehensions. Studies [48] indicate that lack of clinician support is a barrier to mHealth adoption, aligning with this study's conclusions. Thus, remote follow-ups by professionals to guide patients, alongside accessible channels for reporting issues, are proposed to build trust and sustain engagement. The development and implementation of mHealth require collaboration and guidance from multidisciplinary teams. Without such support, unresolved technical or medical challenges during use may lead to unmet needs and reduced compliance [49]. Future initiatives should establish mHealth teams comprising physicians, specialist nurses, rehabilitation therapists, and IT engineers to optimize application effectiveness. Additionally, internal and external factors such as additional costs and unstable network infrastructure hinder mHealth accessibility. Expenses related to data consumption or smart device procurement may impose financial burdens on patients. Research [50] reports that 23% of patients in resource-limited settings abandon mHealth due to unaffordable device costs. To address this, governments and hospitals should establish subsidy mechanisms to reduce user expenses. Developing low-data or offline versions of mHealth platforms could simultaneously mitigate data consumption and connectivity issues, thereby improving resource accessibility.

Stimulating Individuals' Intrinsic Motivation, Enhancing Perceived Benefits, and eHealth Literacy

The findings of this study indicate that the application of mHealth is influenced by individual characteristics, such as intrinsic motivation and perceived benefits. Notably, factors at the individual level are relatively numerous among all identified influences, which is similar to the findings of the previous review by Neil-Sztramko et al [51].

Intrinsic motivation refers to an individual's inherent tendency to seek novel challenges, develop competencies, and engage in exploratory learning driven by personal interest or enjoyment of the activity itself, which is more likely to sustain long-term behavioral adherence [52]. For users lacking intrinsic motivation, motivational interviewing techniques such as goal setting, reflective practices, verbal persuasion, and action planning can be used to initiate and reinforce their motivation, thereby promoting behavioral persistence [53]. This study also reveals that perceived benefits can enhance users' sustained engagement with mHealth. Research demonstrates [54] that perceived benefits indirectly influence behavioral adoption through the mediating role of self-efficacy. Health care professionals should acknowledge and encourage users' perceived benefits, reinforce positive experiences through multiple channels, and further enhance self-efficacy to facilitate long-term mHealth adherence. When users fail to perceive benefits, their behavioral persistence may be compromised [55]. In such cases, practitioners should promptly adjust intervention strategies through telephone follow-ups, video demonstrations, and other methods to strengthen perceived benefits and improve self-efficacy. Furthermore, this study identifies that insufficient eHealth literacy constitutes a barrier to mHealth utilization. Some users experience difficulties in independently operating smartphones or applications due to age, educational background, or limited digital skills, leading to resistance or abandonment of mHealth tools. Therefore, beyond simplifying the usability of mHealth systems during development, health care providers should strengthen preimplementation training on device functionalities. Personalized training programs tailored to users' varying health literacy levels should be developed to compensate for eHealth literacy deficiencies.

Limitations

Limitations of the Included Studies

The inclusion of studies with varied methodological quality, while ensuring comprehensive analysis, may have introduced potential bias. The lower overall ratings for some mixed methods studies primarily reflected limitations in their integrative components rather than in the qualitative or quantitative parts from which data were extracted. Future studies should be more methodologically rigorous and better designed to enhance the overall quality and reliability of the evidence base in this field. All included studies were published in English and conducted in developed countries, introducing both linguistic and geographic bias. Consequently, the findings primarily reflect contexts with abundant resources and well-developed digital infrastructure, which may limit the generalizability of the conclusions. It is imperative to conduct research focusing on developing countries and non–English-speaking regions. No

XSL•FO
RenderX

subgroup analysis was conducted for key variables (eg, age, mHealth type). This was primarily because most studies did not stratify outcomes by age or treated mHealth as a broad concept without specifying functional types, hindering the extraction of subgroup-specific factors. Publication bias was not formally assessed. Due to the nature of this review, which included diverse study designs and focused on synthesizing influencing factors rather than quantifying a single effect size, standard graphical tests for publication bias (eg, funnel plots) were not applicable or were not conducted.

Limitations of the Review Methodology

The transformation from quantitative evidence to qualitative descriptions may have resulted in inevitable information loss. The lack of evaluation of literature in languages other than Chinese and English may have led to the omission of some influencing factors. Although 2 researchers independently performed literature screening and data extraction to minimize subjective bias, the results of consistency testing were not reported. This shortcoming represents a methodological limitation regarding the transparency of the selection process.

Conclusion

Guided by the CFIR, this study systematically analyzed the influencing factors of mHealth apps in kidney transplant care, which were categorized into 5 domains: intervention characteristics, outer setting, inner setting, characteristics of individuals, and process. The findings revealed that intervention characteristics constituted the most prominent influencing domain, while the outer setting and process demonstrated relatively fewer associated elements. Future research should further investigate the impact of these identified factors on mHealth apps in kidney transplant care. Additionally, health care providers should adopt multidimensional strategies targeting these determinants to optimize mHealth integration into clinical practice.

Acknowledgments

The authors express their sincere gratitude to all authors whose papers were included in this meta-synthesis.

Data Availability

The data are from published academic research literature and can be found in the original article.

Abstract

Background: There is increasing research on machine learning in predicting venous thromboembolism after joint arthroplasty, but the quality and clinical applicability of these models remain uncertain.

Objective: This systematic review aims to evaluate the predictive performance and methodological quality of machine learning models for venous thromboembolism risk after joint replacement surgery.

Methods: Web of Science, Embase, Scopus, CNKI, Wanfang, Vipro, and PubMed were searched until December 15, 2024. The risk of bias and applicability were evaluated using the PROBAST (Prediction Model Risk of Bias Assessment Tool) checklist. A qualitative comprehensive analysis was conducted to extract and describe the data related to the model's characteristics and performance.

Results: This review encompassed 34 prediction models from 9 studies. The most frequently used machine learning models were extreme gradient boosting and logistic regression. The results showed that all studies had significant heterogeneity and high risk of bias. Although some models reported nearly flawless area under the curve (>0.9), they lacked external validation and may have overfitted. The models tested on large external datasets demonstrated more conservative performance.

Conclusions: The predictive performance of machine learning models varied greatly. Although the reported area under the curve values indicated that some models have good discriminative ability, this performance varied greatly and was inconsistent among the included studies. These models have a high risk of bias, and it is necessary to take this into account when they are used in clinical practice. Future studies should adopt a prospective study design, ensure appropriate data handling, and use external validation to improve model robustness and applicability.

joint arthroplasty; venous thromboembolism; machine learning; meta-analysis; systematic review

Introduction

Joint replacement surgery is one of the main treatment methods for severe joint injuries, which can alleviate patients' pain and improve joint function [1,2]. In recent years, due to the aging population and the advancement of medical technology, more and more patients have undergone joint replacement surgery. But surgical complications are a big risk that can change how well joint replacement surgery works. Venous thromboembolism (VTE), including deep vein thrombosis (DVT) and pulmonary embolism (PE), is a serious postoperative complication that significantly affects the prognosis of patients [3,4].

Studies have shown that for patients who did not receive preventive medication before undergoing major orthopedic surgeries, such as total hip arthroplasty (THA) or total knee arthroplasty (TKA), the incidence of postoperative VTE can be as high as 26.6% to 60.8% [5]. Asymptomatic VTE may not present any obvious clinical symptoms but can be detected through ultrasound examination or other diagnostic techniques. Some patients with VTE may experience discomfort and swelling in the affected limb, and their functional condition may be poor, which may even affect their postoperative recovery [6,7]. Furthermore, PE also has a significant impact on patients'

XSL•FO
RenderX

lives and prognosis. Studies have shown that up to 34% of postoperative deaths may be caused by PE [8,9].

Being able to accurately identify which patients are at high risk of VTE is of great significance for the prognosis of these patients. Accurate predictions can maximize the effectiveness of anticoagulant drugs and reduce side effects, such as bleeding [10,11]. Through the analysis of vast volumes of high-dimensional data, machine learning (ML) may uncover hidden patterns and intricate nonlinear relationships, aiding illness early warning [12,13]. In recent studies, ML models have been developed to predict the incidence of postoperative VTE. The most commonly used algorithms include extreme gradient boosting (XGB), random forest (RF), and support vector machine (SVM) [14]. In the prediction of VTE, ML technology exhibits many advantages. For instance, compared to traditional approaches, it can provide superior predictions by combining several types of information, such as imaging data, biomarkers, and clinical data [15,16]. Although these studies provide new methods for the field, there are some uncertainties in the consistency and reliability of the results in the existing literature owing to the single data source, small sample size, and the model's limited capacity for generalization. In addition, there are justified concerns about bias, explainability, and applicability [17]. Therefore, this study aimed to assess the effectiveness and methodological quality of ML models in predicting VTE following joint replacement through a systematic review in order to provide evidence-based support for their clinical application, identify current research gaps, and offer guidance for future high-quality studies.

Methods

Registration of the Study

This study adheres to PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; Checklist 1) guidelines for conducting systematic reviews [18]. The study protocol was registered on PROSPERO (International Prospective Register of Systematic Reviews; registration number: CRD42024625842).

Data Sources and Search Strategy

A comprehensive search was conducted in both Chinese and English databases, including Web of Science, Embase, Scopus, CNKI, Wanfang, Vipro, and PubMed, from the time of their formation until December 15, 2024. The following search terms were applied: "joint arthroplasty," "venous thromboembolism," "machine learning," "risk prediction," "prediction models," and their synonyms and variant terms. A manual search of reference lists containing studies to find related publications was conducted. For detailed search strategies, see Multimedia Appendix 1, which includes keyword combinations and database settings.

Inclusion or Exclusion Criteria

The following were the inclusion criteria: (1) studies on patients after joint replacement; (2) observational studies, case-control studies, cohort studies, and randomized controlled trials; (3) postoperative VTE risk was predicted using an ML model; (4) studies that provide performance evaluation metrics (eg, accuracy, sensitivity, specificity, area under the curve [AUC]) for the model and give clear statistical analysis results; and (5) studies published in English or Chinese.

The following were the exclusion criteria: (1) review articles, case reports, opinion pieces, commentaries, conference abstracts, and other nonoriginal research; (2) studies that do not mention particular kinds of ML models or algorithms; (3) animal experiments, simulation studies, and other nonclinical research; and (4) studies for which the entire text was not retrievable.

Study Selection and Data Synthesis

The retrieved results were imported into EndNote 21, and duplicates were eliminated. Two researchers trained in systematic evaluation techniques independently conducted the study selection process based on preestablished eligibility criteria. First, the titles and abstracts of the literature were screened, and the studies failing to meet the eligibility criteria were initially excluded. Second, it was filtered through full-text reading, and if 2 researchers disagreed, a third researcher stepped in to reach an agreement.

The data extraction process was also performed independently by 2 researchers following CHARMS (Critical Appraisal and Data Extraction for Systematic Reviews of Prediction) guidelines [19], and a third researcher settled any discrepancies. There are 2 groups into which the data taken from the chosen studies are separated: (1) basic information: author, year of publication, country, study design, participants, data source, clinical outcome, and sample size and (2) model information: missing data handling, candidate predictors, screening variable methods, prediction timepoint, prediction horizon, model development, internal verification, external verification, model performance, number of variates, calibration, and method of visualization.

Risk of Bias Assessment

The included studies' applicability and bias risk were evaluated using the PROBAST (Prediction Model Risk of Bias Assessment Tool) tool. The assessment has 20 questions, including 4 basic areas: participants, predictors, outcomes, and analysis. There are answers to the questions in each domain: "yes/probably" (low risk of bias), "no/probably not" (high risk of bias), and "no information" (unclear). A domain was deemed to have a high risk of bias if its answer contained "no/probably not." If every question had a "yes/probably yes" response, the domain was deemed to have a low risk of bias. When there is "no information," it is deemed to be highly biased if it cannot be explained by the original or additional material. If each domain was considered low risk, then the total bias risk was considered low. Furthermore, the total risk of bias was deemed high if any domains were deemed to be at high risk.

The bias risk in each model is assessed independently by 2 researchers, and if there are differences, they will be discussed to reach an agreement. Due to the majority of research using various models or having several outcomes, the bias risk is evaluated independently for each model and outcome. Finally, since there are no differences in the risk of bias between models in a single study, each study only shows the result once.

Results

Results of Literature Screening

The study selection process is detailed in the PRISMA flow diagram (Figure 1). A total of 4344 records were initially identified from 6 electronic databases (PubMed, n=2001; Embase, n=661; Web of Science, n=1415; Wanfang, n=112; CNKI, n=73; and Wipro, n=82). After removing 1466 duplicates, 2878 unique records remained for screening. During the title and abstract screening phase, 2863 records were excluded because they were either unrelated to the topic (n=2,641) or were nonoriginal research, such as reviews and newspaper articles. This left 15 reports to be sought for full-text retrieval. The subsequent critical appraisal excluded 6 studies based on predefined criteria: 3 did not use an ML approach, 2 had incomplete outcome data, and 1 did not involve a model development process. Ultimately, 9 studies met the full inclusion criteria and were included in this systematic review.

General Study Characteristics

Table 1 shows the basic characteristics of the 9 studies. These studies were published from 2018 to 2024 and included 1 prospective study [3] and 8 retrospective studies [20-27]. Among them, 4 studies [3,20,21,25] were conducted in China; 3 studies [22-24] were from the United States; 1 was conducted in the Netherlands; and 1 transnational study used data from the Netherlands, the United Kingdom, and Denmark. In terms of study population, 2 studies [3,20] focused on patients with THA, 1 study [21] targeted patients with TKA, and the remaining studies [22-27] focused on both THA and TKA. In terms of clinical outcomes, 2 studies [20,21] concentrated solely on DVT, while the remaining 7 studies [3,22-27] evaluated both DVT and PE. In addition, the studies' sample sizes ranged from 60 to 3,92,661. Cases of VTE ranged from 24 to 4042, with an incidence of 0.9% to 40%.

Table . Basic characteristics of the included studies.

[c]TKA: total knee arthroplasty.

[d]DVT: deep vein thrombosis.

[e]PE: pulmonary embolism.

Characteristics and Performance of ML Models

Table 2 provides a detailed summary of the methodological design and data characteristics of the included studies. Table 3 presents a summary of the performance of the model development, validation, and inclusion of the studies. Among the 9 studies included, 5 studies [3,20,23-25] evaluated multiple ML algorithms, and 4 studies [21,22,26,27] used a single algorithm. Across these studies, 15 kinds of ML algorithms were used to develop 34 predictive models, and each study developed 1-5 models. Logistic regression (LR) and XGB were the most common algorithms, appearing in 5 studies (5/9, 56%) each. This is followed by RF (3/9, 33%) [23-25] and SVM (3/9, 33%) [20,24,25]. In particular, the XGB model showed strong performance in predicting DVT and PE, with an AUC range of 0.71 - 0.982. Figure 2 details the frequency of the model used.

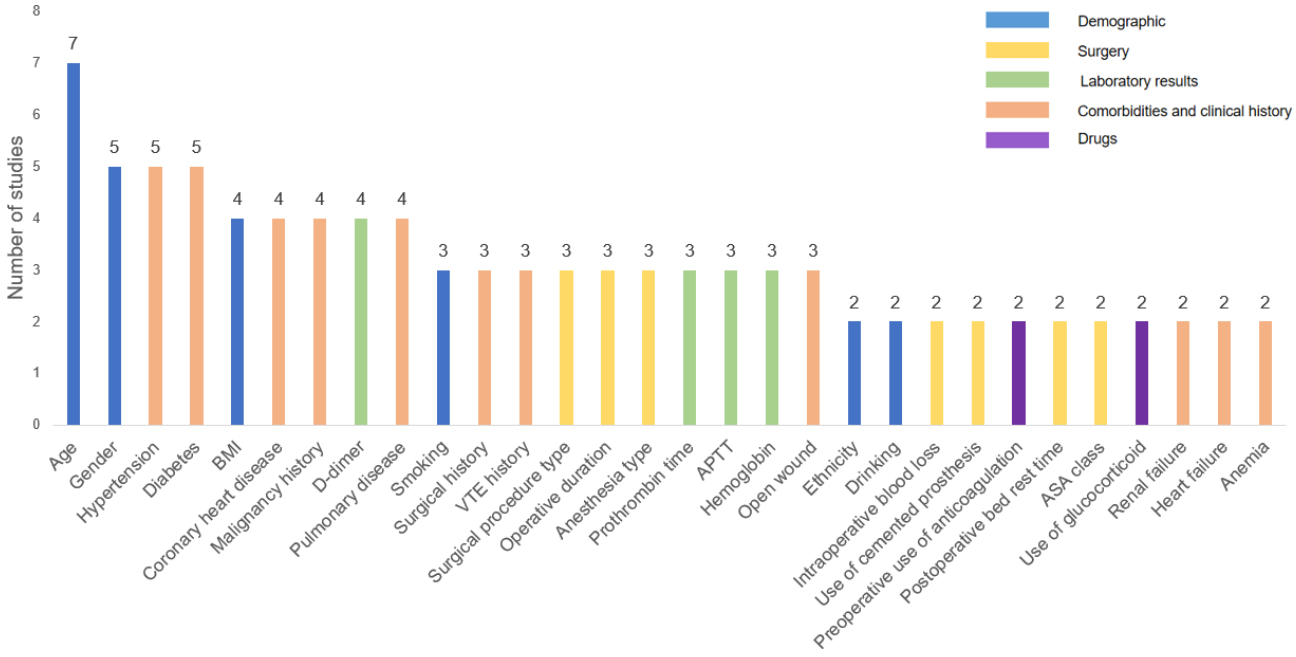
The included studies used a variety of metrics to evaluate ML models, of which AUC was the most common (8/9, 89%). The predicted AUC range for DVT and PE was 0.579 - 0.982. One study did not report AUC but reported C-statistic [22]. XGB, popularized by Chen and Guestrin [28] in 2016, is a widely adopted ML algorithm on the basis of gradient boosting [29,30]. The included XGB studies [3,20,21,24,25] reported AUC ranging from 0.71 to 0.982, demonstrating strong model performance. LR estimates the association of one or more independent variables with binary dependent variables [31,32]. The included LR studies [3,20,25-27] reported AUC ranging from 0.579 to 0.944. RF is a widely used ML algorithm that helps mitigate overfitting and improves the model's stability and accuracy by aggregating the outcomes from various decision trees [33]. It functions as a modeling algorithm as well as a variable selection technique. Three studies [23-25] used RF, with reported AUC ranging from 0.698 to 0.907. In addition, calibration plots were provided in 3 studies [22,24,27]; Brier scores were provided in 1 study [20]; and 1 study [26] also provided Hosmer-Lemeshow, calibration plot, and Brier score. The other 4 studies did not include data on calibration performance. Additional reported metrics encompass accuracy, sensitivity, and specificity.



These 9 studies differ in terms of the optimal timing for risk assessment. Six studies have created preoperative prediction models [3,22,23,25-27] to identify high-risk individuals before surgery. The last 3 studies focused on postoperative prediction, assessing immediate risks using postoperative data [20,21,24]. Additionally, there is diversity in the risk assessment's predictive horizon. Its duration ranges from a brief period following the procedure, such as "within 3 - 5 days after surgery" or "during the postoperative hospital stay" [3,20], to a lengthy risk assessment that might continue for up to a year following the procedure [26]. Common time horizons include 30 days [22,23] and 90 days [24,27].

From a low of 5 [26] to a high of 66 [25], the number of predictor variables that ultimately made it into the model varied

XSL•FO
RenderX

widely. The descriptive analysis of the predictive factors used in each study (as shown in Figure 3) shows that a constant core set of variables is regularly utilized, despite the wide variations in the number of predictive factors used in each investigation. These variables can be broadly classified into four categories: (1) demographic and biological characteristics of the patients (such as age, gender, BMI); (2) major comorbidities (such as hypertension, diabetes, coronary heart disease, and malignant tumors); (3) specific VTE risk histories (such as previous VTE); and (4) key laboratory indicators (such as D-dimer).

Figure 3. Frequency of the predictors. APTT: activated partial thrombin time; ASA: American Society of Anesthesiologists; VTE: venous thromboembolism.

Model Validation

All of the models in the included studies underwent internal validation; however, only 2 studies [22,27] used external validation and reported the AUC value of external validation. The main methods used for internal validation were k-fold cross-validation and random-split validation. External validation plays a key role in confirming whether a model can maintain good performance in different populations and clinical settings. The absence of external validation will limit the generalization and clinical application of these models.

Assessing Risk of Bias

According to the PROBAST evaluation, all models had a high risk of bias (Table 4). The assessment results showed that the main sources of bias were concentrated in the “participants” and “analysis” domains. In the participants domain, 8 studies had a high risk of bias, mainly because these studies relied on retrospective data. In the analysis domain, all models had a high risk of bias. The PROBAST assessment pointed out several specific methodological issues: 4 studies [21,23-25] did not perform model calibration, 4 studies [3,21,23,25] did not report the handling of missing data, and 2 studies [21,23] were insufficient in measures to prevent model overfitting. In contrast, the outcome domain was rated as having a low bias risk level in all studies. In terms of applicability assessment, only 1 study [25] had poor applicability because the model was overly complex and required 66 predictor variables.

[a]Low risk of bias.

[b]High risk of bias.

Discussion

Principal Findings

VTE is a common and serious postoperative complication that is preventable [10]. Risk assessment and management-based strategies can help prevent or reduce the occurrence of VTE [34]. Therefore, selecting an appropriate predictive model for VTE is crucial. This systematic review examined the methodological quality and clinical applicability of ML methods in predicting VTE after joint replacement surgery. Among the reviewed studies, 15 ML algorithms were utilized to construct 34 predictive models. XGB and LR were the most used model types, followed by RF and SVM. The AUC values of the models ranged from 0.579 to 0.982, indicating that the discrimination ability of the models varied greatly, and some of the models showed excellent performance. Two research [1,6] reports demonstrated extremely high discrimination ability, with their AUC values exceeding 0.9. Such high performance often raises concerns about overfitting, where the model learns specific statistical noise specific to the training data rather than the generalizable underlying biological signals, leading to an optimistically biased performance estimate. Moreover, these models have not yet undergone external validation. This deficiency is a major limitation. In the clinical environment of joint replacement, there may be significant differences among patients, and surgical techniques as well as VTE prevention protocols may also vary among different medical institutions. Models trained based on data from a single hospital are likely to learn the specific treatment patterns of that hospital rather than a universally applicable VTE prediction signature. This may lead to unreliable prediction results when the model is applied to different patient groups. The risk of overfitting and the lack of reliable external validation seriously undermine the clinical value of these highly performing models. These models can only be considered for practical application after undergoing extensive external validation.

Another finding is that the XGB model demonstrates superior predictive performance compared to other models. For instance, 2 studies [3,20] compared the XGB and SVM models with the LR models, and the results showed that the XGB and SVM models outperformed the LR model. This supremacy is probably due to the smart way the algorithm was made. First, XGB has strong built-in features (such as regularization) that keep the model from overfitting when working with small datasets, making it stable even when the data are noisy. Second, XGB is very good at identifying the most important risk factors on its own. It can also capture complicated nonlinear interaction relationships, which typical linear models cannot do. Furthermore, the fact that XGB functions so effectively most likely indicates that the research team spent a great deal of time and energy optimizing the hyperparameters and determining the ideal configurations for their particular dataset. However, research has indicated that LR models may be more successful and easier to apply in some situations, whereas XGB and SVM models may not necessarily perform better. LR's fundamental structure makes it simple to comprehend and analyze. Additionally, it produces dependable findings and has strong convergence, particularly when used for small datasets [35]. The Caprini score is a clinically prevalent instrument utilized to evaluate VTE risk by analyzing many clinical risk factors, including age, surgical history, malignancy, and obesity [36]. One study [25] compared the Caprini Score to ML models and showed that the ML models were better at predicting VTE risk. Although the predictive performance of most models ranged

XSL•FO
RenderX

from moderate to good, the risk of bias in all studies restricted the applicability of these models in clinical practice.

Related Work

The PROBAST assessment results indicate that all the models have a high risk of bias, suggesting that their predictive performance in practical applications may be lower than the reported levels. This widespread bias is mainly due to the flaws in the research design and the statistical analysis methods adopted by the models. In terms of the research design, most studies rely on retrospective data, which increases the risk of selecting an unrepresentative patient population, thereby weakening the generalization ability of the models beyond the original dataset. Additionally, there are numerous flaws in the analysis aspects of the model construction and testing processes. The main issues are that some studies did not check the calibration process. This makes it impossible for us to determine whether the "30% risk of venous thrombosis" predicted by the model truly means a 30% probability in reality, thus preventing its use in clinical decision-making. Some studies also failed to provide enough protections against the "overfitting" problem, in which the model just remembered the noise in the training data instead of identifying the true risk patterns, while others did not provide solutions for handling missing patient data. These analytical flaws make these models likely to perform poorly when applied to new patients. Furthermore, the actual usability is also an issue. One model used an excessive 66 predictive variables, making it overly complex and unsuitable for clinical use. To raise the accuracy and clinical application of predictive models, future studies should apply more rigorous methodological methods. Moreover, the significant bias risk indicates inconsistency in the development and validation of current models, which could influence their widespread application. Future studies should give priority to enhancements in a number of important domains, including the research design (ie, cohort or case-control study design), the number of events, the method for predictor selection, the processing of complicated data, and the processes of model calibration and fitting.

One serious and widespread flaw in these studies is the absence of model calibration reports. Although most of the included studies reported high discrimination metrics such as AUC, the discrimination does not guarantee that the predicted probabilities are accurate. Calibration addresses a more fundamental clinical question: Does the predicted "30% risk of venous thrombosis" really mean that there will be a 30% incidence rate among a group of similar patients? Inaccurate calibration might have very harmful consequences. For example, a model that consistently overestimates risks may incorrectly identify patients with low risks as having high risks [37]. This may lead to the improper use of potent anticoagulant drugs, thereby exposing patients to a serious risk of bleeding, a risk that could have been avoided. However, if the model underestimates the risks, it may prevent doctors from taking necessary preventive measures to ensure the safety of patients with high risk. This could lead to potentially fatal thrombosis incidents [38]. Consequently, owing to the absence of calibration data, most of these models are unreliable for informing individual patient decisions, irrespective of their quoted AUC values. Future research must prioritize calibration as the principal measure of model performance. We strongly urge that studies include both visual calibration plots and quantitative indicators (such as the Brier Score) at the same time to make sure their predictions are accurate in the actual world. Additionally, most of the included studies did not provide reports on the sensitivity and specificity of their models. This affects the overall assessment of model performance, as the reported AUC values may not fully reflect its clinical applicability. Future research should follow standardized reporting guidelines to evaluate its model performance.

External validation is critical to confirm the generalizability of the model's performance and its applicability to different populations [39,40]. However, all the studies used internal validation methods, such as K-fold cross-validation or random split validation, and only 2 studies conducted external validation. Most of these models lack external validation, further increasing the challenge of clinical implementation. In such a sensitive sector as health care, where predictive models are finally meant to be employed in real-world situations, these ML models may not accurately reflect their applicability and dependability without outside validation [41]. Future studies should incorporate external validation where possible, such as in different hospitals or using publicly accessible databases, to optimize the model generalization through data synthesis and larger datasets [42]. Additionally, we advise temporal validation to assess the model's resilience at different points in time.

The ML model's predictive variables found in this study have a number of important effects on clinical practice. First, the predictive factors frequently used in these models play a very important role in current clinical practice and future research. For instance, D-dimer is a well-known clinically validated biomarker for VTE. Studies have shown that it is highly sensitive in predicting the risk of VTE. Prothrombin time, activated partial thromboplastin time, and international normalized ratio are a few other markers that may assist physicians better understand the risk of blood clots and quickly identify and treat patients with high risk [43]. Another established risk factor for VTE is age. Research has indicated that the risk of VTE rises with age. People over the age of 60 years account for around 70% of occurrences of VTE [44]. Considering age while evaluating patients before surgery may enhance outcomes and diminish complication rates. Common chronic disorders, such as diabetes and hypertension, were also among recurring factors. Research has shown that these disorders can raise VTE incidence. A personalized anticoagulant treatment strategy might help those with past histories of these disorders lower their VTE risk even more [45]. Second, the results of the 9 studies on the predictors can guide the development of future predictive models and contribute to later studies on related risk elements. For instance, 1 study [20] included bone cement prosthesis as a predictor in the model, although further study is required to confirm its association with VTE. However, variance in the choosing and reporting of predictors in these studies may affect the comparability and practical utility of the models in different clinical settings.

Limitations

To our knowledge, this is the first study to evaluate ML in predicting VTE in patients undergoing joint replacement

XSL•FO
RenderX

surgery. Nevertheless, the study had certain limitations. First, most of the included studies have been conducted in China and the United States. This geographical concentration restricts the general applicability of the model to different areas. Second, numerous studies focused solely on developing predictive models without considering external validation or practical application of the model. The absence of external validation may affect the credibility of our pooled estimates. Third, since the traditional methods used to assess publication bias (such as funnel plots and Egger or Begg tests) are not applicable to AUC data, no quantitative assessment of publication bias was conducted for the included studies. However, the risk of publication bias remains: “positive” studies (eg, high AUC values) are more likely to be published than “negative” or inconclusive ones. Therefore, the studies included in this review may overestimate the true performance of these models. Finally, the included studies exhibited a high risk of bias and insufficient transparency. These methodological shortcomings could affect the accuracy of model predictions, therefore reducing the dependability and application of the conclusions.

Conclusions

The study identified 9 studies with a total of 34 ML models for predicting VTE after joint replacement. Most studies have modest to good discriminative ability from their AUC values. However, among these 9 studies, only 2 of them underwent effective external validation. The widespread neglect of external validation has left the generalization capabilities of these models, which performed well on the original dataset, completely unknown. In addition, these studies also show a high risk of bias and significant heterogeneity. Most of the studies had significant methodological shortcomings, including a lack of rigorous study design and absence of calibration measurements. These deficiencies will affect the reliability of the model in clinical applications and reduce the promotion value of the model. To improve the prediction capabilities of ML models, future research must closely follow the PROBAST criteria, which place a strong emphasis on meticulous study design and quality control. External validation is also necessary to improve the generalization and applicability of ML models in clinical settings.

Abstract

Background: Individual-level behavioral interventions are designed to improve health behaviors and manage noncommunicable diseases. Neighborhood geo-referenced contexts (NGRCs) significantly impact the success of these interventions. Integrating NGRC data into health information systems (HISs), including electronic medical records (EMRs), electronic health records (EHRs), and personal health records (PHRs), can enhance personalized NGRC-focused behavioral interventions and improve health outcomes. Despite the potential benefits, there is a notable gap in the literature about NGRC-focused behavioral interventions using HISs.

Objective: This scoping review aims to review the current status and stakeholder insights of NGRC-focused behavioral interventions using HISs.

Methods: Two reviewers examined publications indexed by MEDLINE (Ovid) and Scopus. Publications reporting on NGRC-focused behavioral interventions using HISs were included. We extracted data on study characteristics, population attributes, diseases, health setting characteristics, HISs, NGRCs, behavioral interventions, outcomes, and conclusions, with suggestions for future research.

Results: The literature search identified 24 studies for inclusion. Of these, EHRs or EMRs were mostly used in 20 studies, with limited focus on PHRs. HISs were not used in the entire process of NGRC-focused behavioral interventions in 23 studies. Behavioral interventions in 21 studies focused exclusively on social needs interventions, with comparatively limited attention given to lifestyle change interventions. NGRCs mainly focused on built environments (n=24), with less attention to natural (n=1) and social (n=4) environments. The spatiotemporal characteristics of NGRCs were described in limited detail. “Destination accessibility” was the main focus within built environments. Other characteristics (“density,” “design,” “diversity,” and “distance”) were less studied. Stakeholders’ perspectives highlighted the value, convenience, patient autonomy, and privacy of integrating content (NGRCs) and/or technology (HISs) into behavioral interventions, despite the persistence of certain social concerns. We summarized 15 recommendations in terms of NGRC-focused behavioral interventions using HISs.

Conclusions: PHRs have the potential to actively integrate more diverse, dynamic, and/or high-resolution NGRCs. Additionally, PHRs can participate in the entire process of NGRC-focused behavioral interventions, particularly in outpatient lifestyle change interventions. Health care providers can support these interventions to help achieve public health goals and advance health equity.

Introduction

Behavioral interventions are strategies and techniques to influence health-related behaviors at the personal, community, and public policy levels [1]. They may encourage individuals to quit smoking or to exercise regularly. At the community level, behavioral interventions aim to change behaviors by modifying the environments that support them [1]. For example, enhancing existing sidewalks with improved lighting, repainting bike lane markings, and adding benches can create a more enjoyable experience that encourages walking and cycling. At the public policy level, the government or private groups can share health information to encourage behavioral change [1]. The absence of individual-level behavioral interventions poses a significant challenge in managing noncommunicable diseases (NCDs), which account for 70% of global deaths annually [2], as effective interventions for NCDs require long-term engagement and multiple follow-ups to detect relapses or late effects as soon as possible [3].

Neighborhood geo-referenced contexts (NGRCs) have been identified as barriers or facilitators to the acceptance of, participation in, and adherence to individual-level behavioral interventions [4]. NGRCs refer to the physical and social environments of a location or locations along one's daily activities, and they influence people's health-related behaviors [5-8]. NGRCs are a spatial manifestation of the social determinants of health (SDoH), which refer to the conditions in which people are born, grow, live, work, and age, as well as the broader systems and forces that shape these daily life conditions [9]. Beyond the social and natural environments in NGRCs, the built environment is characterized using the 5D framework, which includes *density*, *diversity*, *design*, *distance*, and *destination accessibility*. The failure to address NGRCs is evident from the focus on limited prevention programs or resources in health care settings aimed at addressing individual attitudes and behaviors, along with the limited resources for preventive care [10]. NGRC-focused behavioral interventions allow health care providers to tailor interventions to specific contexts, offering a more personalized approach. These interventions can be categorized into social needs interventions (eg, arranging transportation) and individual lifestyle change interventions (eg, walking in a nearby park). To achieve NGRC-focused behavioral interventions, studying the interaction between NGRCs and modifiable health-related behaviors is essential [11-13].

Health information system (HIS) data have been used to investigate the relationships between NGRCs and health behaviors among health providers, HIS vendors, payers, and researchers [14-24]. A HIS is a system for collecting and processing data, information, and knowledge in health care settings [25]. The category includes (1) provider-centric electronic medical record (EMR) systems used within a single health care setting, (2) electronic health record (EHR) systems spanning multiple settings, and (3) patient-centric personal health record (PHR) systems. Among PHRs, standalone PHRs are not integrated with EMRs or EHRs, whereas tethered and interconnected PHRs are linked to EMRs or EHRs [25-27]. These systems enable various stakeholders, such as health providers, patients, and caregivers, to access and process multimodal data, such as diagnoses, medication use, treatments, NGRCs, and behavioral information.

At the individual level, HISs can enhance NGRC-focused behavioral intervention via comprehensive NGRC data capture and effective intervention prescription, monitoring, and assessment [3]. HISs can help collect NGRC data during routine clinical care, supplemented by patient-reported information, or through linkage with publicly available external data sources like geographic information systems. At the community and policy levels, HISs can support cost-effective, large-volume, and time-efficient assessments of large-scale public health efforts, such as environmental interventions to support behavioral changes, compared with traditional surveys [28].

Although integrating NGRCs with HISs is not new [29], many reviews on the functionalities and features of EHRs, EMRs, and PHRs lack clarity regarding NGRCs [30-44]. Additionally, several systematic reviews have investigated the linkage between NGRC data and clinical data sources (eg, EHRs) for population health research, but they lack specifics regarding behavioral interventions [45,46]. Recent systematic reviews on SDoH screening, linkage, extraction, analysis, and interventions within HISs, especially EHRs, similarly show limited attention to NGRCs and/or intervention-based approaches [47-50]. Given the increasing interest and existing research gap in using HISs to prepare, prescribe, monitor, and assess NGRC-focused behavioral interventions, we conducted, to our knowledge, the first scoping review of the literature in this field to distinguish it from broader SDoH-focused reviews and those lacking an intervention-based approach [46,50]. This review excluded standalone PHRs, as they are independent of provider-centric EHRs or EMRs.

This scoping review aimed to answer the following questions:

1. To what extent and what types of HISs have been used in NGRC data capture, intervention prescriptions, monitoring, and assessments of NGRC-focused behavioral interventions, and across the 4 stages?
2. What types, spatiotemporal characteristics, and databases of NGRCs have been utilized in each type of behavioral intervention supported by HISs?
3. What are stakeholders' insights regarding the use of HISs and/or NGRCs in behavioral interventions?
4. What are the gaps in research on the use of NGRCs and HISs in behavioral interventions?

Methods

Checklist

The analysis adhered to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist (Checklist 1) [51].

Search for Relevant Research

An information specialist from the Amsterdam Medical Center library (JGD) was consulted to help define key concepts and establish the evaluation framework, which included selecting the appropriate databases, relevant keywords, and MeSH terms.

XSL•FO
RenderX

MEDLINE (Ovid) and Scopus were searched from inception on April 29, 2024, to include studies up to the search date.

The search strategy could be conceptually summarized as follows: ([GRCs] AND (([neighborhoods] AND ([chronic care model] OR ([HISs] AND [health behaviors]))) OR ([community health facilities] AND [health behaviors]))), involving the following four elements related to our research questions: (1) HISs, (2) geo-referenced contexts (GRCs), (3) neighborhoods, and (4) health behaviors. Detailed information regarding the search terms in Scopus is shown in Textbox 1. The inclusion and exclusion criteria are presented in Textbox 2. For search terms in MEDLINE, refer to Table S2 in Multimedia Appendix 1.

Textbox 1. Search terms in Scopus.

Textbox 2. Inclusion and exclusion criteria.

Inclusion criteria

- Study type: Original empirical research studies.
- Health information systems (HISs) and behavioral interventions: Used HISs to prepare, prescribe, monitor, and/or assess behavioral interventions.
- Neighborhood geo-referenced contexts (NGRCs): Used one or more NGRC attributes about the outside world to assist and/or adjust behavioral interventions.
- NGRCs and behavioral interventions: Studies in which NGRC and intervention data pertain to concurrent or longitudinal periods. Studies in which NGRC attributes and intervention attributes use either objective or subjective measurements.

Exclusion criteria

- Study type: Study protocols without substantive findings and studies without results (eg, experimental descriptions and commentaries).
- HISs: Studies for which it cannot be confirmed whether the records are part of an HIS due to an unspecified format (electronic or paper), or it is not explicitly stated whether these data are connected to HISs. Studies on standalone personal health records managed solely by patients and/or caregivers without the integration of data in medical settings (eg, hospitals). Studies using an HIS that was not focused on interventions but was used as a database to identify participants for empirical studies.
- NGRCs: Studies focusing only on broad geographic categories (eg, county, city, region, nation, and urban/rural), using sensors without specific attributes, NGRCs about health services, or economic factors (eg, transportation reimbursement). Studies for which it cannot be determined whether NGRCs were involved due to a lack of specific details on social determinants of health screening tools and interventions.

Results

Search Term Coverage and Rationale

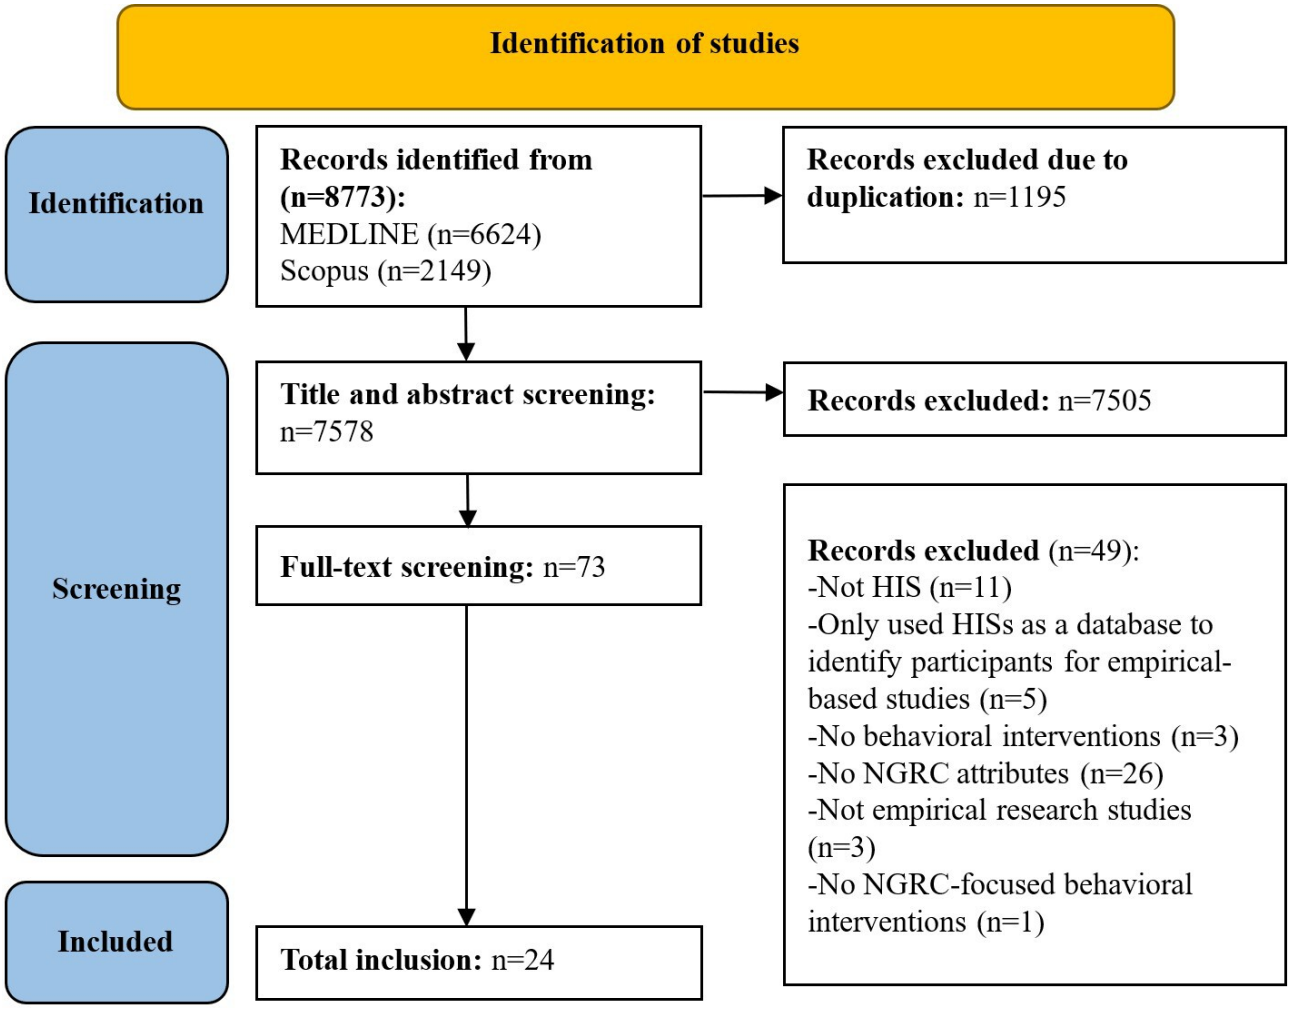
GRCs include (1) built environments from the 5D dimensions (density, diversity, design, distance, and destination accessibility); (2) natural environments; and (3) social environments, which encompass neighborhood socioeconomic status and neighborhood social relationships. Neighborhoods include (1) static administrative areas, (2) various delineations surrounding each participant's address, (3) perceived neighborhoods, and (4) geographic areas encompassing all locations visited by an individual in their daily activities. For the definitions and examples of NGRCs and neighborhoods, see Table S1 in Multimedia Appendix 1 [1,9,26,52-76]. We used 3 different search strategies because some concepts can be merged and replaced by related ones. For example, HISs and health behaviors are 2 critical elements of the chronic care model, which is a valuable framework for patient empowerment, supporting self-management and enhancing health outcomes [53-56]. Consequently, substituting HISs and health behaviors with search terms pertinent to the chronic care model while connecting them with GRCs and neighborhoods constituted the second part of the search strategy. Additionally, community health facility workers may use HISs to address neighborhood-related issues. Therefore, replacing HISs and neighborhoods with search terms relevant to community health facilities (eg, community health centers and community data) while linking these terms with GRCs and health behaviors formed the third part of our search strategy.

Eligibility Criteria

All original peer-reviewed scientific studies in English indexed up to April 29, 2024, were included, while non–peer-reviewed studies and gray literature were excluded. Textbox 2 outlines the inclusion and exclusion criteria.

Selection Process

First, we screened titles and abstracts and excluded studies according to the inclusion and exclusion criteria. When uncertainty arose, studies were retained for the full-text screening stage. Second, XY and MD independently conducted a full-text review and extracted the relevant NGRCs, HISs, and behavioral interventions from the potentially included papers. Any disagreements were first addressed by referring to a predefined inclusion/exclusion checklist. If consensus was not reached using the checklist, the reviewers discussed each case, and, if necessary, a third reviewer (RC) made the final decision. Although interrater reliability was not calculated, this structured approach ensured consistent and transparent decision-making.



Data Extraction

We extracted data from the included studies using a 7-item table. These seven items included: (1) study attributes; (2) population attributes, diseases, and health setting characteristics; (3) HISs; (4) NGRCs; (5) behavioral interventions; (6) results; and (7) conclusions and future studies. Table S3 in Multimedia Appendix 1 provides further details.

Figure 1 presents the PRISMA flowchart, which includes the identification, screening, and selection process. A total of 24 peer-reviewed studies were finally included.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) flowchart. HIS: health information system; NGRC: neighborhood geo-referenced context.

Study Characteristics

We reviewed the descriptive characteristics of all 24 included papers. Basic characteristics of the studies are presented in Table S4 in Multimedia Appendix 1, including information on (1) the type, number, gender, age distributions, and language of participants, and (2) the study type and year of publication. The characteristics with appropriate properties for summarization include (1) the type, NCD, and health and computer literacy of participants, and (2) health settings. All studies were conducted in the United States. Details are provided in Table S5 in Multimedia Appendix 1.

We divided the studies by participant type as follows: 2 studies [29,77] focused solely on providers, 4 studies concentrated on caregivers [78-81], 13 studies examined patients only [10,82-93], and 5 studies involved both health providers and patients [93-97]. Among patients, most studies focused on adults.

Summarization of the Results

Overview

In this section, we aim to summarize the findings from the 24 included articles to address the first 3 research questions. Each of these themes is explored in detail in the subsections that follow.

Question 1: Question Regarding HISs

We summarized whether HISs were used and the types of HISs used. Table 1 presents HIS usage across all stages, while Table S5 in Multimedia Appendix 1 lists the types of HISs. Table S4 in Multimedia Appendix 1 provides the specific names of the HISs.

Table 2 details the stage 1 NGRC data capture, including the settings (eg, health care settings, such as hospitals, and non–health care settings, such as homes), those collecting data (eg, patients, providers, and systems), and those documenting it (systems or providers).

Question 2: Question Regarding NGRCs

We summarized the reviewed studies in terms of behavioral intervention types as follows: (1) social needs interventions, (2) lifestyle change interventions, and (3) whole care without specifying the behavioral intervention type. This categorization agrees with the information in Table S1 in Multimedia Appendix 1. Table 3 summarizes the types and spatiotemporal characteristics of NGRC attributes.

XSL•FO

[a]NGRC: neighborhood geo-referenced context.

[b]B/N/S: built environment (B), natural environment (N), or social environment (S).

[c]Source: NGRC screening (Sc), location-aware devices (L), or public datasets (P).

[d]SDoH: social determinants of health.

[e]Ob/Su: objective (Ob) or subjective (Su).

[f]I/O: inpatient (I) or outpatient (O).

[g]Li/So/E: lifestyle change interventions (Li), social needs interventions (So), or entire care process (E).

[h]PN: perceived neighborhood.

[i]RD: residential address.

[j]Not available.

We specified substructures for the categorization of social needs interventions, lifestyle change interventions, and whole care. Social needs interventions used actively collected, subjective, and static measures of perceived neighborhood social and built environments. Lifestyle change interventions included (1) actively collected, subjective, and static measures of perceived neighborhood social, natural, and built environments at residential addresses, and (2) passively collected, objective, real-time, and location-based distances to high-risk areas (eg, bars). Whole care included passively collected, objective, and static social and built environment indicators derived from the census tract of residential addresses.

In social needs interventions, actively collected, subjective, and static measures of perceived transportation barriers and neighborhood safety were the only 2 assessed NGRCs (21/24, 88%). These were assessed using electronic or paper-based surveys [29,78-82,84-98]. The focus on transportation barriers (21/24, 88%) may reflect their relative ease of mitigation through interventions (eg, door-to-door transportation to medical appointments [8,92]). These interventions were shaped by specific health service settings and available community resources. Similarly, transportation barriers were assessed using a variety of question formats, time frames, destination types, and SDoH screening tools. Despite these efforts, detailed information, such as transport mode, distance, travel time, and the locations of perceived neighborhoods, was generally rarely collected. Additional details are presented in Table 4.

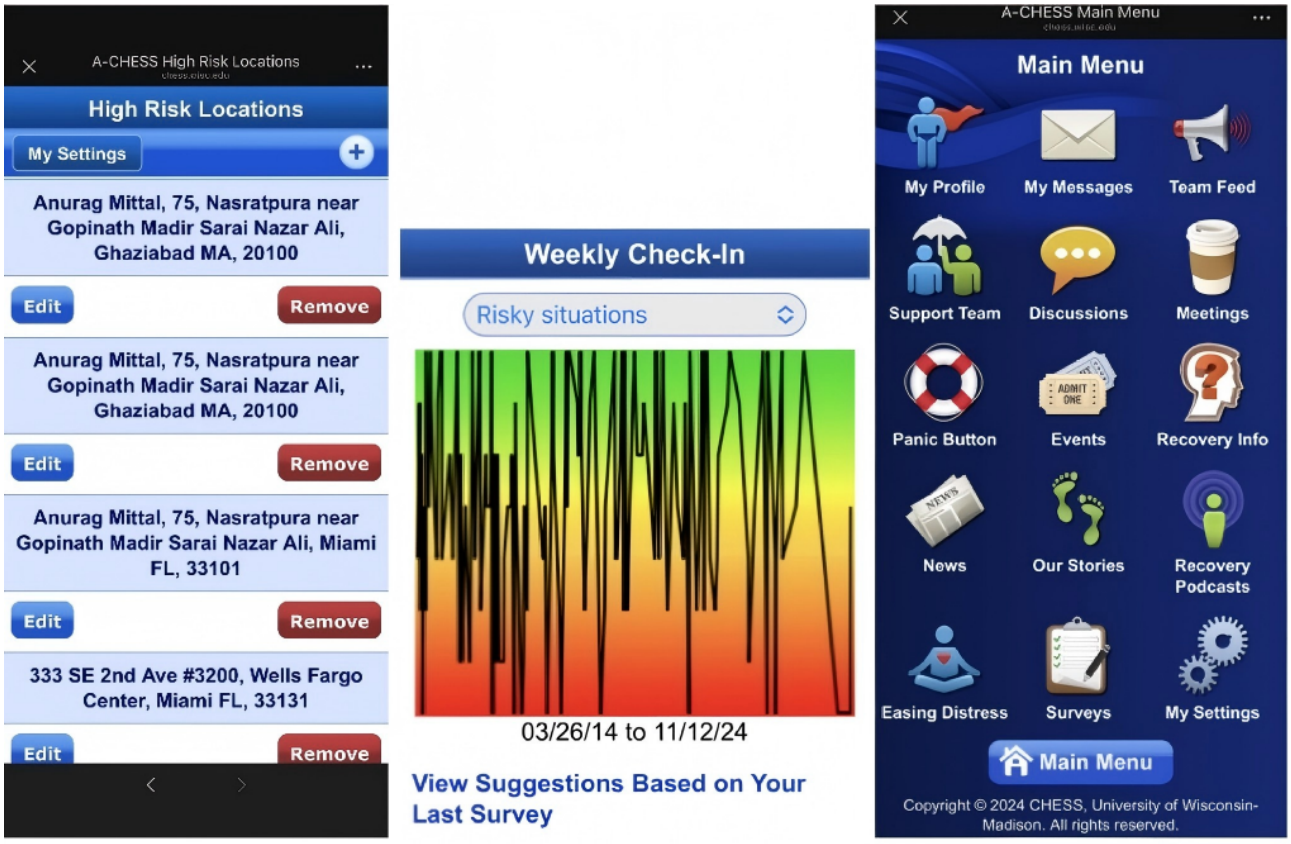
[f]CT: computed tomography.



Lifestyle change interventions assessed actively collected, subjective, and static measures of social, natural, and built environments at participants' perceived residential neighborhoods. These were assessed with "neighborhood assessment" during follow-up visits [10]. These assessments showed the multifaceted interplay between NGRCs and lifestyle behaviors. The environmental barriers to healthy eating and physical activity included air quality, food environment density, physical activity facility density, streetlight design, and neighborhood safety (Table 3). The absence of subsequent similar studies highlights the practical challenges of consistently partnering with community groups and agencies to address environmental barriers to lifestyle change.

In addition, passively collected, objective, real-time, and location-based distances to high-risk areas (eg, bars) were assessed using GPS data from the A-CHESS (Addiction Comprehensive Health Enhancement Support System) app [83] (Figure 2). Unlike approaches that depend on community-level resources of residential addresses, A-CHESS optimizes users' daily routes. This suggests that leveraging existing environments along these routes—not just around residential areas—can be practical without requiring extensive organizational collaboration. A-CHESS also supports weekly surveys to actively assess participants' perceived alcohol use in their residential neighborhoods [83]. While transportation barriers are relatively stable, neighborhood social cultures, such as drinking behaviors, fluctuate rapidly, requiring active and higher-resolution data collection to capture their health effects.

In whole care, passively collected, objective, and static social and built environment indicators based on the census tract level of the residential address were displayed in the Envirome Web Service [77]. Integrated with the Cerner Millennium EHR, this service displays socioeconomic data, food desert status, and contextual information at the census tract level using public datasets (eg, the US Department of Agriculture and the 2010 Decennial Census). Compared with A-CHESS, the Envirome Web Service offers broader, population-level coverage of social and built environment factors through passive data collection but lacks dynamic, route-specific, or nonresidential contextual information.

XSL•FO
RenderX

Figure 2. The A-CHESS (Addiction Comprehensive Health Enhancement Support System) app [83] supports recovery from alcohol use disorder by providing 24/7 smartphone access to services such as cognitive-behavioral therapy, addiction-related resources, and alcohol-free events. The left panel displays a list of identified high-risk locations, the middle panel summarizes risky situations based on weekly surveys, and the right panel shows the app's homepage. Using GPS, A-CHESS monitors when users approach predesignated high-risk locations, such as bars, and sends an alert asking whether they intend to be there. No alert is issued if the user is not near a high-risk location. The screenshots were captured from the app link [99].

Question 3: Question Regarding Stakeholders' Insights

We summarized stakeholders' insights on the use of NGRCs and/or HISs in social needs interventions and whole care from 10 included studies. The details are shown in Table S6 in Multimedia Appendix 1.

Seven studies mentioned attitudes toward NGRC integration. Six out of the seven studies on social needs interventions found that patients, caregivers, and providers valued addressing transportation barriers for comfort and convenience [84,93,96,97]. However, challenges remain in addressing patients' concerns about potential discrimination, such as reduced courtesy or respect, as well as providers' discomfort with stigmatizing questions [81,86,93,96,97]. At the core, the challenge lies in balancing actionable social needs interventions and sensitive care. The last study [77] examined providers' views on NGRC data needs, clinical usefulness, and data visualizations in whole care. Providers emphasized the need for clear definitions and simple visualizations to make complex data more actionable in practice [77].

Nine studies examined HIS integrations from 3 aspects: value and convenience, patient autonomy, and privacy. The efficiency and convenience of electronic NGRC capture tools were recognized by providers, patients, and caregivers, particularly when patients completed them before visits [29,77,86,95-97]. However, providers also expressed concerns about increased workload, time constraints, unfitness to the workflow, and the possibility of raising unmet patient expectations [29,86,94-96]. These concerns underscore the need to integrate NGRC-focused behavioral interventions seamlessly into clinical workflows to avoid a higher administrative burden. Patient autonomy and engagement were enhanced [77,86,95-97]. Improved autonomy can support person-centered and team-based care. However, the absence of data on patients' digital literacy could lead to misinterpretation of patients' attitudes (eg, acceptability, adoption, and usage of HISs), especially for those with low literacy levels, as higher digital literacy can alleviate social concerns [29,84]. Privacy was improved by reducing patients' feelings of judgment and promoting greater honesty in disclosure [84,86,95]. Improved privacy suggests that well-designed digital systems can mitigate stigma associated with sensitive NGRCs.

Discussion

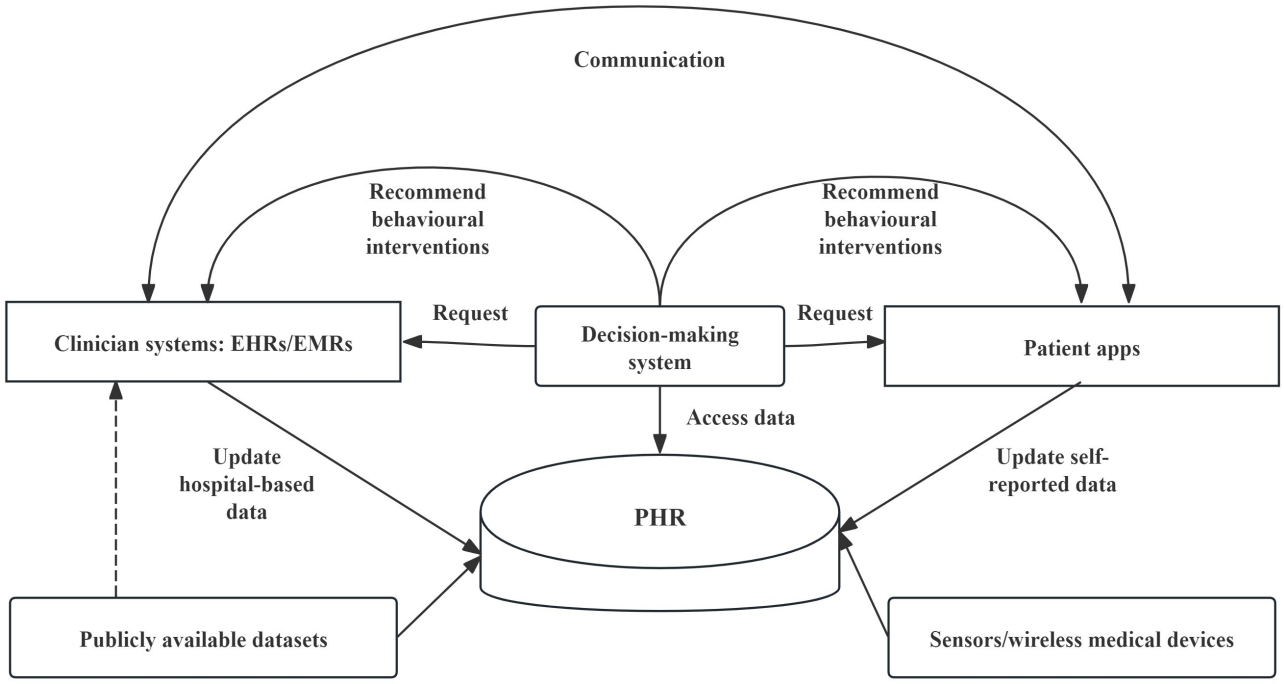
Principal Findings and Recommendations

In this scoping review, we reviewed the current state of NGRC-focused behavioral interventions using HISs in order to propose recommendations for future studies. We included 24 studies, and nearly half of the studies (11/24, 46%) were conducted in 2023 or later (Table S4 in Multimedia Appendix 1). Due to unstructured reporting in many of the included studies, reliably extracting data was difficult. We organized our findings and recommendations according to the 4 research questions.

XSL•FO
RenderX

Question 1: Question Regarding HISs

The predominant reliance on provider-centric EHRs/EMRs and the limited and inconsistently described use of HISs across the entire NGRC-focused behavioral intervention cycle significantly constrain the integration of NGRCs into behavioral interventions. Apart from the unspecified type of HIS in 1 study [10], most included studies relied on provider-centric EHRs/EMRs (20/24, 83%), with limited use of more patient-empowered PHRs. Only 3 studies used tethered PHRs, and none utilized interconnected PHRs (Table S5 in Multimedia Appendix 1). The reliance on provider-centric EHRs/EMRs may lead to difficulties in monitoring and assessment. Therefore, most studies (23/24, 96%) did not apply HISs in the entire process (NGRC data capture, intervention prescription, monitoring, and assessment). HISs were mainly used for (1) NGRC data capture (18/24, 75%), with limited patient-led (5/24, 21%) or system-led (1/24, 4%) cases; (2) intervention prescriptions (13/24, 54%); and (3) assessments (11/24, 46%) focusing on health care utilization, with minimal use in monitoring (2/24, 8%). Limited monitoring and a narrow focus on health care utilization data for assessments leave the sustainability of behavior change largely unaddressed. Given its critical role in improving long-term health outcomes, future research should aim to establish integrated frameworks that embed tethered or interconnected PHRs consistently across the 4 phases. Furthermore, the lack of details on HIS functionalities limits the ability to synthesize evidence and derive practical design recommendations for future interventions. Future studies should provide sufficient details to ensure reproducibility.



Although HISs have been used frequently in NGRC data capture, the dominance of active collection (eg, patient-administered or provider-administered surveys; 22/24, 92%) and the underuse of passive collection (eg, linkage with public datasets; 1/24, 4%) and GPS data (1/24, 4%) have left existing data underutilized, and active collection may cause user information to be unclear. On one hand, the majority of studies (17/24, 71%) relied on manual NGRC collection and documentation into EHRs/EMRs by stakeholders (Table S6 in Multimedia Appendix 1). Active data collection likely contributes to negative provider attitudes due to increased workload and limited consultation time. This potentially hinders the integration of NGRCs into routine care. Self-completed assessments using tethered or interconnected PHRs may address providers' concerns, and both patients and providers hold positive attitudes toward them (Table S6 in Multimedia Appendix 1). However, tethered or interconnected PHRs were underutilized in the included studies. The gap between positive stakeholder attitudes and practice suggests missed opportunities to reduce provider burden and engage patients more actively in their care using PHRs. On the other hand, although the A-CHESS app achieved passive data collection, it relied solely on HISs as assessment tools and had limited provider access to behavioral data, which constrained the understanding of how HISs and providers influence behavior change and its sustainability. Similarly, the Envirome Web Service [77] passively collected NGRC data via public dataset linkages. However, the lack of detailed descriptions of the use of HISs in subsequent steps (eg, monitoring and assessment) further limited insights into their role in supporting sustained behavior change.

The complexity of provider types and roles in the entire process of NGRC-focused behavioral interventions (Table 1) further complicates implementation in clinical settings. Future studies should clearly define the responsibilities of every provider to enhance coordination across care teams, thereby improving intervention fidelity and consistency.

In summary, implementing tethered or interconnected PHRs throughout the intervention process, particularly in outpatient settings, is recommended (Figure 3). Connection with EHRs/EMRs can also achieve provider support. By ensuring privacy, security, and controlled access, PHRs can enhance user acceptance and usage [100]. Secure data exchange among patient apps, public datasets, sensors, and EMRs/EHRs can enable tailored interventions, timely issue detection, improved communication, greater engagement and adherence, better care coordination, higher satisfaction, and reduced treatment burden [86,101]. We have summarized 3 recommendations in Textbox 3.

Textbox 3. Recommendations.

Recommendations regarding the types and roles of health information systems (HISs) in the entire process of neighborhood geo-referenced context (NGRC)–focused behavioral interventions

1. Consider tethered or interconnected personal health records (PHRs), especially in outpatient settings, in the entire process of NGRC-focused behavioral interventions.
    - Use tethered or interconnected PHRs to actively or passively collect multiple NGRCs and generate a more comprehensive view of patients' NGRCs [84]. PHRs can passively obtain location-related NGRCs through connections with electronic health records (EHRs)/electronic medical records (EMRs), public datasets (eg, government data and cohorts), sensors, and wireless medical devices. The locations can include not only the residential address but also regularly visited places or GPS-derived data. On the other hand, PHRs can also embed patient- or caregiver-completed surveys to actively collect perceived NGRCs. Determining the optimal timing and frequency of data capture is essential to balance user burden and data quality [82,84,102,103].
    - Clinical decision support systems (CDSSs) can use NGRC data from PHRs to personalize behavioral interventions, delivering recommendations to patients via apps and to providers via EHRs/EMRs. For instance, real-time CDSS alerts sent at optimal intervals can support providers in adjusting NGRC-focused interventions.
    - Consider integrating PHRs with other portable devices (eg, patient apps, sensors, and wireless medical devices) to allow real-time monitoring through surveys, GPS, and sensors.
    - Integrating PHRs with EHRs/EMRs and other portable devices can provide sufficient long-term follow-up data. CDSSs can then use these data to assess and adapt NGRC-focused behavioral interventions [46,85,104], allowing the evaluation of the sustainability of outcomes and the identification of interventions that produce lasting effects.
2. Incorporate the support of health care providers throughout NGRC-focused behavioral interventions. This support can be provided through (1) providers' guidance on CDSS recommendations and (2) direct patient-provider communication.
    - Explore the roles of various health care providers in the entire process of NGRC-focused behavioral interventions.
3. Balance active and passive NGRC data collection to achieve higher acceptability, feasibility, and effectiveness of NGRC-focused behavioral interventions [24,84,86].

Recommendations regarding the types, spatiotemporal characteristics, and datasets of NGRCs in each type of behavioral intervention

1. Accommodate NGRC-focused social needs interventions with lifestyle change interventions.
2. Include a broader range of NGRCs with detailed spatiotemporal information for different behavioral interventions.
    - Expand the focus beyond influential built environments to also include key natural and social environments for specific behaviors.
    - Incorporate a comprehensive 5D (density, diversity, design, distance, and destination accessibility) framework of built environments.
    - Optimize NGRC spatiotemporal resolution using an evolutionary approach. Apply high-resolution or real-time data when available for precise interventions; otherwise, use static or coarse data (eg, administrative datasets) to capture neighborhood influences. Combining dynamic and static NGRCs can mitigate challenges such as the modifiable areal unit problem, the uncertain geographic context problem, and neighborhood effect averaging.
    - Prioritize key subjective and objective NGRCs for specific behaviors (eg, cycling and walking) and standardize their definitions, spatiotemporal attributes, and measurements through multidisciplinary collaboration. Such efforts should leverage and expand existing terminologies (eg, "community details" in Systematized Nomenclature of Medicine—Clinical Terms [SNOMED CT] and Logical Observation Identifiers Names and Codes [LOINC]) and ontologies (Social Determinants of Health Ontology [SOHO] [105] and social determinants of health ontology [SDoHO] [106]) [24].
    - Assess the availability of influential objective NGRCs in existing datasets and explore opportunities to collect missing objective and subjective data through passive methods (eg, sensors). When certain NGRCs cannot be captured passively, develop self-administered questionnaires to obtain the remaining information. Finally, evaluate the quality, usability, and improvement potential of patient-completed data.
3. Address both technical and social considerations (eg, ethical issues) in NGRC data collection [92].

Recommendations regarding stakeholders' insights on the use of HISs and/or NGRCs in behavioral interventions

1. Assess stakeholder acceptance, attitude, and preferred interactive features for various NGRC-focused behavioral interventions using HISs, particularly those targeting lifestyle changes. For example, evaluate patients' willingness and desired features in PHR-based self-management tools, and design EHR/EMR features that fit providers' workflows to mitigate concerns like time constraints and workload.
2. Develop and iteratively test efficient, user-friendly data visualization tools for stakeholders [33,107-111].
3. Explore stakeholders' perspectives on integrating diverse and/or real-time NGRCs into behavioral interventions, extending beyond transportation barriers to broader applications. Future research should identify which NGRCs stakeholders consider most actionable and relevant for specific interventions, and determine effective, nonstigmatizing data collection methods. For example, assess patient willingness to share GPS data when they can control access to their information.
4. Consider stakeholders' computer and health literacy when evaluating their attitudes toward NGRC-focused behavioral interventions using HISs.

XSL•FO
RenderX

5. Iteratively build support systems, responding to negative feedback by aligning patient expectations and addressing stakeholders' social concerns.

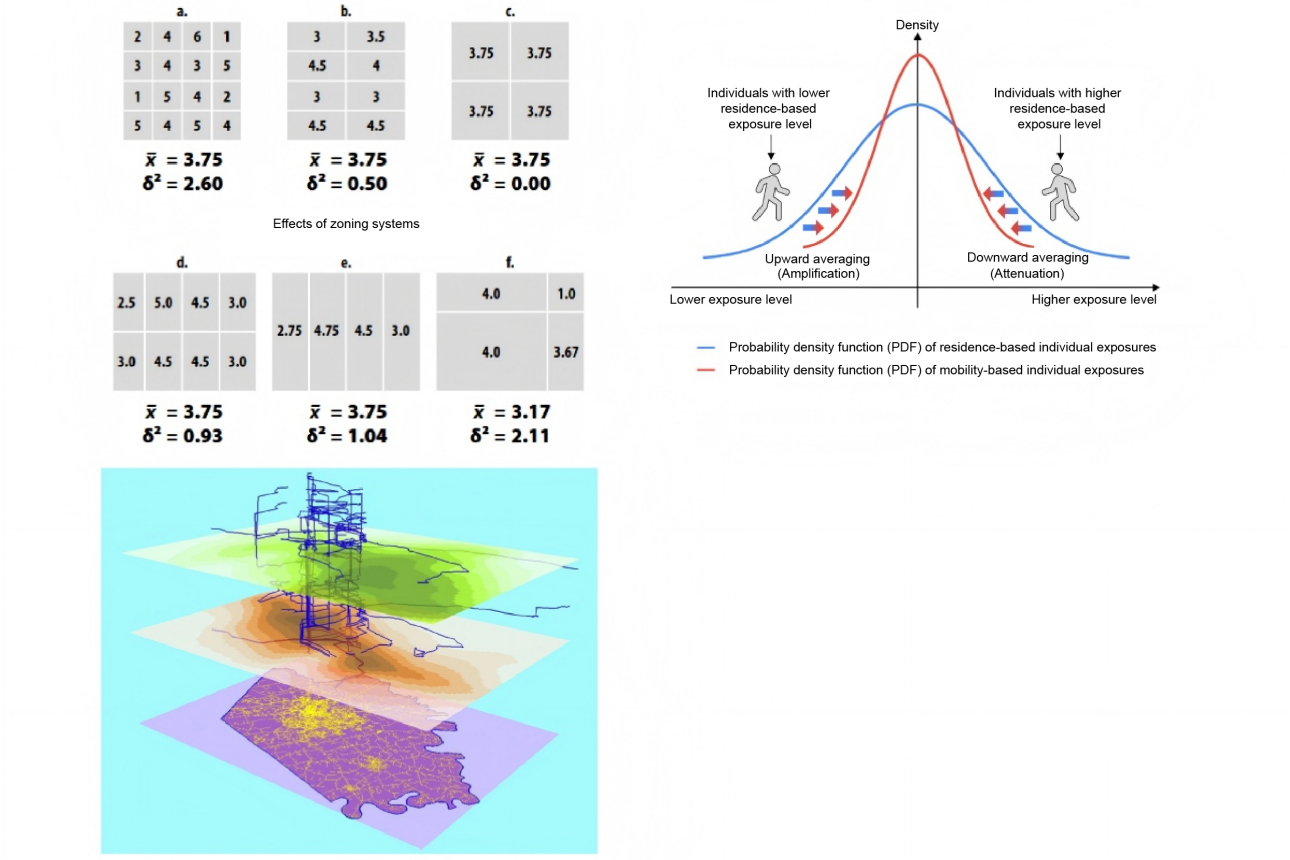
Recommendations regarding research designs

1. Adopt standardized and detailed descriptions of NGRCs [24], HIS functionalities, intervention designs, and relevant disease contexts—ideally guided by common metadata standards or consensus-based frameworks—to enhance transparency, comparability, and collaboration across studies.
2. Evaluate the feasibility, acceptability, adoption, sustainability, effectiveness, cost-effectiveness, ethics issues, and mechanisms of change of NGRC-focused behavioral interventions using HISs, with detailed descriptions of research design for reproduction, testing, and comparison. For example, in research design, the only difference between the intervention and control groups should be whether the intervention is NGRC-focused, in order to isolate the effect of NGRCs.
3. Initiate comparative studies examining how different NGRCs and HIS functionalities influence specific intervention effectiveness, which would further inform the design of evidence-based interventions.

Generalizability

1. Explore the unique challenges and context-specific solutions relevant to countries outside the United States.

Question 2: Question Regarding NGRCs



The dominance of structured, measurable social needs interventions in the involved studies likely reflects that health care prioritizes short-term outcomes. In contrast, long-term lifestyle change interventions are overlooked. This may be due to operational challenges, including reimbursement constraints, lower adherence, long-term evaluation, etc [112-115]. However, lifestyle change interventions are crucial for preventing NCDs. To raise attention on lifestyle change interventions, incorporating NGRCs is beneficial for improving adherence and effectiveness. Future studies should focus on leveraging NGRC data to design and evaluate personalized, NGRC-focused lifestyle interventions aiming at advancing patient-centered and preventive care.

Current research has largely overlooked NGRCs beyond transportation barriers within the "destination accessibility" dimension of built environments. Neglecting other 4D elements, as well as social (eg, community crime, neighborhood safety, and socioeconomic data; included in 4 studies) and natural environments (specifically air pollution; included in 1 study), may limit our understanding of how specific NGRCs can inform behavioral interventions. Within the built environment domain, the exploration of "density," "distance," and "design" in the "5D" framework was limited, and "diversity" was not addressed. Future studies should systematically explore other less-studied NGRCs, such as social, natural, and other built NGRCs, to inform more holistic solutions of behavioral interventions using HISs.

Insufficient attention to objective, dynamic, and/or high-resolution NGRCs has left several key methodological challenges largely unaddressed. These include the modifiable areal unit problem, uncertain geographic context problem, neighborhood effect averaging problem, and problem of temporal variations in NGRCs (Figure 4) [60,116-120]. One likely reason is that 22 studies (92%) relied on actively collected, subjective, and static NGRC data, which require substantial participant effort and are therefore difficult to scale for capturing dynamic and/or high-resolution NGRCs. Passive data collection methods (eg, GPS tracking and linkage with public datasets) could help overcome these limitations by enabling more dynamic and/or high-resolution NGRC measurement. However, passive approaches alone cannot capture all real-time and/or high-resolution NGRCs, particularly those related to individual perceptions. Therefore, active data collection remains essential for assessing perceived NGRCs. While some studies have focused exclusively on perceived measures, others have underscored the added value of combining subjective and objective NGRCs to more comprehensively understand their associations with behavioral outcomes [121-124]. When collecting perceived dynamic and/or high-resolution NGRCs, issues, such as user vagueness and the quality of self-reported data, must be carefully considered. Future work should prioritize developing optimized and balanced approaches that integrate active and passive data collection, thereby leveraging dynamic and/or high-resolution NGRC measures to advance behavioral intervention research.

XSL•FO
RenderX

Figure 4. The top-left figure displays the modifiable areal unit problem. The mean value does not change with aggregation, but the variance declines [118,119]. The top-right figure presents how the neighborhood effect averaging problem operates in individual air pollution exposures [116,120]. The bottom figure shows the uncertain geographic context problem, which arises because of the spatial uncertainty in the actual areas that exert contextual influences on the individuals being studied, and the temporal uncertainty in the timing and duration in which individuals experienced these contextual influences [60,117].

Furthermore, all involved studies illustrated the ongoing challenges of balancing granularity and comprehensiveness in assessing NGRCs. On the one hand, actively collected, subjective NGRC measures provide individualized insights but are limited in granularity and comprehensiveness. On the other hand, passively collected, objective indicators offer broad coverage but often lack individual insights and granularity, potentially due to existing dataset constraints. This trade-off underscores the need for integrated approaches that combine active and passive data to capture the complex, dynamic interplay between NGRCs and health behaviors.

To improve the granularity and comprehensiveness of NGRCs in various behavioral interventions, especially lifestyle change interventions, HISs—preferably tethered or interconnected PHRs in outpatient settings—should be considered. We have summarized 3 recommendations in Textbox 3.

Question 3: Question Regarding Stakeholders' Insights

Improved perceived value, convenience, patient autonomy, and privacy were consistently reported as outcomes of integrating technological (HISs) and content (NGRCs) innovations into behavioral interventions in all 10 included studies. On the other hand, social concerns persisted, including provider workload and the potential for discrimination. These benefits and concerns could be influenced by participants' computer literacy, which was rarely reported in the studies. Given this gap, future research should explore how to balance technological and content innovations with unresolved social concerns, accounting for variations in computer literacy.

The NGRC information needs of providers, the clinical usefulness of NGRC data, and the usefulness of NGRC-related data visualizations are not yet well supported by existing evidence. Future studies should investigate which NGRCs should be presented in HISs, how they should be used in practice, and which interactive features best support their use.

Stakeholders' insights into the integration of NGRCs and/or HISs into lifestyle interventions were not explored in the included studies. This highlights a critical gap in both technological and content innovations, as well as in addressing social concerns and in the integration of HISs and NGRCs into lifestyle change interventions.

We have summarized 5 recommendations focusing on enhancing NGRC and/or HIS integrations in behavioral interventions in Textbox 3.

Question 4: Question Regarding Research Design

We found limited coverage and inconsistent health outcomes of NGRC-focused behavioral interventions using HISs. Health outcomes focused mainly on health care utilization (eg, emergency visits), with limited coverage of clinical indicators, including medication adherence [97], asthma control [92], cancer screening [98], and blood pressure [87]. This limited coverage of clinical health outcomes limits the understanding of long-term

XSL•FO
RenderX

behavior change and highlights the need for more comprehensive assessments. Moreover, the inconsistent health care utilization outcomes [88,91] may be caused by the inconsistent and/or insufficient reporting of 5 aspects. These aspects include (1) NGRC attributes (eg, definitions and spatiotemporal characteristics), (2) HIS types and functionalities, (3) assessment methods (eg, clinical metrics [eg, HbA_{1c}] and health care utilization), (4) stakeholders (eg, only HISs or various health providers), and (5) targeted diseases. Such heterogeneity causes low interstudy comparability and reproducibility. It also limits the ability to determine which behavioral interventions, leveraging specific NGRCs via particular HIS functions, are most effective, thereby complicating the translation of findings into evidence-based practice.

No studies have addressed key issues such as cost-effectiveness and ethical considerations. Future research should examine these critical factors to ensure successful implementation.

To develop evidence, we have summarized 3 recommendations in Textbox 3.

Generalizability of the Results

Our objective was to synthesize global literature on NGRC-focused behavioral interventions supported by HISs. However, we were unable to identify published, peer-reviewed studies conducted outside of the United States. Initiatives, such as the European Health Data Space (EHDS) [125] and China's Healthy China Initiative [126], reflect growing efforts to integrate SDoH, including NGRCs, into HISs. On one hand, contextual differences do not preclude transferability. The contextual differences include cultural norms, socioeconomic conditions, and geographic contexts. With appropriate localization and system-level adaptation, the core principles identified in United States–based studies can be effectively applied in diverse settings. However, the limited diversity of study settings may obscure unique challenges and solutions relevant to low-resource or non-Western countries. Addressing these gaps is essential, and future research should ensure that context-specific NGRC-focused behavioral interventions using HISs are inclusive, adaptable, and globally relevant (Table 3). On the other hand, technological and political differences across the world do not influence the generalizability of our study. These differences include (1) HIS infrastructure, architecture, and integration capabilities, and (2) data standards, privacy regulations (eg, the European General Data Protection Regulation [127]), and governance policies. The commonalities of these differences help support the generalizability of the findings [128].

Strengths and Limitations

Our review has 4 key strengths. First, this article reviews the current state of NGRC-focused behavioral interventions using HISs. This provides a comprehensive analysis from 3 perspectives: technology, NGRC content, and stakeholders' insights. Second, we searched a wide range of databases, leading to publications from diverse disciplines, including medical journals, environmental journals, and computer science conferences. Third, we consulted a library information specialist to develop the search strategy, ensuring its comprehensiveness and accuracy, which thus enhanced the research's quality and credibility. Finally, to provide readers with sufficient context and allow them to assess the reliability of the evidence, we extracted and reported descriptive information, including study type, publication year, and sample size (Table S4 in Multimedia Appendix 1). We did not conduct a critical appraisal of the included studies, as it is not mandatory in scoping reviews. According to the Joanna Briggs Institute (JBI) methodology for scoping reviews [129], a critical appraisal is generally unnecessary unless it is directly relevant to the review objectives. Additionally, most quality assessment tools, including the Mixed Methods Appraisal Tool (MMAT) [130], primarily evaluate study design, data collection, and methodological rigor. Therefore, applying such tools would not provide meaningful information for our objectives (eg, HIS functionalities and NGRC indicators).

Our study also has several limitations that should be considered. First, NGRCs are ambiguous, suggesting that they are open to multiple interpretations or are vague. For example, in various studies, neighborhood safety may refer to different things, but there are no clear details of this concept in the studies. However, resolving this ambiguity is challenging because of the lack of standardized definitions and the context-dependent characteristics of NGRCs. Therefore, future studies should adopt detailed and consistent definitions of NGRCs, ideally guided by standardized terminologies or ontologies. These terminologies or ontologies can leverage and expand existing terminologies (eg, "community details" in Systematized Nomenclature of Medicine—Clinical Terms [SNOMED CT] and Logical Observation Identifiers Names and Codes [LOINC]) and SDoH ontologies [24].

Possible Mechanisms and Implications for Clinicians or Policymakers

HISs are often seen as passive recorders of health data. However, tethered or interconnected PHRs can actively participate in the entire process of NGRC-focused behavioral interventions, especially in outpatient lifestyle change interventions, with the relatively limited help of health care providers. For example, platforms like the iManageCancer platform for cancer patients and the iManageMyHealth app for their physicians provide personalized content from reliable public resources on cancer. However, these platforms do not currently consider NGRC factors and focus on behavioral interventions [3]. This underscores the importance for providers and policymakers to utilize tethered or interconnected PHRs to collect comprehensive, dynamic, and static NGRCs; deliver timely behavioral interventions in outpatient settings; monitor behaviors and the health status; and assess interventions. By doing so, they can achieve public health goals and promote health equity.

Conclusion

In this study, we found that most NGRC-focused behavioral interventions utilized transportation barriers to support social needs interventions. Meanwhile, HISs were involved only in specific aspects of the NGRC-focused behavioral intervention process. To achieve comprehensive dynamic and/or

XSL•FO
RenderX

high-resolution NGRC considerations and the full integration of HISs throughout the behavioral intervention process, given the limited and heterogeneous evidence, further research is needed to determine how tethered or interconnected PHRs can effectively support NGRC-focused interventions, especially lifestyle change interventions. During implementation, it is essential to address social concerns alongside technological (eg, HIS integration) and content innovations (eg, NGRC integration). We compiled a list of 15 recommendations for future research. These recommendations are likely to accelerate the integration of tethered or interconnected PHRs in NGRC-focused behavioral interventions.

Acknowledgments

Generative artificial intelligence (AI) tools were used for writing assistance. Generative AI tools (eg, ChatGPT) were used for language editing and minor improvements in phrasing after the original writing was completed. We would like to thank Valerie Moran from Luxembourg Institute of Socio-Economic Research (LISER) for shaping the thematic focus and structure of this scoping review.

Funding

The study was funded by the China Scholarship Council (CSC) (file number: 202208140027).

Authors' Contributions

XY, MD, and RC are the guarantors of the integrity of the entire study. All authors contributed to the study's conceptualization and design. JGD performed the literature search. XY, MD, and RC contributed to study selection and interpretation. XY wrote the manuscript. MD, RC, HY, MS, and JGD reviewed and edited the manuscript. All authors read and approved the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Nursing care systems face significant challenges due to demographic changes, a workforce shortage, and rising demand for care services. Digital assistive technologies offer potential to address these challenges, but systematic and standardized nursing data are essential to evaluate both innovations and broader care processes. The Nursing Minimum Data Set (NMDS) provides a foundational framework for capturing structured information on nursing care, yet there is no international consensus on its core content, development, and practical use.

Objective: This scoping review aims to map current international literature regarding (1) the core content elements of NMDS, (2) methodological approaches used in NMDS development, and (3) implementation and use of NMDS in different nursing settings.

Methods: Following the JBI (Joanna Briggs Institute) methodology and Arksey and O'Malley framework, a systematic search was conducted on July 2, 2025, in the MEDLINE (via PubMed) and CINAHL (via EBSCO) databases using the term "nursing minimum data set." Inclusion was restricted to studies in English or German focusing on the content, development, or implementation of the NMDS. The research team reviewed studies in an independent and double-blinded fashion for eligibility based on predefined criteria, with discrepancies resolved by consensus. Eligible studies were narratively summarized, with extraction structured into categories based on the review's research questions.

Results: From 1908 initially identified articles, 26 (1.4%) studies met the inclusion criteria. Considerable heterogeneity was found in the structure and scope of the NMDS, with datasets comprising 16 to 145 items. Despite variation, 4 central domains consistently emerged: patient demographics, medical care information, nursing care elements, and institutional or organizational data. NMDS development typically followed a participatory, multistage approach involving literature analysis, stakeholder consensus building, and validation through pretesting and real-world application. Implementation and use of the NMDS serve multiple functions, including documenting nursing care processes, supporting workload measurement and resource planning, quality assurance, benchmarking, and demonstrating nursing's contribution to patient outcomes. However, successful implementation depends on technical, legal, organizational, and educational strategies. Core challenges include a lack of standardized terminology, inconsistent legal frameworks, and varying levels of staff training and acceptance.

Conclusions: The NMDS provides a robust basis for standardized nursing documentation, quality assurance, and health system planning, but international variability and ongoing challenges in harmonization, integration, and acceptability persist. Advancing the NMDS requires collaborative efforts for interoperability, investment in digital infrastructure, and targeted education. Further research should focus on comparative effectiveness, cross-context validation, and strategies to reduce documentation burden while maximizing data utility.

Introduction

The nursing care system in Germany is confronted with significant challenges, including demographic shifts, a shortage of nursing personnel, and increasing demand for care services [1]. From 2014 to 2021, expenditures on long-term care insurance increased more than 2-fold, rising from €25.5 billion (US $30 billion) to €53.9 billion (US $63.4 billion) [2]. To ensure the sustainability of care provision, there is a need for innovative digital solutions. Digital assistive technologies have been shown to have considerable potential in promoting participation and autonomy, as well as reducing care dependency [3]. However, research focusing on the etiology and progression of care needs, as well as the ramifications of digital innovations, has been disproportionately underrepresented to date [4].

Robust and standardized nursing data are essential to evaluate these innovations and their impact on care. The Nursing Minimum Data Set (NMDS) is defined as "a minimum set of items of information with uniform definitions and categories concerning the specific dimension of nursing which meets the information needs of multiple data users in the health care system" [5]. The NMDS provides a structured basis for capturing nursing care across populations, settings, and regions. It facilitates the monitoring of trends in care delivery and resource use, serves as a foundational element for research by establishing connections with broader health information systems, and contributes to the formulation of health policy, thereby ensuring the visibility of nursing contributions in health care planning and decision-making [6]. With a focus on influencing factors and opportunities to prevent or reduce care dependency, the NMDS can also serve as a framework for assessing the impact of digital innovations.

Despite its potential, there is a lack of clarity regarding which elements should be included in a core nursing dataset, how such elements are developed, and what barriers or success factors influence its implementation in practice. The objective of this scoping review is to map the current state of the literature by addressing the following research questions:

1. Which content elements comprise a nursing minimum dataset?
2. Which methodological approaches have been used in its development?
3. What is the implementation and use of such a dataset in different nursing settings?

Methods

This scoping review was conducted in accordance with the JBI (Joanna Briggs Institute) methodology [7] and guided by the framework of Arksey and O'Malley [8], which structures the process into the following phases: identifying relevant studies, study selection, data presentation, and synthesis of results. To enhance rigor and transparency, the reporting process adhered to the PRISMA-ScR checklist (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews; Checklist 1) [9].

Search Strategy

A systematic search was conducted on July 2, 2025, in the MEDLINE (via PubMed) and CINAHL (via EBSCO) databases using the search term "nursing minimum data set," applied identically in both databases. "Nursing minimum data set" is an internationally established and unambiguous term for the concept of interest. Preliminary searches using broader terms such as "nursing data" or "nursing data set" yielded numerous irrelevant results, mostly referring to general medical datasets including nursing-related variables but not specifically designed for nursing care. Searches in other databases (eg, Google Scholar and Europe PMC) produced even more irrelevant hits.

Using the precise term "nursing minimum data set" maximized specificity and relevance. PubMed's Automatic Term Mapping further captured synonyms and MeSH (Medical Subject Headings) terms. This focused approach aligns with Freguia et al [10] but extends their work by also analyzing the development and implementation of the NMDS. The MEDLINE and CINAHL databases were selected due to their comprehensive coverage of peer-reviewed nursing and health services research. No date restrictions were applied, and reference lists of the included articles were manually screened to minimize the risk of missing eligible studies.

The detailed inclusion and exclusion criteria are enumerated in Textbox 1. Exclusion criteria were based on our aim to map the conceptual, methodological, and implementation aspects of the NMDS rather than secondary applications or specialized derivatives. Studies focusing solely on specific clinical conditions, measurement tools, isolated settings (eg, palliative care), or context (eg, quality management) were excluded. Publications on other datasets (eg, the Minimum Data Set Resident Assessment Instrument [11]) or nursing classifications were also excluded. Language was restricted to English and German to ensure reliable screening and data extraction. Although this may introduce language bias, the majority of conceptual NMDS literature is published in these languages.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Primary and secondary studies with abstracts available
- Language: German or English
- Description of content, development, implementation, and use in practical applications of the Nursing Minimum Data Set

Exclusion criteria

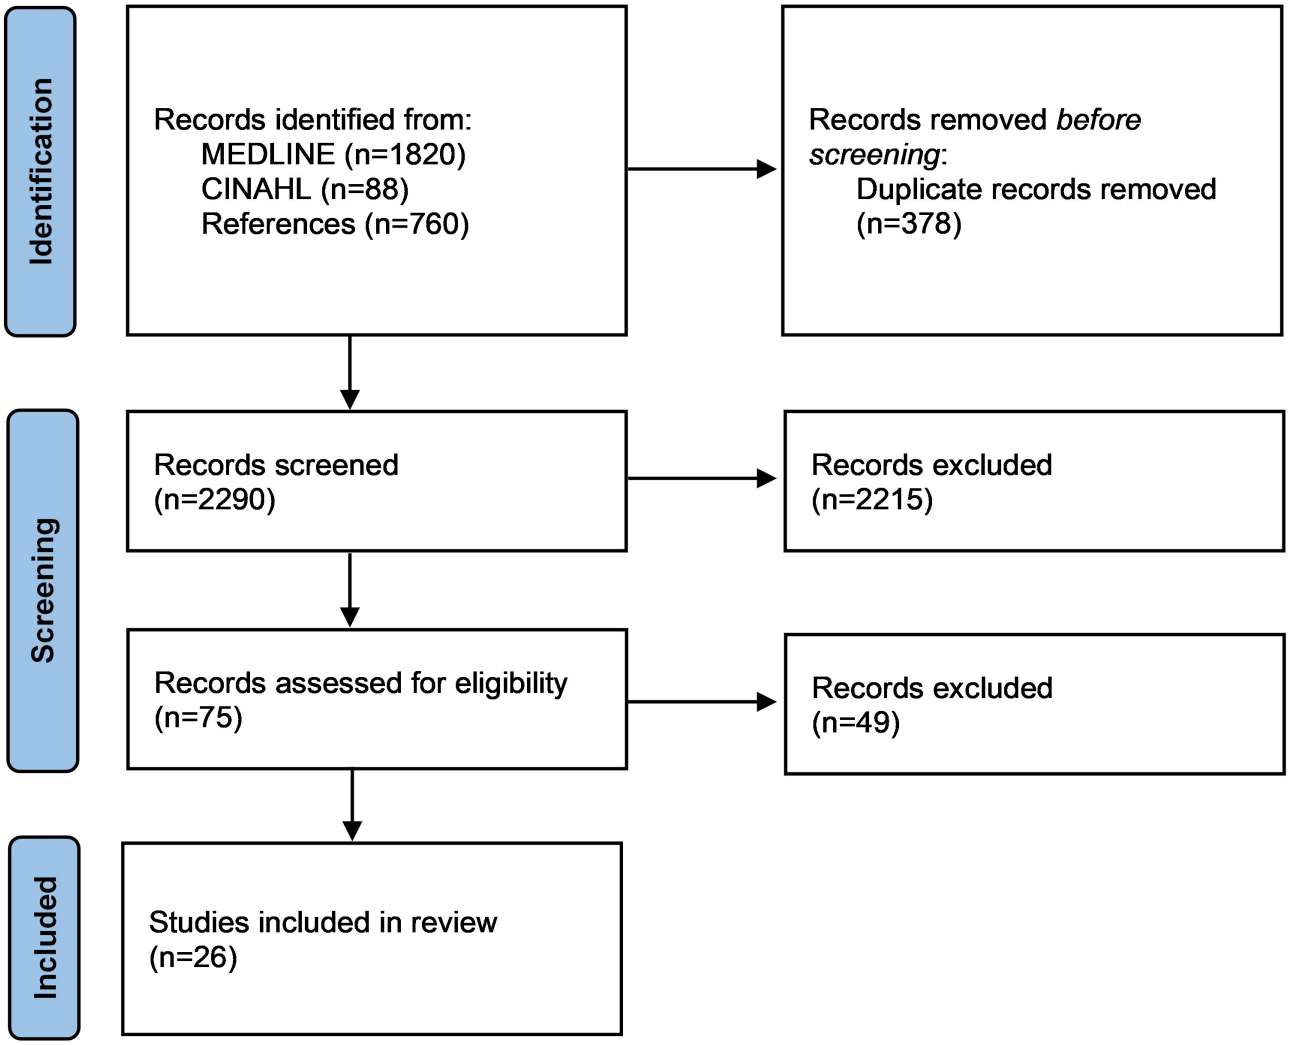
- Secondary analyses of the Nursing Minimum Data Set
- Reference to interventions, specific clinical pictures, or medications
- Reference to quality management, personnel indicators, or specific settings
- Comparison of measurement instruments
- In cases of duplicate publication, only the most comprehensive or earliest version was included to avoid double-counting

Study Selection and Data Extraction

The study selection followed the JBI methodology for transparency and reproducibility. Duplicate removal and screening were conducted using Rayyan (Rayyan Systems, Inc) [12], a web-based collaborative platform enabling independent and blinded review. Duplicates were first removed automatically using the software's matching algorithms based on title, author, DOI, journal, and year and then manually checked to resolve partial matches or inconsistent metadata.

Titles and abstracts of remaining records were independently screened by 2 reviewers (PM and AG) using Rayyan's blinded mode. Records identified as potentially eligible by at least 1 reviewer proceeded to full-text review. Discrepancies were resolved through discussion, with a third reviewer (KG) consulted if consensus could not be reached. The process was independent of study design and focused on studies addressing the conceptualization, development, or implementation of the NMDS. The number of records at each stage is presented in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram. Reference lists of the included studies were manually screened to identify further eligible studies.

To systematically extract and present relevant information, included studies were narratively summarized in a data-charting form. The studies were categorized and analyzed according to the following classifications: "overview" (eg, definition and elements); "development" (eg, methods and processes); and "implementation" (eg, evaluation, availability, reliability, and validity). The primary categories were derived deductively from the review questions. Subcategories were subject to refinement and expansion in an iterative manner as novel themes and patterns emerged from the included studies. This framework enabled the synthesis of structured and flexible approaches, capturing the breadth of the research field.



Results

Study Selection

The database search conducted in July 2025 yielded 1908 results (PubMed: n=1820, 95.4%; CINAHL: n=88, 4.6%). After removing duplicates, 1869 (N=1908, 98%) records remained for title and abstract screening. Of these, 1823 (N=1869, 98%) were excluded due to unavailability of full texts or because they focused on data infrastructure, storage, or evaluation frameworks unrelated to NMDS content, development, or implementation. A total of 36 (N=1869, 2%) articles underwent double-blind full-text review. After applying all eligibility criteria, 23 (N=1869, 1.2%) articles were included. Screening reference lists added 3 more studies, resulting in a total of 26 included studies. No conflicts occurred among independent reviewers. The selection process is presented in the PRISMA flowchart [13] (Figure 1). A comprehensive list of the included studies and the data extraction table are provided in Multimedia Appendix 1 [6,10,14-37].

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart illustrating the study selection process.

Main Characteristics of the Included Studies

The 26 studies originated from 9 countries. Most were from the Netherlands (n=6, 23.1%), the United States (n=4, 15.4%), Austria (n=4, 15.4%), Belgium (n=4, 15.4%), and Ireland (n=3, 11.5%). Additional studies were conducted in Finland (n=2, 7.7%), and 1 (3.8%) each from Italy, Germany, and Thailand. The majority of reported NMDS initiatives have their origins in the United States [10,16,19,25,29], Belgium [10,19,25,29,32-34,36], Canada [10,19,25,29], Thailand [10,25,27,29,37], Switzerland [25,29], and the Netherlands [18,20-23,25,29]. Additional origins including Ireland [14,26,29], Germany [17,29], Finland [24,25,29,35], Australia [19,25,29], Sweden [25], Brazil [25], Japan [25], Austria [28,30,31], and Scotland [19] were mentioned in several studies, which also referenced a European [10,19,25] and an international NMDS [19,25]. Most of the studies focused on universal nursing settings. However, there have also been investigations of specific settings such as hospitals, long-term care facilities, nursing homes, home health care agencies, and public health contexts.

The articles encompassed a period from 1988 to 2022. The predominant language of publication was English (n=24, 92.3%), with 2 (7.7%) articles published in German. The study designs exhibited heterogeneity, encompassing theoretical papers (n=9, 34.6%), mixed methods studies (n=7, 26.9%), quantitative studies (n=9, 34.6%), and a single qualitative study. The predominant focus was the development of the NMDS [14,17,21,27,28,30,33-36], followed by evaluation [16,20,22,31] and implementation [24,26,32]. A subset of these studies was also partially cited in the included systematic review [29] and umbrella review [10].

Data Elements

The datasets have been designed to capture comprehensive and comparable information on nursing practice, patient status, and care context. This facilitates the monitoring, evaluation, and enhancement of nursing care delivery at both the individual and system levels. A review of the existing literature revealed a considerable variation in the number of elements comprising an NMDS, ranging from 16 to 145 items per dataset. Despite this variation, 4 key categories consistently emerged: patient demographics, medical care information, core nursing care elements, and institutional or organizational data (Textbox 2).

The patient's demographic information is typically documented on an initial admission to the health care facility and subsequently serves as a foundational reference point for the patient's characteristics. The medical care items in question prioritize crucial medical information. While certain elements are documented on a single occasion during the patient's hospital

XSL•FO
RenderX

stay, details concerning medical procedures and medications are frequently recorded throughout the patient's stay. Core nursing care elements are typically collected continuously throughout the duration of hospitalization. The exception to this is nursing outcomes, which are generally assessed at discharge. Risk assessments and nursing diagnoses, on the other hand, are updated as the patient's status changes. Institutional or organizational data link patient- and care-level information with structural and organizational attributes, thereby supporting contextual analysis of care processes.

Textbox 2. The datasets are designed to capture information on nursing practice, patient status, and care context.

Patient demographics (3-8 items)

- Personal identification (pseudonymized)
- Date of birth and age
- Gender
- Race and ethnicity
- Place of residence
- Address and phone number

Medical care information (4-7 items)

- *International Classification of Diseases* codes
- Medical history (patient and family)
- Drug allergies or other allergies
- Procedures
- Laboratory tests
- Medication
- Dead or alive codes and resuscitation status
- Admission or encounter date
- Discharge information (date and summary)
- Length and progression of stay
- Health status (stability, severity, complications, and critical events)

Nursing care elements

- Nursing diagnosis (17-48 items)
- Nursing interventions (8-170 items)
- Nursing outcome (4-40 items)
- Intensity of nursing care (3-4 items)
- Nursing process (10 items)
- Client status (activities of daily living)
- Discharge plan
- Care planning (goals of the shift and goals of nursing care)
- Medical instruments' use before discharge

Institutional or organizational data

- Health care setting (4-5 items): type of institution, main point of service, type of nursing delivery system, and other disposition point
- Resource allocation (4 items): number and qualification of available nurses, number of nursing hours available, number of beds, and nurse-to-patient ratios
- Institutional or provider identifiers: service or agency number, health record number, nurse identifier, and physician identifier
- Expected payer of the bills or health insurance

XSL•FO
RenderX

NMDS Development

The development of the NMDS generally follows a three-stage process: (1) selection and definition of relevant data elements based on literature analysis, document analysis, and interdisciplinary consensus; (2) validation and consensus building through expert rounds, pretesting, and reliability assessments; and (3) application and testing the feasibility in real-world settings.

Selection and Definition of Data Elements

Potential items were chosen for clinical relevance and feasibility through literature reviews, analysis of clinical records (n=15-45 per study), and collaborative expert panels or Delphi processes. Participants included field nurses, nurse managers, nursing scientists, informatics specialists, and policy representatives (n=22-287 per study). Semistructured interviews and questionnaires were central, supported by focus groups and multiple rounds of expert panels (up to 11 with n=5-88 participants). The goal was to ensure that the items reflected actual practice, captured the diversity of nursing activities, and could be coded in a feasible manner. Critical decisions included choosing terminology and coding schemes, unit of data collection (eg, patient day or episode of care), and timing of data entry.

Refinement and Validation

The refinement of items and structures was achieved through consensus-building methods, such as repeated Delphi rounds and focus groups, along with pretests and reliability assessments, including Cohen κ and intraclass correlation coefficient. These methods often incorporated interdisciplinary and practice-based feedback, facilitating the continuous improvement and refinement of the research instruments. In the preliminary phase, the expert participants engaged in deliberations concerning the relevance, frequency, and practical feasibility of each item. In addition, they addressed the conceptualization, frequency, and relevance of the items, along with the data that were routinely collected. Lists of nursing diagnoses, interventions, and outcomes were developed and discussed for clarity and practicality. Subsequent rounds entailed the refinement and evaluation of the wording and definitions for their usefulness and feasibility, as well as the systematic testing of the definitions and coding rules. The resulting data collection instruments provided multiple response options for each item, thereby generating a broad range of analyzable variables. Each data element was carefully defined and accompanied by specific operational instructions, including scoring schemes that frequently used 5-point Likert scales to evaluate interventions and diagnoses.

The documentation of nursing care is typically implemented through the use of standardized classification systems. However, a universal system has yet to be established across all NMDS implementations. Instead, a variety of established frameworks are used, including the International Classification of Nursing Practice [38], the North American Nursing Diagnosis Association-I classification [39], the Omaha System [40], and the Home Health Care Classification [41], among others. The NMDS has been designed to either specify a preferred system or permit cross-mapping between local and international standards. The ability to exchange data and information seamlessly across different systems and between different countries is paramount for the comparability of data at both the national and international levels.

Reliability and validity testing constituted a fundamental component of the second stage. Pretests were conducted using samples ranging from 4 to 214 participants, often comparing the extracted information from patient records (n=20 to nearly n=300,000) by pairs of raters (research staff and clinical nurses). The coding agreement was subsequently quantified. The validity of the content was determined through its alignment with existing literature and user evaluations.

Feasibility Testing and Application

The final development stage focused on evaluating the usability and practical implementation of the NMDS. This included structured pilot applications in real nursing settings, such as hospitals, nursing homes, ambulatory care, and home health agencies. Typically, a longitudinal design with repeated measurements over a defined observation period (eg, 7 d or 1 admission episode) was selected. Consequently, the NMDS demonstrated its efficacy in the domains of care process description, workload measurement, resource planning support, benchmarking, and quality improvement across diverse nursing settings.

One such function is to systematically describe the diversity of nursing care and patient populations through frequency analyses of nursing diagnoses, interventions, and outcomes. The application of advanced analytical approaches, such as relative to an identified distribution analysis, has been demonstrated to facilitate the illustration of variations in nursing practice and complexity across a variety of settings, age groups, and medical diagnoses. In addition, the NMDS is instrumental in evaluating the intensity of nursing care. By establishing a correlation between the implementation of each nursing intervention and the temporal and experiential parameters of the nursing personnel involved, health care institutions can facilitate a quantitative assessment of the workload associated with each patient or unit of care. Classification systems such as the nursing diagnosis index or patient dependency models (eg, the San Joaquin classification) are used to establish a correlation between patient needs and staffing requirements, thereby facilitating evidence-based staffing decisions and resource allocation.

A further central benefit of the NMDS is its ability to demonstrate nursing's contribution to patient outcomes. For instance, path analysis can be used to examine the relationship between nursing interventions and patient progress, as illustrated by improvements in functional indices (eg, the Barthel index) during hospitalization. In the context of quality management and patient safety, outcome indicators facilitate the identification of care problems and the evaluation of improvement strategies through the integration of validated assessment instruments. The longitudinal use of these tools adds further value by enabling the tracking of care trends and patient outcomes over extended periods. These analyses are valuable for clinical managers and policymakers in the context of epidemiological

XSL•FO
RenderX

analysis, benchmarking institutions, highlighting areas of best practice, and supporting the dissemination of evidence-based interventions. This facilitates the formulation of strategic decisions regarding care processes and resource distribution.

A comprehensive implementation strategy must encompass not only technical solutions, such as increasing automation and electronic data collection, but also legal, organizational, and educational strategies. For instance, the implementation of the NMDS in specific contexts was terminated due to the absence of a legal foundation or inadequate institutional endorsement. The quality and utility of collected data are contingent on nurses' familiarity with the NMDS content and vocabulary. Educational initiatives are required to enhance nurses' comprehension of the significance of structured data collection and its pertinence for clinical decision-making, quality assurance, and the development of interoperable hospital information systems. To reduce the workload associated with NMDS documentation, it may be necessary to minimize the scope of collected variables, with a push toward electronic and automated data collection.

Discussion

Principal Findings

This scoping review offers a comprehensive mapping of the extant literature on the NMDS with regard to content elements, methodological development processes, and implementation and use across nursing settings. Synthesizing evidence from diverse international contexts and research designs, this review addresses the critical knowledge gaps identified in the introduction and provides an informed basis for further research and policy development in the field of standardized nursing data.

A salient finding of this review is the substantial heterogeneity observed in the structure and length of reported NMDSs, which vary from 16 to 145 items. Nevertheless, 4 core domains consistently emerged: patient demographics, medical care information, nursing care elements, and institutional or organizational data. This convergence on key domains, despite variation in the level of detail and specific items, underscores both the complexity of capturing nursing care and the international consensus on the essential pillars of nursing-relevant information. The comprehensive integration of nursing diagnoses, interventions, and outcomes signifies a worldwide transition toward outcome-oriented, evidence-based nursing practice. However, the absence of a universally adopted classification system for these categories—variously using systems such as the North American Nursing Diagnosis Association-I classification, the International Classification of Nursing Practice, or local taxonomies—continues to challenge the comparability of nursing data both within and across countries. This diversity underscores the necessity for enhanced harmonization to facilitate broader benchmarking, interoperability, and secondary data use.

The development of the NMDS is characterized by rigorous, iterative, and participatory processes. Most of the studies used a 3-stage approach: first, systematic identification and selection of content elements (frequently drawing from the literature, expert consultations, and clinical record analyses); second, consensus building and validation (frequently relying on Delphi processes, focus groups, and pretesting); and third, pilot implementation in real-world settings. The consistent engagement of field nurses, managers, scientific experts, and policy stakeholders supports both the clinical relevance and the practical feasibility of the resulting datasets. However, methodological diversity—particularly in the degree of stakeholder inclusion, the criteria for item selection, and the approach to validation—limits the extent to which the results can be compared and generalized. A fundamental finding is that consensus and interdisciplinary involvement significantly enhance acceptance and operationalization. However, disparities in contextual adaptation and infrastructure availability necessitate context-sensitive approaches, superseding the notion of a universally optimal solution.

The review demonstrates a wide range of applications of the NMDS, encompassing care process documentation, workload measurement, resource planning, quality assurance, benchmarking, and outcome evaluation. Analytical techniques such as frequency analysis, relative to an identified distribution analysis, and path analysis facilitate the sophisticated use of NMDS data. This includes the identification of care trends and variations, the mapping of nursing workload, and the demonstration of the impact of nursing care on patient outcomes. NMDS data have demonstrated their relevance for supporting clinical management, health policy, and epidemiological surveillance in multiple health care systems.

However, the implementation of NMDS is not without challenges. Achieving success in this endeavor necessitates the implementation of a multifaceted approach, encompassing not only technical solutions such as electronic and automated data collection but also legal, organizational, and particularly educational strategies. In certain settings, the discontinuation of NMDS initiatives was attributed to a lack of legal foundation, inadequate institutional support, or suboptimal integration into health information systems. The collection of consistent and high-quality data is contingent upon nurses' familiarity with the terminology and documentation standards. Consequently, training and change management are imperative. Furthermore, the balancing of data comprehensiveness with feasibility, as well as the minimization of documentation burden, emerges as a recurring theme in the pursuit of long-term sustainability.

Strengths and Limitations

A central strength of this review is its comprehensive and systematic approach, which adheres to established methodological frameworks (JBI and PRISMA-ScR) and uses a transparent, replicable search and data extraction process. The program's emphasis on international literature and a diverse array of study types contributes to the generalizability and relevance of the findings. The use of independent, blinded screening and iterative data charting enhances the rigor and credibility of the synthesis.

Several limitations of this review should be acknowledged. First, only 2 databases and a single search term were used. Preliminary scoping checks indicated that broader terms or additional databases yielded mostly irrelevant results, suggesting

XSL•FO
RenderX

a low likelihood of missing studies specifically addressing the NMDS. As NMDS initiatives are sometimes embedded in national health IT programs, relevant reports may appear in gray literature or regional journals not indexed in the MEDLINE or CINAHL databases. Nevertheless, the potential remains that studies using alternative terminology or published outside the MEDLINE and CINAHL databases were not captured. This structural publication bias should be considered when interpreting the findings. Second, the exclusion criteria may limit the mapping breadth by underrepresenting NMDS adaptations in non–English-speaking and non–German-speaking countries or highly specialized settings. This potential exclusion could introduce publication bias and limit the capture of ongoing or context-specific innovations. Third, as is typical for scoping reviews, no formal quality appraisal of included studies was conducted, which may have affected the weight assigned to individual findings. Fourth, the heterogeneity of study designs, settings, and health care systems complicates a direct comparison and synthesis of findings. To conclude, while this review identifies fundamental content and process elements, as well as prevalent barriers and success factors, it does not provide a meta-analytic estimate of the impact of the NMDS on patient or system outcomes.

Conclusions

This scoping review highlights the heterogeneity and evolving consensus on the structure, development, and implementation of the NMDS. Despite international variations, 4 core domains consistently emerged: patient demographics, medical care information, nursing care elements, and institutional or organizational data. The NMDS can enhance the visibility, quality, and effectiveness of nursing care across health care systems, provided that challenges related to standardization, interoperability, and acceptance are addressed.

To translate these findings into practice, policymakers and health care managers should prioritize the standardization of nursing documentation through appropriate legal frameworks, investment in digital infrastructure, and targeted educational initiatives for nursing staff. Practical steps include establishing interoperable digital nursing records; providing structured training on NMDS use; and implementing pilot programs to assess the feasibility, usability, and data utility. Researchers are encouraged to evaluate the NMDS across diverse settings, conduct comparative effectiveness studies, and explore strategies to reduce documentation burden while maximizing actionable insights for care management, resource planning, and policy decisions. Overall, the review underscores that advancing the NMDS requires interdisciplinary collaboration, context-sensitive implementation, and ongoing evaluation to ensure that standardized nursing data meaningfully inform clinical practice and health system planning.

Funding

This research was funded by the Federal Ministry of Research, Technology, and Space (grant 01ZZ2401A). The study has been funded for a 5-year period, starting in November 2024. The study was funded for €4,559,301.88 (US $5,369,253.83). The funder had no involvement in the study design, data collection, analysis, interpretation, or the writing of the manuscript. The authors acknowledge the financial support of the Open Access Publication Fund of the Martin-Luther University Halle-Wittenberg.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Abstract

Background: Technology has improved patient care in hospitals, enhancing the overall patient experience. However, digitalization raises questions on effectively integrating technological strategies to ensure assertive communication of information during emergency department (ED) journeys. Keeping patients well-informed boosts their service perception and satisfaction, a factor often neglected by institutions in EDs.

Objective: This paper analyzes relevant studies on technological strategies designed for EDs aimed at improving patient experience, focusing on communication and information access. We analyze the technologies, outcomes, impacts, and challenges of the strategies.

Methods: A scoping review was conducted using the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines and CADIMA tool. Searches were performed in Scopus, PubMed, IEEE Xplore, and CINAHL databases. Articles published from January 2018 to December 2024 were included. Quality appraisal was performed using the Crowe Critical Appraisal Tool version 1.4. Three reviewers independently examined the title and abstract for eligibility based on the inclusion and exclusion criteria.

Results: Sixteen eligible studies were included. Four technological strategy categories were identified: artificial intelligence−based, simulation-based, infrastructure and hardware technologies, and interfaces and information systems. Mobile and web applications were the main technologies adopted in the studies.

Conclusions: Technological strategies hold significant potential to enhance patient experiences in EDs by providing real-time updates on medical status and care progress. However, their effectiveness depends on usability, literacy, and system design. Existing literature highlights the impact and challenges of deploying and using these strategies in EDs. However, no studies have systematically evaluated long-term outcomes or cost-effectiveness across diverse ED settings.

KEYWORDS

scoping review; PRISMA-ScR framework; emergency department; patient journey; communication technology; patient experience

Introduction

The emergency department (ED) constitutes the gateway to health care for many people, being the place where treatment begins for a wide spectrum of diseases, some of which are life-threatening and require immediate attention [1]. The typical patient journey in the ED involves triage classification, medical evaluation, necessary examinations, medications, or procedures, reevaluation, and finally discharge or observation [2]. However, challenges such as overcrowding, uncomfortable facilities, and poor communication continue to hinder timely and efficient ED patient care, negatively impacting both patient experience and institutional performance [3]. In fact, effective and assertive communication of information about the ED patient journey has been found to be associated with patient satisfaction; thus, studies indicated that the lack of information on the progress and delays has a greater effect on patient satisfaction than perceived waiting times while visiting the ED [4]. In addition, it leads to feelings of powerlessness for patients and their family members [5]. Patients who feel well informed tend to have a better perception of the service [6], leading to higher satisfaction with the care and reduced anxiety [7], which in turn contributes to greater institutional efficiency [8].

XSL•FO
RenderX

With recent technological innovations, the potential to address communication challenges in EDs has increased significantly. Technologies that enhance communication and improve information accessibility have shown promise in improving the patient experience in the ED [9]. However, due to the rapid pace of technological advancement and the growing use of digital solutions in health care, there is an urgent need to review existing evidence to guide future implementation efforts.

This scoping review aims to analyze relevant studies and describe the evidence on technological strategies implemented in EDs worldwide that enhance patients' experiences during their journey in the ED. A technological strategy refers to the approach and implementation of technologies and supporting infrastructure within ED workflows to improve patient experience throughout their journey. Regarding the ED patient experience, the review focuses on two dimensions: communication and access to information. Communication refers to the exchange of timely, accurate, and comprehensible information between health care providers and patients or family members regarding medical status and progress updates during the ED visit. Access to information refers to patients' ability to obtain and understand relevant details about their journey in the ED. The following research questions (RQ) were addressed:

- What technological strategies exist to improve patient experience in EDs, considering dimensions such as communication and information accessibility?
- What infrastructure and technologies support technological strategies?

The scoping review offers a comprehensive and interdisciplinary perspective, integrating insights from clinical, technological, and human-centered design domains. The primary innovation of this study lies in its integrative and multidimensional approach to evaluating technological interventions in EDs, specifically through the lens of patient communication and information accessibility—dimensions often underrepresented in prior reviews. Unlike earlier works that focus predominantly on clinical outcomes or operational efficiency, this review foregrounds the patient experience and satisfaction as central evaluative criteria. It also identifies a critical knowledge gap: the lack of standardized frameworks for evaluating the long-term effectiveness, cost-efficiency, and scalability of these technologies across diverse health care settings. Additionally, the review highlights the insufficient attention given to the adaptability of these tools for vulnerable populations, such as those with low digital literacy or disabilities, and the need for participatory design approaches to ensure equitable and sustainable implementation.

Methods

Databases and Search Keywords

To analyze the current and future landscape of technological strategies in EDs, a scoping review was conducted following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines [10]. Studies were retrieved from Scopus, PubMed, IEEE Xplore, and CINAHL in January 2025. The inclusion of CINAHL and PubMed ensures coverage of nursing and clinical perspectives that are highly relevant to patient care and workflow improvements, complementing the technical focus of IEEE Xplore and the multidisciplinary scope of Scopus. The keywords used in the search queries included technology, strategy, ED, communication, and access to information. The complete search strategy was as follows: ("Technolog*") AND ("Strateg*" OR "Approach*" OR "Solution*" OR "Framework*" OR "System*" OR "Model*") AND ("Emergency Department*" OR "Emergency Service, Hospital" OR "Emergency Room*" OR "Emergency Medical Service*") AND ("Communication" OR "Access to Information"). The final database search queries for the period January 2018 to December 2024 are summarized in Multimedia Appendix 1.

Inclusion and Exclusion Criteria

To ensure the quality of the articles, only those that met the inclusion and exclusion criteria presented in Textbox 1 were considered in the review process. These criteria were chosen to focus on studies that specifically examine technological strategies designed for EDs and their impact on patient experience, particularly in the dimensions of communication and information accessibility. Three reviewers independently applied the criteria to refine the list of eligible articles. In cases of uncertainty, the decision was made collectively after discussion.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Documents published between 2018 and 2024 (including both years)
- Documents published in peer-reviewed journals or conference proceedings
- Full-text articles available in English
- The research setting is at least a hospital or an emergency department (ED), regardless of the age or sex of the patients who have used the ED
- Technological strategies specifically designed for EDs aimed at improving the patient's experience during their ED journey, focusing on communication and access to information
- Studies reporting on at least one patient-centered outcome (satisfaction, experience, or well-being)

Exclusion criteria

- Technological strategies outside the health care sector or those presented as telemedicine, remote medicine, or prehospital solutions
- Patients who have not used hospital or ED services
- Articles that do not present a descriptive evaluation, case study, or empirical evidence regarding the design, implementation, or impact of technological interventions on patient experiences in EDs
- Protocol-only studies or incomplete data reports

Study Selection

A 3-step filtering process was implemented to refine the selection of studies relevant to our RQ:

- In the first filter, *identification*, duplicates were removed. This process ensured the uniqueness of each record for accuracy and to avoid redundancy.
- The second filter involved *screening* by title and abstract, which significantly narrowed down the selection, based on our inclusion and exclusion criteria. This step focuses on identifying papers that are most relevant to ED's technological advancements.
- The third filter involved a full-text review to assess the *eligibility* of studies that addressed our RQ, culminating in the final selection of studies included in the review.

CADIMA was used for both the first and second filtering stages. CADIMA is an open-access online tool developed by the Julius Kühn-Institut during the EU-funded Global Response Against Child Exploitation project to support the conduct of systematic reviews [11].

Data Charting

The data charting process for the studies included in this review was structured into three rigorous rounds to explore the categories of technological strategies in EDs comprehensively. In the first round, we extracted fundamental attributes from each study, such as the authors, publication year, journal, and keywords. This process allowed us to understand the distribution of research over time and identify key categories within the field. A standardized data charting form was jointly developed in Microsoft Excel by three reviewers and piloted on a subset of studies to ensure consistency and clarity before full data extraction.

In the second round, we delved deeper into technological strategies applied in the studies. The charting form included variables such as the affected dimension (communication or access to information), technology and infrastructure used, impact on patient experience, measurement tools for usability or satisfaction, preferred information by patients, implementation details (approach, settings, challenges), and implementation outcomes.

Finally, in the third round, each paper was independently reviewed by three reviewers to ensure consistency and reduce bias in the analytical process. Any discrepancies were discussed and resolved by consensus. The charting process was iterative, and adjustments were made to the Excel form when new variables or categories emerged.

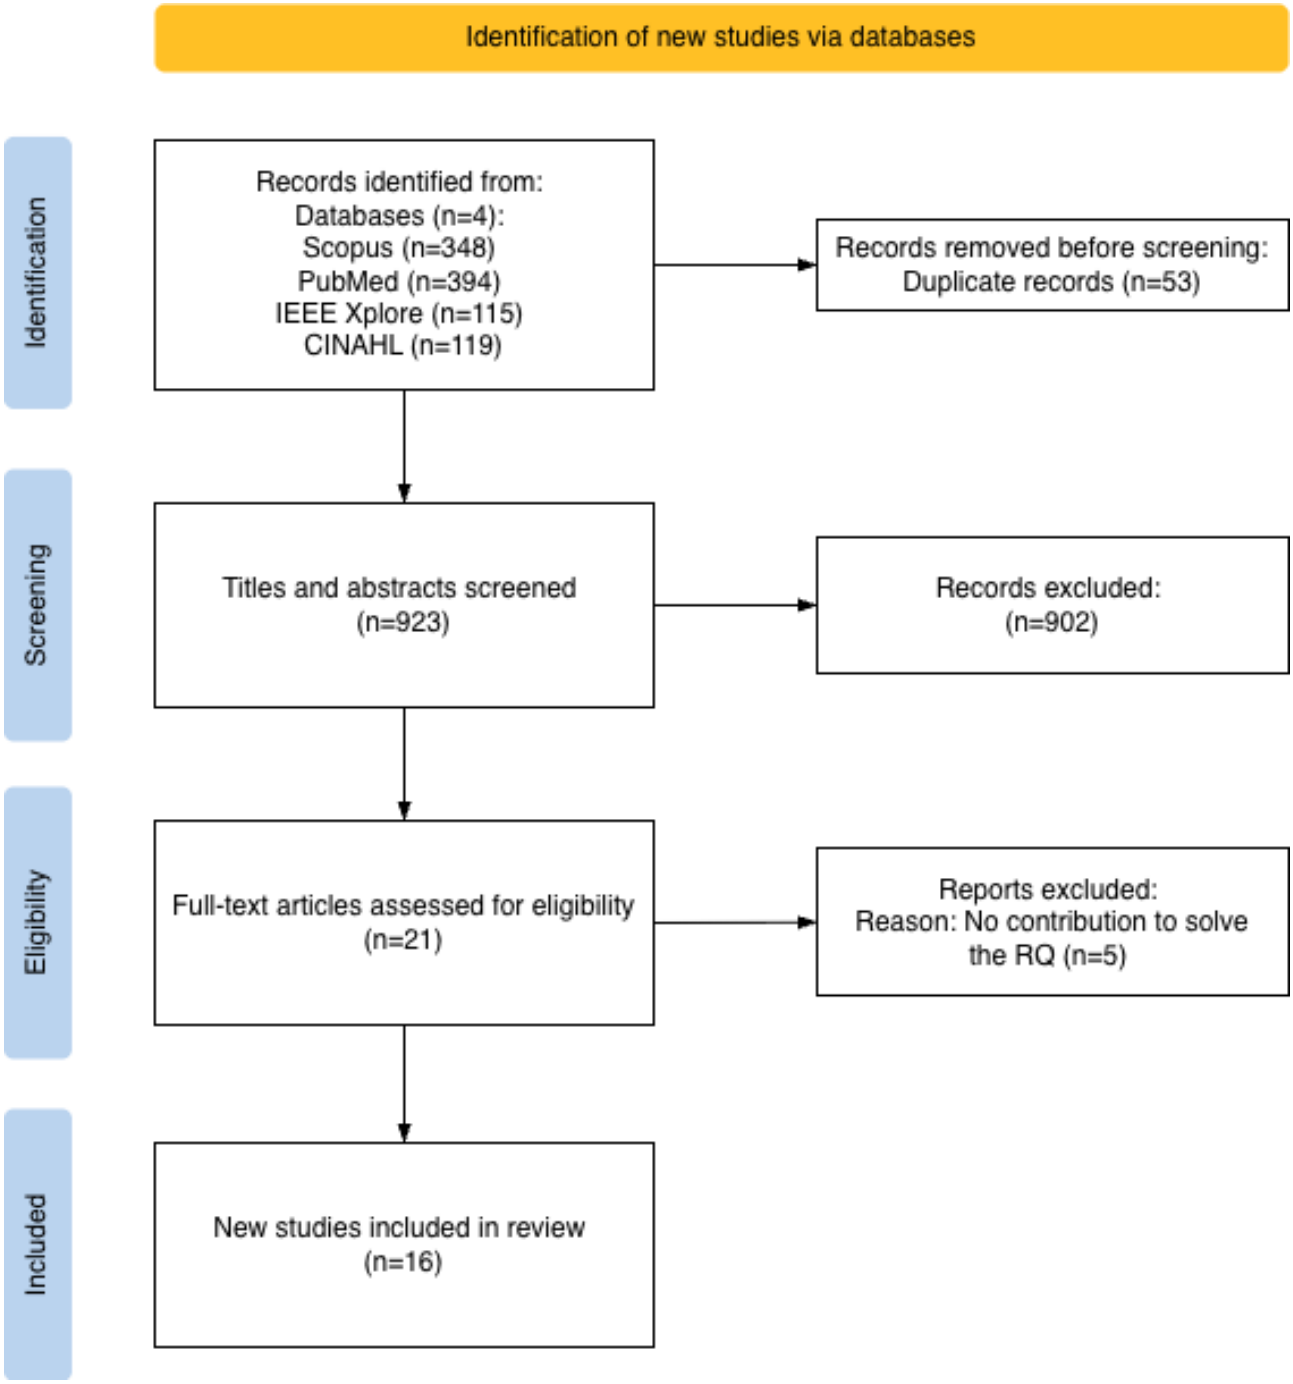
Quality Appraisal

Each selected paper underwent a quality appraisal conducted independently by two reviewers using the Crowe Critical Appraisal Tool version 1.4 (CCAT) [12]. This step was undertaken to assess the methodological rigor and credibility of the included evidence, supporting a more reliable interpretation of the findings in relation to our research questions. The CCAT is a widely used instrument recognized for its high reliability in evaluating research papers [13]. This instrument is organized into 8 categories comprising 22 items. Each category is scored on a 6-point scale ranging from 0 (lowest) to 5 (highest). The overall score is calculated as a percentage, and we arbitrarily considered acceptable a score above 60%. Prior to the appraisal, both reviewers were familiarized with the CCAT manual to ensure consistent interpretation of criteria. In cases of discrepancies between the reviewers' assessments, consensus was reached through discussion of the arguments and evidence.

Synthesis of Results

We grouped the studies by technological strategy category and summarized their associated challenges, as well as related patient experience outcomes and impacts. The strategy categories were defined using a content-based grouping approach: we reviewed all included studies, examined the technologies and their stated purposes, and clustered similar technologies based on their primary function and orientation toward improving ED patient

XSL•FO
RenderX



experience. The synthesis mapped the relationship between each strategy and its impact on communication and access to information, highlighting key outcomes, impacts, and challenges. Technologies and IT infrastructures were tabulated by strategy category, while patients' preferred information and satisfaction improvements were synthesized narratively.

Results

Flow Diagram and Number of Studies

The scoping review process is detailed in the flow diagram shown in Figure 1, presenting the stepwise filtering and the number of studies included at each step. In the *identification* step, 976 papers were identified and selected. Papers were imported into the CADIMA, where duplicates were removed, resulting in 923 papers. These papers were *screened*, applying the defined inclusion and exclusion criteria, where 21 papers were classified as eligible. Finally, after *full-text* reading, 16 papers were selected for further analysis; 5 articles did not contribute to the RQ.

Figure 1. Flow diagram of the scoping review process. RQ: research question.

RenderX

General Description and Characteristics of Studies

The set of 16 studies, published between 2018 and 2024 in journals such as *Journal of Medical Internet Research* and *Applied Clinical Informatics*, examines a range of technological strategies designed to improve patient experience in EDs. These studies address key aspects, including the design and implementation of solutions, the technological and infrastructural components that support them, patients' preferences for information delivery, system usability, and the assessment of their impact on patient satisfaction and overall experience. Methodologically, the articles include qualitative evaluations, observational pilot studies, and mixed methods research, reflecting a diversity of approaches (see Multimedia Appendix 2).

The reviewed literature reveals an interdisciplinary orientation, with collaborations among computer scientists, clinicians, designers, and data analysts. Notably, studies originate from diverse regions, including the United States [14-19], the United Kingdom [20], Italy [21], Israel [22,23], Denmark [5], Australia [24], Thailand [25], Malaysia [26], South Korea [27], and Greece [28]. Finally, the quality appraisal of the 16 studies revealed that 87.5% (n=14) were of high quality and 12.5% (n=2) of medium quality (see Multimedia Appendix 2).

Key Findings on Technological Strategies

Technological Strategies

Based on revised studies and following the process described in the Synthesis of Results subsection, we categorized the technological strategies that help to enhance patient journey experiences in EDs into four primary categories, as outlined below.

1. Interfaces and information systems: This category encompasses tools and information systems designed to provide access to comprehensive patient medical information and ED stage updates, enhancing patients' understanding of their journeys through the ED and facilitating communication with medical staff.
2. Infrastructure and hardware technologies: This category includes strategies focused on the underlying IT infrastructure necessary for ED operations. It encompasses advanced computing systems, integration devices, and hardware that are critical for patient care and tracking.
3. Artificial intelligence (AI)–based strategy: This category includes strategies that utilize machine learning (ML) and deep learning models for predictive analytics and pattern recognition in EDs.
4. Simulation-based strategy: This category encompasses simulation strategies, which are essential for evaluating the performance of health care operations, analyzing patient flow, and modeling complex interactions within ED settings.

Figure 2 illustrates the distribution of these strategy categories by dimension within the reviewed literature. Interfaces and information systems strategies were the most frequently cited, appearing in 14 studies, followed by infrastructure and hardware technologies and AI-based strategies, each appearing in 3 studies, and the simulation-based category, appearing in 2 studies. All categories addressed both dimensions, except the simulation-based category. These findings indicate a clear preference for integrated solutions and reveal a gap in studies dedicated exclusively to communication strategies.

XSL•FO
RenderX

Figure 2. Distribution of articles by technological strategy category and dimension focus.

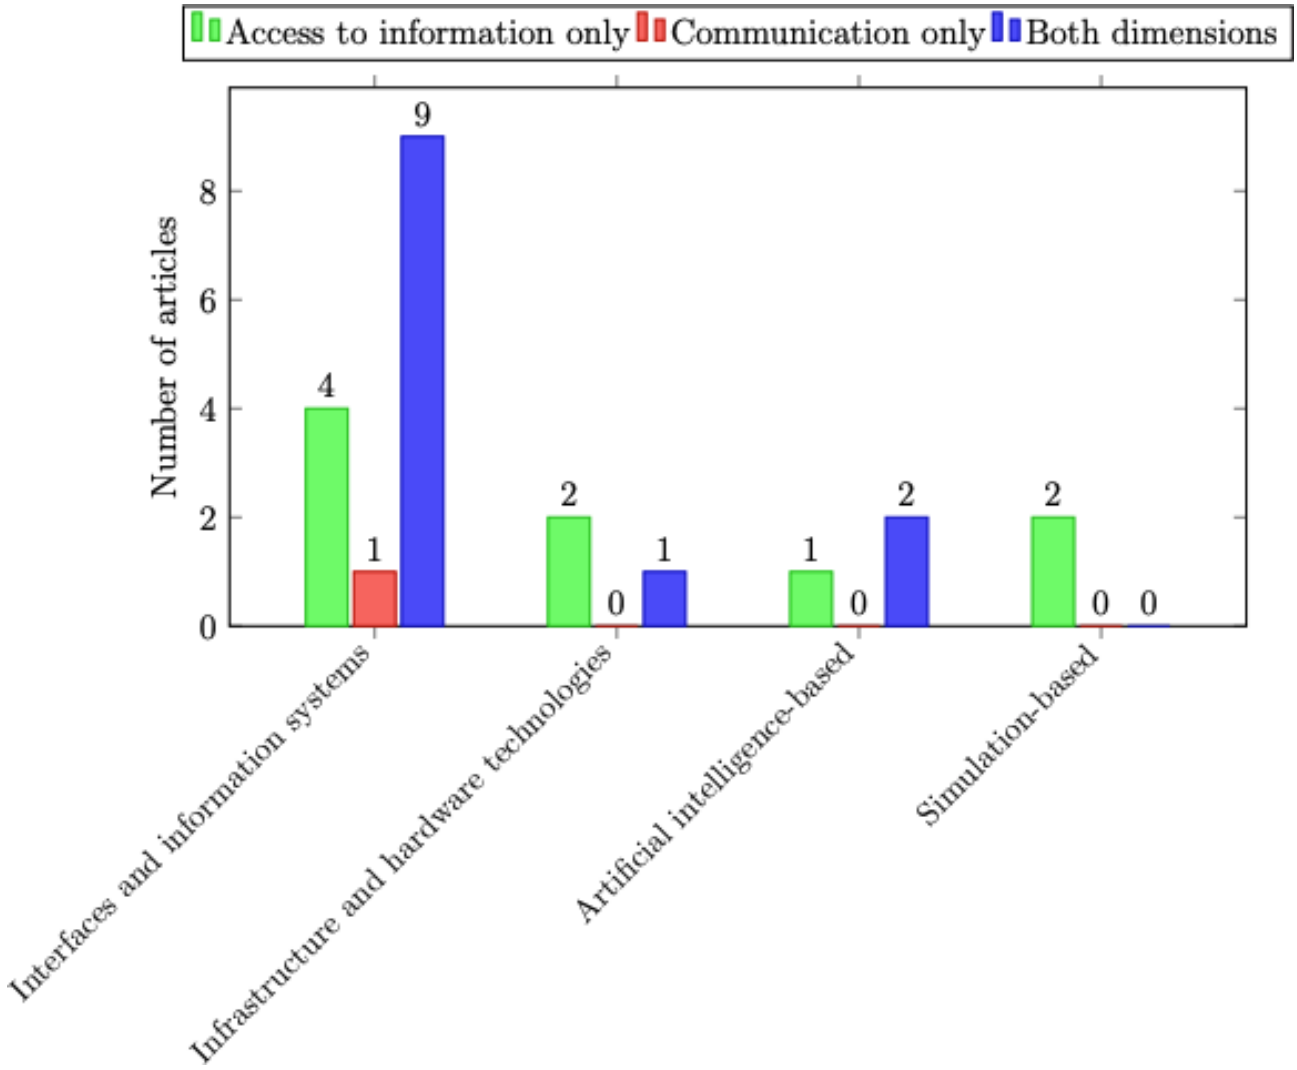

Table 1 provides a comprehensive overview of the key technological strategies implemented in EDs to enhance patient experience. For each strategy, the table details the specific dimension(s) addressed (communication and access to information), the implementation approach used and the target population (patients, family members, or health care staff), the measurement methods used to assess outcomes, the observed outcomes and their impact on patient experience and satisfaction, and the implementation challenges encountered. The results reveal a strong emphasis on systems that integrate both communication and access to information, particularly through interfaces and information systems such as digital whiteboards [16], clinical logic platforms [5], and discharge tools [17,24]. These solutions consistently aim to enhance patient and family engagement, improve satisfaction, and streamline information flow during care transitions [22].

[h]REDCap: Research Electronic Data Capture.

[i]I&H: infrastructure and hardware.

Common measurement methods include satisfaction surveys, usability scales, and structured interviews, reflecting a focus on patient-centered evaluation (see the *Measuring Usability, Patient Experience, and Satisfaction Improvement* subsection for more information). Reported outcomes and impact generally include improved understanding of care processes [22], reduced anxiety [5,26], and better communication with health care professionals [5], although challenges persist, such as technical limitations [17], integration with existing systems [16], and resistance to adoption [26]. Notably, infrastructure-based tools such as patient tracking systems [26] complement these efforts by supporting real-time updates, but they face barriers related to cost and implementation complexity. Overall, the evidence suggests a trend toward multidimensional strategies that prioritize transparency and communication while highlighting gaps in scalability and interoperability. In addition, the literature provides limited discussion on how these strategies can adapt to dynamic changes in ED protocols [22], ensure equity among diverse patient populations—including individuals with disabilities or lower digital literacy [5,18,24]—and effectively support digitally underserved or vulnerable groups [16,17].

Technologies and IT Infrastructures

Table 2 provides an overview of the main technologies and IT infrastructures used in ED settings, grouped by strategy category.

XSL•FO
RenderX

Table . Overview of technologies and IT infrastructures used in EDs, grouped by strategy category.

Strategy category and technology/infrastructure	Description and outcome	References
Interfaces and information systems		
Mobile app	Provides a patient-friendly health information and communication interface through a smartphone app, designed to deliver real-time and comprehensive medical data—such as health status, triage classification, vital signs, discharge instructions, and location within the ED[a] journey—while also enabling communication with patients' next of kin and supporting guidance for effective illness management, thereby improving health care services and enhancing patient satisfaction.	[17,20,26-28]
Web dashboard	Delivers a user-friendly, graphical web interface that provides real-time updates on patients' medical status—including triage classification, clinical conditions, and vital signs—along with their ED treatment progression, open clinical note access, care pathways, and discharge instructions. This interface enhances transparency and patient engagement during the ED stay.	[5,14,18,19,22-25,28]
Digital whiteboard	Provides an electronic paper interface via a digital whiteboard that communicates relevant real-time clinical information to ED patients, including status updates, orientation details, care team assignments, safety alerts, patient orders, and disposition information. This interface enhances patient understanding of their journey through the ED.	[16]
Patient-centered information system	Provides an information system accessible across various devices and interfaces (web and desktop applications), designed to deliver real-time updates and detailed information—including procedures, treatments, associated waiting times, nurse and physician responsible for care, and current and upcoming stages—directly to patients and their family members. This enhances patients' understanding of their individual journeys through the ED and supports informed decision-making and communication.	[5,22]
Infrastructure and hardware technologies		
Internet of Medical Things	Includes IoT[b] devices (eg, wearables) for real-time monitoring of ED patients, providing vital insights into their health status, vital signs, patient stratification for special services, and physical location within the ED. This information supports clinical decision-making and enhances communication by delivering timely and essential updates to both medical staff and patients' families about the health care process.	[26-28]
Computing infrastructure	Covers advanced computing infrastructures, such as cloud computing, that support real-time data storage, processing, and analysis in EDs.	[26,28]
Artificial intelligence–based		
ML[c] algorithms	Encompasses ML algorithms like random forest for predictive analytics in EDs, providing insights into patient treatment, stratification, and predicting waiting times based on workload and patient characteristics.	[14,15,22]
Simulation-based		

XSL•FO
RenderX

Strategy category and technology/infrastructure	Description and outcome	References
Discrete-event simulation	Provides a simulation-based model in R to estimate individual treatment times from aggregated ED data, aiming to assess delays, improve waiting time estimates, and enhance understanding of patient flow.	[21]
Petri net model	Comprises a simulation-based model in Python using Colored Petri Nets to model and analyze ED processes and workflows, supporting improvements in patient flow across treatment paths and enhancing decision-making efficiency.	[15]

[a]ED: emergency department.

[b]IoT: Internet of Things.

[c]ML: machine learning.

Interfaces and information systems emerge as the most significant strategy category for directly improving patient experience through enhanced communication and transparency (14 studies). Within this category, *mobile* and *web dashboard applications* are the most widely adopted technologies (5 and 9 studies, respectively). For example, the Parent Engagement Through Technology Solutions (PETS) [24] and MyEDCare [17] mobile apps support patients and caregivers during discharge by improving comprehension and reinforcing key information about the ED journey. Complementing these mobile tools, the MyED system [22] and the Cetrea Clinical Logistics (CCL) dashboard for patients [5] were designed as web dashboard applications to enhance patients' understanding of their care trajectory by displaying completed, ongoing, and anticipated procedures, as well as identifying the clinicians responsible for their care. Additionally, digital whiteboards, leveraging E-paper technology, deliver real-time notifications on delays and post-discharge instructions, functioning as integral components of the IT infrastructure [16].

Building on these interface-focused solutions, *infrastructure and hardware technologies* provide the foundation for real-time monitoring and data exchange. This category integrates *Internet of Medical Things* (*IoMT*) components with robust *computing infrastructure*. IoMT technologies enable real-time sensing and location tracking through dedicated hardware: beacon devices worn as patient bracelets and beacon readers (gateways) enable continuous wireless monitoring of patient location and status [26]; wearable biosensors capture physiological signals such as heart rate and oxygen saturation, supported by real-time location devices, Wi-Fi hotspots, and Bluetooth-to–Wi-Fi gateways for data transmission [28]; and near-field communication (NFC) tags paired with mobile electronic medical record (EMR) devices (eg, smartphones) allow location-based access to patient information [27]. Computing infrastructure complements these technologies by offering backend systems for secure data storage, processing, and decision support, including cloud-based databases and local servers operating within private networks [26,28]. Examples of strategies include TrackMe [26], which combines beacon-enabled bracelets with a mobile app and a 3-tier architecture for real-time updates; the NFC-integrated Mobile EMR System [27], which accelerates access to patient records; and IntelTriage [28], which uses wearable biosensors and LAN-based communication to monitor vital signs and geo-location, supported by a decision-support subsystem for dynamic prioritization.

Building on these physical infrastructures, *AI-based* strategies leverage computational techniques to enhance decision-making and operational efficiency. Predictive models such as *machine learning algorithms* [14,15] and random forest [22] approaches analyze EMR data—including length of stay, procedures, and clinical notes—to generate actionable insights. For example, the AI-enabled non-English language preference prioritization strategy [14] computes complexity scores for patients with a non-English language preference, while the AI/ML model presented in Gehlot et al [15] provides deeper insights into treatment details and patient experiences, thereby supporting more accurate patient routing based on acuity. Similarly, the MyED strategy [22] combines random forest models with operations research techniques, such as process discovery and queue mining, to predict waiting times for specific procedures and deliver real-time updates to patients through a responsive mobile interface.

Finally, *simulation-based* approaches complement predictive analytics by modeling complex ED workflows to optimize patient flow. Techniques such as *discrete-event simulation* and *Petri Net models* are used to estimate waiting times, identify bottlenecks, and validate algorithms for time-to-treatment predictions. These models support more reliable and equitable resource allocation. Reported strategies use these models to simulate care pathways and assess workflow constraints, enabling validation of predictive algorithms for waiting time and treatment prioritization [21]. A notable example is presented in Gehlot et al [15], where a Colored Petri Net–based simulation is integrated with Python-based AI/ML components to evaluate and refine triage processes, aiming to improve clinical outcomes and enhance patient experience.

Further details on usability, patient experience, and satisfaction impacts are provided in Table 1 and discussed in the subsection *Measuring Usability, Patient Experience, and Satisfaction Improvement*.

Patient's Preferred Information

The selected studies displayed a wide variety of topics that patients preferred on their journey through the ED. Specifically, patients preferred detailed information on their medical status

XSL•FO
RenderX

and progress updates [18,26], including triage status [15,28], treatment, and discharge instructions [17,19,24]. Additionally, patients valued comprehensive medical information related to their vital signs [18,25,28], laboratory results [27] and medical orders [16,18], nursing care plans [15,25,28], and the nurse and physician responsible for care [5,16]. Patients also appreciated personalized medical information and updates on procedures, associated waiting times [5,21], as well as current and upcoming stages of their ED stay [16,22]. They also favored precise tracking of their location in the ED [26,27], safety, and disposition information [16]. These preferences highlight a significant trend toward personalized health care information, underscoring the need for technological strategies to focus on delivering precise, individualized health data and highlighting the importance of accuracy and clarity in the patient communication tools of the ED.

Measuring Usability, Patient Experience, and Satisfaction Improvement

Usability evaluations are essential in health care technology to identify design flaws early and prevent ineffective implementations [24]. Among reviewed studies, the System Usability Scale (SUS) was the most frequently used instrument [5,18,24,27]. SUS is a 10-item Likert questionnaire that generates a score from 0 to 100, interpreted using a grading scheme (eg, >90: “A” [excellent]; <60: “F” [poor]). To illustrate, the PETS mobile discharge tool scored 94/100 (A grade—Excellent), indicating superior design and strong patient acceptance [24]. Similarly, the CCL patient information system achieved near-excellent usability with a mean SUS score of 83.6/100 (B+ grade—Acceptable) [5]. In contrast, NFC-integrated mobile EMR and REDCap eConsent interfaces scored 71.9/100 and 78/100 (B grade—acceptable), reflecting moderate usability and less direct impact on patient experience [24,27]. The electronic health record display for ED patient health status and care plan progress received a mean SUS score of 69.6 out of 100 (C grade—marginally acceptable) [18], suggesting limited effectiveness in improving patient experience.

While SUS provides a standardized measure, complementary approaches are often necessary to capture user perceptions more comprehensively. Likert-scale satisfaction surveys (typically 5- or 10-point) are commonly used to assess design quality, content relevance, and overall user-friendliness [16,25,26]. For example, the web application for emergency trauma patients, using a 10-point Likert scale, reported a mean usability score of 4.09 (SD 0.74) [25]. Similarly, the TrackMe patient-tracking system, using a 5-point Likert scale, reported a mean usability score of 4.0 (SD 1.2) and a mean satisfaction score of 4.4 (SD 1.0), indicating a generally positive user experience during ED waiting periods [26]. These findings reinforce that usability and satisfaction are interrelated but distinct constructs, underscoring the need for multidimensional assessment.

Patient experience and satisfaction are closely linked to usability, which strongly influences technology acceptance in clinical settings. In ED environments, these areas are typically assessed using mixed methods that combine SUS scores, Likert-scale measures, and validated instruments such as Hospital Consumer Assessment of Health Care Providers and Systems (CAHPS) and ED-CAHPS [16,17], complemented by semistructured interviews for contextual insights into patient perceptions [5,22,24]. For example, semistructured interviews in the MyED study showed that patients who used the solution demonstrated significantly better understanding of their ED journey compared with nonusers ($F_{8,299}$=2.519; P=.01) [22]. Using satisfaction surveys, the digital whiteboards intervention improved patient-reported communication about delays (1.96 vs 2.48; P=.03) and clarity of post-discharge instructions (2.41 vs 2.83; P=.02), and users were more likely to recommend the facility (9.66 vs 9.22; P=.05) [16]. Operational benefits were also reported in the MyEDCare study: patients receiving digital discharge instructions had significantly fewer unscheduled ED returns at 72 hours and 30 days compared with those receiving standard paper-based discharge (P=.003 and P<.001) and higher ED-CAHPS scores in nursing communication domains (eg, “Nurses explain in a way you understand”: 86.5 vs 81.9; P=.03) [17].

Collectively, these findings underscore that usability is not merely a design metric but a critical driver of patient experience, satisfaction, and even clinical outcomes in ED technology implementations. In addition, the evidence shows that *Interfaces and Information Systems*—particularly *mobile and web applications*—provide the greatest added value for improving patient experience, primarily by enhancing communication, transparency, and comprehension.

Discussion

Principal Findings

The integration of advanced digital technologies in EDs represents a rapidly evolving but still unstructured field. Among the 16 studies included in this review, 9 reported interventions that achieved measurable improvements in communication, patient satisfaction, or reductions in service fragmentation [5,16-18,22,24-27]. Despite the promising results (see subsection *Measuring Usability, Patient Experience, and Satisfaction Improvement*), the absence of standardized frameworks, definitions, and evaluation models limits comparability and scalability across settings [29]. Developing a shared conceptual and operational framework is essential to ensure consistency in research and guide technology implementation within ED systems.

Patient-facing technologies such as mobile apps, real-time dashboards, and web-based platforms have enabled patients to access individualized health information, often in real time, enhancing their sense of involvement in emergency care [22]. Some tools demonstrated significant benefits—for example, MyEDCare improved patient comprehension and experience (86.5 vs 81.9; P=.03) [17], and digital whiteboards reduced perceived uncertainty (2.41 vs 2.83; P=.02) [16]. However, implementation challenges were common. The MyED system faced difficulties synchronizing live data from hospital databases, and short ED visits limited patient engagement [22]. Usability issues were also reported among older adults, who requested simplified functions [5]. These findings underscore the need for participatory design approaches that incorporate patient perspectives prior to implementation [30]. Ultimately,

XSL•FO
RenderX

usability remains a critical determinant of successful adoption and effective use [31].

Technological impact extends beyond patient interaction to clinical workflows. Real-time data systems and mobile-based discharge tools require adjustments in routines, new training protocols, and additional coordination. While these tools can enhance communication and data accuracy, they often introduce extra responsibilities, increasing cognitive and operational burden on health care professionals [24]. This tension—between intended benefits such as efficiency and the reality of added workload—has been documented in multiple studies [32,33]. Understanding nursing staff perceptions and acceptance is therefore essential for successful adoption [34]. Policymakers and ED managers must consider these trade-offs when planning technological strategies to avoid overburdening staff while pursuing efficiency goals [16].

Additionally, the integration of wearable devices (eg, TrackMe, IntelTriage) and patient-facing platforms (eg, CCL, MyED) is reshaping care dynamics by fostering patient autonomy [5] and involvement in decision-making [20,23]. Although these innovations hold promise for improved outcomes and satisfaction [16,17,23], they raise concerns regarding workflow implications (eg, TrackMe increased nurses' workload [26]; fears of delays with MyED [22]), digital literacy barriers (eg, limited access to Open Notes among non-English speakers [23]; usability issues for older users of CCL [5]), and communication norms (eg, risks of patients viewing information before staff [22]; potential reduction in nurse/physician time) [5]). These factors must be addressed to ensure equitable and safe implementation.

Finally, the economic cost required for the investment, implementation, and maintenance of advanced technologies in EDs must be carefully considered. These expenses may include infrastructure upgrades, software development, technical support, and training for health care personnel [19]. Given the potential financial implications, future studies should explore the cost-benefit relationship of these technological strategies, assessing their feasibility, sustainability, and overall value in diverse health care settings [17].

Strengths and Limitations

A key strength of this study is its multidimensional approach, which provides a holistic view by examining various facets of ED care, including communication and information accessibility. This comprehensive perspective was achieved by focusing on emerging technologies, such as AI and IoT, which represent the forefront of operational efficiency and diagnostic accuracy in EDs. The recent literature (2018 - 2024) grounds the study's findings in current technological trends, ensuring relevance. However, limitations include a focus on English articles, which may have excluded relevant studies in other languages, potentially restricting generalization. Furthermore, since many technologies analyzed are relatively new (eg, IoMT, AI), few studies directly address their long-term impacts. Variability in environments where these technologies are implemented can also affect reproducibility, especially in resource-limited settings. The recent temporal range may not capture emerging trends or long-term effects, highlighting the need for ongoing research to understand their sustained impact.

Conclusions

This scoping review synthesized current technological strategies designed to enhance patient experiences in EDs, primarily through improved communication and access to information. The limited number of studies identified (n=16, published between 2018 and 2024) underscores the nascent and fragmented nature of this research area. Existing evidence suggests that patient-facing tools—such as mobile apps, real-time dashboards, and web-based platforms—can improve information transparency and engagement, while clinical workflow solutions, including digital whiteboards and mobile discharge systems, support communication accuracy and care coordination. Emerging innovations like IoT-wearable monitoring devices further demonstrate potential for promoting patient autonomy and continuous observation. However, these benefits are tempered by persistent implementation challenges. Usability barriers among older adults, technical integration issues, and increased workload for health care professionals remain significant obstacles. Equity concerns related to digital literacy and language accessibility further complicate adoption, raising questions about inclusiveness and fairness in technology-driven care. Importantly, none of the reviewed studies conducted systematic evaluations of long-term outcomes or cost-effectiveness across diverse ED contexts, limiting the evidence base for sustainable integration. Future research should move beyond descriptive assessments toward rigorous, standardized evaluation frameworks that capture clinical, economic, and experiential outcomes. Participatory and inclusive design approaches are essential to address usability and equity gaps, while comprehensive cost-effectiveness analyses will inform scalability and resource allocation. Advancing this agenda is critical to ensure that technological innovations in EDs are not only effective but also equitable, sustainable, and adaptable across varied health care settings.

Acknowledgments

The authors would like to acknowledge all the institutions that supported this work: Clínica Universidad de La Sabana, CAPSAB–Control y Automatización de Procesos Universidad de La Sabana and Sistemas Logísticos–Facultad de Ingeniería, and Cuidado de Enfermería Unisabana-Facultad de Enfermería y Rehabilitación, Universidad de La Sabana (project ING-299-2022). The authors also thank Rosario Lozano and Santiago Lozano for their valuable assistance during the screening and data extraction processes. During the preparation of this work, the authors used ChatGPT (OpenAI 2025) and Copilot (Microsoft 2025) to improve the readability of the paper. After using this tool/service, the authors reviewed and edited the content as needed and take full responsibility for the content of the publication.

Abstract

Background: Large language models (LLMs), such as GPT-3.5 and GPT-4 (OpenAI), have been transforming virtual patient systems in medical education by providing scalable and cost-effective alternatives to standardized patients. However, systematic evaluations of their performance, particularly for multimorbidity scenarios involving multiple coexisting diseases, are still limited.

Objective: This systematic review aimed to evaluate LLM-based virtual patient systems for medical history-taking, addressing four research questions: (1) simulated patient types and disease scope, (2) performance-enhancing techniques, (3) experimental designs and evaluation metrics, and (4) dataset characteristics and availability.

Methods: Following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020, 9 databases were searched (January 1, 2020, to August 18, 2025). Nontransformer LLMs and non–history-taking tasks were excluded. Multidimensional quality and bias assessments were conducted.

Results: A total of 39 studies were included, screened by one computer science researcher under supervision. LLM-based virtual patient systems mainly simulated internal medicine and mental health disorders, with many addressing distinct single disease types but few covering multimorbidity or rare conditions. Techniques like role-based prompts, few-shot learning, multiagent frameworks, knowledge graph (KG) integration (top-k accuracy 16.02%), and fine-tuning enhanced dialogue and diagnostic accuracy. Multimodal inputs (eg, speech and imaging) improved immersion and realism. Evaluations, typically involving 10-50 students and 3-10 experts, demonstrated strong performance (top-k accuracy: 0.45-0.98, hallucination rate: 0.31%–5%, System Usability Scale [SUS] ≥80). However, small samples, inconsistent metrics, and limited controls restricted generalizability. Common datasets such as MIMIC-III (Medical Information Mart for Intensive Care-III) exhibited intensive care unit (ICU) bias and lacked diversity, affecting reproducibility and external validity.

Conclusions: Included studies showed moderate risk of bias, inconsistent metrics, small cohorts, and limited dataset transparency. LLM-based virtual patient systems excel in simulating multiple disease types but lack multimorbidity patient representation. KGs improve top-k accuracy and support structured disease representation and reasoning. Future research should prioritize hybrid KG-chain-of-thought architectures integrated with open-source KGs (eg, UMLS [Unified Medical Language System] and SNOMED-CT [Systematized Nomenclature of Medicine - Clinical Terms]), parameter-efficient fine-tuning, dialogue compression, multimodal LLMs, standardized metrics, larger cohorts, and open-access multimodal datasets to further enhance realism, diagnostic accuracy, fairness, and educational utility.

large language model; virtual patient; medical education; history-taking; simulated patients

Introduction

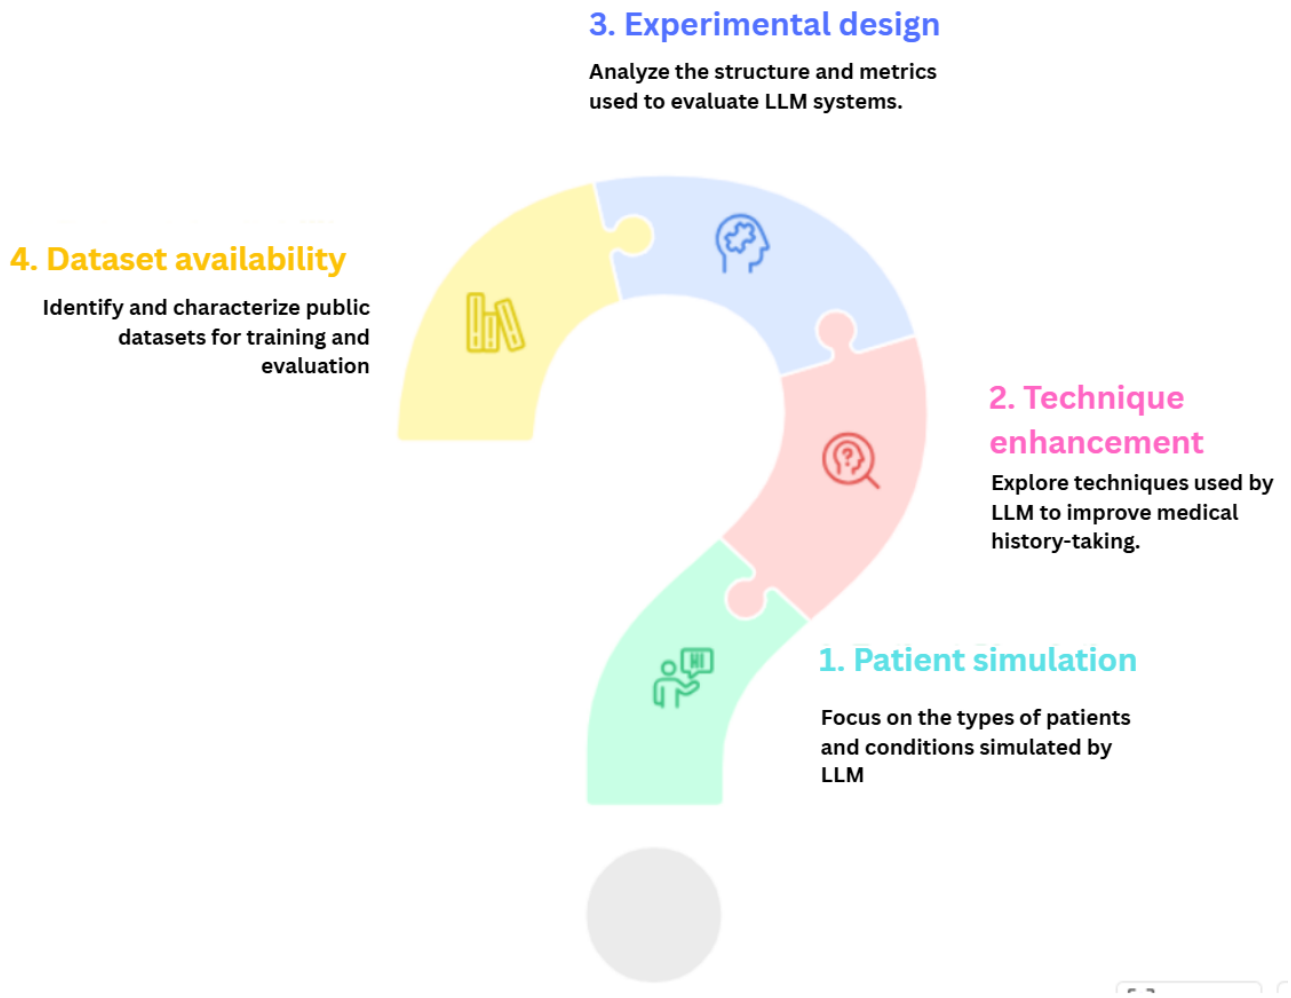
Since 2020, large language models (LLMs) such as GPT-3.5 (OpenAI) [1] and GPT-4 (OpenAI) [2] have significantly enhanced virtual patient systems in medical education. Unlike traditional methods relying on resource-intensive standardized patients or high-fidelity simulators [3], LLMs provide scalable, low-risk, and cost-effective solutions by simulating realistic patient interactions across a wide range of clinical scenarios, including internal medicine, mental health disorders, and surgical and orthopedic cases [4]. This capability addresses key challenges in medical education, such as limited exposure to diverse clinical cases and the high costs of traditional simulation approaches.

Early virtual patient systems, often based on models like BERT (Bidirectional Encoder Representations from Transformers), struggled to generate natural dialogues and adapt to complex clinical scenarios, limiting their effectiveness in medical training [5,6]. In contrast, modern LLMs, leveraging prompt-based techniques for role and scenario customization, demonstrate improved contextual understanding, enabling clinically relevant responses. However, these systems still face challenges with hallucination, defined as the generation of factually incorrect or contextually irrelevant content, which may compromise the accuracy of medical history-taking in virtual patient simulations [7,8].

To ensure effective clinical training, continuous improvement and validation of LLMs are essential to mitigate hallucination rate and ensure the reliability of generated information [7]. Recent studies have incorporated techniques such as Supervised Fine-Tuning (SFT) [9] and Retrieval-Augmented Generation (RAG) [10] to enhance contextual adaptability and diagnostic accuracy, as measured by metrics like top-k accuracy and GTPA@k. However, the specific disease types simulated by LLMs, such as such as neurological and rheumatological or rare multiple disease types and potential gaps in simulation capabilities remain underexplored partly due to variations in experimental design and datasets.

Despite progress, systematic comparative evaluations of these techniques in virtual patient systems are lacking. Existing literature reviews often broadly discuss LLMs in medical education without focusing on virtual patient history-taking, limiting insights into domain-specific challenges [11]. Thus, a systematic literature review is critical to consolidate fragmented research, identify challenges, and guide future work.

Previous systematic reviews have explored LLMs in medical education but lack specificity. For instance, Lucas et al [11] reviewed LLMs' implications for teaching effectiveness, ethics, and reliability but did not focus on virtual patient history-taking. García-Torres et al [12] used a hybrid human-LLM methodology to evaluate virtual patients' impact on clinical reasoning but provided limited technical details on prompt design, knowledge graph (KG) integration, or fine-tuning. Similarly, Fatima et al [13] conducted a cross-disciplinary review of ChatGPT in research, clinical practice, education, and patient interaction but did not systematically analyze virtual patient history-taking. Recent empirical studies on LLM-powered virtual patients with automated feedback have prioritized educational outcomes over methodological comparisons [8].



In contrast, this review specifically examines LLM-based virtual patient systems for clinical history-taking. It systematically analyzes prompt engineering, external knowledge integration, model fine-tuning, and evaluation strategies, synthesizing their implications for medical education and effective clinical training. By adopting this methodological focus, this work addresses gaps in prior reviews, which were either too broad or lacked technical depth.

Given this research gap, a systematic literature review is essential to consolidate fragmented research and guide future studies. This paper addresses four core research questions (RQs), as outlined in Figure 1:

- RQ1: what types of patients, conditions, or diseases, such as internal medicine or rare and multiple disease types, are simulated in LLM-based virtual patient systems?
- RQ2: what techniques do LLMs use to enhance medical history-taking capabilities in clinical interviews?
- RQ3: how are experimental designs structured to evaluate LLM-based virtual patient systems, and what evaluation metrics, such as top-k accuracy or System Usability Scale (SUS), are used?
- RQ4: what public datasets are available, and what are their characteristics for training, simulating, and evaluating medical history–taking in virtual patient systems?

XSL•FO
RenderX

Figure 1. Overview of 4 research questions on large language model–based virtual patient systems, covering simulation types, enhancement techniques, evaluation strategies, and datasets.

This systematic literature review addresses these questions to guide researchers in understanding the potential, limitations, and ethical challenges of LLMs in virtual patient systems. It is critical for advancing effective clinical training tools in medical education. The paper is structured as follows, the first section introduces the background of virtual patient systems and LLM applications; the second section describes the literature search methodology and evaluation criteria; the third section presents results, analyzing effectiveness and challenges; the fourth section discusses findings in the context of existing literature; and the fifth section concludes with key findings and recommendations for future research.

Methods

Overview

This study conducted a systematic literature review adhering to PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines. The research topic and target population were clearly defined, a comprehensive search strategy was formulated, and key search terms were identified. Search results were exported as CSV files via Mendeley (Mendeley Ltd) and Zotero (Corporation for Digital Scholarship) and manually screened. Abstracts were initially evaluated, followed by a comprehensive full-text assessment to confirm relevance and quality.

Eligibility Criteria

Population

The population includes medical students and physicians engaged in medical history–taking. Artificial intelligence (AI)–based virtual patients refer to LLM-based systems simulating patients for training in history-taking. Only transformer-based LLMs (eg, GPT series) are included, excluding older models like BERT (Google AI) or pre-Transformer architectures. Studies focusing on anesthesia, emergency procedures, or intraoperative scenarios are excluded, as these are nontraditional history-taking contexts. Preoperative history-taking for surgical and orthopedic patients is included. This ensures a focus on transformer-based LLMs for history-taking, emphasizing educational and clinical skill development while excluding irrelevant clinical settings. Only studies where LLMs serve as virtual patients for active history-taking and patient communication are included, excluding those focused solely on medical interviews without history-taking.

XSL•FO
RenderX

Intervention

The intervention involves transformer-based LLM technologies applied to medical history-taking, including prompt design, model fine-tuning, KG integration, and other LLM-related techniques. These aim to enhance diagnostic accuracy, interaction quality, and overall performance in virtual patient systems.

Outcomes

Outcomes include performance metrics such as top-k accuracy (eg, top-1 accuracy), empathy scores, readability, system stability (eg, response consistency), user experience (eg, SUS, Chatbot Usability Questionnaire [CUQ]), and other relevant indicators, such as κ (Cohen κ) and *P* value. These metrics evaluate the effectiveness of transformer-based LLM virtual patient systems in medical history–taking.

Inclusion and Exclusion Criteria

Inclusion and exclusion criteria were established to ensure relevance and quality, as shown in Textbox 1. Inclusion criteria prioritize studies with technical depth, validated outcomes, recent publication, and a focus on Transformer-based LLM virtual patients for history-taking, excluding nontransformer models.

Textbox 1. Inclusion and exclusion criteria for transformer-based large language model (LLM) virtual patient studies.

Inclusion criteria:

- IC1: the study population included medical students or physicians involved in medical history–taking or communication training.
- IC2: the intervention involved Transformer-based LLMs (eg, GPT series) used as virtual patients for history-taking or communication training in traditional consultation settings.
- IC3: the study was published between January 1, 2020, and August 18, 2025, including peer-reviewed articles and preprints.
- IC4: the study reported measurable outcomes related to diagnostic performance, communication effectiveness, empathy, readability, or user experience.
- IC5: preoperative history-taking scenarios (eg, surgical or orthopedic patients) were included if they involved conventional patient–clinician consultation processes.

Exclusion Criteria:

- EC1: based on earlier or nongenerative transformer models (eg, BERT [Bidirectional Encoder Representations from Transformers] and GPT-2) rather than modern LLMs.
- EC2: focused solely on medical interviews without explicit medical history–taking.
- EC3: published before January 2020.
- EC4: duplicate titles or redundant publications.
- EC5: review or commentary papers.
- EC6: non-English language studies.
- EC7: focused on anesthesia, emergency procedures, or intraoperative contexts (except preoperative consultations).

Information Sources

A systematic literature search was conducted across 9 authoritative databases PubMed, Scopus, Web of Science, IEEE Xplore, ACM Digital Library, SpringerLink, ERIC, arXiv, and ACL Anthology, covering studies published between January 2020 and August 18, 2025, in medicine, AI, education, and virtual technologies. A secondary search used a snowballing strategy, identifying additional sources from 15 initial articles and relevant publications, including theses from ProQuest. Including peer-reviewed articles and grey literature (eg, preprints from arXiv and theses) ensured comprehensive coverage of the rapidly evolving fields of AI and medical education.

Search Strategy

Two search strategies were used for this systematic review. The first query combined virtual patient terms (eg, virtual patient, simulated patient, AI patient, conversational patient, chatbot patient, intelligent virtual agent, and dialogue agent) with LLM-related keywords (eg, LLM, ChatGPT, GPT-4, GPT, transformer model, generative AI, AI-powered tutor, and natural language generation) and was applied to structured databases including PubMed, Scopus, Web of Science, IEEE Xplore, and ACM Digital Library. The second, simplified query included only virtual patient terms and was applied to broader repositories, namely SpringerLink, ERIC, arXiv, and ACL Anthology, to ensure comprehensive coverage, as strict LLM keywords reduced results in these databases (see Multimedia Appendix 1 for more details).

Selection Process and Data Collection

The literature screening and data collection process followed PRISMA 2020 guidelines [14] (checklist provided in Multimedia Appendix 2). Titles and abstracts were manually screened for relevance to LLM-based virtual patient history-taking, with GPT-3.5 Turbo used for auxiliary verification. Full-text evaluations were conducted for studies meeting preliminary inclusion criteria. A multidimensional quality assessment form recorded key study characteristics and outcomes, as detailed in Multimedia Appendices 3 and 4. The ChatPDF tool was used to cross-check content, and final inclusion decisions were made with the supervising researcher's input.

XSL•FO
RenderX

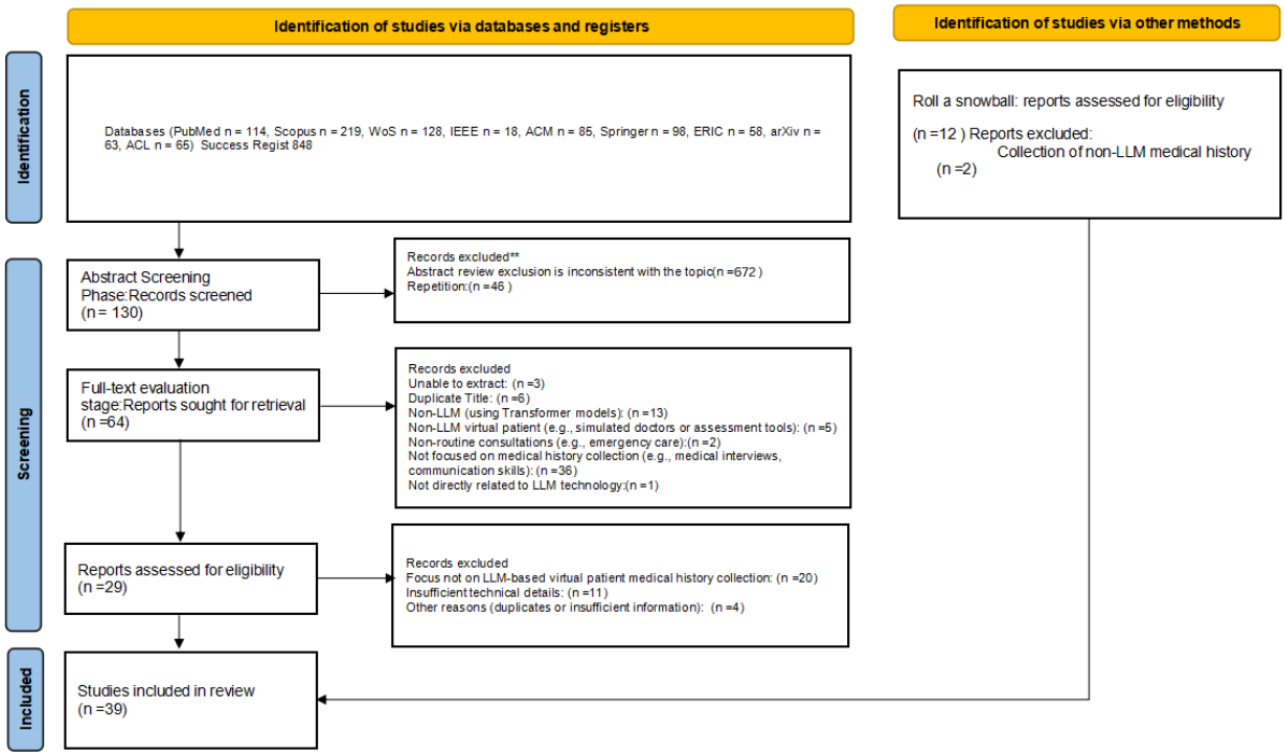
Quality and Risk of Bias Assessment

A reviewer with a computer science background, under the supervision of an experienced research advisor, conducted the quality assessment. A customized multidimensional assessment framework was developed to evaluate the technical quality of the included studies, as described in Multimedia Appendices 3 and 4. Conventional appraisal tools such as the Joanna Briggs Institute Critical Appraisal Checklist (2020) were adapted because they were not fully suitable for LLM-based virtual patient research. The framework incorporated 6 evaluation dimensions methodology clarity, dataset transparency, completeness of system evaluation, innovation or integration level, reproducibility and openness, and the presence of control or baseline comparisons. Each dimension was rated on a 3-point scale ranging from 0 to 2, with 2 indicating the highest quality. The total score for each study, therefore, ranged from 0 to 12. Based on the overall score, studies were categorized into 3 quality levels, high (9-12 points), medium (5-8 points), and low (0-4 points). This classification ensured a consistent and transparent interpretation of the technical quality across studies. The assessment emphasized methodological rigor, technical implementation, system architecture, model training strategies, multimodal integration, and evaluation methods to identify potential sources of bias.

Risk of bias was also assessed across 5 domains—selection or reporting bias, implementation bias, evaluation bias, data bias, and reporting completeness bias—to capture variations in study design, data transparency, technical implementation, and reporting quality. This combined approach ensured a systematic evaluation of both methodological soundness and potential bias in LLM-based virtual patient studies.

Based on the aforementioned screening and evaluation methods, the research results will be presented in detail in the next section.

Results



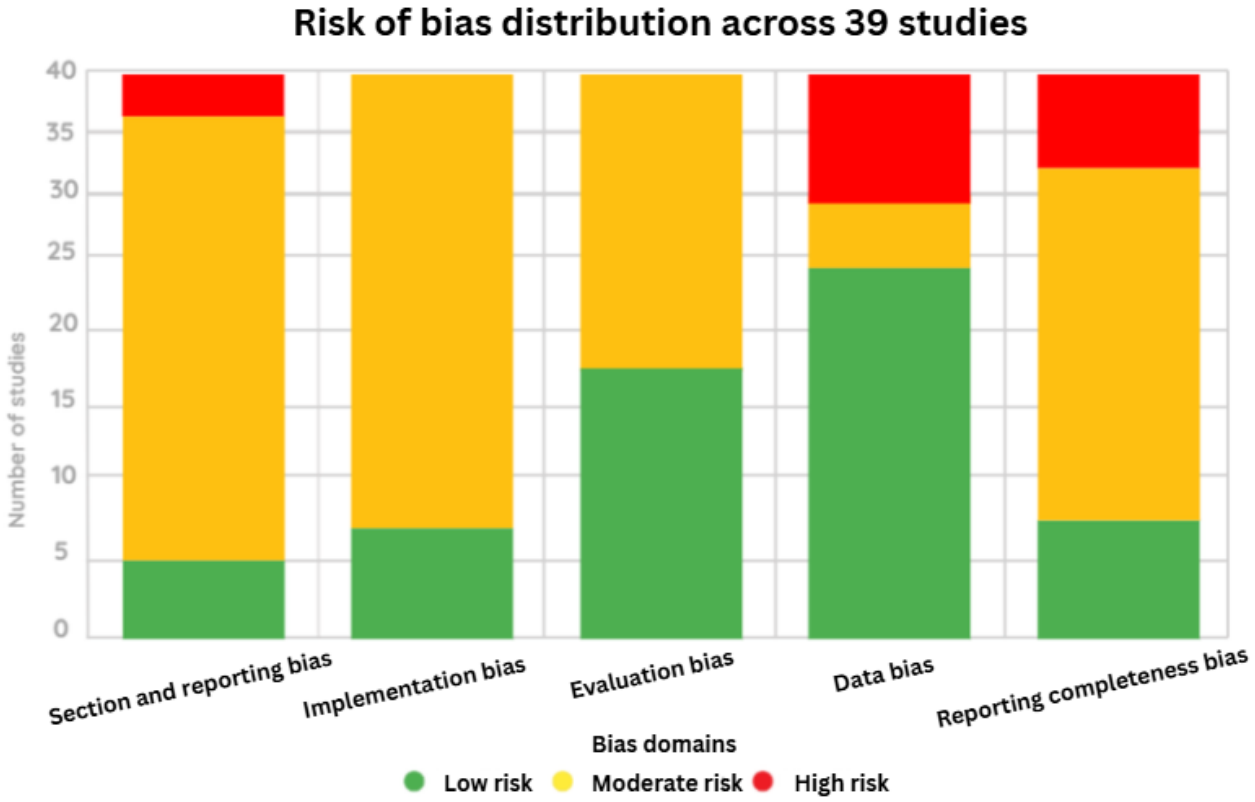
Overview

This section reports the results of literature selection, study characteristics, and findings related to the 4 RQs, avoiding interpretive discussion.

Study Selection Results

During identification (see Figure 2 for the 2020 flow diagram for systematic reviews, including database and register searches), 848 records were retrieved from 10 databases. During abstract screening, 672 records were excluded, and after removing 46 duplicates, 130 unique full-text articles were assessed. Of these, 66 were excluded for reasons including lack of extractable data (n=3), duplicate content (n=6), non-LLM models (n=13), focus not on LLM applications (n=5), nonroutine clinical settings (n=2), no history-taking focus (n=36), or nonrelevance to LLM technologies (n=1), leaving 64 eligible articles. During multidimensional evaluation, 20 studies were excluded for limited relevance, 11 for insufficient technical detail, and 4 for other reasons, yielding 29 articles from database searches. An additional 12 articles were identified through snowballing, of which 2 were excluded as irrelevant, resulting in 10 included snowballed studies. The final synthesis comprised a total of 39 studies [8,10,15-51] (6 high-quality, 33 moderate-quality) (see Multimedia Appendix 5).

Figure 2. PRISMA flow diagram.



XSL•FO
RenderX

Quality and Risk of Bias Assessment Results

Most studies achieved the highest rating (2 points) for methodological clarity, indicating well-defined research procedures and consistent experimental designs. Scores for dataset transparency and system evaluation completeness varied considerably, with approximately 45%-55% of studies receiving moderate ratings (1 point) due to insufficient details regarding data sources or evaluation frameworks. Innovation and integration levels were generally high, with about 80% of studies receiving high ratings (2 points), reflecting notable progress in multimodal integration and technological creativity. Reproducibility and openness received moderate ratings (1 point) in approximately 60% of studies, as some provided replication details whereas others lacked information on model configurations or training strategies. Control or baseline comparison obtained the lowest scores (0-1 point), with only 25%-30% of studies incorporating explicit comparative or controlled analyses. Overall, 6/39 (15%) studies were rated as "high quality," and 33/39 (85%) as "moderate quality," suggesting strong methodological design and innovation but highlighting the need for improved dataset transparency, evaluation completeness, and reproducibility (see Multimedia Appendix 5 for details).

Risk of bias was assessed across five domains—selection and reporting bias, implementation bias, evaluation bias, data bias, and reporting completeness bias—as illustrated in Figure 3.

Figure 3. Overview of risk of bias distribution across studies.

Selection and reporting bias was evident in disease coverage. Approximately 95% (37/39) of studies simulated specific disease types (eg, internal medicine or mental health disorders), but only 50% (20/39) addressed multiple disease stages, thereby limiting generalizability to multimorbidity contexts.

Implementation bias was observed in the limited reporting of model development details. While 80% (31/39) of studies described model types, only 35% (14/39) provided information on training procedures, fine-tuning processes, prompt engineering, reinforcement learning with human feedback (RLHF), domain-specific adaptation, or multimodal integration. This resulted in high technical heterogeneity.

Evaluation bias was reflected in the uneven assessment of educational and user experience outcomes. Approximately 70% (27/39) of studies evaluated educational outcomes, and 65% (25/39) assessed user experience using instruments such as the SUS or the Chatbot Usability Questionnaire (CUQ). However, only 30% (12/39) of studies conducted comparative or controlled evaluations, which limited the interpretability of effectiveness findings.

Data bias stemmed from moderate dataset transparency. Fewer than half of the studies (18/39, 45%) explicitly identified data sources or quality control procedures, constraining reproducibility.

Reporting completeness bias was identified in the limited documentation of personalization mechanisms and quality control for generated outputs, reported in only 25%-30% (10-12/39) of studies, suggesting incomplete methodological reporting.

In summary, this multidimensional quality and bias assessment systematically examined the technical features, methodological design, and potential biases of LLM-based virtual patient research. The findings highlight the need to improve dataset

XSL•FO
RenderX

transparency, enhance the comprehensiveness of system evaluation, and include controlled comparative studies to strengthen reproducibility and scientific validity. Details of the screening results and full bias assessment are provided in Multimedia Appendix 6.

Finding for RQ1: What Types of Patients Are Simulated in LLM-Based Virtual Patient Systems?

This section presents a descriptive statistical analysis and classification of patient types simulated by LLMs in virtual patient history-taking systems, based on a systematic literature review. The classification uses disease categories from Table 1, grouping similar disease types (eg, internal medicine and mental health disorders). For each category, the number of studies, specific simulation scenarios, disease complexity (eg, low: single symptom; medium: multisystem involvement; high: rare or complex interactions), number of simulated cases (if specified), and disease stage (eg, acute and chronic) are summarized.

Table 1. Classification of patient types simulated in virtual patient systems.

Disease category	Simulation scenarios	Complexity	Number of cases	Stage	References
Internal medicine	Chest/abdominal pain, diabetes, COPD[a], COVID-19, hypertension, multisymptom	Medium-high	3-500+	Acute-chronic	12 studies [15,20-30]
Mental health disorders	Depression, PTSD[b], ADHD[c], TRD[d], CBT[e] models	High	1-106	Acute-chronic	8 studies [18,31-35,37]
Surgical/orthopedic	Plastic surgery, hand surgery, joint pain	Medium	3-10	Acute–chronic	4 studies [16,20,24,38]
Neurological/rheumatological	Stroke, meningitis, concussion, polymyositis, brain hemorrhage	High	1-4	Acute	6 studies [20,21,36,39-41]
Ophthalmological	Eye conditions, pain with redness/photophobia	Medium	1-24	Acute	3 studies [17,20,42]
Dermatological	Ear cyst, telogen effluvium, skin conditions	Medium	1-394	Acute-chronic	4 studies [19,25,43,44]
Rare/multiple disease types[f]	Rare diseases, unspecified conditions, broad patient scenarios	High	8-5230	Diverse	10 studies [8,10,25,45-51]

[a]COPD: chronic obstructive pulmonary disease.

[b]PTSD: posttraumatic stress disorder.

[c]ADHD: attention deficit hyperactivity disorder.

[d]TRD: treatment-resistant depression.

[e]CBT: cognitive behavioral therapy.

[f]Only [25] involves rare disease simulation, using the RareBench dataset with 421 rare disease cases. Other references in the "rare/multiple disease types" category focus on multiple disease types or unspecified/broad patient scenarios.

Summary of Research Focus and Coverage

A systematic descriptive analysis of the literature indicates that research primarily focuses on internal medicine, particularly gastrointestinal (eg, abdominal pain, heartburn, hematemesis [20-23,27,28]), respiratory (eg, cough, chronic obstructive pulmonary disease, COVID [20,21,23,29,30]), cardiovascular (eg, chest pain, hypertension [20-22,30]), metabolic and endocrine (eg, diabetes [10,23,24]), and fatigue-related conditions (eg, chronic fatigue [15,26]). These conditions are well-suited for effective clinical training, with LLMs effectively simulating both acute and chronic management scenarios, though vague symptoms like fatigue remain underexplored.

Mental health disorders are a significant focus, including depression and related disorders (eg, suicidal ideation and treatment-resistant depression) [15,32-35], posttraumatic stress disorder (posttraumatic stress disorder; eg, combat trauma) [18,31], attention-deficit/hyperactivity disorder [31], and other mental health conditions (eg, cognitive impairment, cognitive behavioral therapy [CBT] models) [32,37]. These simulations emphasize emotional and psychological complexity, suitable for empathy and CBT training, though behavioral disorders like attention-deficit/hyperactivity disorder are less explored.

Rare and multiple disease types are well represented, focusing on heterogeneous case collections and electronic health record (EHR)–driven simulations [8,46-51], as well as rare disease modeling (eg, 421 rare diseases [10,25,45]). These studies highlight the scalability and diversity of LLMs in simulating complex and varied clinical conditions.

Less studied areas include neurological and rheumatological diseases (eg, stroke, meningitis, and polymyositis [20,21,36,39-41]), dermatological diseases (eg, ear cyst, telogen effluvium, and skin conditions [19,25,43,44]), surgical and orthopedic diseases (eg, joint pain, plastic surgery, and hand surgery [16,20,24,38]), and ophthalmological diseases (eg, eye pain, photophobia, and multiple eye conditions [17,20,42]). These areas, due to specialized or visual simulation requirements, have received less attention, revealing significant research gaps.

XSL•FO
RenderX

Overall, research focuses on internal medicine and mental health disorders due to their prevalence and clinical relevance. Rare and multiple disease types demonstrate LLMs' scalability and generalization potential. In contrast, specialized domains such as surgical and orthopedic, neurological and rheumatological, dermatological, and ophthalmological diseases remain underexplored, presenting opportunities for further innovation in simulation-based medical education.

Finding for RQ2: What Techniques do LLMs Use to Enhance Medical History–Taking Capabilities in Clinical Interviews?

To address RQ2, LLMs use advanced techniques to enable realistic, dynamic, and accurate virtual patient simulations for medical history-taking, providing medical students and professionals with effective clinical training platforms that closely resemble real-world scenarios. The following sections categorize core LLM technologies for history-taking into prompt engineering, KGs and structured data, model fine-tuning and training, and speech interaction, as summarized in Table 2.

Table 2. Technical metrics, evaluation scores, and key strengths and limitations of LLM virtual patient techniques.

Category and technique (source)[a]	Top-k accuracy (%)	Hallucination rate (%)	IRR[b] (%)	AS[c] (%)	Strengths	Limitations
Prompt design						
Role-based prompts [10,23]	81.4	4.97	2.08	28	Realistic role-play; multiagent;	Long prompts inconsistent; complex cases limited
Few-shot [25]	Not used: 25%, used: 52%				Simple, effective;	Limited depth
Multiagent prompt frameworks [21,24]	—[d]	—	—	—	Consistent dialogue	Higher computation
KG[e]						
Entity-relation triples [17]	—	—	—	—	Structured triples	Small-scale realism
Entity layering [10]	97.42	—	—	—	High diagnostic accuracy and interpretability	Limited semantic layers
KG+history and few-shot [10]	97.85	—	—	—	Role continuity	Context overflow
KG+multiagent prompts [10]	97.85	—	—	—	Modular roles	High cost
Fine-tuning						
SFT[f] [17]	—	(Before fine-tuning 3.71%, after fine-tuning 0.31%)	4.79	87.00	Reduces hallucination rate; better reasoning	Limited turn validation
LoRA[g] [17]	—	—	—	—	Efficient tuning	Limited scalability evidence
Speech interaction						
TTS[h] [28,51]	—	—	—	—	Realistic voice; multimodal input	Recognition errors possible

[a]All techniques listed are LLM-based Transformer architectures.

[b]IRR: information-related response rate.

[c]AS: Anthropomorphism Score.

[d]Not available.

[e]KG: knowledge graph.

[f]SFT: supervised fine-tuning.

[g]LoRA: low-rank adaptation.

[h]TTS: text-to-speech.

Prompt Design for Realistic Patient Simulation

1. Role-based prompt design: detailed prompts embed patient demographics, personality traits (eg, Big Five), and clinical symptoms to simulate authentic patient behavior. For instance, Borg et al [41] developed virtual patient cases with approximately 2000 tokens per prompt, including detailed medical histories and contextual information, occupying a significant portion of the LLM's 4096-token context window. Implementations include structured prompts with role context, medical history, and behavioral constraints [16-20,22,24-29,31,33-41,43-46,51]. For

XSL•FO
RenderX

example, Bodonhelyi et al [37] used Satir model roles (eg, "accuser"') to achieve up to 95% dialogue consistency. This ensures consistent role-playing but requires instructor oversight to maintain medical accuracy [36].

2. Few-shot and dialogue history–based prompting: prompts incorporate dialogue history and few-shot examples to maintain conversational coherence and mimic gradual information disclosure. MEDDxAgent uses structured examples to guide diagnostic reasoning, improving top-k accuracy from 25% to 52% in complex cases [25]. Limitations include token constraints, which may restrict handling of intricate scenarios.
3. Multiagent prompt frameworks: multiple agents (eg, patient agent, doctor agent, and behavior controller) collaborate to generate realistic and personalized clinical dialogues, reducing reliance on single prompts and minimizing hallucination rate. For example, EvoPatient, developed by Du et al [18], uses a patient–doctor dual-agent system for natural dialogue via unsupervised learning. LLM-based generative agents integrate memory flows, retrievers, and cognitive mechanisms to enhance dialogue realism and training effectiveness [24]. Additionally, AI self-play agents such as AMIE simulate diagnostic conversations through internal and external self-play loops, applying multirole strategies within a single model to improve diversity and dialogue adaptation [21].

Knowledge Graphs and Structured Data

1. Dynamic KG retrieval: MedDiT uses KG agents to retrieve relevant subgraphs via SPARQL queries, linearizing them into natural language prompts to reduce token load and context loss, achieving significant token reduction [47].
2. Hierarchical KG modeling: AI Patient integrates layered KG with a Reasoning RAG multiagent framework, boosting accuracy from 68.94% to 94.15%. For the difficult "family and social history" category, accuracy improved from 13.33% to 85.56%, showing the value of structured KG reasoning. Compared to role-based prompts, the KG-based method performs better in multiclass tasks. With entity layering [10], accuracy rose by 16.02% (81.4% to 97.42%) in challenging categories such as allergy and social history.

Model Fine-Tuning and Training

1. Instruction fine-tuning and self-play: AMIE uses real and simulated medical dialogues with self-play loops (inner and outer) to optimize diagnostic performance, outperforming primary care physicians (PCPs) [19,45].
2. SFT and LoRA (Low-Rank Adaptation): Liu et al [17] fine-tuned Qwen2.5-72B-Instruct on MedDialog, reducing the hallucination rate from 3.71% to 0.31% [17]. At the same time, in terms of information-related response rate and Anthropomorphism Score (AS).
3. Chain-of-thought (CoT) and RLAIF+MoM: CureFun uses CoT and RAG, while Kumar et al's [26] RLAIF+MoM framework structures ambiguous symptoms, achieving up to 95% output clarity [23].

Speech Interaction

1. TTS and STT integration: Takata et al [28] use Google application programming interface (API) and Unity for synchronized speech [51] and emotional facial expressions, outperforming traditional platforms in interaction realism. Thesen et al [51] leverage Whisper-3 for immersive speech processing, achieving high student satisfaction.
2. Multimodal enhancements: AMIE integrates image uploads (eg, skin photos) to support history-taking, outperforming PCPs in diagnostic accuracy [19]. Ryu et al [35] enhances realism with patient image uploads.

In conclusion, LLM technologies achieve consistent and realistic virtual patient dialogues through multilevel prompt design, few-shot examples, and multiagent mechanisms. The use of KGs and structured data enhances information retrieval and medical history modeling, improving classification and recognition accuracy. Model fine-tuning techniques (SFT, LoRA, self-play, CoT, RLAIF+MoM) effectively reduce hallucination rate, optimize reasoning, and enhance diagnostic performance. Furthermore, speech interaction and multimodal integration improve interaction immersion and provide diagnostic support.

Findings for RQ3: How Are Experimental Designs Structured to Evaluate LLM-Based Virtual Patient Systems, and What Evaluation Metrics Are Used?

To address RQ3, this review synthesized 32 studies listed in Table 3 to examine the experimental design, evaluation methods, and metrics of LLM-based virtual patient systems, focusing on medical education, high diagnostic accuracy, and effective clinical training. Of the 39 identified studies (see Multimedia Appendix 5), 7 were excluded due to the absence of formal evaluations (eg, Takata et al [28] described planned behavioral experiments without data collection; Rodrigo et al [46] outlined testing plans but reported no results; Geer [31] focused on design without providing quantitative outcomes; Li et al [47] emphasized system architecture but lacked performance metrics; Staples et al [34] relied solely on qualitative feedback; Kumar et al [26] discussed workflow but lacked quantified results; Lee et al [15] provided expert Likert scores without statistical analysis). Due to high heterogeneity in evaluation metrics (eg, top-k accuracy, hallucination rate, CUQ, inconsistent scales and dimensions, lack of statistical information such as SDs or confidence intervals in many studies, and large variations in sample sizes that could bias pooled analyses), a meta-analysis was not performed. Instead, a structured narrative synthesis was adopted, supplemented with tabular summaries in Tables 2 and 3, which present the technical approaches and corresponding evaluation metrics.

XSL•FO
RenderX

Table 3. Merged quantitative and qualitative evaluation details for virtual patient systems.

Authors	Participants (N)	Identity	Comparisons	Analysis method	Results	Evaluation type
Du et al [18]	None	AI[a]	Evolved vs Nonevolved	Stats[b]	Relevance 0.7589; Faithfulness 0.8786	Q[c]

[a]AI: artificial intelligence.

[b]Stats: statistical analysis.

[c]Q: Quantitative.

[d]κ: Cohen κ.

[e]PCP: primary care physician.

[f]t and MWU: *t* test/Mann-Whitney *U* test.

[g]Likert: Likert scale.

[h]*P*: Objective Structured Clinical Examination performance comparison between AI-trained and traditionally trained students showed a difference of 28.1 vs 27.1, respectively (Mann–Whitney *U* test, *P*=.01).

[i]M: Mixed.

[j]ICC: intraclass correlation coefficient.

[k]*P*: Feedback group scored 3.60 on CRI-HTI vs 3.02 in control group (ANOVA, ICC=0.924, *P*=.049).

[l]*P*: Robot vs virtual patient authenticity ratings were 4.5 vs 3.9 (*t* test; *P*=.04).

[m]*P*: Students receiving feedback showed higher Likert-scale scores compared to control (*t* test; *P*=.04).

[n]*P*: LLMDP-trained students scored 78.13 (SD 8.35) on history acquisition; traditional group scored 67.08 (SD 7.21), with a mean difference of 11.05 points (*P*<.001).

[o]*P*: Comfort scores improved from 61% to 76% after intervention (*t* test; *P*<.001).

[p]CUQ: Chatbot Usability Questionnaire.

[q]Descr: Descriptive.

[r]QL: Qualitative.

[s]*P*: Robot vs VIC comparison yielded authenticity ratings of 4.47 vs 3.93 (Wilcoxon test; *P*=.035).

[t]Acc: Accuracy.

[u]*P*: Original article did not provide comparative statistical values such as means or test statistics, only reported model accuracy with significance levels.

[v]*P*: Among the 8 evaluated cases, exact *P* values for comparisons 1 and 2 were *P*<.001 and *P*=.04, respectively; the remaining 6 ranged from *P*=.003 to *P*=.011. As per reporting guidelines, *P*=.000 was converted to *P*<.001.

Commonalities and Specificities in Experimental Design

Commonalities

Most studies involved medical or health professional students, typically 10-50 participants, with some including residents or practicing physicians as evaluators (usually 3-5 experts) [10,19,36]. A few studies used AI agents for large-scale automated testing [18,25]. Tasks primarily covered core clinical competencies, including history-taking accuracy [10,36], diagnostic reasoning [45], role-playing [37], and multiturn dialogues [41].

Evaluation paradigms were categorized into 3 types quantitative (18 studies) using randomized controlled trials (RCTs) or comparative experiments with statistical tests (eg, ANOVA, *t* tests, and correlation) [39,45]; qualitative (1 study) using expert interviews, thematic analysis, or questionnaires [32]; and mixed (13 studies) integrating objective metrics (eg, top-k accuracy, and F_1-score) with subjective scales (eg, Likert, CUQ) [36,40]. Comparative baselines included model comparisons (GPT-4 and 4o, Claude, and Gemini) [16], AI versus human physicians [19,45], with or without feedback or platform comparisons [40,41], and variations in prompt strategies, multimodality, or RAG and KG [49]. Most studies applied blinding and reported rater consistency (eg, κ) [8,39]. Details of each study's evaluation type are provided in Table 3 (Evaluation type column).

Specificities

Some studies implemented AI self-play for scalability [18], or AI doctor-AI patient automated evaluation [16]. Social robot-LLM hybrids were used to enhance realism [40,41]. Comparative baselines varied, including direct AI versus human physician comparisons [19,45], modular and hybrid architecture comparisons (eg, RASA or KG or LLM) [49], and multimodel comparisons (GPT-4.5 and 4o, Claude 3.7, and Gemini 2.5)

XSL•FO
RenderX

showing nonsignificant differences, indicating a high performance baseline [16].

Evaluation Metrics: Commonalities and Specificities

Evaluation metrics in LLM-based virtual patient systems generally fall into 5 categories: clinical accuracy and knowledge, communication and interaction quality, robustness and stability, training efficacy and feedback quality, and system performance. Clinical accuracy and knowledge were assessed using metrics such as top-k accuracy [19], GTPA@k [25], information coverage [43], hallucination rate [17,19], and fidelity and relevance [18], evaluating diagnostic and information-gathering capabilities. Communication and interaction quality were measured through readability (Flesch and Flesch–Kincaid) [10], CUQ [22], and Anthropomorphism Score [17,37], reflecting language clarity and interaction naturalness. Robustness and stability were evaluated via paraphrase robustness [10], leak resistance [18], and rater consistency metrics, including κ [8] and intraclass correlation coefficient (ICC) [39]. Training efficacy and feedback quality focused on learning outcomes and user experience, assessed through Objective Structured Clinical Examination (OSCE) score improvements [39], and usability scales (such as CUQ). System performance metrics, including latency, failure rate [49], and confusion or clarification rates [49], captured efficiency and reliability. Specificities included unique metrics such as span-level F_1-score [10] for knowledge extraction, cosine similarity-based fidelity and relevance [18], weighted F_1-score or fuzzy labels for professionalism and ethics [39], and system-level confusion, clarification, or failure rates. Automated evaluation metrics such as GTPA@k [25] provided standardized measures for diagnosis, while expert ratings revealed realism biases, including underestimation by GPT-4. Usability was further examined through instruments such as the CUQ (score of 77/100), 7-dimensional Likert scales combined with ANOVA for accuracy, realism, and empathy, and system latency and confusion reporting (0.5%). These metrics collectively enable comprehensive assessment of both the technical performance and experiential quality of LLM-based virtual patient systems. The calculation formula for the indicators is detailed in Multimedia Appendix 7.

Evaluation Results

The synthesis of evaluation results from the 32 included studies indicates that LLM-based virtual patient systems demonstrate high diagnostic accuracy across key metrics. Quantitative results showed top-k accuracy ranging from 0.45 to 0.98 (based on 34 models and 300 patient cases); Saab et al [19] reported that AMIE achieved a Top-1 Accuracy of 0.65, compared to 0.53 for PCPs, with $P<.001$. Information coverage averaged 33.89% to 94.4% (eg, Liao et al [43] reported 33.89%, based on 150 cases; Holderried et al [22] reported 94.4%, based on 502 questions explicitly covered in case scripts, with a total of 826 answers), while hallucination rate remained low, ranging from 0.31% to 5% (eg, Liu et al [17] conducted experiments with up to 5 dialogue rounds, achieving a hallucination rate of 0.31%).

In terms of communication quality, CUQ scores ranging from 77 to 86.25 (eg, Laverde et al [24] reported 86.25). Training effectiveness was evident in OSCE performance (eg, Yamamoto et al [20] reported posttraining 28.1 vs pretraining 27.1, $P=.01$; Luo et al [42] reported that medical students trained using the LLM-based digital patient system (LLMDP) achieved a medical history acquisition score of 78.13 (SD 8.35), while the control group trained with traditional real patients scored 67.08 (SD 7.21). The difference between groups was 11.05 points, with $P<.001$, indicating a highly statistically significant difference). Robustness metrics such as κ ranged from 0.74 to 0.832 (eg, Holderried et al [8] reported 0.832; Rashidian et al [30] reported 0.74).

Mixed methods studies reported improvements in authenticity (eg, Borg et al [40] reported postuse 4.5 vs preuse 3.9; $P=.04$) and comfort (Thesen et al [51] reported that among 69 participants, average preuse comfort was 61%, increasing to 76% postuse, indicating higher student-reported comfort after training; $P<.001$). Automated baseline systems, such as EvoPatient, achieved a relevance of 0.7589 and a faithfulness of 0.8786 (Du et al [18]), while multimodel comparisons showed no significant differences among top LLMs (Haider et al [16]).

These results highlight the effectiveness of LLM-based systems in simulating realistic interactions, although specific metrics—such as the low failure rate of 2.0% reported by Ng et al [49] (based on 200 dialogue trials) and the high ICC of 0.924 reported by Brugge et al [39]—indicate that further standardization is needed.

The reviewed studies exhibit consistent commonalities in participant composition, task objectives, and evaluation paradigms, typically involving small to medium student samples and multisource evaluations with experts and AI, focusing on history-taking and diagnostic reasoning. Specificities are evident in comparative settings (AI vs humans, multimodel comparisons) and statistical methods such as bootstrap, false discovery rate (FDR), and ICC. Across studies, 5 key evaluation aspects were assessed using objective metrics. Clinical accuracy and knowledge were measured using top-k accuracy [19,21], GTPA@k [25], information coverage [22,43], and span-level F_1-score [18], capturing high diagnostic accuracy and knowledge acquisition. Authenticity was evaluated using hallucination rate [17] and fidelity metrics [18]. Interaction experience was assessed via CUQ [24] and Anthropomorphism Score [17], reflecting communication quality and user perception. Robustness and consistency were quantified using κ [30] and ICC [39]. System performance was captured through latency, failure rate, and confusion rate [21,49]. These categories collectively enable a comprehensive assessment of both technical and experiential quality, highlighting the systems' effectiveness while indicating areas for further standardization and evaluation refinement.

Finding for RQ4: What Public Datasets Are Available, and What Are Their Characteristics for Training, Simulating, and Evaluating Medical History-Taking in Virtual Patient Systems?

A variety of datasets support the development and evaluation of virtual patient systems, ranging from real-world EHRs to structured synthetic clinical scenarios. Table 4 summarizes key datasets used in recent studies, which are either publicly

XSL•FO
RenderX

available or accessible through formal application processes. These datasets provide diverse clinical data resources for effective clinical training and evaluation.

MIMIC-III (Medical Information Mart for Intensive Care-III) is a comprehensive publicly available medical dataset, containing detailed EHR data from over 40,000 intensive care unit (ICU) patients [10]. It covers multiple disease types, including internal medicine and neurological and rheumatological conditions, serving as a critical resource for virtual patient system development. However, its ICU-focused nature, primarily reflecting acute or severe diseases, limits its applicability to noncritical care scenarios, such as outpatient consultations, mental health disorders, or chronic disease management [10].

DDxPlus provides clinical dialogue data for respiratory diseases [25], suitable for training virtual patient systems in specific domains within internal medicine. The iCraft-MD dataset focuses on dermatological cases [25], and RareBench contains region-specific subsets of rare and multiple disease types [25]. While valuable for specialized applications, their scope is limited for building generalized, multitask virtual patient systems.

The medical-NLP corpus provides a broad range of clinical dialogues and records [18], while CCKS 2019 offers a Chinese medical KG dataset, enabling multilingual history-taking simulations [17,56]. The Open-i dataset includes multimodal chest X-ray images and textual descriptions, supporting dynamic image generation alongside history-taking [47]. MedQA provides multiple-choice and long-form medical question-answering data, useful for fine-tuning LLMs for diagnostic dialogues [45]. These datasets enhance multimodal and question-answering capabilities, though their coverage is narrower than MIMIC-III.

In summary, current datasets primarily focus on critical care or specific medical domains, with limited publicly available, diverse resources. These datasets have limitations in generalizability, multitask applicability, and multilingual support for virtual patient systems. Combining MIMIC-III (broad coverage) [10], DDxPlus and iCraft-MD (specialized domains) [25], and CCKS 2019 (multilingual support) [17,56] provides partial coverage. However, further development of diverse, emotionally annotated, and non-English datasets is needed to enhance system generalizability and conversational fidelity.

Table 4. Datasets used in virtual patient systems.

Dataset Name	Index	Description	Access requirements
MIMIC-III[a]	[10]	EHR[b] database from Beth Israel Deaconess Medical Center, over 40,000 ICU[c] patients (2001-2012), including vital signs, medications, laboratory results, diagnostic codes.	Access via PhysioNet; requires CITI training and DUA [52].
DDxPlus	[25]	Synthetic dataset for respiratory diseases, with clinical dialogues and diagnoses.	CC-BY[d]; publicly available, allows commercial use with attribution [53].
iCraft-MD	[25]	Synthetic dermatology dataset from public medical question banks and expert cases.	MIT License; publicly available [54].
RareBench	[25]	Rare disease dataset with regional subsets (Europe, Canada, and China).	Apache-2.0; publicly available [55].
medical-nlp	[18]	Medical NLP[e] corpus with clinical dialogues and records.	GNU General Public License v3.0; publicly available on GitHub [18].
CCKS 2019	[17]	Chinese medical knowledge graph dataset with entity recognition, relation extraction, QA[f] tasks.	Research use only; cite source [56].
Open-i	[47]	Multimodal dataset with 3314 chest x-ray images and textual descriptions.	Open Data Commons Open Database License; publicly available via NIH Open-i project [57].
MedQA	[45]	Multiple-choice and long-form medical QA dataset for diagnostics.	Publicly available via GitHub [45].

[a]MIMIC-III: Medical Information Mart for Intensive Care-III.

[b]EHR: electronic health record.

[c]ICU: intensive care unit.

[d]CC-BY: Creative Commons Attribution.

[e]NLP: natural language processing.

[f]QA: question-answering.

Discussion

Principal Findings

Current LLM-based virtual patient systems exhibit significant limitations in disease coverage, complex case simulation, multimorbidity representation, specialty applicability, multimodal capabilities, and standardization of evaluation metrics, indicating a need for systematic optimization to enhance clinical fidelity, educational adaptability, and interaction quality.

XSL•FO
RenderX

Limitations and Future Directions in Virtual Patient Type Simulation Research

The systematic review reveals several limitations in current virtual patient systems regarding disease coverage, case complexity modeling, and support across medical specialties [20,32]. First, research is heavily concentrated on internal medicine (eg, gastrointestinal, respiratory, and metabolic disorders) and mental health disorders, accounting for over half of the studies [15,32]. This focus reflects the strengths of LLMs in language-driven tasks and the availability of relevant data, but it highlights significant gaps in surgical and orthopedic, ophthalmological, and dermatological domains. Scenarios requiring procedural operations, image recognition, or multimodal interactions are underrepresented, with current systems lacking effective modeling mechanisms [16,43]. This finding aligns with RQ1, indicating that most simulations focus on specific disease categories, leaving certain specialty areas insufficiently covered.

Although some studies involve multiple disease types, current virtual patient systems mainly use single-disease trajectories, with each virtual patient representing only one disease [21,25]. multimorbidity simulations—patients with 2 or more coexisting chronic or acute diseases—are limited. Clinical multimorbidity requires complex decisions, including drug interactions, overlapping symptoms, and conflicting management priorities. Dataset analysis for RQ4 shows most datasets focus on a single primary disease, lacking comprehensive multimorbidity cases. Without simulating this complexity, virtual patient systems have limited use in advanced medical education and clinical reasoning. Future research should emphasize role construction and dialogue design for multimorbidity scenarios to support integrated management across multiple diseases.

Furthermore, current systems exhibit instability in simulating vague or atypical symptoms (eg, chronic fatigue, low mood, attention deficits), demonstrating weak extraction of unstructured chief complaints and incoherent reasoning processes, which limits support for comprehensive clinical assessments [10,31]. Incorporating KGs and CoT reasoning mechanisms may improve knowledge organization and causal chain construction, enhancing models' reasoning and response capabilities in complex clinical scenarios [58,59]. Open-source KGs, such as UMLS (Unified Medical Language System) [60], SNOMED-CT (Systematized Nomenclature of Medicine - Clinical Terms) [61] can be integrated to provide structured, high-coverage medical knowledge. Leveraging these KGs allows LLMs to reference verified entities and relationships during dialogue generation, reducing hallucinations and enhancing reasoning in multimorbidity or complex symptom scenarios.

Additionally, coverage of specialty domains remains limited, particularly in surgical and orthopedic, ophthalmological, and dermatological contexts requiring procedural or visual recognition skills. These fields show constraints in case complexity, multimodal interaction support, and procedural training, limiting educational adaptability and clinical fidelity [43]. This observation is consistent with findings from RQ1 and RQ4, indicating that certain specialty cases and complex patient scenarios remain underrepresented.

In summary, current virtual patient systems require systematic optimization in disease coverage balance, case complexity, multimorbidity simulation, specialty applicability, multimodal capabilities, and interaction depth. These improvements are expected to enhance clinical fidelity, educational adaptability, and natural human-computer interaction, providing a foundation for advancing intelligent medical education and clinical decision support systems.

Technical Challenges and Solutions of LLM-Based Virtual Patient Simulation

In virtual patient simulation, prompts guide LLMs to generate dialogues conforming to specific role characteristics. However, overly long prompts lead to information loss, affecting dialogue quality and coherence. Specifically, GPT-style models based on autoregressive decoder architectures process prompts sequentially from left to right, prioritizing information at the beginning (primacy effect) and end (recency effect), while middle information may be ignored or inadequately processed, impacting content completeness and accuracy [62]. Additionally, few-shot learning maintains role settings using limited historical dialogues, but balancing information completeness and avoiding overload in multiturn complex dialogues remains challenging. To address this, core information should be prioritized at the prompt's beginning and end, with emotional content placed in the middle to ensure accurate and consistent information transmission.

Compared to single-prompt methods, multiagent frameworks decompose dialogue generation into modular components, with agents handling specific functions such as patient history or simulated emotions, or leveraging adversarial training to enhance dialogue quality [18,21,24]. However, multiagent systems increase computational costs, as each agent independently calls APIs, leading to higher financial burdens. Additionally, fine-tuning using older APIs may cause "memory loss," affecting dialogue context continuity. Dialogue saving and restoration mechanisms are necessary to ensure information consistency. To reduce costs and improve efficiency, dialogue compression and summarization mechanisms can simplify context input, and noncritical tasks can be assigned to lower-cost APIs to balance performance and expense.

Research on fine-tuning GPT-style models and integrating KGs remains limited. Liu et al [17] proposed a SFT strategy using synthetic medical records and manually annotated dialogues, significantly enhancing the realism and anthropomorphism of patient history collection dialogues on the Qwen-72B model (Alibaba Cloud), reducing Hallucination Rate from 3.71% to 0.31%. However, their training process did not explicitly embed disease names into the Transformer model, limiting specific disease knowledge mastery. Prior studies indicate that incorporating disease names as labels or input features improves semantic understanding and generalization, particularly for simulating patient histories for specific diseases [58,59]. Combining CoT methods with fine-tuning to guide step-by-step reasoning for complex medical knowledge is underexplored and presents a potential direction for medical dialogue systems.

KGs systematically represent structured medical knowledge, but there is a lack of studies comparing disease embeddings

XSL•FO
RenderX

trained by LLMs with KG embeddings to evaluate differences in knowledge representation and reasoning capabilities. KGs' clear entity and relation structures complement LLMs' limitations in sparse knowledge or verification, while LLM-trained embeddings as a baseline reveal constraints in semantic understanding and improvements from KG enhancement. Future research should establish a unified evaluation framework integrating supervised fine-tuning, LoRA, and CoT reasoning to explore the complementary roles of KG and LLM embeddings, advancing medical dialogue models in logical reasoning and knowledge accuracy.

Evaluation Design Suggestions and Summary of Metrics

Evaluation methods and metrics in LLM-based virtual patient systems are diverse, reflecting the multidimensional nature of performance and educational outcomes. However, the lack of standardized frameworks hinders cross-study comparison and generalizability. Diagnostic accuracy is often measured by top-k accuracy (eg, 65% [19]) and GTPA@k [25], though these coarse metrics may not capture system capabilities. Information Coverage and Hallucination Rate assess retrieval fidelity but usually rely on manual verification. Interaction quality metrics—such as semantic similarity (0.7589 [18]) and user scores (eg, CUQ=77 [22])—highlight interactivity but are limited by subjectivity and small samples. External studies also report high usability, such as SUS=88.1[31], a 10-item scale measuring ease of use, confidence, and learnability, reinforcing the systems' educational value despite inconsistent evaluation standards.

Moreover, system performance assessment remains insufficient. Some studies report response delays affecting conversation naturalness, but lack quantitative measures or systematic evaluations. The absence of standardized key performance indicators exacerbates framework fragmentation, hindering effective implementation and broader application in medical education and effective clinical training [41].

To address fragmented metrics, a unified and scientifically grounded evaluation framework is necessary. Key performance indicators with recommended thresholds are proposed to guide system design and assessment:

- Top-1 accuracy (≥0.80): AMIE achieved a top-1 accuracy of 0.65, outperforming primary care physicians (0.53) [19], while *GTPA*@1 reached 0.96 [25]. A threshold of 0.80 ensures reliable diagnostic performance.
- Hallucination rate (≤0.05): GPT-4o demonstrated a Hallucination Rate of 0.31% [17], with rates below 5% reported in [19], supporting medical safety standards.
- Information coverage (≥0.50): coverage of critical history items was 33.89% [43], indicating room for improvement. A 50% threshold ensures adequate information capture.
- Empathy and Anthropomorphism Score (≥0.75, standardized 0-1 scale): GPT-4o scored 0.87 [17], and [37] reported approximately 0.76, indicating desired human-like interaction and empathy.
- Usability (SUS≥80, CUQ≥75): SUS of 88.1 [59] and CUQ of 77 [22] meet standards for satisfactory usability.
- Robustness (leak resistance≥0.90): a value of 0.9412 was reported in [18], indicating compliance with privacy and ethical requirements.
- Rater consistency (κ and ICC≥0.80): high interrater reliability was observed, with ICC=0.924 [39] and κ=0.832 [8].

Challenges of Data Diversity: Limitations in Corpus Coverage and Adaptability

Existing datasets for training and evaluating LLM-based virtual patient systems are diverse, encompassing real-world EHRs, synthetic clinical scenarios, and multimodal or multilingual resources [10,17,18,25,45,47,56]. Table 4 summarizes key datasets, which are either publicly available or accessible through formal application processes. Analysis reveals several limitations impacting system development.

Mainstream datasets like MIMIC-III primarily reflect intensive care scenarios, containing records from ICU patients with acute or critical conditions, often within internal medicine or neurological and rheumatological categories [10]. This bias limits generalizability to nonacute settings, such as outpatient consultations, mental health disorders, or chronic disease management. Specialized datasets, including DDxPlus (internal medicine), iCraft-MD (dermatological), and RareBench (rare and multiple disease types), provide tailored resources [25]. While valuable for specific domains, their narrow coverage limits suitability for general-purpose or multitask system training.

Linguistic and cultural diversity is limited, as most corpora are English-based and originate from Western health care systems [17,18,45,47,56]. The lack of datasets in other languages, such as Chinese [17,56], and integration with local KGs or region-specific disease contexts constrains performance in multilingual and cross-cultural environments. Modality limitations are evident; most datasets provide textual information and lack multimodal inputs like images, speech, or physiological signals [47], restricting interaction realism and diagnostic reasoning.

Data accessibility and format heterogeneity affect usability. Access requirements, annotation styles, field definitions, and dialogue formats vary [10,17,18,25,45,47,56], hindering integration and comprehensive training. Standardization of data formats and unified interfaces is necessary to reduce development costs and support broader adoption. Additionally, task alignment poses challenges, as datasets like MedQA [45] are structured for multiple-choice or question-answering tasks, requiring extensive adaptation for dialogue generation.

Combining broadly covering datasets like MIMIC-III [10] with domain-specific (DDxPlus, iCraft-MD, RareBench) [25] and multilingual or multimodal datasets (CCKS 2019 [17,56], Open-i [47], medical-nlp [18], MedQA [45]) can partially address gaps. However, developing diverse, emotionally annotated, non-English, and multimodal datasets is essential to enhance generalizability, robustness, and interaction fidelity.

XSL•FO
RenderX

Conclusion

This systematic review, conducted per PRISMA 2020 guidelines, evaluated studies (January 2020-August 18, 2025) on LLM-based virtual patient systems for medical history collection, sourced from 9 databases PubMed, Scopus, Web of Science, IEEE Xplore, ACM Digital Library, Springer, ERIC, arXiv, and ACL Anthology. Following rigorous screening, deduplication, and quality appraisal, 6 high-quality and 33 moderate-quality studies were included, addressing 4 research questions, simulated patient types, performance-enhancing technologies, experimental designs, and evaluation metrics.

Key findings include (1) systems primarily simulate internal medicine and mental health disorders (acute and chronic), with limited coverage of rare and multiple disease types, multimorbidity, and specialties like surgical and orthopedic, neurological and rheumatological, dermatological, and ophthalmological, restricting applicability in complex clinical reasoning and education [15,16,32,43]. (2) Technologies such as role-based prompts, few-shot learning, multiagent frameworks, KGs, and fine-tuning (eg, SFT, LoRA, CoT, RLAIF+MoM) enhance dialogue coherence, retrieval accuracy (+16.02% with KGs) [10], and high diagnostic accuracy, while multimodal integration (eg, speech) improves immersion [18,25]. (3) Evaluations involved medical students and practitioners, using mixed methods (top-k accuracy, F_1-score, SUS, CUQ, and expert ratings) with comparisons across AI models, physicians, or prompt variations; small sample sizes (10-50 students and 3-10 experts) and inconsistent metrics limit generalizability [19,40]. (4) Systems demonstrated high diagnostic accuracy: top-k accuracy 0.45-0.98, information coverage 33.89%-94.4%, Hallucination Rate 0.31%-5%, and high usability (SUS≥80), often outperforming junior physicians [18,43]. Dataset limitations (eg, MIMIC-III ICU bias, restricted access, low multilingual and multimodal diversity) hinder cross-study comparability [10,17,25].

The key discussion points are summarized: (1) Disease coverage is imbalanced, favoring internal medicine and mental health disorders over surgical and orthopedic, dermatological, ophthalmological, and multimorbidity scenarios, limiting effective clinical training [16,43]. Future systems should prioritize multimorbidity and diverse patient populations (cultural and linguistic) to enhance realism [17,56]. (2) Prompt design endures information loss in long prompts; placing critical information at prompt ends and using dialogue compression or multiagent frameworks can mitigate this [18,60]. KG-LLM integration and fine-tuning improve performance, with potential for further gains via hybrid KG-CoT approaches [58,59]. (3) Fragmented evaluation frameworks, inconsistent metrics, and small participant pools reduce reliability. A standardized framework with thresholds (eg, top-1 accuracy≥0.80, hallucination rate≤0.05, SUS≥80, CUQ≥75,κ and ICC≥0.80) and larger samples (50-100 students, 5-10 experts) is needed [19,39]. (4) Dataset biases (eg, ICU focus), format heterogeneity, and privacy restrictions limit inclusivity. Open-access, ethically compliant, multimodal, and multilingual datasets are essential for equitable systems [10,45,47].

Future research should focus on large-scale longitudinal studies, standardized evaluation metrics, diverse open-access datasets (eg, UMLS [60] and SNOMED-CT [61]), and advanced integration of KGs, multimodal training, and optimized prompts to enhance the realism, high diagnostic accuracy, and fairness of LLM-based virtual patient systems in medical education [17,18,59].

Abstract

Background: Observational data are fundamental to medical research but present formidable challenges for causal inference. Machine learning–based causal discovery algorithms have emerged as a promising solution to identify causal structures directly from such data. However, the current literature is skewed toward theoretical and methodological innovations, with a critical gap in systematic assessments of performance in medical research settings and a lack of practical guidance for clinicians and researchers on selecting and applying these algorithms in specific medical contexts.

Objective: This study aimed to systematically map and synthesize the application of causal discovery methods in observational medical research, detailing the methodologies used, their application domains, the robustness of the findings, and the practical challenges encountered.

Methods: Following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines, we conducted a systematic search of Scopus, Web of Science, PubMed, MEDLINE, Embase, and CINAHL from inception to May 2025. We included studies that applied any causal discovery algorithms within a medical research context, encompassing both analyses of real-world observational data and method-validation studies using synthetic or benchmark datasets with a clear medical focus. Purely methodological papers and studies based solely on experimental data were excluded. Data were extracted and synthesized using a descriptive analysis focused on study characteristics, algorithm types, application domains, reported numerical results, and implementation challenges.

Results: Out of 2296 identified publications, 72 (3.1%) met the inclusion criteria. Our synthesis revealed three key themes. The first theme was methodological landscape, where constraint-based algorithms were the most prevalent (38/72, 52.8%), with the fast causal inference (10/72, 13.9%) and Peter-Clark algorithms (9/72, 12.5%) being most common. Score-based (19/72, 26.4%) and hybrid (14/72, 19.4%) methods also represented significant and growing segments (methods were not mutually exclusive). The second theme was application domains and findings, where the majority of studies (54/72, 75%) were in clinical research, with a strong focus on mental health (19/72, 26.4%; eg, identifying symptom networks in schizophrenia and posttraumatic stress disorder) and chronic diseases (19/72, 26.4%; eg, elucidating progression pathways in Alzheimer and diabetes). Etiological research was the primary objective (28/72, 38.9%). Public health applications (18/72, 25%) frequently assessed the causal impacts of behavioral interventions. The third theme was implementation challenges and innovations, where common challenges included pervasive unmeasured confounding, limited sample sizes (noted in more than 20% of studies), and reliance on unvalidated causal assumptions. Emerging innovations focused on longitudinal data frameworks and the integration of multimodal data sources to strengthen causal claims.

XSL•FO
RenderX

Conclusions: This review underscores the growing application of causal discovery algorithms in medical research while also highlighting challenges such as the lack of standardized validation frameworks and persistent confounding. Future efforts must focus on developing evaluation standards and fostering interdisciplinary collaboration to translate these powerful computational techniques into reliable tools for medical research and practice.

causal discovery; medical research; observational data; algorithm; scoping review

Introduction

The advent of big data has driven significant advances in machine learning (ML), yet current methodologies often focus on identifying correlations rather than uncovering underlying causal relationships [1]. This limitation is particularly critical in medicine, where understanding causality is essential for effective clinical decision-making. Contemporary causal research addresses 2 interrelated challenges: causal discovery (identifying causal structures and directions between variables) and causal inference (quantifying effects within predefined causal frameworks) [2-5]. Causal discovery is concerned with deducing the causal structure and directionality among variables from data, with the primary objective of elucidating direct and indirect causal pathways by constructing causal graphs. Typically, it relies on statistical principles such as conditional independence tests to discern potential causal structures from correlational patterns. In contrast, causal inference focuses on quantifying the magnitude of the effect of specific interventions on an outcome variable, presuming a known or assumed causal structure. Therefore, inferring causal relationships, that is, causal discovery, from observational medical data is critical for advancing precision and personalized medicine. A central class of computational methods developed for causal discovery, such as the Peter-Clark (PC) algorithm and fast causal inference (FCI), aims to learn a causal graph that represents the underlying data-generating mechanism. The growing scale and accessibility of diverse medical data resources, encompassing real-world records, such as surgical, therapeutic, and diagnostic information, as well as genetic, lifestyle, and environmental data, have become invaluable for such research [6]. However, these data are often affected by confounding, selection bias, and missing data, posing substantial challenges to deriving reliable causal conclusions. Although randomized controlled trials (RCTs) remain the gold standard for medical decision-making [7], the limits of RCTs and the growing abundance of observational data underscore an urgent need for more robust causal discovery methodologies.

Observational datasets, particularly those derived from real-world settings, offer significant advantages for medical research, including large sample sizes, accessibility, and the ability to reflect real-world clinical scenarios. Previous studies have demonstrated their potential to elucidate disease etiology [8-10], optimize treatment strategies [11,12], and refine prognostic models [13,14]. However, the specific application of causal discovery methods to harness these datasets remains particularly challenging and fragmented. Key barriers include unmeasured confounding, complex data structures, and a lack of consensus on methodological best practices. As a result, there is an insufficient synthesis of how these methods can be robustly applied, validated, and translated into clinical insights. This scoping review aims to fill this gap by systematically analyzing causal discovery methods applied to observational medical studies. Specifically, we critically assess: (1) The evolving methodological landscape and algorithm suitability across clinical contexts; (2) High-impact application domains and translational outcomes; (3) Persistent implementation challenges, such as unmeasured confounding and sample limitations. By mapping these dimensions, we provide a foundation for advancing causal discovery in digital health and precision medicine.

Methods

Study Design

This scoping review adhered to Arksey and O'Malley's framework for scoping review [15] and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines [16] (Multimedia Appendix 1). Our primary research question was: "What are the methodologies, clinical applications, and implementation challenges of causal discovery in observational medical research?" The aim was to synthesize evidence to guide future methodological development and clinical translation. Given the rapidly evolving nature of this field, no temporal restrictions were applied.

Search Strategy

To comprehensively review studies of causal discovery algorithms in medical research and its subtypes, 2 researchers (XY and ZH) performed a systematic literature search of Scopus, Web of Science, PubMed, MEDLINE, Embase, and CINAHL in May 2025 and was restricted to studies published in English, using the following search strategies: "causal discovery/causal structure discovery/causal structure learning/causal graph discovery/learning causal models." The search was focused on biomedical databases (PubMed, Embase, etc) as this review aims to map applications in medical research. While computer science–focused databases, such as IEEE Xplore or ACM Digital Library, include methodological developments, they primarily emphasize algorithmic innovation; seminal methodological papers with medical applications are typically also indexed within the selected biomedical sources. The search strategy was designed in consultation with an information specialist. The entire search strategy for the 6 databases is displayed in Multimedia Appendix 2.

RenderX

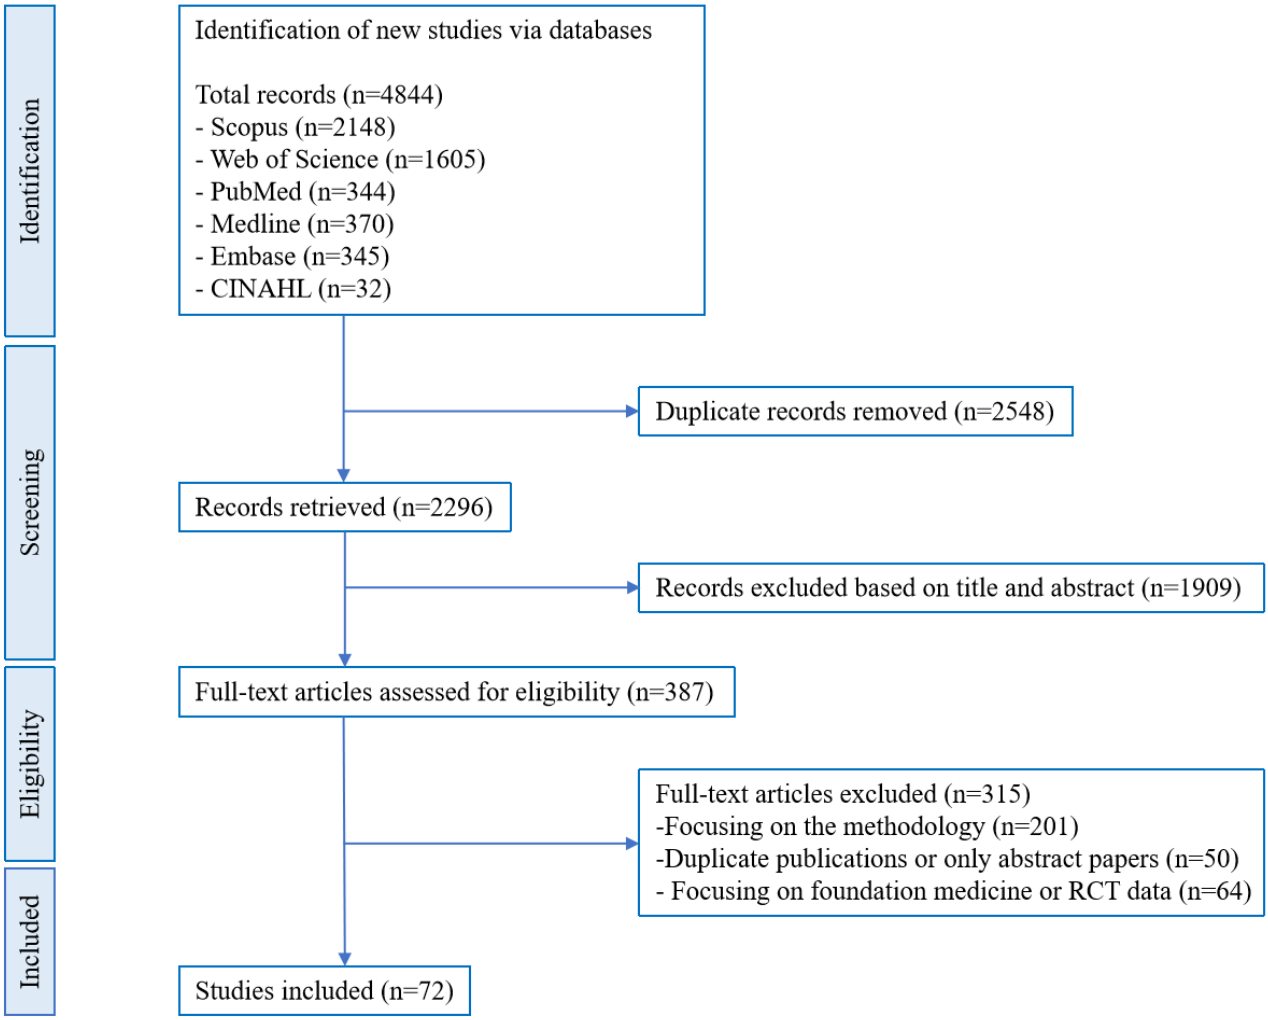
Eligibility Criteria

Two researchers (HM and JM) independently screened studies based on predefined inclusion and exclusion criteria by examining their titles, abstracts, and full texts. Studies met the following inclusion criteria: (1) application focus: empirical implementation of causal discovery algorithms in medical or health contexts. (2) Data and methodology: the study applied a causal discovery approach within the observational research paradigm. This included analyses of real-world observational medical data as well as method-validation studies that used synthetic or benchmark datasets to address a medical research question or simulate a medical data environment. (3) Output: the study generated an explicit causal graph or causal structure. (4) Language: English-language publications. The exclusion criteria were: (1) The study purely focused on methodological or theoretical papers without medical applications. (2) Experimental (RCT) or basic science studies. (3) Duplicate publications, brief abstracts, or conference summaries lacking full methodological and results sections. (4) Studies where causal discovery was not the primary methodology. Discrepancies in study eligibility were resolved through consensus between 2 independent reviewers (JK and JL).

Data Extraction and Synthesis

Screening was performed using Rayyan [17], with dual-reviewer verification at all stages. A standardized electronic form was used to extract the following data items: (1) study characteristics: year of publication, country or region of corresponding author affiliation, study design, and sample size; (2) causal discovery methods: specific algorithms, methodological category, and the primary software or package used for implementation; (3) data properties: data type, dimensionality, and temporal features; (4) application domain and specific clinical or public health objectives; and (5) validation approaches and key reported limitations.

Data synthesis was conducted in 2 complementary ways to align with the scoping review's descriptive aims. First, a descriptive quantitative analysis summarized structured characteristics (eg, causal discovery algorithms, software tools, and application domains) using frequencies and percentages. Second, for textual data on reported methodological considerations and challenges, an inductive content summary was performed. Two reviewers (ZL and TL) independently identified recurrent issues and patterns, which were then discussed, consolidated, and organized into overarching descriptive themes (eg, methodological landscape and challenges). This process ensured the results reflected both the quantitative distribution and qualitative substance of the included literature. While this scoping review did not undertake a formal critical appraisal of individual studies using standardized quality assessment or risk-of-bias tools, we systematically extracted study-reported methodological limitations and implementation challenges as a prespecified data item during full-text screening. These author-reported limitations were subsequently subjected to inductive qualitative synthesis, alongside other extracted textual data, to identify recurrent patterns and to develop the descriptive themes presented in the "Challenges" section. This approach was intended to map commonly reported methodological issues in the literature rather than to appraise or grade the quality of individual studies.



Results

Article Selection

After the removal of duplicates, 2296 unique records were identified for screening. Of these, 72 studies [8-14,18-82] (3.1%) met the inclusion criteria and were included in the final synthesis (Figure 1). After eliminating 2548 duplicates (52.6%), title or abstract screening excluded 1909 records (39.4%). A full-text review of 387 articles led to the exclusion of 315 (81.4%) due to reasons such as a methodological focus (201/315, 63.8%), duplicate publications or abstracts (50/315, 15.9%), and basic research or experimental designs (64/315, 20.3%).

RenderX

Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) flowchart for the study selection process. RCT: randomized controlled trial.

Characteristics of the Articles

The characteristics of the included studies (N=72) [8-14,18-82] are summarized in Table 1, covering publication year, country or region, and document type. The number of annual publications progressively increased from 2017 to 2025, with the years 2023-2025 accounting for the majority (46/72, 63.9%). Publications peaked in 2023 and 2024. The majority of studies were peer-reviewed journal articles (64/72, 88.9%), with the remaining studies being conference proceedings. The studies originated from 18 distinct countries or regions, with the United States contributing the largest proportion (25/72, 34.7%), followed by China (8/72, 11.1%), the Netherlands (6/72, 8.3%), and Japan (4/72, 5.6%), accounting for a combined total of 59.7% of publications. Three primary themes emerged from the analysis: (1) methodological landscape, that is, dominant causal discovery approaches and typologies in medical research; (2) application domains, that is, multidimensional implementation scenarios across observational studies; and (3) challenges, that is, methodological limitations and barriers to clinical translation.

Table 1. Characteristics of the studies used in the review, including the year, type, and country of publication (N=72).

Features	Studies, n (%)	References
Year of publication		
2025	14 (19.4)	[8-10,13,18-26,82]
2024	16 (22.2)	[11,14,27-40]
2023	16 (22.2)	[41-56]
2022	8 (11.1)	[57-64]
2021	5 (6.9)	[12,65-68]
2020	7 (9.7)	[69-75]
2019	2 (2.8)	[76,77]
2018	1 (1.4)	[78]
2017	3 (4.2)	[79-81]
Type of publication		
Journal article	64 (88.9)	[8-14,18-31,33,34,37,38,41-48,50,51,53-63,65-82]
Conference article	8 (11.1)	[32,35,36,39,40,49,52,64]
Country of publication		
United States	25 (34.7)	[18,20,22,23,26,28,36,38,43,46,47,51,56-58,60,61,63,65-67,70,73,74,79]
China	8 (11.1)	[19,29,33,42,52,69,77,78]
Netherlands	6 (8.3)	[9,27,59,71,80,81]
Japan	4 (5.6)	[39,40,49,75]
Other countries	29 (40.3)	[8,10-14,21,24,25,30-32,34,35,37,41,44,45,48,50,53-55,62,64,68,72,76,82]

Themes

Theme 1: Methodological Landscape

Causal discovery methodologies are broadly divided into several major categories: constraint-based, score-based, continuous optimization, functional causal models, and hybrid methods. It should be noted that these categories are not mutually exclusive; a single study could use methods from more than one category. Thus, the percentages reported below are calculated based on the total number of included studies (N=72) [8-14,18-82] and may sum to more than 100%. Among the 72 studies analyzed, constraint-based methods constituted the predominant approach (38/72, 52.8%) [8-10,12,14,18,24,25,27,29-32,34-38,43,45,48,52,53,55,57-59,63,64,68,70,71,73,74,77,79-81], followed by score-based (19/72, 26.4%) [8,11,18-20,23,24,26,28,32,33,35,39,42,61,67,73,74,82], hybrid (14/72, 19.4%) [8,13,22,23,33,41,46,47,51,56,60,63,65,69], continuous optimization (9/72, 12.5%) [29,33,36,40,44,49,50,54,62], and functional causal models (5/72, 6.9%) [21,32,66,75,78]. At the algorithmic level, FCI (10/72, 13.9%) [10,18,29,34,38,43,58,63,73,74] and PC (9/72, 12.5%) [12,18,25,27,29,35,36,53,70] algorithms were the most implemented constraint-based methods, whereas greedy fast causal inference (GFCI) (10/72, 13.9%) [13,22,23,41,46,47,51,60,63,65] and Non-combinatorial Optimization via Trace Exponential and Augmented Lagrangian for Structure learning (6/72, 8.3%) [36,40,49,50,54,62] demonstrated notable dominance within the hybrid and continuous optimization categories, respectively. Additionally, time-series causal discovery (eg, Peter-Clark momentary conditional independence) was actively explored in 11 studies [32,44,48,55,64,66,68,72,76,77,82]. These findings highlight a clear trajectory toward the adoption of more integrated, scalable, and nonparametric causal discovery frameworks. The reviewed studies used methodologies from 2 distinct conceptual frameworks. The majority used structural causal discovery algorithms (eg, PC, FCI, and NOTEARS) to learn causal graphs or networks. An analysis of implementation tools revealed the software landscape for causal discovery (Table 2). Of the 72 included studies, 45 (62.5%) [8-10,12,13,18-22,24,26-28,30,32,36-39,41,43,44,46-48,50,51,54,55,57,60-63,65,68-71,74,75,77,79] explicitly specified the software or package used. Among these, R was the most prevalent environment, used in 22 studies [8-10,12,18,20,22,24,26-28,30,37,38,48,55,57,60,61,68,74,82] (22/45, 48.9% of reporting studies, or 22/72, 30.6% of all studies), with the *pcalg* package being the most frequently cited. The standalone Tetrad suite was used in 10 studies [13,18,41,43,46,47,51,63,65,74] (10/45, 22.2% of reporting studies, or 10/72, 13.9% overall). Out of 45 studies, Python and MATLAB were implemented in 7 [9,21,32,36,50,54,62] (15.5%) and 8 [32,44,69-71,75,77,79] (17.7%) of the software-reporting studies, respectively. A notable finding regarding transparency was that 27 studies [11,14,23,25,29,31,33-35,40,42,45,49,52,53,56,58,59,64,66,67,72,73,76,78,80,81] (37.5% of the total) did not report any software details, posing a significant barrier to reproducibility. For details, refer to Table 2.

[a]PC: Peter-Clark algorithm.
[b]FCI: fast causal inference.
[c]FGES: fast greedy equivalence search.
[d]GRaSP: greedy relaxation of the sparsest permutation.
[e]PC-stable: Peter-Clark stable.
[f]Inter-IAMB: interleaved incremental association Markov blanket.
[g]HC: hill climbing.
[h]Tabu: tabu search.
[i]MMHC: max-min hill climbing.
[j]H2PC: hybrid of HPC and PC.
[k]GES: greedy equivalence search.
[l]BCCD: Bayesian Constraint-based Causal Discovery.
[m]LiNGAM: linear non-Gaussian acyclic model.
[n]GFCI: greedy fast causal inference.
[o]MGM: mixed graphical model.
[p]GraSP-FCI: greedy relaxation of the sparsest permutation fast causal inference.
[q]ARACNE: algorithm for the reconstruction of accurate cellular networks.
[r]iMIIC: interpretable multivariate information-based inductive causation.
[s]GGES: greedy generalized equivalence search.
[t]GAE: graph autoencoder.
[u]Modified PC: modified Peter-Clark algorithm.
[v]AnchorFCI: anchor fast causal inference.
[w]RDCM: regression dynamic causal modeling.
[x]MVGC: multivariate Granger causality.
[y]PCMCI: Peter-Clark momentary conditional independence.
[z]VarLINGAM: vector autoregressive linear non-Gaussian acyclic model.
[aa]CBAMN: cycle-breaking algorithm based on modified NOTEARS.
[ab]SEM: structural expectation-maximization.
[ac]RL: reinforcement learning.
[ad]IIE: inverse information entropy strength.
[ae]CABG: isolated coronary artery bypass grafting.
[af]AVR: isolated aortic valve replacement.
[ag]DYNOTEARS: dynamic noncombinatorial optimization via trace exponential and augmented lagrangian for structure learning.
[ah]SAM: structural agnostic modeling.
[ai]IAMB: incremental association Markov blanket.
[aj]GS: grow-shrink.
[ak]PTSD: posttraumatic stress disorder.
[al]ANM: additive noise model.
[am]PKCL: prior-knowledge-driven local causal structure learning.
[an]T2DM: type 2 diabetes mellitus.
[ao]GLL-PC: global-local learning Peter-Clark algorithm.
[ap]TPC: temporal Peter-Clark algorithm.
[aq]ADHD: attention-deficit/hyperactivity disorder.
[ar]PCDSD: probabilistic causal discovery in sequential datasets.
[as]LSTM: long short-term memory.
[at]McDSL: multiple-cause discovery combined with structure learning.
[au]SVM: support vector machine.
[av]LGMM: latent growth mixture modeling.
[aw]HITON-PC: HITON-PC algorithm.
[ax]ASD: autism spectrum disorder.

XSL•FO
RenderX

[ay]NOTEARS: noncombinatorial optimization via trace exponential and augmented Lagrangian for structure learning.

[az]CVD: cardiovascular disease.

[ba]AKD: acute kidney injury.

[bb]ItsPC: irregular time-series PC.

[bc]ICU: intensive care unit.

[bd]PPCIT: predictive permutation conditional independence tests.

[be]GIES: greedy interventional equivalence search.

[bf]MCMC: Markov chain Monte Carlo.

[bg]GGM: Gaussian graphical model.

[bh]COPD: chronic obstructive pulmonary disease.

[bi]CD-SF: causal discovery based on the streaming feature.

[bj]CD-SU-SF: causal discovery with symmetrical uncertainty based on the streaming feature.

[bk]LiNGAM: linear non-Gaussian acyclic model.

Theme 2: Application Domains

Examination of the 72 studies [8-14,18-82] indicated that causal discovery applications were dominated by clinical research (54/72, 75%), with public health comprising the remainder (18/72, 25%). Etiological investigation emerged as the predominant focus within clinical research, followed by predictive modeling, highlighting the method's central role in elucidating disease mechanisms and enabling clinical prognosis. This application profile demonstrated the adaptability of causal discovery methodologies across the spectrum from individual-level clinical research to population health studies.

Causal Discovery Methodological Approaches to Disease Categories

Among the 54 clinical studies [8-14,18,19,21-23,25-29,31-34,36,38,39,42-46,51-54,58-61,63-65,67,69-81], mental health represented the most extensively examined area (19/72, 26.4%) [13,22,23,27,29,32,45,46,51,53,59,60,65,70,71,75,79-81], with significant attention to schizophrenia (3/72, 4.2%) [13,32,51], posttraumatic stress disorder (3/72, 4.2%) [46,70,79], autism spectrum disorder (2/72, 2.8%) [22,80], and attention-deficit/hyperactivity disorder (2/72, 2.8%) [71,80]. Chronic disease investigations equally comprised 26.4% (19/72) of studies [9-12,14,19,21,26,28,31,36,38,42,52,69,72-74,76], spanning neurodegenerative diseases [10,19,26,72-74,76] (particularly Alzheimer disease [10,19,26,74] and amyotrophic lateral sclerosis [72,76]), malignancies [11,14,28,36,52], diabetes [21,42], and other chronic conditions [9,12,31,38,69]. Additional clinical applications included acute illnesses [8,33,78], pharmacological research [18,63], and other various specialized clinical scenarios [25,34,39,43,44,54,58,61,64,67,77], collectively demonstrating the extensive penetration of causal discovery methodologies in clinical research. For details, refer to Table 2.

Research Focus and Clinical Applications

The 54 clinical studies [8-14,18,19,21-23,25-29,31-34,36,38,39,42-46,51-54,58-61,63-65,67,69-81] showed a distinct concentration in research aims. Etiological exploration represented the predominant focus (28/72, 38.9%) [8-10,18,22,23,25,27,29,31,39,42-46,51,54,60,61,63,65,69-71,74,75,80], establishing causal discovery as a core methodology for investigating disease mechanisms. Predictive modeling constituted the second major application area (13/72, 18.1%) [19,21,26,33,34,58,64,72,73,76-79], while prognostic evaluation [13,14,28,52] and disease diagnosis [32,36,38,53] each accounted for 4 studies respectively. Collectively, these 4 domains accounted for 49 investigations (49/72, 68.1%), underscoring the method's primary use in addressing fundamental clinical questions from causation to outcome assessment.

For example, in a study by Zhang et al [63], causal discovery methods were applied to construct causal networks of COVID-related acute kidney injury using longitudinal electronic health record (EHR) data. Specifically, the FCI and GFCI algorithms were used to automatically identify the development of COVID-19–related acute kidney injury with minimal prior assumptions about pathway connectivity. The results provided a more refined understanding of how remdesivir and other risk factors contribute to acute kidney injury, identifying critical time points for potential intervention and offering valuable insights for clinical decision-making [63]. Similarly, Sokolova et al [80] demonstrated the application of the Bayesian constraint-based causal discovery algorithm to cross-sectional phenotypic data, which revealed directional relationships between attention-deficit/hyperactivity disorder and autism spectrum disorder symptom domains that traditional correlational methods failed to elucidate, generating novel hypotheses regarding the etiological mechanisms underlying their comorbidity [80].

However, the limited applications in clinical decision support development (1/72, 1.4%) [67] and measurement scale implementation (2/72, 2.8%) [59,81] suggested that the translation of causal discovery into practical clinical tools remained underdeveloped, highlighting substantial potential for future research and implementation in real-world health care settings.

Public Health Research Applications

Public health domains were addressed in 25% (18/72) of studies [20,24,30,35,37,40,41,47-50,55-57,62,66,68,82], demonstrating the expanding relevance of causal discovery beyond clinical settings. Health behavior interventions constituted the largest subgroup (8/72, 11.1%) [30,35,37,40,41,49,56,62], primarily focusing on lifestyle quantification and health promotion. Disease management decision-making and health care optimization strategies were examined in 9.7% (7/72) of studies [20,24,47,50,66,68,82], encompassing social determinants of

XSL•FO
RenderX

health, health care use patterns, and nursing home hospitalization reduction. The remaining studies addressed infectious disease transmission research [57,66] and life-course epidemiology [55]. These applications collectively demonstrated the methodological versatility of causal discovery in tackling population-level health challenges and informing public health policy.

Theme 3: Challenges

Common Observational Study Challenges

Medical observational studies using causal discovery methods consistently faced several fundamental limitations. Unmeasured confounding represented the most prevalent challenge (32/72, 44.4%) [11,12,18,20,21,25-27,29,37,38,41,43,44,52-57,59,62,63,65,66,70,71,73,75,82-84], potentially introducing spurious discoveries and biased effect estimates. Sample size limitations were reported in 29.2% (21/72) of studies [9,10,23,24,27,30,31,35,38,40,41,49,55,61,63,69,71,73,78,81,85], restricting statistical power and generalizability. Data quality issues emerged across multiple investigations, including substantial missing data and discretization-induced biases [10,12,30,33,47,49,54,77]. The absence of longitudinal designs in several studies further hindered the verification of temporal directionality in causal relationships [10,13,19,29,54,74,86].

Causal Discovery-Specific Methodological Issues

The application of causal discovery algorithms revealed distinct methodological challenges. Unvalidated algorithmic assumptions were identified in 18.1% (13/72) of studies [8,9,37,43,44,48,52,57,61,71,82,87,88], compromising validity when core assumptions such as causal sufficiency and the Markov property were violated. Limited cross-disease validation [21] and insufficient external validation [59] constrained the broader applicability of findings. Additionally, overreliance on prior knowledge introduced subjectivity into the discovery process, potentially influencing causal structure learning and interpretation [24,36,74,89,90].

Proposed Methodological Improvements

To address these challenges, future research should focus on the following. First, developing confounder-robust algorithms, as demonstrated by AnchorFCI in cardiometabolic disease research [31], and integrating domain knowledge in neurodegenerative studies [10]. Second, advancing longitudinal causal discovery frameworks for irregularly sampled temporal data in EHRs, as seen in nephrotoxicity and intensive care unit studies [63,64]. Third, enabling multimodal data integration strategies, such as coupling neuroimaging with EHRs or synthesizing wearable data with clinical assessments to explore lifestyle diseases [40,49,61]. Finally, incorporating artificial intelligence (AI) architectures like large language models, deep learning, and reinforcement learning to enhance clinical interpretability and model transferability across institutions [21,25,36,42,58,67].

Discussion

Principal Findings

This scoping review represents the first systematic mapping of causal discovery algorithms in observational medical research. It synthesizes key methodological, translational, and implementation gaps across clinical and public health domains. Despite the field's nascent stage, research momentum has accelerated markedly, reflecting growing translational potential. The scarcity of qualifying studies (72 of 2296 screened) underscores both the emergent nature of these methods and the novelty of this review. Our integration of fragmented evidence establishes a foundational framework for interdisciplinary refinement, advancing beyond traditional observational research limitations and supporting the causal discovery's role in medical settings.

Translational Gaps in Application Domains

Clinical research concentrates on etiological exploration, leveraging causal graphs to deconstruct complex diseases (eg, mental health and chronic conditions). However, a severe imbalance exists between mechanism discovery and clinical decision support development (1/72, 1.4%), revealing a critical mechanism-application dissociation. This translational gap primarily stems from 4 interconnected barriers: most methods remain at the proof-of-concept stage without large-scale clinical validation, creating a fundamental trust deficit; existing tools lack seamless integration with clinical workflows and EHR systems; real-world data quality issues and computational demands hinder practical implementation; and crucially, statistically robust findings often fail to translate into clinically actionable recommendations that clinicians can readily understand and apply at the point of care. Public health applications focus on behavior interventions (eg, lifestyle-outcome linkages) and system optimization (eg, health care use patterns), but face domain-specific confounders (eg, policy shifts). Cross-domain translation requires context-adapted methodological frameworks.

Methodological Challenges to Practical Translation

Causal discovery in observational medical research remains dominated by constraint-based (eg, PC and FCI) and score-based methods (eg, GES and FGES), valued for their reliability in exploratory analysis and high-dimensional data, as well as their inherent interpretability; their graphical outputs and testable assumptions align well with clinical reasoning. However, their limitations in identifying causal directions, handling unmeasured confounding, and computational efficiency have spurred new approaches: continuous optimization (eg, NOTEARS) enhances scalability, although often at the cost of transparency; hybrid methods (eg, GFCI) improve robustness; functional models (eg, LiNGAM) enable direction identification; and time-series approaches (eg, PCMCI) capture dynamic causality. This interpretability-scalability trade-off critically guides model selection in clinical settings, where trust and actionable insight depend on understandable outputs. This evolution marks a transition toward more robust, scalable, and temporally-aware causal inference.

XSL•FO
RenderX

Unmeasured confounding remains fundamental, distorting effect estimates and causal structures. Partial ancestral graph algorithms (eg, FCI and RFCI [91]) and negative control designs [92] offer partial solutions but lack universal robustness. Small-sample limitations undermine statistical power and generalizability, particularly in rare diseases or early-phase studies. Transfer learning [93], multimodal data fusion (eg, Cov-Pneum dataset [94]), and cross-disease validation mitigate data scarcity [95], while embedding expert knowledge (eg, in Bayesian networks) reduces model uncertainty. Beyond these challenges, translating causal discovery into practice requires concerted action on 2 fronts: establishing benchmark datasets and implementing a rigorous, explainable, multitiered validation framework. We strongly recommend the curation of medical benchmark datasets derived from gold-standard sources, such as large-scale RCTs or well-validated longitudinal cohorts, to provide a critical foundation for fairly evaluating and comparing algorithms. For instance, the study by Gururaghavendran and Murray [18] used a zero placebo effect as the benchmark to compare multiple causal discovery algorithms, demonstrating that guidance from expert insight and prior knowledge significantly enhances their performance.

Explainable artificial intelligence techniques hold significant potential for improving the causal discovery process. Hasan and Gani [96] introduced a knowledge-guided causal AI system that integrates domain-specific prior knowledge as structural constraints with observational data to refine causal graph discovery. The results show that this approach also lowers computational demands while improving reliability [96]. One study introduced a new causal discovery approach, called REX, leveraging ML models coupled with interpretability techniques, showing REX's effectiveness and robustness in accurately recovering true causal structures, along with its applicability to real-world problems [97]. In addition, moving beyond theoretical sensitivity analyses, a robust validation strategy must integrate internal validation (eg, using bootstrap to assess graph stability), external validation on independent datasets, and most importantly, rigorous evaluation of biological and clinical plausibility against established knowledge or new experimental findings. This comprehensive approach is essential for bridging the current trust gap and generating clinically actionable insights.

Future Directions

To propel the field beyond current methodological constraints and accelerate clinical translation, the following strategic advancements warrant prioritized investigation:

1. Advancing temporal causal inference: integrate time-series data (eg, EHRs) with target trial emulation frameworks to resolve temporal ambiguity, mitigate time-varying confounding, and strengthen causal directionality inference [98].
2. Enabling multimodal data integration: leverage causal ML methodologies to unify heterogeneous data sources (eg, EHRs, genomics, and behavioral data), thereby facilitating robust estimation of individualized treatment effects and bridging critical evidence gaps [10,36,99].
3. Developing AI-enhanced causal discovery: synthesize deep learning (for high-dimensional feature extraction), reinforcement learning (for adaptive decision-making), and causal representation learning to enhance the accuracy, scalability, and interpretability of causal inference in complex biomedical systems [21,25,42,100].
4. Accelerating clinical translation: it is imperative to establish reproducible benchmarking frameworks and standardized reporting guidelines. We encourage journals to adopt policies that actively promote code and data availability, thereby enhancing transparency and reproducibility. The integration of sensitivity analyses into routine methodological reporting should be considered essential for evaluating the robustness of inferred causal relationships. Furthermore, the development of cross-institutional validation protocols and standardized tools that facilitate the incorporation of clinical domain knowledge into causal discovery pipelines will be critical for fostering broader clinical adoption.
5. Enhancing interpretability: improving the interpretability of causal discovery outputs and building clinical trust requires heightened methodological transparency and consistent reporting standards. The field should move toward developing domain-specific reporting guidelines for causal discovery in medicine, which would detail the algorithms used, parameter settings, and evaluation metrics. Systematically embedding interpretability-focused techniques, such as feature importance analysis or causal pathway explanation, can help bridge inferred causal structures with established clinical evidence.

Ultimately, the real-world impact of causal discovery hinges on its ability to deliver comprehensible and actionable insights that resonate with clinical researchers and practitioners. However, whether causal discovery can genuinely drive scientific progress, generate novel insights, and inform scholarly discourse in fields can ultimately be determined only through its repeated application in practice, coupled with rigorous and transparent reporting of the results [101].

Strengths and Limitations

This review provides a timely, comprehensive synthesis of causal discovery algorithms across diverse medical domains. Nevertheless, limitations exist: First, restricting the search to English-language publications may have excluded valuable non-English evidence. Second, our review reveals a pronounced geographic concentration of research, with the majority of studies originating from the United States and China. This likely reflects disparities in access to large-scale digital health infrastructure, advanced computational resources, and targeted research funding. Consequently, the current evidence base and its associated methodological trends may not be fully representative of global research activity or directly generalizable to health care settings in other regions. Third, the search was conducted within biomedical databases and relied on a core set of terms centered on "causal discovery." While this approach efficiently captured studies self-identifying with this paradigm, it is possible that some relevant applications published under different terminology (eg, "Bayesian network structure learning") in computational science venues were not retrieved. Finally, while we mapped application breadth, a formal assessment of reporting quality or bias risk was not

XSL•FO
RenderX

conducted; future work should implement standardized appraisal tools to systematically evaluate methodological rigor.

Conclusions

Causal discovery is emerging as a pivotal approach in medical observational research, offering transformative potential for etiological exploration and clinical decision-making. However, critical barriers impede clinical translation, notably the absence of standardized validation frameworks and persistent confounding. Future progress necessitates rigorous evaluation standards and AI-causal methodology integration to enable robust, generalizable real-world decision support.

Acknowledgments

In accordance with journal policy, we confirm that no generative artificial intelligence tools were used in the writing of this manuscript or in the generation of its scientific content. Artificial intelligence–assisted tools were used solely for minor language polishing and proofreading. All conceptualization, analysis, intellectual interpretation, and authorship of the final manuscript are solely attributable to the human authors.

Data Availability

All data generated or analyzed during this study are included in this published article and Multimedia Appendices 1-2.

Funding

This study was supported by the National Natural Science Foundation of China (grant numbers 82360667 and 82160645), the Natural Science Foundation of Jiangxi Province (grant number 20212BAB206091), and the National Undergraduate Training Program for Innovation and Entrepreneurship (grant number 202510403077).

Authors' Contributions

JK and JL were involved in the concept and design of the review. ZL, TL, HM, JM, XY, and ZH made major contributions to literature search, data collection, data analysis, and data interpretation. ZL and JK wrote and edited the manuscript. All authors read and approved the final manuscript.

Abstract

Artificial intelligence (AI) is increasingly integrated into breast imaging workflows, offering the potential to enhance diagnostic accuracy, efficiency, and early cancer detection. Image interpretation plays a pivotal role in the breast cancer diagnostic pathway, directly influencing therapeutic decisions and patient outcomes. However, the effective implementation of AI-assisted systems relies not only on technical performance but also on radiologists' trust, acceptance, and readiness to incorporate these tools into clinical practice. In addition, system-related, perceptual, and cognitive factors may contribute to diagnostic errors, ultimately affecting overall accuracy and reliability. This paper provides a comprehensive overview of the cognitive and systemic sources of diagnostic inaccuracies in breast imaging, emphasizing the growing role of AI as both a supportive and potentially bias-modulating tool. Recent prospective studies have demonstrated the clinical safety and effectiveness of AI-assisted mammography screening, reporting improved cancer detection rates and reduced workload. Nonetheless, the integration of AI into diagnostic workflows without an appropriate knowledge of the consequences may introduce new cognitive biases, such as anchoring, automation, and confirmation bias, that influence radiologists' decision-making and counteract the intended benefits. To address these challenges, the paper outlines strategies to mitigate diagnostic errors and foster appropriate integration of AI into clinical practice. These include targeted training programs, enhanced interdisciplinary communication, and standardized interpretation workflows that promote consistent evidence-based practice. Furthermore, the adoption of explainable AI approaches is identified as a key factor in improving model transparency and interpretability, allowing radiologists to understand algorithmic reasoning and engage in a more informed, confidence-based human-AI collaboration. Ultimately, a balanced and context-sensitive integration of AI, grounded in continuous professional education and cognitive awareness, is essential for improving diagnostic accuracy while preserving radiologists' critical analytical skills.

Radiological Interpretation Workflow

The increasing integration of artificial intelligence (AI) into clinical medicine has created new opportunities to enhance diagnostic accuracy and therapeutic decision-making across multiple fields. AI is defined as a machine's capability to mimic intelligent human behavior, such as learning, reasoning, and problem-solving [1]. Despite its promise, AI adoption in routine clinical practice faces significant challenges, including disparities in medical imaging access, and remains in early stages across many specialties [2-4].

In oncology, AI facilitates early tumor detection and personalized treatment planning, with a prominent role in radiology, where it analyzes medical images and patient data to detect patterns and abnormalities, accelerating and improving diagnosis. However, its extensive use in clinical decision-making increases exposure to bias with potentially serious clinical repercussions [2].

XSL•FO
RenderX

Radiological interpretations critically influence therapeutic decisions and patient management outcomes [5,6]. These interpretations are based on the careful evaluation of available evidence but remain subject to limitations because of the subjective nature of image assessment, without replacing gold-standard pathological examinations [5]. In health care, AI has been introduced to support complex tasks that require reasoning and decision-making [7]. However, its application must be approached cautiously, as it does not eliminate the possibility of errors.

Given these limitations, it is essential to understand the factors contributing to diagnostic variability and potential errors in radiology.

The process of interpreting medical images is complex, requiring radiologists to evaluate imaging data meticulously to identify potential health issues. Despite their expertise, the diagnostic error rate among practicing radiologists is estimated to be between 3% and 6%, amounting to approximately 40 million errors globally each year, given annual imaging volumes [8,9]. This error rate is even higher, between 31% and 37%, in cross-sectional imaging such as computed tomography (CT) [10]. Given the growing reliance on cross-sectional imaging, it is essential to understand the causes, prevalence, and impact of diagnostic errors to minimize their effect on patient care.

Diagnostic errors have significant consequences for patient outcomes and place a substantial burden on health care systems. They can be categorized into 3 primary groups: system errors, visual-perception errors, and cognitive errors [4,11]. System-related errors include equipment failures or suboptimal image quality. Visual-perception errors occur when radiologists either fail to detect abnormalities or mistakenly classify them as normal, influenced by factors such as fixation duration [5]. Finally, cognitive errors result from incorrect interpretation of detected abnormalities and represent the largest proportion of diagnostic mistakes, reaching up to 74% in some imaging modalities [12].

This paper aims to provide an in-depth overview of the implementation of AI in medical imaging, with a specific focus on breast cancer radiology, based on a comprehensive literature search (see Multimedia Appendix 1). This focus distinguishes our work from previous reviews, such as that of Stogiannos and colleagues [4], which adopt a modality-independent perspective. In contrast, the present review concentrates on how AI is being integrated into real-world breast imaging workflows across screening, diagnostic, and interventional settings. Particular attention is given to the practical challenges of implementation and the evolving dynamics of human-AI interaction in daily clinical practice.

Adopting both a conceptual and practice-oriented lens, it explores the dual nature of AI as both a supportive adjunct and a potential source of diagnostic error, emphasizing strategies for informed and responsible AI use. Finally, it addresses cognitive biases that arise from human-AI collaboration, their implications for clinical decision-making, and possible approaches to mitigate these effects.

Through this perspective, we argue that understanding and managing these biases is crucial to ensuring the safe and effective integration of AI in breast imaging, with the ultimate goal of improving diagnostic accuracy and optimizing patient care.

The Adoption of AI in Radiological Senology

Breast cancer is one of the most diagnosed cancers worldwide, accounting for approximately 2.3 million new cases and 0.7 million deaths among women each year [13]. Early diagnosis is of pivotal importance in reducing morbidity and mortality, and, in this scenario, mammographic screening plays a crucial role, currently being the only screening test that has been shown to reduce breast cancer–related mortality [14].

Despite the proven efficacy of mammographic screening, several challenges persist, particularly in terms of workload and diagnostic consistency. Screening programs are typically addressed to women aged between 40/50 and 70/80 years, with European guidelines recommending double reading of screening mammograms to ensure high sensitivity [15]. Nevertheless, the shortage of experienced breast radiologists and the large workload render the double reading difficult to sustain in several countries [16].

A possible solution might be represented by image analysis tools based on AI, a field of computer science dedicated to the creation of systems performing tasks that usually require human intelligence, aimed, for example, at facilitating triage of screening examinations according to risk of malignancy or supporting the radiologist's decision with computer-aided detection (CAD) highlighting suspicious findings, ultimately reducing the workload and the number of interval cancers [17].

Retrospective studies [18-20] suggest that the accuracy of AI is similar to or better than that of breast radiologists and that AI could help radiologists reduce false negative screening results when used as detection support, as it has been shown that AI retrospectively classifies screening examinations as high-risk before a diagnosis of interval cancer [21-23].

A breakthrough point was reached in 2023, when Lång et al [24] published the results of their randomized, controlled mammography screening with artificial intelligence (MASAI) trial, a study investigating an AI-supported screen-reading procedure involving triage of screening examinations to single or double reading, along with detection support, compared to standard double reading.

The MASAI trial was designed as a randomized, parallel, noninferiority, single-blinded, controlled, screening accuracy study in which, after screening, mammograms were acquired, and examinations were automatically randomized to AI-supported screening (intervention group) or standard double reading without AI (control group).

The examinations randomized to the intervention group were analyzed using Transpara version 1.7.0 (ScreenPoint Medical), a deep learning system to identify and interpret mammographic regions suspicious for cancer. The AI system provided an

XSL•FO
RenderX

examination-based malignancy-risk score on a continuous scale ranging from 1 to 10: examinations were considered as low risk (risk scores 1 - 7), intermediate risk (risk scores 8 and 9), or high risk (risk score 10). Furthermore, the AI system provided CAD marks at suspicious regional findings [24].

In the intervention group, examinations with risk scores of 1 - 9 (low and intermediate risk) underwent single reading, and examinations with risk scores of 10 (high risk) underwent double reading, done by two different breast radiologists [24].

Readers first read the examination without CAD marks and then with CAD marks, if available.

In the control group, screening examinations were read with standard unblinded double reading without AI.

This clinical safety analysis testifies that a screen-reading procedure using an AI tool to triage screening examinations to single or double reading and with the use of AI as detection support in mammography screening was safe because the cancer detection rate (6.1 per 1000 participants screened) was above the prespecified lower limit for safety and was similar to that of double reading without AI (5.1 per 1000). The use of AI did not influence the rates of recalls, false positives, or consensus meetings, while the screen-reading workload was reduced by almost half. Indeed, this study found that the benefit of AI-supported screening regarding screen-reading workload reduction was considerable.

Furthermore, the results of the trial showed that AI-supported screening detected 20% more cancers (244 vs 203) compared to standard screening and increased detection of in situ cancers with AI-supported screening compared with standard screening (60 vs 38), which could be concerning in terms of overdiagnosis.

Nevertheless, improvement in one performance measure, such as cancer detection rates, does not always imply an improvement in terms of outcome, such as recurrence rates or mortality reductions. The results of future screening cycles are going to highlight whether the introduction of new strategies, such as AI-supported screening, has a positive impact on the overall effect of the intervention on outcomes and if the costs are justified [25].

The results of this prospective randomized trial corroborate the findings of several retrospective studies that have shown AI has sufficient diagnostic accuracy to make radiological reads as an independent reader of screening mammograms. Nevertheless, there is currently an absence of specific guidelines regarding the potential introduction of AI as an independent reader or, more broadly, for the application of AI tools in everyday clinical practice [26,27].

A comprehensive systematic review performed by Anderson and collaborators [28], focused on the external validation of AI technologies applied to mammographic screening in real-world clinical settings, highlighted that the majority of studies evaluating either stand-alone AI systems or AI used in conjunction with radiologists reported improved diagnostic accuracy compared to radiologist-only interpretations. Some studies included in the review indicate that combining outputs from several AI models—ensemble modeling—can enhance overall performance compared to relying on a single algorithm [29,30]. However, implementing such approaches in real-world clinical environments may be challenging, particularly when it involves integrating multiple AI system owners. Concerning prospects, they emphasized a significant gap in external validation research, which is essential to assess how well AI models perform across large and varied populations in terms of different race/ethnicities or breast cancer risk profiles, and on different imaging techniques such as digital breast tomosynthesis (DBT) versus digital mammography. Additionally, it was highlighted that there is a need to determine the specific screening scenarios, such as age groups and screening intervals, where AI applications would be most beneficial.

Similarly, Houssami and collaborators [31] reported a satisfying diagnostic accuracy for the AI models proposed by the studies involved in their scoping review, with a median area under the curve of 88.2%. What was pointed out in their work was that most of the existing AI research in breast imaging has relied on data from screen-film or digital mammography. Given that DBT is increasingly becoming a central character in breast cancer screening, future AI development should incorporate DBT imaging data, as AI tools trained solely on traditional 2D mammography may quickly become obsolete as DBT adoption grows in clinical practice [31].

Diagnostic Errors in Radiology

Due to the complex interpretational process executed by radiologists, it may be subject to diagnostic errors in up to 6% of cases [5,6]. Diagnostic errors include system errors, such as those related to the equipment used (ie, poor image quality or suboptimal technique), and visual-perceptual errors, which occur when clinically significant findings are not identified due to specific risk factors, including reader fatigue, rapid interpretation, distractions, or interruptions [5]. However, there is a third type of error, called “cognitive errors,” related to the clinicians’ judgment, when clinically significant findings are correctly identified, but an incorrect interpretation is attributed due to mental shortcuts or preconceptions [32]. Identifying these errors is crucial in the medical field, as it enables early action to prevent inaccurate interpretations.

This type of error is caused by the influence of cognitive biases, systematic and unconscious thinking errors that occur when processing and interpreting information in the environment, and that influence people’s decisions and judgments [33,34].

Over time, various classifications have been proposed to categorize cognitive bias within the field of radiology, with multiple reviews documenting the main typologies encountered during medical image interpretation. These cognitive biases have been identified as significant contributors to radiological errors and diagnostic inaccuracies [5,35]. Furthermore, with the increasing integration of AI into radiological clinical practice, it becomes essential to consider its impact within the theoretical framework. In medical AI, a bias is defined as any factor or prejudice that drives an AI algorithm to generate differential or inequitable outcomes [2]. Consequently, the implementation of AI must be carefully evaluated, as it holds the potential to both mitigate certain diagnostic errors and exacerbate existing

XSL•FO
RenderX

cognitive biases [8]. Indeed, AI has shown promise in reducing subjective prejudices, enhancing image analysis clarity, decreasing interobserver variability, and improving the speed and accuracy of radiological reporting [1]. However, AI algorithms trained on biased datasets may perpetuate or even amplify existing health disparities, leading to compromised diagnostic accuracy and inequities in patient treatment [36]. These issues introduce new challenges that health care professionals must acknowledge, particularly regarding the emergence and influence of cognitive biases in AI-augmented radiology [1].

Overview of Cognitive Bias and AI-Driven Insights

This section describes the main cognitive biases highlighted in the literature regarding radiological interpretation and explores the potential contribution and pitfalls associated with AI application in this medical context. To facilitate a clear understanding and contextualization of these errors, Table 1 summarizes each cognitive bias with a specific clinical example that realistically illustrates its occurrence in practice.

XSL•FO
RenderX

Table . Overview of cognitive bias.

Cognitive bias	Explanation	Practical example	AI[a] contribution
Influence of AI (evidence-based)			
Availability	Overemphasizes easily recalled cases over statistical prevalence	*A breast radiologist has recently dealt with several cases of aggressive triple-negative breast cancer in young patients. Shortly afterward, when performing a preventive check-up in a 30-year-old with vague symptoms and no risk factors, the radiologist overestimates the likelihood of malignancy and recommends an aggressive workup, despite weak evidence. The recent memory of similar high-impact cases is fresh and vivid (availability bias), so the radiologist gives disproportionate weight to that experience, leading to an overestimation of the probability of cancer in situations that statistically may not warrant it.*	AI shifts focus to statistical data rather than anecdotal memory [32]
Nonavailability	Ignores diagnoses not previously encountered	*A breast radiologist, during routine screening, fails to consider a rare presentation of breast cancer because they have never seen a similar case before. This is nonavailability bias, as the radiologist underestimates or overlooks the possibility of cancer because that diagnostic pattern isn't readily available in their memory or experience.*	AI trained on large datasets can identify rare cases effectively [32]
Confirmation	Selectively interprets data to confirm existing hypothesis	*A general practitioner suspects a benign fibroadenoma in a patient with a palpable lump and refers the patient to a breast radiologist for an ultrasound. The radiologist identifies a round, circumscribed mass and, believing that this finding aligns with their first impression, the radiologist selectively focuses on features that support a benign interpretation and ignores subtle signs, like nonparallel orientation and heterogeneous echostructure, that could suggest a phyllodes tumor or malignancy. This is confirmation bias: the radiologist seeks out or gives more weight to evidence that supports an existing belief or hypothesis (in this case, that the mass is benign) while not giving enough importance to contradictory evidence, which can lead to diagnostic error or delayed treatment.*	AI may amplify bias if radiologists unquestioningly accept AI suggestions [37]

XSL•FO
RenderX

Cognitive bias	Explanation	Practical example	AI[a] contribution
Anchoring	Fixates on initial information despite conflicting later evidence	*Example 1: A real-life scenario might be represented by a patient with a history of a benign breast cyst returning for follow-up imaging examinations. The breast radiologist identifies a similar-appearing mass in the same location and assumes it's the same cyst, labeling it as benign without carefully evaluating prior images or subtle changes. Nevertheless, the lesion has grown and, in the present examination, new features of malignancy have appeared (eg, irregular margins and vascularization). The radiologist fixates on the initial impression or past diagnosis (a benign cyst) and fails to adequately update (anchoring bias) their judgment in light of new evidence.* *Example 2: A breast radiologist is reviewing a mammogram assisted by an AI tool that highlights a lesion and assigns a low malignancy score. Trusting the AI's judgment, the radiologist anchors on this benign assessment and disregards their initial concern about subtle spiculations, ultimately reporting the lesion as likely benign. However, a biopsy performed later confirms that the lesion was an invasive carcinoma.*	AI may exacerbate if the radiologist overly trusts the AI's initial assessment [37]
Automation	Prefers automated AI outputs even when conflicting info exists	*During a busy screening session, a radiologist uses an AI tool that flags suspicious lesions with heat maps on mammograms. One mammographic examination shows no AI-detected abnormalities, so the radiologist quickly signs the report as negative, without further close review of the mammograms. In this way, a small spiculated mass, missed by the AI tool goes undetected.*	Risk of overreliance on AI leading to missed diagnoses [4]
Framing	Interpretation influenced by how clinical info is presented	*A surgeon sends a patient complaining of a palpable lump to a breast radiologist for an ultrasound, highlighting the patient's strong family history of breast cancer and assessing that, according to him, this finding is suspicious. The radiologist, influenced by this alarming clinical context, interprets a likely benign nodule as suspicious and recommends a biopsy, even though imaging features alone don't strongly support malignancy.*	AI could reinforce framing if trained on biased clinical data [36]

XSL•FO
RenderX

Cognitive bias	Explanation	Practical example	AI[a] contribution
Premature closure	Accepts the diagnosis too early without considering alternatives	*A breast radiologist identifies a well-circumscribed, round opacity on a mammogram and immediately labels it as a benign nodule (eg, possible expression of a fibroadenoma) based on appearance and the patient's young age, without recommending further examinations; however, the mass was a rare presentation of a malignant phyllodes tumor. This is premature closure bias: the radiologist settles too quickly on a diagnosis without fully considering alternative possibilities or completing the necessary diagnostic workup, leading to missed or delayed diagnosis, especially in atypical cases.*	AI might help by suggesting alternative diagnoses for consideration [36]
Influence of AI (theoretical/hypothesis-driven)[b]			
Satisfaction of report	Accepts previous radiological reports without independent reassessment	*A patient is referred for a diagnostic mammogram after a recent ultrasound (done at another facility), reporting a suspicious lesion in the left breast at 2 o'clock. The breast radiologist, assisted by an AI system that flags suspicious regions, identifies on the mammogram, in the same location where the lesion was reported on ultrasound, a spiculated lesion with a high-risk score for malignancy assigned by the AI tool. The radiologist "satisfied" that the main finding had been identified, both by the AI and by their own review, and stopped further searching, and missed other suspicious lesions. Indeed, on the contralateral breast, there was a small cluster of irregular microcalcifications, suspicious for an in situ lesion.*	AI could provide independent second reads to limit this bias
Attribution	Preconceptions or patient stereotypes influence diagnosis, neglecting relevant info	*A breast radiologist is interpreting a screening mammogram of a woman with a history of prior false-positive findings (eg, cluster of microcalcifications that warranted a vacuum-assisted biopsy under stereotactic guidance, with an oncologically negative result) and assumes her current finding is, even this time, a benign one. This is an attribution bias as the radiologist allows prior patient characteristics or history to inappropriately influence interpretation. Instead of evaluating the image solely on current findings, the radiologist may attribute it to past behavior or outcomes, potentially leading to a missed diagnosis.*	AI may be reduced by focusing on current image data, not patient history

XSL•FO
RenderX

Cognitive bias	Explanation	Practical example	AI[a] contribution
Satisfaction of search	Stops searching for additional abnormalities after finding one	*A breast radiologist identifies a clear spiculated mass in the left breast on a mammogram and correctly reports it as suspicious for malignancy. Satisfied with having found an obvious abnormality, the radiologist stops looking carefully and misses a second suspicious finding: a small cluster of microcalcifications in the contralateral breast.*	AI could help by prompting a full image review
Inattentional blindness	Attention fixation causes missed visible findings	*A breast radiologist is reviewing a mammogram that was previewed by a resident, who believes that there are suspicious microcalcifications on the right upper quadrant; this primes the attending physician to look for calcifications in that specific quadrant. While intensely focused on identifying calcification patterns in that area, the radiologist fails to notice an opacity in a different quadrant.*	AI may highlight all findings objectively, reducing this bias
Hindsight	Overestimates the predictability of diagnosis based on outcome knowledge	*A breast radiologist is reviewing a mammogram taken 12 months before a patient was diagnosed with breast cancer. Knowing the eventual diagnosis, the radiologist now clearly identifies the lesion: a small spiculated mass. Nevertheless, at the time of the original screening, the lesion was subtle, not clearly identifiable due to the high breast density, and not highly suspicious without the knowledge of the outcome.*	AI may provide consistent, unbiased analysis, unaffected by outcome knowledge
Regret	Overcompensation due to fear of past diagnostic miss	*A breast radiologist previously missed a case of subtle ductal carcinoma in situ (DCIS) that led to delayed diagnosis. For this reason, in subsequent cases, the radiologists begin to define benign-appearing calcifications as suspicious, overrecommending biopsies, driven by a fear of repeating the error. Emotional reactions to a past mistake influence the radiologist's judgment: this is regret bias, and the desire to avoid the regret of another missed cancer leads to overcompensation, increasing unnecessary procedures and patient anxiety.*	AI could mitigate by providing probabilistic assessments, reducing emotion-driven bias

XSL•FO
RenderX

Cognitive bias	Explanation	Practical example	AI[a] contribution
Commission	Taking an action without an objective basis for the course of action	*A breast radiologist, while analyzing a clinical mammography of an asymptomatic patient with no personal or family history of breast cancer, identifies a vague asymmetry in the outer quadrant of the left breast, only visible in one projection and basically unchanged in comparison to previous exams, thus likely representing a normal glandular area. Despite the report of this exam being concluded as negative/ BI-RADS 1, the radiologist decided to assign a BI-RADS 3 to the finding, recalling the patient for additional examinations that were all negative.*	AI could mitigate commission bias by acting as a second objective reader, limiting excessive subjective assessments of benign findings

[a]AI: artificial intelligence.

[b]For biases marked as "theoretical/hypothesis-driven," current evidence is extrapolated from the broader literature on cognitive biases, AI-assisted decision-making, and diagnostic radiology. Direct empirical evidence specific to breast cancer imaging workflows is currently limited. Language such as "may," "could," and "theoretically" indicates effects that are conceptually plausible but await clinical validation.

One prominent cognitive bias is the availability bias, where radiologists may overemphasize experiences that are easily recalled to elaborate on the diagnosis, ignoring the base rate or prevalence rate of a particular disease [33,35,38,39]. Conversely, radiologists who have never experienced a specific symptom may exhibit a nonavailability bias, resulting in the oversight of potential diagnoses associated with that symptom [5].

AI could help to limit the availability bias, shifting the focus from anecdotal evidence to statistical patterns by processing comprehensive datasets that human cognition cannot effectively synthesize [32].

Similarly, the confirmation bias is another critical cognitive error where radiologists may selectively gather and interpret clinical data to reaffirm an existing hypothesis while disregarding alternative possibilities [5,35]. Also, in this context, AI may contribute to increasing the occurrence of this cognitive bias by encouraging radiologists to confirm AI-suggested diagnoses without adequately considering alternative possibilities [37]. Conversely, when AI is trained using controlled databases, it provides objective insights that are independent of human preconceptions, thereby reducing the frequency of this bias [32]. This bias is particularly concerning as it can significantly impair diagnostic accuracy.

An opposite example is provided by the anchoring bias that manifests when radiologists tend to fixate on preliminary information despite receiving subsequent data that conflicts with their initial diagnosis [5,33,38,40]. In this case, the use of AI could accentuate the probability of making errors, leading the radiologist to be influenced by the initial results provided by it [37]. This fixation can lead to a failure in adapting their assessment to new evidence.

A further type of bias associated with the adoption of AI in radiology is the automation bias. It consists of preferring automated responses despite the presence of conflicting information, effectively deferring decision-making competence to the automated system [5,12,37]. This phenomenon occurs when radiologists, especially those with less experience, overrely on AI systems, assuming that the absence of findings meant there was no abnormality, which can lead to missed diagnoses [4].

In a related vein, the satisfaction of report bias refers to the tendency of a radiologist to perpetuate radiological error that occurred in a previous assessment [5,39]. A radiologist could tend to accept a prior report or AI finding as sufficient, which prematurely halts the search for additional abnormalities. As a result, a second radiologist may be influenced by the judgment of a first radiologist or by AI tools, perpetuating mistakes. This does not mean that comparison with previous exams [41] or the use of AI systems should be avoided, as it can improve diagnostic accuracy. To mitigate these different types of errors, radiologists should always evaluate images independently before consulting past reports or AI interpretation outcomes.

One prominent cognitive bias is the attribution bias. It occurs when the characteristics of the patients, often shaped by stereotypes, inappropriately influence the radiologist's diagnostic reasoning process, causing them to neglect other peculiar and relevant information [5,35,39]. AI has the potential to reduce this bias by focusing solely on current imaging data, without being influenced by the patient's medical history or previous clinical context, thereby helping radiologists avoid inappropriate assumptions and improve diagnostic accuracy. Another possible bias is the framing bias that highlights the tendency to interpret a diagnosis according to how the clinical scenario is presented to the radiologist, leading them to misjudge the significance of the findings [5,39,42]. A specific symptom or diagnostic imaging finding located within one anatomical-physiological system may potentially divert the radiologist's attention from the involvement of an alternative system [43]. In this case, the dataset on which the AI is trained must be optimal [36]. If the AI is trained on clinical datasets that contain inherent biases or distorted presentations, it could inadvertently reinforce framing bias by reflecting the same distortions in its analyses and recommendations.

XSL•FO
RenderX

Furthermore, the satisfaction of search bias occurs when a radiologist ceases a visual search for additional clinically significant abnormalities upon the initial pathology being identified [5,35,43,44]. This can lead to missed diagnoses of additional issues that may also be present. If the radiologist merely responds to the attending physician's question, other important findings may be overlooked if the radiologist does not perform a comprehensive assessment [43]. AI tools can counteract this phenomenon by prompting comprehensive image reviews, flagging secondary findings, and encouraging comprehensive assessment.

Similarly, some symptoms or entirely visible and clinically significant findings can be neglected because one's attention is fixed on another task or object (ie, inattentional blindness bias) [35,39]. Compelling evidence for this phenomenon was observed in a study conducted in the radiological field, where 24 radiologists were asked to detect lung nodules. In the last CT scan, a gorilla 48 times larger than the average nodule was inserted. About 83% of radiologists failed in their recognition [45,46]. This error occurred not because the lesion was subtle or invisible, but because attention was narrowly directed to the suspected finding, leading to inattentional blindness: the failure to see a visible but unexpected object when attention is engaged elsewhere. This type of bias could be reduced by AI systems that objectively highlight all anomalies detected in the image, drawing attention to findings that radiologists might overlook due to the limitations of cognitive concentration.

The phenomenon of hindsight also plays a crucial role in radiological errors, as radiologists may underestimate the complexity of reaching the initial diagnosis and overestimate the probability of a diagnosis based on prior knowledge of the outcome [5,35,43].

The radiologist's judgment during the review is influenced by hindsight bias, the tendency to see events as more predictable or obvious after they have already occurred. AI, relying on algorithms and statistical models rather than retrospective knowledge, provides consistent and unbiased analysis that is not influenced by previous results, potentially protecting against this bias.

Conversely, regret bias leads to the overreporting of certain diseases due to the negative consequences associated with missed diagnoses [5,43]. Similar to the previous bias, AI can mitigate this emotional and experience-based bias by offering probabilistic assessments based on large datasets, helping physicians strike a balance between caution and evidence-based reasoning.

Another bias to which breast radiologists are commonly exposed is the commission bias, representing the urge to do something that might be unnecessary, such as recalling a patient, ordering additional imaging, or recommending a biopsy, instead of doing nothing [43]. The commission bias might happen in different contexts, but breast imaging is very vulnerable to this bias due to the high psychological, clinical, and medicolegal pressures of this field. Nevertheless, this approach might lead to avoidable expenses and increase the likelihood of false-positive findings, which may prompt unwarranted biopsies or additional imaging, ultimately outweighing any perceived benefit for these patients [47]. AI can mitigate commission bias by acting as an objective second reader, providing quantitative malignancy probability scores to challenge subjective overcalls on benign asymmetries.

Finally, premature closure bias arises when a radiologist prematurely accepts a diagnosis as definitive before any alternative diagnoses are considered [5,35,39]. When trained with adequate datasets [36], AI can assist by suggesting alternative diagnoses based on image characteristics and differential analyses, encouraging radiologists to maintain an open diagnostic approach and avoid hasty conclusions.

In this scenario, the concept of algorithm aversion has also become increasingly relevant. This term refers to the psychological tendency of individuals to distrust and avoid algorithmic decision support, especially after observing even minor errors, despite evidence that algorithms often outperform human judgment. Foundational work by Dietvorst and colleagues [48] demonstrated that when individuals witness predictive algorithms making mistakes, they subsequently prefer human forecasters. Building on this, Dietvorst and Bharti [49] demonstrated that a diminishing sensitivity to forecasting error further reinforces algorithm rejection in uncertain decision-making domains, as people overweight early errors and underweight later accuracy improvements.

Similar dynamics can be observed in breast radiology, where radiologists' interactions with diagnostic AI systems critically shape trust and subsequent use. Early AI misclassifications can disproportionately reduce reliance on algorithmic output, particularly among clinicians with high diagnostic self-efficacy [50]. These patterns of algorithm aversion may hinder the integration of AI tools into routine clinical practice. Consequently, radiologists may continue to favor their own judgments despite well-known human limitations such as fatigue, perceptual bias, and interreader variability. In breast imaging specifically, algorithm aversion may lead to missed opportunities for AI-assisted early cancer detection, reduced returns on investment in AI technologies, and slower adoption of tools capable of improving population-level outcomes.

Preventive Strategies and Future Directions

Preventive strategies aimed at reducing potential physicians' errors represent a critical topic and should be developed based on the most common errors encountered in clinical practice [6].

A fundamental consideration is providing comprehensive education on AI, increasing AI literacy, and enabling individuals to make informed choices [4]. An appropriate education allows health care professionals to be equipped with awareness of its risks and benefits, along with the necessary skills to identify, prevent, and address potential failures arising from its application in radiology [4]. Specifically, targeted training programs designed to reduce certain cognitive errors are essential [51]. For instance, Taussig and colleagues [52] proposed an innovative approach where senior residents present selected interpretative errors to junior residents, fostering peer discussion that enhances knowledge and helps prevent the recurrence of errors.

XSL•FO
RenderX

Continuing education should also foster insight and metacognitive skills by including structured explanations of cognitive biases and clinical examples illustrating their effect on diagnostic reasoning [51]. Encouraging clinicians to critically reflect on their diagnostic processes, rather than relying on immediate problem-solving, can improve diagnostic accuracy. Simulation techniques, such as cognitive exercises and mental rehearsals, further support this learning by exposing trainees to the impacts of biased versus unbiased reasoning [51]. Additionally, training videos and case comparisons reinforce debiasing strategies and facilitate the transfer of these skills to everyday practice.

Another effective strategy to reduce the frequency of cognitive bias in radiological report interpretation is the establishment of a clear communication strategy among health care professionals. Indeed, ineffective communication due to inefficient team interaction or interprofessional tension increases the risk of making medical errors [53]. The European Society of Radiology published in 2013 communication guidelines to provide helpful information on conducting an effective discussion between patients, referrers, colleagues, and students [54]. Furthermore, improving communication between clinicians and radiologists promotes their collaboration, which, in turn, might help in preventing cognitive errors such as attribution, anchoring, or confirmation bias caused by the lack of knowledge about the patient's medical history and proper clinical context, with subsequent incorrect interpretation of the images. Effective communication and discussion with colleagues also allow for timely feedback regarding the clinical decision and enable an understanding of the error and implementation of strategies to correct it [51].

Beyond education and communication, bias mitigation should also be addressed at a structural level through workflow engineering and explainable artificial intelligence (XAI).

Integrating AI into clinical engineering workflow in medical imaging entails structured interpretation sequences through strategic design of reading protocols to optimize diagnostic accuracy while counteracting cognitive biases [55,56]. Sequential workflows require radiologists to interpret images independently before consulting AI-generated marks in a second-reader paradigm, enhancing sensitivity but potentially reducing specificity due to increased false positives and extended reading times [57]. It preserves independent judgment to prevent bias, such as premature closure.

Concurrent integration, by contrast, offers real-time validation against heuristics like anchoring on salient features. Concurrent reading integrates AI annotations during initial interpretation, improving both sensitivity and specificity while reducing reading time [57].

Furthermore, XAI approaches can foster calibrated trust by enabling clinicians to interrogate the rationale and uncertainty of AI outputs rather than passively following algorithmic recommendations. XAI encompasses methods that make deep learning models intelligible to human users, clarifying their internal logic, decision pathways, and case-specific predictions, as well as their capabilities and limitations, instead of treating them as opaque black boxes [58]. In medical imaging, XAI does not remove bias but supports its detection, interpretation, and mitigation by revealing model decision rules and the data patterns on which they rely. By providing interpretable feature attributions, XAI helps counter cognitive biases such as the availability heuristic and anchoring, allowing clinicians to cross-check AI suggestions against the actual imaging findings and to avoid overreliance on salient anomalies [32]. These techniques jointly target algorithmic biases originating from datasets, training procedures, and generalization failures, as well as clinicians' own cognitive biases, thereby promoting a more critical and informed use of algorithmic outputs and enhancing diagnostic accuracy while preserving transparency, including for underrepresented patient groups in training data [32,58].

Integrating AI into radiological practice enhances diagnostic workflows and operational efficiency by reducing workload and optimizing time, critical factors in preventing burnout and fatigue-related errors [56]. The study conducted by Bruno and collaborators explored possible approaches to minimize errors in the field of radiology, including a reduction of working hours, a minimization of interruptions and distractions, and an alleviation of the pressure to maintain a rapid workflow [59]. However, such interventions face practical challenges in some hospital settings and have shown minimal impact. Systematic studies are needed to evaluate how AI can be effectively incorporated into image interpretation processes to support accurate and efficient everyday clinical practice.

Conclusion

The integration of AI in breast imaging represents a promising advancement in radiology, with the potential to improve diagnostic accuracy, optimize workflow, and reduce perceptual, attentional, and interpretive errors. However, as this perspective highlights, AI is not a flawless solution and introduces new challenges, including cognitive biases that may influence radiologists' decision-making. Understanding these biases is crucial to implementing strategies to mitigate these errors, ensuring that AI serves as an effective aid rather than a source of further diagnostic problems.

While AI offers substantial advantages, a cautious approach is required to mitigate its potential risks and limitations. To fully exploit the benefits of AI while minimizing its limitations, further research should focus on optimizing the AI integration into clinical workflows, assessing its impact on diagnostic reasoning, and developing structured guidelines to mitigate automation biases and other cognitive distortions. A successful AI implementation in breast imaging will ultimately require a synergistic approach that blends human expertise with technological innovation. A balanced approach harnessing AI as a complementary tool while maintaining radiologists' critical thinking and expertise will improve breast cancer diagnosis.

Abstract

Clinical decision-making is a critical process where physicians balance risks and benefits. Clinical Decision Support Systems (CDSSs) are increasingly used to help in this process. The regulatory landscape for CDSSs is evolving significantly, with the new European Medical Device Regulation (MDR) now requiring, CE certification for certain CDSSs. This shift poses challenges for health care providers to develop CDSSs in an effective and useful manner while adhering to regulations. This viewpoint comments on diverse challenges and provides solutions to develop a reliable, well integrated and practical tool for clinical use. Using three tools (the Early Onset Sepsis Calculator, Feverkidstool, and Neonatal Procalcitonin Intervention Study algorithm) as examples, we explore the development of CDSSs across four core characteristics: scientific basis, technical aspects, safety, and sustainability. These characteristics recur across the main development processes; scientific development, regulatory assessment, and implementation in routine practice. Successful integration of CDSSs into clinical practice requires a comprehensive understanding of the interconnections between these processes. For example, decisions on algorithm validation and platform selection in the scientific process influence choices for technical safety during the regulatory process. Developers should consider both regulation requirements and clinical needs, to create CDSSs that are not only compliant but also adaptable to the rapidly changing healthcare landscape. We outline a developer's checklist, for practical guidance, but also appeal for structural support, including national protocols and dedicated hospital roles, to help developers implement CDSSs successfully.

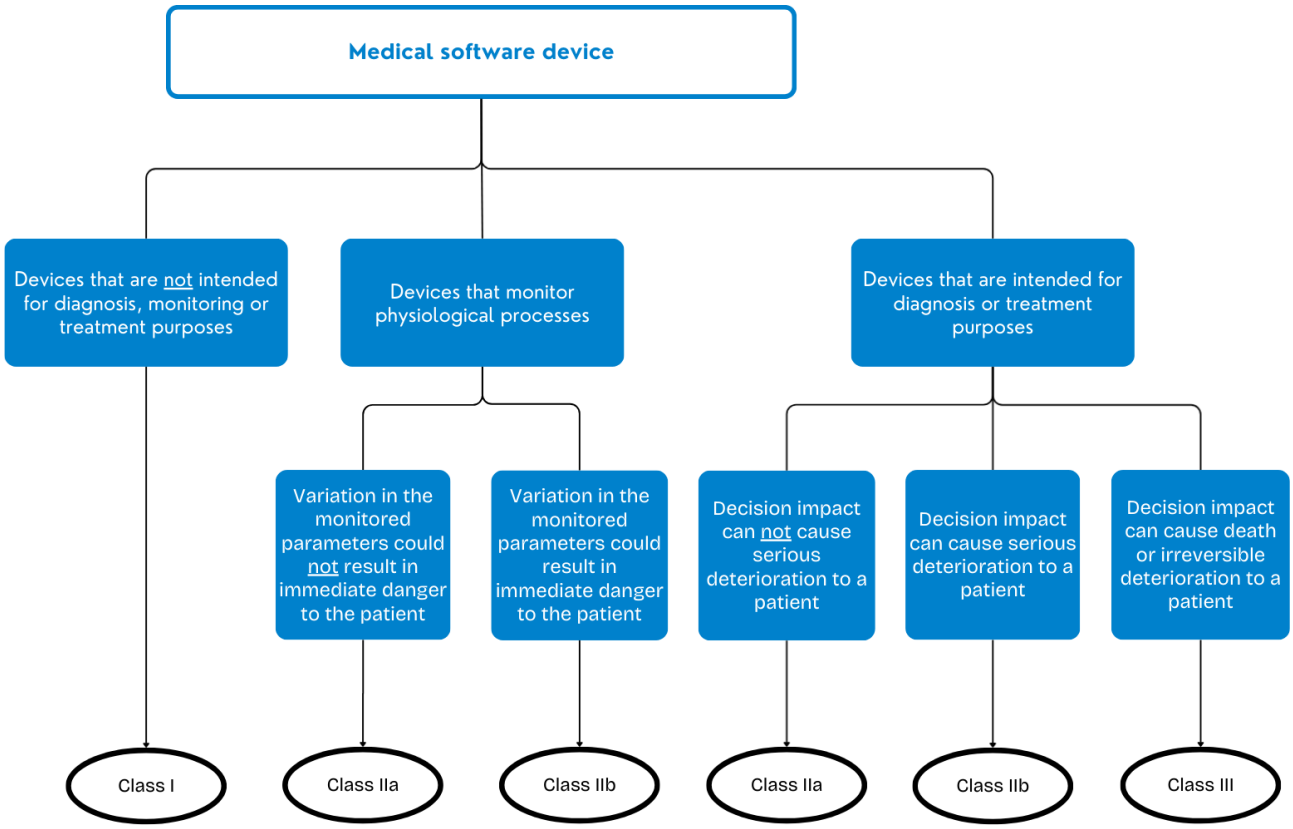
clinical decision support systems; regulatory requirements; pediatrics; infection diseases; diagnostic reasoning

Juggling Risks and Benefits Using Tools—A Doctor's Evolving Job

Clinical decision-making involves a delicate balancing act between risks and benefits. It requires the synthesis of a physician's clinical intuition with objective variables. For instance, deciding whether to start or stop antibiotic treatment in children at risk for severe bacterial infections illustrates this process. Distinguishing between early-stage bacterial illness and viral or physiological causes in neonates and febrile children is particularly challenging, and wrong decisions can have fatal consequences. To aid in making accurate decisions, clinicians may use clinical decision support systems (CDSSs). As these tools become more integral to clinical practice, the regulatory framework governing them is evolving, with significant implications for their development and implementation.

Until 2017, European regulations allowed CDSSs to be used without Conformité Européenne (CE) certification under the Medical Device Directive. However, the introduction of the Medical Device Regulation (MDR) (Textbox 1) expanded the definition of medical devices to include CDSSs [1]. The MDR's implementation has made CE certification more stringent, linking it directly to a CDSS's risk classification (Figure 1) [2]. For instance, any CDSS classified from Class II onwards now requires approval from a notified body. Proper classification is the responsibility of the developer. And using only CE-certified CDSSs is the responsibility of the user. Currently, a transition period allows for the legal use of both CE-certified and noncertified CDSSs until 2028. After this period, hospitals and

XSL•FO
RenderX



healthcare professionals will bear the responsibility for verifying the certification status of CDSSs used in practice. To aid this verification process, certified devices will be listed in the European Database on Medical Devices (EUDAMED), creating a centralized repository for medical devices used within the European Union.

Textbox 1. Highlights from the Medical Device Regulation (MDR) regulatory process

Key changes introduced by the MDR for Clinical Decision Support Systems (CDSSs):

- Risk classification: To ensure safe usage, a 4-scale classification system was added to address appropriate safety measures according to their risk. Additionally, Rule 11 of the MDR regulation states that "software intended tools to provide information which is used to take decisions with diagnosis or therapeutic purposes is classified as class IIa". As a result, CDSSs are at least classified as class IIa.
- Notified bodies: With more devices falling into higher risk classifications, including CDSSs, more devices need to be revised by notified bodies. Also, stricter requirements account for the approval of the impartial notified bodies.
- Post marketing surveillance: It is mandatory for manufacturers to actively monitor and report on the performance and safety of a device (article 10). This obligation also requires data collection post-implementation ensuring ongoing effectiveness and safety of CDSSs.
- Transparency: The MDR mandates the registration of CDSSs in the European Database on Medical Devices (EUDAMED). This is mandatory to improve insight in which tools are CE-certified by different stakeholders (regulatory authorities, manufacturers, and practitioners).

Figure 1. Medical software device classification.

Successful adoption of CDSSs in routine practice depends on overcoming regulatory and (scientific) developmental hurdles [3]. This viewpoint addresses these obstacles and identifies key improvements needed in the development of CDSSs. While the focus is on the European regulatory environment as regulatory pathways differ across regions, for example, in the United States, where the Food and Drug Administration regulates similar tools under a different framework, some principals may be relevant internationally. Our aim is to support clinical researchers and developers who are at the early stages of CDSS development by providing early insight into the scientific and regulatory considerations that will shape the trajectory of their tool development. This viewpoint synthesizes existing requirements and real-world experiences to clarify key obstacles and areas where alignment is needed. By understanding these challenges early, developers may better anticipate what is required to progress toward successful evaluation and clinical implementation.

Learning From the Past: Exploring CDSSs With Diverse Characteristics

In this viewpoint we explore three CDSSs designed to assist in the diagnosis and management of pediatric bacterial infections: the Early Onset Sepsis (EOS) Calculator [4], the Feverkidstool (FKT) [5], and the Neonatal Procalcitonin Intervention Study (NeoPInS) algorithm [6]. We described variability in the development and functionality of the CDSSs using previously

XSL•FO
RenderX

defined characteristics, including the scientific foundation, the technical design, safety considerations, and sustainability (Table 1) [7].

XSL•FO
RenderX

Table . Key characteristics of three pediatric clinical decision support systems.

Characteristics of CDSS	Feverkidstool	EOS[a] calculator	NeoPInS[b]	Regulated by the MDR[c] [1]
Usage	Helps pediatric ED[d] physicians assess the risk of serious bacterial infection and bacterial pneumonia in febrile children (>1 mo and <18 y) presenting to the emergency department	Helps doctors and nurses estimate the risk of early-onset neonatal sepsis to guide antibiotic use and clinical management in newborns born at ≥34 weeks	Helps doctors guide the management of suspected early onset neonatal sepsis by supporting decisions on safely discontinuing g antibiotics in neonates born at ≥34 weeks of gestational age	
Scientific basis				
Scientific evidence (highest support)	Stepped-wedge cluster-randomized controlled trial	Meta-analysis and parallel cluster randomized trial	Individually randomized controlled trial	No
Current evidence/validation	(international) external validation	(international) external validation	(international) external validation	No
Reproducibility	In the application a link to the algorithm is provided	In the application a link to the algorithm is provided	No direct link to the algorithm is provided	No
Technical aspect				
CDSS[e] requirement for algorithm	Tool is required for algorithm	Tool is required for algorithm	A flowchart with reference values is sufficient	No
Platform	Web-based application; accessible through smartphone, tablet, and computer, and integration in the EHR[f]	Webbased application accessible through smart-phone, tablet, and computer, open-source Shiny application, and integration in the EHR	A smart-phone application Print out the flowchart and use it on paper	Yes
Safety				
Accuracy and reliability	Technical assessment	Technical assessment	Superior and noninferior intervention study	Yes
CE-certification	In 2024 under the Medical Device Regulation as a class IIa product	The application in 2021 under the MDD as a class Ia product. The original web-application is not CE-certified[g] by itself but covered by the EHR certification	In 2021 under the Medical Device Directive as a class Ia product	Yes
CDSS's final outcome	Risk score with advice	Risk score and prescriptive guidance	Prescriptive guidance	No
Privacy	Data is stored anonymously according to the in ISO13485 and NEN7510-1 mentioned manners	Usage is anonymous, and data is not stored (apart from general storage by using a webpage). If embedded in the EHR, privacy is guaranteed by hospital security systems	Data within the software is stored by the application supplier according to the applicable laws and regulations	Yes
Sustainability

[i]RCT: randomized controlled trial.

Scientific Basis

Across the three CDSSs we examined, the scientific basis emerged as a central yet variably addressed component. The tools differed in the type and strength of evidence underpinning their recommendations. The EOS Calculator mainly draws from meta-analyses of observational studies [8] with a later parallel cluster-randomized trial [9], while NeoPInS and the FKT are based on an individually randomized and stepped-wedge cluster-randomized controlled trials, respectively [6,10].

All three tools included in our analysis underwent international external validation; however, validation strategies can vary considerably, and some CDSSs rely solely on internal validation [3]. Despite the centrality of the scientific foundation, the MDR does not specify requirements for the level of evidence, leaving developers to navigate this crucial aspect independently. Both clinicians and developers should be aware that the MDR procedure does not confirm a tool's scientific validity.

Transparency also varied across tools. All three publicly display their algorithms in their initial publications [4-6], and both the EOS Calculator and FKT additionally provide algorithm access via their websites, with the EOS Calculator even providing the full algorithm directly on their website. As reproducibility of a CDSS is closely linked to algorithm transparency, this variability may have implications for independent evaluation nevertheless; transparency is not regulated by the MDR.

Finally, the scope plays a significant role in the MDR classification process, as the intended use directly affects the tool's risk classification (Figure 1). While CDSSs often focus on diagnostic support, as the EOS Calculator, FKT and NeoPINS, their scope can extend beyond diagnosis as they may offer insights into prognosis, treatment, or risk assessment.

Overall, the scientific basis, while not comprehensively covered by MDR regulations, remains critical in CDSS development. Particularly, external validity remains a key consideration, requiring careful attention during development to ensure broad adoption [11]. Moreover, the strength of the scientific foundation and the chosen validation approach influence the market scan and validation processes in the regulatory process.

Technical Aspects

In our three example tools, we observed substantial variation in how the tools were technically designed and implemented. Platforms ranged from protocol- or paper-based formats to web-based applications, mobile apps, and full integration into electronic health record (EHR) systems. The EOS Calculator and FKT both rely on more complex algorithms, requiring digital platforms, whereas NeoPInS could also be delivered in a protocol or on-paper format. Ultimately, all three tools were developed into applications to support broader clinical use. These differences illustrate how algorithm complexity and intended use shape the technical form a CDSS can realistically take.

Protocol or on-paper tools, such as NeoPInS can be embedded within clinical protocols, offering continuous access at low cost. However, they face challenges in scalability and ease of use, as manual calculations are often required. The responsibility for updates and modifications lies with individual hospitals or local departments. Importantly, on-paper tools are not directly subject to the MDR certification requirements as their use does not necessitate an additional CE-mark.

Web-based applications, such as the EOS Calculator and FKT benefit from global accessibility and ease of integration in EHRs with hyperlinks. However, reliance on web-based platforms introduces vulnerabilities like downtime and security concerns. The MDR places the certification responsibility on developers, necessitating a representative for CDSSs used within the EU but developed elsewhere [1]. The complexity increases when web-based tools developed outside the EU, such as the EOS Calculator web-based version, are accessed from inside the EU.

Mobile apps like the NeoPInS (deprecated) and EOS Calculator app (currently for research purpose in the Netherlands), offer tailored user experience on devices like smartphones or tablets. Although apps provide tailored interactions, they are costly to develop and maintain, requiring agreements on intellectual property and updates.

EHR system integration, as seen with the EOS Calculator and FKT, offers user-friendliness by aligning with existing healthcare infrastructure. While cost-effective, integration across diverse EHR systems can be complex due to the lack of a universal standard. Maintenance typically falls under the purview of EHR providers, but algorithm updates may require prior agreements as they are not automatically managed by the provider.

Taken together, our comparison shows that technical design decisions, shaped by algorithm complexity, workflow integration needs, and resource constraints, directly influence reproducibility, long-term sustainability, and regulatory obligations. Because these factors determine whether a CDSS can be reliably adopted, maintained, and scaled, they must be considered early in the development process rather than treated as secondary concerns.

Safety

Our comparison shows that safety considerations are shaped not only by the underlying data flows but also by how directive

XSL•FO
RenderX

a CDSS‘s recommendation is. Although both the FKT and EOS Calculator generate risk scores, the EOS Calculator offers more prescriptive guidance compared to the FKT. The NeoPInS, without a risk score, also provides prescriptive recommendations. These functional differences influence potential clinical risk. However, although the MDR considers intended scope for classification, it does not account for recommendation type.

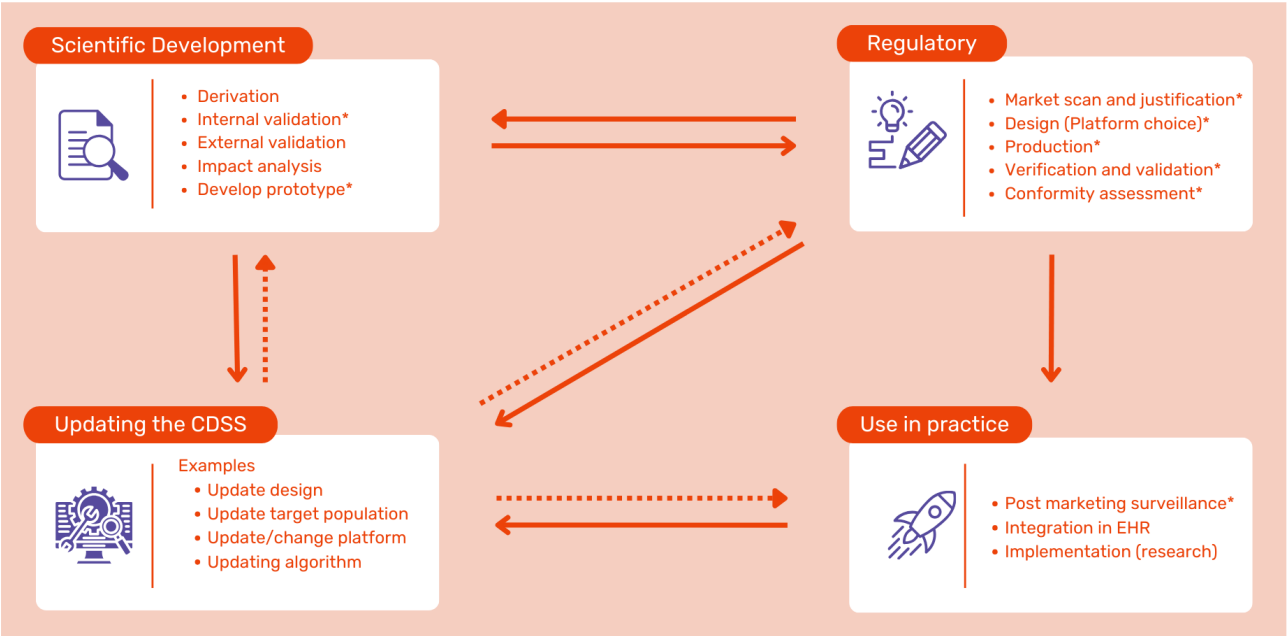
Compliance with privacy regulations is mandatory, as CDSSs often handle sensitive patient data. Adherence to the MDR ensures comprehensive coverage of data privacy requirements. Privacy responsibilities also differ by platform: for the EOS Calculator and FKT embedded within an EHR, hospital security systems guarantee privacy compliance, whereas for the web applications of the three tools, the developer ensures it.

Beyond privacy, safety also depends on accuracy and reliability; this involves the technical correctness of a tool’s output and its scientific validity. A reliable CDSS consistently produces accurate results, as demonstrated by the validation in our examples. Risk assessment and mitigation strategies address potential issues such as misdiagnosis or cybersecurity threats. Developers can implement security measures like dual authentication to safeguard CDSSs against cyber threats. However, user account requirements and time-consuming login processes, as seen with the NeoPInS and FKT applications, may hinder adoption and have even led to discontinuation of the NeoPInS app.

Overall, safety is paramount for CDSSs, ensuring that these tools benefit patients without causing harm. Safety is not a single requirement but an interplay of privacy protection, accuracy, reliability, and risk mitigation, all of which require continuous monitoring throughout a CDSS’s lifecycle.

Sustainability

The sustainability of a CDSS relies on its integration into daily practice, maintenance costs, and available funding. Funding sources vary, ranging from private investors to governmental organizations and research institutions. The funding party’s priorities can influence platform choice, impacting long-term sustainability. In CDSS development, project-based funding is common, posing challenges for continued financial support once projects conclude.



Integration into the EHR, as seen for both the FKT and EOS calculator, can enhance sustainability by facilitating routine use and reducing the need for parallel systems. At the same time, embedding a CDSS within an EHR may introduce challenges related to ownership and governance, as responsibility for the tool, its maintenance, and updates can become less transparent once it is no longer managed as a standalone application. These issues are particularly relevant in the context of MDR requirements, for example post-market surveillance, which mandates ongoing monitoring and data collection after implementation. For EHR-integrated CDSSs, it may be unclear whether such responsibilities lie with the original developer, the EHR vendor, or the health care organization, potentially complicating compliance and long-term accountability.

Leveraging the Process of Developing Scientifically Valid, Regulatory Proven, and Sustainable CDSSs for Clinical Practice

From the above, we argue that the developmental processes involved integrating CDSSs into clinical practice should not be portrayed as three consecutive phases but are dynamic and interconnected in practice (Figure 2). Also, these processes are crucial in determining how effectively a CDSS can be integrated into clinical practice, ensuring that it is both reliable and useful for healthcare professionals. This requires developers to navigate them with a strategic approach. Understanding the interplay between these processes is crucial for creating CDSSs that are scientifically sound, regulatory-compliant, practically effective, and ultimately sustainable. While the MDR addresses certain aspects of these processes (eg, internal validity, market scan and justification and post marketing surveillance) it does not comprehensively regulate every characteristic (Table 1), leaving gaps that require careful consideration by developers and clinicians. To translate the lessons learned from the three CDSSs into actionable guidance, we therefore synthesized our observations into a developer’s checklist (Textbox 2), which highlights key considerations across scientific development, technical design, safety, and sustainability.

XSL•FO
RenderX

Figure 2. Processes in the clinical decision support system development. CDSS: clinical decision support system; EHR: electronic health record. *Aspects part of the Medical Device Regulation are marked with an asterisk.

Textbox 2. Developer's checklist for a Clinical Decision Support System (CDSS).

1. Select the technical platform early and ensure it aligns with all integration and implementation requirements.
2. Engage and communicate with end-users early and throughout the development and design of the CDSS to ensure clinical workflow fits.
3. Ensure the tool's guidance matches user expectations (e.g. if it provides advice rather than full decision-making, clarify this to avoid overreliance).
4. Plan for both internal validation and external real-world testing.
5. Integrate privacy and security requirements from the earliest stage to avoid delays later.
6. Realistically estimate Conformité Européenne certification workload, expertise, and timelines.
7. Define clear ownership and a sustainable long-term maintenance plan.
8. Prepare fallback strategies to manage tool downtime safely.
9. Keep access simple (e.g. avoid unnecessary login steps).
10. Ensure full integration with existing hospital and electronic health record systems.

A critical, yet often overlooked, aspect of CDSS development is the early involvement of end-users in the scientific development process, as this can improve both tool design, effectiveness, and facilitate smoother transitions to later stages. Early strategic choices, such as selecting an appropriate technical platform, also have important downstream consequences for validity assessment and future usability. For example, although the EOS Calculator was initially developed as a web-based tool to maximize accessibility, this choice later complicated retrospective validation due to the need for manual data handling.

Validation should therefore be planned as a comprehensive, iterative process, combining internal testing with external, real-world evaluation, while accounting for the workload, expertise, and timelines required for CE certification. Beyond validation, long-term success depends on clear ownership, sustainable maintenance strategies, and predefined fallback procedures to ensure patient safety during tool downtime. Practical design considerations, such as minimizing burdensome login procedures and enabling seamless integration with existing hospital and EHR systems, further support adoption and routine use. Addressing these elements across scientific development, regulatory assessment, and clinical implementation processes enhances not only the reliability of a CDSS but also its lasting impact in clinical practice. Although all three CDSSs underwent these three key processes, their approaches differed (Table 1). As illustrated by the publication dates of manuscripts on development, the processes were timed sequentially from which important lessons were learned regarding the need for earlier and more continuous alignment.

A limitation of this viewpoint is that it focuses primarily on European MDR regulations nevertheless, similar challenges have been observed in other regions of the world. Also, currently novel AI techniques, performing the functions of CDSSs, such as dynamic risk prediction and providing targeted clinical advice, are often not yet recognized as CDSSs by clinicians. As a result, these tools are used without formal consideration of

XSL•FO
RenderX

their regulatory status, posing challenges to the current MDR regulation.

This viewpoint highlights that the complexity of CDSS development currently places a disproportionate burden on individual developers. While foresight and adaptability remain essential, developers cannot be expected to navigate scientific validation, regulatory compliance, and practical implementation alone. To support clinical scientists, our developer's checklist (Textbox 2) provides concrete guidance for successful CDSS development. Beyond these practical recommendations, structural changes are needed at the system level, for example, the creation of national protocols, standardized regulatory guidance, and dedicated support structures within hospitals. The MDR provides an important safety framework, but realizing the full potential of CDSSs requires both practical guidance for developers and systemic changes to ensure that these tools can be safely, efficiently, and effectively implemented to support clinicians and improve patient outcomes.

Acknowledgments

The manuscript text was refined with the assistance of the generative AI tool ChatGPT, version GPT-5 (OpenAI). All revisions were critically reviewed, edited, and approved by the authors.

Funding

The development of the Feverkidstool was supported by funding from the Dutch National Health Council (ZonMW), grant 170992503. Further validation of the tool was also funded by the Dutch National Health Council (ZonMW), grant 836041001. The implementation of the tool and SV were also supported by the Dutch National Health Council (ZonMW), grant 10390162210012. The Neonatal Procalcitonin Intervention Study trial received financial support from the Trasher Foundation, the NutsOhra Foundation, grant 1101-059, and the Sophia Foundation for Scientific Research, grant 681. Additionally, Thermo Fisher provided procalcitonin kits and an unrestricted grant to facilitate the organization of four investigator meetings in 2008, 2009, 2013, and 2015. SJ is supported by the Sophia Foundation for Scientific Research and Tergooi.

Abstract

Background: Telepathology is widely recognized for improving diagnostic access in remote areas and is strongly promoted in China to address the shortage of pathologists. However, a comprehensive national assessment of its implementation and multistakeholder perspectives remains lacking.

Objective: This study aims to conduct a comprehensive analysis of the infrastructure, practical application, and user experience of telepathology in China from 2018 to 2023 and to identify the key factors affecting its adoption and satisfaction levels.

Methods: A repeated cross-sectional survey was administered to hospitals across China (2018-2023), alongside a parallel survey of telepathology users (2023). Data were analyzed from hospitals (sample sizes ranging from 464 to 188 across years), pathologists (n=262), and patients (n=141). Regression analysis was applied to investigate factors associated with professional satisfaction and willingness to adopt the technology.

Results: The proportion of hospitals with telepathology software grew at an annual average rate of 7.60%, increasing from 29.5% (137/464) in 2018 to 42.6% (80/188) in 2023. The median number of telepathology cases per hospital increased from 51 to 200, with the fastest growth observed in the eastern region. Among pathologists, 61.1% (160/262) used telepathology weekly, 61.5% (161/262) spent 11 to 20 or 21 to 30 minutes. Pathologists reported a 95.8% (251/262) satisfaction rate, and 95% (249/262) were willing to continue participation. Convenience of system operation and service processes were associated with enhanced satisfaction and sustained engagement willingness (P<.05). Among patients, 92.2% (130/141) received diagnostic results within 24 hours, with 100% (141/141) satisfaction, and 99.3% (140/141) were willing to recommend telepathology.

Conclusions: Telepathology in China grew significantly from 2018 to 2023, with high satisfaction among both pathologists and patients. For sustained development, a multilevel approach is essential: improving system usability, implementing supportive policies (eg, funding and insurance coverage), and conducting targeted promotion of its proven benefits. This integrated strategy is key to making telepathology a sustainable solution for equitable diagnostic access nationwide.

(JMIR Med Inform 2026;14:e83514) doi:10.2196/83514

telepathology; digital slide scanners; software; service; usage; satisfaction; perceptions

Introduction

Pathological diagnosis is the gold standard for disease diagnosis, particularly for cancer. However, China's primary medical institutions face a significant shortage of pathologists, especially experienced ones. According to the 2019 China Pathology Quality Report [1], there are only 0.55 pathologists per 100 hospital beds, and 46.3% of secondary hospitals have just 1 pathologist, which is far below the demand for timely and high-quality pathology services. Data from the Pathology Quality Control Center of China [2] reveal that 82% of senior pathologists are concentrated in tertiary hospitals, leaving many primary hospitals without senior-title pathologists. In central and western regions, such as Tibet, Xinjiang, Qinghai, and Guizhou, more than 20% of institutions have no more than 1 pathologist, highlighting a significant imbalance in pathology resource distribution across China.

Telepathology, first proposed in 1987 [3], addresses resource shortages by enabling the transmission of static images, dynamic videos, and whole-slide images (WSIs). As defined in the Basic Functions Specification of Telemedicine Information System (WS/T529-2016), telepathology involves the submission of

XSL•FO
RenderX

diagnostic requests and patient data by an inviting party to an invited expert, who then provides diagnostic opinions and reports. Central to this practice is WSI technology, which converts pathological slides into high-resolution, zoomable digital images and supports the diagnosis of all pathology-dependent diseases, including tumor classification and grading, as well as the identification of specific pathogens or special inflammatory lesions. Its diagnostic reliability is supported by multiple guidelines and studies. The College of American Pathologists (CAP) released relevant validation guidelines in 2013 and 2021 [4,5], and the Royal College of Pathologists issued "Best Practice Recommendations for Implementing Digital Pathology" [6]. Studies by Montgomery et al [7] and Shinohara et al [8] confirmed the high diagnostic accuracy and effectiveness of WSIs in remote diagnosis. Furthermore, Girolami et al's [9] meta-analysis validated the diagnostic concordance between WSIs and light microscopy, reinforcing its role in delivering high-quality diagnostic services to resource-limited regions. At the regulatory and application levels, pathological diagnosis based on WSIs has been approved by the Food and Drug Administrations of the United States, the European Union, and Japan [10-12]. Since the US Food and Drug Administration first authorized a WSI system for primary diagnosis in 2017, multiple integrated digital pathology platforms, combining scanning, storage, viewing, and analysis functions, have received 510(k) clearance [13]. As of December 31, 2025, China's National Medical Products Administration (NMPA) had also approved 71 digital pathology–related medical devices [14]. In practice, WSI-based telepathology has been widely adopted in numerous countries and regions, including Europe [15], Nigeria [16], India [17], Tanzania [18], and Canada [19].

In China, developing a WSI-based telepathology system is a core strategy to address the deficiencies in grassroots pathology services [20]. Preliminary studies have demonstrated the effectiveness of the national cloud-based telepathology platform [21] and its potential to optimize resource allocation [22]. However, the existing literature lacks a comprehensive, long-term, and systematic evaluation of the overall development of telepathology in China. Key questions remain unanswered: What are the national trends and regional disparities in its adoption? As primary users, what are the adoption behaviors, perceptions, and influencing factors among pathologists? Moreover, what are patients' experiences and satisfaction levels with telepathology services? The absence of such critical information limits a thorough understanding of current implementation barriers and hinders targeted interventions.

To address these gaps, this study utilizes nationwide survey data from 2018 to 2023 with the following objectives: (1) to delineate the developmental trends and spatial distribution characteristics of telepathology in China over the past 6 years; (2) to analyze, from the perspective of pathologists, their usage behaviors, attitudes, and key influencing factors; and (3) to conduct the first systematic assessment of patient satisfaction with telepathology services. By integrating multidimensional evidence, including macro-level trends, insights from pathologists, and patient experiences, this study aims to provide an empirical foundation and decision-making support for optimizing China's telepathology infrastructure and promoting the equitable distribution of high-quality pathology resources.

Methods

Study Setting

To understand the current status of and identify obstacles to telemedicine services (telemedicine service items include teleconsultation, telepathology, teleradiology, telemonitoring, tele-outpatient services, etc), the Telemedicine Informationization Professional Committee of China (TIPC) and the National Telemedicine Center of China (NTCC) have conducted web-based surveys on telemedicine since 2018.

Survey on the Development of Telemedicine in Hospitals

This survey targeted hospitals approved by Chinese health administrative departments. The questionnaire was developed by experts with more than 5 years of telemedicine experience and refined annually based on prior findings. Following the initial design, 10 to 18 hospitals were selected for pilot testing, and feedback was incorporated to finalize the questionnaire.

Survey on the Usage and Perceptions of Telemedicine

A survey was conducted among doctors and patients participating in telemedicine services. The questionnaires were designed through needs analysis, a review of telemedicine practices, and relevant literature. After drafting, a pilot test was administered at the Henan Provincial Telemedicine Center and selected subcenters. The instruments were further optimized based on pilot feedback to form the final versions.

Implementation of the Survey

The electronic open survey was an online questionnaire on NTCC's website [23]. The survey announcement was formally issued by TIPC via an official red-headed document. Each annual theme had its own webpage, with up to 42 mandatory questions (the exact number depended on the respondent's answers) across 18 to 25 pages in Chinese. Completion required approximately 8 to 12 minutes based on pilot testing. The surveys were open from July to September 2018, October to November 2019, September to October 2020, and September to October 2023. To ensure data quality, duplicate submission prevention was implemented through IP address verification, response-time logic control, and cross-validation with official hospital records. Response metrics for each questionnaire type were as follows:

- The hospital questionnaire recorded 896 views with a 63.3% (567/896) participation rate and an 81.8% (464/567) completion rate in 2018
- The corresponding figures for 2019, 2020, and 2023 were 482 views (60.8% participation, 82.6% completion), 401 views (61.1% participation, 83.3% completion), and 364 views (63.2% participation, 81.7% completion).
- The doctor questionnaire received 3269 views, achieving a 53.1% (1736/3269) participation rate and a 77.9% (1353/1736) completion rate, including 262 pathologists among the completers.

XSL•FO
RenderX

- The patient questionnaire garnered 3528 views, with a 42.6% (1502/3528) participation rate and a 59.3% (891/1502) completion rate, of whom 141 patients had used telepathology services.

Data Cleaning and Valid Questionnaire

After the collection deadline, data were exported to Excel for cleaning. Hospital questionnaires from identical or conflicting IP addresses that could not be verified against official hospital records (eg, outpatient visits, bed counts) were excluded. Additionally, hospital questionnaires completed in less than 2 minutes and multiple doctor or patient questionnaires submitted from the same IP address within a 3-minute interval were omitted. Valid hospital questionnaires totaled 464 in 2018, 242 in 2019, 204 in 2020, and 188 in 2023.

Study Design

To explore the current status of telepathology development and application in Chinese hospitals, this study used data from TIPC and NTCC. Surveys were conducted in 2018, 2019, 2020, and 2023 across eastern, central, and western China. Due to the COVID-19 pandemic, restrictions on personnel movement during the outbreak disrupted normal work routines and medical services, resulting in the cancellation of surveys that were planned for 2021 and 2022. The eastern, central, and western regions are classified according to standards set by the National Bureau of Statistics of China (Multimedia Appendix 1). The survey coverage area is presented in Multimedia Appendix 2. Pearson chi-square test indicated no significant difference in provincial distribution among these regions across the 4 years (P=.90). Telepathology-related data were selected to assess construction progress and development trends. Based on 2023 survey responses from pathologists and patients who participated in telepathology services, application effectiveness was further analyzed.

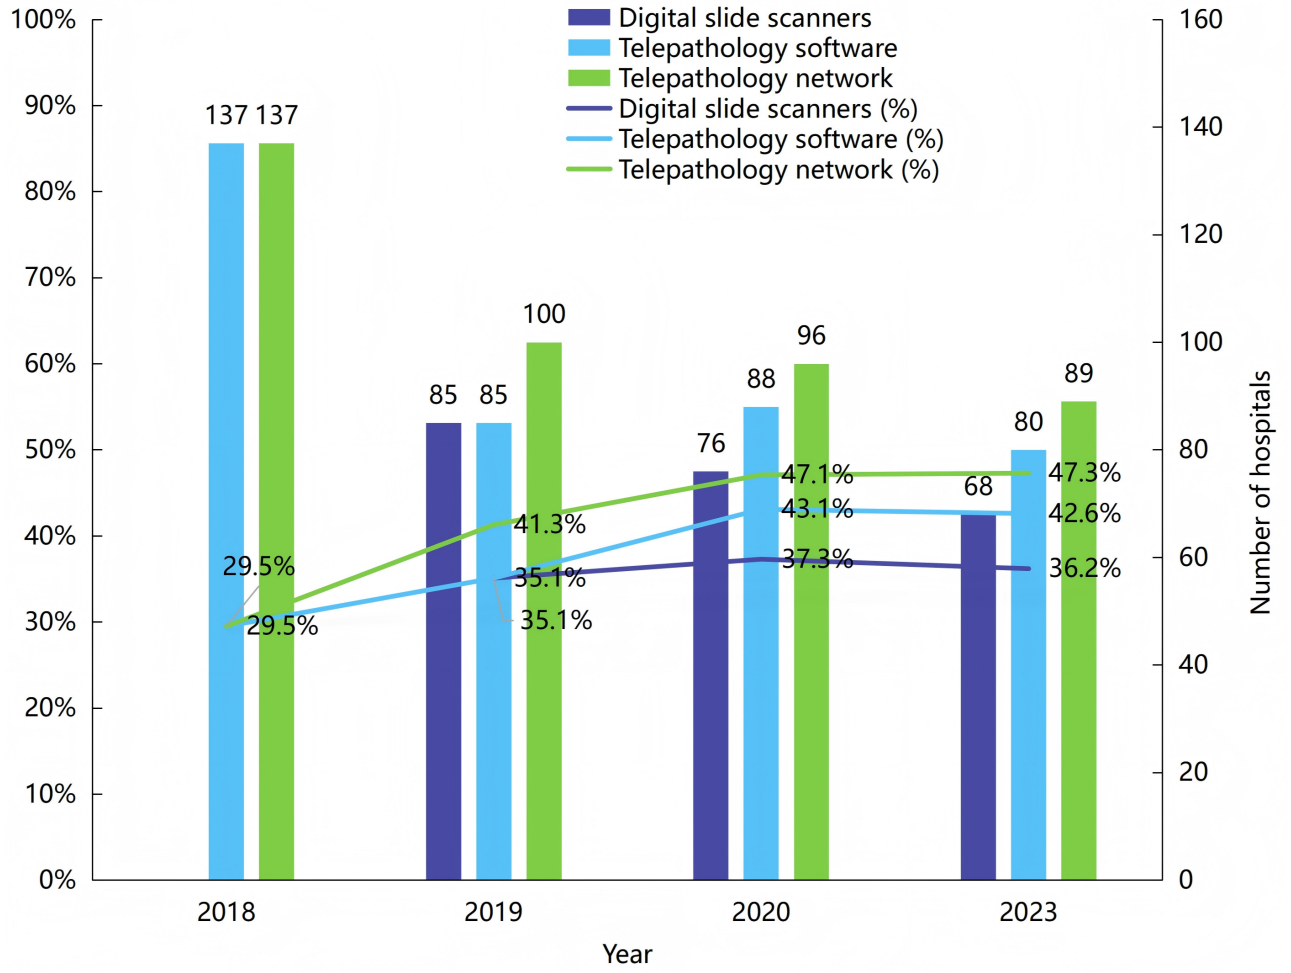
This study was reported in accordance with the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) guidelines (Checklist 1) [24]. The hospital questionnaire included 11 repeated survey questions on telepathology, comprising 9 single-choice questions and 2 fill-in questions. Among them, 6 questions related to telepathology infrastructure and service volume, and 5 questions related to telepathology operations and billing. The questionnaire was completed by telemedicine organizers at each hospital. The doctor questionnaire consisted of 24 questions, including basic information (7 questions), telepathology service usage and experience (9 questions), evaluation and attitudes (6 questions), and open-ended questions regarding problems and expectations (2 questions). The patient questionnaire consisted of 19 questions, including basic information (7 questions), usage (7 questions), and evaluation and attitudes (5 questions) (Multimedia Appendix 3).

Data Analysis

Data cleaning was performed to avoid logical problems and ensure data quality. Descriptive statistics were used to analyze the data. Median values and IQR are reported for quantitative data, and percentages are reported for qualitative data. Chi-square tests and Fisher exact probability tests were used to assess differences. Variables selected through univariate analysis were further analyzed using multivariate ordinal logistic regression to identify factors influencing satisfaction and usage intention [25]. All statistical analyses were conducted using SPSS (version 20.0; IBM Corp). All tests were 2-tailed, and P<.05 was considered statistically significant. Chinese maps were generated using ArcMap (version 10.8.1; Esri Corp) and R language (version 4.4.1; R Foundation for Statistical Computing).

Ethical Considerations

This study was approved by the institutional review board at the First Affiliated Hospital of Zhengzhou University (protocol 2021-KS-HNSR181). Ethics approval was obtained with the stipulation that collected data must not expose respondents' identities and only aggregated information would be addressed in the research paper. Informed consent was obtained from all participants. The survey was conducted without compensation. The questionnaire was anonymous, and the data file was stored on the NTCC intranet server. Only research team members who signed confidentiality agreements were permitted to access the data.



Results

The Construction of Telepathology

Digital slide scanners, software, and networks were investigated, as shown in Figure 1. The configuration status of digital slide scanners was not investigated in 2018. In 2019, 2020, and 2023, the number of hospitals equipped with scanners were 85 of 242 (35.1%), 76 of 204 (37.3%), and 68 of 188 (36.2%), respectively, with an annual average growth rate of 0.75%. From 2018 to 2023, the percentages of hospitals deploying telepathology software were 29.5% (137/464), 35.1% (85/242), 43.1% (88/204), and 42.6% (80/188), respectively, with an annual average growth rate of 7.6%. The telepathology service network comprises private networks and the internet. In 2018, 2019, 2020, and 2023, there were 137 (137/464, 29.5%), 100 (100/242, 41.3%), 96 (96/204, 47.1%), and 89 (89/188, 47.3%) hospitals connected to the telepathology service network, respectively. Private networks were consistently more utilized than the internet, with annual ratios of 68.6% (94/137) vs 31.4% (43/137), 74% (74/100) vs 26% (26/100), 67% (64/96) vs 33% (32/96), and 93% (83/89) vs 7% (6/89).

Figure 1. In 2018 - 2020 and 2023, the construction of telepathology infrastructure.

The Current Status of Telepathology Services

In 2018, 2019, 2020, and 2023, the proportions of hospitals providing telepathology services were 23.3% (108/464), 28.9% (70/242), 33.3% (68/204), and 31.4% (59/188), respectively, with an annual average growth rate of 6.1%. Among hospitals with established telepathology systems, the proportions providing telepathology services were 78.8% (108/137) in 2018, 82.3% (70/85) in 2019, 77.3% (68/88) in 2020, and 73.8% (59/80) in 2023. The median numbers of telepathology cases for these years were 51 (IQR 10 - 200), 95 (IQR 18.25 - 228.5), 100 (IQR 27.5 - 223.75), and 200 (IQR 93 - 331.5), respectively. A statistically significant increase was observed from 2018 to 2023, with an annual average growth rate of 31.4%. Table 1 details the regional and hospital-level distribution. From 2018 to 2020, the Central region led in telepathology services; however, by 2023, the Eastern region took over. Significant differences were observed in telepathology services between the Central and Western regions across the years, with annual average growth rates of 17.7% and 27.2%, respectively. Tertiary hospitals consistently reported higher median telepathology case volumes than secondary hospitals, with a statistically significant annual average growth rate of 26.2%.

The Operation and Charging Situation of Telemedicine in Hospitals That Carry Out Telepathology Services

Among the hospitals providing telepathology services in 2018, 2019, 2020, and 2023, the percentages with established telemedicine departments were 69.4% (75/108), 77.1% (54/70), 76.5% (52/68), and 72.9% (43/59), respectively. The median numbers of telemedicine staff allocated were 3 (IQR 2 - 5) in 2018 and 2019, 4.5 (IQR 2 - 7) in 2020, and 5 (IQR 2.5 - 7) in 2023. Telemedicine operation modes included hospital self-operation, third-party operation, and mixed operation. Surveys over the 4 years showed that hospital self-operation was the primary mode, accounting for 67.59%, 50%, 67.65%, and 72.88%, respectively (Table S1 in Multimedia Appendix 4).

In 2018, 2019, 2020, and 2023, among hospitals providing telepathology services, the percentages of free services were 30.6% (33/108), 30% (21/70), 35.3% (24/68), and 57.6% (34/59), respectively. For charged services reimbursed by medical insurance, the percentages were 15.7% (17/108), 28.6% (20/70), 22.1% (15/68), and 22% (13/59), respectively (Figure 2). Fee standards were based on 3 factors: administrative department guidelines, hospital-specific standards, and telemedical service provider criteria (Table S1 in Multimedia Appendix 4).

Usage of Telepathology Among Pathologists

A total of 262 valid questionnaires were collected from pathologists, as shown in Table 2. The distribution of these pathologists by region was 69 from the eastern, 61 from the central, and 132 from the western regions. There were 129 (49.2%) males and 133 (50.8%) females with a mean age of 35.3 (SD 9.1, range 20-73) years. The dominant frequency was once a week, accounting for 61.1% (n=160). Combined, those who serviced once a week or 2 to 3 times a week made up 84.4% (n=221) of the total, whereas those servicing 4 to 5 times a week or more accounted for 15.6% (n=41). The average time spent on telepathology services was mainly 11 to 20 minutes (n=78, 29.8%) and 21 to 30 minutes (n=83, 31.7%).

Pathologists' Evaluation and Satisfaction With Telepathology

As shown in Table 3, 92.7% (n=243) of pathologists considered the system easy to operate, and the service process was convenient. Additionally, 95.5% (n=250) believed that telepathology could reduce patient burdens. The overall satisfaction rate with telepathology services was 95.8% (n=251), and 95% (n=249) of pathologists were willing to continue participation.

Factors Influencing Pathologists' Satisfaction and Use Intention of Telepathology

According to the univariate analyses shown in Tables 2 and 3, 6 variables were associated with overall satisfaction (P<.25), and 5 variables were associated with use intention (P<.25) (Table 4). Multivariate ordinal logistic regression analysis revealed that 3 variables were included in the models for pathologists' overall satisfaction and use intention, respectively. Both models met the proportional odds (parallel lines) assumption, with test results showing P=.83 for the satisfaction model and P=.44 for the usage intention model. Convenience of system operation and service processes significantly improved both overall satisfaction and willingness to use telepathology. Compared with an average service duration of ≤10 minutes per session, longer service times were associated with improved willingness to continue using the service. In addition, a moderate frequency of participation enhanced pathologists' overall satisfaction.

Patients' Perceptions of Telepathology Service Quality

A total of 141 patients who had used telepathology services participated in the survey, as shown in Table 5. The distribution across eastern, central, and western provinces was 31.9% (n=45), 32.6% (n=46), and 35.5% (n=50), respectively. There were 64 males and 77 females, with a male-to-female ratio of 0.83:1. Ages ranged from 19 to 72 years, with a mean age of 33.5 (SD 10.5) years. Most patients held a bachelor's degree (n=59, 41.8%), followed by an associate degree (n=50, 35.5%). Urban residents accounted for 61% (n=86) of patients. Employee medical insurance was the most common type of coverage

XSL•FO
RenderX

(n=81, 57.5%), followed by the New Rural Cooperative Medical Insurance (n=38, 27%). Notably, 76.6% (n=108) of patients reported an average annual family income below 30,000 yuan (US $4335), which is lower than the national per capita disposable income of 39,218 yuan (US $5667) reported in the 2024 China Statistical Yearbook.

A total of 99.3% (140/141) of patients reported that the doctor thoroughly explained telepathology, and 96.5% (136/141) had signed the informed consent form, as shown in Table 6. All patients received diagnostic opinions from senior experts. Within 24 hours, 92.2% (130/141) received results; within 48 hours, 98.6% (139/141) received results. Only 1 patient (1/141, 0.7%) received results within 72 hours. Overall, 98.6% (139/141) of patients were satisfied with the waiting time. All 141 patients found telepathology convenient and beneficial for their condition. Regarding service cost, 63.1% (89/141) were charged, with 52 of 89 (58.4%) considering the charges very reasonable, 36 of 89 (40.5%) reasonable, and only 1 of 89 (1.1%) unreasonable.

Patient Satisfaction With Telepathology Services

The overall satisfaction rate was 100% (141/141), with 64.5% (91/141) reporting being “very satisfied”. Among patients, 95% (134/141) believed that telepathology could save medical expenses, and 99.3% (140/141) were willing to recommend it to others. The main reasons for recommendation included convenience (91/140, 65%), access to quality medical services (22/140, 15.7%), cost saving (11/140, 7.9%), time saving (6/140, 4.3%), and necessity (1/140, 0.7%).

Discussion

Principal Results

Diagnosis consistency between WSI and light microscopy has been confirmed, and telepathology is increasingly adopted worldwide [26]. It is widely used for remote primary diagnosis, second-opinion consultations, quality assurance, education, and research [27]. In China, the government has actively promoted telepathology to address the shortage of pathologists in primary health care institutions. However, although most medical institutions in China have implemented telemedicine systems, the utilization rate has remained below 20%, as highlighted at the 2019 subforum of the Global Health Forum of Boao Forum for Asia: Innovation for Health—The Future of Internet Medicine [28]. The actual use of telepathology in Chinese hospitals remains systematically understudied. Although annual surveys by TIPC and NTCC provide cross-sectional snapshots of telemedicine development, they are largely descriptive and lack dedicated analysis of telepathology or longitudinal assessment. To address this gap, this study provides the first systematic examination of telepathology development in China through long-term trend analysis, regional comparisons, and dual perspectives from both clinicians and patients. Based on these findings, targeted recommendations are proposed to inform policy-making and support the sustainable advancement of telepathology in China.

Regarding telepathology infrastructure construction, the highest proportion is networks, while the lowest is digital slide scanners. This is because invited experts only need to provide diagnostic suggestions based on WSI uploaded by the inviting institutions, eliminating the need for slide scanners. From 2018 to 2023, the number of telepathology service cases in China grew steadily, with the median per hospital increasing from 51 to 200 cases, reflecting an average annual growth rate of 31.4%. However, surveys revealed that the proportion of hospitals with established telepathology systems exceeded the proportion of those actually providing services each year. The ratio of service implementation to system construction ranged from 73.8% (59/80) to 82.3% (70/85), a trend consistent with the reported service utilization rates of 72.3% (60/83) to 89.1% (74/83) in the China CNCTPS telepathology platform report [21]. Hitchcock [29] pointed out that the limited implementation of telepathology in developing countries primarily stems from a lack of standardized equipment, inconsistent image formats, and insufficient training for pathologists. Practices in Nigeria [16] further highlighted the significant time cost associated with image scanning and uploading (5 - 10 min per slide for scanning and 10 - 30 min for uploading to the cloud), which has become a critical bottleneck affecting service efficiency. Research by Indian scholars [17] also indicated that challenges such as the large file sizes of WSI, insufficient transmission speeds, and the need for security protection of patient data and images during internet transmission are key factors limiting the application of telepathology. In response to these challenges, various technical approaches have been proposed in the academic community. Emerging technologies such as IoT [30], blockchain-based digital identity authentication [31], and aspect-oriented programming [32] have been proven effective in reducing data transmission latency, enhancing medical information security, and improving system interoperability. These technologies offer feasible solutions for addressing the challenges of cross-institutional secure retrieval of large WSI files. Therefore, promoting the integrated application of these technologies in telepathology holds significant potential for increasing service utilization rates in the future. Moreover, policy and standardization improvements are crucial. Health authorities should promote WSI standardization, clarify cross-institutional licensing rules, and include telepathology in insurance reimbursement.

From a regional distribution perspective, the development of telepathology varies across different areas. Similarly, a national survey in Ireland [33] indicated that the advancement of telemedicine differs significantly across regions, with multiple regional networks established in the east, while development in the west predominantly consisted of isolated links. Our study reveals that the eastern region experienced the fastest growth, with an average annual growth rate of 58%, likely attributable to its more abundant medical resources, stronger economic foundation, and the advantages of policy piloting and early implementation. From 2018 to 2020, the central region reported the highest median number of telepathology diagnostic cases, which may be associated with its lower urbanization rate and relatively scarce rural healthcare resources. According to the China Statistical Yearbook, the urbanization rate in the eastern region was 68.5%, compared with 56.8% in the central region and 54.1% in the western region. Additionally, data from the China Health Statistical Yearbook indicate that from 2018 to

XSL•FO
RenderX

2020, the central region consistently had the lowest number of health technicians per thousand rural population. These factors likely contributed to a higher demand in the central region. To address regional disparities in China's telepathology services, a systematic policy intervention is essential. This includes: (1) Investment: establishing a dedicated fund for central/western regions and integrating telepathology into medical insurance; (2) Operations: implementing unified technical standards and regional diagnostic centers with performance incentives; (3) Capacity: training local pathology technicians and physicians.

The dominant frequency of telepathology usage among pathologists in China was once a week, accounting for 61.1% (160/262). In contrast, a national survey in the United Kingdom revealed that telepathology was rarely used on a weekly or monthly basis [34]. Meanwhile, surveys in South Africa showed that 11% (8/71) used telepathology weekly [35], and a study in Switzerland reported a 31% (42/134) weekly usage rate for telepathology [36]. The average time spent on telepathology services is mainly 11 to 20 and 21 to 30 minutes (161/262, 61.5%), which aligns with the reported average duration of telemedicine services in China [37]. In contrast, a study from the United Kingdom reported that the time taken for telepathology diagnosis averaged 3.9 minutes [38]. Pathologists' acceptance of telepathology demonstrates a strong global consensus. In our study, 95.8% (251/262) of participating pathologists reported overall satisfaction, with 95% (249/262) willing to continue its use. This aligns with international findings: a Saudi Arabian study noted only 1.6% (1/64) had no intention to use telepathology [39]; a UK study involving 18 pathologists found 88.89% (16/18) were likely to continue digital reporting [40]; and a Japanese study showed 70% (16/23) were interested in the system for consultations [41]. Notably, our survey revealed a higher rate of strong intention to use (153/262, 58.4%) compared to the Saudi study (23/64, 35.9%) [39]. This trend extends beyond pathology, as evidenced by a global survey of urologists from 58 countries, where 80.9% (197/244) intended to continue using telemedicine in clinical practice [42]. When analyzing the influencing factors of satisfaction and using intention among pathologists, this study demonstrated that the convenience of system operations and service process had a significant positive impact on pathologists' satisfaction and willingness to use telepathology. Additionally, longer service durations were also associated with positive impact, consistent with prior research on telemedicine services [37]. However, no significant associations were found between pathologists' satisfaction or willingness to use telepathology and factors such as gender, age, education level, or professional title. This is consistent with the findings from a survey of 64 pathologists in Saudi Arabia [39]. The manual navigation tools required for digital slides and the single-layer 2D nature of WSIs demand careful scrutiny by pathologists to ensure diagnostic accuracy. Shorter duration of telepathology may compromise diagnostic precision. Conversely, an intuitive system interface and streamlined service workflow facilitate smoother telepathology diagnosis, thereby enhancing pathologists' engagement and platform retention. The research suggests that improving pathologists' engagement in telepathology depends on optimizing both system design and workflow. To achieve this, medical institutions should: (1) enhance system usability and streamline the consultation process; and (2) reasonably schedule telepathology sessions based on workload and diagnostic quality requirements.

While research on telemedicine from an end-user perspective is extensive, studies focusing on telepathology user attitudes remain limited. This may be because telepathology often does not require direct patient involvement. Nevertheless, we surveyed 141 telepathology patients to assess their experiences and satisfaction. Among them, 92.2% (130/141) and 98.6% (139/141) received diagnostic results within 24 and 48 hours, respectively, surpassing the rates from our previous analysis of Henan Province's telepathology network (64%, 14,835/23,167 and 82.9%, 19,201/23,167) [21] and exceeding those reported by the Québec Telepathology Network in Canada [43]. All patients expressed satisfaction, aligning with the high patient satisfaction reported in other telemedicine surveys in Canada (248/272, 91%) [44], Norway [45], Argentina (116/116, 100%) [46], and Africa [47]. Higher than the survey in India, which indicated that 78% (39/50) of patients with cancer expressed interest in future telemedicine opportunities [48], 99.3% (140/141) were willing to recommend telepathology to others, citing high-quality service, time savings, and cost savings as key reasons. Based on the findings of this study and international comparative data, telepathology services have demonstrated clear and significant advantages in diagnostic turnaround time and patient satisfaction. Therefore, it is recommended that in future public education and service promotion, the core messages of "high quality (expert diagnosis), high efficiency (rapid response), convenience (localized diagnosis and treatment)" and "high satisfaction (patient endorsement)" be precisely communicated. This approach aims to enhance patient awareness and trust, thereby encouraging patients to more proactively choose telepathology services when faced with diagnostic options.

Limitations

This study analyzes the construction and application of telepathology in China from 2018 to 2023 through a nationwide survey, focusing on digital slide scanners, telepathology software, and network connectivity. It also evaluates the progress of telepathology services across hospitals of varying levels and regions. As the first detailed nationwide report on telepathology in China, this study uniquely examines perspectives from both pathologists and patients, covering usage, satisfaction, and influencing factors analysis. The findings provide a comprehensive understanding of telepathology in China and offer actionable recommendations for its enhanced application.

Although our findings offer valuable insights into telepathology in China, this study has several limitations. The sample was based on voluntary participation rather than a longitudinal cohort follow-up, and the significant shift in policy focus toward internet hospitals may have reduced engagement with this telemedicine-specific survey, contributing to the annual decline in sample size. The survey was conducted through TIPC, the national academic organization for telemedicine, and administered via the NTCC website, with participating hospitals spanning most regions. However, the online nature of the survey

XSL•FO
RenderX

may have introduced selection bias. The survey spanned from 2018 to 2023, a period marked by significant advancements in telemedicine and a shift toward internet-based healthcare, driven by national policies. Policy shifts and potential survey fatigue contributed to a decline in valid responses each year. Additionally, the surveys for 2021 and 2022 were disrupted due to the pandemic. Despite these limitations, the survey encompassed a sufficient number of medical institutions across China, and data analysis revealed a clear growth trend in telepathology development. Therefore, while these limitations exist, their impact on the study's conclusions is likely minimal. Besides, in-depth interviews with surveyed pathologists and patients are still lacking to fully understand the barriers of telepathology, so as to put forward more reasonable suggestions.

Given that this study is based on a comprehensive national survey in which the items related to telepathology were relatively general, future research will involve the design and implementation of a specialized telepathology survey. This survey will categorize questions according to service types—such as routine histopathological diagnosis and intraoperative frozen section consultation—to obtain more granular and in-depth data. This approach aims to comprehensively and thoroughly reveal the actual clinical application landscape and differentiated needs of telepathology. Additionally, we will further explore the perspectives of pathologists and patients towards telepathology through semi-structured interviews, which can help to devise corresponding strategies for the better development of telepathology in China.

Conclusion

This study provides the first systematic examination of telepathology development in China through long-term trend analysis, regional comparisons, and dual perspectives of both clinicians and patients. The findings indicate significant growth in the construction and application of telepathology in China from 2018 to 2023, with high levels of acceptance from both pathologists and patients. Factors such as the convenience of system operation, smoothness of service processes, frequency of use, and average duration per session were significantly associated with pathologists' satisfaction and willingness to use telepathology. To enhance the adoption rate of telepathology services, targeted recommendations are proposed around a synergistic "technology-institution-promotion" framework: at the technological level, integrating cloud computing and artificial intelligence to improve system usability; at the institutional level, establishing dedicated funds for central and western regions, promoting the inclusion of telepathology in medical insurance reimbursement, and refining cross-institutional licensing and performance incentive policies; at the promotional level, accurately communicating its core values of "high quality, high efficiency, convenience, and high satisfaction" to the public to encourage proactive patient choice. Through multidimensional systemic interventions, the technological advantages of telepathology can be translated into sustainable primary healthcare service capabilities.

Funding

This research was supported by grants from the National Key R&D Program of China (2022ZD0160705), the Science and Technology Research Program in Henan province (242102311012, 242102311021), the Basic Research and Appled Basic Research Program in Zhengzhou City (Grant No. 2024ZZJCYJ017), the Key Research of Higher Education in Henan province (23A330007), and the Joint Co-construction Program of Medical Science and Technology of Henan province (LHGJ20210313).

Abstract

Dynamic Personalized Optimization (DPO) is introduced as a conceptual framework that defines core artificial intelligence (AI) functions required to deliver real-time, personalized, and optimized treatment in digital therapeutics (DTx). DPO continuously refines therapeutic strategies by integrating patient data, treatment content, usage feedback, and status measurements to provide real-time, personalized treatment. Using predictive AI models, DPO adapts treatment approaches based on patient responses, thereby improving therapeutic effectiveness. Furthermore, this paper explores the potential role of large language models (LLMs) in supporting DPO by processing diverse and complex data formats. By addressing current limitations in real-time personalization within DTx, DPO establishes a structured, AI-driven approach to delivering tailored digital interventions. This framework ultimately aims to enhance treatment efficacy and improve patient engagement.

dynamic personalized optimization; digital therapeutics; AI functionality framework; personalized treatment; large language models

Introduction

Digital Therapeutics (DTx) are software-based interventions designed to prevent, manage, or treat medical conditions and provide direct therapeutic benefits through digital technology [1]. Such digital interventions are particularly important for neurological disorders, which require complex, personalized approaches [2]. Neurological disorders such as tinnitus, depression, and mild cognitive impairment require individualized care that DTx can offer [3,4], but the full potential of DTx is realized only with artificial intelligence (AI) integration [5].

These DTx solutions can continuously monitor patients, deliver real-time feedback, and dynamically adjust treatments to improve outcomes [6]. AI plays a crucial role in DTx by analyzing large-scale patient data to enable real-time personalization and improved treatment outcomes [3,7,8].

This study introduces a functional framework for AI in DTx, which supports real-time personalization through dynamic adaptation. Existing DTx lack a formal framework for real-time personalization. Prior work has identified persistent challenges in dynamic personalization [8,9], including the need for more adaptable models and limitations of static content in DTx. This paper addresses this gap by introducing a new framework called Dynamic Personalized Optimization (DPO).

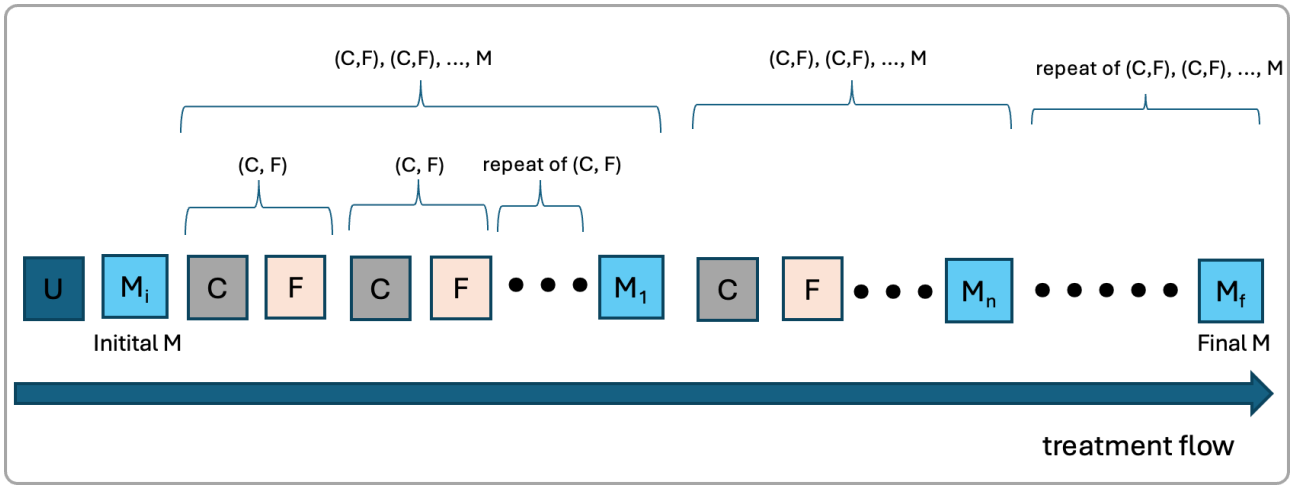
DPO Framework

Definition and Characteristics of DPO

DPO is a conceptual framework that delineates the core AI functions necessary for DTx to achieve dynamic personalization and optimal therapy. It integrates and analyzes patient data to refine treatment strategies in real time. DPO tailors treatment plans by incorporating patient data and responses to offer individualized therapeutic approaches. A predictive AI model anticipates the patient's future status and optimizes treatment accordingly. DPO dynamically optimizes personalized therapy by integrating clinical data, feedback, and treatment content.

Building on just-in-time adaptive interventions [10], DPO formalizes relevant data types and introduces adaptive treatment content optimization through AI-based prediction of patient feedback or status. While traditional just-in-time adaptive interventions primarily focus on determining the timing of interventions, DPO differentiates itself by continuously optimizing treatment content through AI-based prediction of patient feedback, thereby extending the concept from temporal adaptation to content-level personalization.

Necessity of DPO in DTx



Neurological and other complex disorders require personalized, responsive treatment. DPO is essential to achieving this in DTx, as it continuously tailors therapy based on patient-specific data in real time.

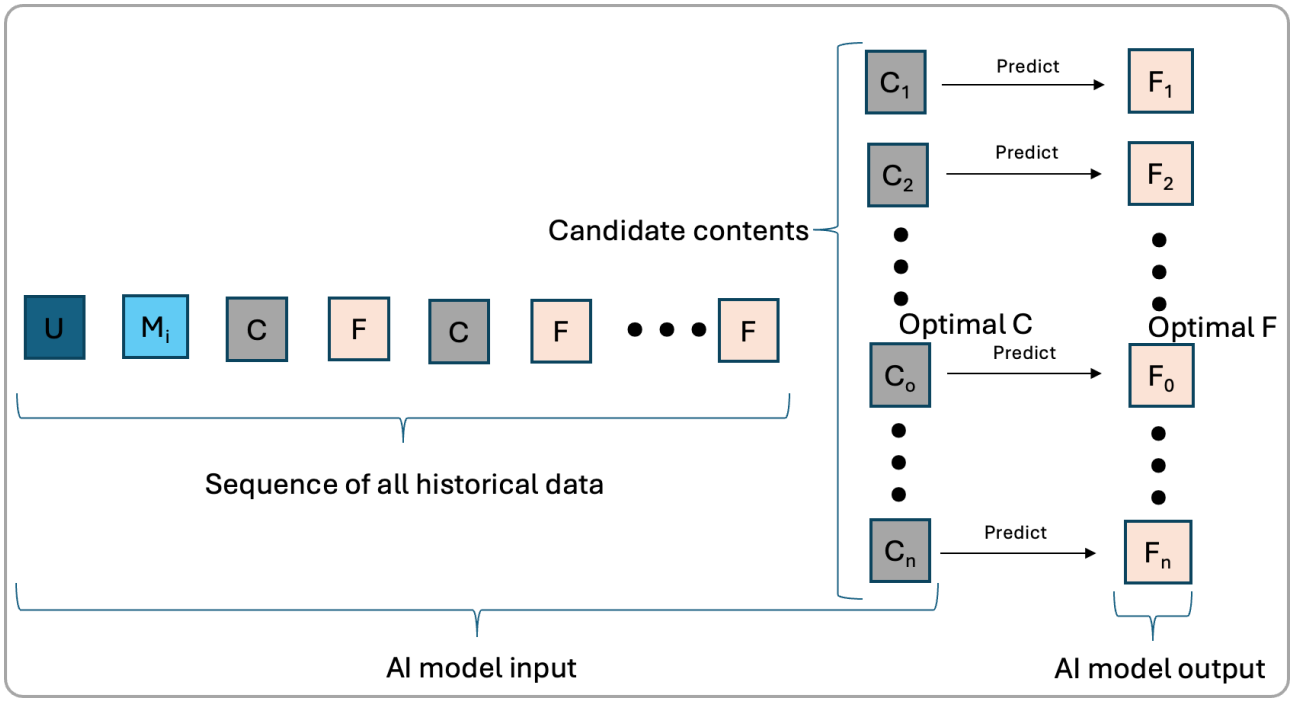
XSL•FO
RenderX

The Four Data Types of DPO

DPO uses four types of data to tailor therapy. User data (U) include information about the patient, such as demographics, medical history, and lifestyle. Status measurement (M) data refer to objective health metrics, including symptom severity and test results. Treatment content data (C) encompass information related to the therapy itself, such as descriptions, types, and formats. Finally, feedback data (F) consist of feedback received after therapy, such as treatment game scores or the patient's reported feelings. AI in DTx uses these 4 types of data to create personalized treatment plans. Figure 1 illustrates how these 4 data types are sequentially processed throughout the therapeutic process.

Figure 1. The treatment process begins with a sequence of 4 data types: initial user data (U), initial patient status (Mi), and a repeated cycle of treatment content (C) and feedback (F), which leads to updated status measurements (M). This treatment-feedback sequence and patient status update continues throughout the treatment period.

Adaptive Treatment Content Optimization



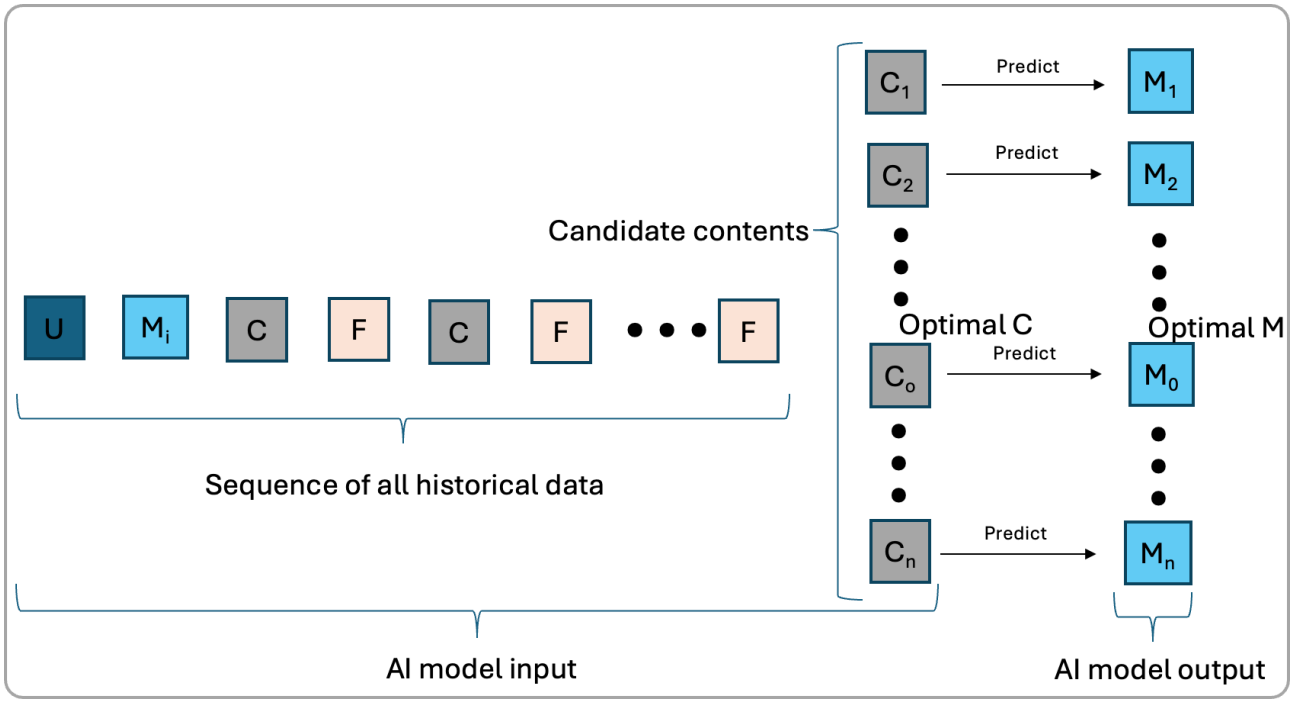
Within the DPO framework, AI is expected to continuously select the treatment content (C) that yields the greatest improvement in a patient's final status (M_f) relative to the initial status (M_i). However, identifying the "best" content in advance for AI model training is nearly impossible because it varies by individual and context and cannot be known until tried.

Predicting F

As Figure 2 illustrates, instead of directly predicting the optimal content C, this approach focuses on predicting F for a given C. In a DTx environment, real-world data collection yields sequential data (U, M, C, and F) throughout the treatment. An AI model can be trained on these historical data sequences to predict subsequent F. Although F does not directly represent treatment efficacy, it informs future treatment decisions. This approach assumes that feedback (F) is a valid proxy for treatment efficacy. Prior research shows a strong correlation between user engagement in digital interventions and improved treatment outcomes [11], though engagement alone may not fully capture clinical efficacy. Nonetheless, leveraging this correlation, the model can predict F for candidate treatment contents and select the optimal one (C_o) with the highest predicted F.

XSL•FO
RenderX

Figure 2. One optimization approach involves predicting the expected feedback (F) for each candidate content. The optimal content (C_o) is selected based on the highest predicted F. An artificial intelligence (AI) model is trained on historical data sequences to predict F for a given candidate C.



Predicting M

Figure 3 illustrates another approach: predicting the patient's M_f. In this approach, an AI model is trained with prior data sequences as input and M_f as the output. If the model learns this relationship accurately, it can predict M_f for a given input sequence and a candidate C. By predicting M for all candidate C options, the model can select the C_o that most effectively improves M.

Together, these approaches eliminate the need to explicitly label C as the correct answer. Instead, AI predicts F or M_f to dynamically determine the optimal C, ensuring that patients engage with the most effective therapeutic content. However, implementing these AI-driven strategies in practice requires managing complex and heterogeneous DTx data, which poses significant challenges.

Figure 3. An alternative approach involves predicting the final patient status (M_f) for each candidate content. The artificial intelligence (AI) model takes historical data and candidate C as input and predicts the resulting status (M_f). The optimal content (C_o) is selected to maximize improvement in M_f relative to the initial status.

XSL•FO
RenderX

In a cognitive intervention context for mild cognitive impairment (MCI) [12], DPO operates as follows. The system first collects U such as demographic and behavioral information including age, education level, daily activity, and sleep patterns. It also gathers initial measurement data (M_i), such as the Mini-Mental State Examination score [13] representing the patient's baseline cognitive state. Based on these inputs and the history of previously delivered C—for example, cognitive games that train memory, attention, or problem-solving skills—and corresponding F, such as game scores reflecting engagement and task performance, the AI model predicts either the expected F or the postsession M for each candidate content option. The predicted value then guides the system in selecting the next C_o for the patient's subsequent training session. This process of providing C and receiving F repeats over time, allowing the system to refine personalized cognitive training. Through this iterative mechanism, DPO continuously optimizes therapeutic content to enhance cognitive function and engagement in patients with MCI.

Challenges of Data in DTx and LLM Strategy

Overview

DTx data appear in diverse forms—text (eg, clinical notes), numeric measurements, images, and video—varying widely in length and quality. This heterogeneity hinders uniform processing of data by AI. Addressing this issue requires careful data preprocessing, stringent quality control, and AI models capable of integrating disparate data types.

LLMs have significant potential to overcome data processing challenges in DTx [14]. The following strategies describe how LLMs can support DPO.

Integrated Processing of Various Data Formats

LLMs can process diverse data formats (including text, numerical data, and images) thereby enabling comprehensive analysis to improve treatment outcomes [15]. They analyze unstructured text, such as medical records and patient feedback, to extract key details and interpret numerical data like vital signs and laboratory results. Additionally, LLMs use embedding techniques to represent each data modality as a numeric vector, enabling integrated analysis across different data types. This approach allows processing of disparate data types within the same mathematical space.

Processing Variable Data Sizes

LLMs can handle data inputs of widely varying lengths [16,17]—from brief notes and detailed medical records to extensive patient histories and multisource health logs. They can also process time-series data to identify patterns and trends in symptom logs and vital signs. This capability enables real-time monitoring and more adaptive care.

Discussion

The DPO framework proposed in this study has been designed as a structural model applicable to a range of DTx scenarios, offering a systematic functional definition of AI capabilities required for the personalization and adaptive coordination of digital therapeutic content. In DPO, LLMs are not used to generate new therapeutic content but rather serve as analytical tools to integrate and interpret multimodal data for personalized optimization. This paper presents a conceptual design framework and does not include empirical validation for 2 primary reasons. First, DPO is formulated as a high-level functional abstraction rather than a model-specific architecture, and its applicability may be realized through various algorithmic implementations. Therefore, the focus of this work is on the completeness and coherence of the framework design rather than the comparative performance of specific models. Second, the DPO framework is currently undergoing pilot-level integration in several ongoing DTx development pipelines within an industry setting, and early experimental outcomes related to these efforts are planned to be reported in a separate study. Future work will empirically evaluate the implementation and performance of each functional component of the DPO framework—prediction, personalization, and optimization—within actual digital therapeutic contexts using real user data. Additional studies will also explore the generalizability and scalability of DPO across diverse clinical domains, including MCI, depression, and tinnitus, to further establish the framework's practical utility and robustness.

Conclusion

The proposed DPO framework offers a structured approach to operationalizing AI in DTx, with the potential to improve both engagement and therapeutic efficacy. Integrating LLMs into DPO could greatly enhance personalized care delivery and improve health care outcomes. At the same time, ensuring data privacy, security, and safety in digital therapeutics remains essential. Moreover, the responsible use of AI-based DTx requires addressing ethical issues such as transparency, fairness, cybersecurity, and data protection, which must be implemented with accountability [18]. Recent studies on responsible AI deployment further emphasize the importance of governance, transparency, and privacy as key foundations for ethical implementation in health care [19,20]. AI must generate transparent recommendations while ensuring clinical validation and ethical oversight. Overcoming these challenges could enable a new level of personalized treatment and substantially improve patient outcomes. Leveraging advanced AI models for DPO may facilitate the integration of heterogeneous patient data in ways previously unattainable, essentially serving as a "brain" for DTx that learns and adapts to each patient. Going forward, the practical implementation and clinical validation of DPO (potentially with LLMs) are crucial next steps. These efforts must be accompanied by careful attention to ethical and regulatory considerations. If DPO can maintain patient engagement by tailoring content to what is therapeutically optimal for each individual, the therapeutic efficacy of DTx could be substantially enhanced. Such personalized adaptation prevents patient dropout or disengagement caused by monotonous or ineffective content [1], thereby further improving outcomes.

Abstract

Retrieval-augmented generation (RAG) systems have emerged as a powerful technique to enhance the capabilities of large language models by enabling them to access external, up-to-date knowledge in real time, and RAG systems are being increasingly adopted by researchers in the medical field. In this viewpoint article, we explore the ethical imperatives for implementing RAG systems in clinical nursing environments, with particular attention to how these technologies affect patient care quality and safety. The purpose of this paper is to examine the ethical risks introduced by RAG-enhanced large language models in clinical nursing and to propose strategic guidelines for their responsible implementation. Key considerations include ensuring accuracy, fairness, transparency, and accountability, as well as maintaining essential human oversight, as discussed through a structured analysis. We argue that robust data governance, explainable artificial intelligence (AI) techniques, and continuous monitoring are critical components of a responsible RAG implementation strategy. Ultimately, realizing the benefits of RAG while mitigating ethical concerns requires sustained collaboration among health care professionals, AI developers, and policymakers, fostering a future where AI supports patient safety, reduces disparities, and improves the quality of nursing care.

KEYWORDS

large language models; clinical decision-making; ethics; fairness; transparency

Introduction

Advances in artificial intelligence (AI) are rapidly transforming the health care field, with large language models (LLMs) playing a pivotal role in revolutionizing nursing practice [1,2]. These models enhance human capabilities by learning patterns from large amounts of text data and generating contextually relevant information, offering benefits such as improved decision support, streamlined care planning, and personalized patient education [3]. LLMs can assist nurses by providing comprehensive insights and generating evidence-based recommendations. However, their integration into clinical workflows faces significant challenges [4], partly because LLMs do not operate like traditional rule-based programs. Instead, they generate responses based on statistical patterns learned from large text corpora, rather than performing logical reasoning or interpreting meaning as humans do.

While this generative capability allows LLMs to produce contextually relevant and fluent text, it also gives rise to several critical limitations in specialized clinical applications. These include biases inherited from training data and the "black-box" nature of their decision-making processes, which make it difficult to understand how outputs are produced. Such issues lead to concerns about trust and transparency, ultimately undermining the reliability of model-generated recommendations in high-stakes health care environments [5,6].

To address these shortcomings, the retrieval-augmented generation (RAG) system has emerged as an enhancement to LLMs. By combining external knowledge retrieval with the language patterns an LLM has learned during training, RAG can provide more accurate, up-to-date, and context-sensitive information [7]. In this paper, the term "RAG system" refers to the practical implementation of the RAG approach, in which an LLM retrieves external information from databases or documents and integrates it with the patterns learned during training to generate context-aware responses. While this approach aims to overcome the static nature of traditional LLMs, it introduces new ethical risks, particularly related to the quality and reliability of external data sources, the complexity of information traceability, and privacy concerns [4].

XSL•FO
RenderX

This article examines the ethical challenges introduced by RAG-optimized LLMs in clinical nursing and proposes strategies for responsible implementation. We focus on three core ethical imperatives: ensuring accuracy, fairness, and bias mitigation; promoting transparency, explainability, and trust; and maintaining responsibility, accountability, and oversight. By addressing these challenges proactively, we can harness the benefits of RAG to enhance nursing practice while safeguarding patient well-being.

The Promise and Peril of RAG in Nursing

Overview

RAG offers significant opportunities to enhance clinical nursing practice by providing more accurate, up-to-date, and context-specific information. By combining the language-pattern learning capability of LLMs with external knowledge retrieval, RAG can address some of the limitations of traditional LLMs [8]. However, alongside its potential benefits, RAG also introduces unique risks that need to be carefully considered, particularly in the context of clinical nursing.

The Promise of RAG in Nursing

The primary advantage of RAG lies in its ability to enhance decision support by integrating real-time, relevant knowledge from external sources. In high-pressure environments, such as hospitals, where quick decision-making is critical, RAG can significantly improve the accuracy of clinical recommendations by ensuring they are based on the latest research and guidelines [7,9]. By enabling real-time access to updated information, RAG helps reduce errors that may arise from outdated or incomplete data [9].

Additionally, RAG systems build on what the LLM has learned from language data to provide personalized and context-specific recommendations by incorporating patient-specific data, such as medical history, treatment plans, and current health status. This ability to tailor recommendations to the individual needs of patients ensures that health care providers can deliver more accurate and effective care [10]. In settings with limited resources, RAG can provide vital support for nurses by offering evidence-based recommendations that might otherwise be difficult to access due to time constraints or a lack of available resources [9].

The Peril of RAG in Nursing

Overview of Risks

Despite its advantages, the use of RAG systems in nursing also introduces a range of ethical challenges and risks. Many of these challenges stem from the limitations of the underlying LLMs on which RAG is built—including issues such as bias, opacity, and a lack of accountability. At the same time, RAG introduces additional, system-specific risks because it retrieves and integrates external information dynamically at query time. These additional risks center on data quality, source reliability, semantic coherence, and information provenance and must be carefully addressed in clinical applications.

Common Risks of LLMs

Many of the risks associated with RAG are rooted in the inherent challenges of LLMs, which include the following:

- Bias and fairness: LLMs may perpetuate biases that are present in their training data, such as racial, gender, or cultural biases [11]. Since RAG systems rely on external sources, they can also inherit and even amplify these biases if the external data sources are not sufficiently diverse or representative [4]. This is particularly concerning in nursing, where such biases can lead to unequal treatment and care disparities, potentially exacerbating health inequalities [12].
- Transparency and explainability: The “black-box” nature of LLMs remains a significant issue, making it difficult for clinicians to understand how the model produces its responses [13,14]. While RAG can improve transparency by citing the sources of external information, the process may still be opaque. This lack of explainability can undermine trust in the system, especially when nurses are unable to interpret the reasoning behind a recommendation [5,15].
- Accountability: Another concern is who should bear responsibility when a RAG system provides a recommendation that leads to an error or harm. It may be unclear who is responsible—whether it is the developers of the model, the clinical staff who implemented it, or the health care institution as a whole. This ambiguity complicates accountability and the governance of AI-driven health care systems [16].

Risks Specific to RAG

While many of the risks in RAG are shared with LLMs, there are several risks that are unique to RAG systems due to their reliance on outside information sources.

- Information provenance and quality: RAG systems pull data from many different websites, databases, and documents. Some of these sources may not undergo rigorous peer review, and there may be discrepancies in the information retrieved [17,18]. When the information used by RAG is incomplete or unreliable, the guidance it gives can also be misleading. It can also be difficult to check exactly where the information came from, which makes it harder for nurses to judge whether a recommendation can be trusted [19].
- Semantic integration and coherence: When a RAG system combines information drawn from many sources, the final advice may sound uneven or use different styles of wording. For a nurse using it, this means different parts of the output may suggest slightly different approaches, which can create confusion or reduce confidence in applying the recommendation [20]. Merging text generated from different materials may result in conflicting or incompatible pieces of information, which can cause confusion or misinterpretation [21]. This issue is particularly problematic in clinical contexts, where accuracy and consistency are essential for patient safety [22].
- Privacy and security risks: To offer personalized advice, RAG systems may need access to sensitive patient data, such as medical histories, to provide personalized

XSL•FO
RenderX

recommendations [18,23]. If the system's security is weak, or if it does not meet privacy standards like HIPAA (Health Insurance Portability and Accountability Act) or GDPR (General Data Protection Regulation), confidential information could be exposed. Such data breaches could harm both patients and the health care institution [5].

- Shifting trust foundations: Traditional LLMs depend only on the language relationships learned during training, but RAG depends on both internal and external sources. This means that the reliability of RAG depends not only on the model itself but also on the trustworthiness of the outside information it uses [24,25]. If that outside data is wrong or biased, the recommendations produced by the RAG system may be wrong too, reducing nurses' confidence in using the system [18,19,26].

An example is as follows: A nurse used a RAG-based tool to check evidence for pressure injury prevention. The system retrieved the 2014 second edition of the international pressure ulcer guideline, which recommended turning the patient every 2 hours on standard foam surfaces. However, the upcoming 2025 fourth edition emphasizes individualized repositioning schedules, the use of alternating-pressure mattresses, and closer monitoring for deep tissue injury in high-risk or obese patients. Because the RAG system relied on outdated data, the nurse followed the older 2-hour rule and missed early signs of a deep tissue injury. This case shows how outdated retrieval sources can lead to substandard care and highlights the need for RAG systems to verify and update their evidence sources regularly.

Focused Ethical Challenges

Overview

The introduction of RAG systems into clinical nursing presents several ethical challenges that need to be carefully considered. These challenges are not only rooted in the inherent limitations of how LLMs learn from data but also amplified by the integration of external knowledge sources [18,27]. In this section, we focus on three core ethical challenges: accuracy, bias, and fairness; transparency, explainability, and trust; and responsibility, accountability, and human oversight. These challenges must be addressed to ensure that RAG-enhanced LLMs support ethically evidence-based decisions in nursing practice [28].

Accuracy, Bias, and Fairness

One key ethical concern when using RAG systems is maintaining the accuracy of the information they generate, especially for clinical decisions [3,19]. The accuracy of RAG depends directly on how reliable and up-to-date the outside sources are [9]. If the outside sources are outdated, incomplete, or inaccurate, the systems' recommendations may mislead nurses and lead to unsafe decisions that could harm patients [18,19]. Therefore, RAG systems should only use checked and high-quality data that fits the medical context [18].

Additionally, bias remains a significant challenge. RAG systems can carry bias from both the training data used to develop the LLMs and the outside sources it pulls information from [26,29]. These biases can manifest in various forms, such as racial, gender, or socioeconomic biases, and can show up as racial, gender, or economic differences and may cause unfair care for some patients [30,31]. In clinical settings, where health gaps already exist, AI-related bias can make these gaps worse. For example, if RAG systems draw information from databases that underrepresent minority populations, the resulting recommendations may be less accurate or effective for these groups [32].

To reduce these risks, we need continued work to make AI systems fair [16,18]. This means checking that outside sources cover different patient groups and reviewing the system's outputs regularly for bias. Furthermore, health care institutions and developers should also focus on including a wide range of patients in AI training data and retrieval sources to avoid making health gaps worse [33,34].

Transparency, Explainability, and Trust

Another significant ethical challenge is transparency and explainability. While RAG systems can increase transparency by showing the sources of information, the process by which these models generate their responses is still not very clear [18,35]. Because their internal workings are complex and often hidden, it can be hard for clinicians to see how external data and built-in knowledge come together to form a recommendation [36]. This lack of clarity can reduce trust in the system, since clinicians might hesitate to use a tool whose reasoning process cannot be easily interpreted [15,37,38].

Explainability is particularly important in clinical settings, where nurses and health care professionals need to understand the basis for AI-generated suggestions in order to trust them and incorporate them into their decision-making process [15,39,40]. It is essential for RAG systems to explain their answers in a way that is easy for health care professionals to understand. For example, providing confidence scores or source citations can help clinicians evaluate the reliability of the information and determine whether it fits the patient's situation [38,41].

Enhancing transparency and explainability will not only help build trust in AI systems but also foster responsible and ethical AI adoption in clinical practice. As RAG systems become more integrated into health care systems, transparency will be key to ensuring that their use aligns with professional standards and ethical guidelines [6].

Responsibility, Accountability, and Human Oversight

Responsibility and accountability are key ethical concerns in the context of AI-driven decision-making. One of the main challenges in using RAG systems is that responsibility can become blurred when many parties—such as AI developers, health care providers, and institutions—take part in the same process [42]. If an error occurs because of a recommendation from a RAG system, it may be unclear who should bear responsibility for it. This uncertainty can make legal and ethical management of such situations more difficult [43,44].

To address this issue, it is important to have clear guidelines that define the roles and duties of everyone involved in the AI decision-making process [45]. Health care institutions must ensure that there are well-defined accountability structures in

XSL•FO
RenderX

place to determine who is responsible when AI systems make errors [6]. Furthermore, RAG systems should be designed with human supervision in mind. While they can enhance decision support, they should never replace human judgment. Nurses and clinicians must be able to step in or question the AI-generated recommendations if they believe the advice is not in the patients' best interest [46,47].

Keeping humans actively in each stage of the process, which is often called "human-in-the-loop" oversight, is crucial to maintaining ethical standards in AI-assisted clinical care [48,49]. This approach ensures that clinical decisions are ultimately guided by human expertise, with AI acting only as a support tool. To support this approach, ongoing training for health care professionals on the use of AI systems, along with mechanisms for reporting and addressing errors, will help uphold ethical standards and ensure that the use of RAG systems benefits patients while minimizing risks.

Addressing these ethical concerns requires not only awareness but also systematic strategies to guide responsible use of RAG systems in nursing practice.

Strategies for Responsible RAG Implementation

Overview

Building on the ethical challenges discussed in the *Focused Ethical Challenges* section, it is essential to implement strategies that ensure the responsible and effective use of RAG systems in clinical nursing. While RAG systems offer significant advantages, such as real-time decision support and personalized care recommendations, they also introduce unique risks. To maximize the benefits of RAG and minimize its ethical concerns, we propose several key strategies for responsible implementation. These strategies are designed as direct responses to the ethical challenges identified in the *Focused Ethical Challenges* section, translating theoretical imperatives into actionable guidance for nursing practice.

Data Governance and Bias Mitigation

Building on the discussion of bias and fairness in *Accuracy, Bias, and Fairness*, effective data governance provides the foundation for responsible RAG implementation. Because RAG systems rely on external knowledge sources, ensuring the integrity and representativeness of these data is essential. Biases in the external data used for retrieval can have a significant impact on the outputs generated by the system, potentially leading to unfair or discriminatory outcomes [12,50,51].

To mitigate these risks, bias detection and correction mechanisms must be implemented at multiple stages of the RAG system's development and deployment. Specifically, RAG systems should incorporate bias auditing practices to identify potential biases in the external datasets used for retrieval. This includes regular audits of the data sources to ensure they are inclusive and reflect a broad range of patient demographics and clinical scenarios [12,50]. Additionally, techniques such as fairness-aware machine learning and adversarial debiasing can be employed to reduce the impact of bias in the model's generated recommendations. By continuously monitoring and correcting for bias, health care organizations can help ensure that RAG systems provide fair and equitable information support for all patients [43].

Explainable AI and Transparent Decision-Making

Building on the transparency challenges identified earlier, explainable AI techniques should be integrated into RAG systems to enhance transparency and help nurses and clinicians trust the information these systems produce. By improving the explainability of RAG systems, health care professionals can better assess the basis of AI-generated suggestions and integrate them into their decision-making processes [5].

One effective way to enhance transparency is by incorporating confidence scores and contextual explanations. Confidence scores provide an indication of how certain the system is about a given output, giving clinicians a clearer understanding of the model's reliability [52]. Contextual explanations, on the other hand, help clarify the basis for a given response by linking it to relevant patient data or clinical guidelines. For instance, a RAG system might explain that a particular medication recommendation is based on the patient's medical history, current health status, and recent clinical studies [18]. This additional layer of information will not only improve trust in the system but also empower nurses to make informed decisions based on AI recommendations [47].

Operationalizing Human Oversight and Collaborative Intelligence

Extending the discussion of accountability from the *Responsibility, Accountability, and Human Oversight* section, it is crucial to emphasize the role of human-in-the-loop oversight. RAG systems should not replace human judgment but rather augment it. Nurses, doctors, and other health care professionals should remain central to the decision-making process, with RAG systems serving as assistive tools to support clinical judgment rather than a substitute for clinical expertise [9,19,26].

To ensure the effectiveness of human-AI collaboration, health care organizations should establish clear guidelines for collaborative intelligence. This includes defining roles and responsibilities for both human and AI components of the decision-making process. Nurses and clinicians should be trained to understand the strengths and limitations of RAG systems and to intervene when they believe the AI-generated recommendation is not appropriate for the patient's context [6,37,53]. In addition, RAG systems should be designed to provide options for clinicians to modify or override system-generated outputs when necessary, allowing for greater flexibility and ensuring that human expertise is always part of the decision-making process [19,54,55].

Continuous Monitoring and Evaluation

To ensure the ongoing effectiveness and ethical integrity of RAG systems, continuous monitoring and evaluation are essential. After RAG systems are deployed in clinical practice, they must be regularly assessed for both technical accuracy and ethical impact. This process should include performance audits,

XSL•FO
RenderX

where the system's outputs and their clinical relevance are evaluated against real-world data. Continuous monitoring should also include version control and scheduled updates of external data sources to prevent outdated or inconsistent information from influencing clinical recommendations [56].

Moreover, it is equally important to assess the ethical implications of RAG systems over time. This involves gathering feedback from health care professionals who use the system, as well as patients who are impacted by the decisions. Implementing a structured feedback mechanism is critical to identify potential ethical risks such as new biases, privacy concerns, or trust issues that may arise after the model has been in use for some time [6,57]. By continuously monitoring the performance and ethical consequences of RAG systems, health care organizations can make necessary adjustments to ensure that these systems remain aligned with ethical standards and improve patient care without causing harm.

Conclusion

RAG systems have the potential to significantly enhance nursing practice by providing accurate, context-aware, and timely information support for clinical decisions. By integrating external knowledge sources into clinical reasoning, RAG can improve patient outcomes, particularly in high-pressure environments where rapid, evidence-based decisions are crucial. However, as with any emerging technology, the deployment of RAG systems in clinical settings must be approached with caution, taking into account both the opportunities and the ethical risks they introduce.

The ethical challenges associated with RAG, including issues of accuracy, fairness, transparency, explainability, accountability, and human oversight, must be proactively addressed to ensure that these systems are used responsibly. By implementing robust data governance, ensuring the explainability of AI recommendations, maintaining human-in-the-loop oversight, and continuously monitoring the model's performance and ethical impact, health care organizations can harness the benefits of RAG while minimizing the potential risks.

Ultimately, responsible RAG implementation will require collaboration between health care professionals, AI developers, and policymakers. By prioritizing ethical considerations in the deployment of RAG systems, we can ensure that they support patient safety, reduce health care disparities, and contribute to the overall improvement of nursing practice. Through careful, responsible integration, RAG systems have the potential to transform the future of clinical decision-making and enhance the quality of care delivered to patients worldwide.

Acknowledgments

This paper was language-polished using the generative artificial intelligence (AI) tool ChatGPT by OpenAI. The authors carefully reviewed and revised all AI-generated suggestions to ensure accuracy, clarity, and academic integrity. The authors take full responsibility for the content.

Funding

The authors declare that no financial support was received for the research, authorship, and/or publication of this article.

Authors' Contributions

XT conceived the topic, outlined the article, and contributed to the manuscript's drafting and writing. CS refined the outline and contributed to the manuscript writing. PQ contributed to the manuscript writing. LW provided revisions and guidance as corresponding author and supervisor. All authors contributed to the study's preparation and approved the final version of the manuscript.

Abstract

We used the free artificial intelligence (AI) tool Google NotebookLM, powered by the large language model Gemini 2.0, to construct a medical decision-making aid for diagnosing and managing airway diseases and subsequently evaluated its functionality and performance in a clinical workflow. After feeding this tool with relevant published clinical guidelines for these diseases, we evaluated the feasibility of the system regarding its behavior, ability, and potential, and we created simulated cases and used the system to solve associated medical problems. The test and simulation questions were designed by a pulmonologist, and the appropriateness (focusing on accuracy and completeness) of AI responses was judged by 3 pulmonologists independently. The system was then deployed in an emergency department setting, where it was tested by medical staff (n=20) to assess how it affected the process of clinical consultation. Test opinions were collected through a questionnaire. Most (56/84, 67%) of the specialists' ratings regarding AI responses were above average. The interrater reliability was moderate for accuracy (intraclass correlation coefficient=0.612; *P*<.001) and good on completeness (intraclass correlation coefficient=0.773; *P*<.001). When deployed in an emergency department (ED) setting, this system could respond with reasonable answers, enhance the literacy of personnel about these diseases. The potential to save the time spent in consultation did not reach statistical significance (Kolmogorov-Smirnov [K-S] D=0.223, *P*=.24) across all participants, but it indicated a favorable outcome when we analyzed only physicians' responses. We concluded that this system is customizable, cost efficient, and accessible to clinicians and allied health care professionals without any computer coding experience in treating airway diseases. It provides convincing guideline-based recommendations, increases the staff's medical literacy, and potentially saves physicians' time spent on consultation. This system warrants further evaluation in other medical disciplines and health care environments.

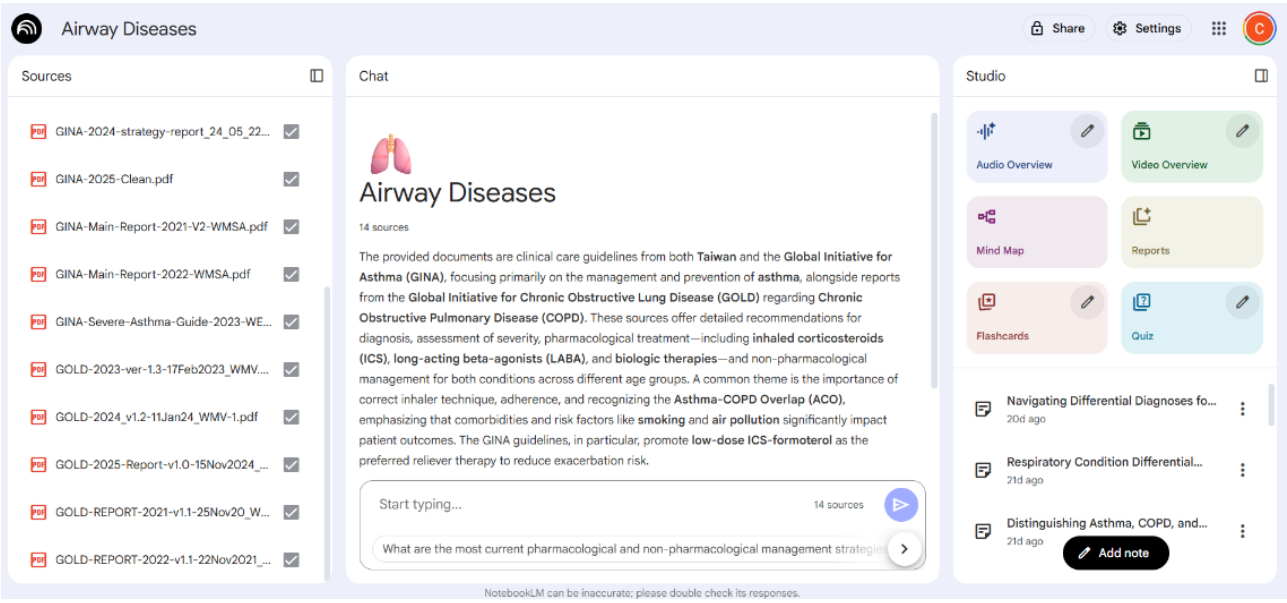
Introduction

Expert Systems and the Decision-Making Aids

An expert system is a knowledge management tool that integrates domain-specific information with an inference engine to facilitate decision-making. When consulted, it delivers timely and relevant solutions to a problem. This concept originated in the 1950s, with medical diagnostic reasoning being among its earliest applications [1,2]. Gradually, expert systems became popular in the 1970s and 1980s [3]. With the advent of the digital era, the concept of expert systems was revisited by the medical community. For instance, oncology, given its rapid evolution and growth in knowledge over the past 2 decades, has required consultation systems to aid patient management.

Knowledge Management and the Large Language Model



Large language models (LLMs) represent a branch of machine learning that has been under development for several years. Their impact became widely recognized on November 30, 2022, when OpenAI released ChatGPT, a free web-based service [4,5]. This milestone illustrated the potential of LLMs to advance toward general purpose artificial intelligence (AI) by enabling natural language–based dialogue. The continuously expanding medical knowledge has traditionally been managed through structured data storage, indexing, and query mechanisms [6] or probabilistic inference algorithms [7]. However, these conventional clinical decision support systems struggle to incorporate new information and adapt to complex clinical contexts [8]. Unlike these approaches, LLM-driven systems enable interaction in natural language, offering a more user-friendly and adaptable knowledge management tool. Such systems can be easily deployed across health care teams, including physicians and allied health care professionals. In this study, we devised a model to understand how this new LLM-based methodology could affect medical decision-making and routine clinical workflow. The process of our project and our key findings were described as follows.

Decision-Making Aid Construction and Assessment

Constructing an Expert System With a Free AI Tool Based on LLM

The free AI tool Google NotebookLM, powered by the LLM Gemini 2.0 [9], provides a platform for knowledge integration through 3 components: a source input pane, a query pane, and a note-taking pane, which function collaboratively (Figure 1). We used this platform to develop a medical decision support system for airway diseases. Relevant published clinical guidelines were uploaded into the source input pane, including the GINA (Global Initiative for Asthma) guideline [10] and the GOLD (Global Initiative for Chronic Obstructive Lung Disease) guideline [11] (version 2021-2025). Additional standard documents from the Taiwan Society of Pulmonary and Critical Care Medicine [12], such as the Taiwan asthma guidelines and the pulmonary rehabilitation guidelines, were also incorporated. The responses of the system to queries were then recorded.

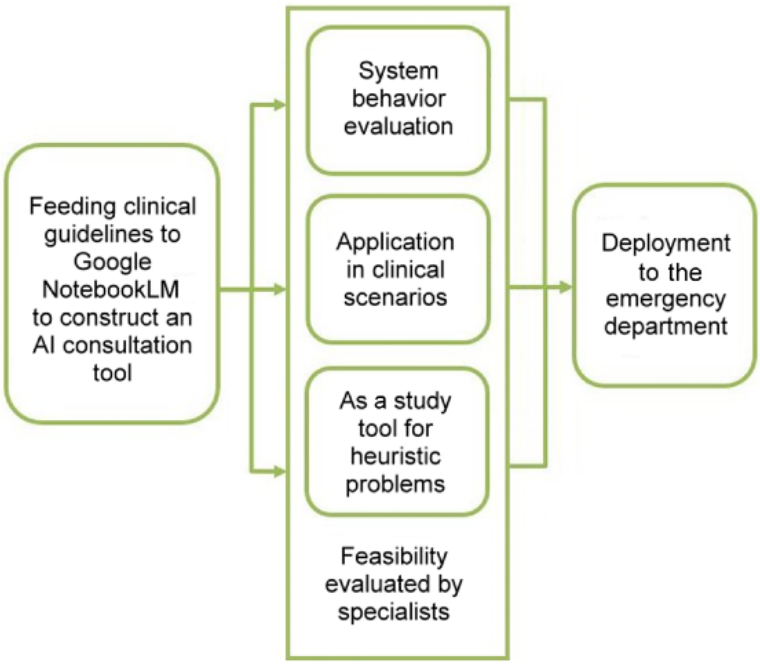
Figure 1. The Google NotebookLM interface.

Feasibility Evaluated by Pulmonologists

Query questions were selected to match the essential requirements of eligible AI tools, such as reproducibility, the ability to develop a treatment plan, and the capacity to handle speculative ideas. They were designed by a pulmonologist with expertise in airway diseases and familiarity with these guidelines, and the appropriateness (focusing on accuracy and completeness) of AI responses was judged (Likert scale 1-5) by 3 pulmonologists independently. Airway diseases were selected as the pilot scenario to evaluate the feasibility of our system because standardized clinical guidelines are widely accepted, and they involve fewer complex and controversial data points than other conditions, such as oncological diseases.

Implementation in the Clinical Workflow

The system was introduced to physicians and allied health care professionals in the emergency department (ED), where patients



XSL•FO
RenderX

with airway diseases commonly present for treatment. Feedback was collected through a questionnaire, and the responses were analyzed to assess the system's effectiveness within the clinical workflow.

The ED setting was chosen because clinicians frequently encounter diverse conditions and require rapid access to specialist knowledge. In this context, an expert system capable of answering clinical queries has the potential to reduce the time burden on patients, frontline clinicians, and the specialists consulted.

The complete workflow of the project is summarized in Figure 2.

Figure 2. Flowchart illustrating the process of constructing our artificial intelligence (AI)–based consultation tool for medical decision-making.

AI Responses to Queries

System Behavior Evaluation

Test 1: Reproducibility

The system consistently generated accurate summaries and responses, each supported by appropriate and reliable references. When prompted to regenerate output from the same sources, this system produced slightly varied responses that retained identical meaning, resembling the variability typically observed in an AI chatbot interaction.

Test 2: Knowledge Consolidation

The asthma and chronic obstructive pulmonary disease (COPD) guidelines contained respective lists of differential diagnoses. When instructed to generate a consolidated table of differential diagnoses for airway diseases, including their distinguishing features and relevant diagnostic tests, the system successfully produced one, as shown in Table 1.

XSL•FO
RenderX

Table 1. Summary of the differential diagnoses for asthma, chronic obstructive pulmonary disease (COPD), and related conditions, including distinguishing symptoms, clinical features, and tests. Full version available in Multimedia Appendix 1.

Condition	Primary differential for	Differentiating symptoms and features	Differentiating tests and findings
Inducible laryngeal obstruction or vocal cord dysfunction	Both asthma and COPD	Dyspnea and inspiratory wheezing (stridor), sometimes with cough and general wheeze	Functional laryngoscopy visualizing vocal cord movement; full flow-volume curve assessing upper airway obstruction
Obesity	Both asthma and COPD	Respiratory symptoms, such as dyspnea and wheeze, that can mimic asthma or COPD, often related to deconditioning or mechanical restriction	Objective measurement of variable expiratory airflow limitation to confirm asthma in obese patients
Tracheobronchomalacia	Both asthma and COPD	Wheeze	Bronchoscopy; high-resolution chest computed tomography scan
Lung cancer	Both asthma and COPD (more common in COPD)	Breathlessness, significant weight loss, hemoptysis, night sweats, and fever	Chest radiograph or computed tomography scan; reduced diffusing capacity for carbon monoxide may be present
Alpha-1 antitrypsin deficiency	Both asthma and COPD (more commonly associated with COPD)	Shortness of breath, with a family history of early-onset emphysema	Blood test confirming alpha-1 antitrypsin deficiency
Tuberculosis	Both asthma and COPD (especially in low- and middle-income countries)	Chronic cough, hemoptysis, dyspnea and/or fatigue, fever, night sweats, anorexia, and weight loss	Sputum induction (to confirm inflammatory phenotype); high-resolution computed tomography of the chest

Test 3: Temporal Order Recognition

The system demonstrated the ability to recognize temporal updates. For instance, it correctly identified that the “ABCD assessment tool” for COPD was replaced by the “ABE assessment scheme” in the 2023 update of the GOLD COPD guideline [11]. When asked to provide treatment recommendations, the system appropriately referred to the most recent guideline version while disregarding outdated ones, as shown in Textbox 1.

Textbox 1. The chronic obstructive pulmonary disease (COPD) grouping follows the most recent version of the clinical guidelines. For full details, refer to Multimedia Appendix 2.

Question

A COPD patient with mMRC=2 and CAT=11, and a history of hospitalization once in the past 1 year. What is his/her treatment suggestion?

Answer

...

3. GOLD Group Classification:

Combining a high symptom burden (mMRC=2, CAT=11) with a high exacerbation risk (one hospitalization), this patient is classified as GOLD Group E [GOLD 2023, p. 40, Figure 2.4; GOLD 2024, p. 29, Figure 2.5; GOLD 2025, p. 38, Figure 2.5]. This classification guides therapeutic recommendations [GOLD 2023, p. 40; GOLD 2024, p. 29; GOLD 2025, p. 38]...

Test 4: Memory Flush

When the COPD guidelines from 2023 onward were deselected from the source input panel, the system could still respond to questions about “ABE assessment” using information retained from previous dialogues, provided those dialogues had not been deleted using the Refresh button (Textbox 2). Interestingly, if the dialogues were deleted and no clues regarding the 2023 update were supplied, the system concluded that “ABE” might be a typographic error for “ABCD” (Textbox 3) or “creatively“ suggested that “B” referred to blood eosinophil count (Textbox 4). This indicates that the AI tool retains dialogue content until it is deliberately erased using the Refresh button.

XSL•FO
RenderX

Textbox 2. The system could respond using information from prior dialogues until those dialogues were removed using the Refresh button.

Question

What is the ABE assessment tool?

Answer

The provided 2021 and 2022 reports do not contain information about merging groups C and D into a single "E" group, nor do they refer to an "ABE" assessment tool. This suggests that the change to the ABE classification, if it occurred, was introduced in a subsequent GOLD report (e.g., the GOLD 2023 report as mentioned in our previous conversation).

Textbox 3. A system response after a memory flush.

Question

Explain the ABE assessment tool for COPD.

Answer

The sources provided do not contain information on an "ABE assessment tool" for COPD. However, they extensively describe the "ABCD" assessment tool used in the Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines for COPD management. It is possible that "ABE" in your query was a typographical error for "ABCD" or refers to a concept not detailed in these documents.

Textbox 4. A creative response after a memory flush.

Question

Explain the ABE assessment tool for COPD.

Answer

While the provided sources do not explicitly define or refer to an "ABE assessment tool" as a named entity for evaluating COPD, they do describe a framework for the initiation of pharmacological management that relies on assessing factors commonly associated with "A" (Symptoms), "B" (Blood Eosinophil Count), and "E" (Exacerbation Risk).

Test 5: Handling Multiple Languages

Leveraging Google's multilingual capability, the system could accept a query in Chinese and respond in either English or Chinese. When asked to compare the 2022 Taiwan adult asthma clinical care guidelines, written entirely in Chinese, with the GINA guideline, the system managed to perform the task without difficulty. Language switching did not appear to affect system performance.

Application in Clinical Scenarios

Scenario 1: Requesting Patient Management Suggestions Based on a Simulated Medical Record

As illustrated in Textbox 5, the system generated guideline-based recommendations that were clinically useful.

Textbox 5. Helpful recommendations generated by the system, supported by guideline-based reasoning. For a complete explanation, refer to Multimedia Appendix 3.

Question

I have a patient diagnosed of COPD adequately maintained with Pulmicort, 2 puffs bid. However, he suffered from more and more dyspnea while walking. What is the management suggestion?

Answer

Based on the information in the sources, here are some management suggestions for your patient with COPD who is experiencing increasing dyspnea on walking despite being maintained on Pulmicort (an inhaled corticosteroid - ICS):

1. Consider adding a long-acting bronchodilator...
2. Consider a combination inhaler containing ICS and LABA...
3. Optimize inhaled therapy. Ensure that the patient...
4. Consider pulmonary rehabilitation...
5. Reassess lung function and consider other diagnoses...
6. Review for modifiable risk factors...
7. Consider stepping up ICS dose (with caution)...
8. Assess for features of asthma-COPD overlap (ACO)...
9. Follow-up and reassess...

XSL•FO
RenderX

Scenario 2: Logical Question

The system addressed a logical question regarding the unavailability of pulmonary function testing by providing a structured, entry-by-entry response. It explained the implications separately for COPD and asthma, as shown in Textbox 6.

Textbox 6. The system presented a comparative response for chronic obstructive pulmonary disease (COPD) and asthma. For the complete answer, refer to Multimedia Appendix 4.

Question

Is pulmonary function test necessary for diagnosis? What if there is no pulmonary function test accessible?

Answer

Here's how pulmonary function tests relate to diagnosing airway diseases, and what to do if these tests aren't accessible:

- COPD Diagnosis: Spirometry is essential to confirm a COPD diagnosis...
- Asthma Diagnosis: Asthma diagnosis relies on a combination of characteristic symptom patterns and evidence of variable expiratory airflow limitation...
- Role of Lung Function Testing: Lung function testing is essential to confirm...
- Spirometry: Forced spirometry is the most reproducible and objective measurement of airflow obstruction. It measures...
- When Spirometry Isn't Available for Asthma Diagnosis:
  - Peak expiratory flow (PEF) can be used, although it is less reliable...
  - Assess the patient for a characteristic pattern of respiratory symptoms.
  - Consider a therapeutic trial with SABA and low-dose ICS...
  - Confirm variable expiratory airflow limitation by PEF. A ≥20% improvement in PEF...
  - Improvement in symptoms and PEF after a 4-week therapeutic trial...
- When Spirometry Isn't Available for COPD Diagnosis: When routine spirometry is not available, home measurement of peak expiratory flow (PEF) combined with validated patient questionnaires could be used to support or refute a possible diagnosis of COPD...

Scenario 3: Personalized Rehabilitation Planning

The system generated a tailored rehabilitation plan and schedule that took into account an advanced age condition, as shown in Textbox 7.

XSL•FO
RenderX

Textbox 7. The system produced a detailed, individualized rehabilitation plan for an extremely older adult patient with chronic obstructive pulmonary disease (COPD) and ischemic heart disease. The complete plan is available in Multimedia Appendix 5.

Question

I have a female patient, age 95, with COPD and ischemic heart disease. Please make a rehabilitation plan and schedule for her.

Answer

For your 95-year-old female patient with COPD and ischemic heart disease, a highly individualized, comprehensive, and carefully supervised rehabilitation plan is crucial, taking into accounts her advanced age and multiple comorbidities. This plan draws primarily from the Taiwan Pulmonary Rehabilitation Practical Guideline and the Global Initiative for Chronic Obstructive Lung Disease (GOLD) reports.

I. Overall Approach and Guiding Principles

1. Personalized and Integrated Care:...
2. Specialist Supervision:...
3. Holistic Goals:...

II. Initial Comprehensive Assessment

...

V. Follow-up and Monitoring

- Regular Review:...
- Response Assessment:...

...

Scenario 4: Vague Question

In this case, the system transformed the ambiguous concept of “prospect” into practical categories of “future challenges” and “research directions.” This approach provided a meaningful response, as illustrated in Textbox 8.

XSL•FO
RenderX

Textbox 8. The system interpreted the vague query as a request for practical insights. The complete answer is provided in Multimedia Appendix 6.

Question

What is the future prospect of airway diseases and their treatment?

Answer

The sources discuss future challenges and research directions for airway diseases such as asthma and Chronic Obstructive Pulmonary Disease (COPD).

Asthma:

- Despite improvements in asthma care and effective medications, many patients worldwide do not benefit from these advances due to inadequate medical facilities and financial resources.
- Future research should focus on clinical and physiological characteristics, biomarkers, outcomes, and underlying mechanisms in patients with respiratory symptoms or chronic airflow limitation...

COPD:

- More research is needed to guide better recognition and safe, effective treatment of COPD.
- There's a need to study clinical and physiological characteristics, biomarkers, outcomes and underlying mechanisms in broad populations of patients with respiratory symptoms or with chronic airflow limitation.
- Future studies should focus on defining phenotypes and mechanisms to ensure the safety of pharmacological treatments...

Scenario 5: Out-of-Scope Questions

The system appropriately declined to answer questions that were beyond the scope of the available sources. It did not fabricate factitious responses, unlike many chatbots.

As a Study Tool for Heuristic Problems

Problem 1: Version Comparison and Trend Analysis

When asked to compare guideline versions across publication years, the system clearly outlined the differences between them. Additionally, when requested to analyze trends in pharmacological use for airway diseases over the past 5 years, it generated a comprehensive summary, as shown in Textbox 9.

XSL•FO
RenderX

Textbox 9. The system analyzed the trend in pharmacological use for airway diseases across the years. A complete list is available in Multimedia Appendix 7.

Question

Find the trend in pharmacological use for COPD and asthma in the past 5 years.

Answer

In the past five years, pharmacological treatment for both Chronic Obstructive Pulmonary Disease (COPD) and asthma has seen a clear trend towards more individualized, exacerbation-focused, and strategically combined therapies, with a strong emphasis on proper inhaler use and minimizing oral corticosteroid exposure.

Overarching Trends for Both COPD and Asthma (Past 5 Years)

1. Individualized and Patient-Centered Care:...
2. Focus on Exacerbation Reduction:...
3. Emphasis on Inhaler Technique and Adherence:...
4. Minimizing Oral Corticosteroid (OCS) Use:...

Trends in COPD Pharmacological Treatment (Past 5 Years): The GOLD reports (2021, 2022, 2023, 2024, 2025) and the 2023 Taiwan COPD Clinical Care Guidelines emphasize these trends:

1. Long-Acting Bronchodilators (LABA and/or LAMA) as First-Line:...
2. Strategic Use of Inhaled Corticosteroids (ICS):...
3. Increasing Role of Triple Therapy (LABA+LAMA+ICS):...

...

Trends in Asthma Pharmacological Treatment (Past 5 Years): GINA reports (2021, 2022, 2023, 2024, 2025) and the 2022 Taiwan Adult Asthma Clinical Care Guidelines highlight significant shifts:

1. Shift Away from SABA Monotherapy:...
2. Introduction of Two Treatment Tracks (GINA):...
3. ICS as the Cornerstone of Controller Therapy:...

...

Problem 2: Further Reading Suggestions

When asked to recommend additional readings on intractable asthma, the system searched both the source text and the reference lists it contained. However, it did not suggest any external articles or books. Notably, the system interpreted the term “intractable asthma” as both “severe asthma” and “difficult-to-treat asthma” to ensure comprehensive coverage, as shown in Textbox 10.

XSL•FO
RenderX

Textbox 10. Suggested further reading items provided by the system. For the complete list, refer to Multimedia Appendix 8.

Question

Can you suggest any further readings about the treatment for intractable asthma?

Answer

For further readings about the treatment of intractable asthma, which is often referred to in the sources as severe asthma or difficult-to-treat asthma, you may find the following publications insightful. These sources provide detailed information on diagnosis, management, and treatment options for patients whose asthma remains uncontrolled despite standard therapies:

Comprehensive Guidelines and Reviews:

- Global Strategy for Asthma Management and Prevention (GINA): The GINA reports are frequently referenced for their comprehensive guidance on asthma management. Specifically, the sections within these reports on "Difficult-to-treat and severe asthma" provide a roadmap for assessment and management. You can refer to the detailed sections in the provided GINA reports, such as:
    - GINA-2023-Report:...
    - GINA-2024-strategy-report:...
    - GINA-2025-Clean:...

...Pharmacological Interventions:

- Biologic Therapies:
    - EAACI Biologicals Guidelines-Recommendations for severe asthma: Agache I et al. offer guidelines and recommendations for biologics in severe asthma.
    - Tezepelumab:...

...

- Add-on treatments (nonbiologic):
    - Tiotropium:...
    - Azithromycin:...
    - Oral Corticosteroids (OCS):...

Diagnostic and Management Strategies:

- Sputum-guided treatment...
- Bronchial Thermoplasty:...
- Importance of Adherence and Inhaler Technique:...

These readings should provide a comprehensive overview of the current understanding and treatment approaches for intractable asthma.

Problem 3: Speculative Question

We designed a question regarding the interchangeability of questionnaires used for evaluating COPD and asthma. Our system provided a reasonable response, as shown in Textbox 11.

Textbox 11. The system addressed this speculative question and provided a supporting rationale.

Question

Can we evaluate asthmatic patients with questionnaires designed for COPD? Can we evaluate COPD patients with questionnaires designed for asthma?

Answer

Asthma and COPD can be difficult to distinguish, especially in older patients and smokers, and these conditions may overlap. Some patients are assigned both diagnoses. While some questionnaires might capture general respiratory symptoms that could be present in both asthma and COPD, it is best to use disease-specific questionnaires to ensure the most appropriate and accurate assessment. There is no evidence that asthma questionnaires can be used for COPD patients, and vice versa.

Problem 4: Diagnostic Skill Training Tool

We instructed the system to generate a simulated case with symptoms and pulmonary function values to test our diagnostic skills. During this exercise, we compared our reasoning and diagnosis with the system's answer to strengthen diagnostic ability, as shown in Textbox 12.

XSL•FO
RenderX

Textbox 12. The system generated a simulated case to facilitate diagnostic training. For the answer, diagnostic rationale, and treatment recommendation, refer to Multimedia Appendix 9.

Question

Please make a case with symptoms and pulmonary function values to test our diagnostic skills.

Answer

Simulated Patient: Mr David Lee

Patient Background: Mr David Lee is a 58-year-old male with a 25 pack-year smoking history, though he states he is currently trying to quit. He reports a chronic cough with some mucus production for the past 8 years. He also experiences intermittent shortness of breath on exertion, particularly when climbing stairs. Lately, he's noticed that his breathing feels tighter in the mornings, and he occasionally hears a whistling sound (wheeze) when breathing out, especially after exposure to cold air. These wheezing episodes are variable in intensity, and he notes that his symptoms sometimes improve with a relative's "asthma inhaler" (a short-acting beta2-agonist, SABA).

Symptoms:

- Chronic cough with mucus production (8 years duration).
- Intermittent dyspnea on exertion (eg, climbing stairs).
- Morning chest tightness.
- Occasional expiratory wheezing, variable in intensity, exacerbated by cold air.
- Reports temporary improvement with SABA.
- Significant smoking history (25 pack-years).

Pulmonary Function Values:

- Pre-Bronchodilator Spirometry:
  - Forced Expiratory Volume in 1 second (FEV1): 60% of predicted
  - Forced Vital Capacity: 80% of predicted
  - FEV1/Forced Vital Capacity Ratio: 65% (indicating airflow limitation)
- Post-Bronchodilator Spirometry (after administering 400 mcg of salbutamol, a SABA):...

Diagnosis, Reasons, and Treatment Suggestion for Mr David Lee

...

Pulmonologists' Judgment on AI Responses to Queries

Most of the 3 pulmonologists' ratings (56/84, 67%) regarding AI responses were above average (Likert scale 4-5), and only 5% (4/84) were below average (Likert scale 1-2). The interrater reliability was moderate for accuracy (intraclass correlation coefficient=0.612; P<.001) and good for completeness (intraclass correlation coefficient=0.773; P<.001) based on a 2-way random-effects model with absolute agreement and single measures options [13]. We also noted that AI responses received more (187/333, 56%) credits from the raters for query questions that required more intelligence (adaptation, deduction, analysis, and planning) to answer, such as scenarios 1 to 3 and problems 1 to 4, than for the other questions. This finding further supports the feasibility of our system.

Responses From the Field Tests in the ED

We collected responses from 20 participants, including 3 physicians, 3 nurse practitioners, 11 ED nurses, and 3 respiratory therapists. Among them, 80% (16/20) expressed interest in the system (Kolmogorov-Smirnov [K-S] D=0.362; P=.008; indicating a deviation from normality). All these participants had prior experience consulting a chatbot. In total, 60% (12/20) of the participants were aware of and ever disturbed by the issue of AI hallucination (K-S D=0.238; P=.18; indicating a normal distribution). All participants in this group thought that guideline-based reasoning provided by the system was essential in clinical practice.

In total, 55% (11/20) of the participants believed that the system could reduce specialty consultation time (K-S D=0.223; P=.24; indicating a normal distribution). Importantly, all participants indicated that the system could enhance their knowledge and diagnostic ability in airway diseases or increase their confidence in explaining conditions to patients.

Discussion

Statistical Findings

Previous studies on LLM-based medical decision support have reported various outcomes [14,15]. These discrepancies may reflect differences in participants' expertise, the difficulty of test questions, and the dimensions measured in study designs. In our evaluation of consultation time, the K-S test indicated a normal distribution of responses. When analyzing only physicians' responses, we observed a trend toward favorable

XSL•FO
RenderX

outcomes, although this did not reach statistical significance (P=.24) across all participants. Thus, the system shows potential for reducing physicians' consultation time, but larger and more comprehensive studies are required to confirm its effectiveness.

What We Expect of a Medical AI Consultation Tool

AI Hallucination and AI Ethics in Medicine

Since the widespread adoption of LLM-based chatbots, users have become increasingly concerned about AI hallucination, that is, plausible but unfounded responses generated without a factual basis. Such errors are unacceptable in medical practice. Amiot and Potier [16] recently emphasized that hallucination is particularly difficult to detect in a health care context. Fortunately, the design of the Google NotebookLM platform mitigates this risk by providing answers supported by explicit references to authoritative sources. With such verifiable citations, concerns about errors, biases, ethics, and safety from autonomous AI actions are substantially reduced.

Beyond a Decision-Making Aid

The project aims to provide a clinical decision-making aid for the diagnosis and management of airway diseases and to assess how this AI tool affected medical staff in the ED during the consultation process. As Wang et al [17] noted, an AI system could uncover subtle relationships in medical data that may elude both traditional decision support tools and human experts. During system development, pulmonologists found that the tool not only consolidated their expertise but also offered novel insights and opportunities to explore speculative ideas, as described in test problems 1 and 3. For medical trainees, the system functions as an effective educational tool, providing not only suggestions but also the underlying reasons.

Limitations Inherent to LLMs

Scope of External Knowledge Considered

NotebookLM generates content strictly from user-provided sources. Because general "common sense" information is often absent from "specialized" clinical guidelines, excluding external knowledge can considerably limit the scope of the system's responses. Moreover, the extent to which external information is incorporated into outputs is undisclosed and therefore unpredictable.

Inability to Pose Differentiating Questions

LLM-based systems generate responses in the form of summaries or abstracts but do not query users. However, accurate clinical decision-making often requires additional patient-specific data obtained through differentiating questions. For example, clarifying whether a patient is a smoker or a nonsmoker or identifying ethnic background (Asian or White) may guide diagnostic pathways. If the system could formulate such discriminative questions and allow users to provide input—ideally guided by Bayesian theorem [18]—its clinical utility would be markedly enhanced. We did not observe this feature in the current implementation.

Future Directions

Once the pilot project is fully operational, the expert system can be refined along several pathways. First, the system should adapt its responses to the user's professional role. For example, when handling a consultation request, it should provide only essential surgical information to an internist while delivering more comprehensive surgical details to a surgeon.

Second, although our study focused on airway diseases and the system demonstrated generally positive performance, its generalizability to other specialties remains uncertain. Disciplines such as oncology, where problems are more complex and controversies are common, may present challenges. Further research is required to determine whether the model can provide reliable and clinically meaningful output in these domains.

Finally, because decision-making, studying, and education are central components of our medical practice routines, integrating such a system into the existing health care information systems presents a logical next step. We expect that this integration could streamline clinical workflows and improve automation across multiple aspects of care delivery.

Conclusions

Our findings suggest that this approach is highly customizable, cost efficient, and accessible to clinicians and allied health care professionals without any computer coding experience in managing airway diseases. It provides convincing guideline-based recommendations, increases the staff's medical literacy, and potentially saves physicians' time spent on consultation. As AI tools gain widespread adoption, we believe that, if validated across additional medical specialties, this methodology could establish a new paradigm in clinical practice. While acknowledging the potential of AI, we emphasize the continued need for human judgment and oversight in evaluating and applying AI-generated recommendations.

Acknowledgments

The authors would like to thank their colleagues Dr Jer-Hwa Chang, Dr Ming-Cheng Wang, Dr Chien-Yeh Chin, Dr Chung-Hui Tang, Dr Tung-Wu Lin, Yung-Chieh Chiu, Feng-Ling Huang, Yu-Ting Su, Tsai-Chi Chen, Yuan-Hsiang Hsieh, Chi-Wen Feng, Syuan-Wen Lai, Yu-Hsiu Liu, Yi-Chen Chiang, Bing-Hua Wu, Ju-Chuan Hsu, Yu-Ping Lin, Cheng-Yang Tu, Pei-Yi Kuo, Chi-Hsin Chang-Chien, Li-Chun Chang, and Pei-Chen Hsieh for their valuable opinions during the evaluation process. We would like to extend our special thanks to Google for providing its free AI tool, NotebookLM [9], which served as the platform for our discussions.

Abstract

Background: Clinical decision support systems (CDSSs) have shown promise in improving diagnosis in primary care, particularly for chronic diseases. The SATURN (Smart Physician Portal for Patients With Unclear Disease) project developed a CDSS prototype for primary care in Germany that uses artificial intelligence to reduce diagnostic uncertainty in unclear and rare diseases. It generates recommendations based on clinical data from university hospitals stored in a standardized common data model. However, integrating primary care data in Germany remains challenging due to the use of country-specific vocabularies and heterogeneous data structures. Therefore, integration of medical concepts into general practitioners' user interfaces (UIs) and improved workflow design is needed.

Objective: This study investigates how the UI of a CDSS for primary care should be designed to facilitate the user-friendly entry of medical concepts.

Methods: A structured, iterative user-centered design process of five steps was applied: (1) conceptualization, including analysis of requirements and objectives, (2) implementation of the CDSS UI, (3) analysis of user and expert feedback, (4) workshop with experts in the primary care electronic health record system, and (5) development of an extended concept for the system UI.

Results: This study identified requirements and options for supporting data entry in the UI of a CDSS for primary care, thus providing a framework for future implementation and prototype development. Usability testing revealed the need to refine input support, particularly the language used to make the system easy for general practitioners to use. Further effort is required to map this. In addition, we have identified a system interface to electronic patient records in primary care as essential for the system.

Conclusions: This paper demonstrates how standardized medical terminologies can be integrated into a CDSS UI for primary care. The user-centered design approach has been effective in developing CDSS UIs that align with clinicians' workflows and provide a user-friendly experience. Although the current technical infrastructure presents significant challenges when connecting to primary care electronic health record systems, collaborating with experts enabled us to identify potential interface solutions. Overall, the results indicate a need for optimized physician language input support and interoperability, including standardized data entry, automated tools, and artificial intelligence–based approaches to enhance data quality and usability.

Introduction

Background and Significance

The use of clinical decision support systems (CDSSs) has been demonstrated to enhance diagnostic accuracy in primary care settings [1,2]. However, the prevailing focus at present is on chronic diseases [1]. In primary care, general practitioners (GPs) play a unique role in the diagnostic and referral processes. They often deal with nonspecific symptoms that may indicate a wide range of potential diagnoses, leading to diagnostic uncertainty. It is therefore essential to provide GPs with adequate support to ensure patient care [3-5]. Although the potential of CDSSs to achieve significant improvements in outcomes has been demonstrated, wide variations remain in the types and methods of CDSS implementation as well as the resulting effectiveness. Further research is required to determine effective implementation strategies for the usage of CDSS in various settings [6].

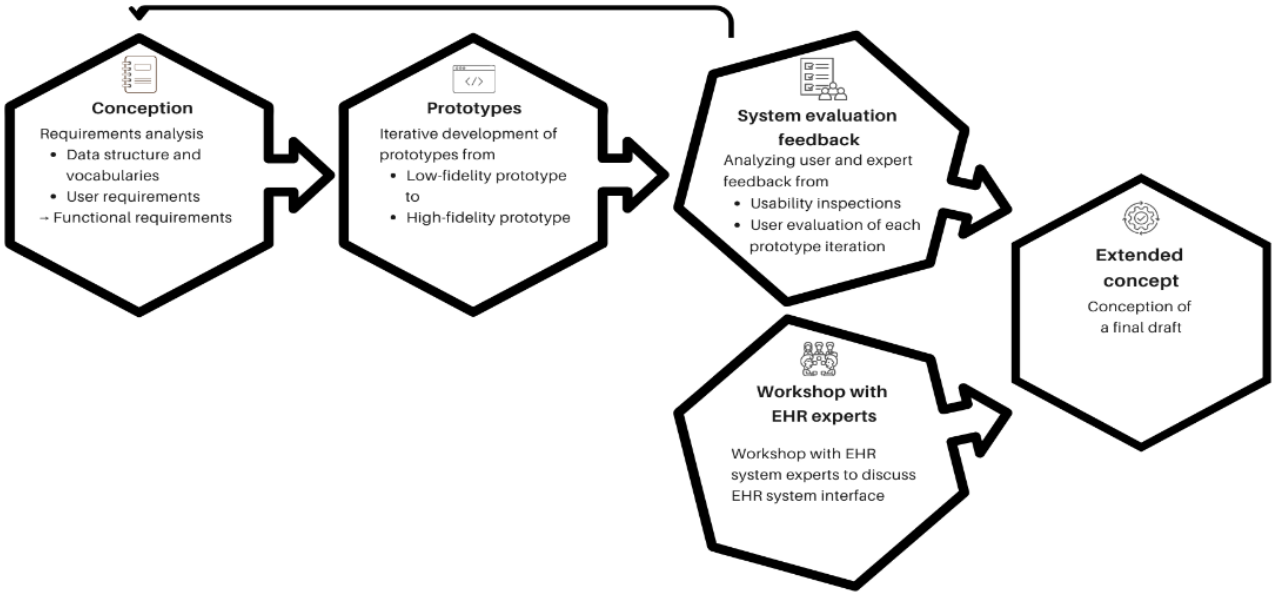
The SATURN (Smart Physician Portal for Patients With Unclear Disease) project has developed a prototype of a CDSS to address unclear diagnoses in primary care in Germany [7,8]. The development was conducted through an iterative, user-centered development process (UCD) [8]. The CDSS generates recommendations for GPs using 3 artificial intelligence (AI) modules based on clinical data (a machine learning algorithm and a case-based reasoning algorithm) and expert knowledge (a rule-based system). Clinical databases (rather than primary care databases) were used to establish connections between GPs and the knowledge data held by the university medicine. The diagnostic recommendations derived from clinical data are based on comparisons with existing cases [7,8]. Specifically, the data for these existing cases were extracted from the electronic health record (EHR) data of the University Hospitals in Frankfurt and Dresden via Data Integration Centers (DICs). The DIC is a central institution responsible for making medical data from hospital patient care accessible for medical research and clinical exchange in a structured, standardized, and pseudonymized form [9]. The CDSS database has been designed in such a way that EHR data from the 2 hospitals are merged into 1 OMOP database and can be used for the AI modules. Only data, not AI logic, is stored in the database. The AI modules are designed as separate modules.

The OMOP Common Data Model (CDM) is an open-access standardized data model [10] that can be used to ensure interoperability. The OMOP CDM harmonizes medical databases through a uniform structure and standardized terminologies such as SNOMED CT (Systematized Nomenclature of Medicine Clinical Terms) and RxNorm (normalized names for clinical drugs) [10-12]. New EHR patient cases from primary care for which a diagnosis recommendation is to be made will also be stored in this database, along with corresponding flags (flag: without diagnosis). In addition, solved patient cases are stored (flag: with final diagnosis). As the CDSS uses OMOP and is used in primary care, the data entered by primary care GPs must be compatible with the OMOP vocabulary standards. However, the use of standardized vocabulary remains a challenge, particularly in Germany's primary care sector, where the predominant classification of diseases is *ICD-10-GM* (*International Statistical Classification of Diseases and Related Health Problems, Tenth Revision, German Modification*). *ICD-10-GM* is complemented by OPS (Operation and Procedure Codes; German: "Operationen- und Prozedurenschlüssel") for procedural coding procedures [13], along with "Einheitlicher Bewertungsmaßstab" as the basis for billing GPs and contract psychotherapists [14]. Heterogeneous data structures in different countries and country-specific vocabularies (such as *ICD-10-GM*) pose significant challenges for exchanging data and comparing results. To our knowledge, there has been no full systematic integration of primary care data into the OMOP CDM, to date, in Germany. The standardization of data could facilitate the development of common tools. Initial international approaches have shown potential but are limited in their scope [15,16]. Henke et al [17,18] investigated the merging and collaboration of primary care and clinical data in Germany. These studies linked data from the DICs of the Medical Informatics Initiative with routine health insurance data and aimed to increase the coverage of the German vocabulary in the OMOP CDM. Another study examined the cross-sector linkage of primary care data and identified challenges, including system interfaces and data extraction processes [19]. Such projects show the need for using CDMs, such as the OMOP CDM and standardized vocabularies, to harmonize cross-sector data. To integrate medical concepts into GP user interfaces (UIs), the UI must be designed to support and streamline existing workflows [20]. Medical concepts are coded according to standards for terminology, listed in terminology management or the OMOP vocabularies.

Objectives

The objective of this study is to explore how the UI of a CDSS for primary care should be designed to allow the entry of medical concepts in a user-friendly way. To our knowledge, it has not yet been investigated how a CDSS UI for primary care can be comprehensively mapped to enable the standardized data collection and integration of data in Germany. This study outlines the requirements and the available options for CDSS UI for primary care, providing both a technical overview and a conceptual framework to support future CDSS implementations. The CDSS UI implementation focuses on medical vocabularies and the input into the CDSS. Other components of the CDSS, and the iterative conception and development, are covered in previous publications [8,21,22].

Methods



Study Design

As in the whole SATURN project, an iterative UCD was used [23]. In this paper, we focus on data entry into the CDSS (Figure 1). The requirement analysis and underlying data model [24], the ongoing evaluation, as well as other parts of the CDSS, are described in previous publications [8,21,22,25]. The UCD, from the perspective of data input, began with a conceptual design stage. During this stage, the GPs' requirements and necessary medical concepts were analyzed. These concepts were then coded into vocabularies and mapped to the UI design (step: conception). The UI then underwent iterative development in

XSL•FO
RenderX

dialogue with the GPs (step: prototypes), followed by the collection of feedback from users and experts to evaluate its usability and to identify potential improvements (step: system evaluation feedback). EHR experts discussed the automation of medical concept entry (step: workshop with EHR experts). All participant groups were selected using a purposeful sampling approach. Finally (step: extended concept), a draft for the final design concept was created.

Figure 1. Methodological steps of this study for the development process of the CDSS data entry UI. CDSS: clinical decision support system; EHR: electronic health record; UI: user interface.

Ethical Considerations

For the conception and development of this study, the SATURN project was previously approved by the Ethics Committee of Goethe University's Medical Faculty (case 2022-1088). The user evaluation was also approved, with the Ethics Committee waiving the need for a separate ethics vote on the inquiry of GPs (case 2022-629). All participants received written information on the study and provided a signed informed consent. All data were pseudonymized before analysis. Participants received €150 (average currency exchange rate in August 2023: US $1=€0.92) for taking part in the usability test.

Participants in the usability inspections and the EHR expert workshop were either project participants or had previously submitted a letter of intent to support the project. All data were pseudonymized before analysis, with only sample data being used for case studies. Participants received no compensation for their participation in the usability inspections.

Conception

In order to facilitate data entry into the CDSS, it is necessary to consider the structure and usage of the vocabularies, as well as the requirements of the end users [21]. The appropriate fields and variables must be defined with the vocabularies for the UI. The data model was defined in a previous study [24] and specifies the following vocabularies, shown in Table 1 [26-37].

All vocabularies shown in Table 1 are fully available in the German language, except for SNOMED CT and Human Phenotype Ontology (HPO). The data to be captured from the requirements and the data model, including its vocabularies, needed to be mapped to the UI and the fields of the UI. To accomplish this, UI data categories were created: basic patient data (patient ID, gender, date of birth, and postcode), diagnosis, symptoms, medication, vital and laboratory values, and procedures. The representation in the UI was described as a UI component with an input format. Where possible, mapping to an OMOP standard concept, such as SNOMED CT and RxNorm, was also ensured and documented. Data in the OMOP CDM are expressed as concepts, which represent the semantic meanings of each data element. A standard concept represents a normative expression of a clinical entity. The others were labelled as nonstandard or source concepts and mapped to the standard concepts [38]. In order to consider the user requirements and data input structure, these were translated into functional requirements. The user requirements collected [21] were analyzed for this purpose and transformed into functional requirements with specific, testable functions that the system should fulfil. Subsequently, use cases and functional requirements were formulated in the following template: [actor] must/should/will [conditions, time aspect] [object] [process description] or something more general [target system] + [priority] + [functionality] + [conditions] [39]. Thus, an example of a functional requirement could be "the system must enable the data to be exported in a usable format." MCN, a medical informatician, carried out the conceptualization step in consultation with the other authors.

XSL•FO
RenderX

Table 1. Selected vocabularies according to the data model for the CDSS[a].

Vocabulary	Description	Availability of the German translation	Progress or version of the German translation in August 2024
ICD-10-GM [b]	Official classification for the encoding of diagnoses in inpatient and outpatient medical care in Germany [26]	Available	*ICD-10-GM* version 2024
HPO[c]	Standardized vocabulary of phenotypic abnormalities encountered in human disease [27]	Translation is not fully available in the German language	The HPO browser allows the display of some German HPO terms or synonyms [28,29], and a study on the translation of HPO terms was conducted as part of the project [30]
LOINC[d]	Database and universal standard for identifying medical laboratory observations [31]	Available	LOINC version 2.76
ATC/DDD[e]	Official classification for pharmacologically active substances. Active substances are divided into different groups according to the organ or organ system on which they act and according to their anatomical, therapeutic, and chemical properties. [32,33]	Available	ATC/DDD version 2024
OPS[f]	Official German classification for the encoding of operations, procedures, and general medical measures [34]	Available	OPS version 2024
SNOMED CT[g]	Systematized Nomenclature of Medicine Clinical Terms [35]	Translation is not fully available in the German language	The German translation group has been actively working on this since 2020 and translated the first national edition with SNOMED CT content into German at the end of 2023 [35-37]

[f]OPS: Operation and Procedure Codes (German: “Operationen- und Prozedurenschlüssel”).

[g]SNOMED CT: Systematized Nomenclature of Medicine Clinical Terms.

Prototypes

The functional requirements defined in the concept were developed and implemented by MCN iteratively (described in more detail in Neff et al [8]) while feedback from users and experts was collected through user evaluations [40,41] and usability inspections [8] (described in section “system evaluation feedback”).

The following intermediate (results) were created in the iterations: (1) low-fidelity prototype (CDSS version 0) [22], (2) first high-fidelity prototype (CDSS version 1) [8], and (3) final high-fidelity prototype (CDSS version 2).

The UI and the vocabulary used were implemented in German wherever possible to suit the German-speaking target. SNOMED CT was used in English due to its limited availability, and HPO was used in an initial partial translation by Noll et al [30]. To ensure good usability, design principles and usability guidelines [42-44] were followed, in addition to the points mentioned above, including principles of dialogue design in accordance with ISO (International Organization for Standardization) 9241 and other ISO standards [43,45,46].

System Evaluation Feedback

The usability of the data entry process was assessed after each developed prototype. Initially, CDSS version 0 was discussed in 2 online user evaluation workshops involving 5 GPs, using a videoconferencing tool. This workshop was conducted and moderated by MCN with support from researchers from the Institute of General Practice (Frankfurt), and key statements were derived [22]. The findings were then documented as user requirements, and new functional requirements were derived where necessary. Usability expert inspections (method: heuristic walkthrough) were carried out in-person by 5 usability experts from the project team to accompany the further development of CDSS versions 1 and 2 (4 inspections conducted and analyzed by MCN: CDSS version 1: 3, CDSS version 2: 1) [8]. Finally, 2 usability evaluations were conducted for CDSS version 1 and version 2. Five GPs who participated in the version 0 evaluation took part in the version 1 evaluation, and 10 GPs (5 of whom were newly recruited) took part in the version 2 evaluation. The evaluations used the thinking-aloud test method, a postsession interview, and the system usability scale. The tests were conducted online by researchers from the Institute of General Practice (Frankfurt) with support from MCN [40].

The tasks that the users were asked to perform in the user evaluation and expert inspections were based on the task model derived from the requirements analysis: perform data entry, review and discuss AI results, plan further diagnosis, refer to specialists, and close the case [21]. The feedback from the expert inspections was categorized as bugs, features, improvements, ideas, or usability heuristics and linked to the individual steps of the task model [8]. When analyzing the feedback from the user evaluations, the usability problems identified in the usability tests were categorized as layout, content, navigation,

XSL•FO
RenderX

comprehensibility, and usability, and also assigned to the steps of the task model [40]. This study focuses on analyzing and interpreting the evaluation results, particularly those concerning the task of "performing data entry." The results of this task were analyzed to inform further development. The analysis of feedback represents an important conceptual intermediate step. Moreover, together with considerations regarding the connection to the primary care EHR system (see Workshop With EHR System Experts), it forms the basis for the final data entry concept within the CDSS.

Workshop With EHR System Experts

As the interface to the primary care EHR system was identified as a key requirement in the analysis and subsequent evaluation iterations, a research workshop was conducted. This workshop was held in a hybrid format, combining in-person participation with remote connections via videoconference [47]. Research workshops focus on analyzing specific cases and collecting reliable and valid data on a participant's future, including organizational change and design. These workshops yield theoretical concepts, methods, and applications that contribute to the discipline. The method involves presenting topics, conducting experiments, and then discussing the findings [48]. The central theme of the workshop was as follows: What should an interface between an EHR system and a decision support system for primary care look like? What is the current state of the art, and what is the vision for the future? The workshop focused on the technical possibilities and challenges of an interface between the CDSS and the EHR system in primary care. The participants were experts in this field, and no GPs were included. However, these experts served as representatives, as it is very difficult to cover the entire spectrum of the system landscape in Germany.

In more detail, the workshop was conducted with (1) project representatives of the SATURN project; (2) representatives from three different companies in the field of EHR systems for primary care, who are considered experts in EHR systems in this study; and (3) two moderators (with medical and medical informatics backgrounds) and one SATURN team member who took notes.

The discussion was supported by a structured discussion guide (Multimedia Appendix 1). This guide addressed the organizational, syntactic, semantic, and structural interface levels of a software. Furthermore, the UI data categories for the decision support system (see description of data categories in the chapter "conception") with related vocabularies were discussed. During the discussion, an initial architectural design was collaboratively sketched on a virtual whiteboard to support the discussion. The workshop analysis was carried out by analyzing the notes and assigning the relevant aspects to the questions in the discussion guide.

Extended Concept

After evaluating the CDSS version 2 prototype, a proposal for an extended concept for future CDSS projects in primary care with the focus on data entry was formulated by MCN in exchange with other authors. This concept considers all the results and describes a design framework that includes UI components, data flows, and system integration.

Results

Overview

The conception and development of the UI for a CDSS—in particular, the process of entering data into the CDSS—led to the development of 3 CDSS prototypes (CDSS versions 0, 1, and 2). CDSS version 2 was developed as a high-fidelity prototype connected to AI modules. Evaluation by users and experts revealed several issues regarding user-friendliness, particularly when entering medications and laboratory values. These issues led to recommendations to improve the search function for symptoms and laboratory values, and to integrate medications from the electronic prescription list. Further improvements to data entry could be achieved by integrating the primary care EHR system. EHR system experts considered middleware to be necessary for this, due to the current data exchange format (data exchange family xDT, which is not transferable via the web). In addition, the low level of standardization for important parameters—such as symptoms, which are currently entered as free text—was identified as a challenge. However, current position papers and technical possibilities may simplify this in the future.

Conception

The results of the conceptualization are presented in 2 tables: Table 2 presents the functional requirements for UI data entry, and Table 3 shows the mapping of the data elements to the UI components and standardization.

Table 3 shows the mapping of the data to be recorded to the UI fields and, if available, the mapping to the standardized international vocabulary of the OMOP database. This is based on the previously defined data model of relevant data entities and vocabularies. The column "mapping to OMOP" represents the mapping to an OMOP standard concept.

Nonstandard vocabularies were mapped in OMOP to SNOMED CT and RxNorm, with the source vocabularies being used in the UI for input. The project aimed to remove free text and to minimize the use of fields not mapped to OMOP.

A few fields were identified as relevant through the requirements analysis, but no direct mapping to OMOP could be established. Symptoms were saved using the HPO vocabulary, which at the time of the project was not supported by OMOP and was not yet available in German. In SATURN, a semiautomatic partial translation was performed for the project using natural language processing [30]. Integration of HPO as vocabulary in OMOP did not take place. HPO and SNOMED CT did not yet have an official mapping at that time—storage therefore took place in the observation table.

Table 2. Functional requirements for UI[a] data entry.

Number	Functional requirement
1	The system must offer the entry of all parameters for diagnoses, procedures, laboratory values, medications, and other clinical entities (in German).
2	The system must contain patient information such as administrative sex and age.
3	The system must generate a unique patient ID for each patient.
4	The system must offer data field-supported input help.
5	The system must ensure the integration of established medical standardized vocabularies used in the data set.
6	The system must allow exclusion diagnoses to be entered in the form (eg, using *ICD*[b] codes).
7	The system must allow time-based documentation during entry.
8	The system must offer the basic functions of a patient file (create, edit, open, or save).
9	The system must enable the continuous processing of a case and the ability to re-request diagnostic suggestions after a change.
10	The system should offer the transfer of a patient ID from the primary care EHR[c] system to the SATURN[d] patient file.
11	The system should offer a parameter query and input support based on previous entries.
12	The system must guarantee the optional input of all data fields.

[h]ATC: Anatomical Therapeutic Chemical Classification.

[i]LOINC: Logical Observation Identifiers Names and Codes.

[j]OPS: Operation and Procedure Codes (German: "Operationen- und Prozedurenschlüssel").

Prototypes

The requirements and the associated vocabularies were implemented step by step. The CDSS version 0 was designed as a low-fidelity prototype in the form of mock-ups [22]. This was followed by the development of the following 2 high-fidelity prototypes: (1) CDSS version 1: JavaScript frameworks nuxt.js 2 (Vuetify), and the UI component framework Vuetify 2 were used with initial sample data (without an active interface to AI modules, as yet, and with integrated vocabularies) [8]. (2) CDSS version 2: React.js (Meta Platforms, Inc) and Mantine were used due to the expiring support of nuxt.js 2. The prototype includes all feasible requirements and has a connection to the AI modules.

Figure 2 shows the first step of the data entry in the final high-fidelity prototype.

CDSS version 0 mock-ups, as well as screenshots of the 2 high-fidelity prototypes, CDSS versions 1 and 2, can be found in Multimedia Appendix 2. At the request of user feedback on this prototype, a step-by-step navigation was incorporated below (see also Neff et al [8] for a more detailed description of prototype version 1).

Figure 3 shows an example of how the integration of vocabularies appears using *ICD-10-GM*: users can search for *ICD-10-GM* terms using the code (eg, E05.0) or the disease name (eg, in the German language "Hyperthyreose mit diffuser Struma").

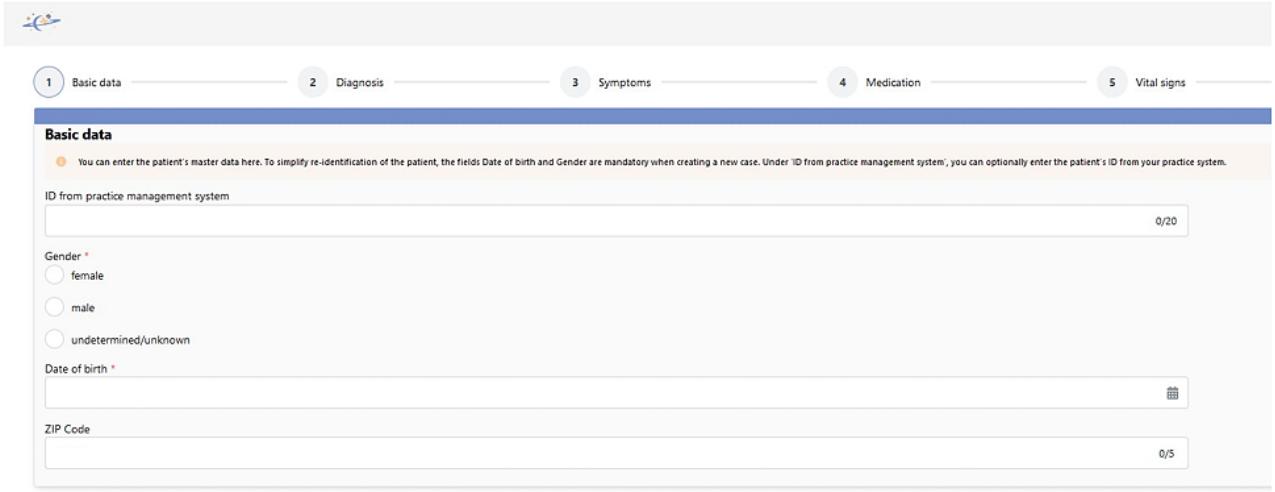

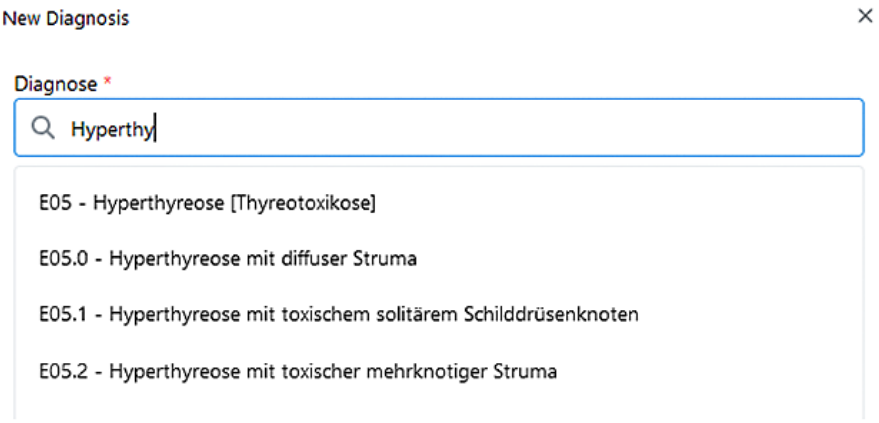

Figure 3. Screenshot of the diagnosis search (CDSS version 2). CDSS: clinical decision support system.

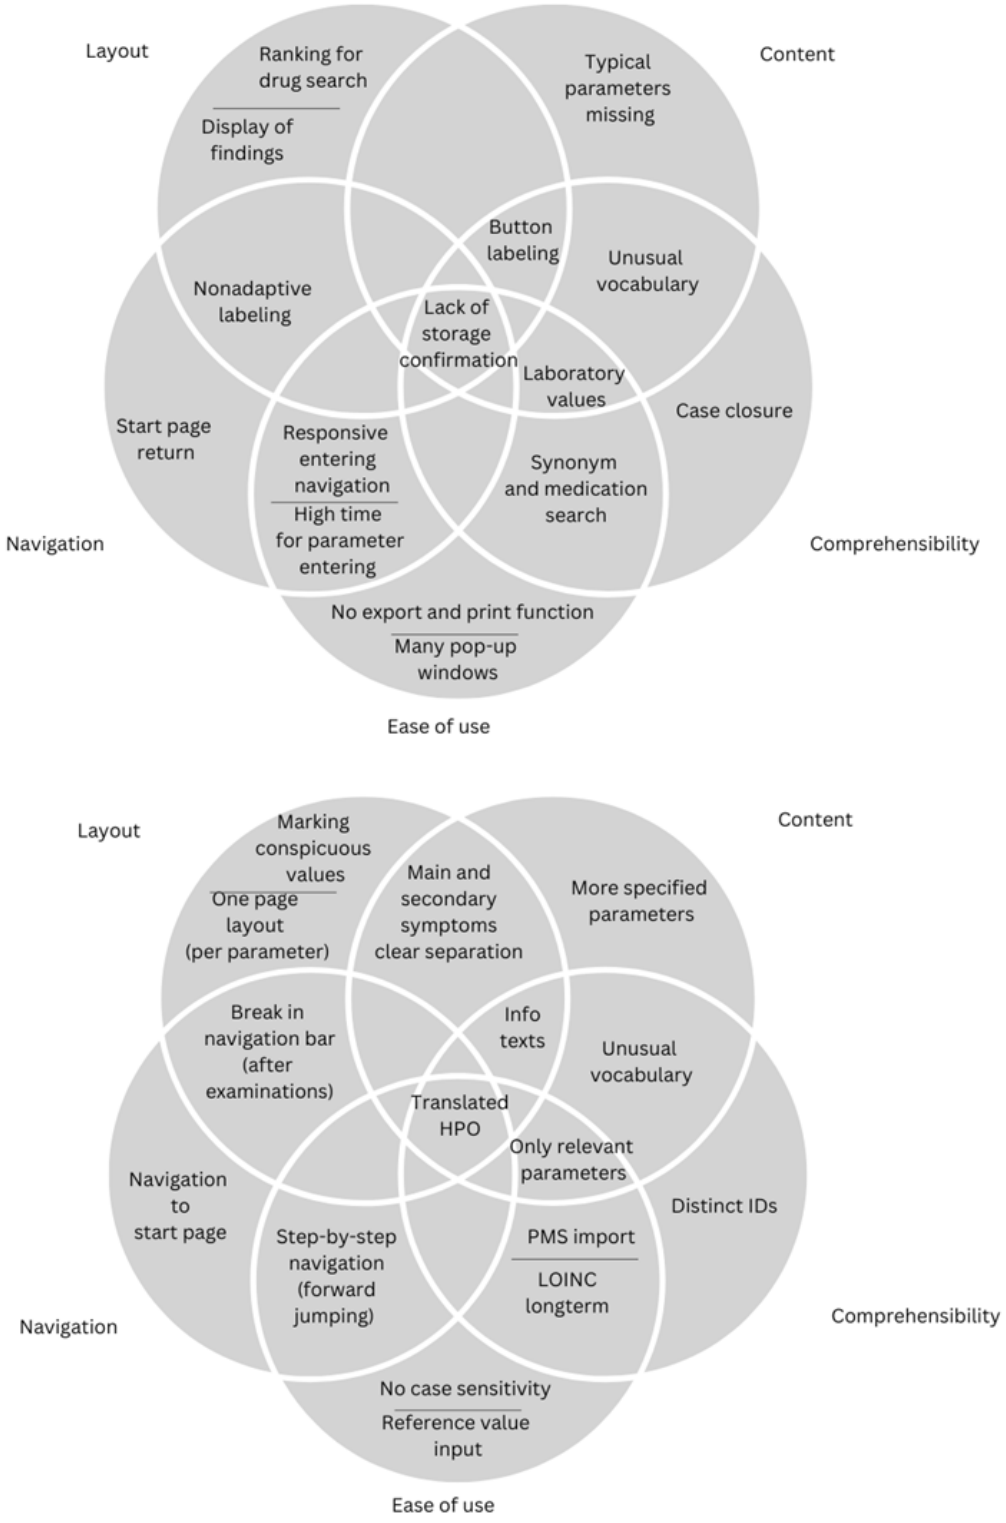

System Evaluation Feedback

During the development of CDSS version 1, expert feedback revealed issues, particularly with search field entry options and inconsistencies between system functions and real clinical practice, for example, the handling of "diagnostic certainty." Feedback also emphasized the importance of automatic saving and clear error messages. Errors were found when entering medications and laboratory values. Some terminology was not displayed in the German language; thus, it is imperative that vocabularies be available in the German language [8]. Detailed information can be found in the publication by Neff et al [8].

In addition to expert feedback from the inspections, further issues were derived from the user evaluations. Feedback on data entry was collated into categories (layout, content, navigation, comprehensibility, and ease of use). The results of the CDSS version 1 usability test (Figure 4) indicated several usability issues. Participants had difficulties entering unlisted symptoms, medications, and tests, and retrieving laboratory values using common abbreviations. Medication data was the biggest problem area. The wide range of laboratory units also caused confusion; thus, specifications for values such as the heart rate were proposed. Some important GPs' diagnostic criteria were absent, with participants proposing their inclusion within the system or the creation of additional free entry fields. The additional fields were proposed to encompass physical examination findings, symptom duration, diagnoses, and family history. GPs also proposed issues for the CDSS version 2 (Figure 4), including automated display of reference range and integration of an updated medication database. GPs were unfamiliar with LOINC (Logical Observation Identifiers Names and Codes) terms, and so better input support was recommended. Participants also recommended focusing on frequency, time, dosage, and extending the search function. This would allow GPs to enter both generic and brand names, as data entry for laboratory values, medications, and diagnoses was considered time-consuming. The information text to each input step was unclear and not sufficiently relevant, and the distinction between some parameter names was not apparent. The GPs also noted several limitations; these included the inability to enter lowercase letters for laboratory reference values and the failure of the symptom search function to recognize certain synonyms.

Figure 4. Summarized results of first and second user evaluations (feedback of the first high-fidelity prototype: version 1, and of the final high-fidelity prototype: version 2). CDSS: clinical decision support system; HPO: Human Phenotype Ontology; LOINC: Logical Observation Identifiers Names and Codes; PMS: patient management system.

Workshop With EHR System Experts

The workshop was attended by a total of 12 participants (7 women and 5 men): (1) four project representatives (experts with backgrounds in medicine, medical informatics, medical technology, or public health) from the SATURN project; (2) five representatives from three different companies in the field of EHR systems for primary care (experts for EHR systems); (3) the workshop confirmed that currently, the most widely used data transmission standard (syntactically) in primary care in Germany is still the xDT data standard family [49]. These include, in particular: Behandlungsdaten-Transfer (further development completed in 2019) for the transfer of treatment data [50], and Labordaten-Transfer for laboratory values [51].

XSL•FO
RenderX

Both standards are defined by the KBV (Kassenärztliche Bundesvereinigung; umbrella organization of the Associations of Statutory Health Insurance Physicians in Germany) [52]. The data transfer (structural) is currently realized via xDT interfaces and is not transferable via the web. A 2022 position paper ([53]) indicated movement toward FHIR (Fast Healthcare Interoperability Resources from HL7 [Health Level Seven]) and thus web transfer. However, the workshop participants have indicated that not all the necessary FHIR profiles have yet been specified. The JSON format was considered a favorable option for the future, with or without a combination with FHIR. Initial data, such as the MIO "Medizinische Informationsobjekte," representing the new KBV data exchange standard [54], are already available in JSON. Table 4 summarizes the terminology and data structure (semantics) for the participants' description of the status quo for the specific CDSS for the primary care use case. All primary care EHR systems are required to provide an electronic physician letter, as part of the telematics infrastructure (TI) in Germany [55].

Participants concluded based on the status quo that middleware is currently indispensable in Germany for integrating EHR systems with CDSS in primary care due to limited data structures and limited data transfer options. Middleware is required to map data to standard medical terminologies used in the CDSS. Ideally, an interface for diagnoses (billing diagnoses in *ICD-10-GM*), laboratory values, and the electronic physician letter should be available via the EHR system. The CDSS should ensure the addressability of the interface and the import of medications from the electronic medication plan. The electronic physician's letter can be used to extract symptoms and examinations. If the electronic physician letter cannot be sent through the EHR system, a new interface is needed. In the future, other medical devices and wearables will connect to the CDSS via middleware. The workshop participants also provided the following feedback on the potential for future developments: data processing with AI is already partially integrated into the EHR systems in primary care. TI measures have also been implemented and are mandatory for manufacturers in Germany.

These include, besides the physician's electronic letters, electronic medication plans and electronic prescriptions, which are set to increase. Connecting the EHR system to other systems, such as the CDSS, is considered feasible and can be implemented depending on the availability and format of data, using REST (Representational State Transfer), a software architecture paradigm.

Table 4. Semantic description of status quo: terminologies and structured data in primary care EHR[a].

Data category	Status quo (data structure)
Basic patient data	Patient data, such as date of birth and postcode, are considered primitive data types and, therefore, are easy to structure and transfer via an interface.
Diagnosis	Diagnoses are structured as billing and permanent diagnoses, with some stored as "suspected diagnoses" and localizations. Transferring the *ICD-10-GM*[b] codes is, according to the current state of the art, challenging.
Symptoms	Symptoms are typically documented as free text, using, for example, nonstandardized categories in chronological index cards.
Medication	Medications are ideally coded using national medication plans (ATC[c] codes or PZN[d]); EHR systems must implement the standardized national medication plan, which has been mandatory since 2016 [56].
Laboratory and vital signs	Laboratory values comply with the LDT[e] 3 standard, although many laboratories continue to use unstructured data that are not LOINC[f] compliant [52,57]. The KBV[g] is developing an MIO[h] for laboratory values [54]. Vital signs can be recorded as either discrete or continuous measurements for billing purposes.
Procedures	Procedure codes (eg, OPS[i]) are structured in hospital outpatient departments but are rarely used in primary care EHR systems; outpatient procedures are often documented as service code justifications for billing purposes.

[a]EHR: electronic health record.

[b]*ICD-10-GM*: *International Statistical Classification of Diseases and Related Health Problems, Tenth Revision, German Modification*.

[c]ATC: Anatomical Therapeutic Chemical Classification.

[d]PZN: Pharmazentralnummer.

[e]LDT: Labordaten-Transfer.

[f]LOINC: Logical Observation Identifiers Names and Codes.

[g]KBV: Kassenärztliche Bundesvereinigung.

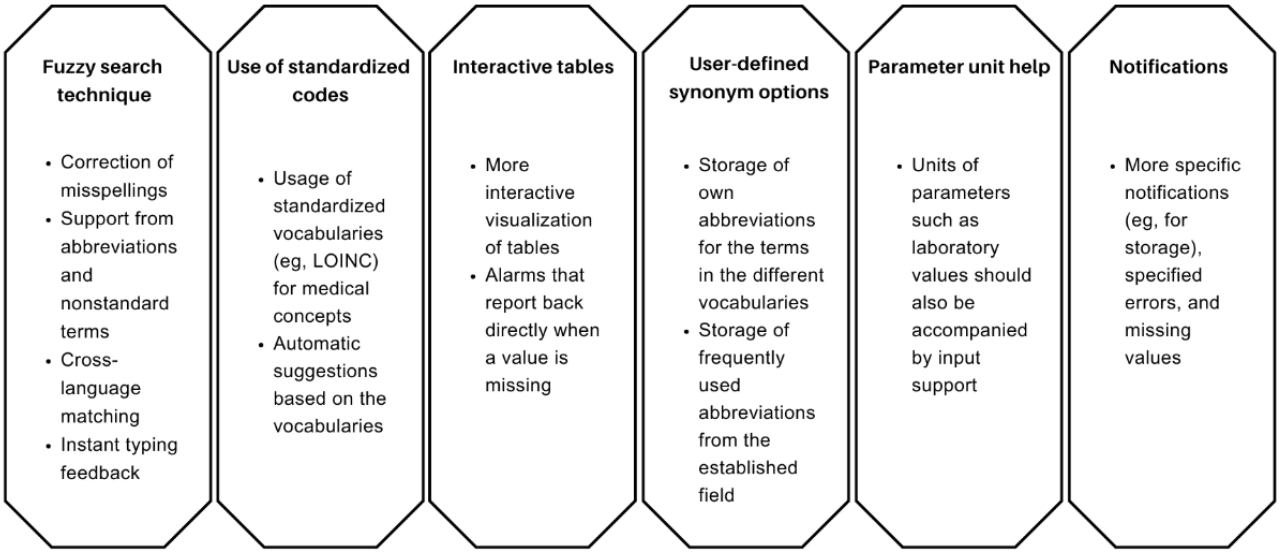
[h]MIO: Medizinische Informationsobjekte.

[i]OPS: Operation and Procedure Codes (German: "Operationen- und Prozedurenschlüssel").

Extended Concept

Overview

The concept is described in the form of a design framework with UI components, data flows, and system integration.



UI Components

The required ontologies will continue to be entered as standardized vocabulary, but will be supported by various factors. These include error-tolerant searching that ignores misspellings and similar spellings, and the use of common

XSL•FO
RenderX

abbreviations [58-60]. These approaches are visualized in Figure 5.

Figure 5. UI component optimizations. LOINC: Logical Observation Identifiers Names and Codes; UI: user interface.

Data Flows

The input of patient data should be possible both via the UI and via an interface to the primary care EHR system or TI applications. Supporting middleware can help with this, especially for laboratory values and medications. The data flow then goes from the UI to the backend for storage, which is connected to the stored database. A data flow from the database via the backend to the UI occurs only when displaying and correcting previously saved cases or when retrieving the vocabularies for input support.

System Integration

System integration is provided by a REST interface from the UI to the backend and REST interfaces to the AI modules.

Discussion

Discussion of Methods

The objective of this study was to investigate how the UI of a CDSS designed for primary care can effectively support GPs in the user-friendly input of standardized vocabulary codes from medical terminologies. It focuses on the CDSS UI, as well as the usability and clarity of medical terminology input.

Methods from software development and UCD were used as part of the iterative process. The UCD design process has been proven to have positive effects in several studies [61-64]. Clinical decision support is generally viewed favorably, providing higher benefits when it improves performance [63]. The current study addresses the integration of the CDSS into the physicians' workflow, an aspect shown in the literature to be essential for CDSS acceptance and usage [65]. To simplify the input of medical terms into the UI for GPs, the UI must be designed to be supportive and user-friendly [20]. One key aspect, therefore, is the reduction of cognitive load. This is described by Miller et al [65] as an important principle for CDSS design: focusing on the input of standardized medical terminology codes can help to reduce the cognitive load on physicians.

The research conducted in this project and other studies has mainly focused on UCD, requirements analysis, and evaluation of CDSS [8,21,63,66]. The formulation of functional requirements and task model methods has proven effective [39,67]. Building on these results, the current study mapped relevant data elements to the UI and collaborated with primary care EHR system experts to develop an extended concept. Zerlik et al [68] took a similar approach in their initial steps, following a UCD process that included requirements definition and iterative development across 3 iterations. We complemented usability expert testing and workshops with feedback from EHR system experts. This approach enabled us to identify potential interfaces to other systems, consistent with recommendations that include different perspectives in the design process [64].

Discussion of the Results

This study identifies requirements and options for entry support in the UI of a primary care CDSS and provides a conceptual framework to support future CDSS implementations. The feedback from the usability test indicates that optimized input support in the language of GPs will be necessary in the future, as will additional mapping work. It is imperative to avoid unfamiliar terms and minimize input restrictions. Ideally, the system would integrate directly with the primary care EHR system in use. The workshop with primary care EHR system experts resulted in initial solution approaches for system interfaces. However, it also highlighted challenges related to limited interoperability, including a simple nonweb-transferable data exchange format and a lack of standardization for important parameters. We propose various optimizations for the UI in our concept for a future CDSS UI. There are several options to better support standardized data entry. Standardizing data entry and using automated tools can significantly improve data quality by minimizing the need for queries and simplifying data collection. Automated features, such as auto-complete, can improve accuracy by relying on predictive modeling. Integration with generative AI can further improve data accuracy and usability. Nevertheless, further research is needed to optimize

XSL•FO
RenderX

the role of standardized data in clinical decision-making and in the research context [69]. AI (eg, machine learning) and natural language processing methods already exist for data integration and mapping, data extraction, and clinical coding.

Models for clinical data extraction, phenotyping, and LOINC mapping also exist [70-74]. A mandatory opt out system for the electronic patient records (ePA) planned for 2025 in Germany, focusing on secure storage and pseudonymized data usage, may facilitate implementing an interface to the ePA data [75,76]. The Unified Medical Language System metathesaurus is another option, already being partially in use, that supports terminology mapping and standardization and enables better interoperability and information retrieval [77]. When searching the medical literature, it is often easier to use the language you are most familiar with. Using one's native language can facilitate the identification of certain concepts that are difficult to translate into English [60]. There is still a need for improvement in this area, particularly regarding the German-language description of symptoms. Further development of standards and translations, as well as data transfer formats such as FHIR for connecting primary care EHR to CDSS, may simplify integration in the future. When implementing in practice, it is important to incorporate the system into the daily workflow and connect it to the practice's own EHR system.

Limitations

This study focused on integrating medical terminologies into the UI, representing 1 task within the task model. The methodological framework was designed to address this objective. However, the steps are transferable to other tasks within the task model. This requires selecting the requirements and involving additional experts (such as EHR system experts) relevant to the task. Further studies in real-world clinical settings, using the implemented system over an extended period, are necessary to develop the CDSS. For the specific task of entering medical terminology into the CDSS, fuzzy search can provide excellent support; however, there are also challenges in the form of high computational effort, false positive results, and balanced precision in different languages [58]. For the integration into practice, the current infrastructure and networking in Germany make it difficult to interface with the primary care EHR system. The slow uptake of ePA in Germany, with only ≈1% penetration by 2023 compared to a target of 80% by 2025, is hampering automation. Barriers to adoption include legal ambiguities, conflicts between stakeholders, and insufficient communication [75,76].

Thanks to their modular structure, the practices will not require significant resources. However, the task here is to ensure secure implementation, including hosting of the AI modules and secure data transfer.

Conclusion

In conclusion, the process of UCD has been shown to be effective in the development of the UI of CDSS, particularly regarding the integration into physicians' workflow and creation of a user-friendly interface. Iterative development with experts identified potential interfaces for other systems. The results indicated a need for optimized entry support in the physician's language and revealed challenges concerning interoperability. Suggestions for improvements include standard data entry, automated tools, and AI to enhance data quality and usability. However, the current infrastructure poses significant challenges for interfacing with primary care EHR systems in Germany. Further studies are required to address these issues.

Acknowledgments

We would like to thank the participants of the workshop with electronic health record system experts and the participants in the expert and user evaluations.

Funding

SATURN is funded by the German Federal Ministry of Health as part of the research focus "Digital Innovation," Module 3: "Smart Algorithms and Expert Systems" (funding code: 2520DAT02B, 2520DAT02C, 2520DAT02D).

Abstract

Background: Artificial intelligence (AI) offers potential solutions to address the challenges faced by a strained mental health care system, such as increasing demand for care, staff shortages, and pressured accessibility. While developing AI-based tools for clinical practice is technically feasible and has the potential to produce real-world impact, only a few are actually implemented into clinical practice. Implementation starts at the algorithm development phase, as this phase bridges theoretical innovation and practical application. The design and the way the AI tool is developed may either facilitate or hinder later implementation and use.

Objective: This study aims to examine the development process of a suicide risk prediction algorithm using real-world electronic health record (EHR) data through a qualitative case study approach for clinical use in mental health care. It explores which challenges the development team encountered in creating the algorithm and how they addressed these challenges. This study identifies key considerations for the integration of technical and clinical perspectives in algorithms, facilitating the evolution of mental health organizations toward data-driven practice. The studied algorithm remains exploratory and has not yet been implemented in clinical practice.

Methods: An exploratory, multimethod qualitative case study was conducted, using a hybrid approach with both inductive and deductive analysis. Data were collected through desk research, reflective team meetings, and iterative feedback sessions with the development team. Thematic analysis was used to identify development challenges and the team's responses. Based on these findings, key considerations for future algorithm development were derived.

Results: Key challenges included defining, operationalizing, and measuring suicide incidents within EHRs due to issues such as missing data, underreporting, and differences between data sources. Predicting factors were identified by consulting clinical experts; however, psychosocial variables had to be constructed as they could not directly be extracted from EHR data. Risk of bias occurred when traditional suicide prevention questionnaires, unequally distributed across patients, were used as input. Analyzing unstructured data by natural language processing was challenging due to data noise, but ultimately enabled successful sentiment analysis, which provided dynamic, clinically relevant information for the algorithm. A complex model enhanced predictive accuracy but posed challenges regarding understandability, which was highly valued by clinicians.

Conclusions: To advance mental health care as a data-driven field, several critical considerations must be addressed: ensuring robust data governance and quality, fostering cultural shifts in data documentation practices, establishing mechanisms for continuous monitoring of AI tool usage, mitigating risks of bias, balancing predictive performance with explainability, and maintaining a clinician "in-the-loop" approach. Future research should prioritize sociotechnical aspects related to the development, implementation, and daily use of AI in mental health care practice.

Introduction

Advances in artificial intelligence (AI; see Textbox 1 for a glossary of key terms) may provide promising opportunities for many actual and future challenges that mental health care faces [1], such as increasing demand for care and staff shortages that affect the quality of care and accessibility of mental health care. AI may enhance multiple domains, such as triage and screening, diagnostics, clinical decision-making, care delivery, chronic care management, self-care, and prevention of (psychiatric) symptoms [2].

Textbox 1. Glossary.

Artificial intelligence refers to a computerized system (hardware or software) that is able to perform tasks or reasoning processes that we usually associate with intelligence in a human being [3,4].

Machine learning is part of artificial intelligence. It is able to build algorithms that can detect patterns in large training datasets to explain variation in data or predict outcomes (predictive algorithms) [3,5-7].

Predictive analytics aims to build models which allow for individual (ie, single subject) predictions, thereby moving from the description of patients (hindsight) and the investigation of statistical group differences or associations (insight) toward models capable of predicting current or future characteristics for individual patients (foresight), thus allowing for a direct assessment of a model's clinical use [8].

Natural language processing refers to ML techniques capable of parsing unstructured texts, such as free written texts or spoken language [9]. Natural language processing enables the use of unstructured data that is otherwise largely inaccessible, such as the dynamic fluctuations of symptoms (eg, by analyzing clinical notes) and can identify social and behavioral factors, which are not commonly registered in EHR [10].

Predictive algorithms are a promising subfield of AI, in which machine learning (ML) models generate predictions on an individual patient level to support decision-making in the diagnosis, prognosis, and treatment of patients [5,8,11]. Predictive algorithms have been shown to be more successful than traditional statistical models, as they provide a new way to gain knowledge from a data set. For example, in the field of predicting suicide risk at the individual level, predictive algorithms can yield more accurate predictions [12-15] than traditional statistical models, which predict only slightly better than chance and whose predictive ability has not improved over time, even after 50 years of research [16]. Not all ML models for suicide risk are adequate, although, as performance can vary depending on various factors, such as data quality, nature of the features used as input, preprocessing steps, and the used techniques [12]. In other mental health care domains, ML models are also able to perform better than traditional models, such as the prediction of psychosis, treatment response [17], or opioid use disorder [18].

Algorithms designed for clinical care often use patient data collected during regular clinical care in the organization's electronic health record (EHR). Combining the expanding possibilities of AI with EHR data fuels the transformation into a data-driven mental health care, as the EHR contains rich, real-world, and real-time data. Reusing EHR data to develop algorithms that support clinical practice on an everyday basis opens many possibilities. However, it may be challenging, as these data are usually noisy, heterogeneous, dynamic, and contain both structured and unstructured data (eg, text) and require careful preprocessing [19]. Developing [20] and implementing AI-based algorithms using real-world EHR data has been proven to be feasible and can have a significant clinical impact [21-23]. However, the studies of algorithms that are actually implemented and used in mental health clinical practice are still scarce [24]. Also, there is a gap between the creation of scientifically sound algorithms and their meaningful application in real-world settings, a challenge often referred to as the "AI chasm" [25].

For mental health care to benefit from AI opportunities and the wealth of EHR data, developing algorithms based on real-world EHR patient data intended for clinical use is a crucial first step toward successful implementation and use. The development phase bridges theoretical innovation and practical application. Therefore, the development phase is not only a preparatory step but an integral part of implementation, as the design and development of the AI tool may either facilitate or hinder later implementation and use (eg, through alignment with organizational workflows and engendering trust) [26].

To enable the successful development, implementation, and actual use of AI and ML in mental health clinical practice, implementation science provides a valuable framework [3], as it studies the contextual factors that enable the process of embedding and integrating new practices into actual care [27,28]. Also, it fosters greater attention for the sociotechnical aspects of technology, focusing not only on the development of technological improvements but also the social changes required for their successful implementation and use [17,29-33]. Multiple barriers and facilitators have been identified in the literature, highlighting aspects of AI technology itself (eg, accuracy, transparency, and generalizability); organizational factors (eg, integration with workflows); governance, ethical, and legal issues; perception of staff and patients; or the implementation process (eg, engagement, user-centered design) [34,35]. However, these barriers and facilitators have, for a large part, been identified not primarily on implementation data but rather based on hypothetical implementation, white papers, and thought articles [34,35]. Therefore, more empirical studies are required to fill this knowledge gap [6,17].

To better understand how this development phase unfolds within the specific context of mental health care, we conducted a case study. This study explores the challenges encountered by a development team in creating a suicide risk prediction algorithm using real-world EHR data for clinical application in close collaboration with clinicians, as well as the team's responses to these issues. Ultimately, we aim to identify key considerations relevant to bridging technical and clinical needs in algorithm

XSL•FO
RenderX

development, offering insights for mental health professionals and organizations seeking to move toward data-driven care.

Methods

Research Design

This study is a detailed case study aimed to explore the challenges involved in the development of a suicide risk prediction algorithm using real-world EHR data in mental health care. Using an exploratory, multimethod approach with both inductive and deductive analysis suited to this emerging field, as the study seeks to identify key development considerations applicable to broader contexts [36].

Case Description

Setting and Background

Suicide prevention in the Netherlands is organized through a national policy agenda focused on public awareness, early detection, and professional care. The national helpline 113 Suicide Prevention is available 24/7 by phone or chat. This organization also provides public campaigns and training for professionals and citizens. The National Suicide Prevention Agenda, developed by the Ministry of Health, Welfare and Sport together with 113 and other partners, offers a framework for collaboration between health care, education, municipalities, and the media. Locally, Municipal Health Services, youth health care, schools, and social services work on prevention and early risk identification. In mental health care, suicide prevention is part of standard practice, including staff training and procedures following a suicide incident. The Health and Youth Care Inspectorate monitors suicide prevention and reporting, while knowledge institutes, such as Trimbos, support professionals through guidelines and research.

GGz Eindhoven and the Kempen (Geestelijke Gezondheidszorg Eindhoven en de Kempen [GGzE]) is a mental health institution in southern Netherlands, providing specialized care to around 17,000 patients annually. At GGzE, a protocol is in place in accordance with the national multidisciplinary guideline [37]. All health care professionals are required to complete suicide prevention training courses. Suicide risk assessments are conducted at the start of each treatment trajectory and at other critical moments, for example, during a crisis; at the beginning, end, and after hospitalization; or prior to the extension of patient privileges during admission. A standardized suicide assessment tool, the Suicide Prevention Questionnaire (SPQ), is embedded within the EHR and should be administered at these key points, at least once or twice per year.

To enhance suicide prevention, GGzE explored the feasibility of developing a predictive algorithm using EHR data to support clinicians in identifying suicide risk in individual patients. Key objectives included establishing a reliable measure of suicide incidents, identifying predictive factors, and creating an algorithm with an accuracy target of 70% - 90% [38]. The development team, consisting of 2 data scientists with support from data science, governance, law, and clinical suicide experts (multiple psychologists and psychiatrists), operated under a structured project organization with a steering committee and project group. Both the steering committee and the project group comprised health care professionals as well as staff members with legal, organizational, and other forms of specialized expertise.

The project was embedded in the organization-wide Suicide Prevention Program, which provided consultation and training, developed organizational guidelines and protocols, organized evaluation of suicide incidents and subsequent quality enhancement of clinical practice, ensured evidence-based treatment options regarding suicidality, and developed a reflective learning culture regarding suicidality within the organization. The organization was part of the Suicide Prevention Action Network (Supranet GGZ), in which mental health institutions work together to make the quality of care for suicidal patients transparent, to learn what can be improved, and to improve care where necessary. Within this network, data on suicide incidents were structurally collected and shared, including core indicators on suicide risk.

The Suicide Prediction Algorithm: Description and Performance

The development team designed the algorithm for hospitalized patients with severe mental illness, using the Cross-Industry Standard Process for Data Mining (CRISP-DM) framework [39], a standard method in data mining and ML, to predict suicide risk within 1 month. Data for the algorithm was taken from the EHR and included data from 5044 patients (December 31, 2015, to August 31, 2021) included demographics (eg, age and sex), administrative details (eg, financing type), treatment history (eg, hospitalization count), psychiatric factors (eg, primary diagnosis), current treatment details (eg, duration and intensity), and social factors (eg, social contacts). Consultations with clinicians, interviews, and a literature search resulted in a list of possible predictors of suicide incidents that were derived from the EHR.

The team applied natural language processing (NLP) to clinicians' daily reports, identifying unreported suicide incidents and capturing patient sentiment as an additional predictor, using topic modeling (BERTopic) [40]. Ensemble learning (extreme gradient boosting) [41] strengthened the model. The development team deemed the algorithm successful based on Hicks et al criteria [38]. The team acknowledged that the performance indicator outcomes were exploratory, as the algorithm would be retrained prior to implementation in a pilot phase and subsequently retrained annually in accordance with quality standards.

The predictive algorithm for suicide incidents will be gradually tested in a small-scale pilot project conducted in close collaboration with health care professionals. The algorithm will be implemented solely as an add-on to existing suicide prevention policies. Health care professionals will remain fully responsible for clinical assessment and decision-making. The pilot project will be evaluated at multiple stages throughout its implementation.

Sampling and Participants

The study's participants included 2 core data science professionals who led the development of the suicide risk

XSL•FO
RenderX

prediction algorithm, supported by internal and external experts. The team worked closely with clinicians (multiple psychologists, psychiatrists, and the Medical Director's office) and experts in data science, law, and data governance, as well as with external data science collaborators from other mental health care institutions. The participants were selected by expert sampling, in which participants are included who have demonstrable experience and expertise regarding the study's aim and objective [42,43]. These participants offered crucial insights into the challenges and considerations of algorithm development. The team worked closely with clinicians (eg, psychologists, psychiatrists, and the medical director) and experts in data science, law, and data governance, as well as with external data science collaborators from other mental health care institutions.

Data Collection and Data Analysis

Data for our study on the development process were collected through desk research, reflective meetings, and iterative feedback sessions with the development team. The study proceeded in three phases: (1) desk research and meetings with the development team to draw up a detailed process description, (2) identification of challenges and responses by thematic analysis, and (3) formulation of key considerations.

The detailed process description formed the basis for thematic analysis, which was conducted following the Braun and Clarke approach [44]. An exploratory, multimethod design combining inductive and deductive analysis was used to identify challenges during the algorithm development process. Deductive analysis was guided by the innovation domain of the Consolidated Framework for Implementation Research (CFIR) [28,45] and concepts from AI-related literature.

Data on process steps, challenges, and responses were analyzed and organized in a chart by 1 researcher (LH). Data was discussed by all 4 researchers to derive the main challenges and describe the team's responses. Communicative validation was achieved through discussions with the development team. Triangulation across data sources strengthened the credibility and transferability of findings. Data collection and analysis were iterative and integrated throughout all phases.

Ethical Considerations

Ethical approval was obtained from the Ethical Review Board of Tilburg University (reference TSB_RP1038). Participants received no financial compensation and provided written informed consent prior to participation. All procedures adhered to principles of privacy and confidentiality: no identifying information was collected or published, and any nonessential identifying details were omitted. No images or supplementary materials contain identifiable participant features.

Results

Overview

The encountered challenges and the team's responses are described below, related to the construction of the suicide incidents (dependent variable) and possible predictors (independent variables), and the building of the model. At the start, the concept of the suicide incidents and the predictors had to be defined, operationalized, and measured. Several challenges were encountered during this phase: data was hard to find, data sources yielded different results, and underreporting was suspected. Regarding predicting factors, psychosocial predictors were not available and had to be estimated. To calculate the algorithm, the team used complex models that improved predictive performance but reduced understandability for clinicians.

Regular consultations between the project team and clinical experts during the development process were important to gain an accurate and profound understanding of the phenomena of suicide incidents and their predictive factors.

The Results section will focus on the development team's challenges and their responses to them. In the Discussion section, the results will be contextualized within the literature to formulate key considerations for algorithm development in mental health care.

Defining, Operationalizing, and Measuring Suicide Incidents

Different Data Sources Provide Different Outcomes

The data science team collaborated with health care professionals to define suicide incidents as the dependent variable. Within the organization, a suicide incident was defined as either a fatal suicide or a nonfatal attempt with a certain intention to die. This also covered self-harming or risky behavior that involved a risk of death or failure to avoid such risk. Severe suicide incidents were those that were fatal or caused, or could cause, severe or permanent physical injury [source: GGzE Protocol Reporting suicides and suicide attempts; consulted 2025-09-19]. Clinicians had to distinguish these from self-harm driven by other motives, such as reducing emotional pain.

Organizational protocols prescribed the registration of every suicide incident in a digital registration system. The Medical Director's office kept its own registration. The 2 data sources within the organization yielded different outputs on the total number of suicide incidents:

> *In the Client Details source there is a variable called Suicide Attempt. In addition, a variable called Suicide Incident has been created based on the incident data. […] there are more numbers […] for Suicide Incident than for Suicide Attempt." [Report of the development team and external partners on characteristics of the suicide incident risk algorithm, p. 10].*

The medical director's office clarified to the data science team that they reviewed the registered suicide incidents in the reporting system and recorded only those suicide incidents classified as severe. The team chose to include all suicide incidents, providing more data to train the algorithm and enabling the prediction of both severe and less severe cases. Clinical experts reflected on the overall numbers and considered them to be low, suggesting underregistration, particularly of less severe cases, possibly due to noncompliance with protocols or sensitivities around suicide. Moreover, ambiguity about the intention behind the behavior in less severe cases may have

XSL•FO
RenderX

played a role. For example, behavior without serious injury or risk of injury that primarily served a communicative function.

Using Unstructured Data to Improve Detection of Suicide Incidents Is Challenging

To detect underreported suicide incidents, the development team added text mining using NLP of clinicians' unstructured daily reports. However, the method produced significant data noise, identifying many reports related to suicidality but failing to pinpoint actual suicide incidents. Text analysis was hindered by clinicians' writing habits, such as negation terms ("not feeling suicidal"), the use of synonyms (eg, "jumping off a bridge"), and the use of standard templates (eg, "has the patient expressed suicidality today?").

Manual labeling of cases was tried, but appeared to be very time-consuming and unfeasible as a permanent solution, especially as the algorithm had to be retrained every 6 months due to quality requirements:

> *We still need to be 100% sure that there is/isn't a suicide incident in the daily report data. Possible solution: Read the data yourself and assess whether there is/isn't a suicide incident (label data). Disadvantages: […] Takes a lot of time (for a small dataset it took 3 days)*

The development team responded to these challenges by making efforts to enhance data quality. The organization was in the process of transitioning to another provider of an EHR system. The team recommended including a check mark for suicide incidents [source: Presentation Suicide Predictive Model_2nd iteration, p. 36] within this new system and advocated this solution in the new EHR project team, underlining the importance of these interventions to transform into a data-driven health care organization. Also, a new executive board took the lead of the organization and, consequently, a new multiyear strategy was developed, in which "working data-driven to enhance decision support" was one of the main ambitions [source: GGzE, multiyear strategy 2024 - 2028; consulted 2025-09-19]. This prompted management to take a more active role in ensuring data quality, such as completing suicide-related information. Also, the organization implemented an alternative instrument for the SPQ. This way, the organization aimed to improve data quality. The algorithm would be retrained when the new EHR system was implemented.

However, the team still had to deal with the fact that possible underregistration of suicide incidents, especially less severe cases, was an issue. From a data science perspective, they could interpret this as missing data, which threatened data quality. From a clinical perspective, the possibility that mild incidents were not always reported was a reflection of the ambiguity of the interpretation of a suicide incident: did the patient actually aim to end their life, or should the behavior be interpreted more as self-harming behavior with the intent to decrease pain or to communicate distress?

Defining, Operationalizing, and Measuring Potential Predicting Factors

The development team compiled a list of potential predicting factors by performing a literature review, reviewing factors from well-known suicide risk assessment methods, and interviewing clinicians to leverage their expertise and to involve and engage clinicians in the development process. The list of predictors then had to be defined, operationalized, and measured. Reflective meetings with the development team revealed several challenges they faced, which are described below.

The EHR Lacks Psychosocial Factors: Construction of Predictors is Necessary

Some predicting factors, like previous suicide attempts or substance dependence, could be directly derived from the EHR. Other predicting factors were psychosocial and could not be directly obtained from the EHR, thus requiring the construction of an estimator.

For example, information on the number of contacts of a patient, as registered in the EHR, along with a selection of characterization of these relationships (eg, spouse, sibling, child, and neighbor) was used to construct the factor "social network." Also, the factor "quality of the therapeutic relationship" was operationalized as the number of primary [1] practitioners during hospitalization. Although it was recognized that these operationalizations did not necessarily reflect the actual factors, in the absence of a better alternative, it was decided to operationalize and measure these concepts in this way.

Data Availability Differs Between Subgroups: Risk of Bias

Clinicians considered the SPQ, available in the EHR, the most promising source of predictors. Although protocols required annual administration for all patients, the data science team found a recent SPQ in only 21.95% of cases. Clinicians confirmed that SPQ variables were highly explanatory but acknowledged their limited availability. They suspected that SPQs were often completed only when suicide risk was already suspected, creating bias and overrepresenting high-risk patients. To include all patients, the data science team had to derive estimators from other EHR data. Additional disparities emerged: SPQs were missing more often for youth (0 - 17 y) than for older patients, despite comparable incident rates. These findings were shared with the Child & Youth Department to improve data quality. Ethnicity was also explored as a predictor but was excluded due to frequent missing values.

Overall, the results exposed a gap between organizational protocols (eg, annual SPQ administration, registration of ethnicity) and actual practice. They also revealed different perspectives: clinicians valued SPQ data but were less familiar with data science principles, such as representativeness and external validity, while data scientists emphasized these risks. Close collaboration was deemed essential to identify predictors and minimize bias.

To address these challenges, the development team worked with the Suicide Prevention Program and a national suicide prevention organization to design a digital toolkit as a

XSL•FO
RenderX

replacement for the SPQ. This decision support tool aimed to make risk assessment more user-friendly, link assessments to targeted treatment advice based on the national guideline, and reduce clinician workload through robotic process automation that transferred data directly to the EHR.

Sentiment Analysis to Construct a Time- and Context-Sensitive Predictor

As the literature review and interviews with clinicians emphasized the role of time- and context-related factors in suicide risk (eg, relationship breakup and intoxication), the development team explored ways to integrate these into the model. Since collecting daily data directly from patients was impractical due to severe psychiatric conditions and low cooperation, daily reports by clinicians about patients were identified as the best alternative. These allowed real-time data to strengthen predictive accuracy.

Although detecting suicide incidents in daily reports was challenging, sentiment analysis proved feasible. Patients with suicide incidents showed lower sentiment in the daily notes by clinicians, especially in the most recent entries, compared to those without incidents (internal document: PowerPoint Suicide Predictive Model_2nd iteration, p. 29).

When the development team presented the results to the medical director's office, new applications were discussed. The algorithm was initially designed as an add-on to existing protocols, such as administering an SPQ annually. Given the time-intensive nature of the SPQ, 1 proposal was to let the algorithm preselect high-risk patients for SPQ administration. This would save time by limiting assessments to flagged patients.

Clinical experts, including the medical director, rejected this option, noting that the algorithm was still in development and should not replace established tools. They did, however, acknowledge that SPQs were not consistently administered in practice. As an alternative, they proposed using sentiment analysis as an alert system: if emotional decline was detected and no recent SPQ was available, clinicians would be prompted to administer one. This approach was accepted, as it integrated the algorithm while reinforcing compliance with existing suicide prevention protocols.

Building the Algorithm: High-Performance Model Appears Hard to Understand by Clinicians

After identifying dependent and independent variables, the development team built the algorithm using ensemble learning, which combines weaker models into a stronger one. This approach delivered high predictive power, meeting the project's feasibility goal, but the model was too complex to interpret directly.

The data science team shared the results with clinicians and the steering group, including the model's performance metrics (eg, accuracy, precision, and recall), acknowledging that the results were exploratory as the model would later be retrained. Clinicians appreciated the potential value of the algorithm but emphasized that understanding why suicide risk was elevated was essential for fostering trust, ensuring accountability, and supporting treatment planning. They highlighted that a well-performing algorithm alone would not be sufficient to generate meaningful benefits in clinical practice. The data science team, therefore, identified explainability as a core requirement. They aimed to develop case-level reports that not only flagged risk but also explained the reasons behind it: "Not only: alarm! But also: alarm, for this reason" [Reflective meeting, 2023-11-07].

To address this challenge, a team member engaged in additional training in explainable AI, noting the scarcity of knowledge within mental health care. Additionally, the data science team planned to organize several collaborative sessions with clinicians to cocreate an explainability dashboard that contextualizes the algorithm's outputs. Also, collaborative sessions were planned to facilitate the integration of the algorithm into existing workflows and jointly reflect on the tasks, roles, and responsibilities of each stakeholder in its use.

Discussion

Principal Findings

This study provided a detailed case study of the development of a suicide risk prediction algorithm using real-world EHR data. Its unique contribution lies in demonstrating how algorithm development is carried out within the clinical practice of mental health care, where technical innovation must be aligned with clinical needs, professional values, and organizational structures. By describing the challenges of a development team and their responses to them, this study offers an in-depth description of the development of a predictive algorithm, in which the development process is seen as a first step in the implementation process.

This paper highlights the sociotechnical and organizational aspects of algorithm development, showing how collaboration, joint efforts to enhance data quality, and clinician engagement are essential prerequisites for algorithm development.

Reflection on the Principal Results

Addressing Data Quality Challenges in the EHR

High data quality is essential for AI in mental health care, yet EHR data are often low in quality, incomplete, "soft," and indirect [46,47]. Also, handling unstructured EHR data requires unique approaches [48,49].

Regarding data quality, EHR data quality in mental health is typically problematic. In the current case, suicide incident data were hard to construct and possibly underreported, although this could also be a reflection of real-world clinical assessment issues. Low data quality is noted in the literature, where suicide incidents are frequently underdocumented [50] due to clinicians' workload [7,46] and departmental workflow inconsistencies [51]. Addressing this, data quality issues span all 5 dimensions identified by Weiskopf and Weng [52]: completeness, correctness, concordance, plausibility, and currency. Organizations are faced with challenges on data quality according to each of these dimensions.

Mental health data often rely on "soft" psychological constructs (eg, social support), which are harder to quantify than "hard"

XSL•FO
RenderX

somatic measures (eg, heart rate) [47]. This raises risks for construct validity [53]. Moreover, much of the data reflects professionals' perceptions rather than patients' own, which may diverge significantly [54-57]. Future approaches using direct patient data (eg, real-time sampling and devices) could help improve accuracy [13].

Analysis of unstructured data, like staff notes, showed high noise, with frequent mentions of suicidality but few actual incidents, a challenge also noted in other mental health domains [13,58]. Variations in writing style and negations further complicate analysis [59-61]. Still, NLP offers potential to capture real-time risk fluctuations and enhance predictive accuracy [62-65].

While low data quality in mental health is a barrier for AI, algorithm development may also support quality improvement. In the current case, feedback on data inconsistencies spurred organizational motivation to enhance quality and adapt the EHR system.

Mitigating Risk of Bias to Ensure Performance for Subgroups

When algorithms are trained on data of low quality, risk of bias (RoB) occurs, in which the algorithm may not perform as well for each subgroup, and human biases are repeated and even amplified. When predictors are constructed from EHR data as data are not readily available, selection bias may occur. Algorithms require balanced representation across subgroups, though, to perform effectively. In this case, using SPQ items as predictors risked overrepresenting high-risk patients and weakening performance for others. While EHR data enables inclusion of all hospitalized patients, including minority groups often underrepresented in research [66], bias remains a major concern. As social factors are often key predictors in mental health care [15,67], social data is often missing due to true absence or nonrandom issues, such as patient refusal, confidentiality concerns, or language barriers, and excluding such cases may worsen bias [15,67]. Selection bias also threatens performance when samples do not reflect the broader population [10,68,69]. Bias is therefore considered an additional dimension of data quality, alongside the 5 identified by Weiskopf and Weng [52,70].

By building algorithms from reused EHR data, human biases in the data may be reinforced. The development team acknowledged this risk but considered the potential benefits sufficient to proceed, provided mitigating measures were applied. Since algorithms are trained on subjective EHR data, cognitive biases, such as stereotypes or in-group favoritism [71-73], may become embedded and systematically applied [66,68,69]. In practice, if an algorithm's outcome aligns with a clinician's initial diagnosis, confirmation bias may lead the clinician to ignore contradictory information. If the outcomes differ, precautionary bias might cause them to trust the algorithm over their own judgment [73]. Automation bias could also emerge, where clinicians rely more on the tool than on other information, potentially diminishing their skills [7]. The question remains what mitigating measures are adequate to prevent systematically disadvantaging subgroups. At the same time, algorithms may also reduce bias by integrating fragmented information across professionals and systematically processing both subjective and objective data [74]. Determining under which conditions algorithms amplify or mitigate bias remains an open question for future research.

Actionability, Trust, Accountability, and Communication in Complex Models

Predictive power and understandability have to be balanced in algorithm development. In our study, data scientists prioritized predictive performance, applying a complex model to enhance accuracy, while clinicians emphasized the need for understandability. This reflects the broader trade-off between complex "black box" models, which yield higher predictive power but limited explainability, and simpler "glass box" models, which are more interpretable but often less accurate [75-77]. Initially, the team focused on feasibility, whether an algorithm with sufficient predictive performance could be built from organizational data, rather than on clinical applicability. Clinician feedback prompted the inclusion of explainability as a key objective, as it enhances the actionability of the outcomes, that is, whether clinicians can use the information to identify actions to change the outcome predicted by the algorithm [78]. In suicide prevention, detecting elevated risk is insufficient; clinicians must also understand which factors contributed most, which are modifiable, and which interventions are likely to reduce risk [79,80]. Explainability is crucial for building trust [81-83], and providing an appropriate level of transparency (not too little and not too much) is necessary in designing for trust [84]. Clinicians should be well informed about the actual capabilities of the algorithm, as responsible use of AI systems also depends on the level of correspondence between a user's trust and the technology's capabilities, known as calibration [83]. Explainability may also enhance patient communication and support shared decision-making [76,79,85]. Also, mental health institutions are accountable for care quality, effectiveness, and safety. In our study, clinicians feared that using complex, nonexplainable models would undermine accountability, as evidence-based protocols are easier to justify than black-box algorithms. Given the high-stakes nature of suicide care, caution is warranted when applying complex models [80].

Whether performance or explainability should be prioritized in mental health care remains unresolved, and future research should examine context-specific trade-offs as well as post hoc strategies to enhance explainability [77,86]. Future research should explore what information should be communicated to clinicians and how it should be presented. Moreover, fostering mutual trust and collaboration between clinicians and data scientists throughout the algorithm development process is essential. Technical performance alone does not guarantee clinical usefulness. Instead, cocreation of both the algorithm and its user interface, combined with joint efforts to integrate it into everyday practice, is crucial for enabling clinicians to trust and meaningfully use the algorithm's outcomes.

Below, we present Table 1 summarizing the challenges encountered during the development phase, the corresponding responses by the team and organization, and the broader considerations derived from these experiences.

XSL•FO
RenderX

Table . Challenges, responses, and considerations during algorithm development in mental health care.

The development phase	Challenges	Responses	Considerations
Defining, operationalizing, and measuring suicide incidents	• Inconsistent detection of suicide incidents across data sources.	• Enhanced suicide incident data by integrating clinician insights. • Broadened incident inclusion. • Tested NLP[a] approaches. • Improved EHR[b] registration.	• Ensure sufficient data availability for the predicted outcome. • Consult clinicians to improve data interpretation. • Consider clinical explanations for data quality issues. • Provide user-friendly EHR options for registering suicide incidents.
Defining, operationalizing, and measuring potential predicting factors	• Limited and uneven availability of psychosocial and contextual predictors constrains robust and unbiased model development.	• Developed high-availability estimators. • Addressed data gaps with clinicians. • Implemented a guideline-aligned assessment tool to simultaneously enhance data registration and support clinical decision-making. • Developed a sentiment analysis for contextual risk signals.	• Ensure predictor validity by prioritizing high-availability EHR data. • Address subgroup gaps through data governance. • Supplement psychosocial information via clinicians or patients. • Develop user-friendly assessment tools that integrate required data registration with clinical decision-making support.
Building the algorithm	• Complex models improve prediction but are difficult for clinicians to interpret.	• Established explainability as a core requirement. • Planned cocreation of an explainability dashboard with clinicians before the pilot.	• Balance predictive performance and explainability through close collaboration between data scientists and clinicians.
Toward an implementation pilot	• Effective use requires full integration into clinical workflows and sufficient clinician experience. • Algorithm use may introduce cognitive and decision biases.	• Planned joint data scientist–clinician sessions to integrate the algorithm into workflows and clarify roles. • Positioned the algorithm as an add-on to suicide prevention care, with clinicians' judgment remaining central.	• Organize data scientist–clinician sessions to support workflow integration and clarify roles. • Clearly communicate the algorithm's role and its support function for clinical decision-making. • Calibrate clinicians' expectations to the algorithm's actual capabilities and limitations.

[b]EHR: electronic health record.

Limitations

This study provided a detailed case study of the development of a suicide risk prediction algorithm using real-world EHR data, highlighting the tension between technical requirements and clinical needs. Using a qualitative, real-world approach, the study captured contextualized knowledge from the development team, who collaborated closely with clinicians. While generalizability is limited by the single-case design, triangulation and detailed process descriptions support transferability. A key limitation is that clinicians' perspectives were obtained indirectly via the development team rather than through direct engagement, although this was partly mitigated by desk research and targeted questions to include broader stakeholder views.

Conclusions and Future Research

Conclusions

Based on the findings of our case study, we highlight the following 5 main recommendations for mental health organizations that aim to evolve into data-driven practice.

1. Data governance and quality: high-performing algorithms require robust data governance and timely, deliberate data preparation to ensure data quality.
2. Cultural change in data entry: a cultural shift is needed to regard and manage data as a strategic asset for algorithm development.
3. Bias awareness and monitoring: organizations must remain sensitive to potential bias in both data and use, requiring careful data handling and regular evaluation of real-world application.

XSL•FO
RenderX

4. Balancing performance and transparency: predictive performance using complex models must be balanced with clinicians' needs for transparency and explainability to ensure actionability, trust, communication, and accountability.
5. Clinician-in-the-loop: it is essential to define the knowledge, skills, and workflows that enable clinicians to use algorithms responsibly while maintaining final clinical judgment.

For mental health organizations aspiring to evolve toward data-driven care, early preparation is essential. First, building predictive algorithms requires sufficient and well-structured data, which demands timely and deliberate data collection. Reliance on existing organizational protocols alone is insufficient; explicit attention must be given to how relevant variables are defined, recorded, and embedded in the EHR system. A cultural transformation is also critical. Second, data should not be viewed merely as an administrative or accountability tool but as a strategic resource for predictive modeling. However, this is not always aligned with clinical practice and may require a change in working processes for clinicians. This transition requires awareness and commitment from clinicians, whose engagement from the earliest stages of algorithm development is crucial. Collaboration between data scientists and clinicians must begin in an early stage of the development process: data scientists contribute technical and data-analytical expertise, while clinicians bring contextual understanding, interpret data inconsistencies, identify meaningful predictors, and help foster a data-driven culture. Organizations must also recognize potential biases within their data and proactively assess how information from subgroups is collected and represented. Third, ongoing attention to bias is crucial, as it may stem not only from data or model design but also from real-world use. Regular evaluation of both performance and application is essential to ensure quality and responsibility in practice. Decisions regarding model design should balance predictive accuracy with interpretability. Fourth, explainable AI techniques may help translate complex model outputs into clinically meaningful insights, allowing clinicians to understand and act upon algorithmic predictions. Clinicians require not only accurate models but also transparency to understand the reasons for the outcome to ensure actionability, trust, and clinician-patient communication. Institutions should further consider how accountability for algorithm use is shared between individual practitioners and the organization. Finally, advancing toward data-driven mental health care requires investment in clinicians' education and professional development regarding AI. Defining the knowledge, skills, and workflows that enable responsible algorithm use, while maintaining clinical judgment as the ultimate decision point, will be key to realizing the added value of predictive technologies in practice.

Future Research

Future research should further explore how robust data governance structures can be established to ensure data quality and readiness for algorithm development. This includes examining how AI techniques may contribute to improving data quality through automation, standardization, and enhanced data validation. Moreover, studies should investigate how cultural change can be fostered to promote viewing data as a strategic resource rather than an administrative by-product, and how such shifts can be maintained throughout the organization.

Attention to bias should extend beyond data collection and model design to the actual use of algorithms. Future studies are needed to determine under which conditions algorithms amplify or mitigate bias, and how systematic monitoring of real-world application can safeguard fairness and responsible use.

The ongoing tension between predictive performance and explainability also warrants investigation. Research should identify context-specific trade-offs between complex, high-performing models and simpler, more transparent approaches and explore how explainability dashboards can enhance actionability, trust, accountability, and clinician–patient communication.

Finally, future research should examine what knowledge, skills, and workflows clinicians need to engage responsibly with predictive algorithms while maintaining final clinical judgment. Integrating sociotechnical considerations throughout algorithm development will be key to ensuring that AI tools are both effective and ethically grounded in clinical practice.

While much focus has been placed on the technical aspects of ML in mental health care, sociotechnical factors related to successful algorithm development, implementation, and use have been largely overlooked [6,13,15,17,24,25,30,33,87]. More research is needed to explore these issues in real-world settings to ensure responsible and sustainable innovation.

Abstract

Background: Frequent vital sign (VS) monitoring is central to inpatient safety but is traditionally performed manually every 4 hours, a century-old practice that can miss early clinical deterioration, disrupt patient sleep, and impose a heavy documentation burden on nursing staff. Continuous VS monitoring (CVSM) using wearable remote patient monitoring devices enables near real-time, high-frequency VS measurement while reducing manual workload and preserving patient rest.

Objective: This implementation report describes the large-scale implementation of CVSM across an 8-hospital health system. The initiative aimed to (1) enhance earlier detection of patient health deterioration through continuous, algorithm-driven monitoring; (2) improve nursing workflow efficiency by reducing reliance on manual VS checks; and (3) minimize nighttime disruptions to support patient rest and recovery.

Methods: The program was designed for system-wide scalability and executed from 2022 to 2024 using a 4-phase framework: strategic program design, program planning, go-live preparation, and implementation and optimization. A Food and Drug Administration–cleared wearable device (BioButton) continuously measured heart rate, respiratory rate, and skin temperature, with data integrated into Epic and monitored 24×7 through a centralized virtual operations center. Rollout followed a staggered playbook across approximately 2700 adult non–intensive care unit beds and was supported by leadership engagement, supply chain readiness, staff training, and phased superuser-led adoption.

Implementation (Results): All 8 hospitals achieved full deployment between April 2023 and February 2024, with more than 95% device use rates and 100% nursing staff training completion. A standardized escalation workflow filtered approximately 50% of the alerts at the virtual operations center review stage, substantially reducing frontline alert burden. Operational refinements included revised heart rate and respiratory rate alert thresholds and the removal of temperature as a single alert trigger. Several units extended overnight manual VS intervals from every 4 hours to every 6 to 8 hours, with staff estimating approximately 4 hours saved per nursing shift. Patient care assistants redirected time toward patient mobility and personal care needs, while staff reported growing confidence in device performance over time.

Conclusions: This initiative represents the first system-wide deployment of CVSM across a diverse, multihospital health system. Success was enabled by early strategic alignment, phased rollout, robust IT and monitoring infrastructure, and iterative optimization. The program demonstrates the feasibility of embedding CVSM into routine inpatient care to improve efficiency and patient experience. Transferable strategies, including phased rollouts, centralized monitoring, and structured change management, may

inform other health systems pursuing digital VS redesign. Future work should rigorously evaluate impacts on patient outcomes, cost-effectiveness, and applicability to postacute and ambulatory care settings.

(JMIR Med Inform 2026;14:e78216) doi:10.2196/78216

KEYWORDS

continuous vital sign monitoring; remote patient monitoring; wearable devices; hospital workflow redesign; patient safety; digital health implementation; implementation science

Introduction

Context

This implementation occurred within Houston Methodist (HM), an 8-hospital health system in Texas encompassing the HM Hospital (a quaternary care academic flagship), 6 community hospitals, and 1 long-term acute care (LTAC) facility serving the greater Houston area, together serving a diverse adult population of more than 140,000 annual admissions and 2 million outpatient visits [1].

During the COVID-19 pandemic, HM established a centralized virtual operations center (VOC) and virtual intensive care unit (VICU) providing 24×7 monitoring for approximately 370 intensive care unit (ICU) beds. This infrastructure created favorable conditions for remote patient monitoring (RPM) and ultimately informed the development of the system-wide continuous vital sign (VS) monitoring (CVSM) program. This CVSM program differs from traditional RPM in its continuous, hospital-based, and fully integrated design, with data integrated into the electronic medical record and supported by 24×7 centralized oversight rather than periodic outpatient review.

In 2022, the health system launched a redesign of inpatient VS practices, with this report detailing the program's scale-up and deployment, which were designed from the outset for system-wide implementation.

Problem Statement

Frequent monitoring of VSs—heart rate (HR), respiratory rate (RR), temperature, blood pressure, and oxygen saturation (SpO_2)—is a cornerstone of inpatient safety [2]. On general hospital floors, VSs are routinely collected manually every 4 hours, reflecting a century-old practice that does not account for patient acuity [3,4]. This approach risks missed deterioration between checks, places substantial time demands on nursing staff, and disrupts patients' sleep, with physiological consequences [5-14]. Deteriorating VSs are well-established predictors of ICU transfer and in-hospital mortality, and CVSM, enabled by wearable RPM devices, now allows for unobtrusive, high-frequency VS measurement [7,11,12]. This work directly addresses health system challenges of limited access to timely clinical data and variable adherence to evidence-based monitoring practices, both of which undermine patient safety and workflow efficiency. However, evidence on broad, system-wide implementation across diverse hospital settings remains limited.

Similar Interventions

Previous CVSM implementations have typically been limited to ICUs, single hospitals, or narrow patient groups, demonstrating feasibility but limiting generalizability [15-17]. Our initiative differs by extending CVSM across all adult non-ICU inpatients in an 8-hospital system, integrated with Epic and supported by centralized monitoring. This report describes the implementation and scale-up process.

This report follows JMIR's implementation reporting guidelines for digital health implementation [18] to ensure transparency in describing the implementation context and processes.

Methods

Aim and Objective

The aim of this initiative was to redesign inpatient VS measurement practices to enhance patient safety, patient experience, and staff efficiency through the implementation of CVSM. Specific objectives were to enable early detection of deterioration, reduce nighttime disruptions to promote patient rest and recovery, and improve workflow by decreasing reliance on manual VS checks. Implementation outcomes included system-wide rollout to all eligible beds, 100% nursing staff training completion, optimal device use, and reductions in manual VS collection, with qualitative observations of staff and patient acceptance. Operational metrics (scale-up timeline, device use, alert filtering, and training completion) were directly measured, whereas workflow impacts and staff acceptance were reflected in qualitative, staff-reported estimates.

Implementation Strategy

The implementation strategy was designed for system-wide scalability and organized into 4 phases, with the observed timeline shown in Figure 1.

XSL•FO
RenderX

Figure 1. Four-phase implementation framework and observed timeline for scaling continuous vital sign monitoring across (CVSM) Houston Methodist's 8-hospital health system. EMR: electronic medical record.

Phase 1: Strategic Program Design (1-2 Years Before Implementation)

The health system defined an enterprise-wide vision for CVSM as part of a broader effort to modernize VS monitoring. Strategic goals emphasized embedding continuous monitoring into routine inpatient care, strengthening patient safety through earlier detection of deterioration, and redesigning workflows to mitigate the impact of nursing staff shortages.

A multidisciplinary team of key stakeholders, including clinical, operational, IT, supply chain, and innovation leaders, was engaged early and consistently to ensure clinical and organizational alignment. The team identified use cases and target populations, prioritizing continuous monitoring of all hospitalized, non-ICU patients to address the safety gap created by every-4-hour manual VS checks. Patient eligibility was intentionally broad; CVSM was applied to general adult medical-surgical inpatients, excluding only ICU patients, with no additional eligibility restrictions.

Implementation sites included the academic flagship, 6 community hospitals, and 1 LTAC facility, with monitoring supported by bedside nurses, unit superusers, and the centralized VOC. The multidisciplinary team guided planning and iteratively refined a scalable model for system-wide deployment, supported by superusers at the unit level and centralized monitoring through the VOC.

Phase 2: Program Planning (1Year Before Implementation)

After defining the overall CVSM strategy, the health system conducted market research to evaluate vendor partners and established planning priorities in workflow redesign, Epic integration, staff training, and IT infrastructure, with a standardized playbook to guide hospital rollouts. Vendor selection considered Food and Drug Administration (FDA) clearance, performance, usability, multiparameter monitoring, battery life, patient comfort, Epic integration, and scalability.

A wearable patch device (BioButton; BioIntelliSense) was selected as the FDA-cleared option that best met these criteria. The adhesive patch is worn on the chest with a battery life lasting 7 to 16 days. It continuously collects HR, RR, and skin temperature (additional parameters are listed in Multimedia Appendix 1) [6,17]. Device selection prioritized accurate RR measurement, given its established predictive value for deterioration [14,19]. Although a BioButton device does not measure SpO_2 or blood pressure, these parameters were acceptable through existing bedside monitoring. Continuous SpO_2 monitoring typically requires a tethered probe that disrupts rest and increases alarm burden [20], whereas the BioButton device allows unobtrusive, trended monitoring aligned with program goals to reduce patient disruptions.

From the outset, the program was designed for system-wide scale, leveraging existing institutional resources and establishing a centralized monitoring team at the main academic hospital. Pilot sites included 2 internal medicine units, 1 neurosurgery unit, and 1 neurology unit selected for innovation experience and staff receptiveness. Program management included site-level and system-level leads, who shared responsibilities with the vendor for workflow design, data integration, training, and support **(**roles are detailed in Multimedia Appendix 2).

Participating entities included HM, a quaternary academic health system whose mission emphasizes patient-centered, digitally enabled care, which led workflows, monitoring staff, and supply chain integration, and BioIntelliSense, which provided devices, hubs, dashboard tools, and technical support. The VOC delivered continuous monitoring, with bedside nurses serving as superusers. Intellectual property for the BioButton device remains with BioIntelliSense, while workflows, data integration, and the operational model belong to HM.

XSL•FO
RenderX

The business case projected nursing and patient care assistant (PCA) time savings from extended overnight VS intervals, supporting adoption and sustainability. Internal funding was secured as part of routine service redesign, with no direct costs to patients. Budget categories included devices, hubs, Epic integration, staff training, supply chain processes, and change management. BioButton devices were supplied through a per-bed subscription model, and approximately 2711 BioHub Wi-Fi gateways were installed across all patient rooms. The largest investments were technology procurement and integration, with ongoing costs for training and supply chain support.

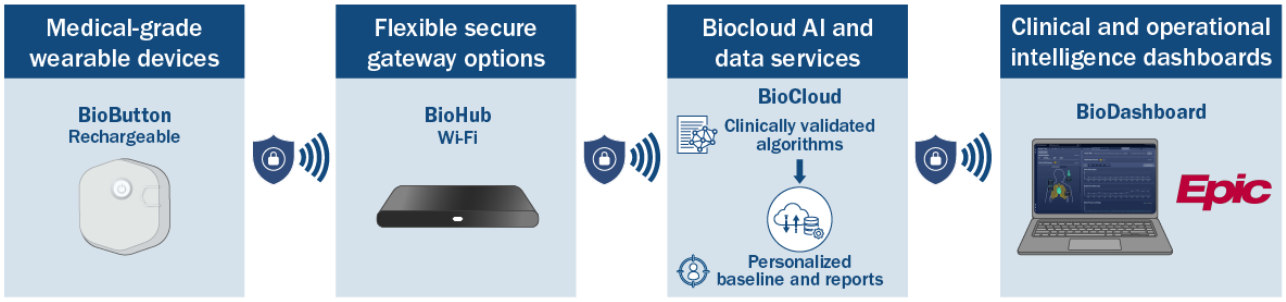
Phase 3: Go-Live Preparation (3-6 Months Before Going Live)

Building on program planning, readiness efforts focused on 5 domains: room and BioHub setup, device and supply chain readiness, Epic and IT validation, unit training plans, and kickoff planning. Activities occurred at both system and unit levels (details are provided in Multimedia Appendix 3). Integration with Epic and the monitoring dashboard followed standard institutional IT and security protocols. IT preparations included configuring BioHub connectivity, enabling secure transmission of physiological data, and validating data flow into Epic flowsheets and early warning score logic. A summary of this pathway is shown in Figure 2.

Device and environmental preparations included stocking BioButton devices, labeling return bins, and completing room readiness surveys. Initial stock levels were based on recent admission volumes, with automated reordering through the supply chain. Workflows were established for device return and sanitation.

Kickoff planning finalized rollout sequencing and support allocation. The central monitoring team staffing within the VOC was expanded by reallocating staff after reducing telemetry use. VOC staff completed vendor-led training and competency demonstrations in alert interpretation, escalation protocols, and workflow integration.

Phase 4: Implementation and Optimization



Implementation emphasized 5 core activities: playbook rollout, staff training, go-live support, protocol refinement, and iterative feedback and optimization. Each unit followed an 8-week rollout guided by the playbook, with superuser and vendor support during the go-live phase.

Training followed a train-the-trainer model, with unit leaders and superusers trained first, followed by cascading training to frontline staff. All bedside nurses completed a mandatory learning management system module (100% completion system wide), which covered device application, alert interpretation, escalation protocols, and workflow integration. Adoption was reinforced through superuser rounding, vendor staff presence, and structured communication plans. Training activities were designed to build knowledge, confidence, and consistency among staff and are consistent with approaches described in the implementation science literature [21-23].

Go-live execution proceeded in staggered groups of 4 to 8 units, allowing overlap between training and operational transitions. Kickoff meetings, leadership communication plans, and coordinated supply chain activation supported each launch.

Protocol refinement was embedded throughout the rollout. Initial thresholds and workflows were iteratively adjusted based on frontline experience. VOC champions and superusers reinforced troubleshooting and informed subsequent launches. Sustainability was achieved by embedding CVSM into standard operations, including VOC monitoring workflows, Epic documentation, supply chain logistics, and updated learning management system training modules. Continued superuser engagement and institutional commitment to operational funding reinforced adoption. Full institutionalization of CVSM into existing structures ensured long-term ownership and positioned the program as a core element of HM's broader digital care transformation strategy.

Ethical Considerations

The Institutional Review Board of Houston Methodist Research Institute reviewed this initiative and deemed it *not human research*, as it represented a service redesign implemented as part of standard care.

Implementation (Results)

Coverage

Between April 2023 and February 2024, the program expanded from pilot units to enterprise-wide coverage across all 8 hospitals, encompassing the full adult, non-ICU inpatient population (approximately 2700 beds across the academic flagship, 6 community hospitals, and 1 LTAC facility).

XSL•FO
RenderX

Rollout Approach and Timeline

The enterprise rollout followed a phased road map. Pilot implementation began on 4 units at the main hospital (2 internal medicine units, 1 neurosurgery unit, and 1 neurology unit). Four months later, deployment scaled through staggered 8-week waves of 4 to 8 units, with 3-week offsets to permit overlap between staff training and transitions, allowing the incorporation of iterative learning. This cadence enabled continuous optimization while maintaining operational continuity.

Monitoring and Escalation Workflow

Five months after the pilot launch, HM introduced a standardized escalation protocol embedded in centralized monitoring workflows. When BioButton device–triggered alerts appeared on the VOC dashboard, a VOC technician performed a first-line review to add clinical content and either dismissed nonactionable events or escalated alerts to a VICU nurse. Approximately half of the alerts were dismissed at the VOC step, reducing alert burden for frontline staff. Illustrative case examples are provided in Multimedia Appendix 4.

The VICU nurse notified the bedside nurse or activated the clinical emergency response team when intervention was indicated. This tiered model concentrated clinical escalation on higher-value alerts. Data on clinical emergency response team activations during the study period have been reported previously in a related outcomes study [24].

Outcomes and Post–Go-Live Protocol Refinement

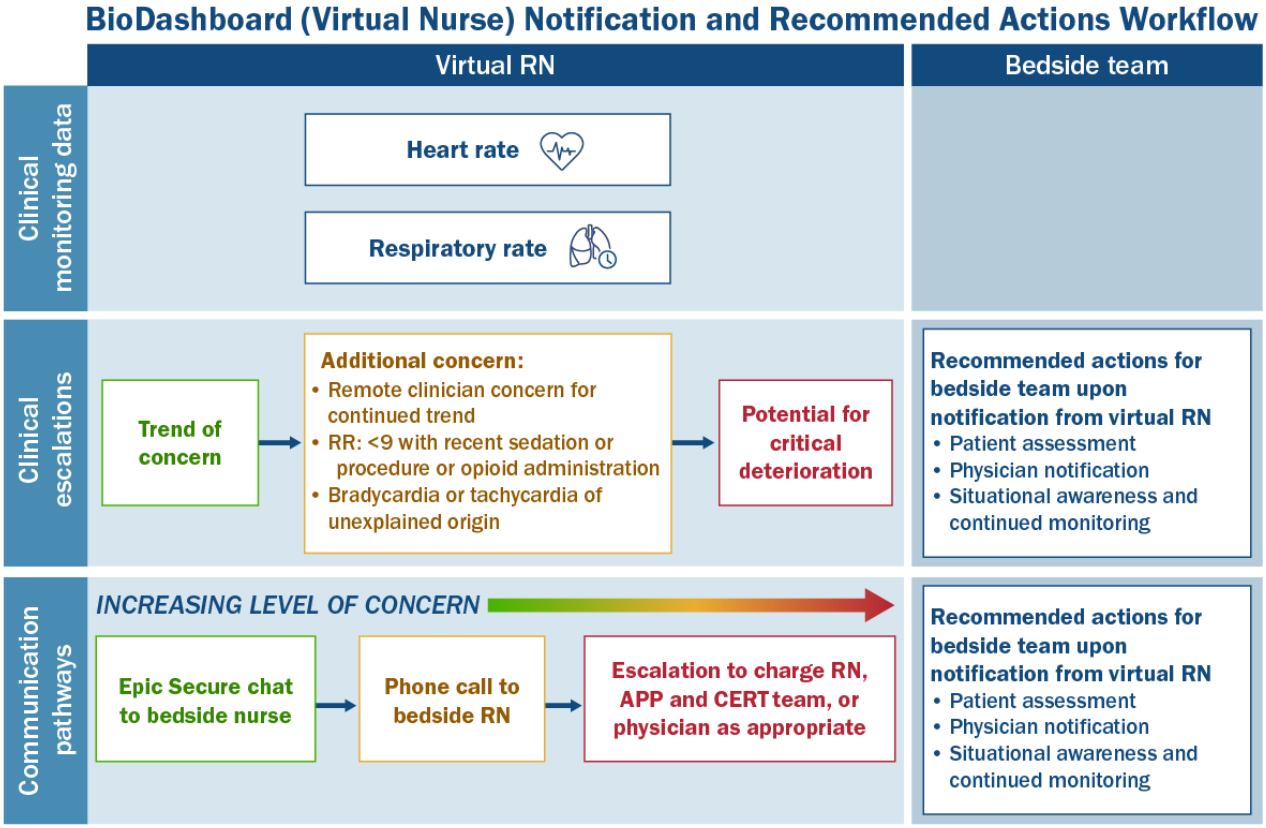
Primary outcomes included system-wide scale-up, reliable Epic integration, and sustained monitoring. Device use exceeded 95%, training completion reached 100%, and approximately 50% of alerts were resolved at VOC review. Secondary outcomes included improved alert specificity, fewer patient refusals, increased staff acceptance, and operational efficiencies (nursing and PCA time savings). Alert thresholds were systematically reviewed with virtual medicine leadership in collaboration with frontline nursing staff, superusers, and the vendor. Baseline thresholds (HR 50-115 beats per minute, RR 11-28 breaths per minute, and skin temperature >36 °C) were operationalized with alerts stratified as single alerts (1 abnormal VS), double alerts (2 abnormalities, typically HR and RR), or triple alerts (3 abnormalities: HR, RR, and skin temperature). Three protocol changes improved the system-wide specificity.

Skin temperature was removed as an isolated escalation criterion and retained only for triple alerts. The RR lower limit was reduced from 11 to 8 breaths per minute to reduce clinically insignificant overnight alerts. The upper HR limit was increased from 115 to 120 beats per minute to reduce nonactionable alerts reported by community hospitals and the LTAC facility. Other parameters (eg, body position and activity) contributed to *low motion* alerts but were not primary triggers.

Collectively, these adjustments improved the balance between sensitivity and specificity, as reflected by observed reductions in nonactionable alerts and staff-reported decreases in false positives during enterprise rollout. The final escalation workflow and logic are depicted in Figures 3 and 4, with detailed initial and revised threshold values in Multimedia Appendix 5.

XSL•FO
RenderX

Figure 3. Escalation workflow for the BioButton device alerts with virtual operations center triage and bedside escalation. Bedside teams are responsible for all button management activities (ie, placement or removal, low battery, and no data). Patient data (from the BioIntelliSense button) will be transmitted into the Epic vital signs flowsheet, and BioDashboard can take up to 20 minutes to fully synchronize. APP: advanced practice provider; CERT: clinical emergency response team; RN: registered nurse; RR: respiratory rate.



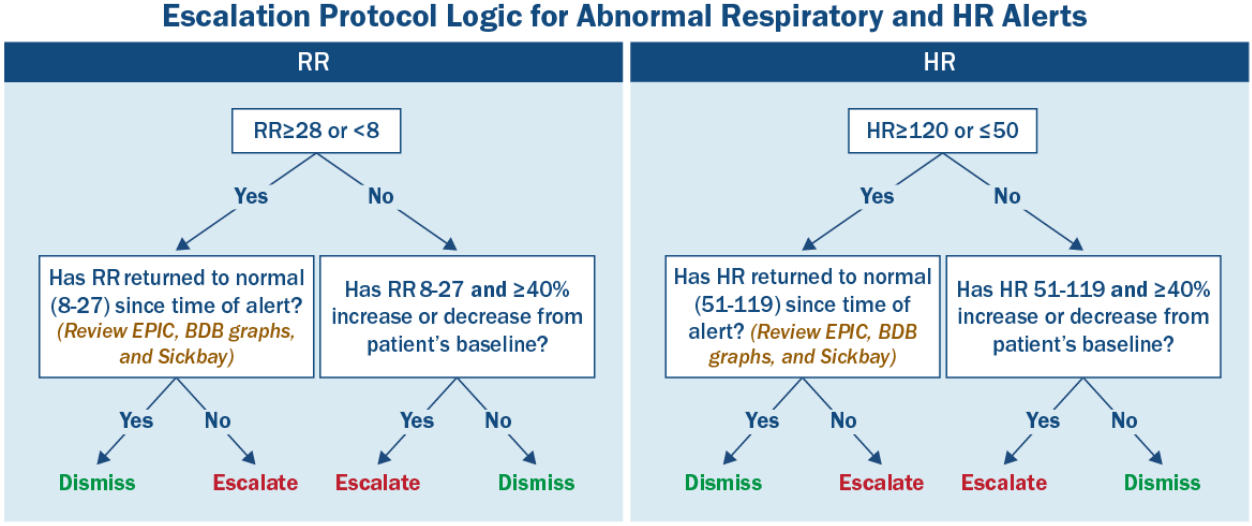


Figure 4. Escalation protocol for respiratory rate (RR) and heart rate (HR) alerts with system-wide thresholds. Final threshold for HR (50-120 bpm) and RR (8-27 bpm). Skin temperature has been removed from the escalation criteria. BDB: BioDashboard.

Lessons Learned and Implementation Challenges

Technical and workflow challenges identified during the pilot informed the enterprise rollout. Barcode scanning difficulties (eg, poor label contrast) occasionally impeded device-to-patient matching; staff used device packaging barcodes and Workstations on Wheels carts as interim work-arounds, and the vendor subsequently improved barcode resolution. Rare *double HR* artifacts (concurrent S1 and S2 detections) produced nonactionable alerts and were resolved via algorithm updates.

Variation in device application sometimes caused skin irritation, which was addressed via staff reeducation and the use of adhesive remover spray. Early staff skepticism about using median CVSM values for documentation declined as experience accumulated, and staff perceived CVSM values to be accurate and consistent with routine bedside measurements; patient

XSL•FO
RenderX

refusals decreased with standardized education. These mitigations and training reinforcements were propagated system wide during enterprise rollout.

As noted previously, unintended consequences, including minor skin irritation, initial device hesitancy, and early false positives, were observed and addressed through staff education, supplies, and vendor refinements; no significant harms were reported.

Discussion

Principal Findings

To our knowledge, this initiative represents the first large-scale deployment of wearable CVSM across a diverse, multihospital health system as part of a system-wide redesign initiative [17]. Our goal was to modernize inpatient VS practices by introducing continuous monitoring to support earlier detection, improve outcomes, and enhance both patient and clinician experience. Several units extended overnight VS intervals from every 4 hours to 6 to 8 hours, saving approximately 4 hours per nursing shift and allowing PCAs to focus on patient mobility and personal needs. Together with early clinical benefits, these efficiencies strengthened adoption and staff buy-in.

Weller et al [17] evaluated the same FDA-cleared device in 11,977 patients across urban and rural hospitals, with initial ICU use before expansion to non-ICU settings. They reported low RR alarms most frequently, while in our implementation, elevated RR emerged as the most common alert, underscoring RR's role as a sensitive marker of cardiopulmonary function. This difference likely reflects patient mix, as sedation in ICU patients tends to lower RRs, while elevated RRs in ward patients more often indicate deterioration.

A key distinction of this program was its breadth and scope. Unlike previous efforts limited to ICUs, daytime hours, or narrow diagnostic groups, this program encompassed all adult non-ICU inpatients, deployed continuously (24×7) across the flagship academic hospital, 6 community hospitals, and 1 LTAC facility. This design addressed gaps in every 4-hour VS collection, enabled earlier detection across diverse patient populations, and supported workflow redesign amid nursing staff shortages.

Device selection prioritized accurate RR measurement, given its strong predictive value. Although the BioButton devices do not measure blood pressure or SpO_2, they remained available through existing bedside monitoring. Continuous SpO_2 monitoring was avoided to minimize alarm burden. The device offered unobtrusive, trended monitoring without disturbing patients' rest while capturing key physiological parameters for early detection. The final escalation protocol's emphasis on HR and RR reflected clinical prioritization and not device limitation. Although formal satisfaction and quality metrics are forthcoming, early stakeholder feedback suggests that reduced overnight disruptions improved sleep quality, potentially enhancing patient satisfaction and reducing overnight nursing workload. Prospective studies are needed to evaluate long-term effects on clinical outcomes, alert trends, workflow efficiency, and satisfaction, including patient-reported outcomes.

Limitations

This report has several limitations. No formal satisfaction survey was conducted, and estimates of time savings were based on staff feedback. BioButton device–derived VSs were not independently validated, as accuracy testing of the FDA-cleared device was beyond the scope of this work. The escalation protocol was intentionally delayed in pilot units; therefore, early data reflect monitoring without active escalation, with finalized protocols introduced later and applied retrospectively. Although guided by an internal business case projecting nursing and PCA time savings, no formal health technology assessment was conducted.

Generalizability may be limited by HM's centralized monitoring model; other health systems may face different challenges. Observed alert trends may also differ across settings, as illustrated by differences between ICU-focused studies and our broad non-ICU deployment. Outcome measures, such as clinical impact, workflow efficiency, and adoption, were not prospectively defined, constraining evaluation but informing priorities for future analyses.

Several transferable lessons emerged: (1) structured change management with engagement, champions, and feedback loops supported adoption; (2) phased rollout with iterative refinements reduced risk and enabled optimization; (3) centralized monitoring enabled 24×7 oversight, while hospitals without such infrastructure could adapt using telemetry staff, rapid response teams, or external partners; and (4) alignment of CVSM with institutional priorities secured leadership support and momentum. Table 1 summarizes key lessons and success factors to guide future implementers in scaling similar initiatives.

XSL•FO
RenderX

Table 1. Key lessons and success factors from system-wide CVSMa implementation.

Domain	Challenges encountered	Lessons learned and success factors
Leadership and Governance	Balancing innovation with standardization across 8 hospitals	Early executive sponsorship and system-wide alignment maintained focus, accountability, and resource continuity.
Implementation Approach	Scaling across multiple hospitals while managing operational risk	Staggered enterprise rollout using an 8-week implementation playbook enabled iterative refinement and risk mitigation before full scale-up.
Workflow Integration	Incorporating CVSM data into existing Epic processes	Integration into Epic flowsheets and early warning scores streamlined workflow and improved adoption.
Technology and Infrastructure	Interoperability issues and alert fatigue	Centralized monitoring filtered ~50% of alerts before bedside escalation; iterative threshold refinements improved specificity and reduced alert fatigue.
Training and Adoption	Staff skepticism and learning curve	Superuser model, LMS[b] training, and vendor support during go-live built confidence and sustained engagement.
Change Management	Variation in readiness and engagement across sites	Phased rollout enabled iterative optimization and local adaptation while maintaining operational continuity.
Data Governance	Managing HIPAA[c] compliance and device data retention	Preimplementation IT security review ensured compliance with institutional privacy and security standards.
Sustainability	Maintaining engagement and support after implementation	Integration into standard operations, funding streams, and training infrastructure supported long-term sustainability.
Cultural Readiness	Early staff skepticism about device accuracy and value	Confidence increased with experience and demonstrated accuracy, reinforcing trust and normalization of continuous monitoring.

Conclusions and Future Implications

This initiative demonstrates the feasibility and operational value of scaling CVSM across a large, diverse health system. Embedding continuous monitoring into standard workflows can improve patient safety, enhance staff efficiency, and build infrastructure for digitally enabled care models.

Future work should rigorously assess clinical outcomes, economic impact, and patient-reported measures while exploring application in postacute and ambulatory settings. Although growing evidence supports continuous monitoring, prospective randomized trials are still needed to confirm clinical and economic benefits. As health systems address workforce shortages and rising patient acuity, wearable monitoring technologies, such as CVSM, could serve as core infrastructure for safer, more efficient, and patient-centered care.

Abstract

Background: Radiotherapy (RT) is a cornerstone of multimodal treatment for rectal cancer (RC); yet, substantial interindividual variability in treatment response persists. Deep learning (DL)–based radiomics offers potential for pre-RT response prediction to support personalized decision-making. **Objective:** This study aimed to develop and compare multiple DL radiomics models for predicting RT response in RC, with emphasis on the performance and clinical utility of Transformer architectures. **Methods:** In this single-center retrospective study, 2000 pathologically confirmed patients with RC who received standard RT were included. Pretreatment computed tomographic and dynamic contrast-enhanced magnetic resonance images and clinical variables were collected. Treatment response was categorized according to RECIST (Response Evaluation Criteria in Solid Tumors) version 1.1 as good (complete or partial response) or poor (stable or progressive disease). The primary analysis used magnetic resonance imaging (MRI)–only input; computed tomography (CT) was used for registration and quality control and evaluated in a late-fusion CT + MRI sensitivity analysis. Data were randomly split into training, validation, and test sets (8:1:1), with 5-fold cross-validation within the training set. Test set tumor masks were manually delineated, whereas a U-Net assisted segmentation was performed only within training to prevent data leakage. Convolutional neural network, graph convolutional network, and Transformer classifiers were compared. Class imbalance (approximately 65% vs 35%) was addressed using class weighting. Performance was evaluated using area under the receiver operating characteristic curve (AUROC) and accuracy with 95% CIs obtained by bootstrapping. AUROC differences were assessed using the DeLong test. Clinical usefulness was evaluated using decision curve analysis. Segmentation performance was quantified by Dice coefficient and intersection over union. Model interpretability was assessed using Gradient-Weighted Class Activation Mapping. **Results:** In the MRI-only primary analysis, the Transformer achieved the best performance on the independent test set, with accuracy of 87.0% (95% CI 84.2%-89.5%) and AUROC of 0.921 (95% CI 0.901-0.945), significantly outperforming the convolutional neural network (AUROC 0.881; *P*=.02) and graph convolutional network (AUROC 0.894; *P*=.041). Sensitivity and specificity were 89.2% and 82.9%, respectively. Decision curve analysis demonstrated higher net benefit across threshold probabilities of 0.3-0.7. U-Net segmentation achieved a mean Dice coefficient of 0.892 and intersection over union of 0.814. In sensitivity analysis, CT + MRI late fusion yielded a comparable AUROC to MRI only (0.926 vs 0.921; *P*=.36), with modest incremental net benefit at higher thresholds. **Conclusions:** In this large pre-RT imaging cohort, an MRI-driven Transformer-based DL radiomics model outperformed conventional architectures in predicting RT response in RC and demonstrated superior clinical net benefit. Late fusion of CT and MRI did not significantly improve overall discrimination but may provide incremental benefit in specific decision contexts. Multicenter external validation is warranted.

deep learning; radiomics; rectal cancer; radiotherapy; Transformer model

Introduction

Rectal cancer (RC) remains one of the leading causes of cancer-related incidence and mortality worldwide, with a particularly notable rise among middle-aged and older adult populations. Radiotherapy (RT) is a cornerstone of RC management; however, its therapeutic efficacy varies substantially among patients [1]. Current clinical indicators and conventional imaging approaches show limited ability to accurately predict individual responses to RT [2], often failing

XSL•FO
RenderX

to identify patients who are truly radiosensitive [3,4]. This variability poses a significant challenge in optimizing treatment strategies [2]. Consequently, there is a pressing need for robust predictive tools to guide personalized treatment and improve clinical outcomes.

The advent of radiomics has introduced the ability to extract high-dimensional quantitative features from medical images, uncovering latent biological information and offering novel insights into tumor behavior and treatment response. Unlike traditional imaging techniques, radiomics enables noninvasive prediction of therapeutic efficacy using imaging-derived biomarkers [5,6]. Nevertheless, conventional machine learning models often struggle to manage the complexity of radiomics data, particularly their high dimensionality and inherent nonlinearity [7,8]. This has led to a growing interest in the application of advanced deep learning (DL) algorithms, which offer superior capacity for feature representation and pattern recognition, to enhance the predictive power of radiomics analyses [9].

DL, particularly convolutional neural networks (CNNs), has achieved substantial advances in medical image analysis in recent years [10,11]. These models can automatically extract hierarchical features from imaging data and effectively recognize and classify complex patterns [12]. Compared with traditional approaches, DL offers notable advantages in handling high-dimensional data and performing intricate pattern recognition, making it especially well suited for analyzing radiomics data [13,14]. However, most existing studies have applied single DL algorithms in isolation, with few providing a systematic comparison of multiple models, particularly in the context of predicting RT response in patients with RC [15].

In recent years, the application of artificial intelligence (AI) in RT, cancer diagnosis, and clinical decision support has shifted from research exploration toward clinical deployment. Within the RT workflow, AI has been increasingly implemented in key steps such as organ autosegmentation, target delineation, (semi-)automated treatment planning, dose optimization, and image registration, yielding measurable time savings and improved plan consistency [16]. In the domain of cancer diagnosis, the integration of DL and radiomics has achieved substantial progress in RC lesion segmentation and feature quantification on magnetic resonance imaging (MRI). Such models can automatically localize tumor regions and characterize morphological and textural features of lesions, thereby facilitating earlier and more consistent assessment and diagnosis; this has been substantiated by both systematic reviews of RC lesion segmentation and specific studies on post–neoadjuvant chemoradiotherapy (nCRT) T2-weighted (T2W) MRI segmentation [17]. Moreover, AI models that integrate multimodal data have demonstrated practical value for personalized treatment strategies and risk prediction in clinical decision-making. For RC, a multicenter study showed that late-fusion models combining multiparametric MRI–derived DL or radiomics features with clinical variables outperformed unimodal approaches in predicting early recurrence risk and provided greater clinical net benefit as assessed by decision curve analysis (DCA) [18]. Against this background, this study integrates DL with radiomics to construct a predictive model aimed at accurately assessing the RT response in RC patients, thereby providing intelligent support for treatment optimization.

We systematically compared multiple state-of-the-art DL architectures, including CNNs, graph convolutional networks (GCNs), and Transformer models, for their ability to analyze and process radiomics imaging data in patients with RC. The Transformer architecture, in particular, exhibited superior capability in modeling complex image features through its self-attention mechanism, allowing it to effectively identify key regions relevant to RT response. By comparing these models in terms of feature extraction and predictive performance, this study investigated the potential of the Transformer model in predicting RT response in RC and evaluated its feasibility for clinical application. Unlike traditional applications of AI in tumor detection or initial diagnosis, this study focused on patients with pathologically confirmed RC. Our objective was to predict their responsiveness to RT based on pretreatment imaging, thereby enabling individualized treatment planning and minimizing unnecessary exposure to RT-related risks.

The key innovation of this study lay in the systematic application and comparison of multiple DL algorithms to enhance the accuracy of RT response prediction, with a particular emphasis on exploring the strengths of the Transformer model. By combining DL techniques with radiomics, we aimed to advance current predictive methodologies and develop a more precise model for RT response assessment. This work provides clinicians with a robust, data-driven tool to support personalized therapeutic strategies, ultimately contributing to the broader goal of precision medicine in oncology.

Methods

Ethical Considerations

This study was conducted in strict accordance with ethical standards. The use of imaging and clinical data was approved by the Medical Ethics Committee of Shanxi Provincial People's Hospital. As this was a retrospective analysis, all data were obtained from routine clinical records and were fully deidentified prior to analysis. The ethics committee confirmed that additional informed consent was not required. All data were anonymized before processing, and no identifiable patient images or information was included in the manuscript or supplementary materials. Data were stored on encrypted servers with access restricted to authorized investigators. Since this study did not involve prospective data collection or patient intervention, no monetary or nonmonetary compensation was provided to participants. For any future studies involving identifiable images, written informed consent will be obtained, and the relevant materials will be submitted with the manuscript.

Data Collection

This retrospective study included 2000 patients with RC who were treated at Shanxi Provincial People's Hospital between January 2015 and December 2023. All patients underwent standard RT and had complete paired pretreatment computed tomography (CT) and MRI data, along with follow-up assessments of RT response.

XSL•FO
RenderX

Inclusion criteria were (1) pathologically confirmed RC, (2) receipt of standard RT, (3) availability of complete pretreatment CT and dynamic contrast–enhanced MRI (DCE-MRI) data, and (4) documented RT outcomes with follow-up records. Exclusion criteria were (1) incomplete or poor-quality imaging data, (2) missing essential clinical information or outcome labels, (3) coexisting malignancies or severe systemic diseases, and (4) patients who did not receive standard RT protocols. Treatment regimens followed the Chinese Society of Clinical Oncology guidelines for RC and primarily consisted of long-course RT (50.4 Gy in 28 fractions). Some patients also received concurrent chemotherapy and subsequent surgical intervention, depending on clinical conditions.

To ensure transparency in patient selection, a CONSORT (Consolidated Standards of Reporting Trials)-style flowchart is provided in Figure S1 in Multimedia Appendix 1, detailing the inclusion process, exclusion criteria, final sample size, and classification of patients into RT-sensitive and RT-insensitive groups.

All imaging data were acquired from routine clinical scanning systems at a single institution (Shanxi Provincial People's Hospital), encompassing MRI and CT examinations performed across different years. Detailed information regarding scanner models and acquisition parameters is provided in Table S1 in Multimedia Appendix 2.

Data Preprocessing

Following data collection, the imaging data were preprocessed to ensure quality and consistency. The preprocessing steps included denoising, cropping, normalization, and resolution adjustment. All images were normalized to a range between 0 and 1 and resized to a resolution of 512×512 pixels. To enhance the model's generalization ability, data augmentation techniques such as rotation, flipping, and scaling were applied to generate more diverse training samples and effectively expand the dataset. In addition, clinical data were standardized to harmonize feature values with different units and ranges, ensuring compatibility with model input requirements. The complete data collection and preprocessing workflow is illustrated in Figure S1 in Multimedia Appendix 3.

To prevent data leakage, the statistical parameters required for image normalization (mean and SD) were computed exclusively from the training set and kept fixed for both the validation and test sets. The test set was not involved in estimating normalization parameters at any stage, thereby ensuring independence and rigor in both preprocessing and model evaluation.

All DL models used in this study were trained and inferred on 2D slices; thus, the input features were derived solely from spatial texture information within single images, without relying on voxel-level 3D volume information. During preprocessing, we did not perform volumetric resampling along the *z*-axis to reconcile slice thickness differences (3 mm vs 4 mm), in order to avoid interpolation-induced artifacts that could distort 2D texture features. Because model training and prediction were conducted at the single-slice level, and all patients' images were acquired using consistent scanning sequences and acquisition protocols, variations in slice thickness were expected to have limited impact on grayscale distribution or spatial structure of the input features. Nevertheless, we discuss the potential biases associated with differing slice thicknesses in the "Limitations" section, and we plan to explore full 3D volume resampling and the integration of 3D models in future work to further improve model robustness in cross-device settings.

Data Annotation and Quality Control

To ensure high-quality data for model training, strict annotation and quality control procedures were applied to all imaging data and RT response labels. For the imaging side, radiologists manually delineated tumor regions, with particular attention paid to tumor boundaries and clinically relevant areas. Semiautomated annotation tools were used to assist in the delineation process. All annotations were independently reviewed by 2 associate chief radiologists (ZW and ZH), each with more than 10 years of experience. All delineation results were further validated through random sampling to ensure the consistency and accuracy of boundary recognition.

RT response labels were assigned based on posttreatment MRI evaluations and classified according to the RECIST (Response Evaluation Criteria in Solid Tumors) version 1.1. Patients who achieved a complete response (CR) or a partial response (PR) were categorized as the "good response (GR) group," while those with stable disease or progressive disease were categorized as the "poor response group." All imaging evaluations were performed in a blinded manner, with evaluators unaware of treatment plans and clinical outcomes. Two independent reviewers (ZW and ZH) assessed the follow-up MRIs, and interobserver agreement was assessed using the Cohen κ coefficient, which reached 0.83, indicating good consistency. Final response classifications were determined through consensus and used as ground-truth labels for supervised model training.

In particular, all tumor masks in the test set were manually annotated by experts without reference to any DL model outputs, thereby avoiding error propagation and ensuring the independence and rigor of model evaluation. The U-Net model was used exclusively on the training set to generate tumor masks as auxiliary inputs for the classification models. Its outputs were not used in any segmentation or feature extraction tasks for the test set, minimizing the risk of information leakage.

DL Model Construction and Training

For the patient-level response prediction task, the model first performs independent inference on each 2D slice, producing a probability score indicating the likelihood of belonging to the "GR" category. Subsequently, the predicted probabilities of all slices from the same patient are averaged arithmetically to obtain an aggregated patient-level probability, and a threshold of 0.5 is applied to generate the final patient-level classification label. This aggregation strategy helps smooth slice-to-slice fluctuations caused by differences in imaging position, preventing any single atypical slice from disproportionately influencing the overall judgment. As a result, the stability and robustness of patient-level predictions are enhanced. This study used multiple DL algorithms to process radiomics imaging data and predict

XSL•FO
RenderX

patient responses to RT (Figure S1 in Multimedia Appendix 4). The models compared included CNNs, GCNs, and Transformer models. All models were trained and tested on the same dataset to ensure comparability.

The Transformer model served as the primary focus due to its self-attention mechanism, which enabled the capture of complex global features and provided unique advantages in tumor region recognition. In this model, input images were divided into 16×16 patches and processed with 8 multihead attention heads and 12 Transformer encoder layers. Standard sinusoidal positional encoding was incorporated to preserve spatial structure information. The model was trained using the Adam optimizer, with an initial learning rate of 1e-4 and a cosine annealing strategy for dynamic learning rate adjustment. Training was conducted over 100 epochs, with early stopping applied if validation loss did not decrease for 10 consecutive epochs.

As the comparative baseline, the CNN used a residual networks (ResNet-34) architecture, consisting of 34 residual convolutional layers organized into 4 residual stages with channel dimensions of 64, 128, 256, and 512, respectively. Feature extraction was performed on 2D patches of the input images. The output of the final global average pooling layer was fed into a 2-layer fully connected classification head (hidden layer size=256, activation function=ReLU) to generate predictions of RT response.

The GCN module adopted a 3-layer GCNConv structure, where nodes represented embedded features of image patches or regions of interest (ROIs). The adjacency matrix was constructed based on spatial proximity using a k-nearest neighbors approach (k=8). Each layer used a ReLU activation function, and dropout (P=.30) was applied between layers to mitigate overfitting. The aggregated node features after global pooling were passed to a classification layer. All models were trained under identical conditions, using the same loss function (weighted cross-entropy), optimizer (Adam, learning rate=1×10^{-4}), and training strategy (cosine annealing schedule with early stopping) to ensure a fair performance comparison. Hyperparameter tuning and L2 regularization were applied throughout training to reduce overfitting risks. The final model was independently evaluated on the test set and compared against other networks, with particular emphasis on its performance in feature extraction and classification accuracy.

Given the class imbalance in RT response labels (approximately 65% of patients in the GR group and 35% in the poor response group), a class weighting strategy was introduced during training. Specifically, inverse-frequency weights based on sample distribution were applied in the loss function to enhance the model's sensitivity to the minority class (poor response patients). This approach effectively mitigated the prediction bias caused by unequal class distribution and yielded higher sensitivity and overall stability in the validation set.

In the final implementation of this study, the Transformer architecture was used solely as an image-level classifier. The network consisted of multiple encoder layers and a classification head, without any decoder branch or explicit segmentation output (eg, a "Seg Head"). The tumor segmentation task was performed entirely by an independent U-Net model, and the 2 models operated independently throughout the training and evaluation processes.

Dataset Splitting and Cross-Validation

To evaluate the generalization ability of the models, the dataset was divided into training, validation, and test sets in a ratio of 8:1:1. Random sampling was used to ensure the representativeness of each subset. The 8:1:1 split was chosen based on the sufficiently large sample size (2000 patients), which supported the high-dimensional feature extraction needs of DL models. A larger training set enabled the model to better learn complex nonlinear patterns, while 200 patients each were retained for independent validation and testing. To further improve model stability and generalizability, 5-fold cross-validation was applied during training, with k set to 5. Stratified sampling was used to preserve consistent class distributions across all folds. All models were trained and evaluated on the same data splits, and the average performance metrics across the 5 folds were reported as the final results. This approach ensured robust evaluation, minimized bias, and enhanced the reproducibility of model performance across different subsets.

To evaluate model generalizability, the dataset was divided into training, validation, and testing subsets in an 8:1:1 ratio. All partitions were performed at the patient level, ensuring that all images, slices, and augmented samples from the same patient were assigned exclusively to a single subset to prevent information leakage. Stratified random sampling was applied to maintain consistent class distribution across subsets. To further enhance model robustness and generalization performance, 5-fold cross-validation (k=5) was conducted within the training cohort, also based on patient-level partitioning. This approach ensured the independence of the validation data and the reproducibility of the experimental results.

To avoid data leakage, data augmentation in this study was applied exclusively to the training set, while no augmentation was performed on the validation or test sets. All augmented samples were strictly linked to their original patients and existed only within the training subset, ensuring that none entered the independent test set. Consequently, each test-set patient corresponded to exactly 1 nonaugmented imaging input during inference, which explains why the total count in the confusion matrix matches the original number of patients (n=200).

Model Evaluation and Performance Analysis

Model performance was evaluated using multiple classification metrics, including accuracy, sensitivity, specificity, receiver operating characteristic (ROC) curves, area under the curve (AUC) values, and confusion matrices, to comprehensively assess the predictive accuracy of RT response in RC. Ninety-five percent CIs were calculated for all metrics to strengthen the robustness and interpretability of results.

To statistically compare model performances and verify the relative advantage of the Transformer model, pairwise bootstrap resampling (10,000 iterations) and DeLong's test were performed for AUC comparisons, with P values reported. ROC curves and their confidence intervals were used to visually and

XSL•FO
RenderX

quantitatively compare the classification performance of different models.

Calibration was evaluated on the independent test set by plotting a calibration curve (reliability diagram) using 10 equal-frequency bins (deciles). For each bin, we reported the mean predicted probability and the observed event rate. Overall calibration was quantified with the Brier score (the mean squared error between predicted probabilities and true labels). All calibration analyses were performed once on the test set without any retraining or post hoc recalibration to avoid information leakage. To ensure fairness, the bin boundaries and the evaluation pipeline were kept identical across input settings (MRI-only vs CT + MRI).

During evaluation, particular emphasis was given to evaluating the Transformer model's performance under varying segmentation input conditions. Its prediction results were further analyzed through Gradient-Weighted Class Activation Mapping (Grad-CAM) visualization to interpret attention regions and their clinical relevance. Tumor segmentation performance using the U-Net model was evaluated on the independent test set, with the Dice Similarity Coefficient (DSC) and the Intersection over Union (IoU) used as primary metrics. Manually delineated tumor regions, confirmed by 2 experienced radiologists, served as the gold standard. Failure cases were manually analyzed to identify potential factors contributing to segmentation inaccuracies, such as blurred tumor boundaries, low tissue contrast, or irregular tumor morphology. Detailed segmentation outcomes are shown in the "Results" section, and representative case images are provided in multimedia appendices.

Image Data Analysis Method

The image data analysis pipeline in this study consisted of 2 independent stages: tumor segmentation and image-level classification. First, a U-Net segmentation network was used to delineate tumor regions on the raw MRI or CT images, generating binary masks (Figure S1 in Multimedia Appendix 5). This segmentation model served solely to provide ROIs and did not participate in subsequent classification learning. Next, image patches or ROI features extracted from the masked tumor regions were fed into 3 types of classification models, CNNs, GCNs, and a Transformer classifier (Figure S1 in Multimedia Appendix 6), to predict patients' RT response.

It is important to emphasize that the Transformer model used in this study was a pure classification architecture composed only of an encoder and a multilayer perceptron classification head. It did not include any decoder structure, upsampling pathway, or segmentation outputs. Accordingly, it was entirely independent of the U-Net segmentation model used to generate masks; the 2 models shared no parameters and had no information exchange during training or inference. The GCN was used to model spatial relationships within the tumor region, further enhancing classification performance. The overall model evaluation and performance analysis workflow is shown in Figure S1 in Multimedia Appendix 7.

Input Modalities and Multimodal Fusion Strategy

In the primary analysis, the classifier used MRI-only inputs—pre-RT DCE-MRI and T2W sequences—and extracted features or patches or embeddings strictly within expert-annotated tumor masks, thereby minimizing bias from cross-modal acquisition heterogeneity and registration error. CT was used solely for quality control and, when necessary, rigid registration and was not provided to the classifier. Per reviewer request, we additionally implemented late fusion of CT + MRI under the same data split, loss function, class weighting, and hyperparameter settings as the primary analysis. Specifically, patient-level representations were extracted from CT and MRI with identical backbone encoders; after feature alignment and normalization, the representations were concatenated immediately before the classification head and trained or evaluated jointly (all other procedures unchanged). To ensure a fair comparison, the independent test set was kept fixed (n=200; good responders, n=130 and poor responders, n=70); only the input modality configuration was varied.

Statistical Analysis

This study applied various DL techniques to analyze radiomics imaging data from patients with RC. Initially, CNNs were used to extract features from the image data, capturing fine-grained details of tumor tissues. During image segmentation, deep segmentation networks such as U-Net and Mask R-CNN were used to identify and annotate tumor regions, ensuring accurate localization of key lesions. The self-attention mechanism of the Transformer model was used to manage complex spatial relationships, thereby improving the model's pattern recognition capabilities. GCNs were also applied to extract global and local spatial features from the images, effectively modeling both tumor and peritumoral tissue characteristics. By integrating multiple DL models, the study aimed to achieve accurate predictions of RT response and support personalized treatment recommendations.

During model evaluation, various statistical methods were used to comprehensively assess predictive performance. Metrics, including sensitivity, specificity, precision, and recall, were calculated to evaluate classification outcomes across different categories. Confusion matrices were plotted to visualize model performance in distinguishing between positive and negative RT responses. To assess predictive ability across varying thresholds, ROC curves and AUC values were generated for each model. These statistical analyses facilitated a detailed comparison of the strengths and limitations of each DL approach in predicting RT response in patients with RC.

Results

Dataset Sample Distribution Balance and Generalization Ability

In this study, radiomic imaging data from 2000 patients with RC were collected and randomly divided into training (1600 cases), validation (200 cases), and test (200 cases) sets using an 8:1:1 ratio. Approximately 65% (1300/2000) of patients exhibited a favorable response to RT and were classified as the "sensitive" group, while the remaining 35% (700/2000) were categorized as "nonsensitive." As shown in Table 1, we further compared baseline demographic and clinical characteristics—including age, sex, T stage, N stage, tumor

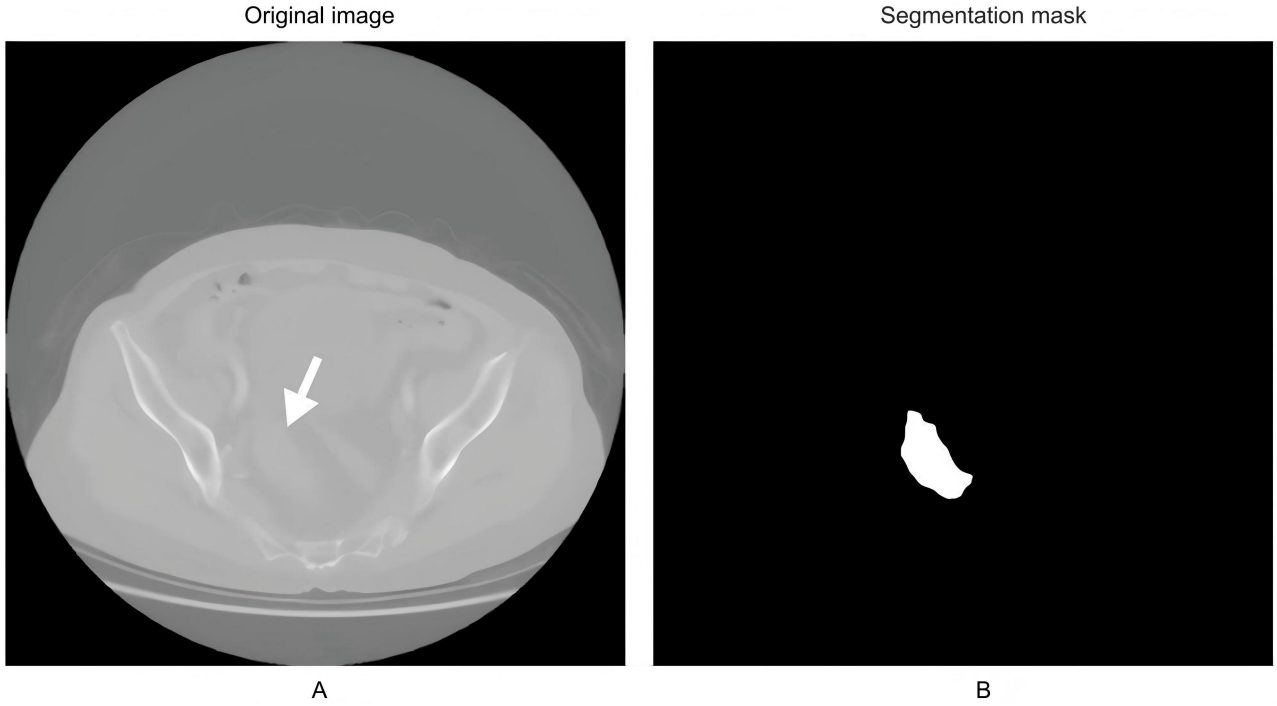
XSL•FO
RenderX

location, and carcinoembryonic antigen levels—between the training and test sets. None of the variables showed statistically significant differences (P>.05). These results indicate that the random partitioning of the dataset was unbiased and that the training and test sets were highly comparable. This balanced distribution provides a reliable foundation for model training and independent validation, thereby enhancing the generalizability and robustness of the proposed approach.

Table . Baseline demographic and clinical characteristics of patients in the training and testing cohorts[a].

Variable	Training cohort (N=1600)	Testing cohort (N=200)	*P* value
Age (years), mean (SD)	58.7 (10.9)	59.1 (11.2)	.62
Sex, n (%)			.53
Male	980 (61.3)	118 (59.0)	
Female	620 (38.7)	82 (41.0)	
T stage, n (%)			.78
T2	430 (26.9)	50 (25.0)	
T3	930 (58.1)	120 (60.0)	
T4	240 (15.0)	30 (15.0)	
N stage, n (%)			.67
N0	610 (38.1)	80 (40.0)	
N1	710 (44.4)	86 (43.0)	
N2	280 (17.5)	34 (17.0)	
Tumor location, n (%)			.79
Upper rectum	310 (19.4)	36 (18.0)	
Midrectum	860 (53.8)	112 (56.0)	
Lower rectum	430 (26.9)	52 (26.0)	
CEA[b] level (ng/mL), median (IQR)	3.6 (2.1-6.8)	3.8 (2.2-7.0)	.73
Response category, n (%)			>.99
Good response	1040 (65.0)	130 (65.0)	
Poor response	560 (35.0)	70 (35.0)	

[a]This table shows the baseline differences between the training and test sets in demographic characteristics (age and sex), tumor clinical staging (T stage and N stage), tumor location, and CEA level. Statistical comparisons were performed using independent-samples *t* tests, chi-square tests, or Mann-Whitney *U* tests, as appropriate. All *P* values were greater than .05, indicating no significant differences between the training and test sets. This demonstrates that the random allocation process was unbiased and that the cohorts were well matched and comparable.



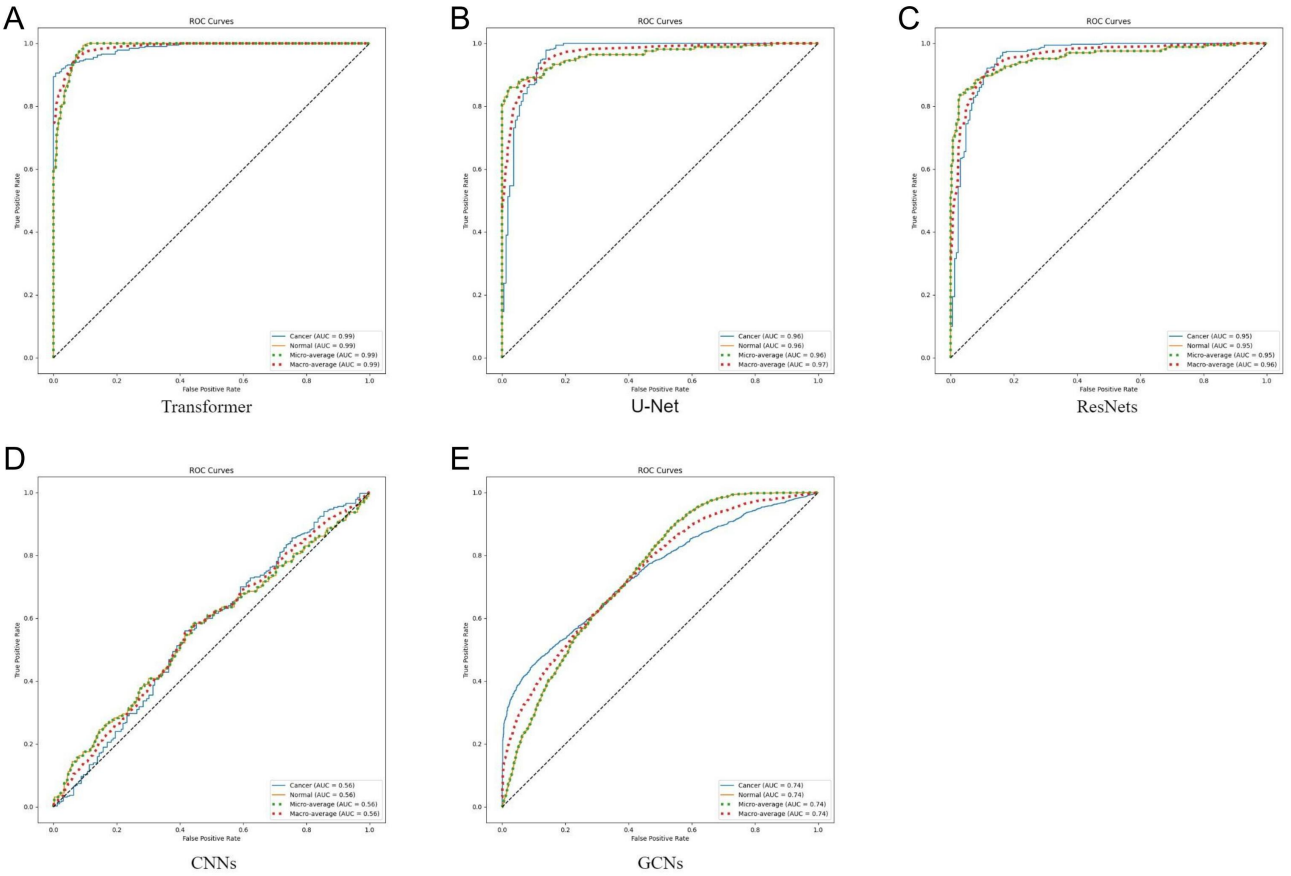
[b]CEA: carcinoembryonic antigen.

High Accuracy of U-Net Model in Tumor Region Segmentation

In this study, a U-Net segmentation network was applied to automatically segment tumor regions in the imaging data of patients with RC. The results demonstrated excellent performance of the model in tumor recognition and segmentation tasks. On the independent test set, the U-Net model achieved a mean DSC of 0.892 (95% CI 0.881 - 0.904) and a mean IoU of 0.814 (95% CI 0.800 - 0.829), indicating high segmentation consistency and robustness. The model precisely delineated tumor boundaries and clearly separated tumor regions from surrounding structures. The original image is shown in Figure 1A, and the corresponding segmentation mask generated by the U-Net model is shown in Figure 1B.

XSL•FO
RenderX

Figure 1. Tumor region segmentation results. (**A**) Original image. The white arrow indicates the rectal tumor lesion. (**B**) Model segmentation result image (tumor region highlighted).



When compared with manually annotated gold-standard segmentations by expert radiologists, the model showed a high degree of agreement in both boundary definition and tumor morphology. Notably, the U-Net model maintained strong performance even when segmenting tumors with irregular shapes or blurred margins. However, a small number of inaccurate segmentations were observed, primarily in cases characterized by indistinct tumor margins, low contrast with adjacent tissues, or atypical tumor morphology. These challenging cases provide directions for future model optimization.

Outstanding Performance of the Transformer Model in Predicting RT Response

This study compared the performance of several DL models in predicting the RT response in patients with RC. The results showed that the Transformer model achieved the highest overall performance, with an accuracy of 87%. As illustrated in Figure 2A, the Transformer leveraged its self-attention mechanism to effectively process complex patterns and fine-grained features within the radiomics imaging data, offering a distinct advantage in capturing global contextual information. In comparison, the CNN (Figure 2D) and GCN (Figure 2E) models achieved accuracies of 82% and 84%, respectively, both lower than that of the Transformer model. Analysis of ROC curves (Figures 2A-2E) further highlighted the Transformer model's superior discriminative ability, as reflected by its AUC value of 0.921 (95% CI 0.901 - 0.945), which exceeded that of the CNN (Figure 2D) and GCN (Figure 2E).

XSL•FO
RenderX

Figure 2. ROC curve comparison of different models. (A) Transformer, (B) U-Net, (C) ResNet, (D) CNN, and (E) GCN. AUC: area under the curve; CNN: convolutional neural network; GCN: graph convolutional network; ROC: receiver operating characteristic.

To enhance the robustness of the results, 95% CIs were calculated for all classification metrics across the models (Table 2). On the independent test set, the Transformer model achieved an accuracy of 87.0% (95% CI 84.2% - 89.5%), sensitivity of 89.2% (95% CI 85.3% - 92.4%), specificity of 82.9% (95% CI 79.2% - 88.1%), and an AUC of 0.921 (95% CI 0.901 - 0.945). In contrast, the CNN model reached an AUC of 0.881 (95% CI 0.854 - 0.906), while the GCN model achieved an AUC of 0.894 (95% CI 0.869 - 0.918).

Table . Performance comparison of deep learning models in predicting radiotherapy response[a].

Model	Accuracy	Sensitivity	Specificity	AUC[b]	*P* value vs Transformer
Transformer	87.0% (84.2%-89.5%)	89.2% (85.3%-92.4%)	82.9% (79.2%-88.1%)	0.921% (0.901%-0.945%)	—[c]
CNN[d]	82.0% (78.9%-85.0%)	83.7% (79.4%-87.6%)	80.2% (75.0%-84.6%)	0.881% (0.854%-0.906%)	.02
GCN[e]	84.0% (80.4%-87.2%)	85.9% (81.7%-89.7%)	82.1% (77.0%-86.4%)	0.894% (0.869%-0.918%)	.041

[a]This table compares the performance of 3 deep learning models (transformer, CNN, and GCN) in predicting radiotherapy response in rectal cancer using an independent test set. All metrics are reported as mean values with 95% CI. The primary evaluation metrics include accuracy, sensitivity, specificity, and the area under the curve (AUC). Differences in AUC were assessed using the DeLong test. The results demonstrate that the Transformer model outperformed both CNN and GCN models across all evaluation metrics, with the differences in AUC reaching statistical significance (P<.05).

[b]AUC: area under the curve.

[c]Not available.

[d]CNN: convolutional neural network.

[e]GCN: graph convolutional network.

To evaluate the statistical significance of AUC differences between the Transformer and other models, pairwise bootstrap resampling (10,000 iterations) and DeLong's test were conducted. The results showed that the Transformer model significantly outperformed both the CNN model (P=.02) and the GCN model (P=.041) in terms of AUC. These findings indicated that the Transformer model provided a statistically significant advantage in identifying imaging features associated with RT response.

Confusion Matrix Reveals the Classification Capability of the Transformer Model

To further assess classification performance, a confusion matrix was constructed to evaluate the Transformer model's predictive ability. As shown in Table 3, among the 200 patients in the test set, the model correctly identified 89% of RT-sensitive patients. The false-positive rate, representing RT-insensitive patients incorrectly classified as sensitive, was only 8%. These results further validated the model's effectiveness across both classes, particularly in correctly identifying RT-insensitive patients. The Transformer model significantly reduced misclassification errors, a critical factor in clinical decision-making. Accurate identification of RT-insensitive patients was essential for enabling timely adjustments to treatment plans, avoiding ineffective RT, and ultimately improving patient prognosis and survival outcomes. On the independent test set, the Transformer's calibration curve closely followed the ideal 45° line, with only mild overconfidence observed in the high–predicted-probability region. The corresponding Brier scores were identical for both input settings: MRI-only, 0.145; and CT + MRI (late fusion), 0.145. Overall calibration was therefore comparable between modalities. Taken together with the AUCs (0.921 vs 0.927) and the DCA results, adding CT did not yield a meaningful improvement in global performance, but it produced a slight and consistent gain in net benefit within higher decision-threshold ranges (Figure 3 and Table 4).

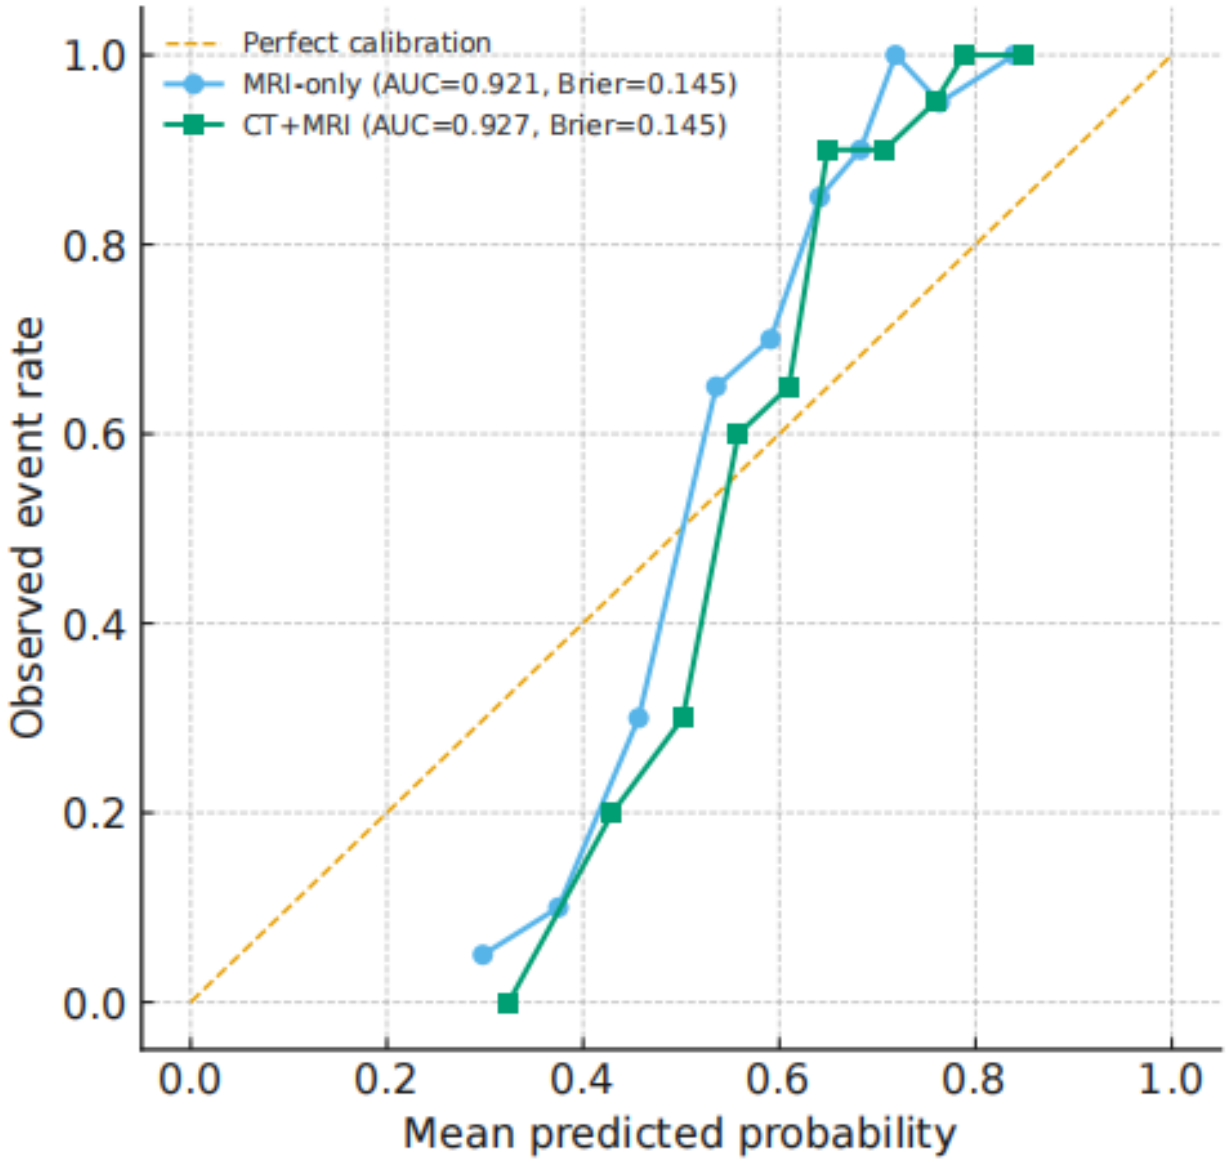

Table . Confusion matrix results for the Transformer model[a].

Category	Sensitive class (good response to radiotherapy)	Insensitive class (poor response to radiotherapy)
Predicted as sensitive class	116 (true positive)	12 (false positive)
Predicted as insensitive class	14 (false negative)	58 (true negative)

[a]This table shows the confusion matrix of the Transformer model on the independent test set (magnetic resonance imaging–only, n=200). True positives represent the number of patients correctly predicted as radiotherapy-sensitive (116 cases); false positives represent the number of patients incorrectly predicted as sensitive but actually nonsensitive (12 cases); false negatives represent the number of patients incorrectly predicted as nonsensitive but actually sensitive (14 cases); and true negatives represent the number of patients correctly predicted as radiotherapy nonsensitive (58 cases). Based on this matrix, the calculated performance metrics were as follows: accuracy=87.0%, sensitivity=89.2%, and specificity=82.9%.

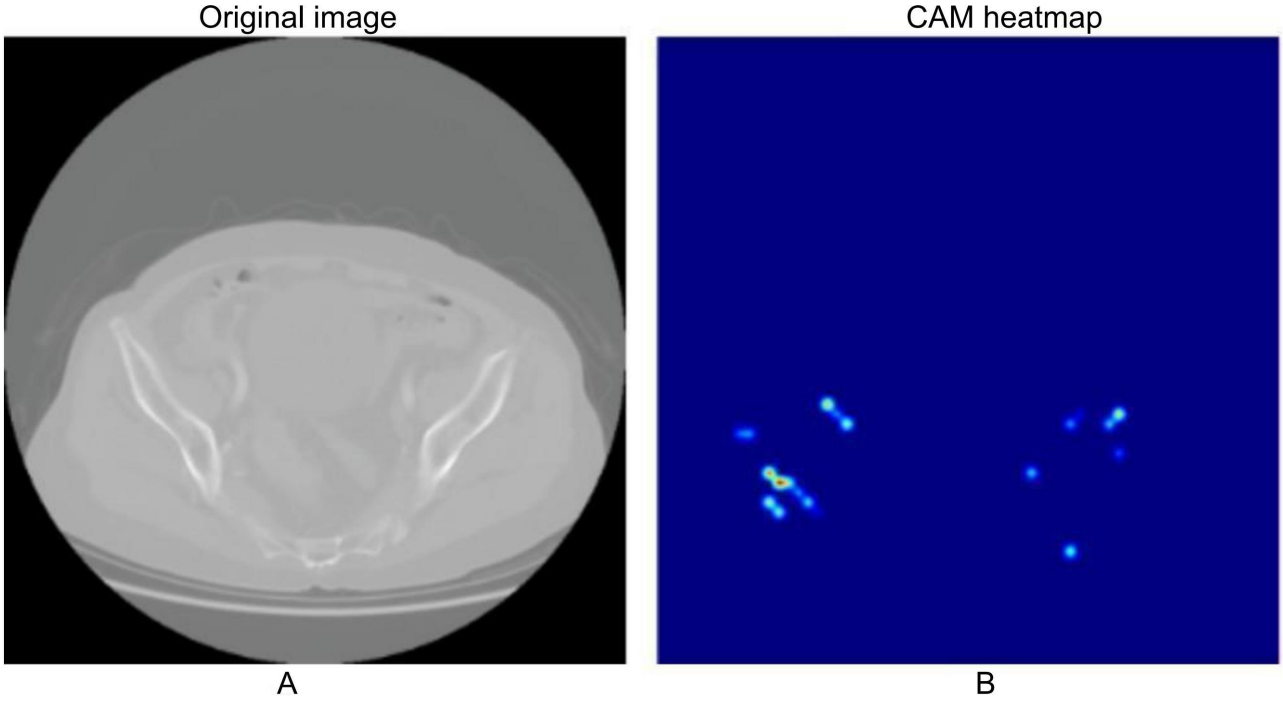
[a]MRI: magnetic resonance imaging.

[b]CT: computed tomography.



[c]This table shows the calibration binning results of the transformer model on the independent test set under 2 input settings: MRI-only and CT + MRI. The predicted probabilities (pred_mean) were divided into 10 equal-frequency bins (bin), each containing 20 samples. Obs_rate represents the observed positive rate (proportion of radiotherapy-sensitive patients), while pred_min and pred_max indicate the minimum and maximum predicted probabilities within each bin, respectively. The results show that both input settings exhibit calibration trends close to the ideal diagonal, indicating good agreement between predicted probabilities and observed rates. Notably, the CT + MRI setting demonstrated a slight improvement in net benefit within the higher threshold range.

Grad-CAM Visualization to Validate the Accuracy of Feature Extraction

The effectiveness of the Transformer model was reflected not only in its overall predictive performance but also in the depth and precision of its feature extraction. Grad-CAM was used to visualize the model's feature extraction process. The results revealed that the model primarily focused on tumor boundaries and high-density regions within the tumor. As shown in Figures 4A and 4B, the model was particularly adept at capturing complex structures in heterogeneous tumor areas and using them to predict RT response. The visualization results further demonstrated that the model effectively filtered out irrelevant background information and concentrated on diagnostically significant regions. This selective focus enhanced both the classification accuracy and the clinical interpretability of the model. The ability to highlight meaningful anatomical and pathological features supported the Transformer model as a reliable diagnostic aid for clinicians in treatment planning and response prediction.

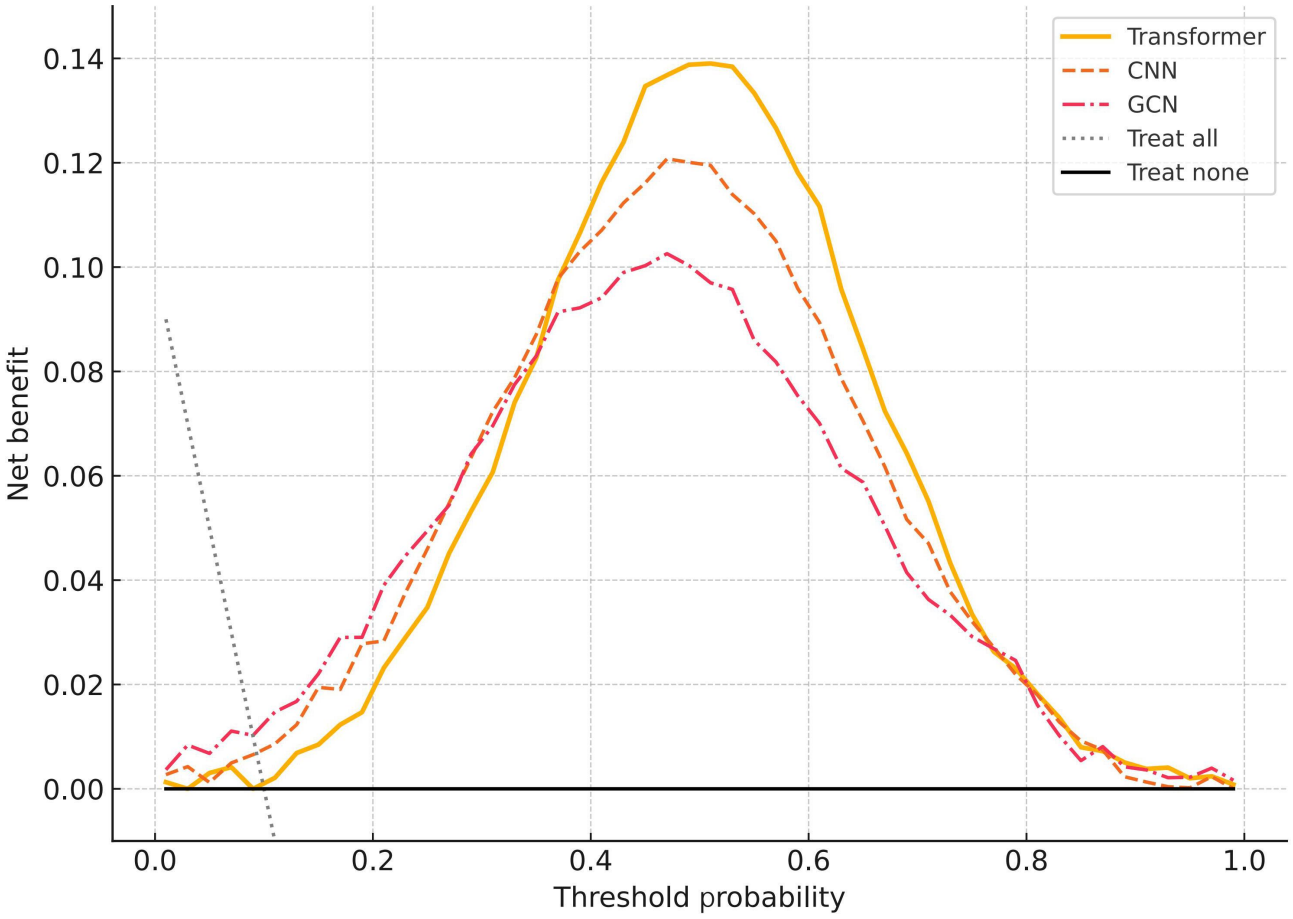
(B) Grad-CAM visualization image: displays the areas where the model focuses, particularly on tumor edges and high-density regions. Red areas represent the regions of high attention by the model. CAM: Class Activation Mapping.

Hyperparameter Optimization and Model Iteration Analysis

During model training and optimization, adjustments to hyperparameters such as learning rate, batch size, and regularization substantially improved the performance of the Transformer model. After 50 training epochs, the validation loss steadily decreased to 0.01, indicating good model convergence and stable training dynamics. As training progressed, the loss curves of the training and validation sets gradually converged, with no apparent signs of overfitting, further confirming the critical role of hyperparameter optimization in enhancing model performance (see Figure 5A for training loss and Figure 5B for validation loss). The model maintained consistently low validation loss and favorable convergence characteristics, establishing a solid foundation for subsequent testing and external validation.

Figure 5. Changes in loss and accuracy for training and validation sets. (A) Loss curve: the loss values for both the training and validation sets decrease gradually over 50 epochs. (B) The validation loss curve (Val loss) indicates that the model stabilized during the later training phase without signs of overfitting.



Clinical Benefit Analysis Based on DCA

To further evaluate the potential clinical use of the DL models in RT decision-making, DCA was performed to compare the net benefit of the Transformer, CNN, and GCN models across different probability thresholds (Figure 6). The results showed that across most threshold ranges—particularly between 0.3 and 0.7—the Transformer model achieved a higher net benefit than both the “treat all” and “treat none” strategies, as well as outperforming the CNN and GCN models. This suggests that the Transformer model provides greater decision support capacity in clinical practice.

XSL•FO
RenderX

Figure 6. Decision curve analysis. The figure shows the comparison of net benefit across different probability thresholds for the Transformer, CNN, and GCN models. The dashed lines represent the "treat all" and "treat none" strategies, respectively. The Transformer model demonstrated higher net benefits within the primary clinical decision-making range of 0.3 - 0.7, highlighting its clinical use in predicting radiotherapy sensitivity. CNN: convolutional neural network; GCN: graph convolutional network.

For example, when predicting RT-sensitive patients, the Transformer model maintained a high true-positive rate while significantly reducing the likelihood of unnecessary RT and associated side effects. These findings highlight the model's potential as a valuable tool for individualized RT decision-making.

Sensitivity Analysis of Imaging Input Settings (MRI-Only Versus CT + MRI)

To quantify the incremental value of CT, we compared MRI-only with late-fusion CT + MRI under identical training or validation procedures (same splits, loss, class weighting, and hyperparameters). Using the Transformer as an exemplar, overall discrimination on the independent test set was similar between modalities: Transformer (MRI-only): accuracy 87.0%, AUC 0.921 (95% CI 0.901 - 0.945), sensitivity 89.2% (true positive 116/130), specificity 82.9% (true negative 58/70), Brier score 0.145, and area under the precision–recall curve 0.900; Transformer (CT + MRI): accuracy 87.5%, AUC 0.926 (95% CI 0.905 - 0.948), sensitivity 90.0% (true positive 117/130), specificity 82.9% (true negative 58/70), Brier score 0.142, and area under the precision–recall curve 0.905.

DeLong's test indicated no significant difference in AUC between the 2 settings (P=.36). In DCA, CT + MRI yielded a slight and consistent gain in net benefit at higher threshold probabilities (>0.6), whereas curves largely overlapped within the primary clinical range (0.3 - 0.7). Overall, given a unified MRI acquisition protocol in this single-center cohort, MRI-only achieved robust performance; adding CT did not confer a statistically significant global improvement but may offer marginal clinical value at specific, higher decision thresholds. For completeness, test-set AUCs (95% CI) across all 3 architectures (CNN, GCN, and Transformer) under both input settings are summarized in Table 5, and full classification metrics for the Transformer are provided in Table 6.

XSL•FO
RenderX

Table . Comparison of the Transformer model performance under different input settings[a].

Input setting	Accuracy	AUC	95% CI (AUC[b])	Sensitivity	Specificity	Brier	AUCPR[c]	DeLong test *P* value
MRI[d]-only	87.00%	0.921	0.901 - 0.945	89.2% (116/130)	82.9% (58/70)	0.145	0.9	—[e]
CT + MRI (late fusion)	87.50%	0.926	0.905 - 0.948	90.0% (117/130)	82.9% (58/70)	0.142	0.905	.36

[a]This table compares the predictive performance of the Transformer model under 2 input settings: magnetic resonance imaging (MRI)–only and CT + MRI (late fusion). The main evaluation metrics include accuracy, area under the curve (AUC) with its 95% CI, sensitivity, specificity, Brier score, area under the precision–recall curve (AUCPR), and the DeLong test *P* value for AUC comparison. The results indicate that the overall discriminative performance of the 2 input settings was comparable (AUC difference, *P*=.36). The CT + MRI configuration showed slightly better Brier score and AUCPR at higher threshold ranges, suggesting a minor net benefit under certain clinical decision thresholds.

[b]AUC: area under the curve.

[c]AUCPR: area under the precision–recall curve.

[d]MRI: magnetic resonance imaging.

[e]Not available.

Table . Comparison of AUC[a] values across architectures under MRI[b]-only and CT[c] + MRI settings[d].

Architecture	MRI-only AUC (95% CI)	CT + MRI AUC (95% CI)	DeLong test *P* value
CNN[e]	0.881 (0.854 - 0.906)	0.888 (0.861 - 0.912)	.22
GCN[f]	0.894 (0.869 - 0.918)	0.899 (0.873 - 0.922)	.29
Transformer	0.921 (0.901 - 0.945)	0.926 (0.905 - 0.948)	.36

[a]AUC: area under the curve.

[b]MRI: magnetic resonance imaging.

[c]CT: computed tomography.

[d]This table compares the area under the curve (AUC) performance and corresponding 95% CI of 3 deep learning models—CNN, GCN, and Transformer—under 2 input conditions: MRI-only and CT + MRI. Differences in AUC were evaluated using the DeLong test. The results show that all 3 models exhibited slight improvements in AUC under the CT + MRI condition; however, none of the differences reached statistical significance (*P*>.05). Among the 3, the Transformer model achieved the highest AUC in both settings (MRI-only: 0.921; CT + MRI: 0.926).

[e]CNN: convolutional neural network.

[f]GCN: graph convolutional network.

Computational Efficiency and Inference Time Analysis

To quantitatively evaluate the computational overhead and deployment feasibility of different models in clinical scenarios, we further compared CNNs, GCNs, and Transformer-based models in terms of parameter count, theoretical computational complexity (Floating-Point Operations [FLOPs]), and inference time on an independent test set. Inference-time evaluation was conducted under a fixed hardware configuration (GPU: NVIDIA RTX 3090, 24 GB memory), using FP32 precision, with synchronized timing performed after model warm-up. The timing scope included model forward inference and patient-level probability aggregation (ie, arithmetic averaging of predicted probabilities across all 2D slices belonging to the same patient), while offline image preprocessing and data-loading overheads were excluded.

As summarized in Table 7, the Transformer model exhibits a larger parameter size (86.4 M) and higher FLOPs (17.8 G) than the CNN (ResNet-34) and GCN architectures, reflecting its increased model complexity. Nevertheless, on the test set, the Transformer model achieves an average per-slice inference time of 3.8 milliseconds. At the patient level (median number of slices: 20, IQR 16 - 24), the overall inference time is 78 (IQR 63-95) milliseconds per patient, which remains well within the acceptable range for real-time clinical decision support. By comparison, the patient-level inference times of the CNN and GCN models are 42 milliseconds and 55 milliseconds, respectively.

XSL•FO
RenderX

Table . Computational efficiency and inference latency of the evaluated models[a].

Model	Parameters, millions	FLOPs[b], billions	Inference time per slice (ms), mean (SD)	Average slices per patient, median (IQR)	Inference time per patient (ms)
CNN[c] (ResNet-34)	21.8	3.6	2.1 (0.3)	20 (16-24)	42 (34 - 50)
GCN[d]	28.5	5.2	2.7 (0.4)	20 (16-24)	55 (44 - 66)
Transformer	86.4	17.8	3.8 (0.5)	20 (16-24)	78 (63 - 95)

[a]Parameter counts and FLOPs were calculated based on a single region of interest input. Inference time was measured on an independent test set (n=200) and includes model forward inference as well as patient-level prediction probability aggregation, while offline image preprocessing and data-loading overheads were excluded. All results were obtained under identical hardware and software environments.

[b]FLOPs: Floating-Point Operations.

[c]CNN: convolutional neural network.

[d]GCN: graph convolutional network.

These results indicate that although the Transformer architecture incurs a higher computational cost than conventional convolutional models, its inference latency remains low. Moreover, when weighed against its substantial advantages in predictive performance and clinical net benefit, the increased computational overhead is acceptable for practical clinical applications.

Discussion

Principal Findings

In this study, a DL-based radiomics model was developed to predict RT response in patients with RC. A systematic comparison of multiple models, including CNNs, GCNs, and Transformers, revealed that the Transformer architecture demonstrated the best overall performance. By leveraging its self-attention mechanism, the Transformer effectively captured complex imaging features within key tumor regions, achieving an accuracy of 87% and an AUC of 0.921 on the test set. In addition to its predictive accuracy, the Transformer model demonstrated strong interpretability, as confirmed by Grad-CAM visualization, which highlighted its focus on clinically relevant tumor regions. These findings underscore the model's potential as a reliable and interpretable tool for supporting individualized RT planning in clinical settings.

During training, 5-fold cross-validation (k=5) was adopted based on the following considerations. First, it balanced statistical stability and sample efficiency. In this cohort (n=2000; class ratio ≈65%/35%), k=5 ensured approximately 200 validation cases per fold, providing sufficient positive and negative samples to stably estimate AUC, calibration, and DCA metrics. Larger k would yield smaller validation subsets, increasing variability in calibration and DCA estimates, whereas smaller k would raise estimation bias and reduce the resolution of hyperparameter selection. Second, it accounted for computational cost and practical reproducibility: compared with 10-fold cross-validation, 5 folds substantially reduced training time and resource requirements, making replication in a clinical research setting more feasible. To assess robustness, we conducted sensitivity analyses using k=3 and k=10 and repeated 5-fold cross-validation with different random seeds under the same patient-level stratification. Across all settings, the relative ranking of the Transformer and baseline models remained consistent, fold-to-fold AUC variability was comparable with the main analysis, and no systematic instability or overfitting was observed. Compared with 5 folds, 10 folds primarily increased training time and triggered more frequent early stopping without materially affecting final test performance. Three-folds showed slightly greater variance in validation metrics and reduced hyperparameter discriminability. In summary, k=5 provided an optimal balance among performance stability, computational feasibility, and methodological rigor. To avoid information leakage, cross-validation was performed exclusively within the training set using stratified, patient-level splits; all images, slices, and augmented samples from the same patient were confined to a single fold. The independent test set was reserved for a one-time final evaluation only.

Comparison With Prior Work

RT remains a cornerstone in RC treatment; however, predicting individual response to RT continues to be a major clinical challenge due to significant patient heterogeneity [19]. Radiomics, an emerging technology capable of extracting high-dimensional features from medical images, has opened new avenues for predicting treatment response [20]. However, traditional machine learning approaches have shown limited effectiveness in modeling the high-dimensional, heterogeneous nature of radiomics data [21]. The advent of DL, particularly CNNs, has markedly improved pattern recognition capabilities in this domain [7,9,22]. Unlike prior studies that applied single-model approaches, our work systematically compared 3 advanced DL architectures and identified the Transformer as the most effective model for complex image-based RT response prediction [23].

Several recent studies have attempted to integrate DL into tumor-imaging analysis and RT response prediction. For instance, Xu et al [24] applied CNNs for breast region segmentation using DCE-MRI in breast cancer, demonstrating strong performance in local feature extraction. However, their approach was limited to 2D analysis and failed to account for the complexity of 3D imaging data [24]. Similarly, Mzoughi et al [25] proposed a multiscale 3D CNN for glioma classification based on MRI, achieving approximately 85% accuracy, but still faced limitations in feature representation and generalizability.

XSL•FO
RenderX

Previous studies have systematically evaluated MRI-based radiomics and DL approaches for predicting response to nCRT in RC. A multicenter study published in *Radiology* demonstrated that MRI radiomics models could predict pathological complete response (pCR) with relatively high accuracy [26]. DL models based on post-nCRT T2W MRI also achieved discriminative performance for pCR or GR that was comparable to, or even surpassed, expert radiologist assessment [27]. Beyond single time point models, delta radiomics—which captures changes in features before and after treatment—showed superior performance in predicting nCRT response [28]. In terms of risk stratification and clinical translation, late-fusion multimodal models that integrated multiparametric MRI–derived DL or radiomics features with clinical variables outperformed unimodal models and provided greater clinical net benefit on DCA [18]. Furthermore, several systematic reviews and meta-analyses confirmed the robustness of imaging AI for predicting pCR, reporting pooled AUCs of approximately 0.90 - 0.91; models based on DL or clinical fusion generally outperformed conventional radiomics approaches [29]. These findings are consistent with the results of this study and support our design rationale of introducing more advanced architectures (eg, Transformers) and evaluating clinical use using tools such as DCA.

In contrast, our Transformer-based model achieved an accuracy of 87% and an AUC of 0.921, outperforming the CNN-based approaches in both precision and discriminative capacity. The multihead self-attention mechanism of the Transformer effectively captured global dependencies within tumor regions, demonstrating enhanced robustness and generalizability, especially in cases with complex morphology or blurred tumor boundaries. Compared with previously reported models, our approach offered distinct advantages in architectural innovation, predictive performance, and clinical interpretability, positioning it as a more reliable framework for RT response prediction.

Additionally, the U-Net model also demonstrated satisfactory performance in tumor segmentation, achieving a mean DSC of 0.892 and an IoU of 0.814 on the independent test set, indicating strong consistency with expert annotations. These results underscore the crucial role of accurate segmentation in radiomics workflows, as it ensures high-quality inputs for downstream feature extraction and classification, even in tumors with irregular edges.

Furthermore, Grad-CAM visualization revealed that the Transformer model concentrated on tumor edges and regions of heterogeneous density, areas known to correlate with RT sensitivity [20,21]. This interpretability enhanced the interpretability and clinical credibility of the model.

Limitations

Despite the promising results, this study had several limitations. First, the dataset was derived from a single center, with limited diversity in race, age, and pathological subtypes, which may have constrained the model's generalizability [20]. Although data augmentation and k-fold cross-validation were applied to mitigate this limitation, future studies should incorporate multicenter datasets to assess the model's robustness across broader populations. Second, the imaging data primarily consisted of DCE-MRI, without the integration of additional clinical variables such as genomic data, pathological classification, or treatment history. This single-modality approach may have limited the comprehensiveness of the predictive model [7]. Incorporating multimodal data in future models could improve both predictive accuracy and biological interpretability. Third, although Grad-CAM was used to enhance model interpretability, it functioned as a post hoc visualization method and did not directly reveal the underlying causal mechanisms driving model predictions. Future research that integrates molecular biomarkers and longitudinal follow-up data may help elucidate the biological basis of model outputs and strengthen their interpretability. Fourth, model performance evaluation was conducted on a single-center dataset and validated only on an internal holdout test set comprising 10% of the cohort. External multicenter validation was not performed. Although cross-validation and regularization techniques were used to reduce overfitting, radiomics models are known to be sensitive to cross-center variations—such as differences in imaging parameters, scanner models, and acquisition protocols—which may lead to substantial domain shift in real-world applications. Future studies should incorporate external datasets from multiple institutions to systematically assess robustness, generalizability, and clinical applicability. Fifth, expert-annotated tumor masks were used in the test set to avoid data leakage; however, this evaluation setup represents an "idealized" condition that does not fully reflect real-world clinical workflows. In practice, errors from automatic segmentation networks may propagate to the Transformer classifier, potentially leading to lower end-to-end performance than the manually masked results reported here. Future work will include validation of a fully automated pipeline and quantitative assessment of how segmentation inaccuracies affect downstream prediction tasks. Sixth, MRI slice thickness varied between 3 mm and 4 mm across patients. Although this study adopted a 2D slice–level modeling strategy, in which the inputs primarily rely on in-plane texture and morphological information, and volumetric resampling along the *z*-axis was intentionally avoided to prevent interpolation-induced artifacts, we acknowledge that differences in slice thickness and spatial resolution may still affect the statistical distributions of intensity and texture features, thereby constituting a potential confounding factor in radiomics-based analyses. We performed patient-level splitting for training, validation, and testing and used data augmentation and cross-validation to mitigate instability arising from acquisition-related heterogeneity; however, such effects cannot be completely eliminated. Future work will further explore standardized resampling strategies or explicit modeling of resolution differences (eg, stratification or covariate adjustment) and will incorporate 3D models and multicenter external validation to systematically evaluate the impact of slice thickness and scanner or protocol variability on model generalizability. Seventh, this study combined CR and PR patients into a single "GR" category to improve class balance, a strategy commonly used in statistical modeling. However, this grouping does not optimally reflect clinical practice: "watch-and-wait" strategies are typically suitable only for patients achieving clinical CR or pCR, whereas PR patients still require further treatment. While the binary classification

XSL•FO
RenderX

framework in this study aimed primarily to demonstrate the DL model's ability to predict overall RT response, future research should investigate multiclass models to enhance clinical interpretability and applicability. Eighth, although the Transformer model demonstrated superior predictive performance compared with CNN and GCN models, this improvement comes at the cost of increased computational burden. Transformers generally require larger parameter counts and higher floating-point computation, with the self-attention mechanism imposing substantial overhead when processing high-resolution image patches. To address this concern, we have supplemented the revised manuscript with a detailed comparison of model parameter counts, FLOPs, and patient-level inference time, thereby quantitatively assessing the computational efficiency of different architectures. The results demonstrate that despite its higher computational cost relative to ResNet-34 and the GCN model, the Transformer maintains a patient-level inference time within the acceptable range for real-time clinical decision support, indicating its practical feasibility for deployment under the current experimental settings. Nevertheless, in larger-scale datasets or resource-constrained clinical environments, model complexity and deployment cost may still pose limiting factors. Future work will therefore explore model compression strategies, such as knowledge distillation, structural pruning, and parameter sharing, to further reduce inference latency and computational resource consumption while preserving predictive performance, thereby enhancing the applicability of the model in real-world clinical workflows.

Future Directions

Future research should aim to extend the application of the Transformer-based radiomics model beyond RC, exploring its transferability and adaptability to other solid tumors such as cervical, lung, and esophageal cancers, in order to evaluate cross-cancer generalizability [15,30]. Another promising avenue involves integrating radiomics with additional data modalities, including genomic, transcriptomic, immunomic, and digital pathology features, to develop comprehensive multimodal fusion models. Such models have the potential to enhance predictive accuracy and provide deeper insights into the biological mechanisms underlying treatment response [21]. Furthermore, the development of lightweight and resource-efficient model versions suitable for deployment on edge devices will be critical for facilitating real-world clinical translation, enabling the routine use of DL-based radiomics models at the point of care to support individualized treatment planning and decision-making.

Conclusions

This study successfully constructed a Transformer-based DL radiomics model for predicting RT sensitivity in patients with RC. The results demonstrate that when using pre-RT MRI features as the primary input, the proposed model achieves superior performance in terms of predictive accuracy, interpretability, and model stability, thereby providing a feasible tool for pretreatment risk stratification and personalized RT decision-making. Supplementary analyses indicate that the multimodal integration of CT and MRI does not yield a statistically significant improvement in overall discriminative performance; however, it may offer a modest and consistent clinical net benefit at specific decision thresholds. Further validation using multicenter datasets is warranted, and future studies should more clearly delineate the potential value of multimodal information across different clinical application scenarios.

Funding

No external financial support or grants were received from any public, commercial, or not-for-profit entities for the research, authorship, or publication of this article.

Disclaimer

No generative AI tools were used in the preparation, writing, analysis, or submission of this manuscript.

Data Availability

To enhance the reproducibility of this study, the complete implementation code, including scripts for data preprocessing, feature extraction, model training, and inference, will be made publicly available on GitHub upon publication. All data processing workflows have been automated and standardized to ensure that external users can replicate the model training process under identical data conditions. Considering patient privacy and institutional policy restrictions, the trained model weight files will be provided only upon reasonable academic request and limited strictly to noncommercial research purposes.

Authors' Contributions

YL and HL contributed equally to this work. YL, HL, and QW designed the study and performed data analysis. ZW and ZH were responsible for data collection and curation. YL developed the deep learning models and conducted experiments. ZH supervised the project and provided critical revisions. All authors contributed to the manuscript writing and approved the final version.

Workflow of deep learning model training and validation. This figure illustrates the overall framework of the deep learning analysis pipeline used in this study, including data preprocessing, tumor region segmentation, feature extraction, model training with cross-validation, and performance evaluation. First, preradiotherapy images were cleaned, normalized, and augmented to generate standardized inputs. Subsequently, a U-Net model was used for automatic tumor segmentation, and the resulting masks were used to extract tumor region features from the magnetic resonance images. The Transformer model then performed classification training based on patch embeddings, leveraging multihead self-attention to capture global feature patterns. Five-fold cross-validation was adopted during training to enhance model robustness and generalizability. Finally, performance metrics, including accuracy, sensitivity, specificity, and area under the curve, were computed. This workflow provides a comprehensive overview of the deep learning analysis pathway from raw imaging data to model prediction.

Multimedia Appendix 5
U-shaped convolutional neural network (U-Net) model tumor segmentation process diagram. This diagram illustrates how the U-Net segmentation model extracts features layer by layer through convolution operations, ultimately segmenting the tumor region. It includes the original image input, convolution process, feature extraction, and segmentation results.
[PNG File, 70 KB - medinform_v14i1e77313_app5.png]

Multimedia Appendix 6
Schematic architecture of the transformer classification model. This figure illustrates the overall workflow of the Transformer-based classification model used to predict radiotherapy response in rectal cancer. First, pretreatment magnetic resonance images are processed using tumor-region masks (masked region of interest). The masked images are then divided into fixed-size 16×16 patches, which are linearly projected to obtain patch embeddings. The model consists of 12 Transformer encoder layers, where multihead self-attention mechanisms capture global contextual features. During classification, a dedicated classification token is passed through a multilayer perceptron (MLP head) to produce the final prediction of radiotherapy response (sensitive vs nonsensitive). This architecture operates exclusively at the image level and does not include any segmentation decoder, remaining fully independent from the U-Net segmentation model used elsewhere in the study.

Abstract

Background: Early life health risks can shape long-term morbidity trajectories, yet prevailing pediatric risk assessment paradigms are often fragmented and insufficiently capable of integrating heterogeneous data streams into actionable, individualized profiles.

Objective: This study aimed to design, implement, and validate an artificial intelligence–driven framework that fuses multimodal pediatric data and leverages advanced natural language processing and ensemble learning to improve early, accurate stratification of key pediatric health risks.

Methods: A retrospective dataset of over 40,000 pediatric participants aged 2 - 8 years was used to train and evaluate the framework. Data were split into training, validation, and test sets (70%, 15%, and 15%, respectively) with a temporally mindful partitioning strategy to approximate prospective evaluation. Baseline comparators included traditional statistical and machine learning models, and the statistical significance of area under the receiver operating characteristic curve (AUC-ROC) differences was assessed using the DeLong test.

Results: The proposed Bidirectional Encoder Representations From Transformers–based model achieved an AUC-ROC of 0.85 (95% CI 0.82 - 0.88), sensitivity of 0.78, specificity of 0.80, and F_1-score of 0.75 on the test set, outperforming multiple baseline models. In an additional manual comparison evaluation, automated and expert assessments aligned with 78% accuracy (78/100), and most discrepancies arose in “equivalent” cases.

Conclusions: This study provides a validated, artificial intelligence–driven, multimodal pediatric health risk stratification framework that translates heterogeneous child health data into clinically actionable risk profiles, demonstrating strong discriminative performance and meaningful agreement with expert assessment. The framework supports proactive, individualized pediatric care and offers a scalable foundation for further validation across broader populations and longitudinal follow-up.

KEYWORDS

pediatric health; artificial intelligence; AI; risk stratification; ensemble learning; framework design; multisource data fusion; predictive modeling

Introduction

The assessment and early identification of health risks in children represent a critical area of research with profound implications for individual lifelong well-being and public health strategies. Establishing healthy developmental trajectories during childhood is fundamental, as health conditions and risk exposures in early life can significantly influence adult health outcomes and susceptibility to chronic diseases [1,2]. Traditional pediatric health surveillance often relies on periodic checkups, which may not fully capture the dynamic and multifaceted nature of health risks influenced by a complex interplay of genetic, environmental, and lifestyle factors [3,4]. Therefore, developing advanced, data-driven methodologies, such as those explored in recent research on artificial intelligence (AI) and machine learning (ML) for tasks like toxicity prediction and broader research applications, to proactively identify and stratify these risks is of paramount importance. Such systems, potentially incorporating guardian-interactive elements, can empower health

XSL•FO
RenderX

care providers and families with actionable insights for timely preventive interventions, ultimately contributing to a healthier future generation and optimizing health care resource allocation [5]. Global health initiatives increasingly emphasize the importance of leveraging innovative technologies, including advanced AI models, such as large language models adapted for specific domains [6], to enhance child health and well-being. The potential for deep learning to enhance diagnostic and prognostic capabilities in areas like child psychiatry further underscores this trend [7].

The rapid popularization of internet-based medical services, including telehealth, mobile health (mHealth) apps, and online consultation platforms, has significantly reshaped health care delivery and accessibility worldwide [8]. This digital transformation has not only provided patients and caregivers with more convenient access to medical advice and health information but also led to the generation of vast amounts of digital health data [9,10]. While much of the initial adoption has been observed in adult care, the principles of leveraging digital platforms for health monitoring, data collection, and remote consultation, often supported by automated systems for tasks like information synthesis [11], are increasingly recognized as valuable in pediatric care. The experience gained from the broader implementation of digital health solutions, including aspects of data security, interoperability, and user engagement, offers important lessons for developing effective and safe digital health tools specifically for children [12,13]. The expanding digital health infrastructure provides a rich ecosystem for collecting diverse health-related data that, if properly managed and ethically used with robust frameworks, can be invaluable for comprehensive risk assessment in pediatric populations [14,15]. Task-oriented dialogue systems, for instance, show potential for structured data gathering in such contexts. Despite progress in pediatric health surveillance, significant clinical voids persist, particularly in the settings of primary care and population health screening. Current risk assessment paradigms are often fragmented, struggling to effectively integrate heterogeneous data streams, such as structured electronic health record (EHR) data, unstructured clinical notes, parental reports, and real-time wearable sensor data, into a single, cohesive risk profile. This leads to a reactive, rather than proactive, approach to care, where risks are often identified only after they have manifested. This research addresses this gap by proposing a framework designed for the following specific end users: (1) pediatricians in primary care, who can use the system for point-of-care decision support; (2) public health officials, who can leverage population-level risk distributions for resource allocation and strategic planning; and (3) clinical care coordinators, who can manage and monitor high-risk pediatric cohorts more effectively.

The increasing availability of EHR data, administrative data, patient-generated health data, and other health-related information sources has fueled the application of health care big data analytics to improve service quality, operational efficiency, and patient outcomes [16-18]. Effective utilization of these data, supported by primers on data handling and the underlying principles of models like Bidirectional Encoder Representations From Transformers (BERT), can support evidence-based clinical decision-making, enhance population health management, facilitate epidemiological surveillance, and enable the development of personalized health care interventions [19]. To enhance clinical utility and facilitate shared decision-making, it is imperative that the reasons behind a child's risk stratification are transparent and interpretable. Shapley additive explanations (SHAP) are used due to their strong theoretical guarantee of consistency and local accuracy, which can provide a unified and reliable framework for model interpretation [20]. For a given prediction, SHAP assigns an importance value (SHAP value) to each input feature, and it is crucial for unlocking its full potential in transforming health care delivery, research, and policy.

AI algorithms can analyze complex, multidimensional datasets to identify subtle patterns, predict the likelihood of various health conditions, and stratify risk earlier and more accurately than traditional statistical methods [20,21]. Researchers have explored various AI-driven systems for health applications. For example, some systems focus on the early detection of developmental disorders using behavioral or imaging data, while others aim to predict adverse outcomes in neonatal intensive care units or identify children at risk for conditions like asthma, obesity, and mental health issues, sometimes using specific BERT-based approaches for analyzing medical records or predicting conditions like Alzheimer disease (AD-BERT), which, while not pediatric, demonstrates domain-specific adaptation [22]. Common approaches in developing such systems involve the curation of large, representative datasets; rigorous data preprocessing and feature engineering; the application of appropriate ML algorithms; and robust model validation using independent test sets and ideally prospective clinical evaluation [23]. For instance, deep learning models have shown promise in analyzing medical images for pediatric conditions, while ensemble methods and sophisticated scoring mechanisms like BERTScore for evaluating text generation quality [24] (analogous to assessing the quality of AI-generated health summaries) are often used to improve the robustness and accuracy of predictive models based on structured EHR data or textual information [25]. The primary contribution of our framework lies in its advanced natural language processing (NLP) capabilities, which distinguish it from prior AI systems in pediatric care that have largely relied on traditional NLP techniques. Methodologies, such as keyword matching, bag-of-words, and term frequency-inverse document frequency models, while useful, are fundamentally limited in their ability to interpret the complex and nuanced narratives found in clinical texts.

Therefore, this study aimed to design, implement, and validate a comprehensive, AI-driven framework for pediatric health risk stratification. We hypothesize that by integrating multimodal data, including EHRs, parental questionnaires, and wearable sensor data, and leveraging advanced NLP and ensemble learning models, our system can identify and stratify key pediatric health risks (eg, obesity and developmental delay) with greater accuracy and at an earlier stage than traditional assessment methods, thereby providing robust support for clinical decision-making and pre-emptive intervention. Methods

Pediatric Health Risk Stratification Framework and Data Foundation

This section addresses the critical, complex, and multifaceted aspects of multimodal data acquisition, encompassing the collection of diverse data types from various sources and the requisite, often intricate, data preparation processes. These preparation stages, including but not limited to data cleaning, normalization, transformation, and feature engineering, are indispensable for effectively fueling the advanced AI models that form the analytical core of this research, ensuring they operate on high-quality, meaningful inputs to generate reliable and actionable insights [29,30]. The overarching goal is to establish robust data and conceptual groundwork upon which sophisticated risk prediction and stratification can be built, ultimately aiming to transform pediatric health care through proactive and personalized interventions. Conceptually, the framework aims to map a complex set of input variables Xdata (representing multimodal pediatric data) through a series of transformations and AI modeling of fAI to an interpretable risk stratification outcome Yrisk :

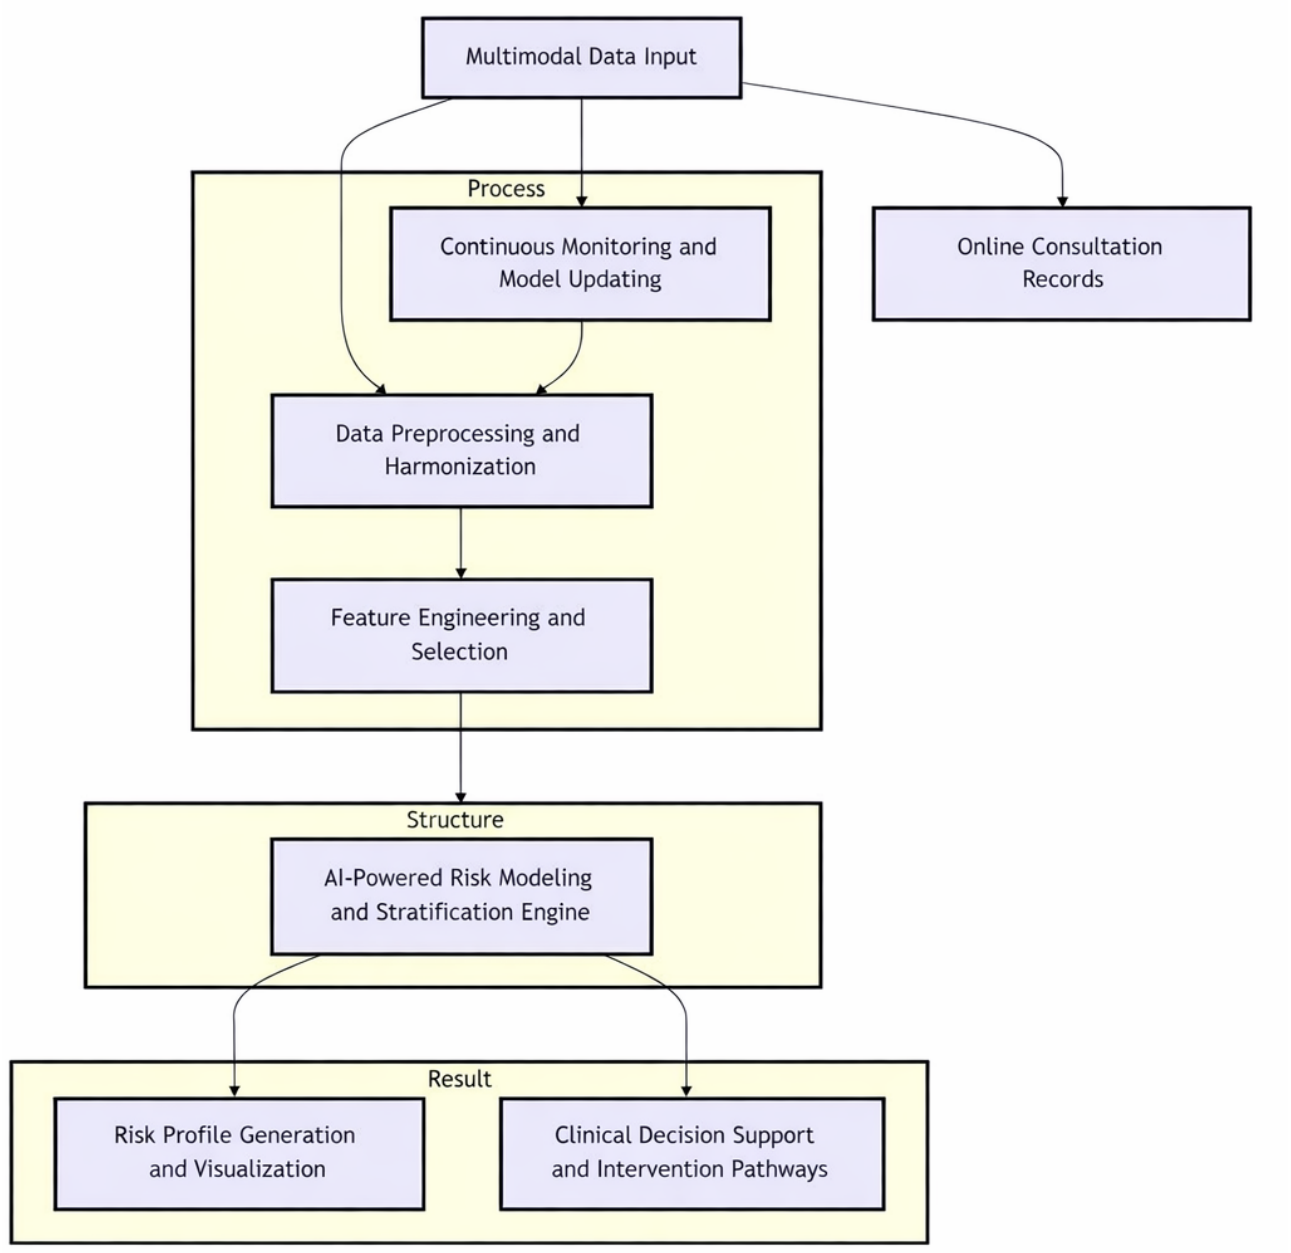
(1)Yrisk=fAI(Preprocessing(Xdata))

This high-level representation underscores the journey from raw data to actionable risk assessment.

Conceptual Framework for Pediatric Risk Stratification

The creation of a robust pediatric health risk stratification system requires a meticulously defined conceptual framework that delineates the core components, their interactions, and the overall data flow. As depicted in Figure 1, the proposed AI-driven framework is architected to be modular, scalable, and adaptable to diverse pediatric health contexts. Its primary objective is to convert raw, multisource pediatric data into actionable risk profiles, thereby facilitating proactive and personalized health care interventions.

Commencing with *multimodal data input*, the framework assimilates a wide array of data sources pertinent to child health. Subsequently, the *data preprocessing and harmonization* layer comes into play. Given the heterogeneity and potential quality issues inherent in real-world pediatric data, such as missing values, inconsistencies, and varying formats from different sources, this layer uses data cleaning, normalization, transformation, and integration techniques to create a unified and analysis-ready dataset.



Next is the *feature engineering and selection* module, which is dedicated to extracting meaningful features from the preprocessed data that are highly indicative of pediatric health risks. This process may involve creating composite variables, transforming existing features, or applying dimensionality reduction techniques to optimize the input for AI models. Domain knowledge from pediatric medicine is crucial in guiding this process to ensure clinical relevance.

At the core of the framework lies the *AI-powered risk modeling and stratification engine*. This engine uses advanced ML algorithms, with a particular focus on ensemble learning techniques, as discussed in the Introduction, to construct predictive models for various pediatric health risks. Trained on historical data, these models learn complex patterns and relationships between input features and health outcomes or risk states. The output of this engine is not merely a binary prediction but a nuanced risk stratification, which may encompass risk scores, probability estimates, or the identification of distinct risk phenotypes. The determination of weights for each data modality is a critical aspect of our ensemble model. Rather than assigning predetermined, fixed weights, our *stacking* framework uses a data-driven approach.

The final layers of the framework are devoted to *risk profile generation and visualization* and *clinical decision support and intervention pathways*. The generated risk profiles are designed to be interpretable by health care professionals and understandable by caregivers, often incorporating visual aids and clear explanations. This output is intended to seamlessly integrate with clinical workflows, offering evidence-based insights to support shared decision-making regarding preventive strategies, further assessments, or targeted interventions. *Continuous monitoring* and *model updating* are also integral to the framework, ensuring that the AI models maintain their accuracy and relevance as new information emerges and clinical knowledge evolves [31].

Identification of Key Pediatric Health Domains and Risk Factors

The primary pediatric health domains identified for this framework, as detailed in Table 2, cover a broad spectrum of child well-being. *Patient safety* focuses on risks, such as adverse drug events and medical errors, typically informed by EHR data and incident reports. *Continuous health monitoring* is crucial, tracking growth parameters and developmental milestones using EHR data and wearable sensor inputs. For children with ongoing conditions, *chronic disease management* addresses factors like glycemic control or asthma exacerbation frequency, primarily using EHR data and home monitoring device information. *Mental health* is a significant domain, evaluating behavioral indicators and emotional well-being via parental, teacher, and direct child assessments. Furthermore, *preventive care* adherence is monitored through risk factors, such as vaccination status and well-child visit compliance, drawing from EHR data and parental questionnaires [32]. The interconnected domains of *nutrition* and *growth* consider risks associated with nutritional intake and growth percentiles, also informed by EHR and parental questionnaire data. Lastly, *physical activity* levels and sedentary behavior duration, identified as critical risk factors, are assessed using wearable sensor data and parental questionnaires.

For each identified health domain, a set of specific, measurable risk factors and associated potential data sources is cataloged. This systematic identification ensures that the subsequent data acquisition and AI modeling efforts are focused and aligned with the goal of comprehensive risk assessment. The dynamic nature of these risk factors across different developmental stages (infancy, early childhood, middle childhood, and adolescence)

XSL•FO
RenderX

is also a key consideration in the framework's design and application.

Table . Key pediatric health domains, associated risk factors, and potential data sources.

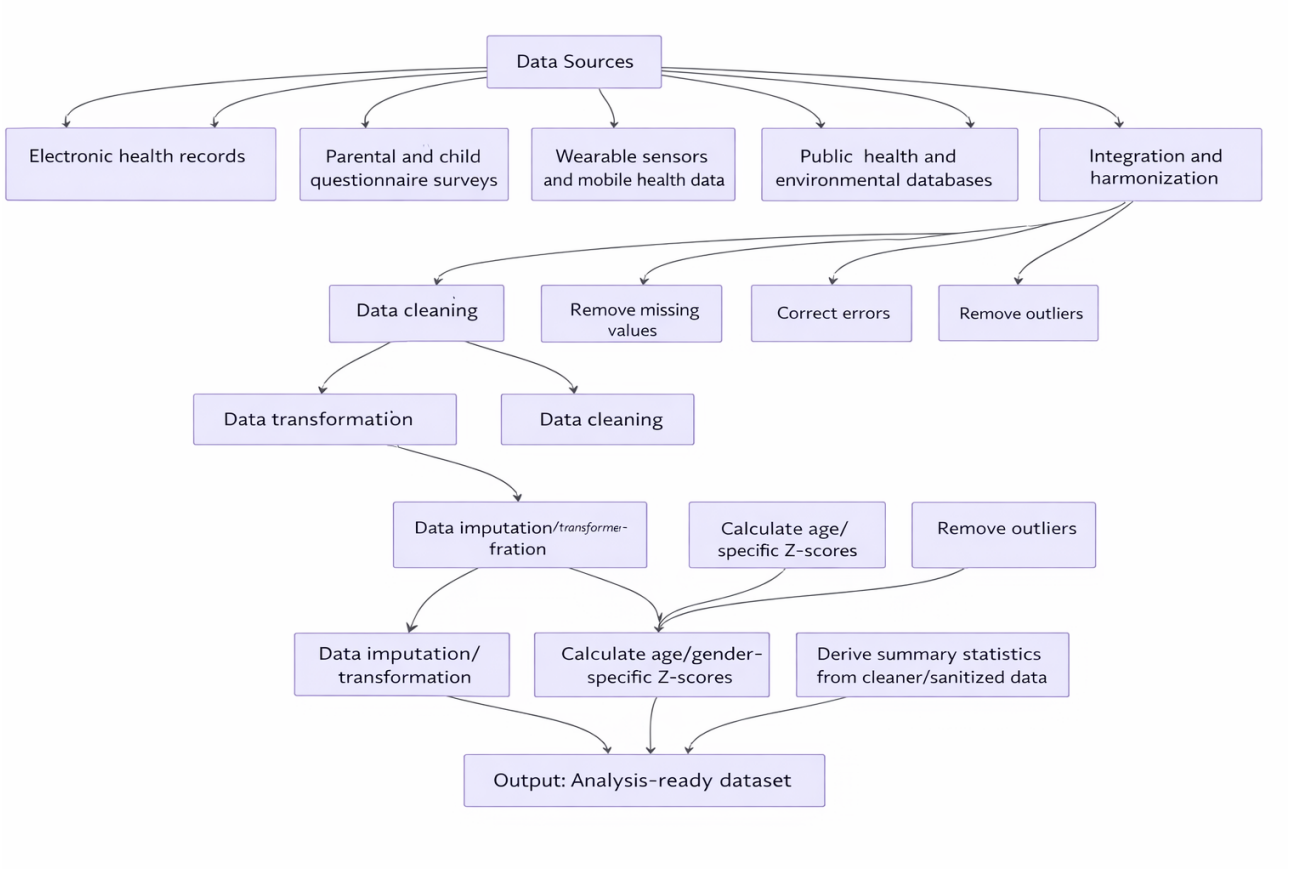
Key pediatric health domains	Associated risk factors	Potential data sources
Patient safety	Adverse drug events and medical errors	EHR[a] data and incident reports
Health monitoring	Growth parameters and developmental milestones	EHR data and wearable sensor data
Chronic disease management	Glycemic control and asthma exacerbation frequency	EHR data and home monitoring devices
Acute illness severity	Fever severity and respiratory distress indicators	EHR data and parental questionnaire responses
Mental health	Behavioral indicators and emotional well-being	Parental and teacher assessments, and direct child assessments
Preventive care	Vaccination status and well-child visit adherence	EHR data and parental questionnaire responses
Nutrition and growth	Nutritional intake and growth percentiles	EHR data and parental questionnaire responses
Physical activity	Activity levels and sedentary behavior duration	Wearable sensor data and parental questionnaire responses

[a]EHR: electronic health record.

Multimodal Data Acquisition and Preparation

The effectiveness of the AI-driven risk stratification framework is fundamentally dependent on the availability of comprehensive, high-quality, multimodal data that accurately reflect the various factors influencing child health. This section details the strategies for acquiring and preparing such data for input into the framework, emphasizing the critical importance of ethical considerations, including informed consent, data privacy, and security, in full compliance with relevant regulations, such as the General Data Protection Regulation (GDPR) and Health Insurance Portability and Accountability Act (HIPAA), adapted for pediatric populations.

The data sources for this framework are inherently multimodal, encompassing a variety of information types. EHRs serve as a primary source, offering longitudinal clinical data that include diagnoses (ICD codes), procedures, medications, laboratory results, growth chart data, and clinical notes. Access to both structured and unstructured EHR data is essential. *Parental and child questionnaires or surveys* are used to capture information often not systematically recorded in EHRs, such as detailed family history, socioeconomic status, lifestyle factors (diet, physical activity, and sleep), environmental exposures, and patient-reported outcomes or symptoms. *Wearable sensors and mHealth data* provide opportunities for continuous, real-world monitoring of physiological parameters (eg, heart rate, activity levels, and sleep patterns) and behavioral data. *School health records* can contribute information on immunizations, health screenings conducted at school, and potentially attendance or behavioral notes relevant to health [33]. *Public health and environmental databases* can offer community-level data on factors like air quality, neighborhood socioeconomic indicators, and access to health care or recreational facilities. *Genomic data*, when applicable and ethically sourced, can provide valuable genetic risk scores or specific genetic markers associated with pediatric conditions.



The data preparation pipeline, illustrated in Figure 2, involves several key steps to transform raw, multimodal data into an analysis-ready dataset. Initially, data from disparate sources must undergo integration and harmonization. This process includes mapping data elements to common terminologies, resolving inconsistencies, and creating a unified data schema. Data cleaning is then performed to address missing values, correct errors, and remove outliers. Data transformation may be necessary to convert raw data into formats suitable for analysis, such as calculating age-specific *z* scores for growth parameters or deriving summary statistics from time-series sensor data. For instance, if xraw is a raw measurement and μage,sex and σage,sex are the age- and sex-specific mean and SD, respectively, from a reference population, the *z* score can be calculated as follows:

$$z = x_{raw} - \mu_{age,sex} \sigma_{age,sex}$$

This normalization is crucial for enabling comparisons of measurements across different age groups and sexes. Finally, data anonymization or pseudonymization is rigorously applied to protect patient privacy before the data are used for model development. The resulting dataset provides the foundation for the feature engineering and AI modeling stages described in the subsequent part.(2)

Figure 2. Multimodal data acquisition and preparation pipeline.

Data Preprocessing and Feature Engineering

The integrity and utility of input data are paramount to the performance and clinical relevance of any AI model, particularly in the pediatric domain, where data can be sparse, longitudinal, and highly variable due to growth and development. Pediatric health data, often derived from multiple heterogeneous sources, such as EHRs, parental questionnaires, school health notes, and wearable sensors, typically present unique challenges, including systematically missing values (eg, developmental assessments not performed at certain ages), measurement noise (eg, variability in home-based measurements), and the presence of irrelevant or redundant information that can obscure true risk signals. Therefore, rigorous data preprocessing and thoughtful, domain-informed feature engineering are indispensable steps to prepare a high-quality dataset for subsequent AI modeling.

The initial phase of preprocessing involves comprehensive data cleaning. Missing data represent a pervasive issue in longitudinal pediatric health care datasets. For instance, growth parameters or developmental screening results might be missing for specific well-child visits. While simple imputation techniques like mean, median, and mode imputation can be applied for variables with a low percentage of missingness and random patterns, they often fail to capture the underlying data structure in pediatric cohorts. More sophisticated methods are typically required, such as k-nearest neighbors imputation, which identifies the k most similar pediatric cases (based on a suite of other observed features) and imputes the missing value for a feature Xj using a weighted average or majority vote from the neighbors [34]. Alternatively, model-based imputation, using algorithms like multivariate imputation by chained equations (MICE), can be used. MICE iteratively models each variable with missing values as a function of other variables in the dataset, cycling through variables until convergence is achieved. For a set of variables X1,…,Xp, MICE specifies a conditional model $P(X_j \mid X_{-j}, \varphi_j)$ for each Xj and iteratively samples from these conditional distributions.

Outlier detection and appropriate treatment are also critical in pediatric data, where extreme values might represent genuine clinical concern or measurement error. Statistical methods, such as the *z* score and IQR, are used. For a data point xi in a feature distribution, its *z* score is calculated as $z_i=(x_i-\mu)/\sigma$, where μ is the mean and σ is the SD. Data points with $|z_i|>\theta_{outlier}$ may be flagged. The IQR method defines outliers as points falling below Q1-1.5×IQR or above Q3+1.5×IQR, where Q1 and Q3 are the first and third quartiles, respectively, and IQR=Q3-Q1. Decisions on handling outliers (removal, transformation, or winsorization) are made cautiously, considering the potential clinical significance of extreme values in child health.

Feature engineering in the pediatric context is a highly domain-driven process focused on creating new, informative features from raw data to capture developmental trajectories, critical exposure periods, and clinically relevant interactions. This enhances model performance and interpretability. In child health, this includes deriving age- and sex-adjusted *z* scores for growth parameters, such as height, weight, BMI, and head circumference, based on standardized pediatric growth charts like World Health Organization (WHO) and Centers for Disease Control and Prevention (CDC) growth standards. It also involves

XSL•FO
RenderX

creating features like developmental velocity, calculated as ΔD/Δt=Dt2-Dt1/t2-t1, reflecting the rate of change in developmental milestone scores between assessments. Additionally, it covers quantifying cumulative exposure to risk factors, such as days with poor air quality and screen time during early childhood, generating features for adherence to pediatric guidelines like vaccination completeness and well-child visit schedules, and creating interaction terms reflecting synergistic effects in child health, such as genetic predispositions interacting with environmental exposures.

To reduce dimensionality, mitigate the risk of overfitting (especially with potentially limited sample sizes in specific pediatric subpopulations), and improve model training efficiency and interpretability, various feature selection techniques are used. These are broadly categorized into filter methods, wrapper methods, and embedded methods. Filter methods evaluate features independently of the AI model, using statistical measures relevant to pediatric outcomes, such as the chi-square test for assessing associations between categorical risk factors (eg, maternal smoking during pregnancy) and a binary child health outcome, and the ANOVA *F* value for assessing the relationship between numerical predictors (eg, birth weight) and different risk groups. Wrapper methods, such as recursive feature elimination, use the performance of a specific AI model to iteratively build and evaluate models with different subsets of features. Embedded methods perform feature selection as an integral part of the model training process. For instance, tree-based algorithms like random forest and gradient boosting inherently provide feature importance scores based on how much each feature contributes to reducing impurity or error across the ensemble of trees. Regularization techniques, such as L1 regularization (Lasso), are particularly useful. The Lasso objective function for a linear model predicting a child's health outcome y based on features X and coefficients β is as follows:

$$(3) LLasso=\sum i=1n\ (yi-\beta 0-\sum j=1p\ xij\beta j)2+\lambda \sum j=1p\ |\beta j|$$

where λ is the regularization parameter that controls the penalty on the sum of absolute values of the coefficients, effectively shrinking less important feature coefficients to zero. The selection of λ is typically done via cross-validation.

To provide an overview of the preprocessing pipeline and feature engineering strategies across different data modalities, the key steps are summarized in Table 3.

Table . Summary of pediatric data preprocessing steps and feature engineering strategies.

Data type	Preprocessing methods	Feature engineering	Examples
Growth indicators	Missing data imputation (KNN[a] and MICE[b])	*z* score calculation and velocity features	Age- and sex-adjusted *z* scores
Early exposure	Outlier detection (*z* score and IQR)	Cumulative exposure and interaction terms	Poor air quality days and screen time
Questionnaires	Data cleaning and encoding	One-hot encoding and label encoding	Vaccination scores and visit adherence
School records	Data integration	Feature extraction	Immunization records and attendance
Wearables	Noise reduction and smoothing	Activity patterns and sleep metrics	Activity levels and sleep duration
Genomics	Data anonymization	Genetic risk scoring	Genetic predispositions

[a]KNN: k-nearest neighbors.

[b]MICE: multivariate imputation by chained equations.

Risk Stratification Algorithm

The process of risk stratification involves translating the continuous risk probabilities or composite risk scores generated by AI models into distinct, actionable risk categories that are meaningful in a clinical context. This is achieved by defining specific thresholds that convert model outputs into discrete risk strata. The thresholds are determined through a combination of clinical expertise, statistical methods, and decision theory principles, ensuring they are both clinically relevant and statistically valid. P(Risk / Xchild) represents the feature vector for a specific child. For a 4-tier stratification system, the risk categories can be defined as follows:

- Low risk: P(Risk /Xchild)<θ1
- Moderate risk: θ≤P(Risk / Xchild)<θ2
- High risk: θ2≤P(Risk / Xchild)<θ3
- Very high risk: P(Risk / Xchild)≥θ3

The selection of the thresholds θ1,θ2,θ3 is guided by clinical expertise, statistical methods, and decision theory. Pediatric specialists define thresholds based on established clinical guidelines, acceptable risk levels for specific age groups, and the availability and efficacy of preventive interventions. Statistical methods, such as using percentiles of the predicted risk distribution in a well-characterized pediatric reference population, can also be used. For example, thresholds might be set to correspond to the 50th, 80th, and 95th percentiles of this distribution. Decision theory principles can further refine threshold optimization by considering a utility function that balances the costs and benefits associated with true positives, false positives, true negatives, and false negatives. This might involve analyzing metrics like Youden J statistic (J=sensitivity+specificity−1) or finding points on the precision-recall curve that correspond to desired tradeoffs for pediatric screening or intervention programs.

XSL•FO
RenderX

When the system is designed to predict multiple distinct health risks for a child, such as the risk of obesity, developmental delay, or asthma exacerbation, the framework requires a mechanism to present these risks in a consolidated and understandable manner. This can be achieved by either displaying the stratified risk level for each condition independently or by developing a composite pediatric health vulnerability index (CPHVI). The CPHVI is calculated by assigning weights wi to each risk score *S*(Ri) based on factors, such as the clinical severity of risk Ri, its impact on long-term child development, its prevalence in the target pediatric population, and its responsiveness to an intervention. To translate the CPHVI into clinical practice, we propose a tiered intervention model based on predefined, clinically meaningful thresholds developed in collaboration with pediatric experts. For example, a CPHVI score exceeding a "high risk" threshold could automatically trigger an alert in the EHR system for the primary care physician, along with a recommendation for a direct referral to a relevant specialist. The formula for the CPHVI is as follows:

$$(4)\text{SCPHVI}=\sum i=1\text{N wi}\cdot\text{S(Ri)}\sum i=1\text{N wi}$$

The determination of the weights wi is a complex task, often requiring expert consensus or data-driven approaches. Another advanced approach involves using unsupervised learning techniques, such as clustering algorithms, applied to the vector of predicted individual risk probabilities for each child. This can help identify common co-occurring risk patterns or distinct pediatric subphenotypes that share similar multirisk profiles, guiding more tailored multifaceted interventions.

To enhance clinical utility and facilitate shared decision-making with families, the reasons behind a child's stratification into a particular risk category must be as transparent and interpretable as possible. Techniques, such as SHAP and Local Interpretable Model-Agnostic Explanations (LIME), are used. For a given prediction f(Xchild), SHAP assigns an importance value (SHAP value, φj) to each input feature j, representing its marginal contribution to pushing the prediction away from a baseline. The sum of SHAP values for all features plus the baseline prediction equals the model's output for that child:

$$(5)\text{fXchild} =\varphi 0+\sum j=1\text{M }\varphi j$$

This allows clinicians to understand which specific factors (eg, low birth weight, specific dietary patterns, and lack of physical activity) are most influential in determining a child's assessed risk level, thereby guiding targeted advice and interventions.

BERT-Based Knowledge Extraction and NLP Modeling

BERT-based NLP is used to extract informative representations from unstructured pediatric clinical text (eg, consultation records, clinical notes, and parental narratives), which are subsequently used as input features for pediatric health risk stratification models.

Pediatric medical journals serve as a vital source of pediatric disease knowledge, encompassing a wealth of information on pediatric diseases, including clinical symptoms, diagnostic methods, treatment approaches, and prognoses. These journals are written by pediatric experts and researchers and are based on extensive clinical practice and scientific research. They contain detailed case studies, research findings, and expert opinions, providing a solid foundation for the extraction and application of pediatric disease knowledge. The knowledge derived from these journals can help health care professionals better understand the characteristics and progression of pediatric diseases, thereby improving the quality of pediatric health care services [14].

The pediatric disease knowledge base is a structured repository that integrates information from pediatric medical journals and other authoritative sources. It includes various aspects of pediatric diseases, such as disease names, symptoms, signs, laboratory test results, imaging findings, treatment methods, and prognoses. This knowledge base is designed to provide comprehensive and accurate information on pediatric diseases, supporting clinical decision-making and research. By organizing and structuring the information from pediatric medical journals, the pediatric disease knowledge base enables efficient retrieval and utilization of pediatric disease knowledge, facilitating the application of this knowledge in clinical practice and research.

The process begins with the ingestion of pediatric medical journal data into our system. These textual data, rich in pediatric disease knowledge, undergo meticulous preprocessing to align with BERT's input requirements. The text is tokenized into a sequence of tokens [T1,T2,…,Tn], where each Ti represents a word or subword unit. Additionally, the pediatric disease knowledge base is incorporated to enhance the model's understanding of pediatric medical concepts. BERT's architecture consists of multiple transformer encoder layers, each equipped with self-attention mechanisms. The input tokens, enriched with special markers like [CLS] and [SEP], pass through these layers, generating a matrix of contextualized embeddings z={z1,z2,…,zn}. These embeddings capture intricate semantic relationships and contextual information within the text, forming the basis for subsequent knowledge extraction tasks.

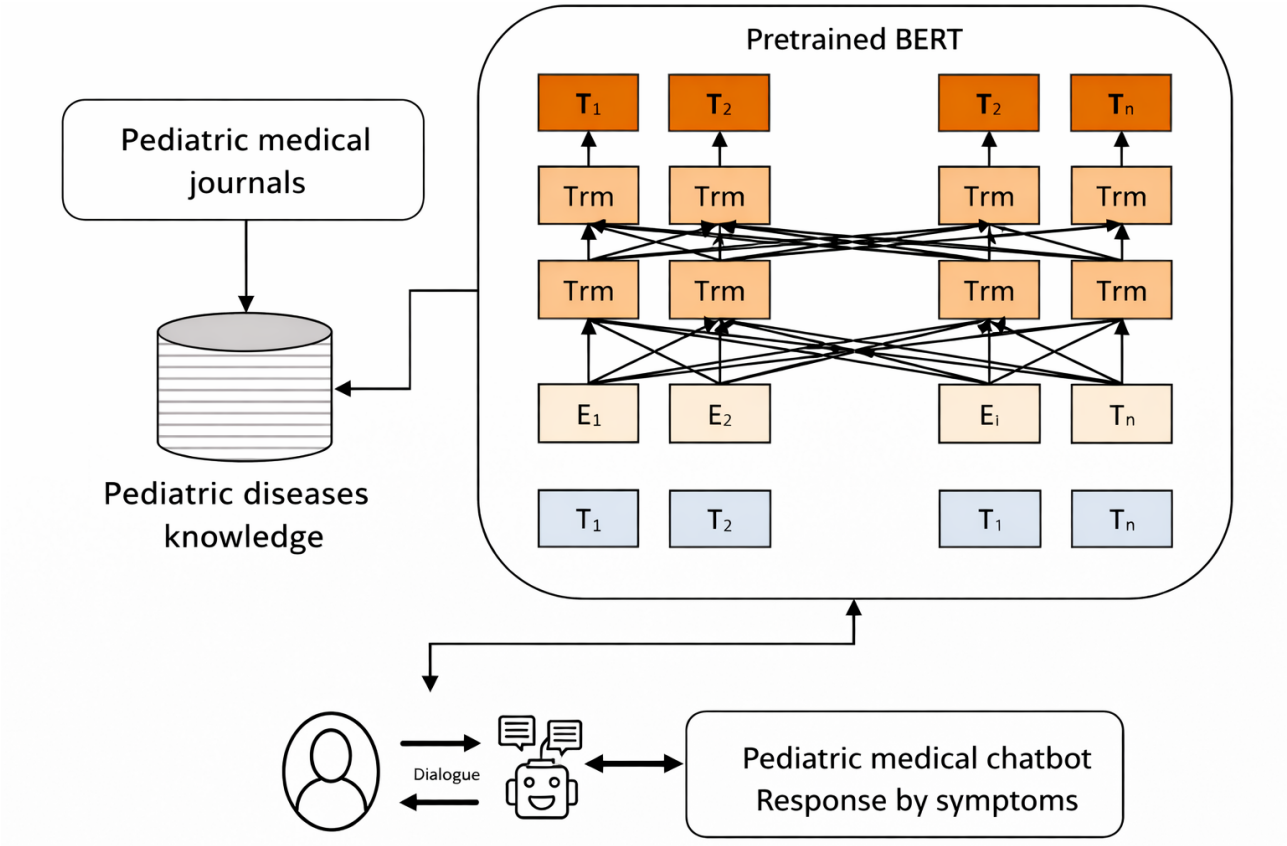
To identify key pediatric disease entities and their relationships within the text, named entity recognition and relation extraction techniques are applied to the BERT-generated embeddings. For named entity recognition, a linear layer combined with a conditional random field is used. The conditional random field loss function is defined as follows:

$$(6)\text{LNER}=-1\text{N}\sum i=1\text{NlogP(yi} \mid \text{Xi)}$$

where N is the number of samples and Pyi ∣ Xi is the probability of the true label sequence yi given the input sequence Xi. For relation extraction between entities, a classifier is trained using a cross-entropy loss function as follows:

$$(7)\text{LRE}=-\sum i=1\text{M }\sum j=1\text{C yi,jlogy}\hat{}\text{i,j}$$

where M represents the number of entity pairs, C is the number of relation types, and yi,j and y^i,j are the true and predicted probabilities for relation *j* between the entity pair *i*, respectively. The extracted entities and relationships are then integrated into the pediatric disease knowledge base. This knowledge base, enriched with entities and relationships from pediatric medical literature, serves to enhance a medical chatbot's responses. When users input symptoms, the chatbot leverages this



XSL•FO
RenderX

knowledge base to generate accurate and contextually relevant diagnostic suggestions and risk assessments.

Figure 3 illustrates a comprehensive workflow where BERT's robust language understanding capabilities are harnessed to extract valuable pediatric disease knowledge from medical texts. This knowledge is subsequently used to empower a medical chatbot, enabling it to deliver precise and informative responses to user inquiries regarding pediatric symptoms. The integration of BERT with pediatric medical journals and a pediatric disease knowledge base provides a powerful tool for advancing pediatric health care through improved diagnostic accuracy and personalized treatment recommendations.

Our knowledge extraction module is built upon BioBERT, a pretrained language model optimized for the biomedical domain. We chose BioBERT as our base model due to its demonstrated strong performance on various biomedical text mining tasks. For fine-tuning, we used a domain-specific corpus comprising over 50,000 articles from leading pediatric medical journals and over 100,000 deidentified clinical notes. The model was fine-tuned for 5 epochs with a learning rate of $2e^{-5}$. The performance of our fine-tuned model on key NLP tasks was rigorously evaluated on a manually annotated test set of 500 clinical notes, which were dual-annotated by pediatric domain experts to ensure quality.

System Architecture Design

The successful deployment, scalability, and usability of the AI-driven pediatric health risk stratification framework critically depend on a meticulously planned and well-engineered system architecture. This architecture must robustly support efficient multimodal data processing pipelines; reliable and timely execution of complex AI models; secure and compliant management of sensitive pediatric health data; and an intuitive, actionable interface for diverse end users, including pediatricians, specialist clinicians, public health officials, researchers, and potentially, with appropriate safeguards, parents or caregivers. A multitier, service-oriented architecture is proposed to ensure modularity, maintainability, and scalability. This typically comprises the following tiers:

1. Data tier: This foundational tier is responsible for the persistent storage and comprehensive management of all relevant pediatric health data. This includes raw input data from diverse sources (EHRs, wearables, and questionnaires), preprocessed and feature-engineered datasets, trained AI models (including their versions and metadata), generated risk profiles for individual children, and audit logs. This tier would likely involve a hybrid database strategy, combining relational databases (MySQL) for structured metadata, patient demographics, and well-defined clinical entities, with potentially NoSQL databases for handling large volumes of heterogeneous, unstructured, or streaming data (like continuous sensor readings). Robust data governance, backup, and recovery mechanisms are integral.
2. Application logic tier (backend services): This is the computational core of the system, housing the data

XSL•FO
RenderX

preprocessing pipelines, sophisticated feature engineering modules, the AI model inference engine, and the risk stratification algorithms. It handles all computational tasks, business logic for risk assessment, and interactions with the data tier. This tier would be developed using scalable and efficient programming languages and appropriate backend frameworks. It may be implemented as a set of microservices to enhance scalability and independent deployability of different functionalities.

3. Presentation tier (frontend interfaces): This tier provides the user interface and user experience for interacting with the system. This could manifest as a secure web-based application accessible via standard browsers, designed with responsive layouts for use on various devices. For specific user groups like parents or children (with age-appropriate design), a dedicated mobile app might be considered. The frontend allows authorized users to view individualized pediatric risk stratification results, explore interactive visualizations of risk factors and trends, access evidence-based decision support information or guideline recommendations, and potentially (for clinicians) trigger further diagnostic or intervention pathways.

Key functional system modules are designed to support the end-to-end pediatric risk stratification process (Figure 4).

1. Pediatric data ingestion and management module: It securely handles the import of data from diverse, often disparate, pediatric health information systems and sources. It performs initial data validation and schema mapping and manages data storage, versioning, and provenance tracking, which are crucial for longitudinal pediatric studies.
2. Preprocessing and pediatric feature engineering module: It implements complex algorithms described in the preceding section, tailored for pediatric data. This module needs to be highly configurable and extensible to accommodate new data types, evolving pediatric clinical knowledge, or updated feature definitions.
3. AI model execution and management engine: It loads versioned, trained AI models and performs inference on new or updated pediatric patient data to generate risk predictions. This engine must be optimized for performance and scalability, especially if real-time or near real-time risk assessment is required for acute pediatric conditions. It also manages the model lifecycle, including retraining triggers and performance monitoring.
4. Pediatric risk stratification and profiling module: It implements the sophisticated algorithms from the preceding section to convert raw model outputs into clinically interpretable risk strata and comprehensive, multidimensional pediatric risk profiles, potentially including age-adjusted interpretations.
5. Reporting, visualization, and alerting module: It generates customized reports, interactive dashboards (eg, showing population-level pediatric risk distributions and trends over time for specific age cohorts), and dynamic visualizations (eg, individual child risk timelines and feature importance charts for specific predictions). It may also include an alerting mechanism for clinicians when a child's risk profile crosses critical, predefined thresholds.
6. User authentication, authorization, and audit module: It ensures secure, role-based access to the system and its sensitive pediatric data, adhering strictly to privacy regulations (eg, HIPAA, GDPR, and Children's Online Privacy Protection Act [COPPA]). Comprehensive audit trails of data access and system actions are maintained.
7. Interoperability layer (application programming interfaces [APIs]): It provides well-defined APIs, possibly using standards like Fast Healthcare Interoperability Resources, to allow secure data exchange and interaction with other clinical systems (eg, pediatric EHRs, laboratory information systems, and clinical decision support tools embedded in existing workflows).

The data flow within the system begins with secure data ingestion from multiple sources into the *data tier*. The *application logic tier* then orchestrates the preprocessing and feature engineering pipelines. The processed features are subsequently fed into the *AI model execution engine* for risk prediction. These predictions are passed to the *risk stratification and profiling module*, and the final, interpretable pediatric risk profiles are stored and made available for secure access and visualization through the *presentation tier* or via the *API layer*. The technology stack will be carefully chosen based on criteria, such as scalability for large pediatric populations, real-time performance requirements, security mandates for child data, ease of development and maintenance, and compatibility with existing health care IT infrastructure. This might include Python with libraries like Pandas, NumPy, Scikit-learn, TensorFlow/Keras, and PyTorch for AI or ML development; web frameworks, such as Django/Flask (Python), Spring Boot (Java), and Node.js, for the backend services; modern JavaScript frameworks like React, Angular, and Vue.js for building responsive and interactive frontend interfaces; and a combination of SQL and NoSQL databases as described for the *data tier*. Containerization technologies like Docker and orchestration tools like Kubernetes may be used for deployment and scaling.

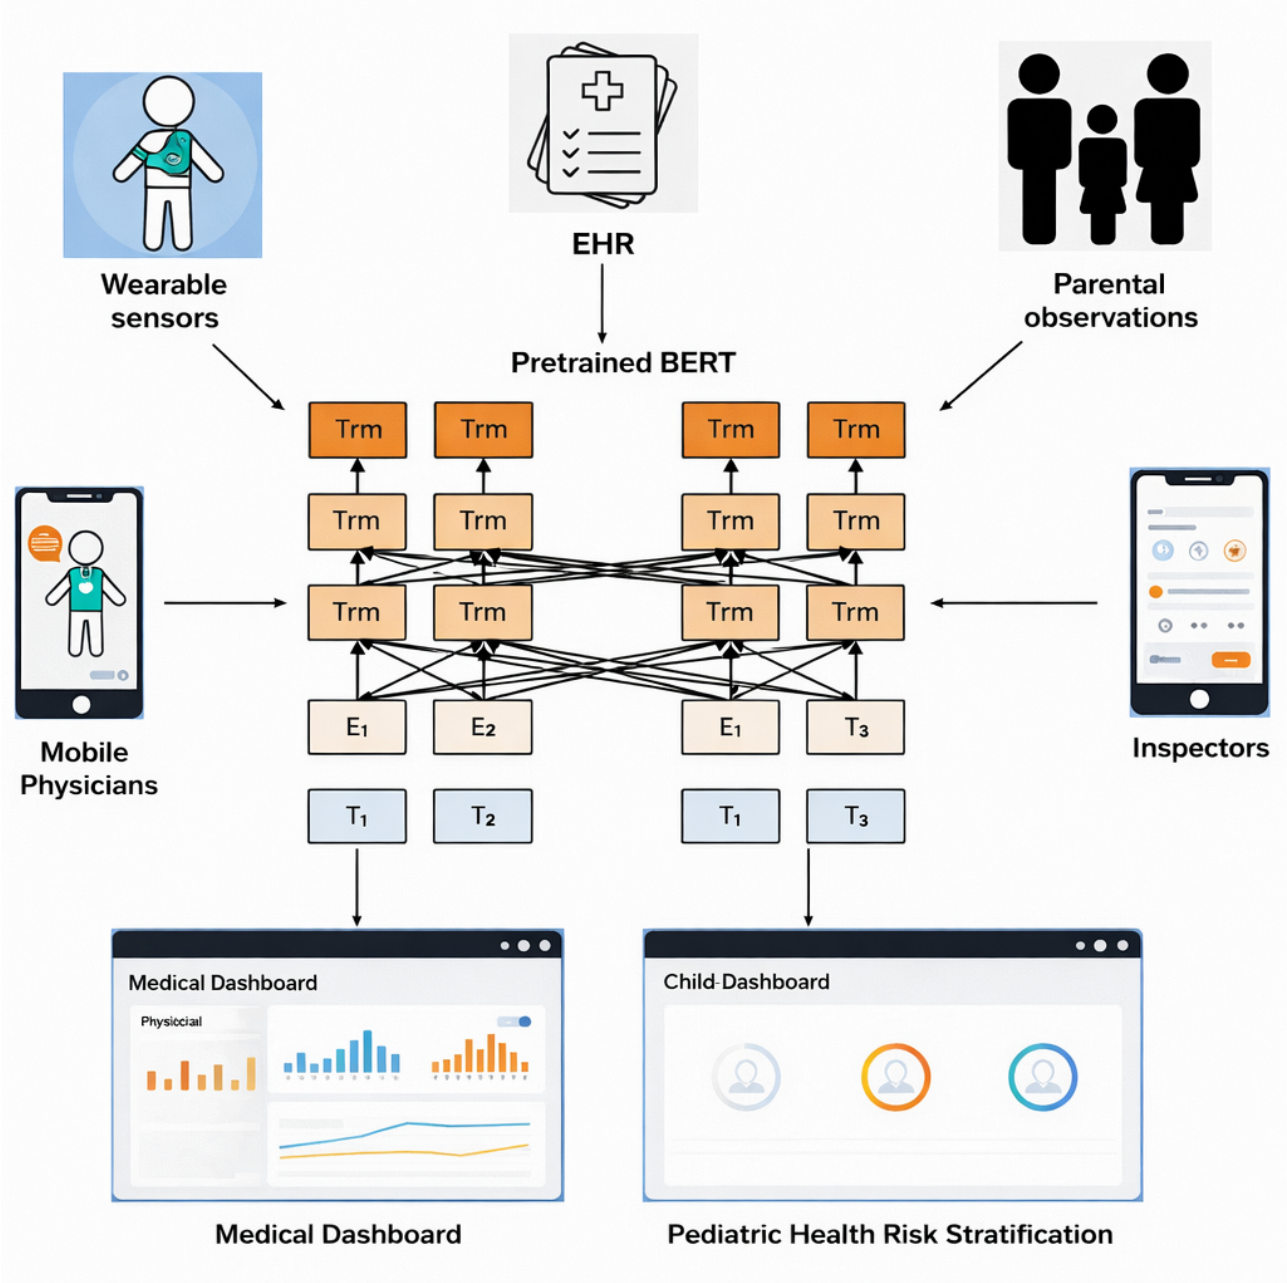
Prototype System Implementation

The pediatric health risk stratification prototype system integrates multisource data input with advanced AI models to deliver a comprehensive risk assessment platform. As illustrated in Figure 5, the system collects diverse data types, including patient demographics, clinical records, and parent-reported outcomes, which serve as the foundation for subsequent analysis and risk assessment. This integration ensures a holistic view of pediatric health, enabling more accurate and nuanced risk predictions.



At the core of the system is a pretrained BERT model, specifically fine-tuned to handle pediatric health terminology and context. The model processes input text data through multiple Transformer modules, which encode the text to capture complex linguistic patterns and semantic relationships. Feature extraction layers then distil these encoded representations into risk-relevant features. These features are passed to risk assessment components where the actual risk stratification takes place, transforming raw data into actionable insights regarding children's health risks.

The system's implementation leverages a robust technology stack to ensure efficiency, scalability, and user-friendliness. The backend, developed using Python and its rich library ecosystem, handles data processing and model execution. It uses microservices, potentially orchestrated by lightweight frameworks like Flask, to manage distinct functionalities such as data ingestion, preprocessing, and model inference. Data storage follows a hybrid approach, combining PostgreSQL for structured data with MongoDB for unstructured or semistructured content. The frontend, built with modern JavaScript frameworks, offers tailored interfaces for different users, including physicians and parents. It includes features like risk profile visualizations and population-level risk trend dashboards. Docker is used for containerization to ensure smooth deployment and scalability of the application components.

To illustrate the practical utility of the framework, consider a hypothetical clinical scenario. Dr Smith, a pediatrician, begins her day by logging into the system's dashboard. The system flags one of her patients, a 5-year-old child, for a significant increase in the composite risk score for developing obesity. Dr Smith clicks on the patient's profile and is presented with an interactive, multimodal dashboard. An explainable AI feature, using SHAP values, highlights the primary contributing factors: a recent decrease in physical activity levels captured by wearable data and parent-reported dietary logs indicating high consumption of processed foods. Based on these insights, the system provides Dr Smith with evidence-based, actionable recommendations, including a referral to a pediatric nutritionist and a set of tailored educational materials for the parents. This scenario demonstrates how the framework can transform raw data into clinically actionable insights to facilitate timely and personalized preventive care.

Experimental Setup

The primary dataset used for training and validating the AI models included data from over 40,000 pediatric participants, with an age range of 2 to 8 years at the time of data collection or follow-up. The dataset was partitioned into 3 mutually exclusive sets: a training set (70% of the data), a validation set (15%), and an independent holdout test set (15%). To ensure temporal validity if longitudinal data were used, the split was performed such that data from earlier time periods were used for training and validation, while data from later periods were reserved for testing, mimicking a prospective evaluation.

To benchmark the performance of the proposed AI-driven framework, a selection of robust baseline models was implemented and rigorously evaluated on an identical dataset and predictive task. These comparators included established traditional statistical models frequently used in pediatric risk prediction, specifically logistic regression for binary risk outcomes, where the probability of risk $P(Y=1 \mid X)$ is modeled as $P(Y=1 \mid X)=(1+e^{-(\beta 0+\sum i=1p \beta iXi)})-1$, and Cox proportional hazards models in scenarios where time-to-event data for risk onset were available. Furthermore, simpler yet effective ML algorithms, namely support vector machine (SVM), configured with various kernels (linear and radial basis function), and standard single decision trees, were also incorporated as baselines. In instances where existing, validated pediatric risk scores or established rule-based systems were pertinent to the specific health outcomes under investigation and applicable to the dataset, these were also included in the comparative analysis to provide a comprehensive performance context. To rigorously

XSL•FO
RenderX

assess the statistical significance of our model's superior performance, we used the DeLong test to compare the area under the receiver operating characteristic curve (AUC-ROC) of our proposed model with that of each baseline model.

Ethical Considerations

This study involved research with human participants. The study protocol was reviewed and approved by the Institutional Review Board and Research Ethics Committee of Hunan University of Arts and Science (HUAS-20250504). All procedures were performed in accordance with the ethical standards of the responsible institutional committee and with the principles of the Declaration of Helsinki. Informed consent was obtained from all participants prior to their inclusion in the study. Participants were fully informed about the purpose of the study, the procedures involved, and their right to withdraw at any time without penalty. The privacy and confidentiality of all participants were strictly maintained throughout the study. All data were anonymized prior to analysis, and no personally identifiable information was collected, stored, or reported. No financial or material compensation was provided to participants for their participation in this study.

Results

This section reports the empirical performance of the proposed AI-driven pediatric health risk stratification framework evaluated on the independent test set, in comparison with multiple baseline models.

Table 4 summarizes the predictive performance of the proposed model and baseline methods across targeted pediatric health risks. The proposed model achieved an AUC-ROC of 0.85 (95% CI 0.82 - 0.88), an area under the precision-recall curve of 0.70 (95% CI 0.65 - 0.75), a sensitivity of 0.78, a specificity of 0.80, and an F_1-score of 0.75. In comparison, logistic regression, SVM, random forest, gradient boosting, and a conventional deep learning model yielded lower AUC-ROC and F_1-score values.

Table . Key performance metrics of the proposed artificial intelligence model and baseline models for targeted pediatric risks in the test set.

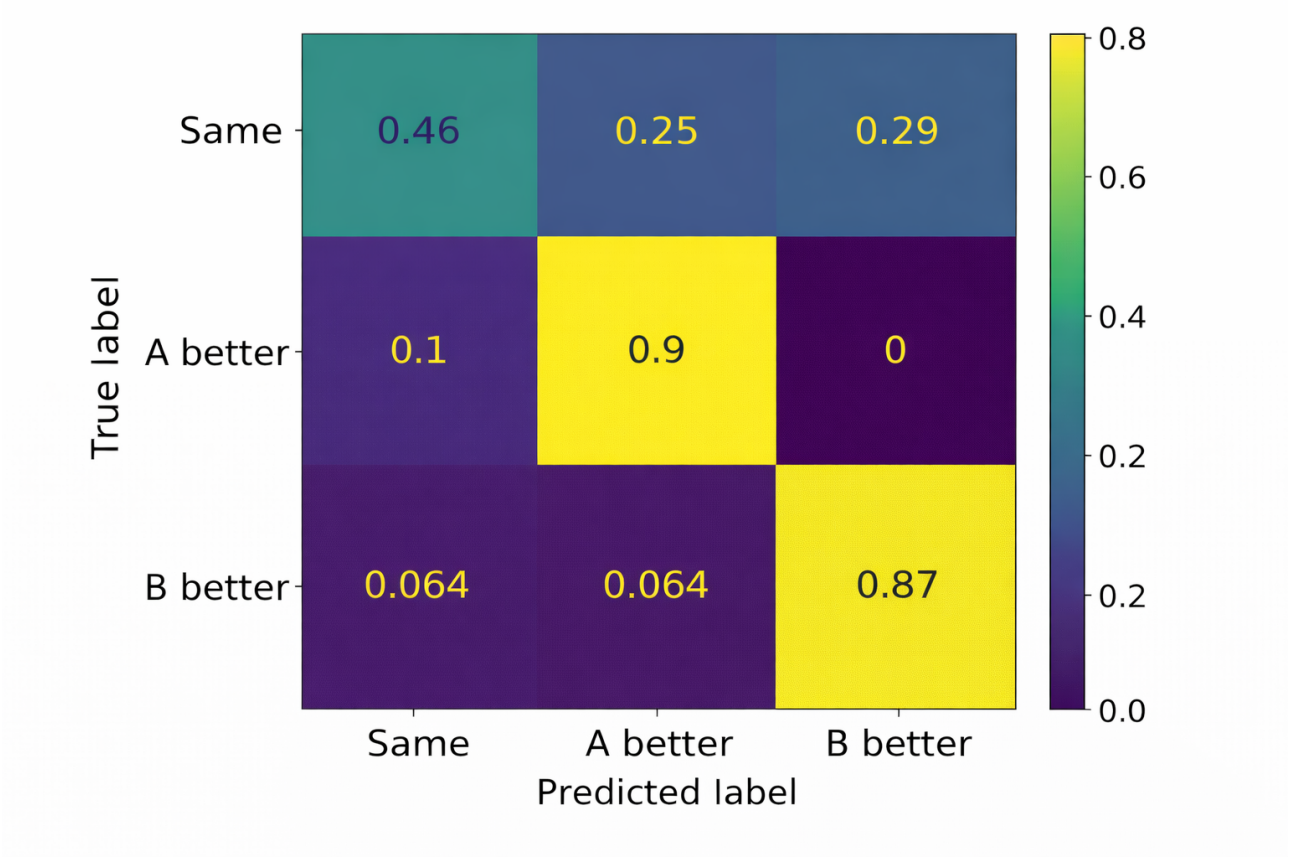
Model name	AUC-ROC[a], value (95% CI)	AUC-PR[b], value (95% CI)	Sensitivity	Specificity	F_1-score	Brier score
Proposed BERT[c] model	0.85 (0.82 - 0.88)	0.70 (0.65 - 0.75)	0.78	0.80	0.75	0.15
Logistic regression	0.72 (0.68 - 0.76)	0.60 (0.55 - 0.65)	0.65	0.70	0.62	0.20
SVM[d]	0.75 (0.71 - 0.79)	0.65 (0.60 - 0.70)	0.70	0.72	0.66	0.18
Random forest	0.78 (0.74 - 0.82)	0.67 (0.62 - 0.72)	0.72	0.75	0.69	0.17
Gradient boosting	0.80 (0.77 - 0.83)	0.69 (0.64 - 0.74)	0.75	0.76	0.72	0.16
Deep learning	0.83 (0.80 - 0.86)	0.72 (0.67 - 0.77)	0.76	0.79	0.74	0.14

[a]AUC-ROC: area under the receiver operating characteristic curve.

[b]AUC-PR: area under the precision-recall curve.

[c]BERT: Bidirectional Encoder Representations From Transformers.

[d]SVM: support vector machine.



The DeLong test demonstrated that the AUC-ROC of the proposed model was significantly higher than that of each baseline model (all $P<.05$). Paired t tests on F_1-scores similarly indicated statistically significant improvements in predictive accuracy for the proposed model relative to all comparators.

To further assess alignment with expert judgment, a manual comparison evaluation was conducted using 100 randomly selected pairs of online consultation cases. Automated predictions and expert assessments were concordant in 78 cases, corresponding to an agreement rate of 78%.

A confusion matrix (Figure 6) shows that most discrepancies occurred in cases manually labeled as "equivalent," whereas predictions for clearly differentiated cases exhibited higher agreement with expert assessments. Misclassifications were predominantly observed within the equivalent category, while the majority of nonequivalent cases were correctly identified.

XSL•FO
RenderX

Figure 6. Artificial intelligence prediction confusion matrix.

Model performance was further examined across predefined pediatric subgroups, including age categories, sex, and socioeconomic status (Table 5). Comparable AUC-ROC and F_1-score values were observed across all subgroups. For age-based stratification, the AUC-ROC values were 0.84 for children younger than 2 years, 0.85 for those aged 2 - 5 years, and 0.86 for those older than 5 years. Similar performance consistency was observed across sex and socioeconomic strata.

Table . Model performance across different pediatric subgroups for early childhood obesity.

Group	AUC-ROC[a], value (95% CI)	F_1-score
Age		
<2 years	0.84 (0.80 - 0.88)	0.74
2 - 5 years	0.85 (0.82 - 0.89)	0.75
>5 years	0.86 (0.83 - 0.89)	0.76
Sex		
Male	0.85 (0.82 - 0.88)	0.75
Female	0.84 (0.81 - 0.87)	0.74
Status		
Low SES[b]	0.83 (0.79 - 0.87)	0.73
Medium SES	0.85 (0.82 - 0.88)	0.75
High SES	0.86 (0.83 - 0.89)	0.76

[a]AUC-ROC: area under the receiver operating characteristic curve.

Discussion

Conclusions

This study successfully designed and validated a novel AI-driven framework for comprehensive pediatric health risk stratification. The primary findings were threefold. First, the framework demonstrates the capability to effectively integrate heterogeneous, multimodal data sources to create a holistic view of a child's health status. Second, our proposed predictive model, which combines a fine-tuned BERT architecture with an ensemble learning strategy, significantly outperformed established baseline models, such as logistic regression and SVM, in predicting key health risks, achieving an AUC-ROC of 0.85 for early childhood obesity. Third, the prototype system's risk assessments showed substantial agreement with manual expert evaluations (78% accuracy), confirming its potential clinical utility and feasibility. The successful implementation of the prototype system, featuring intuitive dashboards for both clinicians and parents, further illustrates the practical applicability of this approach in facilitating early and personalized interventions, thereby contributing a novel and robust technological foundation for proactive pediatric health care.

Limitations and Future Work

While the presented framework shows considerable promise, certain limitations and avenues for future research warrant discussion. The current validation, though rigorous, was based on a specific dataset of over 40,000 pediatric participants aged 2 - 8 years. Broader validation across more diverse pediatric populations and longitudinal follow-up are essential to ascertain long-term predictive accuracy and generalizability. One limitation of our study is the observed slight dip in model performance for the subgroup of children aged 3 - 5 years, which we attribute to the relative scarcity of rich, unstructured text data for this age cohort. To mitigate this issue in future work, we plan to incorporate alternative text sources. A promising approach, as suggested, is the inclusion of open-ended responses from parental questionnaires. These narratives, which capture detailed parental concerns and observations, can be processed by our fine-tuned BERT model to generate rich semantic features, thereby enriching the feature set for younger children and addressing the data sparsity issue. A crucial direction for future work is the implementation of advanced bias mitigation techniques. We plan to further explore methods, such as adversarial debiasing, which involves training the model to make predictions that are invariant to sensitive attributes, thereby proactively enhancing the fairness and equity of our risk stratification framework.

Funding

The research project was supported by the Education Department of Hunan Province: Multidimensional Risk Assessment and Sports-Health Integrated Intervention Model Development for Postural Health in Children in Northwestern Hunan (project number: 24B0629), and the Aid Program for Science and Technology Innovative Research Team in Higher Educational Institutions of Hunan Province.

Abstract

Background: In large-scale clinical data analysis, CSV and traditional relational database management system–based approaches are widely used but impose substantial storage and processing constraints that delay research preparation and hinder multicenter collaboration. Although column-oriented storage formats such as Apache Parquet have gained attention in data science, systematic end-to-end evaluations in clinical environments remain limited, particularly regarding efficiency and scalability.

Objective: This study aimed to empirically evaluate whether a Parquet-based end-to-end pipeline could improve computational efficiency and scalability in large-scale clinical data analysis while preserving predictive performance and protecting privacy.

Methods: Electronic health record data comprising 13.76 million rows from a large academic medical center in Korea were analyzed using Parquet, CSV, PostgreSQL, and DuckDB environments. Standardized SQL workloads and multilabel classification models—implemented using graphics processing unit–accelerated Extreme Gradient Boosting and classifier chain (CC) ensembles to address class imbalance—were applied to evaluate storage efficiency, time to analysis, and predictive performance. Statistical equivalence testing with prespecified clinical margins and bootstrap resampling ensured rigorous comparison, while privacy risks were assessed through advanced membership inference attacks (MIA), including shadow MIA and likelihood ratio attacks.

Results: Compared with CSV, Parquet demonstrated enhanced computational efficiency by lowering disk access from 940.2 to 44.2 seconds (95.3% reduction). End-to-end processing latency was substantially reduced across feature transformation (15.0 vs 9.3 s) and model training (8.1 vs 6.7 s). To address complex clinical correlations, we implemented CC and one-vs-rest architectures, which effectively captured interdependencies between disease labels. Classification performance remained statistically equivalent across area under the receiver operating characteristic curve, area under the precision-recall curve, accuracy, and F_1-score, with all differences falling within prespecified clinical equivalence margins (P<.001). Notably, the CC ensemble demonstrated high technical rigor, minimizing Hamming loss (2.2×10^{-4}) and ensuring robustness even in imbalanced cohorts. MIA performed at chance level (area under the curve=0.500), suggesting no measurable increase in privacy risk.

Conclusions: By significantly mitigating data processing bottlenecks, a Parquet-based pipeline enabled high-throughput, large-scale clinical evidence generation without compromising model integrity or patient privacy. This framework provides a scalable and robust infrastructure for precision medicine, facilitating agile multicenter collaborations and real-world data analysis in resource-constrained clinical environments.

Introduction

Clinical data, including diagnostic reports, prescriptions, laboratory results, and imaging data, hold substantial potential for precision medicine, predictive modeling, and collaborative research. The volume of electronic health records (EHRs) generated in clinical practice has grown exponentially with the expansion of digital health systems [1-4]. However, as datasets expand, bottlenecks, such as storage overhead, transmission delays, and slow query execution, become increasingly common. These challenges cannot be resolved simply by expanding storage capacity; instead, they necessitate more efficient frameworks for data storage and processing.

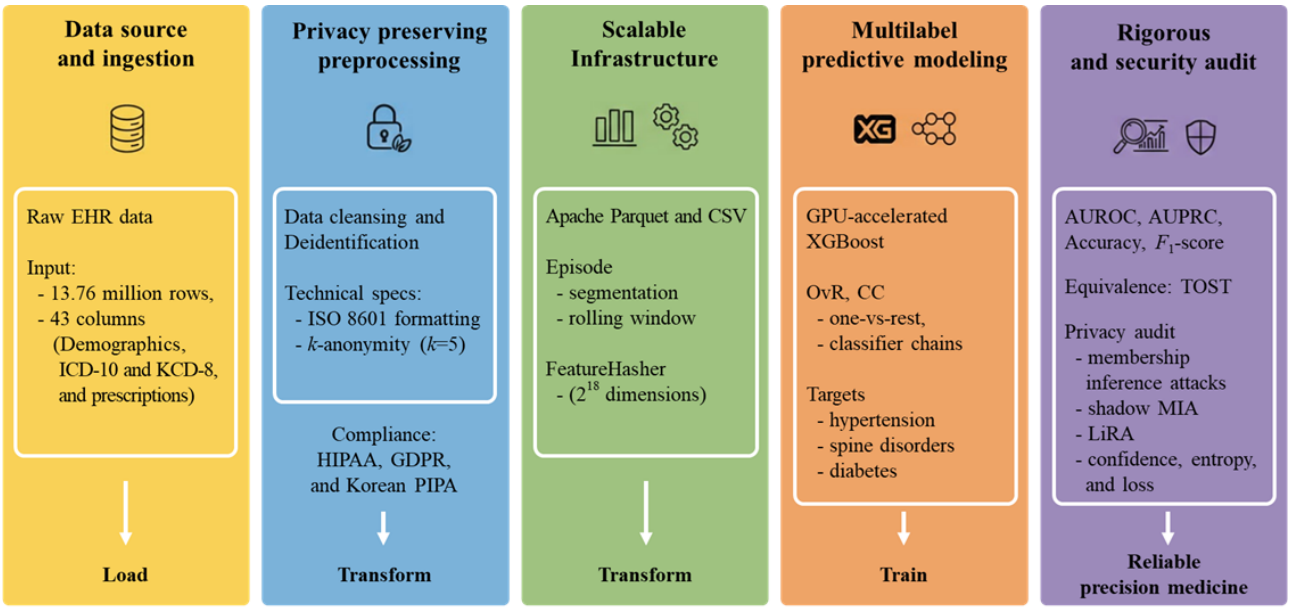
In medical informatics, data are most commonly stored in row-oriented formats, such as CSV files, spreadsheets, and relational databases. Although valued for their simplicity and interoperability, these approaches exhibit clear limitations in storage efficiency and analytic scalability. CSV files are uncompressed and large in size, restricting input and output throughput, while relational databases often underperform in column-level operations. In contrast, column-oriented formats offer high compression and selective input and output, making them well suited for high-volume and cloud-based environments. Among these, Apache Parquet is widely used as a standard solution owing to its scalability and interoperability [5,6]. However, few studies have systematically evaluated its end-to-end performance in clinical pipelines that incorporate deidentification procedures.

A further challenge in clinical data use is balancing privacy protection with data utility. Deidentification is mandatory in multicenter research and machine learning, but it may affect statistical distributions or compromise predictive performance. Understanding how storage architectures interact with deidentification to influence analytic outcomes is therefore of both academic and practical importance [7-13].

Unlike prior studies that focused solely on benchmarking computational efficiency, this work integrates privacy risk assessment and formal equivalence testing into a real-world end-to-end pipeline, thereby providing a clinically meaningful evaluation of Parquet as a foundation for precision medicine and collaborative research. Against this background, this study developed a scalable Parquet-based pipeline for high-volume clinical data and empirically assessed its storage efficiency, computational throughput, and preservation of predictive performance. This study also sought to establish a reliable infrastructure that enables cohort construction, secure data sharing, and clinical decision support in multicenter and precision medicine research [14-23].

Methods

Ethical Considerations



This retrospective observational study was conducted using real-world EHR data. The study protocol was approved by the institutional review board of Wonju Severance Christian Hospital (CR325065). The requirement for informed consent was waived by the institutional review board due to the retrospective nature of the study and the use of deidentified data. All data processing was performed within an independent honest broker system, and investigators had access only to deidentified data. No compensation was provided to the participants as there was no direct contact or intervention involved. The entire process complied with the Personal Information Protection Act of Korea, the Health Insurance Portability and Accountability Act Safe Harbor standard, and the General Data Protection Regulation [24-28].

Integrated End-to-End Clinical Data Processing Workflow

We developed an integrated pipeline connecting 5 core stages: raw EHR ingestion, privacy-preserving preprocessing (ISO 8601 and *k*-anonymity), scalable infrastructure using Apache Parquet, multilabel modeling via graphics processing unit (GPU)–accelerated Extreme Gradient Boosting (XGBoost), and rigorous statistical and privacy audits (Figure 1). To optimize analytic performance, we adopted a column-oriented storage format (Apache Parquet) over the traditional row-oriented structure (eg, CSV) [6]. For comparative evaluation, the same dataset was also maintained in CSV format. While row-oriented structures excel in transactional tasks, columnar storage significantly reduces input and output overhead and enhances compression efficiency for complex analytic queries. This architectural choice is specifically tailored for the high dimensionality and sparse distribution of clinical datasets, ensuring both system scalability and robust privacy protection across the entire workflow.

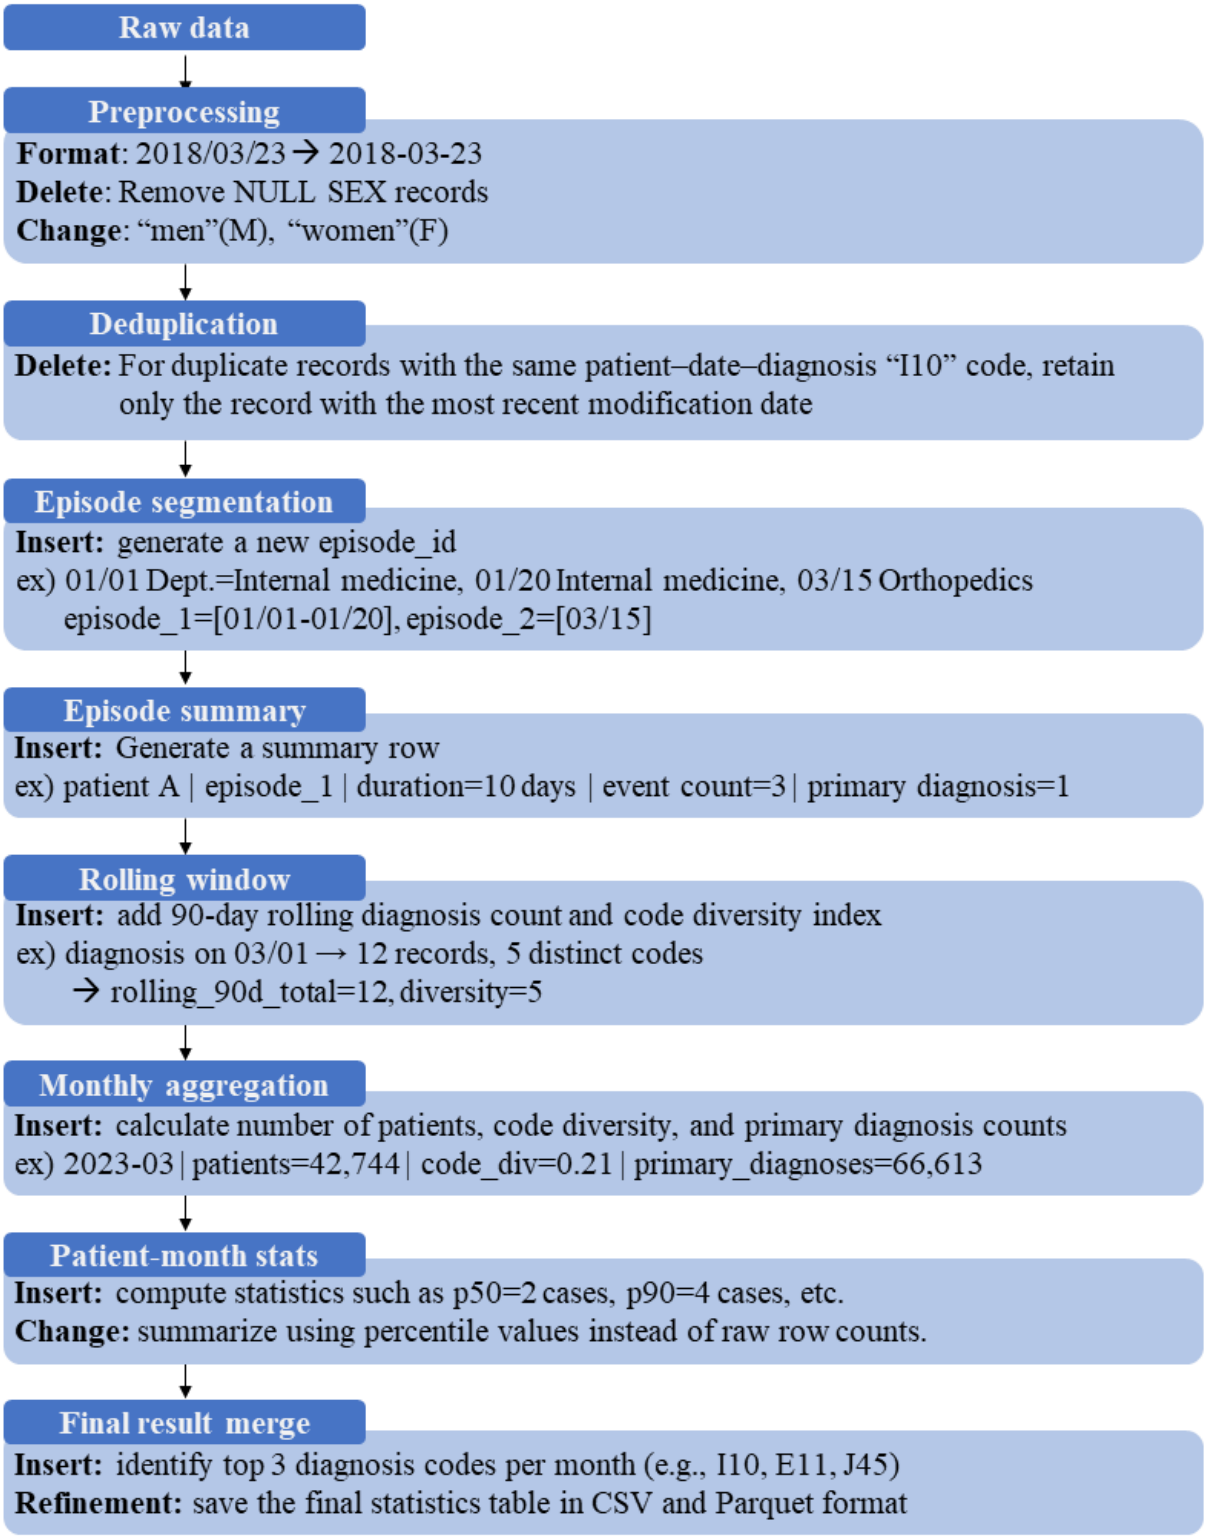
Data Preparation and Transformation



The dataset included patient demographics, diagnostic codes based on the International Classification of Diseases, Tenth Revision (ICD-10) [29-35] and the Korean Classification of Diseases, Eighth Revision (KCD-8), visit type, and prescription records. In total, the dataset comprised approximately 13.76 million rows (43 columns, approximately 3.2 GB), as detailed in Multimedia Appendix 1. After replacing patient identifiers with randomly generated surrogate IDs, quasi-identifiers were generalized to satisfy *k*-anonymity (*k*=5). Data cleansing further ensured quality control by standardizing date fields into the ISO-compliant format (YYYY-MM-DD).

Clinical Data Processing Pipeline

Clinical data processing followed a stepwise pipeline designed to reflect clinical context. In preprocessing, we standardized date formats, removed records with missing sex, and normalized sex codes (eg, “men” to M and “women” to F). Duplicate entries were resolved by retaining only the most recent record for identical combinations of patient, date, and diagnosis code. Visits were segmented into episodes by department changes or temporal gaps, and each episode was assigned an episode identifier. Episode-level summaries included episode duration, event count, and primary diagnosis status. To capture temporal continuity, a 90-day rolling window was applied to compute diagnosis counts and code diversity per patient. Monthly aggregates were then derived, including patient counts, code diversity, and primary diagnosis counts, with patient-month statistics summarized using quantiles (eg, p50 and p90). The diagnostic records for the targeted conditions—including I10.9, E10-E14, and M48.06—were identified and extracted to construct the final summary tables, which were then stored in both CSV and Parquet formats for comparative analysis. The stepwise process is illustrated in Figure 2.

XSL•FO
RenderX

Figure 2. Stepwise scenario of the clinical data processing pipeline.

Database Workload Benchmarking

To evaluate the efficiency of storage formats, scenario-based workloads were executed in DuckDB (DuckDB Labs) [36] and PostgreSQL (PostgreSQL Global Development Group) [37] environments. Synthetic example data are provided in Multimedia Appendix 2. Identical datasets were loaded into Parquet-based DuckDB and row-store PostgreSQL, and complex SQL queries—adapted from TPC-DS patterns [38,39] (eg, window functions, multidimensional aggregation, and ROLLUP)—were applied to compare performance. Resource use was further examined by varying chunk sizes (10,000-50,000 records) with detailed results in Multimedia Appendix 3.

Predictive Modeling and Multilabel Strategy

Predictive modeling assessed the impact of storage formats on classification performance for hypertension (I10.9), spinal disorders (M48.06), and diabetes (E10-E14). Patient-level

XSL•FO
RenderX

diagnostic histories were transformed into 2^{18} dimensional sparse vectors (approximately 262,000 features) via FeatureHasher (scikit-learn; Python Software Foundation) [40-42]. The dataset was randomly partitioned into training (65%), validation (15%), and test (20%) subsets with a fixed seed of 42. Classification models were implemented using GPU-accelerated XGBoost with positive class weighting to address imbalance [43-45]. Hyperparameter details are provided in Multimedia Appendix 4.

For multilabel classification, we applied one-vs-rest (OvR) [46] and classifier chains (CC) [47]. To mitigate label-order dependence and evaluate interlabel dependencies, we constructed ensembles of 5 strategically ordered chains encompassing a prevalence gradient—from high-prevalence anchors (hypertension and diabetes) to the sparse target, spinal stenosis (M48.06, 0.50%; Multimedia Appendix 5). Prioritizing M48.06, a domain-independent and sparse condition, served to demonstrate model robustness even without the clustering benefits of related disease families (eg, I-series codes). To ensure the rigorous prevention of label leakage and validate the integrity of the performance gains, all defining ICD-10 codes were strictly excluded from the feature space. This setup ensured that the model's predictive capability relied solely on statistical associations across hundreds of thousands of nondiagnostic features. Model performance was evaluated using area under the receiver operating characteristic curve (AUROC), area under the precision-recall curve (AUPRC), accuracy, and F_1-score, calculated for each label as well as macroaverages and microaverages.

Statistical Evaluation and Privacy Assessment

Model performance was evaluated using AUROC, AUPRC, accuracy, and F_1-score. To assess model reliability, calibration was further evaluated using the Brier score and expected calibration error (ECE), with detailed results provided in Multimedia Appendix 6. CSV and Parquet results were compared using paired runs with shared identifiers. Normality was assessed via the Shapiro-Wilk test, followed by paired 2-tailed *t* tests or Wilcoxon signed-rank tests with Bonferroni correction (P<.05) [48-50].

Equivalence was assessed via two 1-sided tests (TOST) [51] and 95% bootstrap CIs. Equivalence margins (δ) were prespecified at 0.02 for AUROC or AUPRC and 0.01 for accuracy or F_1-score. These thresholds were selected to be narrower than the 0.05 margin commonly used in clinical equivalence trials [52] and are more conservative than performance variances typically observed in the external validation of clinical artificial intelligence (AI) systems [53]. Such strict margins were intended to constrain observed differences to ranges generally regarded as clinically negligible, particularly for high-performing models operating within an elevated accuracy range (0.98-1.00).

To mitigate stochastic variation, a fixed random seed was applied across all experiments, ensuring that observed differences reflected data handling effects rather than algorithmic randomness. Privacy was further audited using membership inference attacks (MIA)—including confidence, entropy, loss-based (Yeom), shadow, and Likelihood Ratio Attack (LiRA) strategies—under patient-level stratified splits (train: 240,596; test: 240,597) to verify model robustness.

Experimental Setup and Reproducibility

All experiments were conducted on a Linux Ubuntu 22.04 server with a 24-core central processing unit (CPU), 128-GB memory, and an NVIDIA RTX 5090 GPU (CUDA 12.2, cuDNN 8.9, driver 550.54). Data processing used Python (version 3.10; Python Software Foundation) with Pandas 1.5.3, PyArrow 12.0.1, scikit-learn 1.3.2, and XGBoost 2.0.3 (GPU-hist). Multiprocessing was implemented using the standard Python multiprocessing module.

As specified in the modeling strategy, XGBoost was configured with a learning rate of 0.08, maximum depth of 6, and 1000 estimators. To handle class imbalance, task-specific *scale_pos_weight* and an ensemble of 5 CCs were used. All random operations used a fixed seed of 42 for reproducibility. For robust performance evaluation, we conducted 20 independent experimental runs and used 5000-iteration bootstrap resampling to compute 95% CIs. Detailed hyperparameters and the statistical framework for equivalence testing are provided in Multimedia Appendix 4.

Results

Storage and Pipeline Efficiency

Conversion to Parquet substantially improved storage efficiency, reducing file size by nearly 6.9-fold relative to CSV. As summarized in Table 1, Parquet also consistently outperformed CSV across the end-to-end pipeline. File loading (input and output) time decreased by more than 95%, and both feature transformation (FeatureHasher) and model training (XGBoost) were faster under Parquet. Although peak CPU memory was about 1.3 GB higher, GPU memory consumption decreased by 326 MB, resulting in stable overall resource use. Resource consumption remained stable at 9 to 10 GB across chunk sizes, reflecting consistent scalability, with efficiency varying by chunk size. The values in Table 1 represent peak use in end-to-end runs, with minor variations arising from measurement conditions, whereas CPU, memory, and disk input and output patterns remained consistent across chunk sizes (Multimedia Appendix 3).

Classification Performance and Calibration

Single-label results are presented in Table 2. All 3 tasks achieved AUROC values above 0.920, with AUPRC ranging from 0.488 to 0.580. Hypertension (I10.9) yielded the highest F_1-score (0.599), followed by spinal disorders (M48.06, 0.536) and diabetes (E10-E14, 0.521). Macroaveraged performance reached an AUROC of 0.920, an AUPRC of 0.545, an accuracy of 0.934, and an F_1-score of 0.552. Calibration analyses [54,55], reported in Multimedia Appendix 6, demonstrated excellent reliability for hypertension (Brier score 2.1×10^{-5}; ECE 6.0×10^{-6}), while spinal disorders (ECE=0.016) and diabetes (ECE=0.018) showed mild miscalibration but remained within recommended thresholds (ECE<0.020).

Table 2. Per-label classification performance using extreme gradient boosting.

Labels	AUROC[a]	AUPRC[b]	Accuracy	F_1-score
Hypertension	0.920	0.580	0.906	0.599
Spine disorder	0.941	0.488	0.982	0.536
Diabetes[c]	0.899	0.567	0.915	0.521
Macroaverage	0.920	0.545	0.934	0.552

[a]AUROC: area under the receiver operating characteristic curve.

[b]AUPRC: area under the precision-recall curve.

[c]Diabetes mellitus (International Classification of Diseases, Tenth Revision codes: E10-E14).

Table 2 evaluates label-specific discrimination under substantial class imbalance, whereas Table 3 summarizes overall multilabel prediction performance using microaveraged aggregation across all label–instance pairs. Specifically, Table 2 focuses on the predictive performance of individual sparse labels, while Table 3 reflects aggregated performance across all prediction events. Multilabel results in Table 3 confirmed high-performance consistency for both OvR and CC, with AUROC >0.999 and AUPRC >0.998. Subset accuracy was identical (0.999), but CC showed slight improvements in Hamming loss and Jaccard index [56], suggesting modest benefits from capturing label dependencies. A numerical gap was observed between per-label AUPRC (approximately 0.5; Table 2) and multilabel AUPRC (near 1.0; Table 3). This reflects the technical difference in aggregation: multilabel metrics were calculated using microaveraging to evaluate the overall model efficacy.

XSL•FO
RenderX

Table 3. Multilabel classification performance.

Models	AUROC[a]	AUPRC[b]	Hamming loss	Subset accuracy	Jaccard index
One-vs-rest					
Microaverage	0.999	0.998	2.4×10^{-4}	0.999	0.997
Macroaverage	0.999	0.998	—[c]	—	—
Classifier chains					
Microaverage	0.999	0.998	2.2×10^{-4}	0.999	0.997
Macroaverage	0.999	0.998	—	—	—

[a]AUROC: area under the receiver operating characteristic curve.

[b]AUPRC: area under the precision-recall curve.

[c]Not applicable.

Although discrimination remained high across all tasks, calibration analyses revealed modest overconfidence for diabetes and spinal disorder models. These deviations, while within accepted thresholds, emphasize the importance of calibration-aware adjustments when deploying predictive models in clinical workflows.

Database Benchmarking

As summarized in Table 4, DuckDB executed analytic workloads with an approximately 28-fold reduction in wall-clock time compared with PostgreSQL, which required 2546.4 seconds. DuckDB also exhibited higher CPU use (72.1% vs 39.6%), while memory consumption was comparable across systems.

Table 4. Performance comparison of DuckDB and PostgreSQL in scenario-based SQL workloads.

Metrics	DuckDB[a]	PostgreSQL[b]
Wall-clock time (s)	90.2	2546.4
CPU[c] use (%)	72.1	39.6
Memory use (GB)	13.7	14.8
Read throughput (MB/s)	554.7	365.2
Write throughput (MB/s)	1116.0	998.0

[a]DuckDB: column-oriented database optimized for analytical workloads.

[b]PostgreSQL: row-oriented relational database primarily designed for transactional workloads, with support for analytical queries.

[c]CPU: central processing unit.

Equivalence Analysis

Paired experiments (20 runs per condition) were conducted using shared run identifiers, with median and IQR values provided in Table S1 in Multimedia Appendix 7. Several metrics converged across all repetitions, producing zero IQR values and demonstrating high algorithmic stability. Overall, both formats achieved robust numerical consistency across all experimental iterations; for instance, mean AUROC was 1.000 for CSV and 0.984 for Parquet ($\Delta=-0.015$). While other metrics (AUPRC, accuracy, and F_1-score) were slightly higher under the CSV format, paired *t* tests and Wilcoxon signed-rank tests confirmed statistical significance after Bonferroni correction ($P<.001$; Table S2 in Multimedia Appendix 7). However, these numerical variations remained minimal.

Notably, all observed differences fell within the prespecified equivalence margins ($\delta=0.02$ for AUROC and AUPRC and $\delta=0.01$ for accuracy and F_1-score). TOST confirmed statistical equivalence ($P<.05$) across all evaluated metrics, and bootstrap 95% CIs for AUROC Δ (−0.016 to −0.015) further reflected near-zero variability consistent with asymptotic performance stability (Table S3 in Multimedia Appendix 7).

Privacy Assessment

The MIA evaluations, performed based on established methodologies [57-59] and summarized in Table 5, produced area under the curve (AUC) values of 0.501, 0.502, and 0.499 for confidence, entropy, and loss-based strategies, respectively. The maximum advantage did not exceed 0.007, and the gain over random guessing was ≤0.003. Attack performance was indistinguishable from random guessing, indicating no additional privacy risk. Additional shadow and LiRA [60,61] results are available in Multimedia Appendix 8, corroborating these findings.

XSL•FO
RenderX

Table 5. Membership inference attack results across different attack strategies.

Attack strategy	Attack AUC[a] (95% CI)	Advantage	Best accuracy	Gain vs baseline
Confidence	0.501 (0.501-0.503)	0.006	0.503	0.003
Entropy	0.502 (0.502-0.503)	0.007	0.503	0.003
Loss (Yeom)	0.499 (0.498-0.499)	0.002	0.500	0.001

[a]AUC: area under the curve.

Discussion

Principal Findings

This study successfully implemented an integrated end-to-end pipeline (Figure 1) that ensures a seamless transition from raw EHR data ingestion to predictive modeling. By leveraging Apache Parquet, the framework effectively addressed storage and processing bottlenecks—specifically, input and output latency—inherent in traditional row-oriented workflows, substantially enhancing data throughput and accelerating the analytic preparatory phase while maintaining high predictive fidelity. Furthermore, our findings indicate that the minor performance discrepancies between formats are attributable to systematic data handling effects under a strictly controlled environment. Beyond these computational efficiencies, privacy evaluations demonstrated that the optimized workflow maintains rigorous data protection standards, providing a secure foundation for multicenter research operations without introducing additional vulnerabilities.

Although paired statistical tests yielded highly significant *P* values ($P<.001$), this result reflects the sensitivity of paired testing under large-scale data and repeated bootstrap evaluation rather than clinically meaningful divergence. From an equivalence perspective, all performance differences remained well within the prespecified margins, confirming that the Parquet-based pipeline achieves practical performance equivalence to the traditional CSV workflow.

The substantial improvement in multilabel AUPRC compared with per-label performance highlights the system-level predictive advantage gained by explicitly modeling interlabel dependencies. While individual disease prediction remains challenging under substantial class imbalance, the multilabel formulation enables the model to capture clinically meaningful comorbidity structures, thereby reframing the observed performance gap as a reflection of holistic predictive efficacy rather than a metric artifact. This gap was also driven by the extreme class imbalance inherent in clinical datasets (eg, 0.50% prevalence for spinal disorders), where high AUROCs can coexist with lower F_1-scores. By integrating these dependencies within the CC architecture, the model leveraged frequent clinical co-occurrence patterns—such as hypertension and diabetes—to stabilize predictions for sparse conditions, including spinal stenosis. Importantly, the consistent performance observed despite the strict exclusion of all defining ICD-10 codes provided strong evidence against label leakage and underscored the model's reliance on nondiagnostic clinical associations.

Clinical Implications and Research Operations

The clinical implications were considerable. By substantially shortening preparatory phases and enabling analyses to be completed within hours rather than days, Parquet-based pipelines allowed investigators to progress more rapidly from raw data to actionable evidence. Such improvements not only accelerated study initiation but also facilitated the integration of predictive models into research and clinical workflows. In multicenter settings, scalability supported the efficient integration of heterogeneous patient populations without excessive computational cost, thereby enhancing reproducibility and advancing precision medicine initiatives. These efficiencies were directly relevant to clinical workflows and regulatory-grade analyses. They enabled interim analyses and timely regulatory submissions, supporting more responsive and efficient research operations.

Privacy and Security Safeguards

Privacy evaluation reinforced the suitability of this approach. Deidentification procedures satisfied k-anonymity, and MIA yielded chance-level performance. The chance-level performance of multiple MIA methods confirmed that computational gains do not compromise patient confidentiality, a prerequisite for secure collaboration across institutions. Patient-level stratification and consistent pipeline design acted as effective safeguards. While residual risks remain inherent to secondary data use, our findings suggested that Parquet does not introduce additional vulnerabilities. For collaborative research networks—where privacy assurances are essential for sharing—these results provide practical reassurance.

Interpretation of Predictive Performance and Label Dependencies

Classification analyses revealed stable performance for common conditions such as hypertension, whereas imbalanced disorders such as diabetes and spinal disease yielded lower scores. This pattern highlights the need to account for dataset structure and interlabel dependencies when interpreting predictive outputs. The elevated AUROC values likely reflect the combination of high-prevalence conditions and extensive diagnostic feature sets. Consistent with the modeling strategy, defining codes were excluded from the feature space; however, correlated diagnostic features may still have influenced performance estimates.

While performance convergence at elevated levels constrained the sensitivity to subtle comparative differences, it underscored the robustness and reproducibility of the pipeline, supporting its suitability for large-scale clinical research, where stability and reliability are critical. Predictive reliability was not compromised by storage structure, supporting Parquet as a

XSL•FO
RenderX

dependable option for secondary use of EHR data in diverse research settings.

Model Reliability and Calibration

Calibration analyses further showed that hypertension models were well aligned with observed risks, whereas diabetes and spinal disorder tasks exhibited modest miscalibration. These results underscore that even high-performing classifiers may generate overconfident probability estimates, a limitation directly relevant to clinical decision support. Future studies should evaluate calibration-aware techniques, such as temperature scaling or isotonic regression, to improve the reliability of probability estimates (Multimedia Appendix 6).

Beyond technical validation, the findings demonstrated practical value for clinical research operations. Large-scale trials and observational studies often face delays in cohort assembly and iterative validation; Parquet-based pipelines shorten these steps, enabling more adaptive study designs. In multicenter collaborations, they promote secure and efficient data exchange, reducing delays that commonly impede cooperative studies.

Limitations

Several limitations should be acknowledged. First, the datasets analyzed were derived from specific institutional cohorts, which may constrain generalizability to other health care systems. Second, the elevated performance baseline of the predictive models limited the sensitivity to subtle differences between CSV and Parquet formats. Third, while MIA offered a widely accepted proxy for privacy risk, broader adversarial evaluations were not included. Fourth, the evaluation was primarily conducted in on-premise settings, so the scalability of findings in distributed or cloud-based environments remains to be established. Finally, despite the clear efficiency advantages of Parquet, its adoption may introduce a technical learning curve for clinical researchers who are less familiar with column-oriented storage formats or big-data frameworks. Transitioning from traditional row-oriented workflows to optimized columnar architectures requires initial investments in technical training and infrastructure adjustment. However, these upfront efforts are likely to be offset by the long-term gains in scalability and processing speed demonstrated in our results, ultimately supporting more efficient and reproducible clinical evidence generation.

Future Work

Future research should extend the evaluation of Parquet-based pipelines to distributed and cloud-based environments, focusing on both scalability and cost-effectiveness. In addition, validation across hybrid and federated architectures will be important to confirm applicability in multicenter collaborations where data cannot be centralized. Beyond structured EHR data, future studies should also investigate applications to unstructured modalities, such as clinical narratives, imaging metadata, and time-series signals. Such efforts would test the versatility of Parquet-based pipelines in supporting multimodal learning and integrative analyses. Privacy assessments should likewise be expanded to encompass attribute inference, linkage, and other adversarial scenarios, ideally within federated or privacy-preserving analytic frameworks. Moreover, interoperability across international coding standards should be validated using external multicenter datasets to ensure global applicability. Pursuing these directions will enhance the technical robustness of Parquet-based infrastructures while reinforcing their clinical relevance, ultimately enabling secure collaboration and more efficient integration of evidence into patient care.

Conclusions

This study demonstrated that Parquet-based end-to-end processing effectively alleviated the storage and computational bottlenecks inherent in traditional row-oriented and relational database workflows while maintaining predictive fidelity and privacy safeguards. By improving computational efficiency and enabling the rapid preparation of analysis-ready cohorts, Parquet reduces the resources required for large-scale clinical data handling. These efficiencies translate into tangible research benefits, enabling earlier study initiation and more adaptive study designs across diverse clinical research settings.

The integration of efficiency with privacy safeguards further ensures that accelerated workflows remain suitable for secure data sharing across institutions. In parallel, these capabilities support regulatory-grade analyses and health technology assessments, where timely and reproducible evidence is critical. For clinicians and researchers, the central implication is that Parquet-based pipelines reduce the manual effort and computational overhead required to transform raw EHR data into analysis-ready cohorts. This capability not only strengthens multicenter collaboration but also facilitates the timely translation of evidence into clinical decision support.

Ultimately, by aligning computational efficiency with privacy-conscious infrastructure, Parquet-based pipelines reinforce the evidence base that informs clinical decision-making, positioning this approach as a robust foundation for sustainable precision medicine.

Abstract

Background: In the field of precision medicine, pan-cancer survival prediction is crucial for individualized oncology diagnosis and treatment. Although multimodal data fusion techniques have significantly improved prediction accuracy, existing studies generally overlook the sensitivity of medical data and the need for privacy protection.

Objective: To address the aforementioned problem, this study aims to propose a bilayer feature fusion framework based on the multihead attention mechanism and adaptive differential privacy, which balances precise feature extraction and sensitive data protection.

Methods: Specifically, the multihead attention mechanism was integrated into bilayer feature extraction and fusion. Layer-wise relevance analysis was used to calculate the correlation between features and outcomes, and Laplacian noise was adaptively added based on the calculation results to achieve collaborative optimization of precise feature extraction and sensitive data protection. Additionally, the concordance index (C-index) and 5-fold cross-validation were used to compare the proposed method with state-of-the-art approaches.

Results: The proposed model achieved superior performance in both pan-cancer and single-cancer survival prediction, validated via the C-index and 5-fold cross-validation. In pan-cancer scenarios, the trimodal combination of clinical data, messenger RNA data, and microRNA expression data achieved the highest C-index of 0.799, outperforming multiple existing multimodal survival prediction approaches. After adaptive Laplacian noise injection for privacy protection, the model's accuracy decreased by only 0.01-0.03 while satisfying -differential privacy. For single-cancer prediction, the proposed method achieved higher C-index values in 18 out of 20 cancer types compared with representative deep learning–based survival models, with 7 types showing significant improvements (C-index difference >0.1) and more stable performance distributions. Furthermore, pan-cancer–trained models generally outperformed single-cancer–trained counterparts in most cancer types, highlighting the value of shared predictive features across cancers.

Conclusions: This study provides a solution that balances prediction accuracy and privacy security for pan-cancer survival prediction, laying the foundation for the efficient use of medical data under privacy protection. Future work may further integrate pathological images and proteomics data to expand the model's applications in cancer subtype classification and biomarker discovery.

Introduction

In the era of precision medicine, pan-cancer survival prediction refers to the task of modeling and predicting patient survival outcomes across multiple cancer types simultaneously by leveraging shared and cancer-specific prognostic patterns. As a core component of individualized oncology diagnosis and treatment, pan-cancer survival prediction has been widely validated for its clinical value. Accurately estimating survival risk for patients with different cancer types not only enables clinicians to optimize treatment strategies and personalize follow-up schedules, but also facilitates risk stratification and more efficient allocation of medical resources [1].

Early survival prediction efforts were predominantly anchored in unimodal data paradigms, relying on either genomic features or clinical variables in isolation. Statistical models laid the foundational groundwork for this field: the random survival forest (RSF) [2], for instance, addressed key challenges in survival analysis (eg, right-censored data and missing values) through log-rank–based tree splitting and adaptive imputation, establishing a robust nonparametric framework. Meanwhile, the classic Cox proportional hazards model (CPH) [3] became a clinical staple for its interpretability via linear combinations of clinical indicators, though its inability to capture complex nonlinear biological mechanisms limited its predictive power in heterogeneous cancer cohorts. The advent of deep learning catalyzed a paradigm shift in unimodal modeling: approaches like DeepSurv [4] integrated neural networks with Cox regression to automatically learn nonlinear covariate–treatment relationships, outperforming traditional models on genomic datasets. Subsequent studies further validated deep learning's superiority in capturing complex variable interactions; for example, in clinical data for oral squamous cell carcinoma [5] and histopathological images for colorectal cancer [6]. Weakly supervised learning also emerged as a promising direction for leveraging unannotated whole-slide images across multiple cancer types [7], while transfer learning facilitated cross-dataset generalization in disease-specific prognostic tasks [8]. Despite these advances, unimodal models inherently suffer from incomplete information capture: genomic data alone overlooks the spatial heterogeneity of tumor microenvironments (eg, angiogenesis patterns in pathology slides), while clinical variables fail to reveal molecular-level prognostic markers, creating an inherent ceiling for predictive performance.

In response to these limitations, multimodal data fusion has emerged as a transformative research focus in pan-cancer survival prediction, driven by the recognition that complementary data modalities (omics, imaging, and clinical) can synergistically enhance prognostic accuracy. Early multimodal frameworks integrated clinical, transcriptomic (messenger RNA [mRNA]/microRNA [miRNA]), and pathological data to achieve cross-cancer prediction [9], while recent innovations have incorporated advanced techniques such as unsupervised learning and attention mechanisms to dynamically weight modality contributions [10]. A key trend in this space is the development of specialized fusion architectures: the Multimodal Affinity Fusion Network [11] and MultiCoFusion [12]; for example, use attention mechanisms and graph convolutional networks to model intermodal dependencies and gene-gene interactions, respectively. Furthermore, bilinear fusion approaches, such as the attention-based multimodal bilinear fusion [13] and hierarchical factorized models [14], have addressed the curse of dimensionality to enable deeper cross-modal interactions. Notably, methods like Dynamic-DeepHit [15] have pioneered the use of recurrent neural network–based attention to model longitudinal dependencies for dynamic risk prediction, while cross-modal translation and alignment (CMTA) [16] explicitly learn and aligns intra- and cross-modal representations between pathology and genomics via encoder-decoder structures. End-to-end multimodal models such as MultiSurv [17], which integrate up to 6 modalities (whole-slide images, clinical data, and multiomics), have demonstrated state-of-the-art performance (concordance index [C-index]=0.779) across 33 cancer types, validating the value of comprehensive data integration. Other frameworks have incorporated multitask learning [18] or alternating training [19] to jointly optimize survival prediction and auxiliary tasks (eg, cancer grading), further improving model robustness. Recent work by Flack et al [20] introduced a robust multimodal survival prediction framework that effectively handles data heterogeneity and missing modalities through a regularization-based fusion strategy, showing competitive performance across multiple cancer types. Despite these advancements, critical challenges persist: inefficient cross-modal information alignment, inadequate intramodal feature refinement, and unresolved issues of intermodal heterogeneity and noise propagation remain major barriers to achieving consistent performance across diverse cancer types at the pan-cancer scale. More critically, the majority of these state-of-the-art multimodal survival prediction models, including MultiSurv [17], HFBSurv [14], attention-based multimodal bilinear fusion [13], and MBFusion [18], operate under the implicit assumption of centralized, nonsensitive data. They fundamentally lack integrated mechanisms to protect the highly sensitive genetic and clinical information inherent in medical datasets, creating a significant gap between methodological advancement and real-world clinical applicability where privacy is paramount.

Although multimodal data fusion has significantly improved pan-cancer survival prediction accuracy, existing research generally ignores the sensitivity of medical data and the need for privacy protection. Medical data contain sensitive information such as patients' genomic data, pathological images, and clinical records, whose leakage may lead to ethical risks such as identity recognition and insurance discrimination. For instance, empirical studies have demonstrated that even aggregated genomic data remain vulnerable to linkage attacks using auxiliary public databases, potentially inferring an individual's identity with high confidence [21]. Additionally, during the training and sharing of deep learning models, gradients or intermediate features may inadvertently leak sensitive patterns of the original training data [22]. While Chen et al [23] proposed an optimized logistic regression model (batch gradient descent logistic regression and balanced differential privacy logistic regression based on hybrid feature selection (Pearson correlation test + random forest out-of-bag algorithm) and differential privacy (DP) protection to address the problems

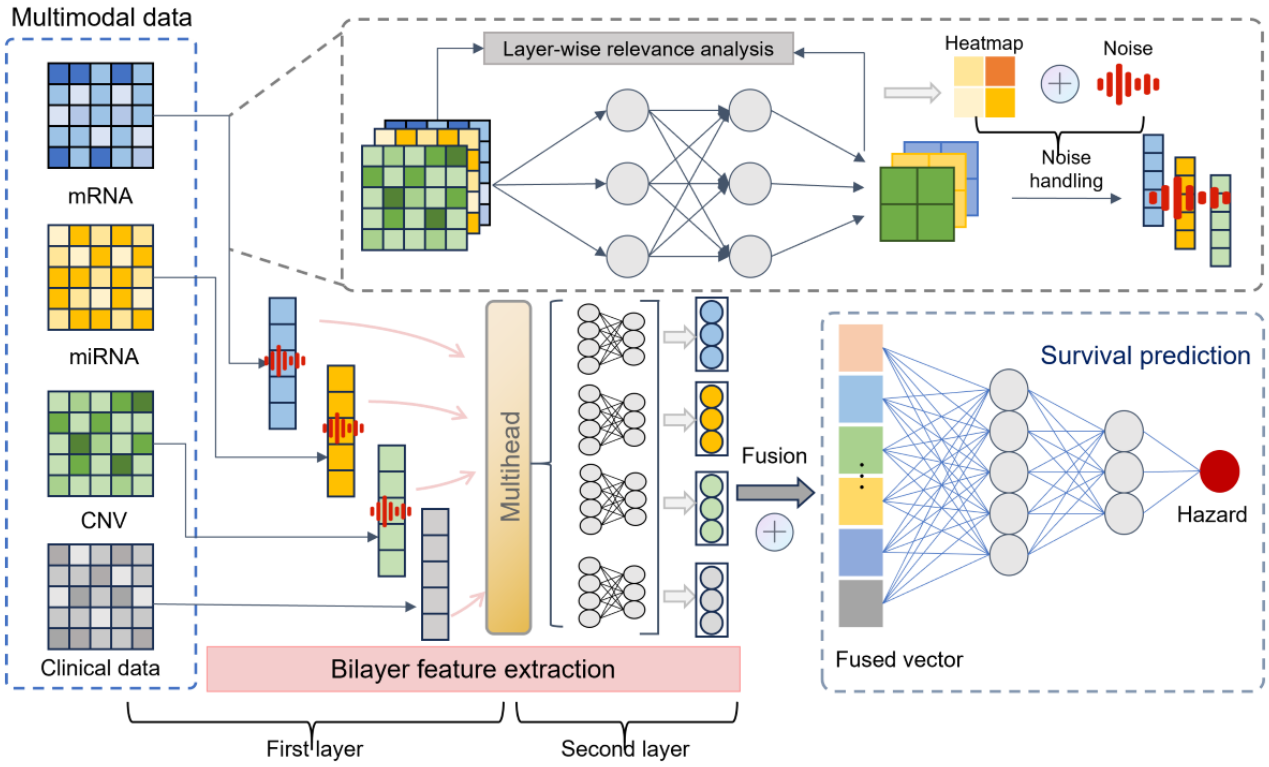
XSL•FO
RenderX

of insufficient prediction accuracy and privacy leakage in existing machine learning models for breast cancer prediction, and Chai et al [24] proposed the decentralized federated learning framework AdFed, combining regularization methods to train models without sharing raw data while achieving feature selection and privacy protection. To protect DNA data, Wu et al [25] proposed the DP-Motif Finding algorithm based on -DP, which uses closed frequent patterns to reduce redundant motifs, allocates privacy budget by constructing a perturbed extension tree, and uses best linear unbiased estimation postprocessing to optimize the noisy support. Wu et al [26] also proposed an adaptive federated learning scheme integrating DP, which adjusts the gradient descent process through an adaptive learning rate algorithm to avoid model overfitting and fluctuations, while introducing a DP mechanism to resist various background knowledge attacks, providing quantifiable privacy protection for the federated learning process. Wang et al [27] proposed a blockchain-based access control framework for genome-wide association studies in federated learning to protect the security of genetic data—this framework implements automated quality control to ensure training data quality, designs a blockchain-based authentication mechanism to filter malicious attackers, and adopts a periodic aggregation method combined with DP to accelerate cloud model training and resist multiple attacks [28]. Wang et al [29] proposed a method based on the ant colony optimization algorithm to detect gene interactions for genome-wide association studies—an intelligent privacy-preserving scheme. Current studies still suffer from problems such as single datasets and heavy reliance on data anonymization or centralized storage, failing to embed dynamic privacy protection mechanisms.

To solve the above problems, this study proposes a bilayer feature fusion framework based on the multihead attention (MHA) mechanism and adaptive DP, achieving collaborative optimization of precise feature extraction and sensitive data protection through technological innovation. Specifically, for feature fusion, traditional methods typically rely on fixed weights or simple concatenation to handle heterogeneous data. Simple concatenation, however, merely "physically stacks" feature vectors from different modalities, posing notable limitations. Multisource data (clinical, mRNA, miRNA, and gene copy number variation [CNV]) vary drastically in feature dimensions, semantics, and distributions; forcing them into a single-vector space postconcatenation overlooks inherent intermodal correlations; for example, links between specific mRNA expression and clinical survival time, or regulatory relationships between miRNA and CNV. Additionally, concatenation assumes "all features are equally important," failing to differentiate their contributions to survival prediction. This often buries key signals (eg, driver gene mutation sites) under redundancy, and may trigger the curse of dimensionality via rapid feature expansion, increasing computational complexity and overfitting risk. Given the aforementioned limitations of simple concatenation, our first contribution is the design of a structured bilayer feature extraction module. The first layer performs modality-specific feature extraction on clinical, mRNA, miRNA, and CNV data through fully connected (FC) networks and embedding layers. The second layer innovatively uses an MHA mechanism not merely as a fusion tool, but as a structured cross-modal interaction model that explicitly quantifies feature-level contributions. Unlike single-head attention, which models only single correlations, MHA captures differentiated correlations between features from different subspaces through parallelized independent attention heads and focuses on key survival-related features through dynamic weight allocation. Our second and primary contribution lies in the novel integration of adaptive DP directly into the multimodal feature extraction pipeline. At the privacy protection level, this study proposes adaptive DP based on layer-wise relevance analysis, balancing prediction accuracy and privacy security through a 2-step strategy. First, the layer-wise relevance propagation algorithm is used to quantify the association strength between neurons at each layer and survival prediction outcomes, identifying highly sensitive features (eg, driver gene mutation sites) in mRNA, miRNA, and CNV data; then privacy budgets are dynamically allocated based on correlation scores to inject Laplacian noise into the gradient update process—features with higher correlations receive less noise, preserving key prediction information while suppressing privacy leakage risks.

In summary, the novelty of our work is not merely the combination of MHA and DP, but the creation of a synergistic framework where (1) the bilayer MHA structure provides the granular feature importance signals necessary for adaptive noise allocation and (2) the adaptive DP mechanism, guided by layer-wise relevance analysis, protects privacy in a targeted manner that minimizes damage to the model's core predictive capability. This integrated solution addresses the specific limitations of prior multimodal models (which neglect privacy) and prior DP applications (which impair use in complex models), paving the way for clinically viable, privacy-preserving pan-cancer prediction tools.

Methods



Overview

As shown in Figure 1, the proposed model architecture consists of 2 parts: a bilayer feature extraction module based on MHA and an adaptive DP protection module based on layer-wise relevance analysis. The bilayer feature extraction part, based on MHA, first performs first-layer feature extraction through FC layers and embedding layers, and then uses the MHA mechanism in the second layer for further feature extraction and multimodal data fusion. By integrating the MHA mechanism, the bilayer feature extraction module fully uses the advantage of parallel heads to capture different correlations, comprehensively and deeply mining key information from multimodal data. Additionally, a privacy protection component is added during the first-layer feature extraction, integrating layer-wise relevance analysis into the FC layers to deeply analyze the correlation between features and survival prediction outcomes through backpropagation. Noise is adaptively added based on the obtained correlation results. This study introduces a bilayer feature extraction module into the multimodal survival prediction model to better mine data features and provides privacy protection, effectively preserving the privacy information in the training data. The data preprocessing and

RenderX

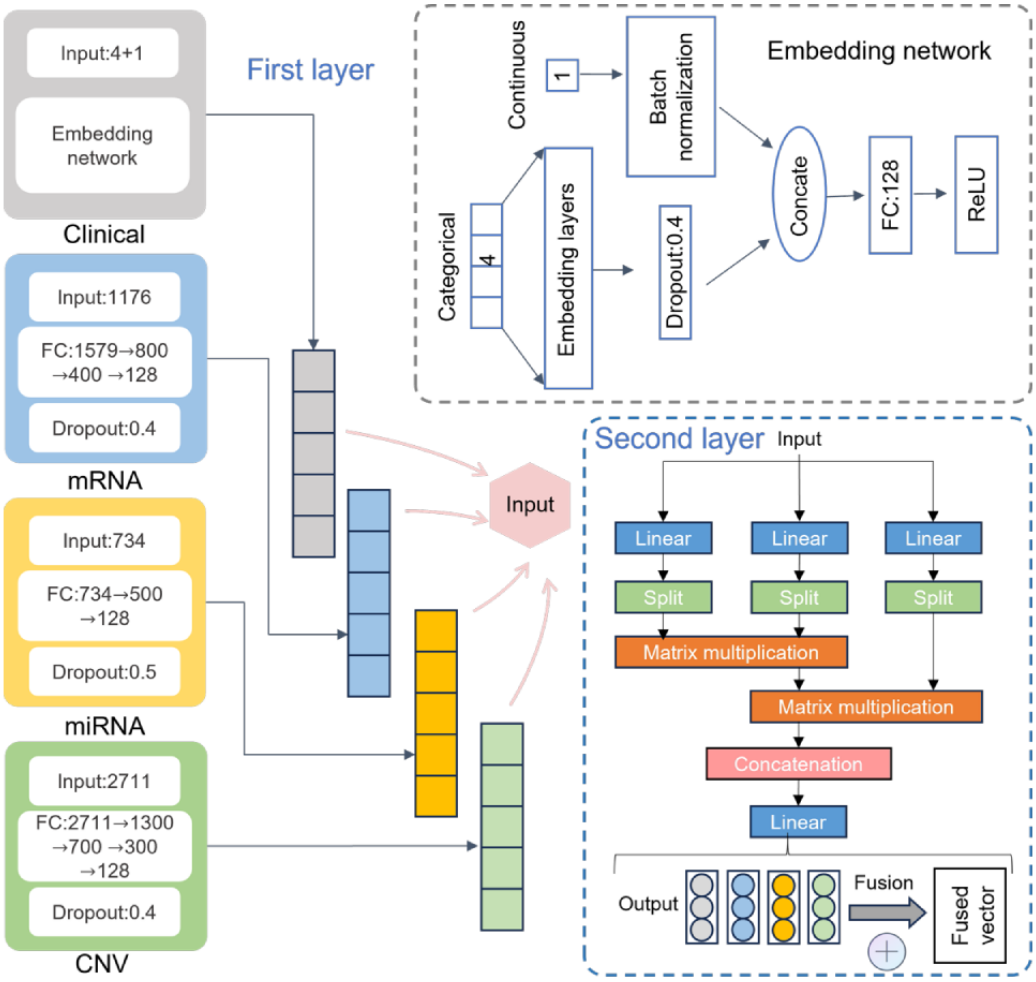
detailed method descriptions are presented in the following sections.

Figure 1. The architecture of the proposed model. CNV: gene copy number variation; miRNA: microRNA; mRNA: messenger RNA.

Data Preprocessing

In this study, 4 types of data were used: clinical data, gene expression (mRNA) data, miRNA data, and CNV data.

This section performs data screening for different data features. For clinical features, patient data with missing values and/or missing follow-up times were excluded. For gene expression data, a variance threshold method was used to select features with variances greater than a given threshold calculated from all patients [18,30]. In this study, the same thresholds as Fan et al [10] were used for mRNA and CNV modalities: 7 and 0.2, respectively. This processing retained 1579 mRNA features and 2711 CNV features. Subsequently, all continuous variables were normalized to the interval (0, 1) using minimum-maximum normalization [31].



Considering the variations in diagnosis and treatment methods across different cancer types, samples in the dataset may lack some required modalities. This study adopts zero-vector imputation for missing modalities, with its rationale mainly reflected in 2 aspects: first, zero vectors can explicitly indicate "no measured data for the modality," avoiding false biological signals introduced by statistical imputation methods. Second, zero-vector imputation ensures the consistency of feature dimensions across all samples, simplifies the model's input structure, and avoids additional computational overhead from complex missing-value processing modules, providing stability guarantees for gradient updates in the integration of adaptive DP mechanisms.

Bilayer Feature Extraction Based on MHA

To improve the accuracy and efficiency of feature extraction, this study designs a bilayer feature extraction method based on MHA, which can more comprehensively and deeply mine key information from multimodal data, as shown in Figure 2.

XSL•FO
RenderX

Figure 2. The architecture of bilayer feature extraction based on multihead attention. CNV: gene copy number variation; FC: fully connected; miRNA: microRNA; mRNA: messenger RNA; ReLU: rectified linear unit.

In recent years, neural networks with FC layers have been widely used for representation extraction [15]. In this study, different neural network settings with FC layers were used as the first-layer feature extraction to obtain representations from the raw numerical data of different modalities. Batch normalization was adopted to normalize the layer inputs and accelerate neural network training [30]. For the clinical data, we used categorical embedding layers for the 4 categorical variables, namely, cancer type, gender, race, and histological type, with dropout to encode the categorical variables into a numerical vector. The normalized continuous variables (ie, age) were then concatenated with these numerical vectors and fed into an FC layer with a fixed representation length. For miRNA, mRNA, and CNV modalities, 2-4 FC layers with rectified linear unit activation and batch normalization were used to extract fixed-length representations. The representation vectors  were obtained from modality-specific configurations to form the representation matrix  where m is the sample size and d is the feature dimension.

To effectively capture the complex interaction relationships between multimodal data and enhance feature representation capabilities, the MHA mechanism was introduced in the second-layer feature extraction stage.

The proposed MHA mechanism consists of 3 components similar to the self-attention in the transformer model: query (Q), key (K), and value (V). The matrix B is projected to generate keys K and values V. Specifically, V is processed using an identity function because the features extracted in the first layer already have sufficient representational power. For K, it is generated by:

Where  (d represents the feature dimension) is a trainable matrix randomly initialized from a standard Gaussian distribution and updated during training; B is the representation matrix obtained from the first-layer feature extraction. The dropout layer and rectified linear unit activation function are used to prevent overfitting and introduce nonlinearity. The query  is a learnable vector initialized randomly, with elements sampled from a uniform distribution  .

The attention aggregation feature is calculated as:

Where A is the attention weight. After softmax normalization along the sample dimension, the sum of the attention weights

XSL•FO
RenderX

A for *N* samples is 1, enabling dynamic focusing on key survival-related features.

To capture multidimensional survival associations, the attention layer is extended to *H* heads. Specifically, *Q*, *K*, and *V* are split into blocks of size *d*/*H* along the embedding dimension. The attention for each head is calculated as:

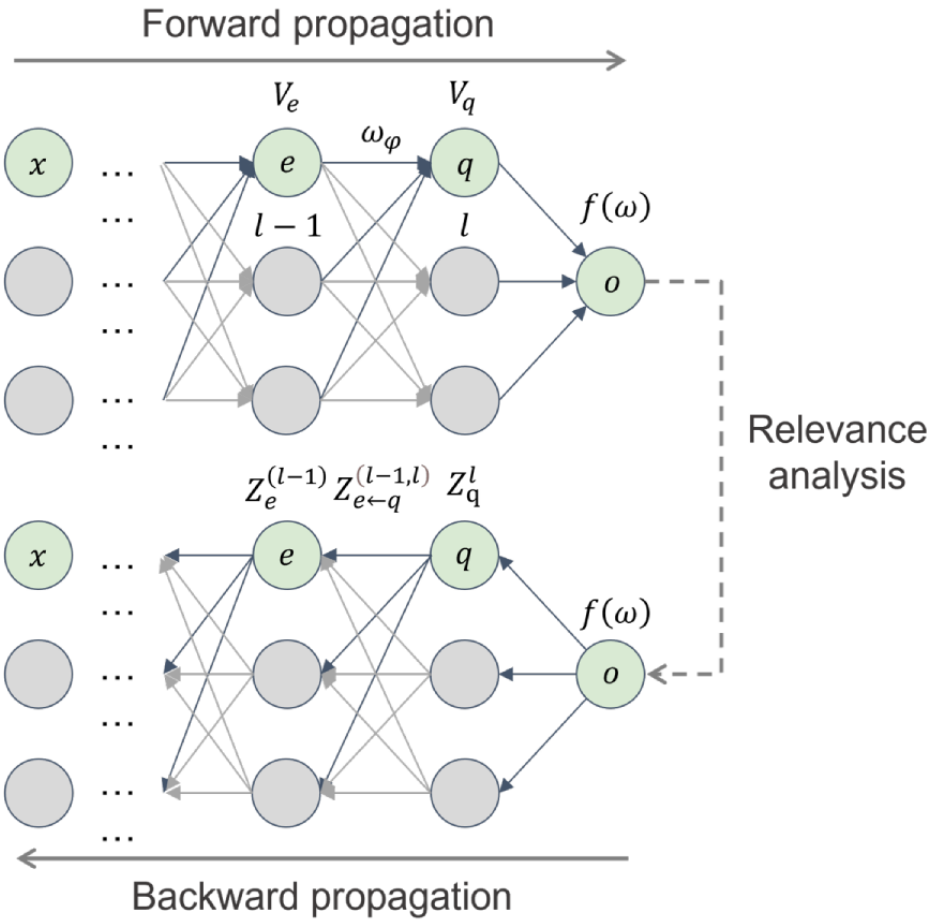
These heads are then concatenated into a multihead output:

This process allows different heads to capture interactions between different types of data separately.

Finally, the fused features are obtained by:

Where  is the weight of the last layer. In evaluation mode, the dropout layer is disabled. Thus, the fused feature *Y* can be written as:

The attention mechanism focuses on key information through dynamic weight allocation, efficiently handling long-range dependencies in sequence data and suppressing noise interference. However, its single-head structure has limitations in modeling multidimensional correlations. Therefore, based on the features extracted from the 4 modalities in the first layer, this study introduces the MHA mechanism. By parallelizing multiple independent attention heads, it captures differentiated correlations between features from different subspaces, providing more comprehensive feature representations for pan-cancer survival prediction. The above method achieves deep fusion of multimodal survival features, offering high-precision feature representations for pan-cancer survival prediction.



Adaptive DP Based on Layer-Wise Relevance Analysis

In the field of cancer survival prediction, privacy protection of medical data is of utmost importance. Genetic data, such as mRNA, miRNA, and CNV data, contain highly sensitive personal information, posing a risk of privacy leakage. Therefore, during the feature extraction process, this study designs a method based on layer-wise relevance analysis to construct a noise addition mechanism by adding Laplacian noise for privacy protection, ensuring data security.

First, during the extraction of mRNA, miRNA, and CNV features in the first layer, this paper adds appropriate Laplace noise to the training gradient of neurons based on analyzing the correlation between each neuron layer and the output layer. The core theoretical operation process is shown in Figure 3. Relevance analysis begins after forward and backward propagation, calculating the correlation results of each feature in a layer of neurons. Importantly, the correlation analysis results are adjusted with the forward and backward propagation processes until the propagation ends.

XSL•FO
RenderX

Figure 3. The process of the layer-wise relevance analysis method of the proposed model based on the backpropagation algorithm.

The correlation between each input feature x_{ij} and the output $Hx_i(0)$ is calculated by decomposing the neurons of the previous layer. Given $Z_e^{(l)}(x_i)$ as the correlation result between x_i and neuron e in layer l, define as the process of neuron e sending information to q. The neuron correlation is:

The decomposition rule for layer-wise relevance analysis is:

Where is a predefined stabilizer to address the unboundedness of $Z_e^{(l)}(x_i)$. R_q is the affine transformation of neuron e, defined as:

Where v_e is the value of neuron e,$_{eq}$ is the weight between neuron e and q,u_q is the bias term.

In the last hidden layer, for the output variable o, the correlation is calculated as:

This study directly calculates the correlation score $Z_j(x_{ij})$ between each feature x_{ij} inlayer j and the survival prediction result for mRNA, miRNA, and CNV features.

Next, a noise addition rule is defined. Through the above layer-wise relevance analysis, the value range of these correlation scores is divided into n nonoverlapping threshold intervals , and T_1 corresponds to the features with the highest relevance scores.

A privacy-budget mapping function is then defined, which assigns a specific privacy parameter $_k$ to each interval T_k. The function is designed to be strictly monotonic, satisfying the following condition: for any $g<h$,$\eta(T_g)<\eta(T_h)$, thereby ensuring that features with stronger predictive correlations are allocated a higher privacy budget (less noise), while features with weaker correlations receive a lower privacy budget (more noise).

Formally, for an interval index $k\in\{1,2,...,n\}$,the privacy parameter $_k$ is given by:

Where $_{max}$=0.5 and $_{min}$=0.1 define the permissible range of the privacy budget; $\delta_k \sim U(-\Delta,\Delta)$ is a bounded random perturbation term that preserves the strict monotonicity $_1 > _2 > ... > _n$.

XSL•FO
RenderX

Privacy budgets are adaptively allocated according to the function :

Where denotes the global privacy budget.

Laplacian noise is added to the training gradients of neurons, where is the total privacy budget for protecting mRNA, miRNA, and CNV features.

At the start of training, the gradient update objective function of the general optimization method is defined. In each training step, using a set of random training samples L from the genetic data feature set X (where $X = \{x_{11}, x_{12},..., x_{ij}\}$), starting from the initial point $_0$, the parameters are updated at step t as:

where is the learning rate at step t, is the regularization parameter, and  is the loss function.

Subsequently, the training gradients are perturbed to ensure the security of genetic data during training and sharing:

Where Y_t is the Laplacian noise.

After detailing the process of adding Laplacian noise to features based on layer-wise relevance analysis, this section proceeds to prove the implementation of -DP. The following proof shows how the proposed method satisfies -DP requirements:

Proof: assume L and L' are 2 adjacent batches, and $_{t+1(L)}$ and $_{t+1(L')}$ are the parameters for L and L', respectively. The formula is expressed as follows:

Then, the inequality for the difference between the 2 output results is:

From the above formula and DP, $_t$ is the sensitivity of the neural network **Inline graphic 27**. To protect the privacy information of the neural network, the gradient is perturbed based on relevance analysis, and the noise can be written as:

We have:

This proves that the method satisfies -DP, ie,

 , where M is the model after adding Laplacian noise to features. It ensures that the model's noise addition mechanism is consistent with the definition of DP while protecting the privacy of mRNA, miRNA, and CNV features.

This method not only effectively reduces the risk of data leakage but also maximizes data usability, providing a more secure and reliable solution for cancer survival prediction and promoting the efficient use and sharing of medical data under privacy protection.

Ethical Considerations

All data used in this study were obtained from The Cancer Genome Atlas (TCGA), a publicly available database. The TCGA project obtained informed consent from all participants and received ethical approval from the appropriate institutional review boards. As this study involved only the use of deidentified, publicly accessible data, no additional ethical approval was required.

Results

Data

The clinical, mRNA, and miRNA data were downloaded from the Pan-Cancer Atlas of TCGA project (publicly accessible at the Genomic Data Commons), where more than 11,000 patient samples across 33 tumor types [32,33] were collected. The clinical dataset provides annotations for 11,160 patients, using 5 variables consistent with Silva and Rohr [17]: cancer type, gender, race, histological type, and age. The miRNA data set contains 743 miRNA feature records, and the mRNA dataset contains RNA sequencing counts for 20,531 mRNAs. The CNV data were downloaded from the University of California Santa Cruz Xena [34].

Table 1 describes the data information after preprocessing in detail. In this study, the pan-cancer datasets were partitioned into training (6656/11094, 60%), validation (2219/11094, 20%), and testing (2219/11094, 20%) subsets, with model performance evaluated using 5-fold cross-validation.

Experimental Settings

We conduct all experiments on a simulation environment equipped with a 64-bit Intel(R) Xeon(R) Silver 4210R CPU @ 2.40 GHz processor, 32 GB RAM, and an NVIDIA GeForce RTX 3080 GPU for accelerated computation. The experiments are implemented on the Windows 11 operating system, with Python (version 3.10; Python Software Foundation) as the primary programming language and PyTorch (version 2.6.0; Meta AI) as the deep learning framework.

For model training, the Adam optimizer is adopted with a fixed learning rate of 0.001. Key hyperparameters are configured as follows: sequence length is set to 128, batch size is 256, and total training epochs are 100.

Evaluation Metrics

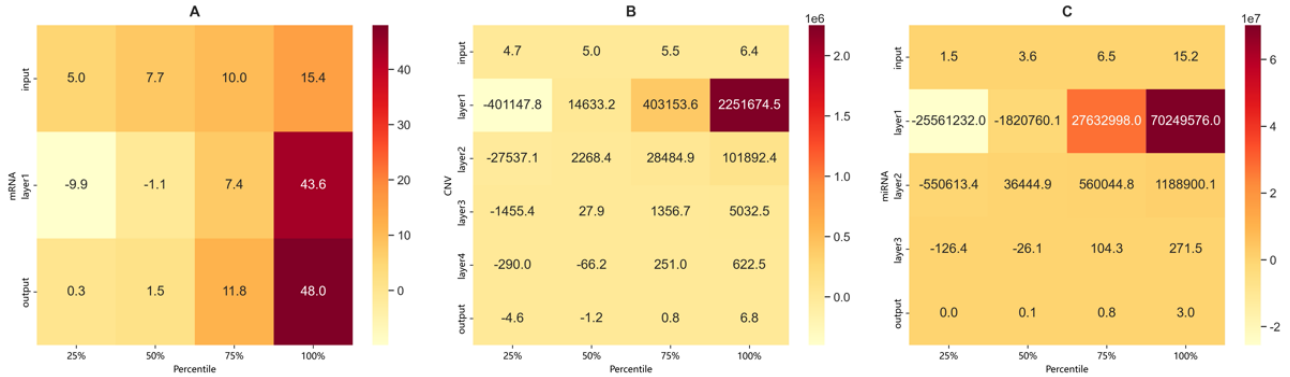
In this study, we assessed the performance of our model by using the C-index, a widely adopted metric for evaluating survival predictions in censored survival data [2,35]. The C-index measures the proportion of concordant pairs among all possible evaluation pairs, defined as:

where 1 is the indicator function of whether the expression in parentheses is true or false. The C-index ranges from 0 to 1. The closer the C-index is to 1, the closer the prediction order is to the real one; the closer the C-index is to 0.5, the closer the model's prediction is to a random prediction. Notably, the C-index focuses on the ordinal relationship of predictions rather than the accuracy of individual sample forecasts, making it particularly suitable for evaluating proportional hazards models.

Accuracy was also used for performance evaluation. The metric is evaluated as follows:

Layer-Wise Relevance Analysis

To evaluate the model's performance in privacy preservation, this study determines the privacy budget through hierarchical correlation analysis and subsequently adds Laplacian noise based on the results. Specifically, this study analyzed the strength of correlations between features and different FC layers using heatmaps for the 3 modalities: mRNA, miRNA, and CNV. The computed correlation scores are sorted in descending order, and the feature scores at the 25th, 50th, 75th, and 100th percentiles are visualized. The heatmaps show that higher correlation scores indicate stronger associations between the corresponding features and survival prediction outcomes.



A more detailed analysis of each modality's heatmap reveals that, as shown in Figure 4A, the output layer and mRNA layer 1 exhibit significantly higher correlation scores at the 100th percentile (48.0 and 43.6, respectively), with notable increases compared to the 25th, 50th, and 75th percentiles. This suggests that these 2 layers are particularly effective in capturing high-correlation features, which are strongly associated with survival outcomes. These findings indicate that privacy-preserving noise injection should focus on these layers to avoid the leakage of critical predictive information.

For the CNV and miRNA modalities, as illustrated in Figures 4B and 4C, layer 1 demonstrates markedly higher correlation scores at the 100th percentile compared to subsequent layers and the output layer. This suggests that the model primarily extracts key features from layer 1, with diminishing correlation strength in deeper layers. Therefore, noise injection strategies should prioritize high-correlation features in layer 1, enhancing privacy protection while maintaining the model's feature extraction performance.

Overall, the heatmaps of layer-feature correlations across the 3 modalities not only identify the core layers and key percentile-based features involved in the model's internal processing, but also provide empirical support for refining noise injection strategies. This contributes to achieving a better balance between privacy protection and model performance.

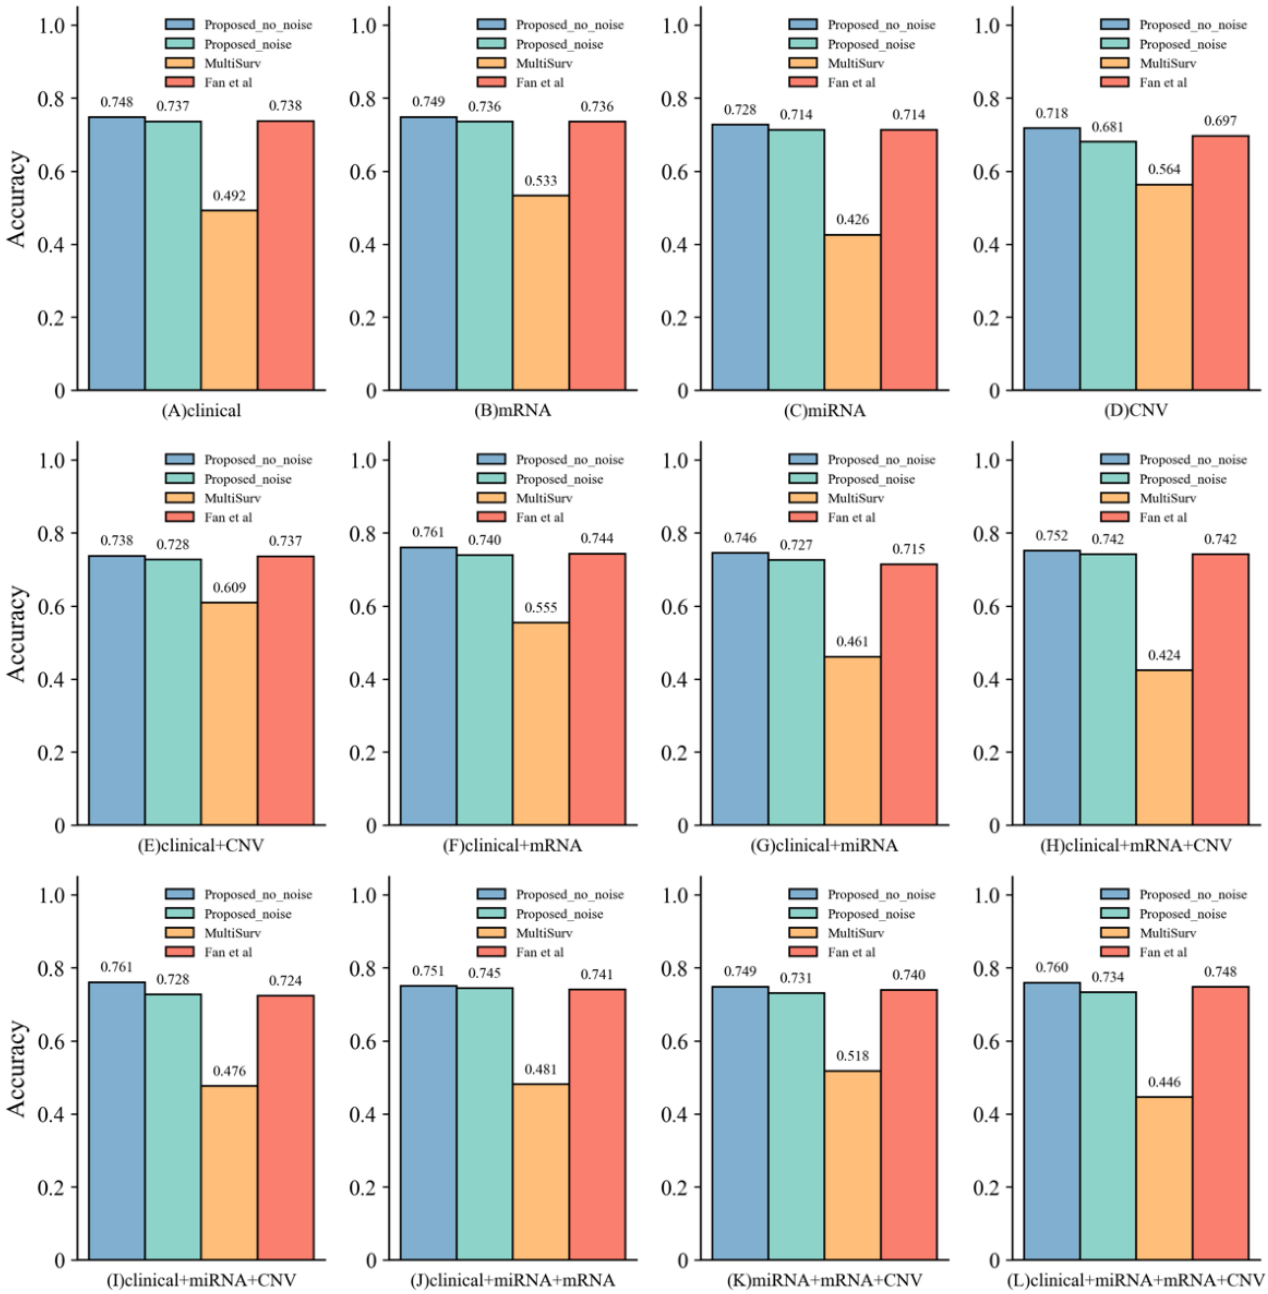
Privacy Protection Effect Comparison of Multimodal Methods



To further evaluate the impact of noise addition on model performance, this study uses accuracy as an auxiliary metric, with patients' survival status as the classification criterion (where deceased patients are labeled as 1 and surviving patients as 0), and implements the classification and prediction of survival status through a neural network with 3 FC layers. Leveraging the pan-cancer dataset, a systematic analysis is conducted on the model's survival classification performance across 4 data combinations: clinical data, mRNA, miRNA, and CNV. The proposed model is compared with 2 state-of-the-art attention-based models for pan-cancer survival prediction: MultiSurv [17] and Fan et al [10].

In unimodal settings, as shown in Figures 5A-5D, the proposed model demonstrates strong robustness. For instance, in the miRNA modality, accuracy slightly decreases from 0.728 before noise injection to 0.714 after; in the mRNA modality, accuracy drops modestly from 0.749 to 0.736.

Experiments involving multimodal combinations were conducted in dual-, tri-, and 4-modality settings. As shown in Figures 5E-5L, the model also maintains stable performance under multimodal conditions. For example, the clinical + miRNA + mRNA combination achieves an accuracy of 0.751 before noise addition and 0.746 afterward; for the clinical + mRNA combination, accuracy declines from 0.761 to 0.740 after noise injection.

Survival Prediction Using Pan-Cancer Training Dataset

To evaluate the survival prediction advantages of the proposed model across different modalities, this study adopted the C-index as the performance metric and compared it against 6 state-of-the-art models: the CPH [3], RSF [2], MultiSurv, DeepHit [15], CMTA [16], and Fan et al [10]. The experiments are conducted using clinical data, mRNA, miRNA, and CNV data in both unimodal and multimodal settings. All results were obtained via 5-fold cross-validation and are summarized in Table 2.

Clinical + miRNA + mRNA + CNV	—	—	0.768 (±0.013)	0.770 (±0.010)	0.772 (±0.012)	0.779 (±0.010)	0.787 (±0.007)[d]

[a]CPH: Cox proportional hazards model.

[b]RSF: random survival forest.

[c]CMTA: cross-modal translation and alignment.

[d]$P<.05$ vs MultiSurv, DeepHit, CMTA, and Fan et al [10] (paired *t* test with Bonferroni correction, n=1000 bootstrap samples).

[e]mRNA: messenger RNA.

[f]miRNA: microRNA.

[g]CNV: gene copy number variation.

[h]Not available.

[i]$P<.01$ vs CMTA (top competitor; paired *t* test with Bonferroni correction, n=1000 bootstrap samples).

To substantiate claims of superiority despite modest C-index differences, statistical significance testing was performed using bootstrapped resampling and 2-tailed paired *t* tests. For each model and modality combination, 1000 bootstrap samples were generated from the test set. Paired *t* tests were conducted on the bootstrapped C-index values (n=1000) to test the null hypothesis that the mean performance difference is 0, with Bonferroni correction applied for multiple comparisons. Additionally, 95% CIs were derived from the bootstrap distributions. Nonoverlapping CIs are interpreted as indicating statistically significant differences ($P<.05$).

In unimodal prediction scenarios, the proposed model achieves C-index scores of 0.775, 0.779, 0.760, and 0.659 for clinical, mRNA, miRNA, and CNV data, respectively—significantly outperforming the CPH and RSF, which are limited to unimodal survival prediction. Notably, the proposed model yields the highest performance on mRNA data, with a C-index of 0.779, compared to 0.715 for CPH and 0.739 for RSF.

Furthermore, in the multimodal setting, this study compared the performance of MultiSurv, DeepHit, CMTA, Fan et al [10], and the proposed model across various combinations of data modalities. As shown in Table 2, the proposed model consistently achieves C-index values around 0.78 across different combinations. The highest performance is observed in the trimodal configuration (clinical + mRNA + miRNA), which yields a C-index of 0.799—surpassing MultiSurv (0.771),

XSL•FO
RenderX

DeepHit (0.773), CMTA (0.779), and Fan et al [10] (0.777). To statistically validate these performance improvements, paired significance testing with multiple-comparison adjustment was conducted. For each model and modality combination, 1000 bootstrap samples were generated from the test set. Paired *t* tests were performed on the bootstrapped C-index values (n=1000) with Bonferroni correction applied for multiple comparisons. The proposed model demonstrated statistically significant improvements over all competitors in the optimal trimodal configuration (clinical + mRNA + miRNA) after multiplicity adjustment: vs CMTA (*P*=.008), Fan et al [10] (*P*=.006), MultiSurv (*P*=.003), and DeepHit (*P*=.004). These adjusted *P* values (<.05) confirm that the observed C-index improvements (0.020, 0.022, 0.028, and 0.026 relative to CMTA, Fan et al [10], MultiSurv, and DeepHit, respectively) are statistically robust and not attributable to random variation.

This superior performance is attributed to the model's dual-layer feature extraction architecture, which, leveraging multiview parallel processing, enables finer-grained automatic weight adjustment. Notably, our proposed model further integrates an adaptive DP protection mechanism to safeguard sensitive medical data, while still achieving a higher C-index compared to existing state-of-the-art multimodal models that lack privacy-preserving designs. These findings reinforce the advantage of multimodal inputs over unimodal inputs, as multimodal data provide more comprehensive and informative cues for survival prediction.

Comparison With Standard Privacy Protection Methods

To comprehensively validate the superiority of the proposed adaptive DP framework in balancing privacy protection and predictive utility, this study adopted 2 core metrics—C-index for survival outcome ranking accuracy and classification accuracy for binary survival status prediction (deceased=1 and surviving=0)—and systematically compared it against 3 standard DP-aware baseline models: DP-Stochastic Gradient Descent (SGD) [36], DP-Adam [37], and Private Aggregation of Teacher Ensembles (PATE) [38]. The experiments were conducted under the optimal multimodal setting (clinical + mRNA + miRNA), with a fixed global privacy budget of = 0.8 (δ = 1e-5 for DP-SGD and DP-Adam, as per their standard implementations) to ensure a fair comparison of use under identical formal privacy guarantees. Consistent data preprocessing (zero-vector imputation for missing modalities, minimum-maximum normalization) and model training configurations (Adam optimizer, learning rate=0.001, batch size=256, and 100 epochs) were used across all methods to eliminate confounding variables. All results were derived from 5-fold cross-validation on the pan-cancer test set and supplemented with 1000 bootstrap resamples for statistical significance testing (paired *t* test with Bonferroni correction, *P*<.05). Detailed performance metrics and comparative analysis are summarized in Table 3.

Table 3 clearly shows that the proposed adaptive DP framework outperforms all standard DP baselines in maintaining predictive utility under the same formal privacy guarantee (=0.8). Regarding the C-index—the gold standard for survival prediction that assesses the ordinal consistency between predicted risk scores and actual survival times—the proposed model achieves 0.799 (±0.012), which is 4.3, 3.7, and 6.5 percentage points higher than DP-SGD (0.756 ± 0.015), DP-Adam (0.762 ± 0.014), and PATE (0.734 ± 0.016), respectively. Its utility loss compared to the non-DP counterpart (0.821 ± 0.008) is only 0.022, which is less than half of DP-SGD's loss (0.065) and about 1/3 of PATE's loss (0.087). This confirms that the layer-wise relevance propagation–guided targeted noise injection strategy more efficiently uses the privacy budget, preserving high-relevance prognostic features while satisfying -DP.

In terms of binary survival status classification accuracy, the proposed model maintains a high level of 0.745 (±0.013), outperforming the aforementioned baselines by 0.8, 1.0, and 1.4 percentage points, respectively. Its accuracy drop (0.006) is also significantly smaller than that of the baselines (0.014-0.020), further validating the efficiency of adaptive noise allocation in minimizing utility degradation for a given . Statistical analysis (paired *t* test with Bonferroni correction, n=1000 bootstrap samples) reveals that the proposed model's C-index and accuracy are significantly different from all baselines (*P*<.05), with nonoverlapping 95% CIs, confirming the robustness of the observed improvements.

Table 3. Use comparison of proposed model vs standard differential privacy (DP) baselines (multimodal: clinical + messenger RNA + microRNA; =0.8).

Modality	C-index[a]	Accuracy
Proposed_no_noise	0.821 (±0.008)	0.751 (±0.008)
Proposed model	0.799 (±0.012)	0.745 (±0.013)
DP-SGD[b]	0.756 (±0.015)	0.737 (±0.010)
DP-Adam	0.762 (±0.014)	0.735 (±0.008)
PATE[c]	0.734 (±0.016)	0.731 (±0.009)

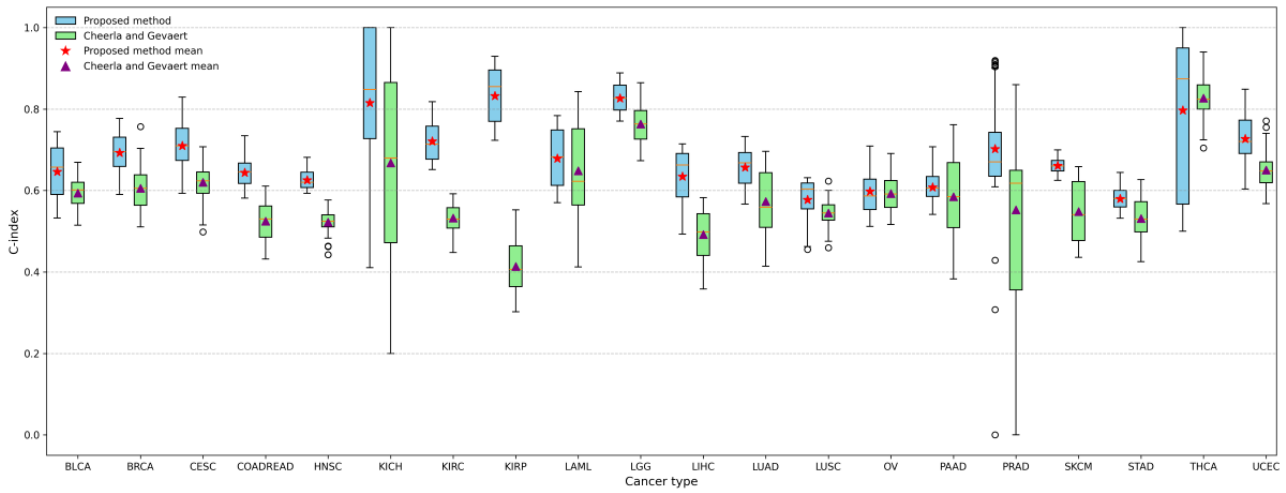
Analysis of Privacy Protection Effectiveness

The proposed adaptive DP mechanism is designed to satisfy -DP (=0.8) as formally proven in equation 20. Compared with traditional uniform noise injection methods (DP-SGD and DP-Adam) under the same global privacy budget, our method significantly improves the accuracy of survival prediction (with the C-index increased by 3.7-6.5 percentage points; Table 3). This result indicates that, for the same formal privacy guarantee ( ), our adaptive allocation strategy achieves higher predictive utility. The adaptive mechanism identifies features with high relevance to prediction and allocates a larger portion of the privacy budget to them (injecting less noise), thereby preserving critical prognostic information. Conversely, features with low predictive contribution receive a smaller budget (more noise), which theoretically enhances privacy protection for those elements without harming overall model utility. Therefore, the proposed method provides a stronger formal privacy guarantee for low-relevance features and achieves superior utility for high-relevance features under the same constraint, representing a more efficient use of the privacy budget.



Comparison of Survival Prediction Performance for Individual Cancer Types

To investigate the effectiveness of the proposed model in predicting survival outcomes for individual cancer types, this study conducted a comparison between our proposed model and the state-of-the-art deep learning–based model (Cheerla and Gevaert [9]) for single-cancer prediction using pan-cancer datasets. For consistency, this study adopted a multimodal input comprising clinical, miRNA, and mRNA data. The results are presented in Figure 6.

Compared with Cheerla and Gevaert [9], our proposed method achieved a higher C-index in the majority of cancer types—18 out of 20. Notably, in 7 of these 18 cancer types, the performance improvement was substantial, with C-index differences exceeding 0.1.

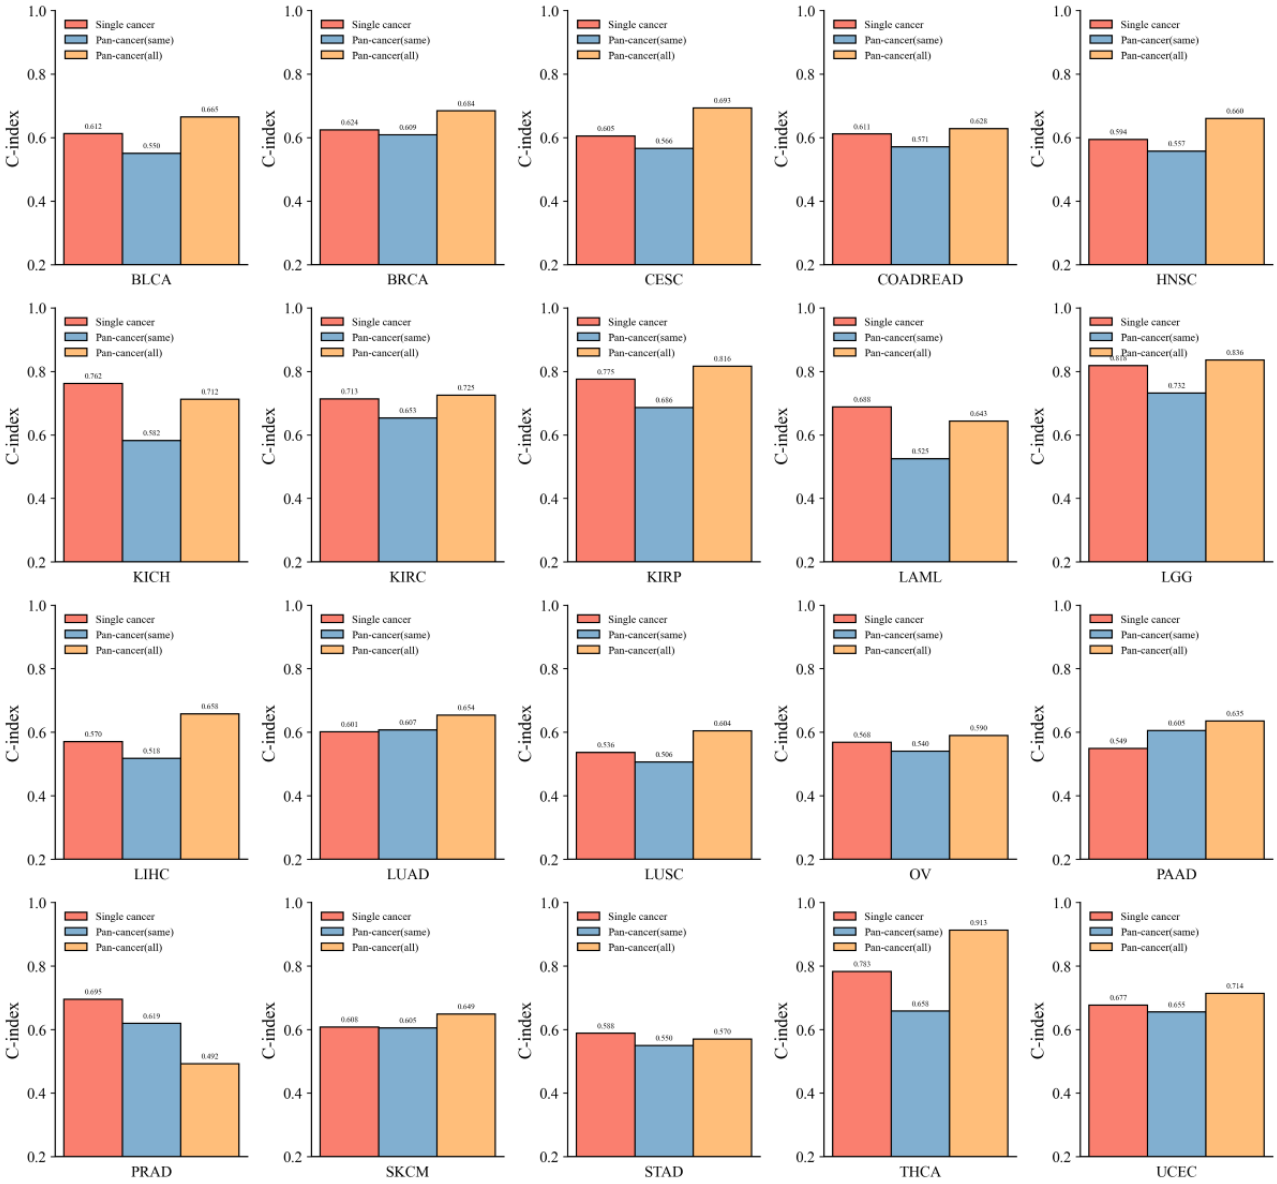
Furthermore, as illustrated in Figure 6, our model exhibits higher median C-index values for several cancer types and demonstrates more concentrated distributions in the upper range. This indicates both superior and more stable predictive performance. In contrast, Cheerla and Gevaert [9] show relatively lower C-index scores in some cancer types, with several boxplots revealing greater data dispersion and reduced stability.

Figure 6. Concordance index (C-index) of the proposed model (blue bars) and the previous work (Cheerla and Gevaert [9]; green bars) on the 20 cancer types using the modality combination of clinical, microRNA, and messenger RNA. BLCA: bladder urothelial carcinoma; BRCA: breast invasive carcinoma; CESC: cervical squamous cell carcinoma; COADREAD: colon adenocarcinoma/rectum adenocarcinoma; HNSC: head and neck squamous cell carcinoma; KICH: kidney chromophobe; KIRC: kidney renal clear cell carcinoma; KIRP: kidney renal papillary cell carcinoma; LAML: acute myeloid leukemia; LGG: low-grade glioma; LIHC: liver hepatocellular carcinoma; LUAD: lung adenocarcinoma; LUSC: lung squamous cell carcinoma; OV: ovarian serous cystadenocarcinoma; PAAD: pancreatic adenocarcinoma; PRAD: prostate adenocarcinoma; SKCM: skin cutaneous melanoma; STAD: stomach adenocarcinoma; THCA: thyroid carcinoma; UCEC: uterine corpus endometrial carcinoma.

Comparison Between Using Single-Cancer and Pan-Cancer Training Datasets

To further investigate the predictive performance of the proposed model across different types of datasets, this study conducted experiments using both pan-cancer and single-cancer datasets. The first objective was to examine whether training on pan-cancer data improves survival prediction accuracy for individual cancer types. In this study, we selected the same 20 cancer types as those used by Cheerla and Gevaert [9], where patients have significantly different survival patterns.

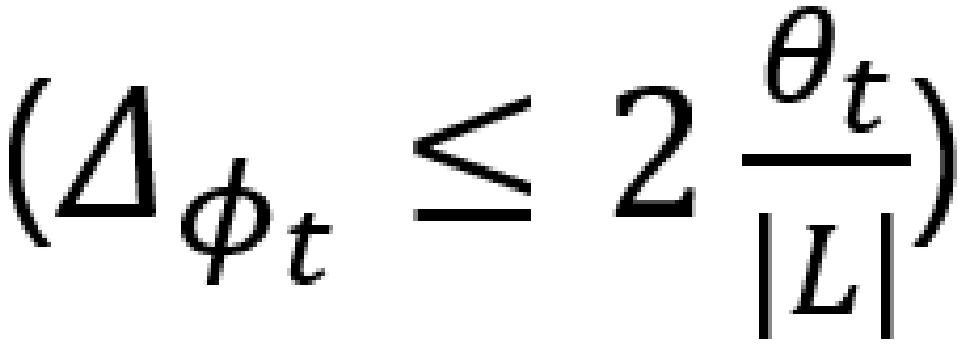
This study first compared the performance of models trained solely on single-cancer data with those trained on all pan-cancer samples, using consistent test sets for each cancer type. For single-cancer experiments, this study selected patients with the same cancer type in pan-cancer training-validation-test sets to form the single-cancer training-validation-test sets. The model was trained using integrated clinical, mRNA, and miRNA modalities, and the results are shown in Figure 7.



As shown by the bar plots labeled “Single cancer” and “Pan-cancer (all)” in Figure 7, the model trained on pan-cancer data generally outperformed the single-cancer–trained model

XSL•FO
RenderX

on the same test sets, with the exception of 4 cancer types: kidney chromophobe, acute myeloid leukemia, prostate adenocarcinoma, and stomach adenocarcinoma. For example, in the case of bladder urothelial carcinoma the pan-cancer–trained model achieved a C-index of 0.665, significantly higher than the 0.612 achieved by the model trained only on bladder urothelial carcinoma data.



To control for potential biases due to varying training sample sizes, this study further evaluated model performance when trained on an equal number of samples from the pan-cancer and single-cancer datasets. Specifically, we selected subsets of pan-cancer data matching the sample size of each individual cancer dataset. As illustrated by the bar plots labeled "Single cancer" and "Pan-cancer (same)" in Figure 7, the single-cancer–trained models generally outperformed the pan-cancer–trained counterparts under equal training size conditions.

Figure 7. Concordance index (C-index) scores of the proposed model trained on single-cancer and pan-cancer datasets on 20 cancer types using clinical, messenger RNA, and microRNA modalities. Red bars represent models trained on single-cancer datasets, where only patients with the same cancer type were used. Blue bars indicate models trained on pan-cancer datasets with sample sizes matched to each single-cancer dataset to control for sample size bias. Orange bars correspond to models trained on the full pan-cancer dataset. BLCA: bladder urothelial carcinoma; BRCA: breast invasive carcinoma; CESC: cervical squamous cell carcinoma; COADREAD: colon adenocarcinoma/rectum adenocarcinoma; HNSC: head and neck squamous cell carcinoma; KICH: kidney chromophobe; KIRC: kidney renal clear cell carcinoma; KIRP: kidney renal papillary cell carcinoma; LAML: acute myeloid leukemia; LGG: low-grade glioma; LIHC: liver hepatocellular carcinoma; LUAD: lung adenocarcinoma; LUSC: lung squamous cell carcinoma; OV: ovarian serous cystadenocarcinoma; PAAD: pancreatic adenocarcinoma; PRAD: prostate adenocarcinoma; SKCM: skin cutaneous melanoma; STAD: stomach adenocarcinoma; THCA: thyroid carcinoma; UCEC: uterine corpus endometrial carcinoma.

External Validation on Independent Cohorts

To address the critical question of generalizability beyond the TCGA dataset, we conducted an external validation on 2 independent cancer cohorts from the International Cancer Genome Consortium (ICGC) database [39]. Specifically, we selected the hepatocellular carcinoma (HCC; ICGC-HCC) and clear cell renal cell carcinoma (ccRCC; ICGC-ccRCC) projects, which provide clinical survival information and mRNA expression data compatible with our model's input requirements. To maintain consistency with our multimodal input configuration (clinical + mRNA + miRNA), the same zero-vector imputation strategy described in the Methods section ("Data Preprocessing") was applied to handle the missing miRNA modality and any mRNA features absent in the external data. The ICGC-HCC cohort comprised 242 patients with overall survival data, and the ICGC-ccRCC cohort comprised 530 patients. For each cohort, we preprocessed the mRNA expression data by aligning gene features to the 1579 mRNA features used in our TCGA training set. All continuous features were normalized using the minimum and maximum values derived from the TCGA training set to ensure consistent scaling.

This study applied our proposed model (trained on the pan-cancer TCGA dataset with clinical + mRNA + miRNA modalities) directly to the preprocessed ICGC cohorts without any retraining or fine-tuning. The model's survival prediction performance was evaluated using the C-index.

Our proposed model, trained on the pan-cancer TCGA dataset, achieved a C-index of 0.721 on the independent ICGC-HCC cohort and 0.708 on the ICGC-ccRCC cohort. This demonstrates that the model maintains its generalizable prognostic discriminatory power on unseen, external patient populations.

Discussion

Principal Results

In this study, we evaluated the model's classification performance in survival prediction across 4 data combinations—clinical data, mRNA, miRNA, and CNV—using the pan-cancer dataset. Compared with MultiSurv [17], the proposed model exhibits an approximately 0.3 improvement in prediction accuracy across all modality combinations after noise injection. When compared with Fan et al [10], the proposed model achieves higher accuracy in all settings before noise addition, and maintains comparable accuracy after noise injection, despite the latter model not incorporating any privacy-preserving mechanisms.

The improvement in survival prediction across different modalities stems from the model's ability to capture key information from different subspaces in parallel, thereby overcoming the representational limitations of single-attention mechanisms. By effectively integrating core features from each modality, the model enhances the flexibility and expressiveness of the fusion process. Notably, the inclusion of the CNV modality generally leads to a decline in predictive performance, suggesting that CNV data contain relatively fewer informative features relevant to patients' survival. This further underscores the value of multimodal data fusion in enhancing the generalizability of survival prediction models.

Comparisons in single-cancer survival prediction further demonstrate that the model achieves higher and more stable C-index values in 18 out of 20 cancer types compared with existing deep learning methods, highlighting its robustness in individualized survival prediction. Our study not only confirms the effectiveness and superiority of the proposed model in individualized cancer survival prediction but also demonstrates its ability to preserve patients' privacy. Collectively, these results provide a more reliable and privacy-conscious solution for precision oncology applications.

XSL•FO
RenderX

In addition, experiments conducted on both pan-cancer and single-cancer datasets show that the proposed model maintains strong predictive capability across diverse data settings, demonstrating robust generalization ability.

Challenges

While the model demonstrates strong privacy-preserving capabilities through DP, the integration of DP mechanisms into clinical artificial intelligence models introduces certain challenges. First, DP may impact the interpretability of the model, as the noise added to the gradients or model parameters can obscure the relationships between input features and predicted outcomes. This could reduce the transparency of the model, making it more difficult for clinicians to trust and understand the model's decisions, which is critical in medical applications. In addition, DP mechanisms may complicate auditability, as it becomes harder to trace the influence of individual data points on the model's predictions due to the noise injected for privacy protection.

Second, the integration of privacy mechanisms such as DP into clinical workflows or federated research environments can be practically challenging. In clinical settings, where data are highly sensitive, ensuring that privacy is preserved while maintaining the usability and accuracy of predictive models requires careful consideration of computational resources and model deployment strategies. In federated research environments, where data are distributed across multiple institutions, ensuring that DP mechanisms are applied consistently across all sites without compromising the model's predictive performance can be technically difficult. Moreover, adapting these privacy-preserving mechanisms to existing clinical systems and ensuring compliance with data protection regulations (eg, General Data Protection Regulation requires close collaboration with regulatory bodies and careful planning of data-sharing protocols.

These considerations highlight the need for further research into improving the balance between privacy protection, model interpretability, and practical integration in clinical and research settings.

Limitations

The proposed model has certain limitations. First, while we have demonstrated the model's effectiveness on the TCGA pan-cancer dataset and provided initial evidence of generalizability through external validation on ICGC cohorts, the performance on independent datasets shows a nonnegligible decline. This underscores the inherent challenge of translating models trained on 1 cohort (even a large and diverse one like TCGA) to others due to population, treatment, and technical variability. More extensive validation across multiple, prospectively collected cohorts is needed to fully establish clinical readiness. For example, training efficiency requires improvement. Analysis suggests that one possible reason is the introduction of the bilayer feature extraction module based on MHA and the adaptive DP protection mechanism, which increases algorithmic computational complexity. Additionally, the model exhibits increased inference time compared with simpler architectures such as CPH or RSF, due to the MHA mechanism and the privacy-preserving noise injection process. This may limit its deployment in real-time clinical settings where rapid predictions are required. Meanwhile, comparative experiments with other advanced models on larger-scale multimodal datasets are necessary. Indeed, in the era of big data and multimodal data fusion, new challenges lie ahead.

Future Work

Future work will expand in several directions. On the one hand, integrating pathological images and proteomics data will enhance multimodal feature fusion, extracting and fusing more information to further improve prediction performance. On the other hand, the model will be applied to additional tasks such as cancer subtype classification and biomarker discovery. Finally, research on other noise mechanisms based on DP is needed to protect sensitive information from multiple perspectives and ensure the security of model training and sharing. Moreover, efforts will be made to optimize the computational efficiency and reduce inference time through techniques such as model pruning, quantization, or lightweight attention mechanisms, thereby enhancing the model's practical applicability in clinical environments. To address potential limitations of zero-vector imputation, future work will also explore advanced missing-modality handling strategies, including masking strategies and missing-modality–aware attention mechanisms.

Conclusions

To address the key challenges of inefficient multimodal integration, insufficient privacy protection, and limited generalizability in pan-cancer survival prediction, this study proposes a bilayer feature fusion model integrating the MHA mechanism and adaptive DP. Innovatively, the framework uses modality-specific FC networks in the first layer to extract features from clinical, mRNA, miRNA, and CNV data. The second layer uses MHA to model cross-modal interactions through parallel attention heads, dynamically allocating weights to focus on survival-related features and overcoming the limitations of static fusion. Additionally, layer-wise relevance analysis is used during first-layer feature extraction to quantify the correlation between features and outcomes, enabling adaptive DP—injecting less Laplacian noise into the gradients of high-correlation features and more noise into low-correlation features to balance privacy and utility. Experimental results on pan-cancer datasets from TCGA demonstrate the feasibility and superiority of our proposed method. Furthermore, external validation on independent ICGC cohorts provided preliminary evidence of the model's generalizability, showing retained predictive power superior to clinical-only models despite expected performance attenuation due to cohort heterogeneity.

Abstract

Background: The early detection of diseases is one of the tasks of general practice. Artificial intelligence (AI)–based technologies could be useful for identifying diseases at an early stage in general practices. As approximately 90% of the population regularly consults a general practitioner during one year, this could increase the percentage of citizens who take part in meaningful screening measures.

Objective: This study aimed to evaluate the level of trust among citizens in rural and urban areas in AI-supported early detection measures in general practice.

Methods: This cross-sectional study was conducted in the federal state of Schleswig-Holstein, Germany, from November 2023 to December 2023, on the topic of early detection measures with AI in general practice care, among other things. For this purpose, 5000 adult residents of rural areas (Ostholstein, Pinneberg, and Nordfriesland) and urban areas (the city of Kiel) were invited to take part in the survey. Data analysis was carried out using descriptive statistics, subgroup analysis, and linear and stepwise regression analysis to identify the factors that influenced trust in AI-based diagnoses.

Results: Most respondents (787/1790, 44.0%) considered the introduction of an AI-based screening measure to be a sign of modern medicine. Moreover, 21.7% (n=388) of respondents feared that the introduction of such services could lead to a deterioration in the physician-patient relationship. The role of AI in future care was rated as very important by 35.4% (n=634) of respondents. The stepwise regression analysis showed that a positive attitude toward AI in medicine was the strongest predictor (ß=0.420) of trust in AI-based diagnoses. In contrast, trust in physician diagnoses was associated with lower age (ß=–0.111) and shorter waiting times for test results (ß=0.077).

Conclusions: Trust in general practitioner–based diagnoses was approximately 6 times greater than trust in AI applications. Despite concerns about their impact on the physician-patient relationship, approximately one-third of participants believed that the role of AI in health care will grow.

KEYWORDS

artificial intelligence; AI; citizens; cross-sectional study; diabetic retinopathy; general practice; trust

Introduction

The basic care of all patients in emergency, acute, and long-term care, as well as in prevention and rehabilitation, constitutes a central responsibility of general medicine [1]. Therefore, the early detection of diseases represents an important aspect of secondary prevention in a general practitioner (GP) practice. Appropriate measures can be initiated through early detection, which can considerably improve the course of an individual illness. GPs are often the first to diagnose diseases such as diabetes, hypertension, and cardiovascular diseases [2].

More than 90% of the population regularly consults their GP per year [1], which offers a significant opportunity to increase the proportion of citizens who take part in appropriate screening measures.

Screening for eye diseases is a promising extension of these early detection measures. Diabetic retinopathy (DR), in particular, can lead to severe visual impairment or even blindness if it is not detected and treated early. The number of people in Germany who become blind as a result of DR is approximately 15,000 per year [3]. DR is therefore the second most common cause of blindness [4]. According to a European study, 48% of patients with diabetes do not undergo the recommended screening examination [5].

The current diagnosis of these diseases requires a referral to an ophthalmologist, which can lead to long waiting times, especially in rural areas with limited access to specialists [6].

XSL•FO
RenderX

In this context, artificial intelligence (AI)–supported technologies could play an important role by complementing and extending traditional screening approaches. For example, in general practice, these technologies may include AI-assisted analysis of skin lesions for cancer screening or algorithms that identify abnormal heart rhythms in long-term electrocardiograms. In this study, we focused on DR as an illustrative example.

AI-assisted diagnostic tools could be used to analyze retinal images without requiring the presence of an eye specialist [7,8]. At the same time, recent studies indicate good diagnostic performance of deep learning algorithms. For example, in a study conducted in 2019, the detection of DR was analyzed on 25,326 retinal images of diabetes patients from Thailand. The algorithm showed a sensitivity of 97%, higher than the 74% observed for human experts, and a specificity of 96%, compared with 98% of specialists [9].

The implementation of AI-supported technologies could enable screening for DR directly in the GP practice as part of disease management programs. In this way, suspicious findings could be detected early, and patients could be referred to ophthalmologists accordingly.

It is still unknown whether trust in AI-supported technologies for early disease detection varies across population groups. However, significant variations in attitudes toward eHealth were observed between urban and rural respondents, highlighting a potential disparity in the future implementation of these technologies in general practice across demographic areas [10,11]. Therefore, the aim of the study was to evaluate the level of trust citizens in rural and urban areas have in AI-supported early detection measures in general practice.

Methods

This cross-sectional study was conducted in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines [12].

Study Design and Participants

A cross-sectional study on early detection measures using AI in GP care was conducted in the federal state of Schleswig-Holstein, Germany, from November 2023 to December 2023. To this end, 5000 adult citizens from Schleswig-Holstein were invited to take part in the survey. The citizens were randomly selected from the databases of the local registration office.

Following the first invitation, 2 reminders to participate in the study were sent out at 3-week intervals. A stamped and preaddressed return envelope was included in all mailings to facilitate participation. A short version of the questionnaire was enclosed with the third reminder letter. This approach, which is consistent with the Tailored Design Method in survey research, was chosen to maximize the response rate and reduce the participation barrier for citizens who had not yet responded, by minimizing the time required.

Data Collection and Questionnaire

Data were collected using a self-constructed questionnaire in paper form. The development of the questionnaire was rigorously based on the findings of a qualitative study that served as a formal pilot phase and informed the generation of items [13]. This preceding qualitative study explored the determinants of AI implementation for DR screening in primary care. In addition, a subset of items—especially those assessing trust in AI vs physician diagnosis and general attitudes toward AI—was pilot-tested in a small qualitative pretest with GPs (1 female GP and 3 male GPs) to ensure clarity and face validity.

To account for different levels of respondent burden, 2 versions of the questionnaire were used:

- The long version consisted of 35 items, covering all conceptual domains in depth (telemedicine use, attitudes toward AI, perceived impact of AI-supported screening, importance ratings for screening attributes, expectations about examination duration, trust in diagnoses, and sociodemographic variables).
- The short version was reduced to 5 core study-related items, capturing only the core constructs (general attitude toward telemedicine, general attitude toward AI in medicine, trust in AI diagnosis, trust in physician diagnosis, age, gender, and region).

The use of long and short questionnaire versions was chosen because shorter instruments in postal surveys can increase response rates and reduce dropout, especially when sent as reminders [14].

The long questionnaire consisted of five sections:

1. Telemedicine experience and attitudes
2. Attitudes toward AI in health care
3. Perceived impact of AI-based screening in general practice
4. Importance of specific aspects of AI-assisted eye disease screening
5. Trust in AI-based diagnosis vs diagnosis by physicians

The participants' general attitude toward AI applications in general practice was assessed using a 6-point Likert scale ranging from "very positive" to "very negative." In addition, questions were asked about the expected future role of AI in their own health care and the potential impact of integrating AI into general practice.

Participants were asked to rate from a list of options what impact the use of AI-based screening measures would have on their everyday life and care, such as improving or worsening patient care and physician-patient relationships. In addition, specific aspects were asked about the importance of performing AI-based screening tests. The importance of these aspects was rated on a 6-point scale, ranging from "very important" to "very unimportant." Finally, respondents were asked about their trust in diagnoses made by AI compared with diagnoses made by GPs.

The questionnaire also included sociodemographic parameters such as age, gender, and regional origin. Sociodemographic information (age, gender, and regional origin) was collected at the end of the instrument. Regional origin was dichotomized

XSL•FO
RenderX

into rural (Ostholstein, Pinneberg, and Nordfriesland) and urban (Kiel).

Statistical Data Analysis

The analyses were carried out using the SPSS software (version 29.0; IBM Corp). The sociodemographic characteristics of the sample (full and short versions of the questionnaire) were analyzed descriptively. Variables with continuous values were summarized using mean values and SDs. Variables with categorical values were represented by absolute (n) and relative (%) frequencies. The regional origin was dichotomized: the regions Ostholstein, Pinneberg, and Nordfriesland were assigned to the rural area, and the Kiel region to the urban area.

The sociodemographic characteristics of the sample (full and short versions of the questionnaire) were analyzed descriptively. Variables with continuous values were summarized using mean values and SDs. Variables with categorical values were represented by absolute (n) and relative (%) frequencies. The regional origin was dichotomized: the regions Ostholstein, Pinneberg, and Nordfriesland were assigned to the rural area, and the Kiel region to the urban area.

The nonparametric Mann-Whitney *U* test was used to compare the full and short versions of the questionnaire regarding the general preferences of telemedicine and AI. Furthermore, a subgroup analysis was performed by using the nonparametric Mann-Whitney *U* test to assess whether the regional origin (0=rural region and 1=urban region) differed concerning the preferences for telemedicine and AI.

Moreover, linear correlations between trust in diagnosis with AI and trust in diagnosis through physicians, the sociodemographic variables, and various influencing factors were calculated using Spearman correlation coefficient. Testing for connections using a correlation is a common procedure to reduce the number of variables for subsequent model calculations. In a further step, significant correlations identified in this way were taken into account in the linear regression models.

Afterward, 2 stepwise regression analyses were performed to evaluate which factors were strongly associated with the outcome variables. Trust in diagnosis with AI and trust in diagnosis through physicians were the outcome variables, while other aspects, such as preferences for telemedicine and AI, attitudes to early detection measures, and some characteristics of participants (such as gender, age, regional origin), were considered potential predictors and handled as covariates. Additionally, the possibility for multicollinearity was considered in both models. The variance inflation factor (VIF) and the tolerance value were reported for the final step of the regression models. Values for VIF should not exceed 5.0, and tolerance values should not be lower than 0.25 [15]. Statistical significance was set at $P<.05$.

Ethical Considerations

The ethics application for conducting the study was approved by the ethics committee of the University of Lübeck in March 2023 (2023-258_1). All participants provided informed consent prior to participation and were informed that their participation was voluntary and that they could withdraw from the study at any time without consequences. The study involved only the analysis of data collected within the scope of the approved protocol; no additional data were evaluated beyond those covered by the original ethical approval. All data were anonymized prior to analysis, and no personally identifiable information was accessible to the researchers. Appropriate technical and organizational measures were implemented to ensure data protection and confidentiality in accordance with applicable data protection regulations. No incentives were offered for participation.

Results

Description of the Sample

Of the 5000 citizens contacted, 1790 (35.8%) took part in the survey, corresponding to a response rate of almost 36%. Of the participants, 785 (43.9%) were male and 972 (54.3%) were female. A total of 10 participants (0.6%) identified themselves as diverse, while 23 (1.3%) did not specify their gender. Of these participants, 352 (19.7%) chose the short version of the questionnaire. Of these, 160 (44.1%) were male, 189 (52.1%) were female, 3 (0.8%) were diverse, and 7 (1.9%) had missing data for this variable. The average age of all participants was 56 years (range 18-96 years).

Of the 1790 participants, 764 (42.7%) lived in the city and 979 (54.7%) lived in a rural area. Most participants lived in Kiel (764/1790, 42.7%), followed by 520 (29.1%) in Ostholstein, 335 (18.7%) in Pinneberg, and 124 (6.9%) in Nordfriesland districts. Table 1 provides further details on the comparison between the long version and the short version of the questionnaire.

[b]Ranging from 1 (very good) to 6 (very bad).

General Attitude, Future Role of AI, and Trust in Diagnosis Through AI and Physicians

A descriptive analysis of general preferences regarding telemedicine and AI in health care was carried out (Table 2). The variables analyzed included general attitudes toward telemedicine and AI, as well as specific aspects such as trust in diagnoses by AI and the future role of AI in one's own health care.

Table . General preferences for telemedicine and artificial intelligence (AI)—descriptive analysis.

Variables	Long version, mean (SD)	Short version, mean (SD)	*P* value
General attitude to the topic of telemedicine[a]	3.44 (1.50)	3.58 (1.37)	.06
General attitude to applications of AI in medicine[a]	3.35 (1.49)	3.47 (1.47)	.19
Future role of AI for own health care	2.91 (1.48)	—[b]	—
Trust in diagnosis through AI[c]	3.53 (1.43)	—	—
Trust in diagnosis through physician[c]	1.96 (0.82)	—	—

[a]Ranging from 1 (very positive) to 6 (very negative).

[b]Not available.

[c]Ranging from 1 (very small) to 6 (very big). These items were not asked in the short version.

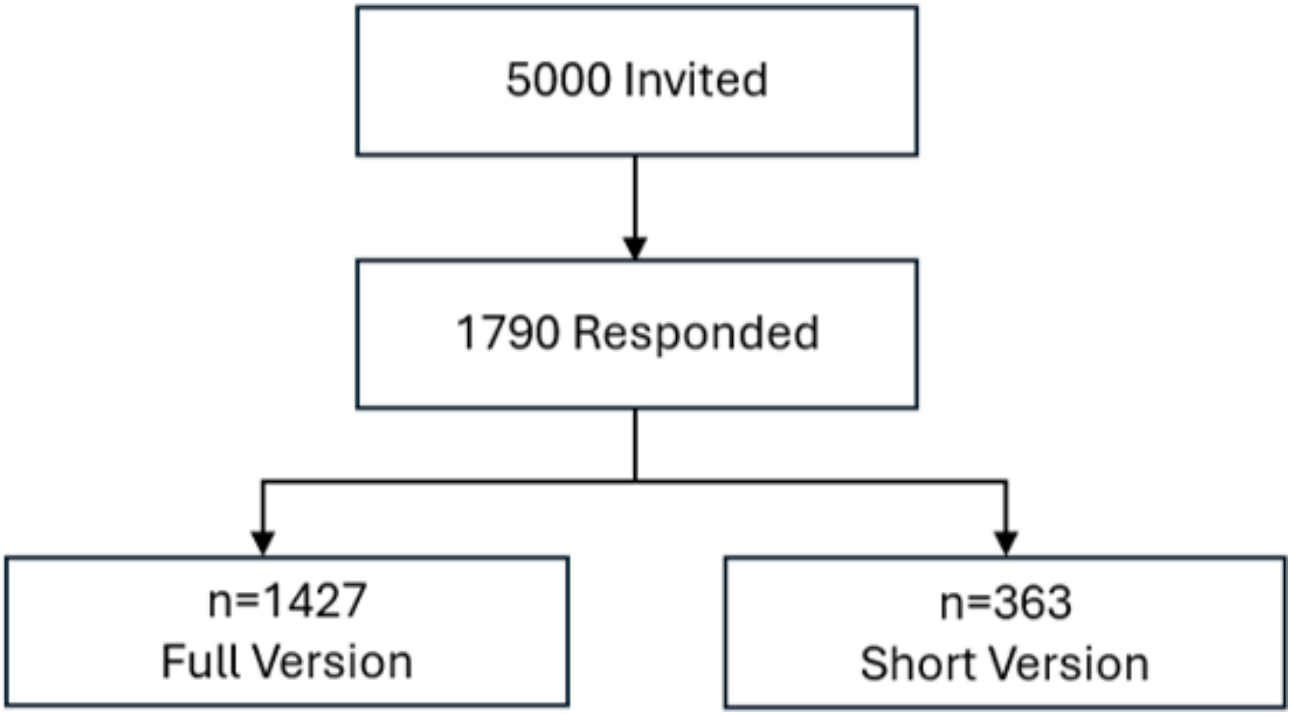
For the general attitude toward applications of AI in medicine, a mean value of 3.35 (SD 1.49) was observed for the long version of the questionnaire, and a mean value of 3.47 (SD 1.47) was observed for the short version.

The assessment of the future role of AI in personal health care had a mean value of 2.91 (SD 1.48). The SD of 1.48 suggests a wide distribution of responses. It was rated important by 35.4% (n=634) of respondents.

Trust in diagnoses by AI is rated with a mean value of 3.53 (SD 1.43). In comparison, trust in diagnoses by physicians had a mean value of 1.96 (SD 0.82).

Subgroup Analysis Concerning Regional Origin and General Preferences to Telemedicine and AI

Participants from urban regions were more positive toward telemedicine ($mean_{urban}$ 3.26, SD 1.5; $mean_{rural}$ 3.56, SD 1.5; $P<.001$) and toward applications of AI in medicine ($mean_{urban}$ 3.11, SD 1.4; $mean_{rural}$ 3.52, SD 1.5; $P<.001$) than participants from rural regions. Moreover, for respondents from urban regions, AI was perceived to play a bigger future role for own health care ($mean_{urban}$ 2.65, SD 1.4; $mean_{rural}$ 3.09, SD 1.5; $P<.001$), and they reported greater trust in diagnoses made by AI ($mean_{urban}$ 3.38, SD 1.4; $mean_{rural}$ 3.63, SD 1.5; $P<.001$) than participants from rural regions. No significant difference was



XSL•FO
RenderX

observed for trust in diagnosis through physicians ($mean_{urban}$ 1.99, SD 0.80; $mean_{rural}$ 1.93, SD 0.81; *P*=.14).

Relevance of AI-Based Screening Measures in the GP Practice

Participants were asked to rate the use of AI-based screening measures in GP practices (Figure 1). Respondents had the opportunity to select several statements that applied.

Figure 1. Response rates for the long version vs short version of the questionnaire.

The analysis of the survey results showed a differentiated perception of the AI-based screening measures, which reflected both potential benefits and concerns among the citizens surveyed.

Out of the 1790 respondents, the most frequently mentioned statement was “signs of modern medicine,” selected by 787 (44.0%) participants. The statement “improved patient care” was selected by 618 participants (34.5%), followed by “easing everyday life” with 445 (24.9%) responses. In contrast, 388 (21.7%) participants stated that they would expect a “worsened doctor-patient relationship,” and 270 (15.1%) respondents described the measure as “intensifying uncertainty.”

The statements “improved doctor-patient relationship” (n=167, 9.3%), “signs of unnecessary technologization” (n=162, 9.1%), “deterioration in patient care” (155, 8.7%), and “difficulty in everyday life” (n=37, 2.1%) were selected less frequently (Multimedia Appendix 1).

Aspects of the Implementation of Screening Examinations for Eye Diseases Using AI in GP Practices

In the data received from the long version of the questionnaire, the most important factors from the citizens’ perspective were trust in the GP (mean 1.78, SD 1.24) and the reliability of the examination (mean 1.43, SD 1.01), followed by data security (mean 2.19, SD 1.52).

With regard to organizational factors, the accessibility of the practice (mean 2.14, SD 1.31) and the waiting time for an ophthalmologist appointment (mean 2.13, SD 1.26) were also rated as relevant. The protection against additional examination costs (eg, Individual Health Services; mean 2.30, SD 1.42) was rated as moderately important.

Factors considered less important from the citizens’ perspectives included not having their pupils dilated (mean 3.24, SD 1.65), the duration of the examination (mean 2.93, SD 1.45), and the distance to the nearest ophthalmologist (mean 2.50, SD 1.39).

The results showed that trust in the GP conducting the examination, the reliability of the examination, and data security were the most important aspects considered by the participants when implementing such technologies in GP practices (Table 3).

XSL•FO
RenderX

Table . Evaluation of the aspects of artificial intelligence–supported screening for eye diseases in general practitioner practices.

Variables[a]	Factors, mean (SD; 95% CI)
Trust in general practitioner	1.78 (1.24; 1.71 - 1.86)
Duration of the examination	2.93 (1.45; 2.84 - 3.02)
Waiting time until the test results are available	2.44 (1.29; 2.37 - 2.52)
Data security	2.19 (1.52; 2.10 - 2.29)
Reliability of the examination	1.43 (1.01; 1.37 - 1.49)
Not having the pupils dilated	3.24 (1.65; 3.14 - 3.35)
Accessibility of the practice	2.14 (1.31; 2.06 - 2.22)
Distance to the nearest ophthalmologist	2.50 (1.39; 2.41 - 2.58)
Waiting time for an eye specialist appointment	2.13 (1.26; 2.05 - 2.21)
Waiting time in an ophthalmologist's practice	2.49 (1.31; 2.41 - 2.57)
Protection against additional examination costs	2.30 (1.42; 2.22 - 2.39)
Performance of the examination by medical assistants	2.12 (1.30; 2.04 - 2.20)

[a]Scale from 1=very important to 6=very unimportant.

Factors Associated With Trust in Diagnosis With AI

The stepwise regression analysis is presented in Table 4 and reports only coefficients with statistical significance at the $P<.05$ level. A 9-step model was fitted and explained more than 60% ($R^2=0.602$) of the variance in the dependent variable, "trust in diagnosis through AI." In the first step of the stepwise regression analysis, the variable "general attitude to applications of AI in medicine" showed the highest explained variance ($R^2=0.509$). A higher positive level of attitude toward applications of AI in medicine was strongly associated with higher level of trust in diagnosis through AI. Individual characteristics were not included in the regression model, as $P>.05$. Collinearity statistics ranged between 2.112 (VIF value) and 0.473 (tolerance value) for "general attitude to applications of AI in medicine" and 1.140 (VIF value) and 0.877 (tolerance value) for "improved patient-physician relationship."

Table . Associations of individual characteristics, general preferences for telemedicine and artificial intelligence (AI), and attitudes toward early detection measures in general practitioner care with general trust in AI (results of stepwise linear regression analysis).

Variables[a]	β	*P* value
General attitude to applications of AI in medicine	0.420	<.001
Intensifying uncertainty	0.136	<.001
Future role of AI for own health care	0.164	<.001
Signs of unnecessary technologization	0.120	<.001
Improved physician-patient relationship	−0.063	.003
Providing security	−0.091	<.001
Duration of the examination	0.063	.004
Worsened physician-patient relationship	0.066	.004
Reliability of the examination	0.053	.02

[a]Last step was reported.

Factors Associated With Trust in Diagnosis Through Physicians

The stepwise regression analysis is presented in Table 5 and reports only coefficients with statistically significances at the $P<.05$ level. A 5-step model was fitted and explained more than 4.8% ($R^2\approx.048$) of the variance in the dependent variable, "trust in diagnosis through physicians." For example, a higher positive level of trust in diagnosis through physicians was strongly associated with lower age and greater importance attributed to the waiting time until the test results were available. Collinearity statistics ranged between 1.308 (VIF value) and 0.765 (tolerance value) for "distance to the nearest ophthalmologist" and 1.007 (VIF value) and 0.993 (tolerance value) for "providing security."

XSL•FO
RenderX

Table . Associations of individual characteristics, general preferences for telemedicine and artificial intelligence, and attitudes toward early detection measures in general practice care on general trust in diagnosis through physicians (results of stepwise linear regression analysis).

Variables	β	*P* value
Age of the participants	−0.111	<.001
Waiting time until the test results are available	0.077	.03
Providing security	0.093	.003
Local general medical care	0.089	.005
Distance to the nearest ophthalmologist	0.090	.01

[a]Last step was reported.

Discussion

This study examines citizens' attitudes toward the use of AI in general practice, particularly in the context of early detection measures. The study showed that the introduction of AI-supported technologies is met with mixed reactions.

Differences Between Rural and Urban Areas

Significant differences emerged between urban and rural participants. People from urban areas were significantly more positive about the use of AI in medicine than those from rural areas.

Differences in access to medical services between urban and rural areas are deeply rooted and reflect a complex mix of infrastructural, socioeconomic, and cultural factors [16,17]. While urban areas often provide a wide range of medical services and specialists, some rural areas experience a shortage of physicians, greater distances to health facilities, and limited access to specialized treatment [17].

The introduction of AI and telemedicine is often promoted as a solution to these inequalities by extending access to care. However, emerging research suggests that these technologies are not always met with acceptance [10,11]. The reasons for this are varied and include technological barriers, a lack of trust in digital diagnostic methods, and a preference for in-person physician-patient interactions [12,18,19].

To ensure equal access to care, a deeper understanding of the specific needs and concerns of the rural population is needed. This means not only providing technology but also taking into account the cultural and psychological aspects that influence attitudes toward technology.

Dynamics of Trust in General Practice Care and Technology

This study pointed to a trust deficit in AI-supported technologies. Trust plays an essential role both in interpersonal interactions and in the use of technology. The patient-physician relationship is built on trust, particularly in the physician's commitment to voluntary responsibility and compassionate judgment [20]. This dimension of trust is crucial, as patients in vulnerable health situations depend heavily on the expertise and care of their treating physicians.

This trust is primarily shaped by the quality of the physician-patient relationship, in particular effective communication, interpersonal care, and the physician's knowledge of the patient's individual needs. The study emphasized that these factors play an important role in strengthening patient trust, while other aspects, such as the duration of registration at a practice or the frequency of visits, had less influence on trust [21].

Interpersonal interaction and trust in the treating physician are essential for patient satisfaction and adherence to treatment [20]. Research also highlighted that perceived empathy and individualized care are particularly important to patients, reinforcing the importance of these qualities in maintaining trust in medical professionals [21].

Central to this trust is the concept of continuity of care, particularly relational continuity, in which patients consistently see the same physician over time.

The association between continuity of primary care and patient mortality has been described by categorizing continuity into 3 types: relational continuity, informational continuity, and management continuity. A review of 13 quantitative studies found that greater continuity of care is significantly associated with lower all-cause mortality, particularly among older patients and those with chronic conditions. This protective effect was explained by improved physician knowledge, increased patient confidence, and better adherence to medical advice [22].

Therefore, in an increasingly digitalized world, it is essential that new digital health applications are designed from a patient-centered perspective.

Trust in technologies is predominantly based on functional aspects, such as reliability, security, and predictability [23]. From the perspective of the citizens in our study, the reliability of the examination was the most important factor.

Trust in technology is a construct that is strengthened by a combination of experiences with the technology, trust in users, and trust in regulators. Each of these components plays a critical role in maintaining and fostering trust over time. Past experiences, especially the reliability of the technology, had a significant impact on user trust [24]. In addition, trust is strengthened by the integrity and competence of those who use the technology, especially in the medical field [25], as well as by trust in regulatory authorities responsible for the safety and effectiveness of the technology [26].

The ways in which AI technologies work are currently incomprehensible to the public. This technological opacity requires a certain degree of explainability and interpretability

XSL•FO
RenderX

[27]. This lack of transparency means that damage caused by interaction with an AI system cannot be easily proven or clearly attributed [28]. This poses a major challenge and underlines the urgency of developing mechanisms that clearly regulate responsibility and liability in connection with AI decisions.

AI is often seen as a potential solution to current challenges in the health care system, such as relieving the burden on physicians and promoting a person-centered physician-patient relationship [29,30]. In a systematic analysis of 45 studies, the impact of AI on the person-centered physician-patient relationship was investigated. The researchers identified various ways in which the use of AI tools could promote person-centered care. One of these ways was the use of AI tools in a supportive role [31].

The rising interest in AI for medical applications should not overshadow the need for proper scientific review and evaluation. It is crucial that the medical field maintains its high standards of evidence and ethical responsibility to ensure both the credibility and effectiveness of patient care in an increasingly digital world.

While a large body of research demonstrates the benefits of primary care, there is comparatively less evidence for the use of AI technologies in health care. This discrepancy has substantial implications for evidence-based medicine, where clinical decisions should be based on solid scientific research [32].

A lack of uniform evaluation protocols introduces several challenges, such as doubts concerning the long-term effectiveness, safety of patients, security of data, and ethical dilemmas. To integrate telemedicine and AI into health care systems responsibly and effectively, we need flexible and comprehensive evaluation methods that conform to clinical objectives and regulatory guidelines [33].

The literature highlights that the factors influencing health are complex and influenced by a variety of factors [34,35]. Future studies should continue to explore how aspects beyond technology influence health to ensure that the design of new health systems considers a balanced integration of digital and human resources.

Future Role of AI in Medical Care

While concerns remain about the integration of AI in health care, a significant proportion of participants believed that AI-based early detection measures in general practice could enhance patient care. The application of patient-specific medical data combined with AI assistance systems has the potential to improve treatment outcomes by facilitating prevention, early diagnosis, and individualized therapies. Such advancements could lead to the identification of new medical correlations and innovative approaches to prevention [36].

However, despite these potential benefits, significant challenges and concerns remain. The use of AI necessitates access to substantial amounts of sensitive medical data, raising concerns about data privacy and security. Robust security protocols are essential to safeguard patient privacy and prevent data misuse [37].

The development and integration of AI in health care also bring significant ethical considerations, particularly around accountability for poor decisions or unexpected outcomes. Establishing clear guidelines and defining responsibilities are essential to address these ethical concerns and build trust with patients [38].

In this context, the European Union's "AI Act" represents a critical step toward creating uniform regulations for AI use within the European Union to ensure safety and trustworthiness. This regulation uses a risk-based approach, categorizing AI applications into different risk levels, with high-risk applications, such as those often found in the medical field, subjected to strict requirements. These requirements include transparency, security, and the avoidance of discrimination, all aimed at ensuring that AI systems in the health care sector adhere to high-quality standards and guarantee patient safety [39].

Strengths and Limitations

With a response rate of approximately 36%, the study provides a robust insight into the attitudes and opinions of the population of Schleswig-Holstein on the use of AI in GP practices.

The study was limited to Schleswig-Holstein, which could limit the generalizability of the results to the whole of Germany. Furthermore, the sample could be biased by self-selection of participants who may have had a greater interest in or familiarity with digital technologies. Future studies should therefore aim for a broader geographical spread to improve the representativeness and applicability of the results to the entire German population.

Conclusions

These findings suggest that despite the growing importance of AI in some areas of health care, the traditional physician-patient relationship is seen as absolutely essential. This emphasizes the enduring value of the human elements in health care—personal interaction, empathy, and understanding—features that AI cannot replicate.

Nevertheless, the introduction of AI is still recognized as a sign of modern medicine. People in urban areas are somewhat more open to AI technologies in health care. The integration of AI into health care raises crucial considerations regarding the principles of evidence-based medicine. Balancing technological innovation with the fundamentals of patient-centered care will be crucial in navigating the future landscape of health care.

Funding

This work was supported by grants from the Joachim Herz Foundation as part of the PASBADIA (smartphone-based point-of-care diagnostics) Project.

Abstract

Background: Operational health data interoperability in post-transition health systems requires not only technical standards but also enforceable governance arrangements. Affinity domains, as defined in the IHE XDS (Integrating the Healthcare Enterprise Cross-Enterprise Document Sharing) framework, represent a structured organizational-technical model for cross-enterprise document sharing. However, evidence from Central and Eastern Europe on their governance feasibility and implementation readiness remains limited, particularly in systems characterized by institutional fragmentation and evolving regulatory mandates.

Objective: This study aimed to examine stakeholder perceptions of the prerequisites, risks, benefits, and governance conditions for implementing affinity domains in the Czech health care system. The study further sought to identify system-level readiness factors relevant to national interoperability initiatives in the context of the European Health Data Space regulation.

Methods: We conducted 18 semistructured interviews between January 2025 and April 2025 with policymakers, regional health authorities, health care providers, health insurance funds, health IT vendors, and independent experts. Participants were selected using purposive and snowball sampling to ensure institutional diversity. Interviews explored governance roles, legal accountability for shared data, enforcement of standards, financing models, and technical readiness. Data were analyzed inductively using thematic analysis in MAXQDA 24 (VERBI Software GmbH), supported by dual coding, consensus discussions, and reflexive memoing. Inductively derived themes were subsequently interpreted against core governance dimensions of affinity domains (rule-making authority, membership and participation, accountability, enforcement, and trust).

Results: Five major thematic categories emerged: (1) ambiguous roles and responsibilities marked by fragmented mandates and vendor influence; (2) perceived risks, including institutional distrust, legal uncertainty regarding liability, technical fragmentation, and vendor lock-in; (3) system-level prerequisites such as the need for an empowered coordinating authority, binding interoperability standards (IHE XDS and HL7 FHIR [Health Level 7 Fast Healthcare Interoperability Resources]), sustainable financing, and human resource capacity; (4) perceived benefits, including improved continuity of care, reduced duplication, and enhanced transparency; and (5) structural implementation barriers including political discontinuity, weak enforcement mechanisms, and limited stakeholder engagement. Across stakeholder groups, feasibility was consistently linked to 3 actionable readiness conditions: clearly assigned responsibility and liability for shared data, enforceable technical requirements supported by certification or audit mechanisms rather than voluntary compliance, and financing models addressing both IT infrastructure and organizational change.

Conclusions: Affinity domains are recognized as a viable interoperability model in the Czech Republic, but their implementation is constrained primarily by governance deficits rather than technical immaturity. Establishing an empowered coordinating authority, piloting enforceable domain structures, and aligning national governance with European Health Data Space requirements represent necessary steps toward operational interoperability. These findings provide empirically grounded insights into the governance conditions required for scalable health information exchange in post-transition health systems.

Introduction

The digital transformation of health care systems is widely recognized as a strategic priority across Europe, aiming to improve care quality, efficiency, and patient safety while enabling sustainable system governance [1]. A key enabler of this transformation is the establishment of interoperability infrastructure that allows secure and standardized exchange of medical information among health care providers, patients, and administrative entities [2]. Within this context, the concept of affinity domains, as defined within the IHE XDS (Integrating the Healthcare Enterprise Cross-Enterprise Document Sharing) architecture, constitutes a sociotechnical construct that combines a technical framework for cross-enterprise document sharing with an explicit governance arrangement. Beyond interoperability per se, affinity domains are characterized by shared rule-making, defined membership, accountability for data stewardship, and enforcement mechanisms governing participation and compliance among involved organizations [3,4]. While health information exchange (HIE) or electronic health record (EHR) interoperability primarily refers to the technical ability of systems to exchange data, an affinity domain additionally defines shared governance rules, membership criteria, accountability, and enforcement mechanisms for participating organizations. In this paper, we use the term "interoperability infrastructure" to refer broadly to the technical and governance ecosystem enabling cross-enterprise data exchange, "HIE" to denote operational exchange systems, and "affinity domains" to describe a governance-anchored interoperability model as conceptualized in the IHE XDS framework.

While the implementation of affinity domains has been successfully institutionalized in several Western and Northern European countries—such as Austria (Elektronische Gesundheitsakte [ELGA]), Switzerland (Elektronisches Patientendossier [EPD]), the Netherlands (Landelijk Schakelpunt), and Sweden (Národní plán obnovy)—their adoption across Central and Eastern Europe remains limited and fragmented. Although conceptual frameworks and technical standards such as IHE XDS have been available for over a decade [4], countries in this region continue to face systemic, organizational, and legislative barriers to real-world deployment [5]. The Czech Republic, despite recent improvements in its eHealth strategy and digital infrastructure, continues to lack the operational governance and institutional capacity required to implement affinity domains at scale. In practical terms, the Czech Republic currently lacks a national HIE system comparable to ELGA or EPD, and interoperability initiatives remain primarily project-based or regionally bounded. Although Act No. 325/2021 Collection of Laws established a legal framework for digital health governance, implementation mechanisms, certification procedures, and clearly mandated coordinating authorities remain only partially operational. As a result, interoperability is shaped more by institutional negotiation and vendor configurations than by enforceable national governance structures.

Since the early 2000s, the Czech health care system has initiated multiple digitalization efforts—most prominently the Internet Health Information Portal (Internetový zdravotní informační portál [IZIP]) and ZDRAVeL platforms—but these have largely failed to achieve widespread adoption due to fragmented governance, insufficient standardization, institutional resistance, and lack of sustained stakeholder engagement. The IZIP system, launched in 2004, was a pioneering national web-based EHR that demonstrated clear potential but achieved limited integration and impact in routine care [6]. Its successor, ZDRAVeL, introduced improved functionality but similarly failed to secure institutional alignment and embed itself into clinical workflows [7]. At present, the only digital health applications with nationwide coverage and consistent daily use are the Outpatient Electronic Prescription System [8] and the Digital Imaging and Communications in Medicine (DICOM) image exchange platform [9]. Other systems exist but remain fragmented, region-specific, or limited to pilot projects, which restrict large-scale interoperability. A notable example of a successful local secure health data exchange platform is the eMeDOcS (Exchange Medical Documents System) project [10]. The eMeDOcS system is an electronic platform designed to enable structured data exchange across affinity domains, supporting interoperability and standardized clinical communication. It is mainly used by hospitals in the Vysočina Region. The eMeDOcS system is based on the ICZ ISAC (Integration, Share and Communication System) platform [11], which enables easy integration between EHRs and other specific systems, including telemedicine solutions [12].

More recent evaluations note that although the COVID-19 pandemic accelerated telemedicine adoption, this progress remains fragmented and contingent, hampered by legal uncertainty and the absence of a functional interoperability infrastructure [13]. Comparable challenges have been documented in other post-transition systems, where weak enforcement mechanisms, unclear institutional mandates, and limited technical standardization obstruct effective interoperability [14,15]

Despite these conceptual and technical advances, affinity domains have not progressed beyond policy discussions in the Czech Republic, and no operational implementation currently exists. Several domain experts note that while the IHE-affinity domain concept is acknowledged and debated at the policy level in the Czech Republic, actual system-level implementations are deferred due to government ambivalence about central steering versus federated emergence, and the absence of pilot registries or unified patient identity mechanisms. Similarly, an interoperability pilot (Semantic Interoperability Platform) launched in the mid-2000s demonstrated the technical readiness to adopt international standards but failed to scale due to institutional fragmentation and a lack of sustained governance frameworks [16].

As of 2024, electronic medical record systems are widely adopted at the institutional level in the Czech Republic, with nearly all hospitals and most outpatient providers operating some form of digital documentation. However, these systems remain predominantly vendor-specific and lack cross-enterprise interoperability. No nationwide HIE system comparable to ELGA or EPD is operational. Regional exchange initiatives, such as eMeDOcS in the Vysočina Region, demonstrate

XSL•FO
RenderX

technical feasibility using IHE XDS–based architectures, but their implementation remains geographically limited and institutionally fragmented. National digital infrastructure is currently centered around selected vertical services (ePrescription and DICOM image exchange), while unified patient identity management, master patient indexing, and certification mechanisms for interoperability remain underdeveloped. Although the legal framework for digital health governance was established by Act No. 325/2021 Collection of Laws, operational governance structures and mandatory interoperability enforcement are still evolving.

Despite the availability of technical standards and formal policy documents, existing literature [17] provides limited insight into how the governance attributes of affinity domains, such as rule-making authority, accountability, participation, enforcement, and trust, are interpreted and operationalized by institutional actors in practice. While affinity domains are technically defined within the IHE XDS framework, these governance dimensions are only partially reflected in legal texts or technical specifications and tend to emerge through organizational interactions, negotiation processes, and implementation experiences. Existing research has primarily focused on legal or technical aspects rather than governance practices. To address this gap, we adopted a qualitative design based on stakeholder interviews, which enables analysis of how abstract interoperability models translate into real-world decision-making contexts and how governance responsibilities are perceived and enacted by key system actors [18].

Therefore, in this study, we aim to contribute to the evolving discourse on digital health governance in post-transition health care systems by (1) presenting key findings from stakeholder perceptions regarding the implementation of affinity domains in Czech health care, (2) analyzing these findings in comparison with selected European experiences, and (3) offering evidence-informed recommendations for advancing interoperability through affinity domains as part of the national eHealth policy.

Methods

Study Design and Objective

This study used a qualitative, exploratory design using semistructured interviews and stakeholder analysis to examine perceptions, expectations, and barriers related to the implementation of affinity domains in the Czech health care system. The qualitative approach was selected to capture governance-related attributes of affinity domains—such as the allocation of roles, accountability for shared data, enforcement mechanisms, and trust relationships—that are central to their feasibility but are not directly observable through policy documents or technical specifications. The research objective was to identify enabling and constraining factors from the perspective of key stakeholder groups and derive actionable insights to inform policy and strategy. At the start of each interview, participants were provided with a standardized, brief explanation of an “affinity domain” based on IHE XDS, emphasizing both its governance components (shared policies, membership, accountability, and enforcement) and its technical scope (cross-enterprise document sharing under agreed profiles). Participants were asked to reflect on prerequisites, risks, benefits, and barriers specifically in relation to this defined model. Where participants referred to interoperability challenges more broadly, such statements were retained in the analysis only insofar as they directly constrained or enabled the feasibility of implementing affinity domains in practice. The study adhered to the COREQ (Consolidated Criteria for Reporting Qualitative Research) 32-item checklist to ensure methodological transparency (Checklist 1) [19].

Research Team and Reflexivity

Interviews were conducted by PH and IF, both of whom have formal training in qualitative health research and prior experience conducting semistructured interviews in digital health policy projects. JB co-led the analytic phase. A brief relationship with some participants existed through professional networks used for initial identification; however, no direct supervisory or contractual dependency was present. Participants were informed about the researchers’ institutional affiliation, study aims, and interest in interoperability governance. To mitigate potential bias, we used an a priori protocol, a piloted interview guide, maintained an audit trail, and implemented dual independent coding with consensus resolution; reflexive memos documented assumptions and analytic decisions throughout. We did not compute formal intercoder reliability coefficients, opting instead for iterative consensus and peer debriefing.

Stakeholder Framework and Selection

The selection of stakeholder groups was based on a combined analytical and policy-relevant approach, aligned with established digital health governance frameworks, including multilevel governance approaches and actor-based interoperability models [17,18]. Stakeholders were defined as individuals or institutions that directly influence or are affected by the implementation of national eHealth infrastructure, specifically interoperability components such as affinity domains. Stakeholder groups were selected to reflect core governance roles within an affinity domain, including regulatory authority, payers, providers, vendors, and independent technical experts. These roles correspond to the key governance dimensions of affinity domains, namely rule-setting authority (Ministry of Health [MoH]), implementation coordination (regional health authority [RHA]), operational participation (health care providers), financing and regulatory oversight (health insurance fund [HIF]), technical standard implementation (health IT vendors), and advisory or normative alignment (independent consultants and expert advisors). Inclusion criteria were (1) active involvement in drafting or implementing national or regional eHealth strategies, (2) responsibility for management or governance of hospital information system or interoperability solutions, or (3) technical or advisory roles in pilots or standard-setting activities. Exclusion criteria included the absence of formal responsibility for digital health governance or purely end-user roles without decision authority. Stakeholders were identified through a purposive sampling strategy supplemented by snowball sampling [20]. First, 6 stakeholder categories were defined a priori based on their formal roles in national and regional digital health governance. Within these predefined categories, individuals

XSL•FO
RenderX

were primarily identified through purposive selection based on their formal responsibilities, documented involvement in national or regional eHealth initiatives, and participation in legislative or technical working groups. Snowball sampling was subsequently used as a supplementary strategy to identify additional relevant informants, particularly within the independent expert group and in cases where formal role-based identification was insufficient. The recruitment process continued until adequate coverage of all predefined categories was achieved. This resulted in a final pool of 25 identified candidates, of whom 22 were formally invited; 4 declined due to time constraints, resulting in 18 completed interviews.

To ensure both diversity of perspectives and relevance to the Czech health care context, the following 6 stakeholder groups were identified.

Table 1 shows the stakeholder groups and corresponding inclusion criteria applied in a qualitative semistructured interview study examining the implementation of IHE XDS–based affinity domains in the Czech health care system. Eighteen interviews were conducted between January 2025 and April 2025. Participants were recruited using purposive and snowball sampling to represent regulatory, financing, service provision, health IT vendor, and advisory roles. Detailed participant characteristics are provided in Multimedia Appendix 1.

Table . Stakeholder selection criteria (N=18).

Stakeholder group	Role in eHealth system	Inclusion criteria	Participants, n (%)
Ministry of Health[a], Czech Republic	Policy development, legislation, and national coordination	Direct involvement in drafting or implementing Act No. 325/2021 Collection of Laws or national eHealth strategies	3 (16.6)
RHAs[h]	Regional eHealth implementation and funding oversight	Responsibility for managing or co-funding regional eHealth projects, or an active role in local Hospital Information System governance	3 (16.6)
Health care providers	Operational users of interoperability infrastructure	Senior managers or digital transformation leads in hospitals participating in national eHealth projects or data-sharing pilots	4 (22)
HIF[c]	Data consumers, payers, and system regulators	Participation in interoperability-related initiatives; responsibility for data security or claims data infrastructure	2 (11)
Health IT vendors	System developers and integrators of interoperability solutions	Experience with IHE[d] XDS[e] or HL7[f] FHIR[g] implementations; vendors of Hospital Information Systems used in the Czech or European Union interoperability frameworks	4 (22)
Independent consultants and expert advisors	Strategic or technical advising, legislation support	Recent collaboration with MoH or regions on legislative drafting, standard setting, or coordination of digital health pilot programs	2 (11)

[a]MoH: Ministry of Health.

[b]RHA: regional health authority.

[c]HIF: health insurance fund.

[d]IHE: Integrating the Healthcare Enterprise.

[e]XDS: Cross-Enterprise Document Sharing.

[f]HL7: Health Level 7.

[g]FHIR: Fast Healthcare Interoperability Resources (HL7).

The purposive strategy targeted participants with substantial experience or formal responsibility in health information systems, eHealth projects, or regulatory implementation. Recruitment prioritized individuals actively engaged in national-level working groups, projects funded through the Integrated Regional Operational Program or National Recovery Plan (Národní plán obnovy) schemes, and the development of Czech national digital health legislation. This ensured that all selected informants had first-hand knowledge of operational, regulatory, or strategic aspects of digital health implementation.

As noted above, snowball sampling complemented the primary purposive strategy by enabling the inclusion of additional consultants and advisors involved in recent pilot initiatives or standard-setting activities. Recruitment followed a structured, multiphase logic: initial identification through professional networks, follow-up invitations by email, and confirmation of eligibility against the inclusion criteria.

XSL•FO
RenderX

The final sample reflected both policymaking and operational perspectives, as well as representation from public and private sector stakeholders. While not statistically representative, the composition was sufficient to achieve thematic saturation across the predefined analytical categories, thereby increasing the credibility and contextual depth of the findings. Group-level distributions (MoH, RHAs, health care providers, HIFs, health IT vendors, and independent consultants and expert advisors) are detailed in Checklist 1 to support COREQ-aligned reporting.

Data Collection

Data were collected through semistructured interviews, providing a flexible yet systematic approach to exploring stakeholder perspectives. Interviews were conducted between January 2025 and April 2025. An interview guide was developed based on a review of relevant literature and pilot-tested with 2 external experts, which led to minor refinements in question wording and flow. Interviews were scheduled for approximately 50 minutes and were conducted online via secure video conferencing tools to accommodate participants' geographical distribution.

All interviews were audio-recorded with participants' consent, and detailed field notes were authored immediately after each session. No repeat interviews were conducted. Only the interviewer and participant were present during each interview; no third parties attended. Interview transcripts were returned to all participants for member checking. Of the 18 participants, 12 provided feedback or explicit confirmation, and minor clarifications were incorporated where relevant. The remaining participants did not request modifications. The full semistructured interview guide, including main questions and illustrative probes, is provided in Multimedia Appendix 2 to enhance transparency regarding question framing and potential prompting effects.

The interview guide focused on 4 main domains: stakeholders' perceptions of opportunities and barriers in digital health implementation, experiences with project governance and interinstitutional collaboration, anticipated impacts of national digital health strategies and legislation, and suggestions for improving effectiveness, efficiency, and trust in digital health projects.

Data saturation was monitored throughout the process and was judged to have been achieved after the 12th interview; subsequent interviews confirmed existing themes without generating substantial new insights. A saturation grid documenting the last occurrence of novel codes is included in Multimedia Appendix 3. A summary of preliminary themes was also shared with participants, who provided confirmation or minor clarifications.

Data Analysis

To support construct validity, the concept of affinity domains was analytically specified through a set of governance and technical dimensions derived from the IHE XDS framework and relevant digital health governance literature [3,4,17].

Table 2 shows the conceptual specification of governance and technical dimensions constitutive of affinity domains, which were used as an interpretive reference in this qualitative interview study conducted within the Czech health care system (18 interviews; January 2025-April 2025). The dimensions were derived from the IHE XDS framework and relevant digital health governance literature, serving as an analytical lens rather than a deductive coding framework.

Table . Conceptual specification of affinity domain dimensions used as an interpretive reference.

Affinity domain dimension	Conceptual basis	Relevance for analysis
Shared rule-making	IHE[a] XDS[b] governance model; digital health governance literature	Framing how rules and standards are defined and legitimized
Membership and participation	Affinity domain concept; institutional governance	Understanding inclusion or exclusion of actors
Accountability and liability	Governance and health law literature	Interpreting responsibility for shared data
Enforcement mechanisms	EHDS[c] and interoperability governance debates	Assessing compliance beyond voluntary adoption
Trust relationships	Trust and legitimacy literature in digital health	Explaining willingness to participate
Technical scope (IHE XDS)	IHE XDS architecture	Anchoring findings in document-based exchange

[a]IHE: Integrating the Healthcare Enterprise.

[b]XDS: Cross-Enterprise Document Sharing.

[c]EHDS: European Health Data Space.

These dimensions were not applied as a deductive coding scheme but served as an interpretive reference for examining how inductively derived themes relate to the core attributes of affinity domains. This approach preserved the inductive nature of the thematic analysis while ensuring conceptual alignment with the affinity domain construct.

Interview transcripts were subjected to a thematic analysis using MAXQDA 24 (VERBI Software GmbH, Berlin, Germany, version 24.1.0) to support the organization and coding of qualitative data. An initial inductive codebook was developed and iteratively refined; the final coding tree with major themes and subthemes is provided in Multimedia Appendix 4. Minor and divergent views were also reported, ensuring that less frequent but important perspectives were not overlooked. A worked example (quote → in-vivo code → category → theme) is provided in Multimedia Appendix 5, along with a table of representative quotes by theme and subtheme. The higher-order thematic categories were subsequently interpreted in relation to the governance dimensions constitutive of affinity domains.

XSL•FO
RenderX

The analysis followed a multistep, reflexive process consistent with best practices in qualitative health research:

- Familiarization: researchers conducted repeated readings of transcripts and field notes to identify initial patterns.
- Coding: inductive, in vivo codes were applied independently by 2 coders (PH and IF); discrepancies were discussed until consensus was reached, with an audit trail documenting decisions. We did not compute a formal intercoder reliability coefficient; instead, we used iterative consensus meetings and peer debriefing to ensure dependability.
- Theme development: codes were clustered into broader thematic categories capturing recurrent stakeholder perspectives. Some empirical phenomena spanned multiple domains and were analytically differentiated according to their primary governance implications. To enhance readability in the "Results" section, conceptually related phenomena are discussed under their primary governance function, with cross-references where appropriate. For instance, vendor dominance was interpreted under "roles and responsibilities" as an issue of rule-making authority, whereas vendor lock-in was classified under "perceived risks" as a structural constraint affecting enforceability and participation. This approach ensured conceptual clarity while maintaining alignment with governance attributes central to affinity domains.
- Verification: a third qualitative expert reviewed the coding scheme and thematic structure to ensure rigor and validity. Conceptually related codes (eg, vendor dominance and vendor lock-in, and legal uncertainty) were critically examined during iterative refinement. Where retained in separate higher-order categories, distinctions were based on their primary governance function (eg, structural power asymmetry vs enforceability constraints), thereby avoiding post hoc theme allocation. The use of MAXQDA facilitated systematic data management and the creation of thematic maps. The relative prominence of each domain was visualized through frequency-weighted displays, supporting the interpretation and presentation of the findings.

Quotations in the "Results" section are labeled using a dual system: a unique respondent code (R1-R18) and the corresponding stakeholder group (MoH, RHAs, health care providers, HIFs, health IT vendors, and independent consultants and expert advisors). Each code was assigned to a single participant and used consistently throughout the analysis. The distribution of respondent codes mirrors the sample composition described in Table 1: MoH (n=3), RHAs (n=3), health care providers (n=4), HIFs (n=2), health IT vendors (n=4), and independent consultants and expert advisors (n=2). This labeling strategy enhances the transparency of reporting while preserving participant anonymity. Where appropriate, we report countervailing or minority views to avoid over-generalization.

To contextualize the Czech findings, we conducted a focused desk-based review of selected European countries with operational HIE systems comparable to IHE XDS–based affinity domains (Austria, Switzerland, the Netherlands, Sweden, and Belgium). Countries were selected purposefully to reflect different governance architectures (centralized, federated, and regional) and based on the availability of official documentation and peer-reviewed analyses.

Data were extracted from national eHealth portals, legislative documents, and relevant academic literature. Information was synthesized descriptively, focusing on governance structures, legal mandates, implementation scopes, and coordination mechanisms. This component served as a contextual comparison and did not constitute a separate systematic review.

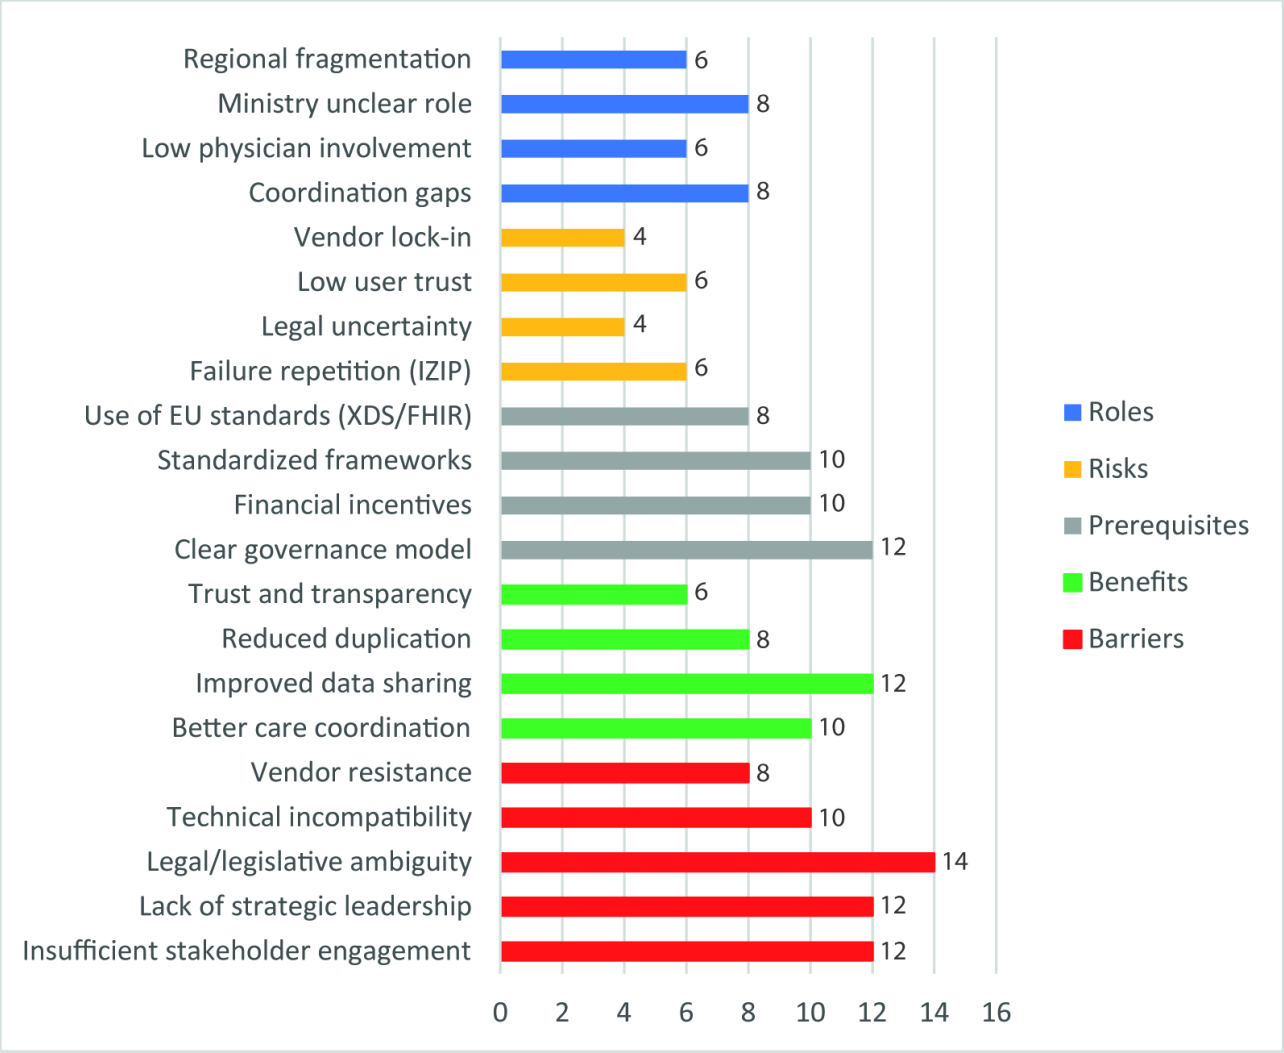
Ethical Considerations

The study was approved by the ethics committee of the Faculty of Biomedical Engineering under protocol C59/2025. Research procedures were conducted in compliance with local legislation and institutional requirements [21]. The ethical approval covered the recruitment of participants from external public and private institutions in their professional capacity. No additional institutional approvals were required beyond individual informed consent.

All participants received an information sheet explaining the study's purpose, procedures, and their rights, including confidentiality and the voluntary nature of participation. Written informed consent was obtained before data collection. Participant identities were anonymized and institutional affiliations were masked to protect confidentiality and comply with data protection standards. Audio files and transcripts were stored on secure institutional servers with restricted access, and deidentified transcripts were used for analysis. There was no compensation awarded.

Results

Overview



The thematic analysis yielded five major categories concerning the implementation of affinity domains in the Czech health care system: (1) roles and responsibilities, (2) perceived risks, (3) system-level prerequisites, (4) perceived benefits and opportunities, and (5) implementation barriers. These categories capture institutional expectations, governance concerns, and perceived feasibility conditions articulated across stakeholder groups.

The categories are presented thematically according to the dominant governance implications identified across stakeholder groups. Where phenomena intersected multiple governance dimensions (eg, vendor influence or legal uncertainty), they are discussed under their primary governance function.

Figure 1 illustrates the distribution of major thematic categories derived from 18 semistructured stakeholder interviews conducted within the Czech health care system between January and April 2025. The bars represent the frequency of coded text segments assigned to each theme across the dataset. The values reflect relative thematic prominence and do not indicate the number of participants endorsing a theme or statistical significance.

Figure 1. Distribution of major thematic categories derived from stakeholder interviews (N=18 interviews). FHIR: Fast Healthcare Interoperability Resources; HL7: Health Level 7; IZIP: Internetový zdravotní informační portál; MoH: Ministry of Health; XDS: Cross-Enterprise Document Sharing.

Thematic Categories

Roles and Responsibilities

The analysis of stakeholder interviews revealed a systemic ambiguity in the definition and operationalization of roles within the governance of affinity domains in the Czech health care system. While the MoH formally holds responsibility for strategic direction in digital health, respondents consistently emphasized its limited engagement in operational implementation. As 1 participant noted:

> *The Ministry sets strategies but does not enforce them. We're left guessing what they really want.* [R18, independent consultant and expert advisor]

Several participants highlighted the absence of an empowered intermediary body with the technical and legal authority to coordinate interoperability initiatives—a role that, in other countries, is fulfilled by institutions such as Gematik (Germany).

At the regional level, fragmentation emerged as a critical barrier. Regional IT departments reportedly operate with minimal alignment, resulting in uncoordinated and heterogeneous solutions. This decentralization exacerbates interoperability issues and complicates accountability. According to another respondent:

> *Each region develops its own system, with no national integration in sight. We're building isolated islands.* [R4, RHA]

The lack of nationally endorsed technical and procedural standards reinforces these inconsistencies.

Stakeholders also identified a pronounced disconnect between digital governance structures and clinical end-users. Physicians, despite being primary users of EHRs, are reportedly excluded from planning and decision-making processes, as 1 respondent explained:

> *We receive new systems and tools, but no one asks whether they match how we work. That's why so many doctors ignore them.* [R7, health care provider]

This exclusion leads to suboptimal system design and limited adoption.

Finally, vendor dominance was perceived as a significant factor undermining coherent governance. In many facilities, technology suppliers exert considerable influence, effectively establishing

XSL•FO
RenderX

de facto standards and resisting external integration. As 1 respondent put it:

> *In some hospitals, the vendor decides more than the IT department. They lock the system and then dictate what's possible.* [R13, health IT vendor]

The absence of regulatory mechanisms to counterbalance these dynamics contributes to role diffusion and undermines long-term governance sustainability. This asymmetry also underpins later concerns regarding vendor lock-in and resistance during implementation.

In governance terms, this ambiguity signals the absence of clearly defined rule-making authority, membership criteria, accountability allocation, and enforceable coordination mechanisms that are constitutive of affinity domains as structured interoperability arrangements.

Perce ived Risks

Interviewees articulated a range of interrelated risks that threaten the feasibility and sustainability of affinity domains. The most frequently cited concern was reputational damage and institutional distrust rooted in the failed IZIP initiative. As 1 respondent recalled:

> *IZIP left a scar. We've all seen what happens when things go wrong—and no one wants to be blamed again.* [R17, independent consultant and expert advisor]

Respondents noted that the legacy of IZIP continues to generate reluctance among stakeholders to participate in digital health projects, particularly those lacking transparent governance and legal protection.

Legal uncertainty regarding liability for shared data was another dominant theme. Many stakeholders expressed concern over the absence of clear accountability frameworks for data integrity and clinical liability once information is shared across domains. As 1 respondent emphasized:

> *If a patient is harmed due to outdated or missing data, who will take responsibility? No one wants to be exposed.* [R8, health care provider]

This regulatory vacuum exacerbates institutional risk aversion, particularly in environments where errors could directly affect patient safety.

Technical risks were linked to the heterogeneous landscape of health IT systems and the lack of mandatory, enforceable interoperability standards. Interviewees reported variability in the implementation of HL7 FHIR and IHE profiles, often contingent upon vendor willingness rather than policy mandates. As 1 respondent observed:

> *Everyone does their own thing. Some use FHIR; some don't. There's no technical backbone that guarantees compatibility.* [R14, health IT vendor]

The absence of a national HIE system or compliance framework further limits reliable data exchange.

Building on earlier concerns about vendor dominance in rule-setting processes, stakeholders described vendor lock-in as a structural risk limiting enforceable participation. One respondent remarked, "Why would a vendor enable data sharing if it means losing business to a competitor?" (R15, health IT vendor). Additionally, low trust among clinical professionals—linked to past failures and limited inclusion in governance—was reported as a persistent obstacle to stakeholder engagement. As 1 respondent stated:

> *It feels like another bureaucratic project we're supposed to accept without discussion. That erodes trust, not builds it.* [R9, HP]

These risks indicate fragile institutional preconditions for affinity domains, particularly with respect to trust, liability clarity, and enforceable participation rules.

System-Level Prerequisites

Participants outlined several prerequisites critical for the successful implementation of affinity domains. Chief among these was the establishment of a functionally independent governance structure capable of coordinating the technical, legal, and strategic aspects of interoperability deployment. Respondents advocated for a body with a defined mandate, cross-sectoral legitimacy, and operational capacity. As 1 respondent pointed out:

> *You can't just publish a strategy and hope that hospitals will fall in line. Someone has to own it, drive it, and manage it.* [R2, MoH]

Funding was highlighted as a key enabling factor, given the substantial costs of system upgrades, training, and organizational redesign. According to 1 respondent:

> *We're not against interoperability. But who's going to pay for all the technical and organizational changes it requires?* [R11, HIF]

Incentive structures, including European Union–linked funding or performance-based reimbursement, were proposed as potential levers to foster participation.

Technical prerequisites included the uniform adoption of recognized standards such as HL7 FHIR and IHE XDS, as well as the creation of centralized compliance frameworks, reference implementations, and certification schemes. Interviewees also emphasized the need for inclusive interoperability beyond hospitals, incorporating social services, emergency care, and public health actors. As 1 respondent highlighted:

> *You can't build a regional domain if the social care system is left out. It's half of the equation.* [R5, RHA]

Such integration would necessitate coordinated policymaking across ministries.

Human resource capacity was also noted as a critical constraint. Respondents cited a shortage of professionals with the requisite skills to implement and manage interoperability solutions at both the institutional and regional levels. As 1 respondent explained:

> *The biggest bottleneck isn't technology. It's people who understand the standards and can actually implement them.* [R18, independent consultant and expert advisor]

XSL•FO
RenderX

These prerequisites correspond to the foundational governance conditions of affinity domains, including the need for an empowered coordinating authority, formally recognized participation rules, technical compliance enforcement, and sustainable operational capacity.

Perceived Benefits and Opportunities

The perceived benefits of affinity domains were principally associated with improved clinical coordination, operational efficiency, and patient safety. The most prominent advantage cited by stakeholders was seamless access to structured patient data across institutional boundaries. Respondents described scenarios in which inadequate information sharing resulted in redundant diagnostics, delayed care, or clinical uncertainty. As 1 respondent described:

> *If a patient comes from another hospital, I usually start from scratch. Even allergy history is often missing.* [R10, health care provider]

Affinity domains were also perceived as a mechanism to reduce redundant diagnostic procedures, particularly in oncology and chronic care, where patients often traverse multiple providers. One respondent reported:

> *We see the same CT scans being done twice just because the systems don't talk. That's both costly and unethical.* [R8, health care provider]

In addition to financial savings, stakeholders emphasized the ethical imperative to avoid unnecessary patient burdens.

Improved continuity of care and support for integrated service delivery was also recognized. Interoperable access to discharge summaries, medication histories, and treatment plans was seen as essential for primary care physicians managing complex patients. As 1 respondent mentioned, "A GP who sees a patient after hospital discharge should not have to guess what happened during hospitalization" (R7, health care provider).

Some respondents identified the potential for interoperability to facilitate system-level accountability through audit trails and standardized documentation. According to 1 respondent:

> *If we can see who accessed what, when, and why, it becomes easier to ensure compliance and trace responsibility.* [R1, MoH]

Secondary uses of data, including research, surveillance, and planning, were identified as long-term opportunities, albeit contingent on the establishment of trust and robust legal and technical safeguards. As 1 respondent suggested:

> *Affinity domains could eventually feed anonymised data into registries or support AI models. But that's the next step.* [R17, ICEA]

These anticipated benefits reflect the governance potential of affinity domains to structure accountability, enable traceable exchanges, and foster coordinated cross-institutional participation.

Implementation Barriers

Stakeholders identified multiple barriers hindering the adoption of affinity domains, spanning legal, organizational, technical, and cultural domains. The lack of a comprehensive legal framework was cited as the most significant impediment. Beyond the liability-related uncertainty described under the "Perceived Risks" section, respondents also identified broader legal uncertainty—particularly regarding consent procedures and data stewardship—as an operational barrier. As 1 respondent stated:

> *We operate in legal gray zones. Everyone is afraid of making a mistake, so they'd rather do nothing.* [R6, RHA]

Political instability and weak leadership continuity were also seen as undermining implementation. Respondents described repeated strategic resets with governmental turnover, leading to policy fatigue and limited stakeholder confidence. One respondent observed:

> *There's no continuity. One government introduces a concept, the next one cancels it. That's how we fail by design.* [R18, independent consultant and expert advisor]

Technical fragmentation, particularly the coexistence of proprietary, noninteroperable systems, was noted across both hospitals and outpatient facilities. The absence of national technical infrastructure (eg, a HIE system) was seen as a structural constraint on scalability. As 1 respondent described:

> *Every vendor builds their own castle. And no one checks if the drawbridges align.* [R16, health IT vendor]

In operational terms, stakeholders also described vendor resistance as a practical barrier during implementation, including commercial disincentives such as excessive application programming interface fees and limited technical transparency. As 1 respondent explained:

> [If interoperability isn't part of the contract, don't expect vendors to care.] [R15, HV]

Finally, limited stakeholder engagement—especially among frontline providers—was identified as a barrier to implementation. The top-down nature of digital health policy development was seen as excluding key actors, undermining system ownership, and contributing to resistance at the operational level. According to 1 respondent:

> *Doctors, nurses, even IT departments—most of them hear about new projects for the first time at the rollout stage. [R9, health care provider]*

Taken together, these barriers reflect a structural misalignment between current institutional arrangements and the governance logic required for affinity domains, particularly in terms of enforceability, defined domain membership, leadership continuity, and coordinated policy execution.

Discussion

Summary of Main Findings

Our findings indicate that the feasibility of affinity domains in the Czech health care system is primarily shaped by governance-related constraints rather than by the absence of

XSL•FO
RenderX

technical standards. Across stakeholder groups, barriers clustered around unclear institutional mandates, weak enforcement mechanisms, fragmented implementation structures, and limited stakeholder inclusion—factors that collectively undermine trust and coordination required for cross-enterprise data sharing.

Synthesis of Themes and Policy Implications

To enhance the policy relevance and readability of the findings, we synthesized the 5 empirical themes into a structured overview linking governance gaps to corresponding policy implications. While the themes emerged inductively from stakeholder interviews, their interpretation reveals actionable dimensions relevant to affinity domain implementation.

Table 3 shows the synthesis of empirically derived thematic categories and their corresponding governance implications for affinity domain implementation in the Czech health care system. The table is based on findings from 18 semistructured stakeholder interviews conducted between January 2025 and April 2025 and reflects author-derived implications grounded in qualitative analysis rather than direct participant recommendations.

Table . From thematic findings to policy implications for affinity domain implementation.

Empirical theme	Governance gap identified	Policy implication
Roles and responsibilities	• Ambiguous mandates • Absence of empowered coordinating body • Vendor dominance	• Establish an independent national interoperability authority with clear rule-making and enforcement powers
Perceived risks	• Legal uncertainty regarding liability • Institutional distrust • Vendor lock-in	• Clarify liability frameworks • Introduce binding interoperability requirements • Create contractual enforcement mechanisms
System-level prerequisites	• Lack of certification frameworks • Inconsistent standard adoption • Limited human capacity	• Implement mandatory technical standards (IHE[a] XDS[b] and HL7[c] FHIR[d]) supported by certification, audit, and national reference implementations
Perceived benefits	• Recognized value for continuity of care and accountability, but unrealized due to governance gaps	• Use pilot affinity domains to demonstrate measurable clinical and operational benefits
Implementation barriers	• Political discontinuity • Fragmented regional approaches • Weak stakeholder engagement	• Introduce phased pilots with co-design mechanisms and multilevel governance coordination aligned with EHDS[e].

Comparison With International Literature

The study identifies several systemic, structural, and contextual obstacles that complicate the implementation of affinity domains within the Czech health care system. While some of these challenges correspond to broader trends observed across European countries, the Czech case is distinguished by shortcomings in governance architecture, legal frameworks, and stakeholder involvement.

Although affinity domains are not always explicitly addressed in major European policy and governance studies, the structural conditions underpinning their creation and sustainability are frequently analyzed. Affinity domains, as defined by the IHE XDS framework, require not only interoperable technical architectures but also clearly defined governance structures, implementation standards, and legal-operational certainty. Recent literature in digital health governance thus offers critical insights into the enabling—or inhibiting—factors for their deployment.

To contextualize the Czech findings, we purposively selected European countries representing distinct governance architectures of affinity domain–like models (centralized, federated, semicentralized, and regional). These cases were chosen to reflect variation in institutional authority, legal mandates, and implementation maturity, thereby enabling analytical comparison with the governance gaps identified in the Czech interviews.

Table 4 shows a comparative overview of affinity domain–like interoperability governance models in selected European countries, based on desk-based document review conducted as part of this qualitative study. The comparison contextualizes findings from 18 stakeholder interviews (Czech Republic, January 2025-April 2025) against operational governance

XSL•FO
RenderX

structures in Austria, Switzerland, the Netherlands, Sweden, and Belgium.

Table . Comparative overview of affinity domain implementation in selected European countries.

Country	Affinity domain model	Governance structure	National coverage	Key characteristics
Austria	ELGA[a]	Centralized, state-owned	National	Mandatory for providers; opt-out for patients; based on IHE[b] XDS[c] [22]
Switzerland	EPD[d]	Federated; regulated at the federal level	Regional or national	Voluntary for patients; multiple affinity domains operated by certified communities [23]
The Netherlands	LSP[e]	Semicentralized	National	Opt-in system national broker connects providers to shared exchange services [24]
Sweden	NPÖ[f]	Regional (county-level)	Regional	Based on regional initiatives, integrated into national strategy and opt-out model [25]
Belgium	Vitalink	Federated (per region)	Regional	Strong focus on authentication via national electronic identity and platform-based document exchange [26]
Czech Republic	Not operational (conceptual phase)	Central coordination planned via MoH[g] and ÚZIS[h]	None	Legal framework in place, no piloting or operational deployment, and unclear governance

Comparative analysis illustrates that successful affinity domain models, from Austria's centralized ELGA to Switzerland's federated EPD, share common elements: empowered coordinating authorities, integrated legal mandates, robust access infrastructures, and sustained stakeholder engagement. In alignment with interviewees' accounts of legal uncertainty, fragmented coordination, and the absence of empowered governance bodies, the Czech Republic currently appears to remain at a largely conceptual stage, with limited piloting, incomplete governance clarification, and no operational affinity domain deployment.

The comparison is not intended as an exhaustive review but as an analytical reference illustrating governance configurations that directly contrast with constraints identified in the Czech case. These comparative patterns reinforce the governance gaps identified in the Czech interviews. Our analysis demonstrates that without clearly defined responsibilities, legal clarity, and enforceable standards, practical progress in interoperability remains unattainable. A comparable pattern is observed in a recent World Health Organization (WHO) or European study, which shows that although 83% of countries in the region have adopted a formal digital health strategy, only 79% have fully developed implementation and performance monitoring mechanisms—a relatively high figure, yet with substantial variation in maturity, funding, and institutional authority [27]. A multi-country qualitative study by Papadopoulos et al [18] further underscores that public trust in national EHR systems hinges on data security, privacy, and the perceived legitimacy of actors—key governance issues also relevant for affinity domains. In parallel, a scoping review by Gazzarata et al [14] confirms that although adoption of HL7 FHIR is growing, particularly in chronic disease management, the lack of binding implementation guides, certification frameworks, and coordinating authorities continues to hamper interoperability and data reusability. In affinity domain terms, such structural vendor dependencies undermine enforceable participation rules and coordinated document exchange across institutional boundaries.

Vendor lock-in and proprietary architecture remain structural barriers. As Kapitan et al [28] emphasize, the adoption of open standards such as HL7 FHIR is not sufficient unless accompanied by open-source implementations and integration toolkits tailored to local constraints. A scoping review of European chronic care implementations found that only 20%

XSL•FO
RenderX

of projects reference formal implementation guides, and certification or central coordination mechanisms are rare, resulting in persistent heterogeneity that undermines interoperability [14]. A recent review on telemonitoring [29] likewise highlights that despite using FHIR and ISO/IEEE (International Organization for Standardization and the Institute of Electrical and Electronics Engineers) 11073, inconsistent governance models and fragmented implementations remain widespread.

Clinician and stakeholder engagement also remains minimal. This finding directly resonates with interviewees' descriptions of the limited inclusion of clinical end users in governance processes. According to the Organisation for Economic Co-operation and Development [30], the average quality score for stakeholder engagement in primary lawmaking rose modestly from 2.00 in 2014 to 2.26 in 2024 (on a 0 - 4 scale). Engagement in subordinate regulation remains weaker (1.95-2.16), with oversight and quality control scoring particularly low (0.37 out of 1). Despite rapid growth in remote care and patient access metrics, the sustainability of interoperability gains remains uncertain. The Czech Republic's maturity score increased by 26 points in 2024—the largest annual improvement in the European Union—yet full interoperability remains unachieved, as key structural mechanisms are still absent or only partially implemented.

Building public trust in digital infrastructures is essential. A structured review of semantic interoperability methods shows that meaningful trust-building relies on transparent data standards supported by policy frameworks [31,32]. A cross-country analysis of personal EHR access further validates the importance of standards, usability, and stakeholder inclusion in fostering acceptance and trust [33]. In the absence of such frameworks, Czech narratives around health data governance often neglect data security, privacy, and stakeholder legitimacy—undermining the sustainable implementation of affinity domains.

Implications for Policy and Practice

The following implications represent author-derived interpretations informed by the empirical findings, relevant literature, and EHDS regulatory requirements, rather than direct requests expressed by the interviewed stakeholders.

Given stakeholders' repeated emphasis on legal uncertainty, fragmented governance structures, weak enforcement mechanisms, and institutional risk aversion, phased pilot deployments may represent a pragmatic policy instrument for reducing uncertainty and strengthening trust in domain-based interoperability arrangements.

International evidence [22,23,26] suggests that pilots anchored in regional settings and supported by co-design can facilitate stakeholder engagement and accelerate scaling. In the Czech context, and consistent with the governance constraints identified in the interviews, the current absence of pilot deployments, test registries, or structured sandbox environments limits opportunities for iterative validation of both technical and governance arrangements under real-world conditions.

Building on the governance gaps identified in this study, we recommend that the Czech Republic adopt maturity assessment frameworks such as those used in the WHO or European survey [27] or embedded in the EHDS implementation model [34] to evaluate readiness across legal, organizational, and technical dimensions. These tools may guide prioritization, funding allocation, and benchmarking toward operational interoperability.

In alignment with the EHDS regulation, national interoperability governance frameworks—including potential affinity domain structures—should be coordinated with national metadata catalogs and designated health data access bodies to ensure transparency, lawful data access, and structured secondary use.

Limitations

This study has several limitations. First, purposive and snowball sampling may have over-represented stakeholders who were more accessible or willing to participate, which could limit the transferability of the findings. Second, interviews were conducted with senior policymakers and institutional leaders, including representatives of the MoH and regional authorities. The hierarchical and professional status of these participants may have influenced the framing of responses, potentially introducing elements of social desirability or correctness bias. Although anonymity was guaranteed and reflexive strategies were applied, responses may still reflect institutionally aligned perspectives rather than fully critical accounts. The sample predominantly consisted of highly experienced professionals in senior governance roles. While appropriate for analyzing institutional decision-making and regulatory structures, this composition may under-represent early-career or operational-level perspectives and thus limit generational diversity in the findings. In addition, representatives of primary care professional associations, organized medical chambers, and patient advocacy groups were not directly included. Although senior provider representatives participated, frontline primary care clinicians and organized patient stakeholders were under-represented, which may privilege governance-level perspectives over operational or user-level experiences. Third, while dual independent coding and consensus resolution were implemented, no formal intercoder reliability coefficients were calculated. Fourth, the perspectives analyzed are context-specific to the Czech governance and regulatory environment and may not be generalizable to countries with more mature certification frameworks or long-standing national HIE systems. In addition, the study did not include patients or the general public, despite recurring interview themes related to trust, legitimacy, and institutional credibility. The absence of these perspectives represents a substantive limitation, as public trust is a foundational condition for sustainable affinity domain governance and cross-enterprise data sharing. Furthermore, data collection (January 2025-April 2025) coincided with the finalization and publication of the EHDS regulation in February 2025. The findings may therefore reflect stakeholder perceptions during an early transition phase marked by regulatory uncertainty rather than a stabilized postimplementation environment. Finally, the research did not evaluate pilot implementations or real-world affinity domain deployments, which limits the ability to draw conclusions about operational

XSL•FO
RenderX

feasibility. These limitations should be considered when interpreting the results and designing future studies.

Future Directions

Future research should build on these findings in several directions. First, empirical evaluation of pilot affinity domains is needed to examine how the identified governance attributes—such as role allocation, accountability, and enforcement—operate in practice once interoperability infrastructure moves beyond the conceptual stage. Longitudinal studies following pilot implementations could assess how trust, compliance, and institutional coordination evolve over time.

Second, future research should prioritize the inclusion of patients and public representatives, particularly to examine how trust, legitimacy, and perceived data governance affect the willingness to participate in affinity domain–based information exchange. Incorporating these perspectives would allow for the triangulation of governance assumptions identified in this study.

Third, comparative research across post-transition health systems could help distinguish context-specific barriers from more general governance patterns affecting affinity domain implementation. Such work would also support benchmarking national readiness in relation to EHDS requirements and inform transferable policy lessons.

Conclusions

This study examined stakeholder perceptions of affinity domains as a governance and interoperability construct within the Czech health care system using qualitative interviews. The findings show that while affinity domains are recognized as a promising model for cross-enterprise data sharing, their feasibility is constrained by unclear governance mandates, limited enforcement mechanisms, legal uncertainty, and fragmented implementation capacity. By explicitly linking these challenges to the governance attributes of affinity domains, the study clarifies why interoperability barriers persist despite the availability of technical standards. These findings contribute empirical insight into the governance conditions required for operational interoperability in post-transition health systems and provide a grounded basis for further policy and implementation research.

Acknowledgments

The authors thank all stakeholders for their participation and time, as well as colleagues from the Czech Technical University and the Technical University of Liberec for their support. The authors also acknowledge administrative support from the Faculty of Biomedical Engineering. Generative artificial intelligence tools were used for language clarification and editorial support in cases of ambiguity. No generative artificial intelligence was used for data generation, analysis, or interpretation.

Funding

This study was supported by a grant from the Czech Technical University in Prague (SGS23/197/OHK5/3T/17).

Data Availability

Due to confidentiality and General Data Protection Regulation restrictions, full interview transcripts cannot be publicly shared. Deidentified coding frameworks and illustrative quotes are available in the multimedia appendices. Additional anonymized materials may be made available upon reasonable request to the corresponding author. This statement complies with JMIR Publications' data availability policy.

Authors' Contributions

JB and PH conceived the study design and co-led the analysis. PH and IF conducted the interviews and initial coding. All authors contributed to the interpretation of findings, drafting, and revising the manuscript, and approved the final version.

Abstract

Background: The implementation of Clinical Data Interchange Standards Consortium (CDISC) standards is essential for accelerating clinical research and is mandated for new drug applications in Japan. However, the current status of their implementation and associated challenges in Japanese academic medical centers has not been comprehensively investigated.

Objectives: This study aimed to comprehensively clarify the current status, challenges, and opportunities associated with implementing CDISC standards in Japanese academic medical centers.

Methods: We conducted a questionnaire survey targeting 91 academic medical centers (83 university hospitals, 7 national centers for advanced and specialized medical care, and 1 national hospital organization) from June to August 2024. The survey assessed experience with contracted CDISC data creation, implementation status, barriers, and available resources. We performed Mann-Whitney *U* tests to assess the association between the number of data managers or biostatisticians and CDISC implementation status.

Results: Responses were received from 84 institutions (response rate: 92%). While 29% (26/91) had experience with contracted CDISC standards data creation, 22% (20/91) had implemented CDISC standards. The most frequently cited barrier to CDISC standards implementation was “significant human and financial effort and resource shortages” (62%, 56/91). A significant “supply and demand” gap was identified: while 66% (60/91) of institutions expected support (eg, materials, workshops) from other organizations, only 5% (5/91) were capable of providing such resources. Furthermore, 66% (60/91) of institutions had not yet decided on a future policy regarding CDISC compliance. Notably, institutions that had implemented CDISC standards had significantly higher numbers of data managers (P<.001) and biostatisticians (P<.001) compared to those that had not.

Conclusions: The implementation of CDISC standards in Japanese academia is limited, primarily due to resource shortages and a lack of specialized personnel. However, the discrepancy between the high demand for support and limited supply highlights a significant opportunity. Experienced academic research organizations, in cooperation with pharmaceutical companies and contract research organizations, can drive nationwide adoption by taking a strategic leadership role in providing educational resources and training, thereby addressing the critical shortage of specialized personnel and know-how.

(JMIR Med Inform 2026;14:e83774) doi:10.2196/83774

KEYWORDS

Clinical Data Interchange Standards Consortium; CDISC standards; academic research organization; ARO; Clinical Data Acquisition Standards Harmonization; CDASH; Study Data Tabulation Model; SDTM; Analysis Data Model; ADaM

Introduction

The Clinical Data Interchange Standards Consortium (CDISC) is a nonprofit organization dedicated to developing global electronic standards for clinical trial data. The “CDISC standards” refer to the set of standards developed by this consortium. Implementing these standards entails a series of technical activities throughout the clinical data lifecycle. Specifically, it involves designing case report forms based on Clinical Data Acquisition Standards Harmonization (CDASH), mapping collected raw data to Study Data Tabulation Model (SDTM) domains, and creating analysis-ready datasets according to Analysis Data Model (ADaM). These processes require writing programming scripts for data transformation, generating

XSL•FO
RenderX

metadata files such as define.xml, and rigorously validating the datasets and their conformance to the standards. In Japan, the Pharmaceuticals and Medical Devices Agency (PMDA) has been accepting electronic clinical trial data submissions compliant with CDISC standards for new drug marketing approval applications since October 2016 [1]. Furthermore, the Japan Agency for Medical Research and Development has expressed the view that compliance with CDISC standards from the planning and execution stages will become essential in academia-led clinical research and trials in the future [2].

Additionally, global data sharing platforms promote the sharing and reuse of clinical trial data [3-9], and several of these advance data standardization in collaboration with the CDISC [3-6,8].

The sharing of clinical trial data is expected to promote advancements in medicine and science [10,11]. Moreover, since July 1, 2018, the International Committee of Medical Journal Editors has mandated the inclusion of a data-sharing statement in manuscripts reporting the results of clinical trials submitted to International Committee of Medical Journal Editors member journals [12].

In 2017 in Japan, the University Hospital Medical Information Network Center and Japan Agency for Medical Research and Development cohosted the "CDISC Public Symposium" [2]. Furthermore, in 2018, University Hospital Medical Information Network, PMDA, and CDISC cohosted the "Workshop on CDISC Utilization in Academia" [13]. These activities aim to promote the dissemination of CDISC standards in Japanese academia.

The implementation of CDISC standards is expected to accelerate clinical research [14]. In particular, researchers and related institutions are beginning to recognize the importance of planning research and preparing case report forms based on the premise of electronic submissions compliant with CDISC standards throughout the processes of data collection, data management, and statistical analysis. These initiatives are expected to help reduce costs and workloads while maintaining data quality [15].

A previous study investigated the current status and challenges associated with the implementation of CDISC standards in Japanese academic medical centers [16]. However, in that study, the definition of "academia" was ambiguous.

Therefore, the present study aimed to comprehensively clarify the current status and challenges associated with implementing CDISC standards in Japanese academic medical centers.

Methods

Ethical Considerations

This study was a questionnaire survey targeting administrative personnel at academic medical centers regarding the operational status of CDISC standards. The study did not involve interventions on human participants or the collection of sensitive personal health information from patients. Therefore, an ethics review board assessment was not sought, in accordance with the ethical guidelines for medical and health research involving human subjects in Japan.

The purpose of the study was clearly explained in the invitation to the online questionnaire, and the completion and submission of the questionnaire were regarded as implied consent to participate. Participation was voluntary, and respondents could withdraw at any time by not submitting their responses.

To protect the privacy and confidentiality of the respondents, the collected data were stored securely and accessed only by the research team. The data were aggregated for analysis, and no personally identifiable information was reported. No compensation was provided to the participants for this study. This manuscript and the supplementary materials do not contain any images or data that could identify individual participants.

Participants and Survey Administration

In this study, "academia" is defined as institutions in Japan legally mandated to conduct research as part of their official duties. Based on this definition, the following 91 academic medical centers (hereinafter referred to as "institutions") were selected as survey targets: 83 university hospitals (43 national university hospitals, 8 public university hospitals, 31 private university hospitals, and 1 ministry-affiliated university hospital), 7 national centers for advanced and specialized medical care, and 1 national hospital organization. We contacted these institutions by email, requested their cooperation in the questionnaire survey, and sent them the questionnaire.

The survey period was from June 12 to August 16, 2024. The questionnaire survey was conducted online using Google Forms. As a general rule, 1 response per institution was accepted. No duplicate responses were received from any single institution; therefore, all submitted responses were included in the final analysis.

The survey was primarily distributed to the directors of clinical research centers or heads of data centers at each institution. In cases where direct contact information for these roles was unavailable, we identified the appropriate respondents through personal professional networks. For institutions where no direct contact could be established, the request was sent to the general administrative office of the Clinical Research Support Center, with instructions to forward the questionnaire to the staff member most knowledgeable about CDISC standards.

Questionnaire Items

The main questionnaire items were as follows:

Experience with contracted CDISC standards data creation

Implementation status of CDISC standards

Barriers to CDISC standards implementation

Future policies regarding CDISC standards-compliant data creation

Availability of CDISC standards-related documents and training

Ability to provide CDISC standards-related documents and training

Expectations for pharmaceutical companies, contract research organizations (CROs), and other academic research organizations (AROs)

XSL•FO
RenderX

Ability to provide to pharmaceutical companies, CROs, and other AROs

Number of data managers and biostatisticians

In this study, "implementation" was defined as CDISC data creation conducted internally, jointly with external partners, or externally with acceptance reviews performed by internal CDISC experts. "Experience with contracted CDISC standards data creation" was defined more broadly to encompass these implementation categories as well as external data creation performed without such internal expert-led acceptance procedures.

Further details regarding the questionnaire items are presented in Multimedia Appendix 1.

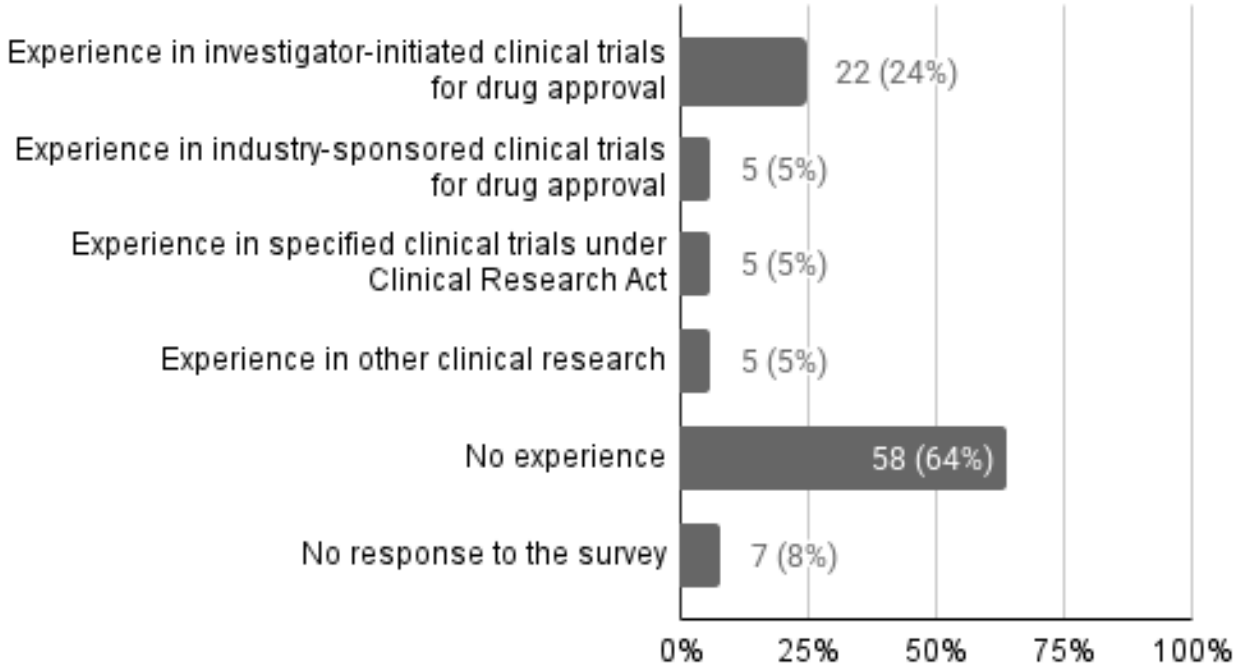
Statistical Analysis

Descriptive statistics were calculated using the total number of targeted institutions (n=91) as the denominator. This approach was adopted to establish a consistent baseline for future longitudinal surveys targeting the same population. Furthermore, using the total population as the denominator prevents the overestimation of implementation rates caused by selection bias—where institutions with greater interest in CDISC standards are more likely to respond—and ensures the results accurately reflect the status across all defined Japanese institutions. Categorical variables are presented as numbers and percentages. To assess the association of the number of data managers and biostatisticians with the CDISC implementation status, we performed the Mann-Whitney *U* test. In this analysis, the number of staff was treated as a continuous variable. Although staffing levels were categorized (0‐3, 4‐10, and ≥11) for visualization purposes, the statistical hypothesis testing was based on the continuous data. To examine potential confounders, we also analyzed the association between institution type (public/national vs private) and CDISC implementation using Fisher exact test. A *P* value <.05 was considered statistically significant. All statistical analyses were performed using R statistical software (version 4.4.1; R Foundation for Statistical Computing).

Results

Response Rate and Participant Characteristics

In this study, 91 institutions were targeted, among which responses were received from 84 (response rate: 92%). Of these, 7 (8%) institutions did not respond. The breakdown of the responding institutions was as follows: 42 national university hospitals, 27 private university hospitals, 7 public university hospitals, 7 national centers for advanced and specialized medical care, and 1 national hospital organization. No responses were received from ministry-affiliated university hospitals. The breakdown of respondents by job title is shown in Multimedia Appendix 2.



The percentages in these results were calculated with the total number of targeted institutions (N=91) as the denominator and rounded to the nearest integer, unless otherwise specified.

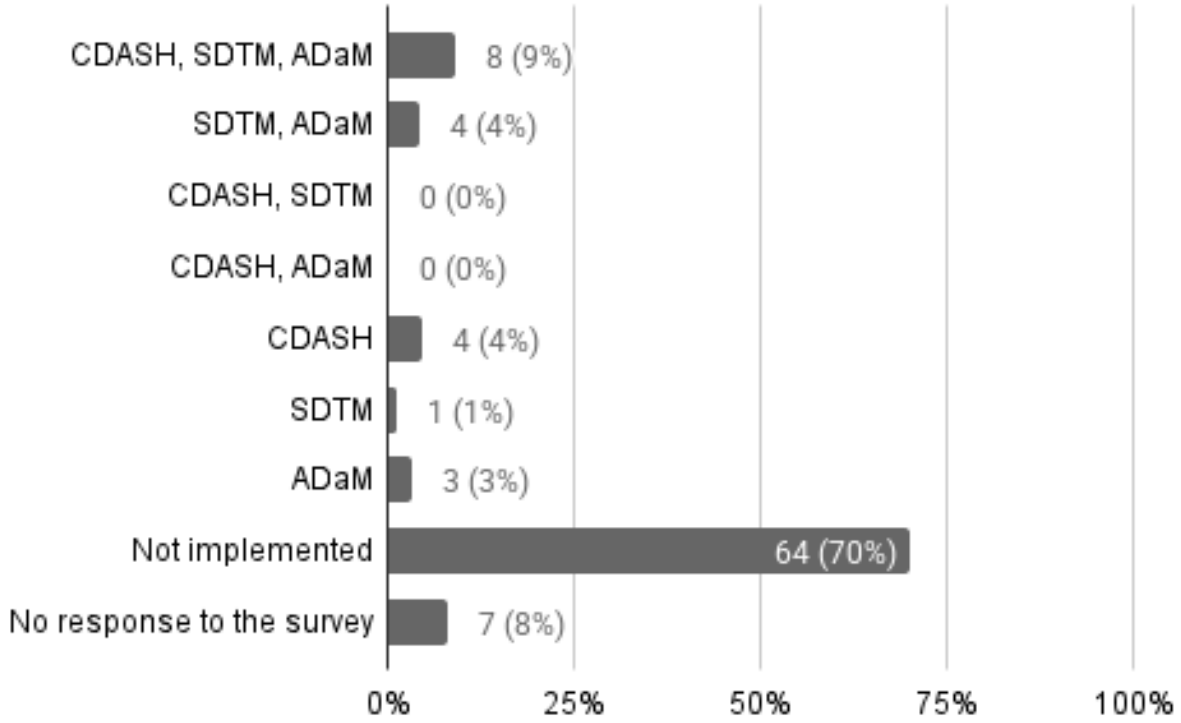
Experience With Contracted CDISC Standards Data Creation

Experience with contracted CDISC standards data creation refers to the track record of accepting projects for CDISC data creation. This includes cases where the actual data creation was outsourced to a third party. Regarding experience with contracted data creation using CDISC standards, 26 (29%) institutions reported having such experience, while 58 (64%) did not; 7 (8%) institutions did not respond to this question. Among the types of trials for which institutions had experience (multiple answers allowed), investigator-initiated clinical trials for drug approval were the most common, at 22 (24%), followed by industry-sponsored clinical trials for drug approval (n=5, 5%), specified clinical trials under Japan's Clinical Research Act [17] (n=5, 5%), and other clinical research (n=5, 5%) (Figure 1).

XSL•FO
RenderX

Figure 1. Experience with contracted Clinical Data Interchange Standards Consortium standards data creation (multiple responses allowed) (N=91).

These results indicate that slightly less than 30% (26/91) of the institutions had experience with contracted data creation using CDISC standards. Notably, this experience extends beyond trials for drug approval to include specified clinical trials and other clinical research.



Implementation Status of CDISC Standards

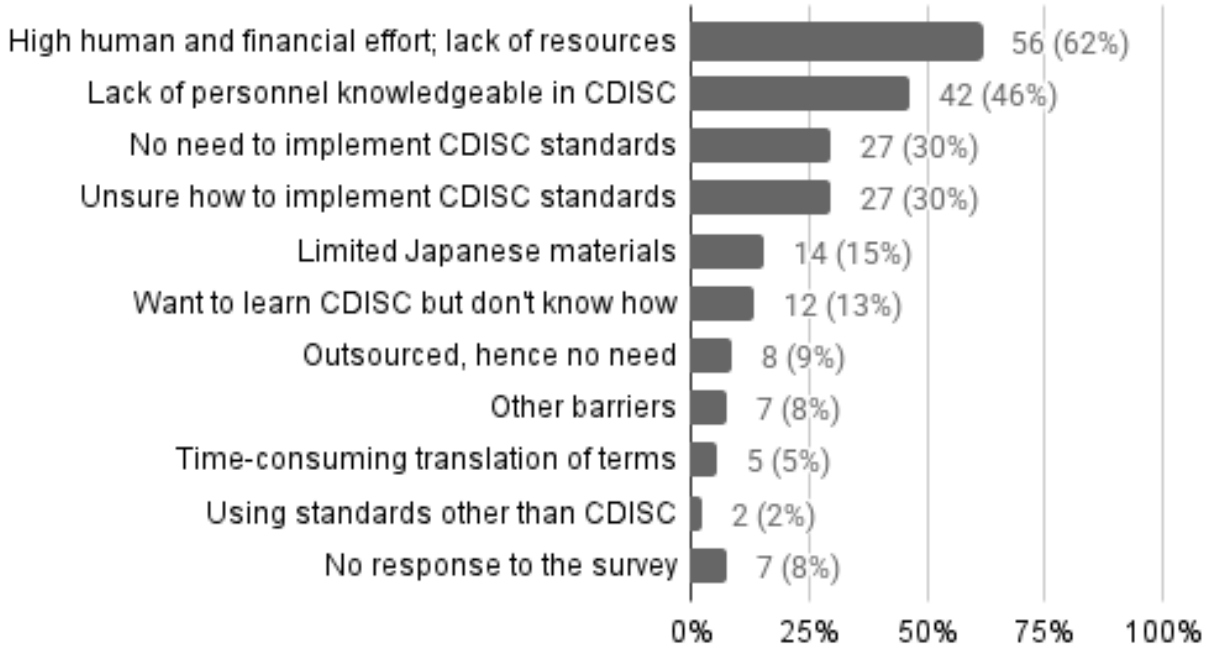
Implementation of CDISC standards refers to creating CDISC data using internal resources or, in the case of outsourcing, conducting acceptance work by CDISC experts. Regarding the implementation status of CDISC standards, 20 institutions (22%) reported having implemented them, whereas 64 institutions (70%) reported not having implemented them; seven institutions (8%) did not respond.

Among the 20 institutions that had implemented CDISC standards, the most common combination of standards (multiple answers allowed) was the implementation of all three—CDASH, the SDTM, and the ADaM—reported by eight institutions (9% of the 91 institutions). This was followed by institutions implementing SDTM and ADaM (n=4, 4%), CDASH only (n=4, 4%), ADaM only (n=3, 3%), and SDTM only (n=1, 1%) (Figure 2).

XSL•FO
RenderX

Figure 2. Implementation status of the Clinical Data Interchange Standards Consortium standards (N=91). ADaM: Analysis Data Model; CDASH: Clinical Data Acquisition Standards Harmonization; SDTM: Study Data Tabulation Model.

Regarding individual standards, ADaM was implemented by 15 (16%) institutions, SDTM by 13 (14%), and CDASH by 12 (13%).



These results indicate that while only 22% (20/91) of all institutions had implemented CDISC standards, many of these implementing institutions use multiple standards (CDASH, SDTM, and ADaM) in combination.

Barriers to CDISC Standards Implementation

Barriers with CDISC implementation refer to the obstacles or challenges that institutions face when attempting to adopt or maintain CDISC standards. Institutions cited the following items as barriers to CDISC standards implementation (multiple answers allowed). The most frequently cited barrier was “high human and financial effort and lack of resources” (n=56, 62%), followed by “lack of personnel knowledgeable in CDISC” (n=42, 46%), “no need to implement CDISC standards” (n=27, 30%), and “unsure how to implement CDISC standards” (n=27, 30%) (Figure 3).

XSL•FO
RenderX

Figure 3. Barriers to CDISC standards implementation (multiple responses allowed). Note: Percentages were calculated based on the total number of survey targets (N=91). "No response to the survey" indicates institutions that did not answer this survey entirely. CDISC: Clinical Data Interchange Standards Consortium.

These results indicate that the main barriers to CDISC standards implementation are the significant human and financial effort required, resource shortages, and a lack of personnel knowledgeable about CDISC.

Future Policies Regarding CDISC Standards-Compliant Data Creation

Regarding future policies for CDISC standards-compliant data creation (single answer), the most common response, reported by 60 (66%) institutions, was "no decision made," followed by "will not undertake" (n=7, 8%), "will undertake, and external experts will perform the work with internal involvement" (n=6, 7%), "will undertake, and both internal and external personnel will perform the work" (n=5, 5%), "will undertake, but only external experts will perform the work without internal involvement" (n=5, 5%), and "will undertake, and the work will be performed internally" (n=1, 1%) (Table 1). These results indicated that 66% (60/91) of the institutions had not yet decided on their future policy; only 19% (17/91) had a clear policy for undertaking such work.

Table . Future policies regarding CDISC[a] standards-compliant data creation (N=91).[b]

Future policy regarding CDISC compliance	All institutions (N=91), n (%)	Currently implemented (n=20), n (%)	Currently not implemented (n=64), n (%)
Internal execution	1 (1)	1 (5)	0 (0)
Joint internal and external execution	5 (5)	3 (15)	2 (3)
External execution with internal involvement	6 (7)	5 (25)	1 (2)
External execution without internal involvement	5 (5)	1 (5)	4 (6)
Will not undertake	7 (8)	2 (10)	5 (8)
No decision made	60 (66)	8 (40)	52 (81)
No response to the survey	7 (8)	—[c]	—

[a]CDISC: Clinical Data Interchange Standards Consortium.

[b]Note: All values are n (%); percentages are calculated based on the total number of survey targets (N=91). "Implemented" and "not implemented" columns represent the current status at the time of the survey, where "implementation" is defined as internal CDISC data creation or expert-led acceptance work for outsourced tasks. "No response to the survey" refers to institutions that did not return the questionnaire.

[c]Not available.

The association between current implementation status and future policies is detailed in Table 1. Among the 20 institutions that had already implemented the standards, fewer than half (9 institutions, 45%) intended to continue "implementation"

XSL•FO
RenderX

(defined as work involving internal resources or internal expert-led acceptance). A similar lack of interest was observed among the 64 nonimplementing institutions, with only 3 (5%) planning for future implementation.

CDISC Standards Implementation Resources: Availability and Ability to Provide

Among all, 15 (16%) institutions reported having documents or training related to implementing CDISC standards. A breakdown of these resources (multiple answers allowed) indicated that "beginner-level training" was the most common, reported by 12 (13%) institutions, followed by "Japanese-language educational materials" (n=9, 10%), "documents on implementation know-how" (n=8, 9%), and "tools supporting CDISC" (n=8, 9%) (Table 2).

Table . Availability of and ability to provide CDISC[a] standards-related documents and training (multiple responses allowed) (N=91).[b]

Item	Availability, n (%)	Ability to provide, n (%)
Japanese-language educational materials on CDISC standards	9 (10)	4 (4)
Documents on implementation know-how for CDISC standards	8 (9)	4 (4)
Tools supporting CDISC standards implementation	8 (9)	4 (4)
Beginner-level training on CDISC standards	12 (13)	5 (5)
No response to the survey	7 (8)	7 (8)

[a]CDISC: Clinical Data Interchange Standards Consortium.

[b]Note: Percentages were calculated based on the total number of survey targets (N=91). "No response to the survey" indicates institutions that did not answer this survey entirely.

Next, regarding the question of whether these documents and training could be provided to other institutions, 5 (5%) institutions responded that they "could provide" them. A breakdown of providable resources is shown in Table 2.

These results indicate that while 16% (15/91) of institutions had CDISC standards implementation resources available, only 5% (5/91) were able to provide these resources to other institutions.

Support Expected From and Providable to Pharmaceutical Companies, CROs, and Other AROs

Regarding expectations for pharmaceutical companies, CROs, and other AROs (multiple answers allowed), 60 (66%) institutions responded that they had "some expectations." Among these 60 institutions, the most desired item was "materials and information on CDISC" (n=53, 58%), followed by "training sessions (seminars, workshops, etc) on CDISC" (n=45, 49%) and "on-the-job training related to CDISC" (n=33, 36%) (Table 3).

Table . Expectations for and ability to provide support to pharmaceutical companies, contract research organizations, and other academic research organizations (multiple responses allowed) (N=91).[a]

Item	Expectations, n (%)	Ability to provide, n (%)
Training sessions (seminars, workshops, etc) on CDISC[b]	45 (49)	2 (2)
On-the-job training related to CDISC	33 (36)	2 (2)
Materials and information on CDISC	53 (58)	4 (4)
No response to the survey	7 (8)	7 (8)

[a]Note: Percentages were calculated based on the total number of survey targets (N=91). "No response to the survey" indicates institutions that did not answer this survey entirely.

[b]CDISC: Clinical Data Interchange Standards Consortium.

Next, regarding support that could be provided to pharmaceutical companies, CROs, and other AROs (multiple answers allowed), 5 (5%) institutions responded that they "could provide" some support. A breakdown is shown in Table 3.

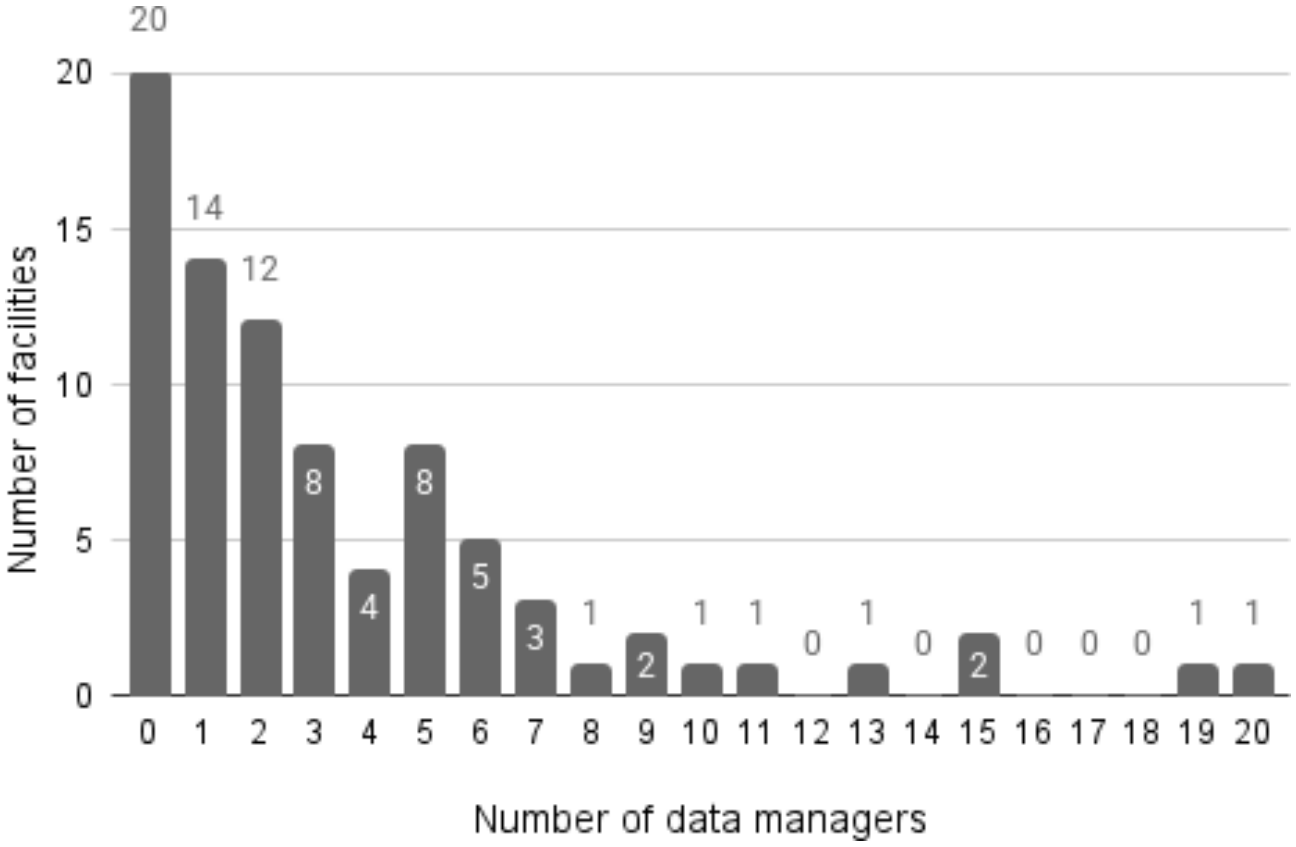
These findings revealed that 66% (60/91) of the institutions expected CDISC-related material provision, information sharing, and workshop hosting from pharmaceutical companies, CROs, and other AROs. On the other hand, only 5% (5/91) of the institutions were able to provide such support, indicating a limited capacity.

Number of Data Managers and Biostatisticians

Among the 84 responding institutions, the median number of data managers was 2 (mode: 0; range: 0‐20) (Figure 4). Similarly, the median number of biostatisticians was 2 (mode: 1, range: 0‐13) (Figure 5).

XSL•FO
RenderX

Figure 4. Number of data managers at responding facilities (n=84). Note: Analysis excluded the 7 institutions that did not respond to the survey.



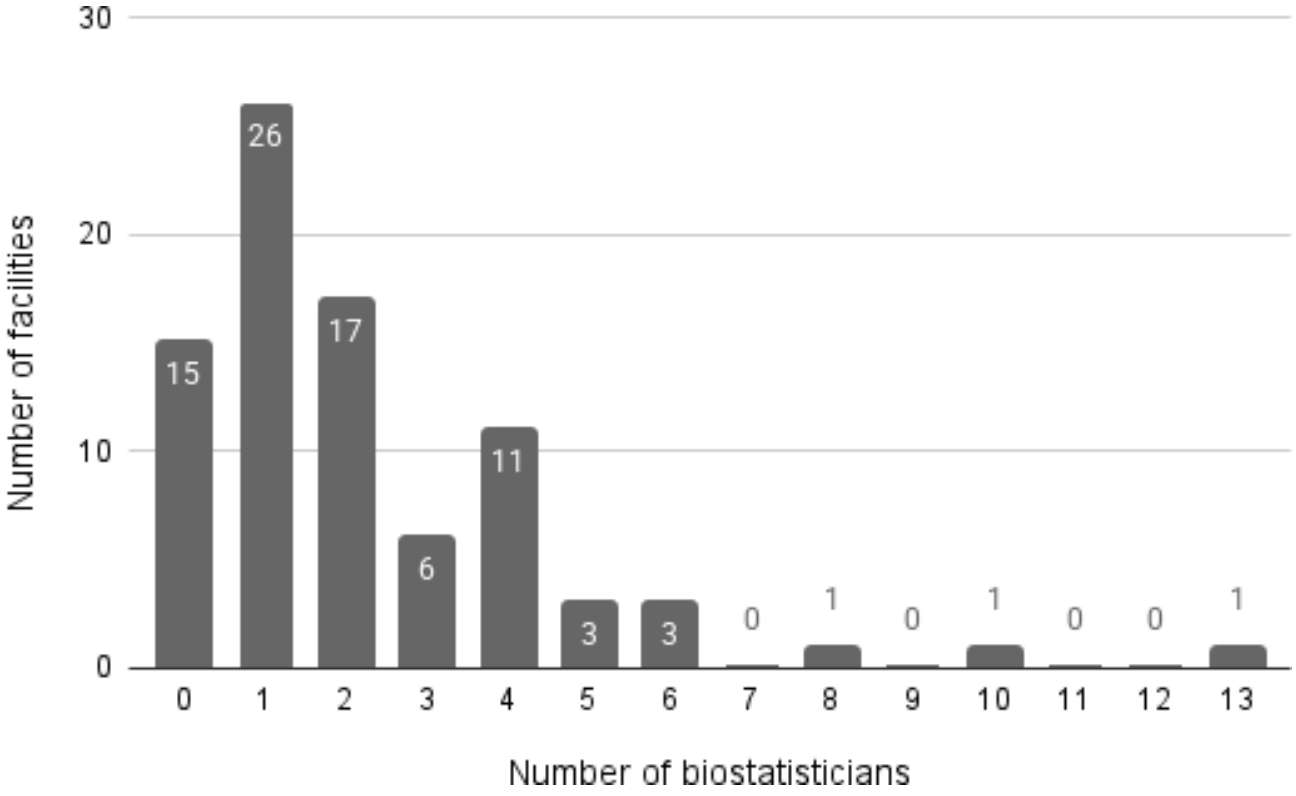


Figure 5. Number of biostatisticians at responding facilities (n=84). Note: Analysis excluded the 7 institutions that did not respond to the survey.

Association Between Staffing Levels and CDISC Standards Implementation Status

An analysis of the relationship between staffing levels and CDISC implementation showed that institutions with more data managers tended to be more advanced in their implementation (median 5, IQR 2 - 9.25 vs median 2, IQR 0 - 4; *P*<.001) (Figure 6). A similar trend was observed for biostatisticians (median 3.5, IQR 1.75 - 5 vs median 1, IQR 1-2; *P*<.001) (Figure 7).

XSL•FO
RenderX

Figure 6. Number of data managers and status of Clinical Data Interchange Standards Consortium standards implementation (n=84). Note: Analysis excluded the 7 institutions that did not respond to the survey. Data were categorized for visualization purposes, while the Mann-Whitney *U* test was performed on continuous variables (*P*<.001).

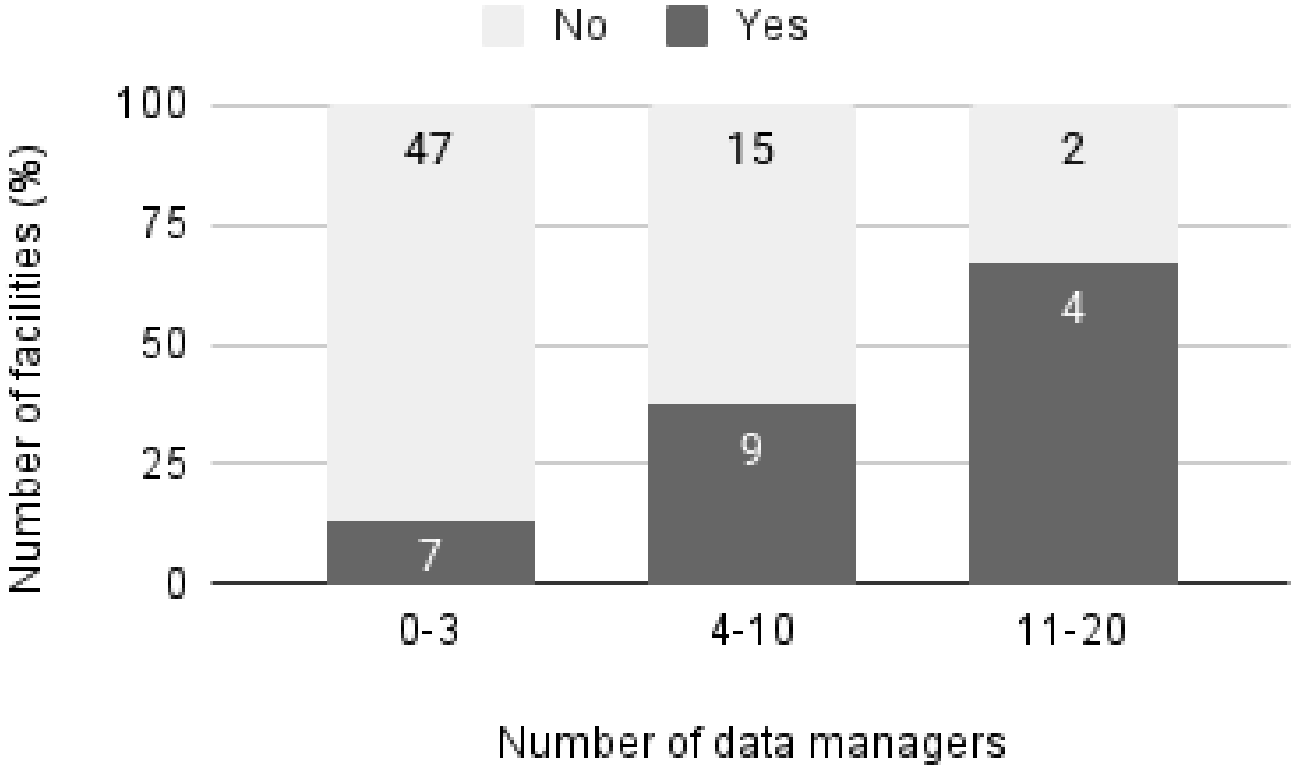

Figure 7. Number of biostatisticians and status of Clinical Data Interchange Standards Consortium standards implementation (n=84). Note: Analysis excluded the 7 institutions that did not respond to the survey. Data were categorized for visualization purposes, while the Mann-Whitney *U* test was performed on continuous variables (*P*<.001).

These findings suggest that institutions with more data managers and biostatisticians tend to be further along in implementing CDISC standards.

In addition to staffing levels, we evaluated the association between institution type and CDISC implementation. Implementation rates were 28.1% (16/57) in Public/National

XSL•FO
RenderX

institutions and 14.8% (4/27) in private institutions; however, no significant difference was observed (Fisher exact test, *P*=.27).

Discussion

Current Status and Significance of CDISC Standards Implementation

In a questionnaire survey conducted in 2020 to clarify the current status of and challenges associated with CDISC standards implementation in Japanese academic medical centers [16], the definition of "academia" was ambiguous, which posed challenges in interpreting the results and tracking changes over time. Therefore, in the present study, "academia" was more strictly defined to ensure the accuracy of longitudinal comparisons. By selecting institutions based on this clear definition, the present study could assess the current status and challenges associated with implementing CDISC standards more accurately, thereby providing foundational data to promote future adoption.

In a questionnaire survey conducted in 2020 to clarify the current status of and challenges associated with CDISC standards implementation in Japanese academic medical centers [16], the definition of "academia" was ambiguous, which posed challenges in interpreting the results and tracking changes over time. Therefore, in the present study, "academia" was more strictly defined to ensure the accuracy of longitudinal comparisons. By selecting institutions based on this clear definition, the present study could assess the current status and challenges associated with implementing CDISC standards more accurately, thereby providing foundational data to promote future adoption.

The findings revealed that only 29% (26/91) of institutions had experience with contracted CDISC standards data creation. Furthermore, institutions with experience in contracted data creation most frequently undertook investigator-initiated clinical trials for drug approval. This finding suggests that the application of CDISC standards in Japan, particularly that centered around investigator-initiated clinical trials for drug approval, is progressing. On the other hand, the present findings also confirmed that institutions had some experience in contracted CDISC standards data creation for specified clinical trials under the Clinical Research Act and other clinical research not intended for marketing approval applications. These findings suggest that CDISC standards are being used not only for regulatory submissions but also for standardizing and improving the efficiency of overall clinical research operations. In addition, it has been reported internationally that CDISC standards are also being used for Real-World Data [18]. We believe that clarifying the significance of standardization and efficiency and sharing practical case studies could lead to the promotion of CDISC standards implementation.

Regarding the implementation status of CDISC standards, the present study found that only 22% (20/91) of institutions had implemented them, indicating limited adoption. Notably, this study confirmed that while a high proportion of implementing institutions adopt multiple CDISC standards in combination, a certain number of institutions implement only individual standards. These results suggest that varying needs and resource situations at each institution may influence the form of CDISC standards implementation.

Barriers to CDISC Standards Implementation

Regarding implementation barriers, this study confirmed that "human and financial effort and resource shortages" remains the greatest challenge, followed by "a lack of personnel knowledgeable about CDISC." This finding suggests that securing human and financial resources and developing CDISC specialist personnel within institutions are crucial for promoting CDISC standards implementation. The findings also revealed that only 16% (15/91) of institutions possess documents or training related to CDISC standards, and furthermore, only 5% (5/91) of institutions can provide these resources to other institutions, which suggests that the expansion of CDISC-related educational resources within the country remains a challenge. We hypothesize that this discrepancy may stem from proprietary restrictions, copyright issues, or the lack of generalized templates that can be easily shared across institutions. In AROs in other countries as well, there is a demand not only for formal training by experts but also for open-source resources and "bite-sized" educational materials that are easily accessible online, such as the W3Schools model, as suggested by Jentoft et al [19]. Therefore, developing similar practical and accessible educational resources may serve as an important strategy for addressing the shortage of training materials in Japan.

Regarding barriers to implementation, 27 (30%) institutions cited "no need to implement CDISC standards." Within this group, some respondents cited "outsourced, hence no need." Furthermore, our detailed analysis revealed that the majority of these 27 (81%, 22/27) institutions selected "will not undertake" or "no decision made" regarding their future policies on CDISC standards-compliant data creation. The primary reason for these responses is likely that the PMDA requires CDISC compliance exclusively for new drug marketing approval applications, whereas many institutions primarily conduct research under the Clinical Research Act that falls outside this mandate. We included these institutions in our analysis to accurately reflect the current status of adoption, as excluding them would overlook the reality that a significant segment of academia operates outside the regulatory scope.

Regarding the respondents who cited outsourcing, it is important to distinguish this group from institutions that outsource but are considered to have "implemented" CDISC standards. As defined in our survey, "implementation" via outsourcing requires the institution to perform acceptance work using internal CDISC experts. In contrast, we interpret that respondents viewing outsourcing as a reason for nonimplementation may rely entirely on vendors without maintaining internal standards or oversight capabilities. However, as acknowledged in the Limitations section, the lack of explicit definitions in the survey may have led to variations in respondent interpretation regarding this distinction.

XSL•FO
RenderX

Future Policies and Opportunities for Strategic Support

Furthermore, the finding that a significant majority of institutions (66%, 60/91; Table 1) have made "no decision" regarding future CDISC policy suggests a deeper issue than mere resource constraints. Notably, this trend extends even to institutions that have already implemented CDISC standards. Half of these institutions (11/20) are uncertain about, or have decided against, continuing the implementation of CDISC-compliant data in the future, suggesting serious challenges in the sustainability of CDISC operations. This strategic inertia may indicate a systemic barrier, potentially stemming from the lack of regulatory incentives or clear mandates for the application of CDISC standards in clinical research not aimed at marketing approval. We considered that addressing this structural uncertainty is essential to enable institutions to commit to definitive standardization strategies.

While experienced AROs can play a pivotal role in driving adoption, the survey results indicate that 66% (60/91) of institutions specifically expect support from "pharmaceutical companies, CROs, and other AROs," with a primary desire for "materials and information." This highlights that academic institutions often cannot address the implementation gap on their own. Therefore, future strategies should not rely exclusively on peer-to-peer academic support but should also leverage industry resources. Active involvement and support from pharmaceutical companies and CROs were considered essential to provide the resources needed to bridge the gap between supply and demand.

Association Between Staffing Levels and Implementation

The present findings revealed significant variation among institutions in terms of the number of data managers and biostatisticians on staff. However, institutions with more of these specialists tended to be further along in regard to implementing CDISC standards. This result suggests that securing personnel with specialized knowledge is important for the effective implementation of CDISC standards, and as such, data managers and biostatisticians play a central role in the implementation process.

Limitations

A major limitation of this study is that adjustments for institutional resources such as hospital bed count or budget were not performed; these factors may be stronger determinants of CDISC adoption than staffing levels alone. The observed association between dedicated staffing and implementation may, therefore, be a reflection of overall institutional size or resource availability. Furthermore, the primary outcome variable, CDISC implementation status, was based solely on self-reported metrics from respondents and was not verified by external audit or inspection of the actual data standards used. This introduces the potential for response bias, such as the overestimation of institutional compliance. Finally, we acknowledge the nonresponse from specific institutional types; specifically, no responses were received from ministry-affiliated university hospitals. However, as this institutional category comprised only 1.1% (1/91) of the total institutions surveyed, the impact on the overall representativeness of Japanese academic medical centers is likely minimal. Furthermore, this study relies on self-reported data, which may be subject to respondent bias or misunderstanding of technical terms. For instance, a small number of sites reported implementing "ADaM only" without SDTM. Given that ADaM datasets are typically derived from SDTM, this discrepancy suggests a potential lack of accurate understanding of the standards among some respondents. Therefore, the results regarding technical proficiency should be interpreted with caution as they represent the respondents' subjective assessments rather than objectively verified capabilities. Furthermore, the questionnaire option labeled "outsourced, hence no need" was presented without explicit definitions distinguishing between outsourcing as a form of implementation and outsourcing as a reason for nonimplementation. Consequently, respondents may have selected this option based on their own interpretation. This lack of clarity may have led to misclassification, where institutions that had successfully implemented the system via outsourcing (with internal acceptance work) categorized themselves as having "no need."

Recommendations and Future Work

Therefore, developing these specialized human resources is likely essential for promoting their adoption. Expanding training opportunities and improving access to information regarding CDISC standards are key to promoting their wider adoption in Japanese academic medical centers.

Conclusions

The findings of the present study indicate that the implementation of CDISC standards in Japanese academic medical centers remains limited. The primary barrier identified was a lack of human and financial resources. On the other hand, many institutions are interested in implementing CDISC standards and seeking support such as workshops and the provision of materials. To bridge the gap between this high demand and the limited supply, future strategies should involve not only peer-to-peer academic support but also active resource sharing and cooperation from pharmaceutical companies and CROs. Notably, instances were observed where CDISC standards were being used even in clinical research not directly aimed at marketing approval applications, which is interpreted as a preliminary indication of the potential recognition within the research community of the operational efficiencies gained through standardization. Furthermore, the present findings suggest that the number of data managers and biostatisticians on staff is strongly associated with the implementation status of CDISC standards.

Abstract

Background: Electronic medical records are a vast and valuable source of information, useful for tasks such as estimating disease prevalence. However, in routine primary care, much of this information is in free-text format rather than in a structured form and, therefore, not readily amenable to analysis. Manual coding of this textual data is both time-consuming and resource-intensive, making it impractical for large datasets. Although powerful open-source language models offer new opportunities for automated coding, their use on short heterogeneous primary care notes, particularly in German-language settings, remains insufficiently studied.

Objective: By providing hands-on guidance for applied health researchers, this study aims to demonstrate the effective and accurate automatic classification of free-text notes using a language model fine-tuned for automated *International Statistical Classification of Diseases, Tenth Revision* (*ICD-10*) coding.

Methods: Building on the extensive Family Medicine Research Using Electronic Medical Records (FIRE) routine database from the Institute of Primary Care at the University Hospital Zurich and the University of Zurich, we trained a large language model–based multilabel classifier on a dataset of 38,728 free-text notes, which had been manually categorized into 47 classes using specific *ICD-10* codes and code ranges or nondiagnostic/ad hoc labels (eg, “unclear diagnosis,” “status post”). We stratified the labeled data into training (70%), validation (15%), and posttraining test (15%) sets, ensuring similar label distributions across these sets. Using the Transformers Python library, we trained the model over 10 epochs and evaluated it on the posttraining test dataset.

Results: Across 48 classes, the FIRE classifier achieved strong performance on the held-out posttraining set, with F_1-scores of 0.85 (micro, overall across all predictions), 0.86 (macro, mean of per-class scores treating classes equally), and 0.84 (weighted, per-class scores weighted by class frequency).

Conclusions: This study demonstrates steps for training open-source large language models and highlights the potential to streamline and scale the extraction of diagnostic information for practical applications. Our model can be robustly deployed, for example, for prescreening and labeling of free-text information, thus potentially reducing the burden of repetitive and error-prone manual handling.

Introduction

Electronic medical records (EMRs) contain rich diagnostic information, but in routine primary care, much of this information is documented in short unstructured free-text format rather than as structured records. As a result, large-scale analysis and reuse of diagnostic data remains challenging, since manual coding of free-text notes is both time-consuming and resource-intensive, making it impractical on a large scale. Therefore, automated assignment of diagnostic codes, in particular from the *International Statistical Classification of*

XSL•FO
RenderX

Diseases, Tenth Revision (*ICD-10*), has long been of practical interest for research and health care.

The emergence of powerful open-source language models offers new opportunities to automate text-based diagnosis extraction for research or health care. Transformer-based models like bidirectional encoder representations from transformers (BERT) and generative pretrained transformers have gained traction for *ICD-10* coding of clinical texts, achieving strong performance on English language EMR datasets [1,2]. However, research on the classification of text data into *ICD-10*–anchored classes has been conducted mainly in English [1]. While recent studies demonstrate that domain-adapted transformer models can perform well on non-English clinical texts—including Portuguese [3], French [4], and Spanish [5,6]—the availability of data and pretrained models varies widely across languages. For German clinical texts, resources remain limited, and existing work has largely focused on well-structured, high-quality documents such as discharge summaries or surgery reports. In routine primary care documentation in particular, notes are often short, loosely structured, and heterogeneous. Diagnostic coding may also combine *ICD-10* codes with administrative or primary care–specific systems such as the *International Classification of Primary Care*. These characteristics limit the direct reuse of existing models and underscore the need for approaches that are robust to real-world data and adaptable to local coding practices.

Taken together, these factors—a scarcity of annotated German clinical text datasets from routine care, the predominance of English language research, and the short heterogeneous nature of primary care notes—leave little guidance on how to adapt open-source large language models (LLMs) for routine use in German primary care. To address this gap, our study describes the implementation of a flexible, German-language, multilabel LLM classifier for real-world free-text notes in primary care. Although focused on a German-language dataset, the methodological approach may serve as a blueprint in settings beyond English.

Methods

Data Source: The Family Medicine Research Using Electronic Medical Records Database

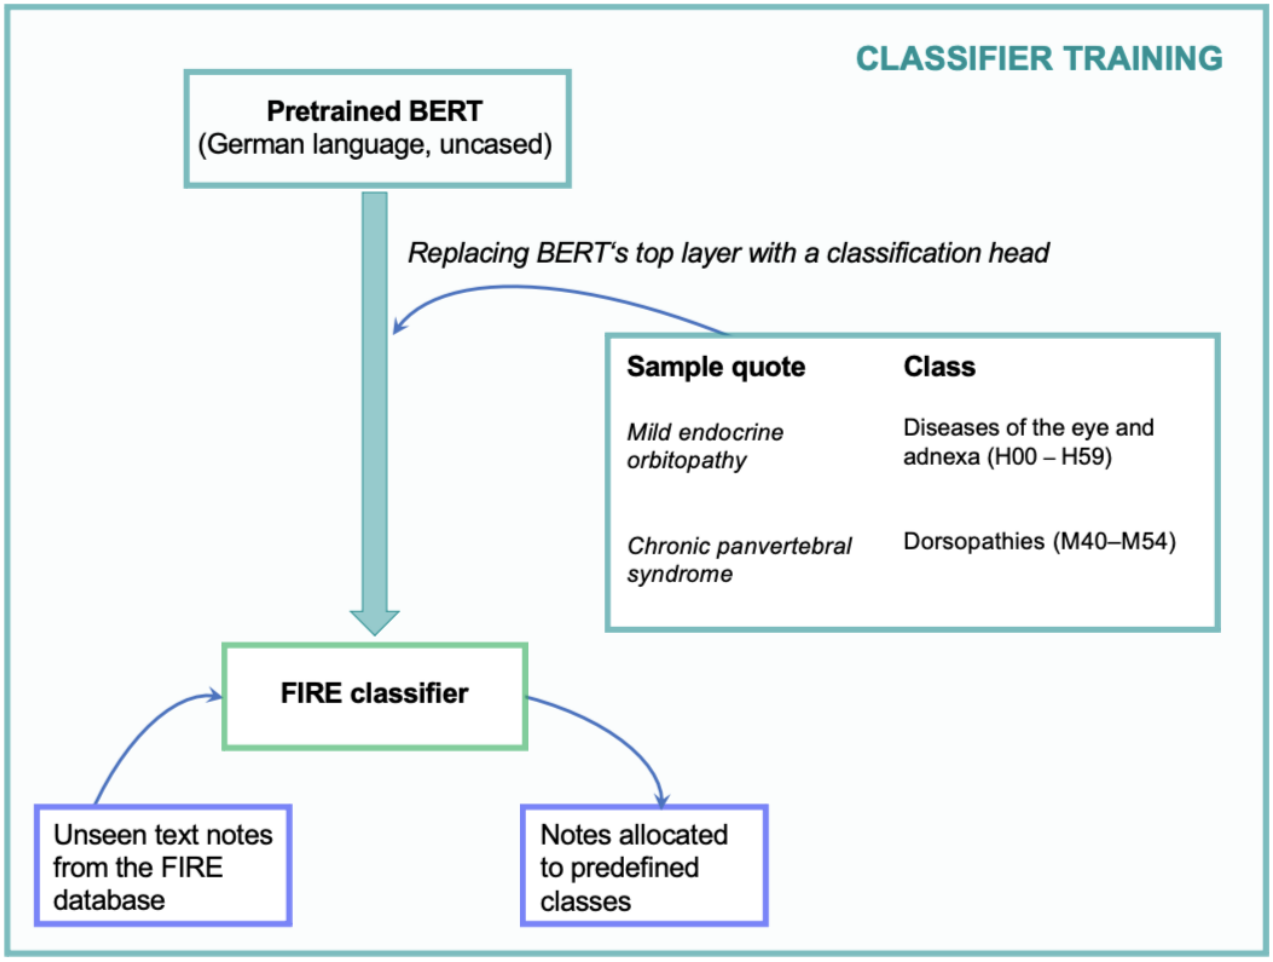
The Swiss Family Medicine Research Using Electronic Medical Records (FIRE) database was initiated in 2009 and has been designed as a basic knowledge base for primary care research through the use of EMRs [7]. So far, the FIRE project has enrolled around 450 general practitioners throughout Switzerland who are willing to contribute their patients' EMRs to the database. General practitioners in the FIRE project routinely document patient encounters—in clinics, at home, or by phone—and records are regularly exported to the FIRE database. The reasons for physician encounters are encoded using the *International Classification of Primary Care, 2nd edition*, albeit not systematically by all participating clinicians. Instead, many participating physicians often include unstructured free-text notes, particularly in the health problems and diagnoses fields, where diagnostic and health care use information is recorded.

Ethical Considerations

The local ethics committee of the Canton of Zurich waived approval for research with the FIRE database because patient data is fully anonymized and, therefore, outside the scope of the Swiss Human Research Act (BASEC-Nr. Req2017– 00797). The study was conducted in accordance with the Declaration of Helsinki and Good Clinical Practice guidelines.

Diagnosis and Problem List Free-Text Notes

This study used manually annotated free-text notes from the diagnosis and problems lists in Swiss general practitioners' EMRs. In Swiss primary care, these lists function as longitudinal note-based records with brief entries summarizing patients' current and past health problems (eg, "hypertension," "low back pain") as well as related events or observations. Each note represents a single, concise observation that persists across consultations, as structured diagnostic coding is not routinely used in Swiss outpatient care.



Training an LLM-Based Classifier for Automated Text Classification

Overview

All analyses and visualizations were performed in Python (version 3.11; Python Software Foundation), using the Jupyter Notebook environment (version 2024.3.2; Project Jupyter). Individual analysis steps and specific Python libraries are detailed in the following sections. The overall procedure is visualized in Figure 1. The Jupyter Notebook containing the Python code and complete model training output is provided in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 1. The figure visualizes the modeling procedure to build the multilabel classifier based on the FIRE dataset. BERT: bidirectional encoder representations from transformers; FIRE: Family Medicine Research Using Electronic Medical Records.

Step 1: Ground Truth Data for Classifier Training

We worked with a total of 53,481 free-text notes, incorporating data from Wallnöfer et al [8] and additional notes annotated thereafter (n=26,501, 49.6%). Wallnöfer et al [8] developed an *ICD-10*–anchored framework comprising 105 diagnostic codes, including both individual *ICD-10* codes and code ranges, as well as a nonspecific "no diagnosis" category. For the present study, a subset of these codes was consolidated into broader groups by combining related diagnostic categories into higher-level ICD classifications, resulting in 44 categories. In addition, three less specific encounter codes not included in the original framework were introduced—"suspected diagnosis," "unclear," and "status post"—bringing the total to 47 categories. Reported interrater reliability for the original codes used in this study—either directly or in aggregated form—ranged from moderate to almost perfect (κ=0.53-0.98); however, these values are not directly transferable to the aggregated categories. For the Wallnöfer et al [8] dataset (n=26,980, 50.4%), two physician raters independently coded the notes (full details are reported in Wallnöfer et al [8]). The remaining 26,501 (49.6%) notes were annotated by a single trained physician.

Step 2: Data Preprocessing

To create a more balanced dataset, we reduced the number of entries for the most heavily overrepresented *ICD-10* code range Z00-Z99 "factors influencing health status and contact with health services," which occurred in 42.5% (n=22,714) of all free-text notes, either alone or in combination with other labels. Specifically, we removed all 14,316 free-text entries assigned exclusively to this code range, reducing the overall dataset to 38,728 free-text notes. As a result, this code range's representation was reduced to 8226 (21.2%), reflecting only those entries where Z00-Z99 appeared alongside other labels.

Step 3: Subdividing the Data Into Training, Validation, and Posttraining Test Data

We then divided the preprocessed dataset (n=38,728) into three parts: 70% (n=27,108) for training, 15% (n=5810) for validation during training, and 15% (n=5810) for final testing. To ensure each class label was proportionally represented in all three sets, we used a stratified splitting process based on the final list of 47 labels, using the *iterstrat* Python package and its MultilabelStratifiedShuffleSplit class for multilabel stratified splitting. In other words, if a particular class made up, for instance, 10% of the entire dataset, it also contained roughly 10% of the training set, 10% of the validation set, and 10% of the posttraining test set.

Step 4: Model Training

To build our classifier, we used a German BERT LLM (dbmdz/bert-base-german-uncased) from the Hugging Face

XSL•FO
RenderX

model hub [9] and replaced its top layer with a classification head to identify the 47 classes in unstructured medical free text. Tokenization was performed using the pretrained tokenizer associated with GermanBERT, a German-language–specific model; no multilingual or custom tokenization was applied (see executed Python script in Multimedia Appendix 1). The model's maximum input length was 512 tokens. No truncation was applied during training or inference, and the model always processed the complete note (median 15 tokens, mean 18 tokens, maximum 111 tokens). Since a single free-text note may belong to multiple categories, we used a multilabel classification approach to allow the assignment of several labels to each note. For model training, we used the Trainer class from the Transformers [10] Python library, which streamlines model training and metric calculation. We set the decision threshold for the binary predictions (true/false) at 0.5 per class.

Step 5: Classifier Evaluation During Training

We monitored evaluation metrics across all 10 epochs throughout training. During each epoch, the model iterated over all training batches, updating its weights via backpropagation based on the binary cross-entropy training loss.

Overall Model Evaluation

After each epoch, we evaluated model quality on the validation set. We first recorded training loss—the average discrepancy between predictions and ground truth on the training data; lower is better. We computed the same metric on the validation set (validation loss) to assess generalization: if validation loss falls and then rises while training loss keeps falling, the model is starting to memorize rather than generalize. We also tracked the microaveraged F_1-score (the harmonic mean of precision and recall), which gives more weight to more frequent classes. In addition, we measured the area under the receiver operating characteristic curve, summarizing how well the model separates positives from negatives across all thresholds (values near 1 indicate excellent separation; values near 0.5 indicate chance performance). Finally, because examples can have multiple labels, we reported subset (exact match) accuracy on the validation set—the fraction of examples for which every label is predicted correctly.

Per-Class Evaluation

Because each free-text note could belong to multiple classes, we examined model performance for each label individually using precision, recall, and F_1-score metrics. These metrics are particularly informative for multilabel classification because they capture how well the model identifies positive cases (recall), avoids false positives (precision), and balances both aspects (F_1-score). Accuracy was not used on a per-class basis, as it is dominated by true negatives in imbalanced datasets and may, therefore, provide a misleading indication of classifier performance.

Step 6: Classifier Evaluation on the Posttraining Test Data

The classifier was subsequently evaluated on the held-out 15% posttraining test set, which had not been used during model training or validation.

Overall Model Evaluation

To provide an overall measure of performance across all diagnostic labels, we calculated the micro-, macro-, and weighted averages of precision, recall, and F_1-score. The microaveraged metrics combine all true and false positives and negatives across labels, capturing the model's overall ability to classify instances correctly. The macroaveraged scores assign equal weight to each label, offering a balanced view that is not influenced by class frequency. In contrast, the weighted average metrics account for label prevalence, summarizing performance in proportion to how often each label occurs in the data.

Per-Class Evaluation

To complement the aggregate measures, the classifier's performance was also examined for each diagnostic category in the posttraining test set. For every label, precision, recall, and F_1-score were computed based on the corresponding ground truth and predicted binary vectors. These per-class metrics highlight how accurately the model distinguishes between individual diagnostic groups, allowing detailed insight into which classes were predicted most reliably and which proved more challenging.

Results

Overview

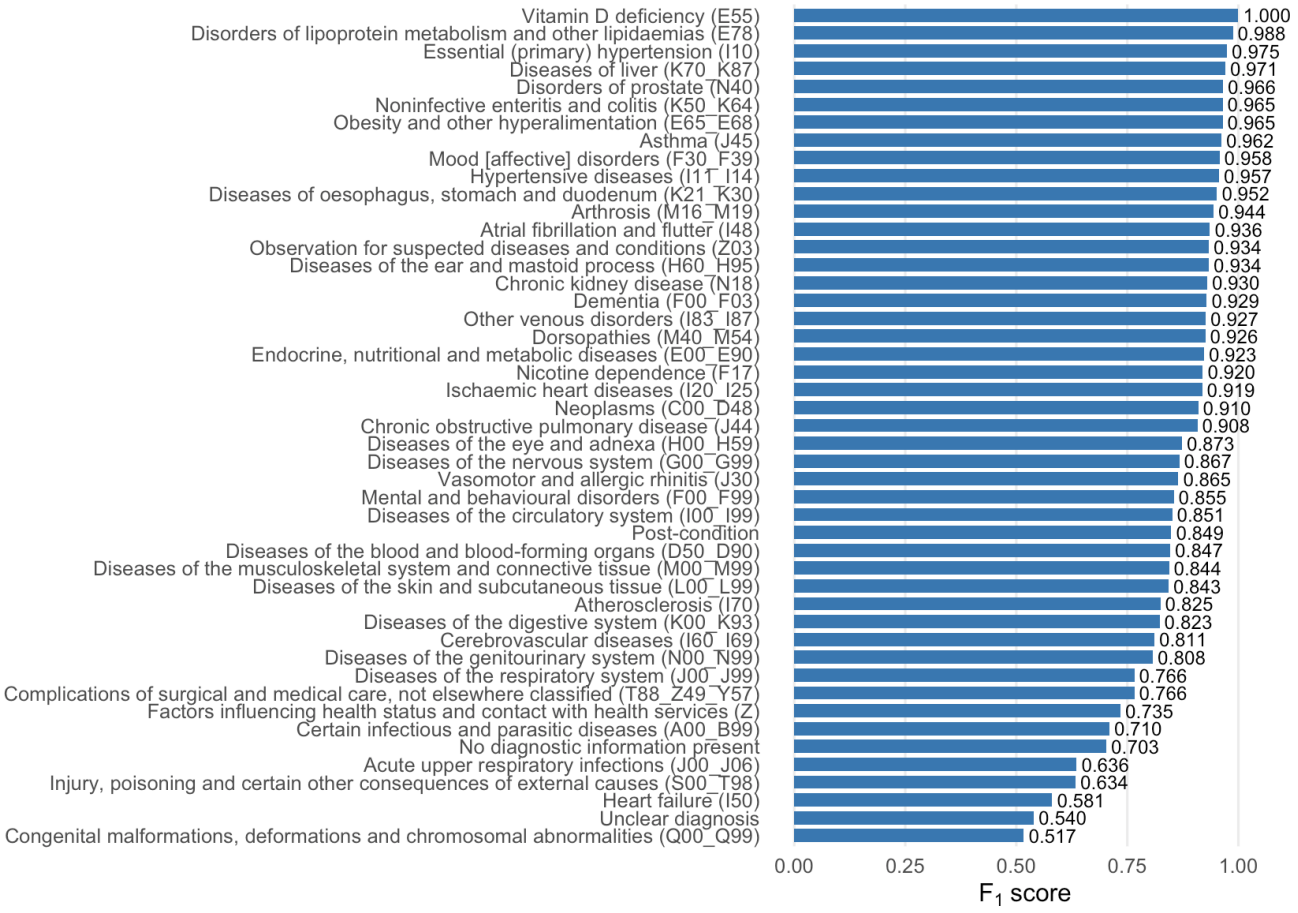
On average, each free-text note was assigned to 1.27 different classes, with the number of classes per free-text note ranging from 1 to 4. The class with the highest number of free-text notes was the umbrella class "factors influencing health status and contact with health services" (Z00-Z99; n=8226). Other classes with particularly high counts included "status post diagnosis" (n=3655) and "diseases of the musculoskeletal system and connective tissue" (M00-M99; n=2883). Conversely, classes such as "dementia" (F00-F03; n=97), "heart failure" (I50; n=116), and "acute upper respiratory infections" (J00-J06; n=163) were among those with the lowest number of free-text notes.

Monitoring Model Metrics

All model metrics during training and for the test data are provided in Multimedia Appendix 1.

Model Metrics During Training

Over the course of 10 training epochs, overall model performance reached a plateau, with the highest F_1-score reaching 0.85 achieved at epoch 10, indicating convergence of model learning. Overall model accuracy at this point was 0.75, and the area under the receiver operating characteristic curve equaled 0.92. The trained FIRE classifier demonstrated robust performance across the majority of classes; specifically, precision during training averaged 0.88 (SD 0.08), recall averaged 0.84 (SD 0.14), and the F_1-score averaged 0.86 (SD 0.11).



Performance on Posttraining Test Data

Across 47 classes, the FIRE classifier achieved strong performance on the held-out posttraining set, with F_1-scores of

XSL•FO
RenderX

0.85 (micro, overall across all predictions), 0.86 (macro, mean of per-class scores treating classes equally), and 0.84 (weighted, per-class scores weighted by class frequency). The classifier achieved the highest performance for "Vitamin D deficiency" (E55) with an F_1-score of 1.0, followed closely by "Disorders of lipoprotein metabolism and other lipidaemias" (E78), "Essential (primary) hypertension" (I10), and "Diseases of liver" (K70-K87), all exceeding 0.97. Strong results were also observed for a range of chronic and metabolic conditions such as obesity (E65-E68), "Asthma" (J45), and "Mood disorders" (F30-F39), with F_1-scores above 0.95. In contrast, performance declined for certain classes with fewer samples or greater diagnostic overlap, such as "Unclear diagnosis" (F_1-score 0.54) and "Congenital malformations, deformations and chromosomal abnormalities" (Q00-Q99; F_1-score 0.52). As displayed in Figure 2, F_1-scores for the posttraining test data were generally high, with variation across the different labels.

Figure 2. Performance of the Family Medicine Research Using Electronic Medical Records (FIRE) classifier on the posttraining test dataset. The bar chart displays the F_1-scores (x-axis) for each diagnostic class (y-axis) predicted by the FIRE classifier on the 15% test posttraining dataset, unseen during training. Larger bars indicate better classification performance.

Discussion

Extracting medical diagnoses or encounters from free-text EMRs or research data still poses critical practice challenges. By using a labeled dataset of ~53,000 records from a nationwide general practice research database, our study developed a classifier to predict appropriate codes in German free-text notes using a locally adapted diagnosis and medical encounter classification system. As such, our study offers insights into not only the challenges but also the potential rewards of creating locally adapted multiclassifier systems for medical free-text notes. Our multilabel classifier showed robust performance in classifying 47 different diagnostic and medical encounter categories during training and on unseen posttraining test data, with varying amounts of available labeled training data across categories. Our multilabel classifier was able to predict around half of the included diagnostic and medical encounter categories with high F_1-scores of 0.8 or greater. These findings showcase the potential usefulness of our classifier approach for systematic use in research.

Therefore, our study demonstrates the feasibility for health care providers to develop locally adapted text classification models designed to meet their unique data requirements and integration needs within operational workflows. We encountered challenges previously discussed in the literature [11], such as predicting a large number of classes simultaneously (a large label space) and dealing with an unbalanced label distribution, in particular with the predominant class "factors influencing health status and contact with health services." Despite preprocessing to mitigate its overrepresentation by removing free-text notes labeled with this class label, its high prevalence persisted due to co-occurrence with other classes, which we did not wish to thin out. This feature, while not ideal, reflects the real-world data scenario and underpins the relevance of our findings.

XSL•FO
RenderX

Importantly, despite these real-world challenges, our classifier maintained commendable performance on both common and rare classes, as well as on new, unseen data, providing valuable insights for health care providers interested in developing custom models amid similar data challenges.

Determining the optimal sample size for training multilabel classifiers remains a topic of debate, as there is no straightforward method such as the power analysis used in hypothesis testing. Our study shows that even for low-frequency classes (ie, with fewer than 100 labeled free-text notes available) such as hypertensive diseases, model performance can still be high. For health care providers looking to develop their own classifiers, our results suggest that the required sample size for each category could be fewer than 100 text samples when training a multilabel classifier of a similar size. However, it's important to note that the required sample size varies depending on how well the classes are defined by specific terms, such as "dementia," versus more ambiguous terms, such as "suspected diagnosis." Generally, our manual error investigation suggested that the quality of data labeling is of crucial importance.

There has been ongoing discussion about shifting toward prompt-based classification and moving beyond manually curated training data by leveraging industry-developed, general-purpose LLMs such as Google's Gemini or OpenAI's ChatGPT. However, a key drawback of currently available powerful general-purpose LLMs, such as OpenAI's GPT-4o, is that they are proprietary, closed-source, and tied to cloud-based paid services operated by large technology companies. This makes them unsuitable for sensitive clinical data, where local processing and data privacy are essential. Nonetheless, in the future, open-source general-purpose LLMs that can be run on local infrastructure are very likely to become more capable.

Our research has several limitations that merit consideration. We used a dataset specifically designed for this use case, which is characterized by its short text notes. Documents of different types, especially those with more extensive content such as admission or discharge summaries, might require alternative methods. For example, researchers dealing with longer documents may need to use models such as Longformer [12], which are designed to process longer text data. Most transformer-based models, including German BERT, typically have a default input constraint of 128 tokens, which can be extended to a maximum of 512 tokens—any text data longer than this is omitted. In the context of the German BERT tokenizer, a token is generally equivalent to a single word. Consequently, training LLMs on longer documents using Longformer models [12] could lead to different results. In addition, the text data was manually labeled by medical school graduates, and labeling may be prone to errors. Errors in data labeling can affect model performance and are a common challenge in the data labeling process. Finally, the predictive results of the model trained in this study are specifically tailored for use at the Institute of Primary Care.

An important consideration when interpreting our results is the *ICD-10* code range Z00-Z99 "Factors influencing health status and contact with health services," which primarily captures contextual or encounter-related information rather than explicit disease entities. In routine primary care documentation, such codes may function as a nonspecific "catch-all" category, particularly when diagnostic certainty is low. To mitigate potential bias, we excluded notes labeled exclusively with these encounter-related categories and retained them only when they co-occurred with disease-related labels, treating them as contextual modifiers rather than stand-alone outcomes. Nonetheless, its continued prevalence reflects real-world documentation practices. Notably, macro- and microaveraged F_1-scores were very similar, suggesting that performance was not driven solely by the dominant encounter-related class. Accordingly, overall performance should be interpreted with an emphasis on macroaveraged metrics and alongside per-class results (Figure 2 and Multimedia Appendix 1, which contains the executed analysis and full per-class results), providing a more balanced view across both common encounter codes and less frequent disease categories. Moreover, predictions of encounter-related codes should be interpreted as reflecting health care use context rather than disease burden, and the classifier should be viewed as a screening tool rather than an autonomous diagnostic system.

Beyond these methodological considerations, an important ethical issue is the potential for residual bias amplification given the imbalanced category distribution, mainly due to the overrepresented encounter-related codes. Although we excluded free-text notes labeled exclusively with encounter-related codes, the high prevalence of this class may still influence model behavior. For this reason, transparency regarding model design, training data, and class-specific performance is essential to support responsible use and clinician adoption. The classifier presented in this study is therefore best suited for screening and structuring heterogeneous clinical free-text notes, rather than as an autonomous diagnostic system, and it should not be used in settings requiring very high precision, such as downstream epidemiological analyses. Future research should focus on improving model explainability to support clinical acceptance and to facilitate the identification of potential biases during deployment.

This study uses supervised multilabel classification, which requires a sufficient number of positive examples per label to learn stable decision boundaries and produce reliable, interpretable performance estimates. We therefore focus on more prevalent *ICD-10* classes. Diagnostic categories with very low prevalence fall into a few-shot or zero-shot regime and cannot be robustly modeled within the same supervised fine-tuning framework. Although we explored prompt-based zero-shot label assignment using an open-source German LLM, performance was inconsistent and substantially inferior to supervised classification. Accordingly, this study concentrates on diagnostic categories with adequate training data for robust supervised model development. Rare conditions remain an important but distinct methodological challenge and may be better addressed through alternative paradigms such as few-shot retrieval-based methods or entailment-based classification.

For classification, we used *bert-base-german-uncased* as a well-established and widely used baseline model to demonstrate

XSL•FO
RenderX

supervised multilabel classification of German free-text notes in primary care. While alternative transformer architectures may offer performance gains, particularly through domain adaptation or different pretraining objectives, systematic comparisons were beyond the scope of this work. Relevant candidates for future evaluation include domain-adapted German biomedical models such as medBERT.de [13], GottBERT [14], and Me-LLaMA 70B [15], as well as alternative pretraining paradigms such as German ELECTRA [16], which has shown strong performance in text classification tasks. In addition, multilingual architectures (eg, the multilingual mBERT [17]) may be of interest for cross-lingual transfer scenarios. Future research would benefit from systematically assessing trade-offs between predictive performance, computational requirements, and deployment feasibility when applying these architectures to real-world clinical settings.

In summary, our study demonstrates the feasibility and benefits of training tailored multilabel text classifiers to categorize diagnostic physician notes in primary care. Combined, our work and documentation of the classifier development process lay a solid foundation for applied researchers and health care providers to leverage their own rich datasets for sophisticated statistical analyses and rigorous research. Moreover, after further validation, such multilabel classifiers could potentially also be used for generating more meaningful, precise, and actionable feedback to the participating general practitioners and thus help them improve the quality of care for their patients. We believe that our work is particularly relevant for health care organizations that accumulate vast amounts of data over time, including rich open text records that often exceed the amount of data typically collected by large research studies in a feasible time frame and budget. For example, many inpatient clinics have extensive longitudinal data, both quantitative and qualitative, including detailed patient histories across multiple admissions. However, our work also underscores the importance of high-quality data labeling and thoughtful integration of artificial intelligence into health care workflows to meaningfully enhance patient care.

Funding

This study is supported by a grant from the Federal Quality Commission c/o Federal Office of Public Health, Bern, Switzerland. The funder had no role in study design, data collection and analysis, preparation of the manuscript, and decision to publish.

Abstract

Background: Clinical data warehouses store large volumes of unstructured text containing valuable information about patients' medical status. Traditional extraction systems based on named entity recognition (NER) identify medical terms but often fail to capture the contextual cues needed for accurate interpretation. Existing approaches to context-aware extraction differ in their reliance on expert annotation, computational power, and lexical resources, leading to uneven feasibility across institutions. Combined with heterogeneity in documentation practices and data-sharing restrictions, these limitations hinder the scalability and reuse of trained models. There is thus a need for practical frameworks that can be deployed and adapted locally within medical institutions.

Objective: This study aimed to introduce the Medical Status Extraction Pipeline (MSEP)**,** a methodological framework that extracts patients' medical status from clinical narratives through sentence classification and supports the local deployment of hybrid extractors, illustrated through an institutional case study.

Methods: MSEP extracts medical status by classifying sentences into predefined categories (presence, absence, or unknown) for each targeted condition. The pipeline combines modules for data selection, expert annotation, and model development, with parameters customizable to different settings. It was applied within our institutional environment on 6 conditions: smoking, hypertension, diabetes, heart failure, chronic obstructive pulmonary disease, and family history of cancer, using 12,119 manually annotated sentences from the eHOP Clinical Data Warehouse (Rennes University Hospital). Three types of extractors were compared: fine-tuned CamemBERT, large language model (LLM) prompt, and a rule-based baseline, evaluated through stratified 3-fold cross-validation, measuring precision, recall, specificity, macro *F*-score, balanced accuracy, as well as manual annotation time and model inference speed.

Results: Among the tested approaches, the CamemBERT-based extractor achieved the best overall performance, with macro *F*-scores above 0.94 for 5 of the 6 medical conditions. The study also highlights that when a medical status is very sparsely represented in the training data, rule-based extractors can outperform learned models (average macro *F*-score 0.94 vs 0.73 for family history of cancer). This shows the pragmatic value of choosing the extraction method according to data availability. Manual annotation time per sentence ranged from 1.2 to 2.9 seconds within the pipeline (2.23 to 4.25 seconds for informative sentences), compared with 7.8 to 16.5 seconds for named entity recognition–based systems. In our institutional experiments, the minimum time to complete all pipeline modules, from dataset construction to final extractor refinement, was 8 hours.

Conclusions: In our institutional case study, MSEP enabled rapid construction of datasets and extractors across multiple clinical conditions while reducing the effort required for local development. Its modular and configurable design allowed the adoption of hybrid extraction approaches and adaptation to different resource settings. These features highlight MSEP's value as a research tool and upstream component that facilitates local deployment of clinical information extraction workflows.

Introduction

In recent years, a substantial amount of clinical data has been collected from numerous patients and stored in clinical data warehouses (CDWs) [1]. These databases represent a valuable resource for clinical research. In many cases, a significant portion of their content exists as free unstructured texts, such as hospital discharge summaries and emergency reports, which can be difficult to process [2]. Nonetheless, these texts contain valuable information about patients' medical status that, once extracted, can be leveraged for clinical and epidemiological research [3-5]. Harnessing these unstructured data requires developing natural language processing (NLP) methods specifically adapted to the medical domain. Extensive efforts have been made in this area, as reflected in shared tasks such as the n2c2 (National NLP Clinical Challenges) competitions, which have addressed problems of extracting patients' family history regarding diseases, smoking, suicide, and drinking [6].

According to a recent review, most NLP approaches for medical information extraction rely on named entity recognition (NER) [2]. At first, rule-based approaches using dictionaries and terminologies to match terms and concepts were proposed [7,8]. However, their reliance on lexical resources and medical expertise for rule construction limits their long-term viability, since rules and vocabularies require regular manual updates to reflect evolving clinical practices. To cope with this, machine learning approaches arose. These methods take advantage of the large amount of medical knowledge in databases and can automate the construction and maintenance of medical information retrieval systems [9]. Its latest branch, deep learning approaches, has improved the ability to capture and use contextual information compared with rule-based and traditional machine learning methods, thanks to their neural network architectures; accordingly, this also makes their performance highly dependent on the availability of sufficient annotated data [10,11].

However, NER-based information extraction approaches present a significant limitation. While NER can effectively extract medical entities (eg, "cancer" and "hypertension"), it cannot capture the contextual information required for a full understanding of the patient's status. A comprehensive assessment involves interpreting the complete syntactic and semantic structure, including subject (patient or family member), predicate (having or not having), and object (the medical condition), to determine whether a condition is present, absent, or mentioned in a familial context [12-14]. Standard NER captures only the object component, necessitating additional processing by context qualifiers to detect negation, temporality, and subject attribution [6,15-17]. Clinical narratives further amplify these challenges, as they are typically unstructured, context-dependent, and institution-specific, with such cues often expressed at the sentence or discourse level [18,19]. For example, in "Tabagisme pendant 7 ans, reprise récente malgré un sevrage en 2020" (Smoking for 7 y, recent relapse despite cessation in 2020), successful interpretation requires resolving the temporal relation between cessation and relapse to infer that the patient is an active smoker, dependencies that standard NER pipelines, which treat entities and assertions separately, struggle to capture. These linguistic characteristics highlight the need for approaches more capable of sentence-level semantic interpretation.

At the same time, developing context-aware information extraction systems can be resource-intensive. The development and evaluation of NER models require extensive expert annotation to label entity boundaries and associated features within large-scale corpora [20], a process made even more laborious by the sparsity of clinically relevant content [21-23]. With the advancement of deep neural networks, embedding fusion techniques have been adopted to enhance context utilization and improve recognition accuracy in NER tasks [24]. However, their cross-domain applicability is limited by high computational cost and reliance on external resources for comprehensive feature engineering. To overcome the limitations of traditional NER pipelines and handcrafted feature engineering, recent research has shifted toward the use of transformer-based pretrained language models that inherently capture richer contextual representations [25]. Encoder-only language models such as BERT [26] and CamemBERT [27] have demonstrated high performance in domain-specific tasks through fine-tuning on relatively small annotated datasets [28]. Decoder-only large language models (LLMs), such as ChatGPT [29] and Mistral [30], can achieve similar goals via prompt engineering without requiring fine-tuning. However, both approaches still depend on domain-specific expertise for model adaptation [31,32], and decoder-only models introduce substantial computational costs that limit their feasibility for routine institutional deployment [33].

Beyond technical constraints, institutional heterogeneity, including differences in documentation practices, terminologies, and privacy regulations, presents major barriers to developing and sharing information extraction systems across institutions [34-36]. Clinical documentation varies widely across institutions, incorporating nonstandard abbreviations, local terminology, and inconsistent formatting [19,37], which hinders the generalizability and scalability of information extraction models, requiring substantial annotation and model adaptation for each use case [19,38]. The sensitive nature of patient data further restricts access to real-world electronic health records and limits the sharing of pretrained models, due to risks of unintended information leakage [39,40]. Consequently, research teams often need to rebuild extraction systems from scratch, even when addressing similar clinical objectives [16,41]. In light of these limitations, there is a critical need for practical, context-aware information extraction systems that can be developed and reused within institutional boundaries.

To address these limitations, we designed the Medical Status Extraction Pipeline (MSEP) as a methodological framework that supports the local development of hybrid approaches for information extraction. MSEP reframes medical status extraction as a sentence classification task, which directly leverages contextual cues such as negation, temporality, and subject attribution while reducing annotation complexity. In addition, by accommodating rule-based methods, fine-tuned language models, and LLM prompting, MSEP allows institutions to select extraction approaches suited to their data availability and computational resources.

XSL•FO
RenderX

To support its interest, the MSEP has been applied to build extractors of patients' status for 6 clinically relevant medical conditions [16,42,43] from a French CDW: smoking, hypertension, diabetes, heart failure, chronic obstructive pulmonary disease (COPD), and family history of cancer. This paper first outlines the steps, functions, and requirements of the MSEP pipeline, along with the materials and tools used. Next, we present the evaluation results of extractors built using MSEP and compare them with different medical information retrieval approaches (rule-based methods and prompt-based LLM extraction). Finally, we discuss the operational benefits of MSEP, particularly reduced annotation effort, and its potential use as an upstream research tool within institutional settings.

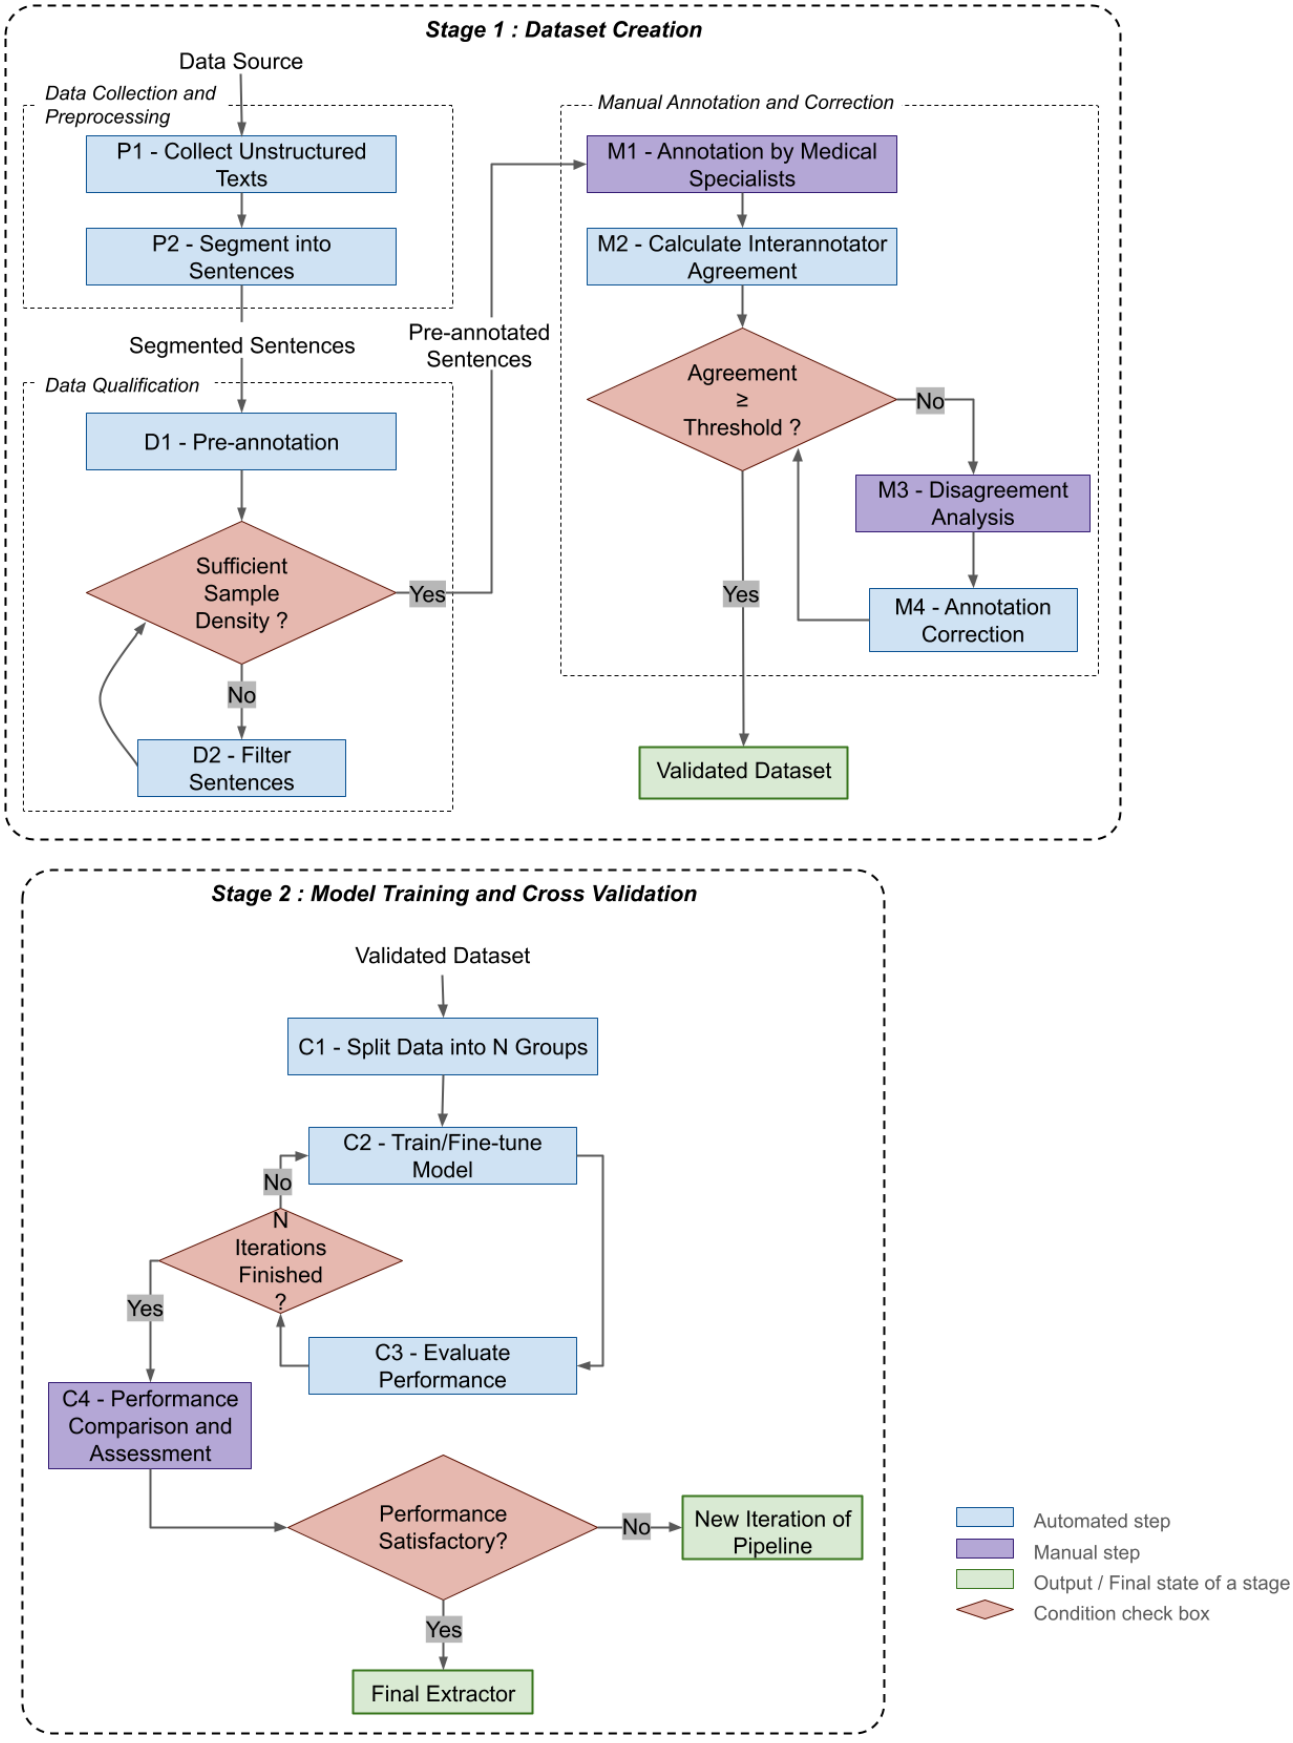
Methods

Overview

The MSEP pipeline classifies sentences in clinical documents as present, absent, or unknown regarding a patient's medical condition. Available as a Python package (repository link in Multimedia Appendix 1), the framework includes configurable parameters that allow its components to be adapted to local research needs and institutional constraints. In the following sections, we first describe the general design of the pipeline and then detail its implementation within our institutional setting.

Ethical Considerations

Ethics approval for data reuse was obtained from the Commission Nationale de l'Informatique et des Libertés (agreement number 2206739). This study was conducted on pseudonymized secondary clinical data provided by the Clinical Data Center of Rennes Hospital. In accordance with French regulations and the guidelines of the Commission Nationale de l'Informatique et des Libertés. Patients were informed of the potential use of their data for research purposes through the hospital's standard information notice. All data were pseudonymized by the Clinical Data Center before being transmitted to the research team. No identifying information was accessible at any stage of the analysis. No compensation was applicable or provided to participants.



Generic Pipeline Design

Overview

The global framework of our method is depicted in Figure 1. The framework consists of two main stages: (1) dataset creation and (2) model training with cross-validation. In order to facilitate the comprehension of the framework, the abbreviations of the steps in the figure are also mentioned in the text.

XSL•FO
RenderX

Figure 1. Overview of the proposed iterative medical status extraction system. This pipeline is primarily designed to extract the status of one medical condition at a time; it may repeat multiple times (iterations) to improve the extractors. This diagram mainly shows the process of the first iteration.

XSL•FO
RenderX

Dataset Creation

Overview

The objective of this stage is to construct the datasets required for training and validating medical status extractors. It involves three processes: (1) data collection and preprocessing, (2) data qualification, and (3) manual annotation and correction.

Data Collection and Preprocessing

Data collection gathers unstructured texts from CDW (P1), which are preprocessed by segmenting into sentences for classification (P2). The output is a corpus of sentences with relevant metadata that maintains the relationship to their source documents.

Data Qualification

The input to the data qualification process is the preprocessed sentence corpus. This phase assesses whether the collected data have appropriate sample density and size for effective model training. Sentences undergo automatic preannotation (D1), preferably using quickly implemented rule-based approaches that match medical status keywords. When preannotating sentences from all documents is impractical due to time and resource constraints, a random subset may be selected. If sample density is low, based on preannotation results, a portion of sentences unlikely to contain medical status information is filtered out (D2). This supervised sampling approach is designed to enhance annotation efficiency and final data quality by optimizing the training sample structure. The output is a preannotated sentence dataset with optimized annotation density and a balanced representation of target medical statuses.

Manual Annotation and Correction

The preannotated sentences serve as input for manual annotation, which requires multiple medical specialists to classify them according to annotation guidelines (M1). Annotators should collaboratively annotate a subset of the sentences to calculate interannotator agreement (M2). If the agreement exceeds the predetermined threshold, the annotations form the training and validation datasets. Otherwise, disagreements are analyzed (M3) to improve guidelines, with corrections applied to the annotated data accordingly (M4). The correction approach depends on the type of disagreements, but preferably through manual review. The disagreements analysis-correction process can be repeated until the interannotator agreement exceeds the threshold. The output is a validated annotated dataset ready for model development.

Model Training and Cross-Validation

The annotated datasets become the input for training or fine-tuning neural network models for medical status extraction. Since the pipeline is designed to extract the status of one medical condition at a time, each corresponding model is trained in a multiclass classification setting, where the possible status labels (eg, present, absent, and unknown) are mutually exclusive. Model stability is assessed through cross-validation by dividing annotated data into several groups (C1), using one group for validation (C3) and the remainder for training (C2) in each session. The number of cross-validation sessions equals the number of groups of data. The data grouping strategy for cross-validation should align with study objectives; for example, testing model stability across different document types requires data partitioning by document type. The extractor's performance metrics across multiple validation sets are assessed and compared with extractors based on other approaches, if available, to decide whether it has stable and state-of-the-art performance (C4). The flexibility of the pipeline configuration allows for easy benchmarking of different models (such as BERT-based models, rule-based systems, or LLM prompts), facilitating comprehensive performance comparison with minimal additional setup.

If the assessment result is positive, the pipeline ends, and the output is a trained medical status extraction model with satisfactory performance.

Iterative Improvement Process

If, according to the assessment step (C4), the extractor does not achieve satisfactory performance (eg, a macro *F*-score below 90%), the pipeline allows for iterative refinement. The definition of "satisfactory" performance may vary depending on the objectives and standards of different research projects.

The iterative process involves both quantitative and qualitative improvements. Quantitatively, additional annotated sentences are incrementally introduced to expand the training and validation datasets. The number of added samples per iteration is not fixed and depends on multiple factors, including the time allocated for manual annotation, the number and availability of annotators, and computing resources.

Qualitatively, the pipeline may be refined by improving preannotation rules, updating annotation guidelines based on annotator feedback, or replacing rules with more accurate extractors from previous iterations for preannotation. The first iteration serves as an exploratory phase to identify bottlenecks, such as insufficient data for certain labels, weak vocabulary coverage in preannotation rules, or annotation inconsistencies, allowing for targeted improvements in subsequent iterations.

Study-Specific Implementation

Data Source and Working Corpus

We used the eHOP CDW from Rennes University Hospital, which contains 80 million unstructured and 430 million structured data elements covering over 1.8 million patients [44]. For this study, we extracted unstructured documents from our previous bladder cancer research dataset [3], obtaining 799,470 documents from 5398 patients. This corpus encompasses diverse medical document types including nursing care reports, medical reports, multidisciplinary follow-up & daily notes, imaging reports, prescriptions, and medication orders (Table 1).

XSL•FO
RenderX

Table . Numbers and ratios of the 9 most frequently found document types (as well as the rest of the 5020 documents in "Other") in our corpus.

Medical document type	Value, n (%)
Nursing care–procedures	329,359 (41)
Medical reports	187,370 (23)
Nursing care–monitoring and vitals	153,865 (19)
Multidisciplinary follow-up and daily notes	54,187 (7)
Imaging reports	31,430 (4)
Prescriptions and medication orders	13,163 (2)
Paramedical care	13,083 (2)
Administrative and admission	6839 (1)
Results and pathology reports	5225 (1)
Other	5020 (1)

Rationale for Extraction Method Design

MSEP is designed as a hybrid framework capable of accommodating different resource-availability scenarios. To assess this flexibility, we evaluated 3 extraction approaches that represent distinct requirements: fine-tuning an encoder-only transformer (high annotation demand and moderate computational cost), rule-based extraction (minimal computation and annotation requirements but substantial reliance on domain expertise), and LLM prompting (low annotation requirements but high computational and expertise demands) [45]. Our experiments focused primarily on encoder-only fine-tuning in order to assess how effectively MSEP can reduce the associated annotation burden in practice, while the rule-based and LLM-prompting approaches served as comparative baselines for low-annotation settings. The rule-based approach is used for preannotation (D1) before fine-tuning, reinforcing the hybrid nature of the MSEP framework.

Regarding the models and tools used in these approaches, CamemBERT was selected for encoder-only fine-tuning strategy because it aligns with the sentence-classification paradigm and has demonstrated strong performance in French NLP tasks [25,46,47]. Furthermore, we opted for the original CamemBERT rather than domain-adapted variants such as CamemBERT-bio [48], as the latter are pretrained on specialized biomedical corpora, which may bias them toward known biomedical tasks and entities [49,50]. Using a general-domain model allows us to evaluate the pipeline's components without relying on domain-specific pretraining and to examine how it behaves in our institutional corpus when applied to varied clinical conditions. For LLM prompting, we used Mixtral-8×7B-v0.1 [51], which offered the strongest performance that could be efficiently supported by our institutional infrastructure (an NVIDIA A100 40 GB GPU). The rule-based extractors were developed using regular expressions and terminology specific to each targeted medical condition, provided by medical experts.

Pipeline Configuration

The pipeline was independently evaluated on 6 medical conditions: smoking, hypertension, diabetes, heart failure, COPD, and family history of cancer. For each condition, we defined 3 possible statuses: "present," "absent," and "unknown," corresponding to confirmed presence, negation, and uncertainty regarding the patient's condition. For the smoking condition, an additional status, "former," was included to indicate that the patient previously smoked but has since quit (Table S1 in Multimedia Appendix 2 provides a detailed definition of medical statuses). Multimedia Appendix 2 contains the annotation guidelines, which give more details about the criteria for annotating the medical status.

We used Spacy's fr_core_news_md model [52] for sentence segmentation (P2) and manually crafted rules based on specialist-provided keywords for preannotation (D1), supplemented by EDS-NLP's negation and family context qualifiers [53] for smoking and family history of cancer. Two medical specialists performed annotations (M1) using the Prodigy interface [54], with Cohen kappa [55] measuring interannotator agreement (M2), which is defined as:

$$(1)\kappa=(Po-Pe)/(1-Pe)$$

where *Po* is the observed agreement and *Pe* is the expected agreement by chance. A threshold of 0.8 was used to determine acceptable agreement.

For CamemBERT-based extractors, we performed a 3-fold stratified cross-validation. The full annotated dataset was randomly partitioned into 3 equally sized folds (C1), preserving the proportion of annotated categories within each fold. Duplicated (identical) sentences were removed before the partition to prevent data leakage across folds. In each of the 3 cross-validation rounds, two folds were used for training and the remaining fold served as the validation set (C2). We trained the CamemBERT-large model [27] with loss weighting to address class imbalance. The weighted cross-entropy loss with class weighting is defined as:

$$(2)L=-\Sigma i\ wi\times\log\ p(yi|xi),wi=N/(C\times Nyi)$$

where $p(yi \mid xi)$ is the predicted probability for the true class *yi* of input *xi*, *wi* is the class-specific weight, *N* is the total number of samples, *C* is the number of classes, and *Nyi* is the number of samples in the class of example *i*. Model performance was evaluated (C3) using precision, recall, specificity, *F*-score on individual status, balanced accuracy, and macro *F*-score on all statuses of a medical condition. Balanced accuracy was defined as:

XSL•FO
RenderX

(3)Balancedaccuracy=(1/C)×Σc[((TPc/(TPc+FNc))+(TNc/(TNc+FPc)))/2]

and macro *F*-score was defined as:

(4)F1macro=(1/C)×ΣcF1(c)

where *C* is the number of classes, and *TPc*, *FNc*, *TNc*, and *FPc* are respectively the true positives, false negatives, true negatives, and false positives for class *c*. This set of metrics is supposed to cover all necessary aspects of evaluation for an information retrieval system according to [56]. For comparison (C4), we evaluated our rule-based extractors and Mixtral-8x7B-v0.1 LLM prompts on the same validation sets used for the cross-validation (C2+C3). To ensure a quite fair comparison, the Mixtral-8x7B prompts were designed using few-shot examples derived from the annotation guidelines, combining basic extraction instructions with expert-crafted example and counter-example sentences embedding specialist-provided keywords and clinical context narration.

Detailed configuration information for each step in MSEP appears in Multimedia Appendix 1. The MSEP python package (repository link in Multimedia Appendix 1) provides configurable modules to realize each step of the pipeline.

Results

Overview

We conducted 2 iterations of the pipeline in our institutional setting to create and refine the extractors, after which most targeted medical conditions reached satisfactory performance (average macro *F*-score>0.94) for our use case. This section presents the results of these iterations, describing implementation paths, dataset characteristics, cross-validation results, and comparisons between our extractors and alternative approaches.

Pipeline Execution and Time Requirements

Figure 2 details the implementation path and time consumption for each medical condition across both iterations.

XSL•FO
RenderX

Figure 2. Steps in the 2 iterations of the pipeline were realized to extract each medical status. The steps within the curly braces mean that they are repeatedly realized within one iteration, and the number after the * marks how many times these steps have been repeated. The color of the steps is consistent with Figure 1; blue means automated steps and purple means manual steps. The type of model used for preannotation (PA) and the interannotator agreement score calculated at step M2 are given underneath the list of steps. The last 4 columns show the total time consumption of preannotation (D1), manual annotation (M1) during both iterations, model fine-tuning during cross-validation (C2), and the total time consumed to go through the pipeline in 2 iterations (Ttl). The time consumption is calculated by hours (h) or by minutes (m), depending on the convenience of data representation. COPD: chronic obstructive pulmonary disease.

Medical condition	Steps (1st iter)	Steps (2nd iter)	Consumed time			
			D1	M1	C2	Ttl
Smoking	P1-P2-D1-D2-M1-M2-C1-{C2-C3}*3-C4 Preannotation: rule-based Cohen kappa: 0.91	P1-P2-D1-D2-M1-M2-C1-{C2-C3}*3-C4 Preannotation: CamemBERT based Cohen kappa: 0.96	1st iter : 8 h 2nd iter : 11 h	10 h	66 m	30 h
Hyper-tension	P1-P2-D1-D2-M1-M2-C1-{C2-C3}*3-C4 Preannotation: rule-based Cohen kappa: 1.0	P1-P2-D1-D2-M1-M2-C1-{C2-C3}*3-C4 Preannotation: rule-based Cohen kappa: 0.96	4 h	5 h	123 m	11 h

Heart failure	P1-P2-D1-D2-M1-M2-C1-{C2-C3}*3-C4 Preannotation: rule-based Cohen kappa: 1.0	P1-P2-D1-D2-M1-M2-M3-M4-C1-{C2-C3}*3-C4 Preannotation: rule-based Cohen kappa: 0.57 (0.80 after the correction steps (M3, M4))	4 h	7 h	42 m	12 h
COPD	P1-P2-D1-D2-M1-M2-C1-{C2-C3}*3-C4 Preannotation: rule-based Cohen kappa: 0.80	P1-P2-D1-D2-M1-M2-C1-{C2-C3}*3-C4 Preannotation: rule-based Cohen kappa: 0.98	3 h	5 h	30 m	9 h
Family history of cancer	P1-P2-D1-D2-M1-M2-C1-{C2-C3}*3-C4 Preannotation: rule-based Cohen kappa: 1.0	P1-P2-D1-D2-M1-M2-C1-{C2-C3}*3-C4 Preannotation: rule-based Cohen kappa: 1.0	24 h	4 h	33 m	29 h

Most medical conditions were preannotated using rule-based matching, except smoking status, which was preannotated in the second iteration using a CamemBERT-based extractor fine-tuned from the first, which outperformed the rules. Heart failure annotation during the second iteration initially yielded insufficient interannotator agreement (57%), necessitating disagreement analysis and correcting annotated data. The analysis revealed that the inconsistencies arose from concept confusion among annotators. A list of ambiguous terms was identified and clarified with a medical expert, incorporated into updated annotation guidelines, and used to automatically extract sentences that need revision from all annotations. These

XSL•FO
RenderX

sentences were then reviewed and corrected by the annotators based on the updated guidelines.

Time requirements varied by medical condition and process step. We focused on the 3 most time-intensive steps: preannotation (D1), manual annotation (M1), and extractor training during cross-validation (C2). Preannotation (D1) speed ranged from 0.02 to 0.17 seconds per sentence, with COPD and diabetes being fastest (0.02 s/sentence) and smoking and family history of cancer slowest (0.12 - 0.17 s/sentence). Manual annotation (M1) required 1.2 - 2.9 seconds per sentence when considering all status labels, with diabetes and family history of cancer being the most efficient (1.2 s/sentence) and smoking being the most time-intensive (2.9 s/sentence). After removing the speed bias introduced by quickly dismissed sentences labeled as unknown, annotation speed ranged from 2.23 to 4.25 s/sentence, with hypertension being the fastest and family history of cancer the slowest, indicating that annotation speed is partly driven by sentence complexity and semantic load. Cross-validation training (C2) averaged 5 - 22 min per session (of cross-validation), with COPD training being fastest (5 m/session) and hypertension slowest (22 m/session). Final extractor inference speed ranged from 0.09 to 0.12 s per sentence. Total implementation time across both iterations (Ttl) ranged from 8 hours (diabetes) to 30 hours (smoking). The time consumption and speed of all automatic steps (D1, C2, and inference of extractors) are calculated on a GPU of NVIDIA A100 40 GB graphics card.

Training and Validation Datasets

The first iteration involved quickly preannotating 9997 medical documents and selecting 991 sentences from them for manual annotation. In order to improve extractors' performance by training them with more medical status samples, the second iteration preannotated an additional 18,994 documents, yielding 11,128 sentences for manual annotation. Table 2 shows the distribution of medical status in sentences annotated during each iteration. The training and validation dataset for the 2nd iteration of the pipeline is the combination of all sentences annotated during both iterations (12,119 sentences in total).

Table . Number of samples of different medical status in sentences respectively annotated during the 1st (itr1) and the 2nd (itr2) iteration of the pipeline.

Medical condition	Present		Absent		Former		Unknown		Total	
	itr1	itr2	itr1	itr2	itr1	itr2	itr1	itr2	itr1	itr2
Smoking	75	646	42	211	87	417	787	9854	991	11,128
Diabetes	279	257	29	37	—[a]	—	683	10,834	991	11,128
Hypertension	217	1184	8	30	—	—	766	9914	991	11,128
Heart failure	46	183	41	217	—	—	904	10,728	991	11,128
COPD[b]	22	366	0[c]	1[c]	—	—	969	10,761	991	11,128
Family history of cancer	5	2	0[c]	1[c]	—	—	986	11,125	991	11,128

[a]Not applicable.

[b]COPD: chronic obstructive pulmonary disease.

[c]Status with too few samples for cross-validation.

Sample sparsity was evident for certain status classifications. During the first iteration, most conditions had fewer than 300 samples per status, with absence samples typically fewer than presence samples. No samples were found for the absence of COPD and family history of cancer. We then increased preannotated documents for the second iteration, which successfully increased sample counts for most status classifications, though samples remained limited due to the absence of COPD and both the presence and absence of family history of cancer.

Among the 12,119 sentences, approximately 10% (n=1200) were randomly selected from the medical documents without preannotation, yielding an unbiased subset of 1200 sentences (unfiltered sentences [US]). We compared the distribution of medical statuses in this subset with that of the remaining 10,919 sentences (preannotated filtered sentences [PS]) selected through preannotation to assess the extent of bias introduced by this data qualification process (D1, D2).

Table 3 shows the result of this comparison. For each medical condition, we calculated the proportion for each of its statuses within US and PS, which is defined as:

(5)proportion=c(status)/c(present,absent,former)

XSL•FO
RenderX

Table . Comparison of medical status samples' distribution (%) in 10,919 preannotated filtered sentences (PS) and 1200 unfiltered sentences (US).

Status	Smoking		Diab		Hyper		CHF[a]		COPD[b]		Fam	
	US	PS	US	PS	US	PS	US	PS	US	PS	US	PS
Present	44	49	100	89	100	97.3	33.3	47.1	100	99.7	0	88
Absent	12	17	0	11	0	2.7	66.7	52.9	0	0.3	0	12
Former	44	34	—[c]	—	—	—	—	—	—	—	—	—
Prevalence of relevant statuses	0.75	13.5	0.25	5.49	0.75	13.1	0.25	4.43	0.17	3.54	0	0.07

[a]CHF: congestive heart failure.

[b]COPD: chronic obstructive pulmonary disease.

[c]Not applicable.

where *c*() denotes the total number of samples of one or more statuses in the set. Since the purpose of the data qualification is specifically to reduce the proportion of sentences that do not express any status information (ie, the class unknown), this category was excluded from the computation to avoid inflating the proportions of relevant statuses (ie, present, absent, and former) in the PS and obscuring the assessment of distributional changes. Instead, we report the prevalence of relevant statuses in US and PS to quantify how effectively steps D1+D2 have increased relevant samples' density in PS by filtering out irrelevant sentences (class unknown). This measurement is defined as:

$$(6) prevalence = c(present, absent, former) / c(present, absent, former, unknown)$$

Across most medical conditions, the distribution of status labels remained stable after the data filtering steps. The proportions of present status for smoking, diabetes, hypertension, and COPD, as well as the absent status for COPD and hypertension, showed only minor deviations between US and PS. A modest shift was observed for the former and absent statuses of smoking, whereas heart failure exhibited a more substantial change in the present status (from 33.3%, 1/3 in US to 47.1%, 228/484 in PS). Larger apparent shifts for rare categories, such as family history of cancer or the absent status of hypertension, reflect the extremely small number (or absence) of these samples in US, making baseline proportions unstable and limiting interpretability. Overall, despite shifts in certain conditions, the relative ordering of status frequencies remained consistent, suggesting preservation of the dominant patterns. Finally, the prevalence values show that the filtering steps substantially increased the density of relevant samples. For most conditions, the proportion of samples in PS was more than 10 times higher than in US (eg, from 0.75%, 9/1200 to 13.45%, 1469/10,919 for smoking, and from 0.25%, 3/1200 to 5.49%, 599/10,919 for diabetes), demonstrating the effectiveness of steps D1+D2 in removing irrelevant sentences while introducing only minor distributional bias.

CamemBERT-Based Medical Status Extractors Evaluation

As a reminder, each extractor was trained in a multiclass classification setting to predict the status of a single medical condition. Evaluation metrics include precision, recall, specificity, and *F*-score for each individual status, as well as balanced accuracy and macro *F*-score aggregated across all statuses. Table 4 presents the performance metrics for the best-performing extractor of each medical condition after the second iteration. Extractors for diabetes and heart failure achieved excellent overall performance (macro *F*-scores of 99% and 96%, respectively). The COPD extractor achieved a macro *F*-score of 99%, although evaluation was limited to the present and unknown classes due to the lack of absent samples. The diabetes, hypertension, and COPD extractors exceeded 98% *F*-score for presence detection. The smoking extractor achieved balanced performance across status classifications (93% - 94% *F*-scores), while the hypertension extractor showed imbalanced performance between presence (98% *F*-score) and absence (86% *F*-score). The extractor for family history of cancer underperformed with only 80% *F*-score for presence detection.

XSL•FO
RenderX

Table . Performance of the best CamemBERT-large based extractors obtained after the cross-validation of the 2nd iteration of the pipeline. For each of the studied 6 medical conditions—smoking, diabetes (diab), hypertension (hyper), congestive heart failure (CHF), chronic obstructive pulmonary disease (COPD), and family history of cancer (fam)—the extractor is evaluated on each of its status (unknown, absent, present, or former) with 4 metrics: *F*-score, precision, recall, and specificity. The macro *F*-score and balanced accuracy are calculated on (and only on) the evaluated status.

Extractor	Smoking	Diab	Hyper	CHF	COPD	Fam
Unknown *F*-score	0.98	0.99	0.98	0.97	0.99	0.99
Unknown Precision	0.99	1.0	0.98	0.96	1.0	1.0
Unknown Recall	0.97	0.99	0.99	0.99	0.99	0.99
Unknown Specificity	0.99	1.0	0.98	0.94	1.0	1.0
Absent *F*-score	0.94[a]	1.0[a]	0.86[b]	0.97[a]	—[c]	—
Absent Precision	0.94	1.0	0.86	0.98	—	—
Absent Recall	0.93	1.0	0.85	0.96	—	—
Absent Specificity	0.99	1.0	0.99	0.99	—	—
Present *F*-score	0.93[a]	0.99[a]	0.98[a]	0.92[a]	0.99[a]	0.80[b]
Present Precision	0.91	0.99	0.98	0.96	0.98	0.67
Present Recall	0.95	1.0	0.98	0.89	1.0	1.0
Present Specificity	0.97	0.99	0.99	0.99	0.99	0.99
Former *F*-score	0.94[a]	—	—	—	—	—
Former Precision	0.93	—	—	—	—	—
Former Recall	0.94	—	—	—	—	—
Former Specificity	0.99	—	—	—	—	—
Macro *F*-score	0.95[a]	0.99[a]	0.94[a]	0.96[a]	0.99[a]	0.89[b]
Balanced accuracy	0.95	0.99	0.94	0.95	0.99	0.99

[a]Status (other than Unknown) whose *F*-score has surpassed 90%.

[b]*F*-score has not surpassed 90%.

[c]Not applicable.

Table 5 presents the results of the 3-fold cross-validation from both iterations. For each medical condition, we evaluated the stability of the extractors by reporting the mean and SD of the *F*-score for each status category, as well as for the overall macro *F*-score, across the cross-validation folds. All extractors demonstrated improved performance after the second iteration. After the first iteration, only the diabetes extractor achieved a macro *F*-score exceeding 90%, while by the second iteration, most condition extractors surpassed this threshold. Hypertension, heart failure, and COPD extractors showed the most substantial improvement (>30%).

XSL•FO
RenderX

Table . Result (average *F*-score, SD) of 3-fold stratified cross-validation with CamemBERT-large based extractors trained during the 1st (iter 1) and the 2nd (iter 2) iterations of the pipeline.

Medical condition	Present *F*-score, mean (SD)	Absent *F*-score, mean (SD)	Former *F*-score, mean (SD)	Unknown *F*-score, mean (SD)	Macro *F*-score, mean (SD)

Hypertension	0.94 (0.002)	0 (0)	—	0.97 (0.003)	0.63 (0.003)
Heart failure	0.24 (0.03)	0.14 (0.1)	—	0.71 (0.09)	0.36 (0.05)
COPD[c]	0 (0)	—	—	0.93 (0.04)	0.31 (0.01)
Family history of cancer[d]	0 (0)	—	—	0.99 (0.003)	0.33 (0.001)
Iter 2					
Smoking	0.93 (0.008)	0.93 (0.005)	0.92 (0.01)	0.98 (0.0004)	0.94 (0.003)
Diabetes	0.98 (0.008)[a]	0.98 (0.02)[a]	—	0.98 (0.004)	0.98 (0.01)[a]
Hypertension	0.98 (0.002)[a]	0.85 (0.01)[e]	—	0.98 (0.002)	0.96 (0.009)[a]
Heart failure	0.90 (0.02)	0.95 (0.02)[a]	—	0.97 (0.003)	0.94 (0.003)
COPD	0.99 (0.002)[a]	—	—	0.99 (0.003)	0.99 (0.002)[a]
Family history of cancer[d]	0.55 (0.37)	—	—	0.99 (0.003)	0.73 (0.17)

[a]Average *F*-score more than 95% at detecting medical status other than Unknown (either iteration).

[b]Not applicable.

[c]COPD: chronic obstructive pulmonary disease.

[d]For family history of cancer, with only 7 positive samples across 2 iterations, calculating a SD of 37% for the *F*-score is statistically unstable and potentially misleading regarding the extractor's reliability.

[e]Average *F*-score less than 90% after the second iteration.

Despite these improvements, the family history of cancer extractor achieved only 73% macro *F*-score with 17% instability, primarily due to poor performance in detecting presence (55% *F*-score, 37% instability). The hypertension extractor also showed suboptimal performance for absence detection (85% *F*-score, 1% instability). Due to insufficient samples, absence classification for COPD and family history of cancer could not be trained or evaluated.

To go one step deeper into the assessment of the extractor performances, a post hoc analysis according to document type was conducted. Table 6 reports the average *F*-scores with SD, obtained during three-fold cross-validation during the last iteration of the pipeline, for each medical status across the major clinical document types represented in the dataset.

XSL•FO
RenderX

Table . Average *F*-scores (SD) per medical status (present: pr, absent: ab, former: fm, and unknown: un) across clinical document types: Nursing care–Procedures (Nurs-Proc), Medical reports (Med report), Nursing care–Monitoring and vitals (Nurs-Monit), Multidisciplinary follow-up and daily notes (daily note), Imaging reports (image), Prescriptions and medication orders (Presc), Paramedical care (Paramed), Administrative and admission (Admin), Results and pathology reports (Patho), and Other.

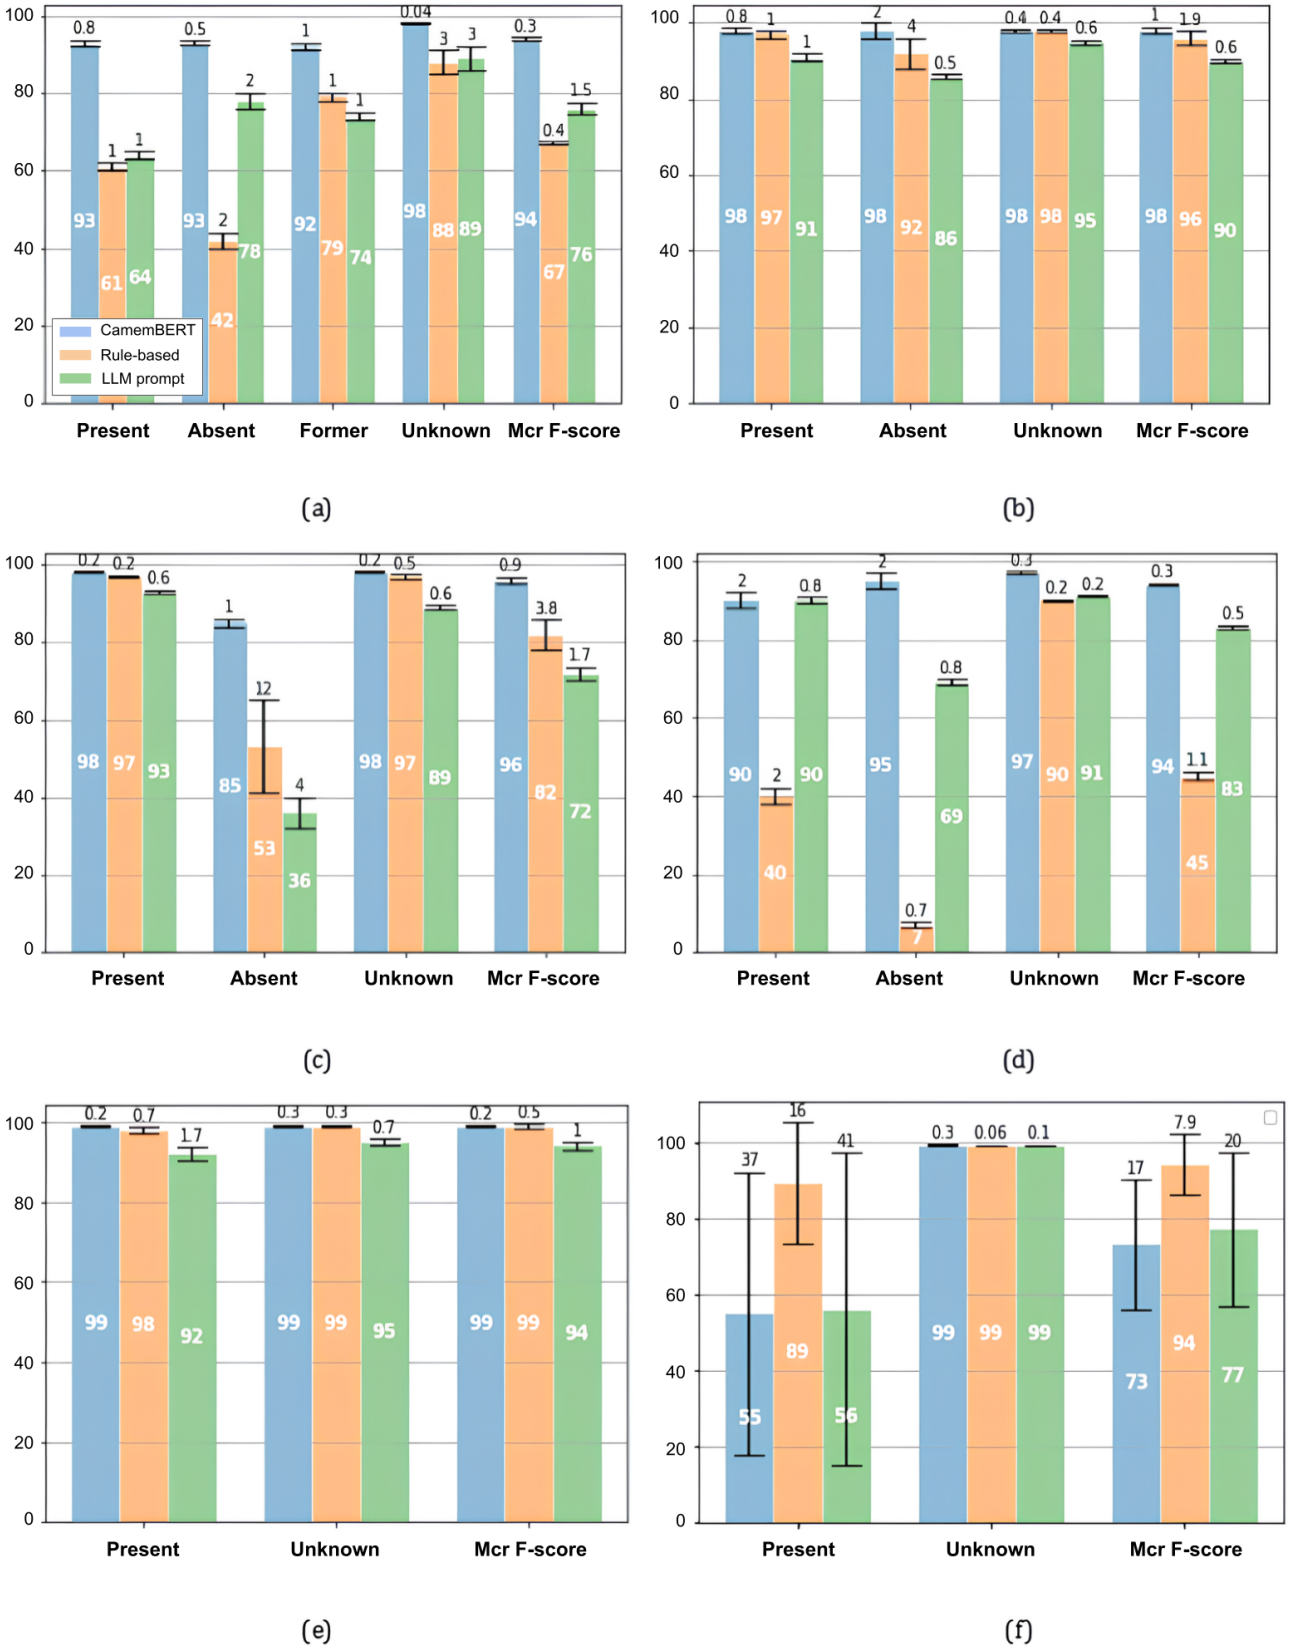
For 72 status–document-type combinations, no sample was retrieved in validation sets, and performance cannot be discussed (marked with an "-"). For the remaining 115 status document-type combinations, we can divide results into 2 categories.



Those with comparable performance (less than 5% decrease) or improvement on specific documents (109/115, 94.8%) and those where a decrease is observed (6/115, 5.2%). In the first category, 79 instances show a score of 1.0 +/– N/A, indicating that only one-fold contains content for evaluation. This perfect performance also suggests that few samples were available for evaluation. In the second category, 2 instances were only evaluated in one fold, and extractors missed the status (ie, for hypertension presence and heart failure presence in the nurse report). For the 4 others (smoking presence and diabetes indifference in paramedical report, absence of heart failure in daily note, and presence of COPD in administration note), a decrease is observed, but performance remains acceptable (>80%). Examination of false positives and false negatives in these 4 cases suggests that most errors stem from the misleading narrative style of clinical notes. For example, in a paramedical report, "OH chronique sevré tabac syndrome dépressif" (Chronic alcohol use weaned tobacco use depressive disorder) was misclassified as former smoking because the boundary between alcohol withdrawal and smoking was unclear. Another sentence, "des atcd cardio,HTA,DT2non traité" (A history of cardiac disease, untreated hypertension, and type 2 diabetes) was misclassified as absence of diabetes because the negation "non" was attached to the diabetes "DT2" rather than to the treatment "traité." The extractor also produces some persistent errors due to the medical complexity of the content, which is challenging even for specialist reviewers; for instance, a sentence in a daily note was misclassified as absent of heart failure because it contains this expression "avec une fraction d'éjection ventriculaire conservée" (with a preserved ventricular ejection fraction), which does not exclude entirely the possibility of having a heart failure. In conclusion, although the representation of entities is very sparse, we observe overall good robustness of the extractors depending on the type of document encountered. To go further, the number of annotated sentences would need to be increased.

Comparison With Alternative Approaches

Figure 3 presents a comparison of the extractors developed using CamemBERT fine-tuning, rule-based methods, and LLM prompting (Mixtral-8×7B-v0.1). As a reminder, all extractors were evaluated on the same validation sets used for the 3-fold cross-validation of CamemBERT-based extractors. For conditions with ample annotated examples, such as smoking and heart failure, CamemBERT-based extractors achieved the highest performance (also confirmed by paired *t* test analysis; Multimedia Appendix 3). In contrast, for conditions with limited training data, rule-based extractors performed comparably to or better than CamemBERT-based models, reflecting their robustness in low-data scenarios. This was particularly evident for family history of cancer, where CamemBERT-based extractors achieved an average macro *F*-score of 0.73 with a cross-validation SD of 17%, while the rule-based approach reached an average macro *F*-score of 0.94 with a substantially lower SD of 7.9%.

XSL•FO
RenderX

Figure 3. Comparison of the performance of extractors based on 3 different approaches: fine-tuned CamemBERT, (**A**) rule-based extraction and large language model prompt query for smoking, (**B**) diabetes, (**C**) hypertension, (**D**) heart failure, (**E**) chronic obstructive pulmonary disease, and (**F**) family history of cancer. The white number on each bar marks the average macro *F*-score percentage, and the number above each bar represents the SD (also percentage) calculated from cross-validation. The performance is evaluated by testing all extractors on the same validation datasets used during the 3-fold cross-validation of the 2nd iteration of the pipeline.

Compared with CamemBERT-based and rule-based extractors, LLM-prompted extractors showed intermediate performance overall but were less efficient in our setting. Using Mixtral-8×7B-v0.1, sentence-level extraction required 12 - 24 seconds per sentence and 35 GB of GPU memory, which is

XSL•FO
RenderX

slower and more resource-intensive than CamemBERT (0.09 - 0.12 s per sentence; 2 GB GPU).

These findings indicate that CamemBERT-based and rule-based methods are the most suitable approaches for our institutional resource constraints, and that no single extraction approach is universally optimal across all clinical scenarios.

Discussion

Overview

This section examines the advantages and limitations of the MSEP pipeline within our institutional setting and explores how its design can support local development of clinical NLP extractors.

Technical Advantages

Efficiency Gains for Clinical Text Annotation

The MSEP pipeline addresses challenges posed by the low density of medical-status information in large institutional corpora, which can hinder the efficient local development of information extraction systems. Its preannotation step helps prioritize sentences with potentially relevant information, and reframing extraction as sentence classification allows annotators to make quicker labeling decisions. Together, these components streamline dataset construction and reduce the operational burden of annotation.

Although our annotators were unavailable for extensive medical entity annotation, preventing a direct comparison of annotation speed in our institution, prior work has shown that sentence classification generally requires less annotation time and effort than word-level NER [57-60]. This is expected, as sentence classification involves assigning a single label to an entire sentence, whereas NER requires annotators to identify multiple entities within a sentence and decide on their boundaries, increasing the complexity and time required for annotation [61]. This improvement in annotation speed is also supported by an empirical comparison with a previous study on NER efficiency [20], as our manual sentence classification ranged from 1.2 to 2.9 seconds per sentence (or 2.23 to 4.25 s per sentence when considering only informative sentences), significantly faster than the 7.82 to 16.48 s reported for NER.

The sentence classification-based extractors also demonstrated faster inference speed than the traditional composite extractors (NER + qualifier). In our study, extractors of rule-based NER combined with EDS-NLP qualifiers were tested for smoking and family history of cancer during the preannotation step of the first iteration of the pipeline. The composite approach (0.17 s/sentence) was notably slower than our CamemBERT-based extractor (0.09 - 0.12 s/sentence) and rules-only preannotation models (0.02 - 0.04 s/sentence). Importantly, this efficiency gain did not compromise performance. Compared with recent medical status extractors, our pipeline achieved comparable or superior results. Our extractors reached *F*-scores of 99%, 95%, 96%, and 99% for diabetes, smoking, heart failure, and COPD, respectively, matching or exceeding performance metrics reported in recent literature [16].

Hybrid, Configurable, and Locally Deployable Pipeline Architecture

The MSEP pipeline was designed as a flexible and configurable framework that enables the local deployment of hybrid extraction approaches across diverse institutional settings. The accompanying Python package (repository link in Multimedia Appendix 1) exposes all key components, such as preannotation models (D1), sentence filtering criteria (D2), cross-validation strategy (C2), and extractor choice, as configurable arguments. This modular design allows researchers to tailor each step of the workflow, including the choice of extraction approach, according to their resource constraints, characteristics of the targeted information, and institutional requirements. For instance, in our experiments, fine-tuned CamemBERT models produced satisfactory performance for most medical statuses, whereas rule-based extractors yielded more stable results for conditions with limited representation in the dataset. This means that the pipeline can be configured to favor rule-based extraction in low-example scenarios. Conversely, in settings with limited annotation resources or domain expertise, the pipeline can be configured to generate LLM prompt-based extractors, which can be readily improved by providing more detailed instructions and examples in the prompts [62].

Our institutional experiments further illustrated the practical feasibility of deploying MSEP within a local clinical setting. First, the full workflow, including preannotation, manual validation, model training, and validation, was applied independently to 6 medical conditions and completed within 99 hours in total (approximately 16.5 h per condition). This was achieved with 2 annotators and a single NVIDIA A100 40 GB GPU, a setup feasible for many medical research institutions. Second, the models were trained and evaluated on a heterogeneous set of clinical documents (including hospital discharge summaries, consultation notes, and reports from multiple specialties). The comparable performance observed across these diverse sources indicates that the workflow can be operationalized effectively within diverse documentation practices at a single institution.

While our current evaluation remains monocentric, MSEP's packaging and explicit parameterization are designed to facilitate reproducible deployment in other institutions. Applying identical configurations on comparable data would be expected to yield consistent results, and extending the approach to multicentric validation represents an important next step toward confirming generalizability and cross-site reproducibility.

Enhanced Monitoring and Optimization Mechanic

The pipeline provides means for evaluating and improving each of its mean processes (data qualification, manual annotation and correction, model training, and cross-validation). Preannotation (D1) allows estimation and supervision on corpus' sample density and medical status' distribution, which can be adjusted by sentence filtering (D2); interannotator agreement calculation (M2) and analysis of annotation disagreements (M3) not only revise the quality of annotated sentences, but also reveal problems in annotation guidelines and improve them accordingly (M4); extractors' assessment and comparison (C4) enables

XSL•FO
RenderX

comprehensive model evaluation and informs decisions on the need for and direction of further improvements.

The iterative nature of our pipeline provides a means for monitoring and optimizing dataset size. By accumulating annotated data gradually and evaluating extractors with cross-validation at each iteration, we can determine when to halt manual annotation, limiting resource expenditure to reasonable levels. We also considered active learning as an alternative approach, where the model selects samples difficult to predict for prioritized manual annotation and updates itself with the received annotation [63]. In theory, this approach can maximize annotation efficiency by prioritizing the most informative samples for model improvement. However, we ultimately rejected it because model updates were disproportionately influenced by status categories with the most samples, and uncertain sample distribution prevented effective loss function weighting. Nevertheless, active learning remains valuable when balanced datasets are available or when sample balancing can be implemented during data acquisition [64].

Importance for Clinical Research

Response to Clinical Text-Mining Challenges

Clinical text mining remains challenging due to the unstructured and context-dependent nature of medical narratives. Our evaluation shows that sentence-level classification, as implemented in MSEP, effectively addresses several of these challenges in practice. The approach demonstrated high accuracy across heterogeneous document types, confirming that the model captures contextual cues, such as negation or temporality, without relying on context qualifiers. Compared with traditional NER-based systems, which require token-level annotation and post hoc context detection, the sentence classification strategy substantially reduces annotation time and complexity. The high *F*-scores obtained for conditions such as smoking and diabetes illustrate that this formulation aligns well with the way medical status is expressed, which is typically at the sentence level rather than through isolated entities.

To our knowledge, there is currently no existing pipeline in the clinical NLP literature that applies sentence classification for medical status extraction. While sentence classification has been explored in other domains, such as sentiment analysis or social media mining, its application to clinical narratives remains underdeveloped and has not yet been systematically assessed for this purpose.

Easy Implementation as a Research Tool for Clinical Studies

Clinical text-mining efforts are often constrained by privacy regulations and institutional heterogeneity that prevent direct data or model sharing across sites [16,19,36-38]. The MSEP framework was designed to address these issues by enabling efficient local dataset construction, providing flexible configuration of extraction approaches according to institutional constraints, and supporting controlled resource expenditure through performance-monitored iteration.

Beyond initial model development, MSEP demonstrated utility as an upstream component in broader research workflows that can support more specialized downstream tasks. When applied first, MSEP extractors can identify only the documents or sentences that contain the targeted medical status, allowing researchers to exclude irrelevant material entirely and thus avoid expending effort on processing noninformative documents. In practice, this functionality has already been demonstrated within our institution, where a smoking-status classifier created by MSEP was applied to an independent corpus of 300 clinical reports, efficiently filtering for documents concerning patients who were smokers and achieving an *F*-score of 99.6% for detecting smoking-related content. Downstream tasks, such as extracting smoking duration or tobacco brand, can then be focused solely on these filtered documents, reducing workload and improving overall efficiency.

Current Limitations

Our study has several limitations worth noting. First, due to the availability of medical experts, we did not conduct a direct comparison between sentence classification and NER. Instead, we relied on empirical observations and general consensus to suggest that sentence classification offers greater annotation efficiency. While the improvement in annotation speed appears supported, the impact on annotation quality remains to be verified.

Second, clinical document type is a factor that can influence the interpretation of medical status occurrence in text, which was not fully addressed in our study. For instance, a mention of “hypertension” in a medical report, especially within the “Past Medical History” section, typically refers to a chronic condition. In contrast, if hypertension is noted in daily progress notes, it is more likely to reflect an acute episode under current observation or management. Therefore, when applying MSEP to clinical documents from a CDW, it may be necessary to incorporate a document selection step during data collection (P1), not only to include relevant document types, but also to focus on specific sections within documents, such as the “Past Medical History” section, when these are more likely to align with the study objectives.

Third, the construction and usage of the datasets are subject to several sources of bias. Preannotation and filtering were used to increase the density of informative samples in the dataset, but mislabeling by preannotation rules could have led to the exclusion of relevant sentences (eg, those labeled as “unknown”). To assess this risk, 10% of our dataset consisted of nonpreannotated sentences, which were used to evaluate potential bias introduced by the preannotation rules. While most conditions showed limited distortion, a notable shift was observed for the present status of heart failure, underscoring that preannotation can influence class distributions. A further concern is the risk of circular bias, which may be induced by using sentences initially selected by rules to evaluate those same rule-based extractors. To limit this risk, we constructed the annotated corpus by combining the preannotations from all descriptors rather than relying on a single rule-based extractor per condition, resulting in a relatively small proportion of validation sentences originating from the same rule set (eg, 3.4% - 3.6% for COPD). Evaluating extractors is a complex task in such large datasets. Ideally, most of the dataset would

XSL•FO
RenderX

need to be annotated to determine actual performance. However, this task requires too much annotation time for most noninformative sentences. Our approach to selection by multiple preannotations allows us to limit this time while verifying that little bias appears to be induced (eg, confirmed using sentences without preannotation). Finally, although identical sentences were deduplicated before cross-validation, dataset partitioning was not stratified by Patient_ID. As a result, sentences about the same patient could appear across validation folds, introducing a potential risk of data leakage. The proportion of validation sentences with patient overlap ranged from 3% to 8%. To assess the impact of this overlap, we revalidated the models after removing these sentences from the validation sets. Performance changes were minimal (less than 1% of drop for macro *F*-score of each cross-validation fold), suggesting that patient-level overlap did not artificially inflate extractor performance. Moving forward, these extractors should be used on other datasets while keeping in mind their potential limitations.

Fourth, the evaluation of certain medical statuses was limited by their very low prevalence in the corpus. For COPD and family history of cancer, the Absent status was represented by only a single instance, preventing meaningful assessment of the extractor's ability to distinguish absent from unknown. Consequently, both extractors effectively functioned as binary classifiers (present vs unknown). This limitation reflects typical documentation practices: the absence of a specific condition (eg, COPD) is rarely stated explicitly, as doing so would require exhaustively listing all conditions that are not present; the issue is somewhat different for family history of cancer, where the absence of this condition is generally more informative ("no family history of cancer") and therefore more likely to be mentioned, although such mentions remained infrequent in our dataset.

Finally, decoder-only LLMs were not fully used due to initial infrastructure limitations. Our computing environment, a secure server at the University Hospital of Rennes with 112 Intel(R) Xeon(R) Gold 6258R CPU cores and limited access to an NVIDIA A100 40 GB GPU, was insufficient for efficient, prompt-based inference (12 - 24 s/sentence when performing medical status extraction) or fine-tuning (requiring ≥64 GB VRAM).

Perspectives and Future Applications

Beyond its current implementation, the pipeline can be extended to broader medical information extraction tasks. Ongoing work includes detecting additional statuses relevant to bladder cancer [3] and extracting finer-grained information such as smoking duration and cigarette type. By first classifying sentences containing smoking mentions, the pipeline narrows the scope for subsequent extractions, improving efficiency.

Future studies will also address current limitations. First, a direct comparison of annotation speed and quality between sentence classification and NER will provide stronger evidence for our methodological choice. Second, it is well known that medical documents contain information, structures, and sometimes vocabulary that are unique to them. For our specific study, we have demonstrated a certain robustness of extractors to these phenomena. To reinforce this finding, more instances will need to be annotated, bearing in mind that we are working in a very sparse context. Third, synthetic datasets will be explored to mitigate preannotation bias, balance category distributions, and reduce reliance on sensitive records. They may also improve extractor performance on medical conditions with scarce samples (eg, family history of cancer). Prior studies have investigated GANs for generating synthetic structured EHRs [40]; while ensuring both utility and confidentiality remain challenging, synthetic data offer a promising path forward for clinical NLP.

Finally, the Ollama framework [65] will be used for a better exploration of LLM prompt potential. This framework enables accelerated local inference, improving medical status annotation speed with Mixtral-8x7B-v0.1 to 0.2 seconds per sentence. Although LLM prompting has not yet reached the same level of performance as CamemBERT fine-tuning for certain conditions, further exploration of prompt design and fine-tuning strategies may be pursued as infrastructure improves. However, it is important to keep in mind the computational and ecological cost of such a strategy when rule-based and CamemBERT-based approaches can provide satisfactory results.

Together, these perspectives aim to strengthen the robustness, reproducibility, and applicability of the pipeline across diverse clinical research settings.

Conclusions

We introduced MSEP, a modular and hybrid methodological framework for extracting medical status information from unstructured clinical text using sentence classification. In our institutional case study, the pipeline substantially reduced annotation effort: sentence-level labeling with preannotation required only 1.2 - 2.9 seconds per sentence. MSEP successfully supported the implementation of 3 extraction approaches: rule-based methods, fine-tuned CamemBERT model, and LLM prompting, each suited to different data and resource scenarios. Fine-tuned CamemBERT model achieved high performance for conditions with sufficient training examples (macro *F*-score>94%), whereas rule-based methods provided more stable results for sparsely represented conditions. Together, these findings highlight MSEP's value as a research tool that accelerates local dataset creation and enables flexible deployment of extraction systems. Importantly, all components of the pipeline are distributed as a ready-to-use Python package.

Abstract

Background: Harmful suicide content on the internet poses significant risks, as it can induce suicidal thoughts and behaviors, particularly among vulnerable populations. Despite global efforts, existing moderation approaches remain insufficient, especially in high-risk regions such as South Korea, which has the highest suicide rate among Organisation for Economic Co-operation and Development countries. Previous research has primarily focused on assessing the suicide risk of the authors who wrote the content rather than the harmfulness of content itself which potentially leads the readers to self-harm or suicide, highlighting a critical gap in current approaches. Our study addresses this gap by shifting the focus from assessing the suicide risk of content authors to evaluating the harmfulness of the content itself and its potential to induce suicide risk among readers.

Objective: This study aimed to develop an artificial intelligence (AI)–driven system for classifying online suicide-related content into 5 levels: illegal, harmful, potentially harmful, harmless, and non–suicide-related. In addition, the researchers construct a multimodal benchmark dataset with expert annotations to improve content moderation and assist AI models in detecting and regulating harmful content more effectively.

Methods: We collected 43,244 user-generated posts from various online sources, including social media, question and answer (Q&A) platforms, and online communities. To reduce the workload on human annotators, GPT-4 was used for preannotation, filtering, and categorizing content before manual review by medical professionals. A task description document ensured consistency in classification. Ultimately, a benchmark dataset of 452 manually labeled entries was developed, including both Korean and English versions, to support AI-based moderation. The study also evaluated zero-shot and few-shot learning to determine the best AI approach for detecting harmful content.

Results: The multimodal benchmark dataset showed that GPT-4 achieved the highest F_1-scores (66.46 for illegal and 77.09 for harmful content detection). Image descriptions improved classification accuracy, while directly using raw images slightly decreased performance. Few-shot learning significantly enhanced detection, demonstrating that small but high-quality datasets could improve AI-driven moderation. However, translation challenges were observed, particularly in suicide-related slang and abbreviations, which were sometimes inaccurately conveyed in the English benchmark.

Conclusions: This study provides a high-quality benchmark for AI-based suicide content detection, proving that large language models can effectively assist in content moderation while reducing the burden on human moderators. Future work will focus on enhancing real-time detection and improving the handling of subtle or disguised harmful content.

KEYWORDS

artificial intelligence; dataset; suicide; suicide-related content; large language models

Introduction

Harmful suicide content on the internet poses a significant risk because it can induce suicidal thoughts in readers, potentially leading to self-harm or suicide [1,2]. The harmful suicide content includes materials that encourage or glorify suicide [3], making it appear as an attractive option and sharing suicide methods or instilling suicide knowledge in individuals with suicidal thoughts, thereby increasing the likelihood of actual suicide attempts [4]. In some cases, exposure to such harmful suicide content has led middle school students to commit suicide [5]. An analysis of adolescent suicide cases reveals that this age group, particularly female adolescents, is more vulnerable to the influence of triggering content [6,7]. Therefore, it is crucial to moderate such harmful suicide content before it spreads extensively.

Therefore, efforts to moderate harmful suicide content are intensifying. In the United States, initiatives focus on raising public awareness and safe content distribution, aligning with the World Health Organization guidelines [8]. Meanwhile, in 2022, the United Kingdom passed a law that makes such content illegal, emphasizing its serious commitment to addressing this issue [9]. In the Republic of Korea, which has the highest suicide rates among Organisation for Economic Co-operation and Development countries [10], the National Assembly of the Republic of Korea amended the Suicide Prevention Act, and the government has declared the dissemination of such content as illegal since 2019 [2]. Despite the increasing spread of harmful suicide content, its moderation is currently handled by only a single official and fewer than a thousand volunteers [11,12]. Considering the extensive use of social media in Korea [13], monitoring the large amounts of content is extremely challenging. In addition, moderating suicide content often leads to a high level of mental stress, hindering their ability to consistently and effectively monitor such content. Therefore, the need for an automatic harmful suicide content moderation system is urgent. The system can efficiently manage a growing volume of the content and ease the burden on human moderators.

However, previous research on online suicide content primarily focused on predicting the suicide risk of the authors who wrote the content. Zirikly et al [14] classified the suicide risk of authors based on content posted online (Reddit) into 4 levels. Similarly, Milne et al [15] and Yates et al [16] conducted research to predict the suicide and self-harm risks of online content authors. Subsequently, Yang et al [17] and Sawhney et al [18] used weakly supervised learning to enhance detection performance or collaborated with clinicians. Furthermore, Rawat et al [19] and Sawhney et al [20] performed tasks to detect suicide ideation and suicide events. All these studies focused on detecting the suicide risk of the author presented in the posts; they did not consider the potential propagation of suicide risk to readers by increasing their susceptibility to self-harm or suicidal behaviors. Other studies focused on understanding the negative effects of suicide content [6,21], or identifying the individuals who are most affected by the content [22-25]. Studies among Chinese adolescents have shown significant correlations between digital media usage and suicide or self-harm [23], and a meaningful relationship between suicide cases among Korean youths and searches related to suicide or self-harm [25]. In addition, three-quarters of young adults who have attempted suicide have reported using the internet for suicide or self-harm–related reasons [26], highlighting the risk posed by information that can induce suicide or self-harm.

Therefore, we introduce a *harmful suicide content detection* task that determines the level of harmfulness of the harmful suicide content to viewers. We then develop a multimodal *harmful suicide content detection benchmark* and a *task description document*. This document contains detailed instructions for annotators on how to assess the harmfulness of suicide-related content, which could also be useful for building instructions for large language models (LLMs). The benchmark and the document are developed by medical professionals, because such content might involve harmful visual language information that requires the judgment of the professionals (eg, self-harm photographs, or name of illegal drugs that can be used for suicide). Because labeling harmful suicide content causes mental stress, we focus on creating a small yet high-quality dataset. Furthermore, we demonstrate various methods using LLMs that can be effectively performed with few-shot examples.

Our contributions are as follows: (1) We propose a harmful suicide content detection task that classifies multimodal harmful suicide content as illegal, harmful, potentially harmful, harmless, or non–suicide-related. (2) We build a harmful suicide content detection benchmark that is multimodal and a Korean benchmark of 452 curated user-generated contents with corresponding medical expert annotations and a detailed task description document including the task details and instructions for annotators. (3) We create an English harmful suicide content detection benchmark translated from the Korean benchmark using a model (GPT-4) and analyze the quality and issues of translating suicide contents. (5) We demonstrate strategies to use LLMs to detect harmful suicide content by using the task description document and a small yet high-quality harmful suicide content detection benchmark. We test various closed and open-sourced LLMs using the machine-translated English benchmark. We observe that GPT-4 achieves F_1-scores of 66.46 and 77.09 in detecting illegal and harmful suicide content, respectively.

Methods

Study Design

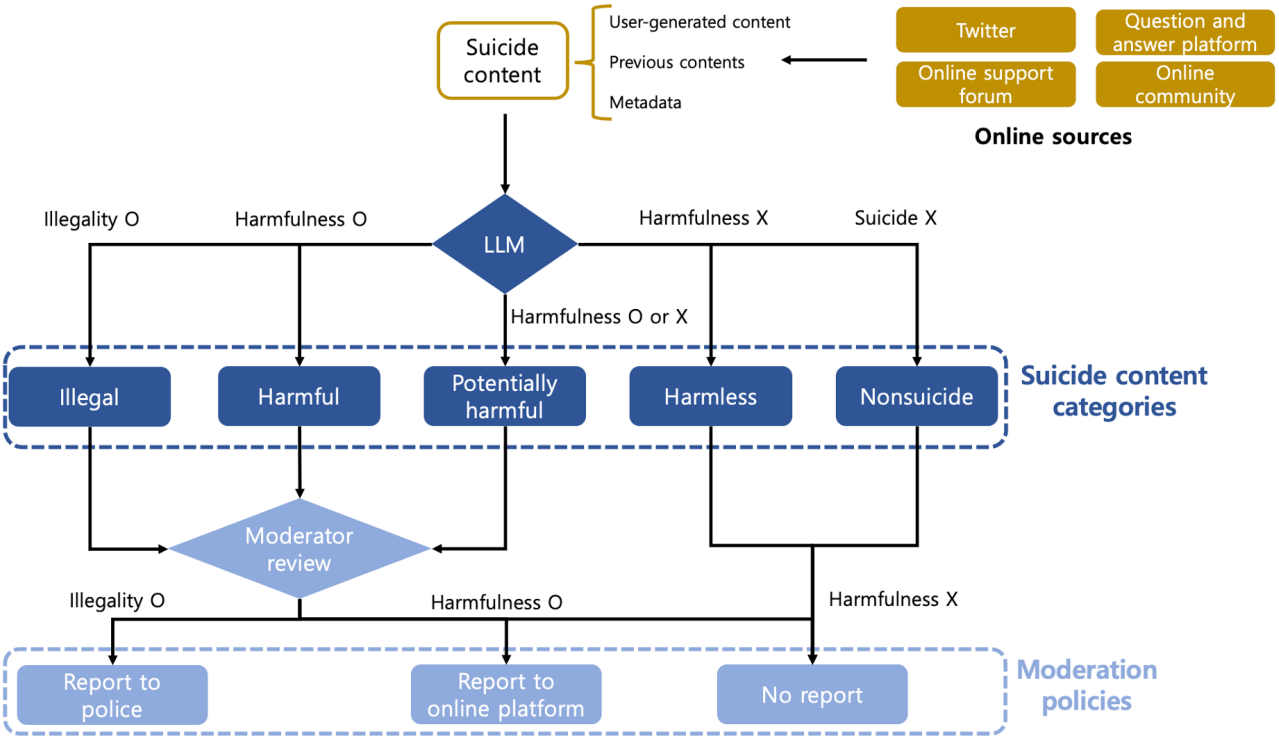
In this section, we describe the design process for the harmful suicide content detection task and the steps to construct a harmful suicide content detection benchmark for this task. First, in the “Task Design” subsection, we outline the process of designing the task with emphasis on real-world implementation for detecting harmful suicide content in real time from online sources. This design phase includes detailed considerations for building the dataset.

XSL•FO
RenderX

Next, the "Data Processing Workflow" subsection describes the end-to-end process, from collecting harmful suicide content to developing the final harmful suicide content detection benchmark. Harmful suicide content is gathered from various online sources, and the preannotation process [27,28], which uses LLMs, is used to reduce annotators' exposure to vast quantities of harmful suicide content. Feedback generated from the annotation process by medical experts is used to update the task description document, which includes the categories and descriptions of harmful suicide content. This task description document is then used as an instruction for the preannotation process, creating an iterative process that builds and refines the harmful suicide content detection benchmark. Through this process, we ensure the inclusion of diverse, accurately labeled real-world harmful suicide content in the harmful suicide content detection benchmark while constructing a task description document that provides precise and comprehensive classification and explanations of the harmful suicide content.

As a result, from a collection of 43,244 harmful suicide content data points, we created a harmful suicide content detection benchmark consisting of 452 data points annotated by medical experts with suicide content categories, subcategories, and rationales for their classifications.

Ethical Considerations



We obtained institutional review board (IRB) approval (approval number: KHUH 2023-04-072) from the IRB of Kyung-Hee University Hospital, South Korea, based on the principles of the Declaration of Helsinki, ensuring adherence to ethical standards. The IRB approval includes the collection of suicide-related data, the development of guidelines for data classification, and data labeling. It also specifies the acquisition of data through the collection of publicly available posts from online spaces targeting the general public, and it outlines the development of an artificial intelligence model for detecting suicide-related content using these data. All personally identifiable information (PII) (eg, user IDs, names, addresses, and phone numbers) was anonymized and replaced with standardized tags. The benchmark contains extremely disturbing text and images, including self-harming photographs, blood, tools used for suicide and self-harm, and drug information. Even among medical professionals and researchers, prolonged exposure to such images can lead to severe mental stress. Therefore, we have deliberately chosen not to aim for the creation of a large-scale dataset but rather to limit the workload to prevent further intensifying mental stress. All these processes were conducted with IRB approval obtained prior to data collection. Given the nature of harmful suicide content and the legal restrictions against its unrestricted distribution, it is challenging to share the benchmark dataset openly. We understand the legal implications of distributing data containing information that potentially induces suicide. Despite these concerns, we believe that collecting such data to build a benchmark and conducting research to prevent its spread on the internet outweigh these legal issues. Access to the benchmark will be strictly limited, allowing only those researchers with IRB approval and a commitment not to distribute the content further, ensuring responsible use for research purposes only and adherence to legal standards. We believe that our work contributes significantly to the ongoing international effort against harmful suicide content and hope to aid in preventing its spread on the internet.

Task Design

Figure 1 illustrates the concept of using harmful suicide content detection in a real-world *moderation system*. The moderation system uses a model to automatically detect harmful suicide content and checks for illegal or harmful content and implements the appropriate *moderation policy* through a moderator's review. As this study introduces the harmful suicide content detection for the first time, our focus is on developing a model to automatically detect harmful suicide content rather than implementing an end-to-end moderation system. Therefore, this study focused on developing a harmful suicide content detection with this moderation system in mind, leaving the implementation of an end-to-end moderation system for future work. Specifically, we considered the inputs and outputs of harmful suicide content detection, considering the various real-world information on harmful suicide content that a moderation system might encounter as well as the moderation actions by a moderator.

XSL•FO
RenderX

Figure 1. Moderation system for harmful suicide content detection, categorizing online user-generated content into 5 classes by legality, harmfulness, and suicide relation. A moderator reviews content with potential illegality or harm, leading to legal reporting or content removal requests. No action is taken if no risks are found. "O" indicates that the corresponding value exists, and "X" indicates that the value does not exist. "O/X" denotes the potentiality of whether the corresponding value exists or not. LLM: large language model.

The model classifies the content into 5 distinct *suicide categories* based on illegality, harmfulness, and suicide-related aspects. For categories identified as having minimal harmfulness, a moderator validates the harmfulness through a review. Finally, the moderator moderates harmful suicide content using a moderation policy suitable for the identified harmfulness and illegality of the content, thereby minimizing human intervention and effectively moderating harmful suicide content.

To ensure that the detection system is applicable to real-world online data, the task targets various data from diverse sources to encompass a broad spectrum of user-generated content encountered on the internet. This approach ensures that the system effectively addresses the complexities and nuances of online posts ("Task Input" section).

The classification results produced by the harmful suicide content detection were crafted considering the functionality of a moderation system in mind. This means that the categories into which the content is sorted are specifically designed to facilitate the practical use of these results in moderating the content, ensuring that the system can serve as an effective tool for maintaining online safety and supporting mental well-being ("Task Output" section).

A moderator review was designed to validate the model's classification results and implement appropriate moderation. Specifically, for content categorized under the harmful categories, the process validates the harmfulness to ensure the reliability of the moderation system. In addition, because this process involves confirming the results of the model rather than newly identifying and classifying suicide content, it is more efficient in terms of reducing mental stress on moderators. Finally, suitable moderation policies were implemented based on the validation results. This system was developed to regulate suicide content and execute different moderation policies based on the illegality and harmfulness, thus preventing the spread of harmful suicide content online ("Moderator Review" section).

In summary, the entire process involves the model classifying online content into suicide categories, the moderator reviewing the results, and then implementing the corresponding moderation policy to ensure that the moderation system functions effectively. Throughout this process, multimodality information such as text and image data are used to reflect various aspects of the content in the model's input. Metadata from diverse sources and previous content serve as context. The model's output comprises 5 suicide categories, each differentiated by the presence or absence of illegality, harmfulness, and suicide-related aspects. Finally, the moderator review efficiently uses the model's classification results for validation, and effective moderation policies are implemented based on the content's illegality and harmfulness, thereby preventing the spread of harmful suicide content online.

Task Input

Considerations

We consider the following for designing the input of the task. (1) *Multimodality*: Because 50% of harmful suicide content contain images or videos [29], we consider text and images as inputs. (2) *Source diversity*: Harmful suicide content appears across various platforms, from social media to online communities [29]. We collected data from diverse sources for comprehensive coverage. (3) *Context information*: We also

XSL•FO
RenderX

incorporate previous content and metadata into our inputs. Previous content reveals the context of the target content, whereas metadata, such as user descriptions and view counts, provides additional insights, aiding in accurate harmfulness assessment.

Inputs

Given the considerations, the inputs for the task are as follows: (1) *User-generated content*: Contents created by users. The content includes text, and possibly images and URLs. Images and URLs are converted to text manually or using machine learning models (eg, image captioning and summarization). (2) *Previous content*: Previous content is often required because it provides context, clarifies references, and provides background information essential for the full comprehension of user-generated content. (3) *Metadata*: Other contextual information about the user-generated content such as view counts, like counts, creation time, user self-description, and so on.

Task Output

Considerations

We consider the following for designing the outputs of the task. (1) *Expert judgment*: Harmful suicide content involves specific terminology related to suicide, such as professional drug names, slang, and abbreviations. Thus, clinical expertise is required to accurately determine the legality and harmfulness of such suicide content and to decide on an appropriate response to the content. (2) *Moderation policy*: If an automatic harmful suicide content detection model is developed, it should be part of a moderation system and collaborate with human moderators or domain experts [18]. This implies that once the model detects harmful suicide content, it is necessary to consider appropriate actions. Therefore, the response of each output was considered when defining the output.

Outputs

We develop five harmful suicide content categories. Content should be mapped to one of the following categories: (1) *illegal* content that encourages or assists suicidal behavior; (2) *legal but harmful* content that, while not illegal, significantly induces suicide; (3) *potentially harmful* content that could be triggering for certain individuals, whereas it may be benign for others; (4) *harmless* content that is either neutral or positive for suicide; and (5) *nonsuicide* content that is not related to suicide.

Moderator Review

Moderator review includes the process of reexamining the suicide content classified by the model using moderator (eg, a clinical expert) and implementing the appropriate moderation policy. The moderation system identifies the harmfulness and illegality of suicide content and implements a corresponding moderation policy to block the spread of such content online. Thus, through moderator review, the moderator (1) verifies the classification result of the model and (2) implements the corresponding moderation policy. The moderator review is conducted for results classified as illegal, harmful, and potentially harmful because most online information is unrelated to suicide and reviewing all the information would increase moderator fatigue. Hence, reviews are conducted only for suicide information that may cause harm. The moderator verifies the illegality and harmfulness of content within these categories and conducts the corresponding moderation policy. Therefore, the moderator requires knowledge to comprehend and understand the content and distinctions of suicide content.

Moderation Policies

The moderator reviews the model's classification results and implements a corresponding moderation policy. The moderation policies are as follows: (1) *Report to police*: This is the strongest form of moderation policy intended to subject content creators to legal regulations by reporting to legal institutions. (2) *Report to online source*: Reporting the content to the online source where it is posted intends to prevent the spread of harmful information by requesting the deletion of the content. (3) *No report*: No additional actions, such as reporting the posts, are taken, allowing it to circulate online.

Report to police responds to content within the illegal suicide category containing illegal information. According to Korean law, certain types of content related to suicide are defined as illegal. Such content often includes illegal activities, such as the sale of illegal drugs; hence, reporting to legal institutions (eg, the police) imposes legal sanctions on the poster of such content.

Report to online source prevents the online spread of content containing or potentially containing harmful information related to suicide, such as illegal, harmful, and potentially harmful content. Because information spreads quickly online, it is reported to the online source where it was posted, and its removal is requested to prevent dissemination. For potentially harmful information, the harmfulness of which can vary depending on the reader, the moderator assesses the degree of harmfulness and reports whether it is severe.

No report is for harmless or nonsuicide content that poses no problem when posted online. Most online content is unrelated to suicide; therefore, it does not require reporting.

Table 1 shows the features of each category in terms of legality, harmfulness, and association with suicide. *Illegal suicide content* contains the most dangerous information, explicitly encouraging or facilitating suicidal behaviors. This category is critical for immediate intervention, embodying content that can actively propel individuals toward self-harm or suicide. *Harmful suicide content*, while not directly inciting suicide, significantly affects the audience by portraying suicide or self-harm in a manner that can trigger such actions among vulnerable individuals. The specificity of the depiction, whether through graphic imagery or detailed descriptions, amplifies its potential harm, making it a crucial target for moderating content. *Potentially harmful suicide content* traverses a gray area, with content that might not universally trigger harmful behaviors but could potentially do so in susceptible populations. This category underscores the complex challenge of content moderation, in which the impact of the content is not universally harmful and may vary significantly among individuals. *Harmless suicide content* focuses on providing support, hope, or neutral information regarding suicide without posing a risk of harm. This category

XSL•FO
RenderX

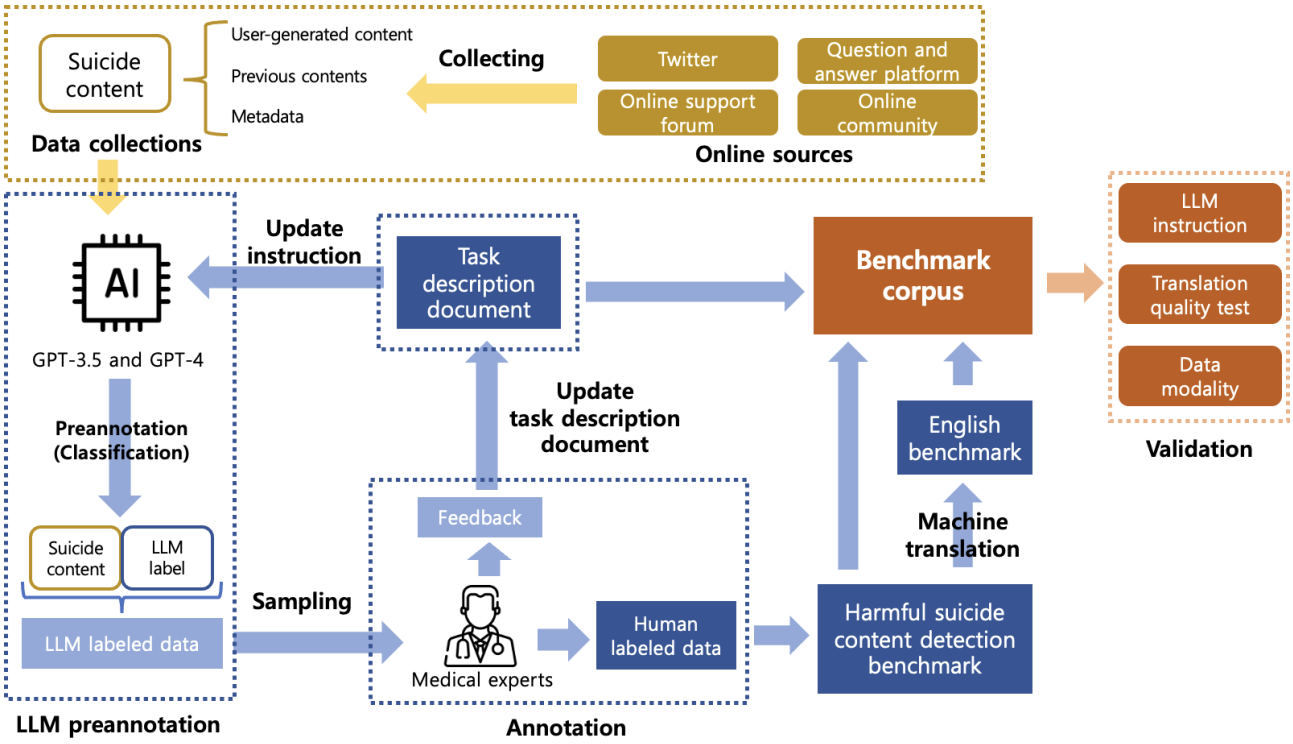
plays an essential role in suicide prevention by offering resources, support, and information to reduce suicide rates. Finally, *nonsuicide content* serves as a catchall for material that does not pertain to suicide or self-harm, highlighting the importance of distinguishing between genuinely harmful content and content unrelated to suicide.

Table . Illegality, harmfulness, and suicide relativity of categories and the moderation protocols[a].

Category	Illegality	Harmfulness	Suicide-related	Moderator review	Moderation policy
Illegal	O	O	O	O	Report to police and online source
Harmful	X	O	O	O	Report to online source
Potentially harmful	X	Δ	O	O	Report to online source or no report
Harmless	X	X	O	X	No report
Nonsuicide	X	N/A[b]	X	X	No report

[a]The (Δ) symbol represents a state that is in a gray area, indicating that the characteristic is neither fully present nor completely absent. "O" denotes the presence or applicability of a given attribute, whereas "X" denotes its absence. For instance, data categorized as "Harmful" are characterized by the absence of illegality (X), the presence of harmfulness (O), suicide-related (O), and the moderator review (O).

[b]N/A: not applicable.



Data Processing Workflow

This section describes the data processing workflow used to create a high-quality harmful suicide content detection benchmark for detecting harmful suicide content. As illustrated in Figure 2, the workflow starts from data collection, detailed in “Data Collections” subsection, and outlines the process to develop a robust and diverse benchmark for harmful suicide content detection, described in “Data Annotation” subsection. The primary goal is to create a small but high-quality benchmark that can comprehensively capture real-world scenarios and task description document that can be effectively used for LLM instruction. Key challenges include the stressful nature of the annotation process, the extremely low prevalence of illegal suicide content, and the need to ensure the benchmark’s completeness and use, given that this is a newly proposed task that must reflect various aspects of real-world data.

The methods used to address these challenges include (1) LLM sampling to reduce annotator exposure to a large volume of harmful suicide content while increasing the representation of rare, illegal suicide content; (2) an iterative annotation approach to continuously update the task description document and incorporate real-world scenarios, aiming to reflect diverse data until no further updates are required, while also considering modality (image and context) to adapt annotators effectively; and (3) filtering and validation, which involve updating the harmful suicide content detection benchmark to align with the latest task description document, categorizing and subcategorizing data accurately, and removing outliers such as incomprehensible content.

XSL•FO
RenderX

Figure 2. Overview of the data processing workflow, which consists of data collection, benchmark construction, and benchmark validation. We collect suicide content and annotate it with medical experts, leveraging LLM-based preannotation to balance categories, and we iteratively refine the task description document through feedback. We then construct the benchmark corpus with human-labeled data, an English-translated version, and the updated task description, and we validate it for applicability to LLMs. AI: artificial intelligence; LLM: large language model.

Data Collections

Developing a large-scale harmful suicide content dataset is highly challenging. Harmful suicide content is infrequently encountered in real-world scenarios [30], and the distressing nature of such content can cause mental strain for annotators. In addition, obtaining annotations from medical experts is expensive. Therefore, we focus on developing a high-quality curated benchmark dataset. Prior to the dataset collection, we obtained approval from the IRB of Kyung-Hee University Hospital, South Korea.

To cover the diverse source domains of the content, we collect user-generated content related to suicide from social media, Q&A platforms, online support forums, and online communities. Table 2 lists the number of raw data, benchmark data, descriptions of content, previous content, and metadata of each source.

Table . Number of collected harmful suicide content and harmful suicide content detection benchmark dataset for each domain[a].

Source	Raw data (no. of images)	Benchmark (no. of images)	Content	Previous content	Metadata
Twitter	12,125 (3,671)	359 (78)	Tweets written by users	Previous tweets in the thread where the content is written	User description, view count, like count, etc
Online community	794 (794)	48 (48)	Title and bodies of post written by users	N/A[b]	User nickname, view count
Q&A[c] platform	13,104 (0)	33 (0)	Question or answers written by users	Questions (if the content is an answer)	N/A
Online support forum	17,325 (0)	23 (0)	Counseling request posts or responses written by users or counselors	Counseling request posts (if the content is a response)	N/A
Total	43,244 (4,429)	452 (126)	N/A	N/A	N/A

[a]User-generated suicide content was collected along with source-specific metadata and previous content as context.

[b]N/A: not applicable.

[c]Q&A: question and answer.

RenderX

Twitter

Twitter constitutes the majority of social media posts flagged for containing suicide-inducing information, with a substantial share of 74.69% [29]. To collect data related to suicide from Twitter, we used the Twitter application programming interface (API) v2 to gather posts that include suicide-related keywords in their text or hashtags. These suicide-related keywords were collected from previous research [31] and the guidelines of the "Korean Suicide Inducing Information Monitoring Group" [32]. We gathered 12,021 tweets, including 3635 with images, from May to August 2023 using the Twitter API. The suicide-related keywords used in the Twitter API are summarized in Table 3.

[a] Search terms and synonyms are defined in the study by Park et al [33].

Q&A Platform

On Q&A platforms, users often post questions about suicide-related issues, such as suicide methods, or respond to these queries. We collected questions and answers containing suicide-related keywords from Naver Knowledge In (a Korean Q&A platform) [33]. We collected data from March 2022 to March 2023, using the same keywords as those used for Twitter, resulting in 13,104 content items.

Online Support Forum

In online support forums, people write about their suicide-related concerns, and counselors provide responses to support them [31]. We collected posts from Lifeline Korea [34] and the Companions of Life Suicide Prevention Counselling [35]. We collected 17,325 pieces of content posted from March 2021 to June 2023.

Online Community

DCinside [36], a widely used online community in Korea comparable to Reddit, includes boards that function similarly to subreddits. We collected posts from 2 depression-focused boards (depression-minor and depression-mini boards) on the DCinside, known to contain suicide-related posts and where actual suicide incidents have been reported [37]. We collected posts including those containing images, resulting in a total of 794 data entries. Overall, we collected 43,244 entries of harmful suicide content, in total, from 4 online sources, with each harmful suicide content entry comprising content, previous content, and metadata.

Data Preprocessing

To remove private information from the benchmark and generate information that requires human intervention, such as link or image descriptions, we took the following steps. First, we

XSL•FO
RenderX

removed all PII. This involves replacing URLs, names, locations, phone numbers, emails, and IDs within the text with corresponding tags. Thereafter, we provided supplementary descriptions for the contents of the external links. Given that these links may contain significant information for accurately understanding the content, we manually reviewed the links and summarized their content. Third, we added text descriptions to the images whenever they were included in the content. We used GPT-4 to generate initial descriptions, which were subsequently reviewed and refined for accuracy by the researchers. Consequently, all PII values were removed from the text of the data, and we created link descriptions that summarized the content of any URLs present in the content text, along with text descriptions for the images.

Data Annotation

Task Description Document

The task description document was designed to explain the harmful suicide content detection and to provide guidance to the annotators. It contains vital information, including the purpose of identifying harmful suicide content and a detailed guide for annotating the content. In addition, it outlines the categories and subcategories of harmful suicide content, supplemented with real-world examples.

Our basis for understanding the definitions, categories, and examples of harmful suicide content was the “Korean Suicide Prevention Law” [2] and documents published by the “Korea Life Respect Hope Foundation’s suicide/harmful information monitoring team” [32]. We found that certain category names and descriptions were unclear or overlapped, thus requiring more distinct clarifications. To address this, we involved medical professionals in the data annotation process, which led to significant revisions and refinements of the categories and their descriptions, as well as the expansion of examples for each category. Following the studies by Fiesler et al [38] and Moon et al [39], we used an iterative coding process such that the medical experts individually annotate the real-world content, come together to refine the task description document, and then repeat the coding process individually. This updating process was iterative and performed 3 times to ensure comprehensive refinement. Further details of the iterative process are presented in the “Annotation Process” section. We demonstrate each category and its description in Table 4.

Table . Name and description of each suicide category.

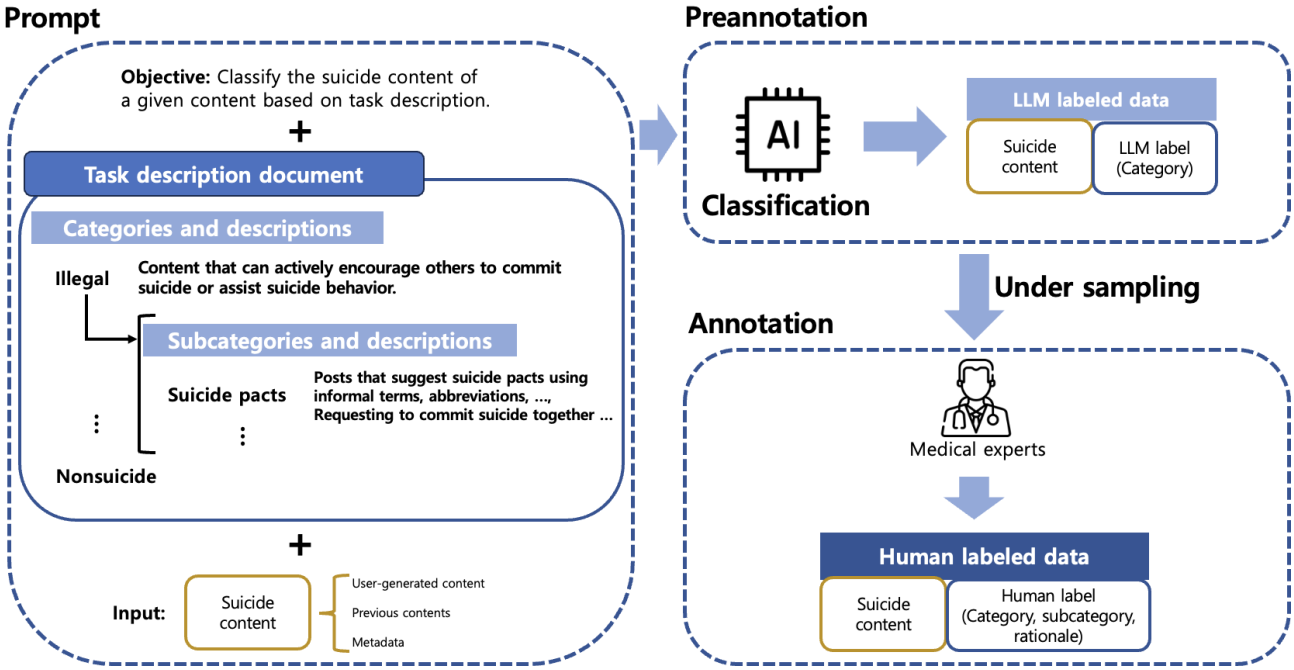
Name	Description
Illegal suicide content	Content that can actively encourage others to commit suicide or assist suicide behavior.
Harmful suicide content	Harmful content that is not as harmful as illegal suicide content but clearly has the effect of causing suicide or self-harm in the general public.
Potentially harmful suicide content	Content that may trigger suicide or self-harm in some people but may not cause it in others or may rather have a positive effect in others.
Harmless suicide content	Content that is not harmful, such as content that helps prevent suicide to the general public or provides neutral information related to suicide.
Nonsuicide content	Content unrelated to suicide.

Annotation Process

The annotation process was divided into 3 phases. In each phase, medical experts (a clinical expert with an MD degree and a psychiatry professor with a PhD degree) annotated real-world harmful suicide content, using the task description document as a reference. At the end of each phase, the authors and annotators reviewed and enhanced the task description document through discussions, before proceeding to the next phase.

In the first phase, medical professionals annotated harmful suicide content by referring to the initial task description document. Before starting the annotation, we preannotated and sampled the contents to be annotated from the data collections, as illustrated in Figure 3. Although the contents are gathered using suicide-related keywords, only a small fraction is actually harmful suicide content that can cause harm to others. Therefore, we used the task description document as instruction for the LLMs, allowing them to preliminarily categorize the content into predefined categories. This approach enhances the efficiency of the annotation process for medical experts and reduces mental strain and costs. Consequently, we used the OpenAI GPT API to preannotation and sampled 196 harmful suicide content for human annotation from the collected 2272 Twitter data, 17,325 online forum data, and 13,104 Q&A data. Medical professionals then proceeded to annotate the sampled 196 harmful suicide content by following the annotation protocol and the initial task description document. The annotation protocol is described in the later part of this section. During the annotation process, they did not refer to the LLM labels generated by the LLM. Following the annotation, both the categories and subcategories were updated, leading to a revision of the task description document. Specifically, we refined 7 subcategories, added 2 new ones, and removed one.

In the second phase, we diversified the harmful suicide content in the benchmark and refined the task description document. Before annotation, we further preannotated and sampled 175 harmful suicide content for annotation from a pool of 8408 Twitter data points collected between May and June 2023. Similar to the first phase, we preannotated them using OpenAI GPT API with instructions written based on the task description document. Subsequently, medical professionals began the annotation of sampled harmful suicide content, strictly adhering to the annotation protocol and using the revised version of the



XSL•FO
RenderX

task description document as their guide. Once the annotation process was completed, we merged the 4 subcategories into 2.

In the final phase, we added multimodal (text and image) harmful suicide content to the benchmark dataset and included online communities as an additional source domain. For the image content, we initially generated textual descriptions of harmful images using visual language LLMs ("Data Preprocessing" subsection). These initial descriptions were then revised to correct any inaccuracies or fill in missing details. The refined descriptions were subsequently used to preannotate the content into categories and subcategories, as defined in the task description document from the second phase. Following this process, we preannotated and sampled 95 multimodal harmful suicide content items for annotation. Medical professionals then annotated based on the annotation protocol, and the task description document was finalized by revising the previous version.

Finally, we manually verified the entire benchmark dataset. This involved identifying and eliminating any remaining PIIs from all harmful suicide content and validating the final labels. During the finalization process, 14 content items were excluded from the benchmark. These contents deal with subcultures (such as games and comics) and, therefore, are incomprehensible to all annotators and cannot be categorized into any suicide category, leading to their exclusion. In addition, the task description document was completed, providing comprehensive information on the 5 categories and 25 subcategories, including their harmful category names, descriptions, and illustrative examples.

Figure 3. Illustration of the preannotation process. We construct prompts from the task description document, which includes categories, detailed descriptions, and subcategories (Table 4), and we use LLMs such as GPT-3.5 and GPT-4 to generate LLM-labeled data. We then sample the data to balance category distributions and have medical experts annotate them to build the human-labeled benchmark. AI: artificial intelligence; LLM: large language model.

Annotation Protocol

In every phase, we adopted a consensus-based method for biomedical research and clinical practice [40,41]. For each harmful suicide content, 2 separate medical professionals (a clinical expert with an MD degree and a psychiatry professor with a PhD degree) independently labeled the category, subcategory, and rationale for their decisions regarding both the category and the subcategory. Each individual annotator assigned the label based on a comprehensive review of the user-generated content (text and image), previous content, and metadata associated with the harmful suicide content. The Inter-Annotator Agreement for category labels reached a high agreement of 0.77 (Cohen κ) after the second phase of the annotation process. In cases where there is a discrepancy in the category label assigned by individual annotators, a consensus is established through the input of 3 annotators, which includes an additional clinical expert (a psychiatry professor with a PhD degree). During this consensus, rationales written by the 2 individual annotators are combined into a single rationale. In addition, annotators comment on any data whose association with suicide content is uncertain, as well as on instances that imply a potential need to revise the task description. These comments were used at the end of each annotation phase to refine and update the task description document.

Construction of English Benchmark

We further created an English benchmark by translating all input attributes (content text, link or image descriptions, and metadata such as user descriptions). To enhance the usability of the Korean harmful suicide content detection benchmark, it was translated into English using machine translation with GPT-4 - 0613 for each attribute. As a result, we produced an English harmful suicide content detection benchmark containing the same 452 data entries as the original Korean harmful suicide content detection benchmark. The quality of the English

XSL•FO
RenderX

benchmark is evaluated in detail in the "English Benchmark Validation" subsection.

Results

Overview

After constructing the harmful suicide content detection benchmark through the data processing workflow, we evaluated the dataset from 3 perspectives. First, we assess whether the categories and descriptions of harmful suicide content outlined in the task description document are appropriate for providing sufficient information as instructions to LLMs to classify suicide contents ("Leveraging Task Description" subsection).

Next, we evaluate whether the data modalities included in the benchmark (eg, images) are suitable for classification by LLMs ("Leveraging Multimodality" subsection). In addition, we verify whether the LLMs can perform classification using only few-shot examples without further training through few-shot experiments ("Leveraging Few-shot Examples" subsection).

Finally, for the English harmful suicide content detection benchmark, we conduct experiments using various LLMs to compare performance with the original Korean benchmark to verify the use and carry out a direct analysis of data quality to verify the translation's quality ("Comparison Between LLMs" subsection and "English Benchmark Validation" subsection).

Setup

We used the GPT-3.5-turbo-16k API with a temperature of 0.0 and default hyperparameters, conducting 3-8 runs to calculate the average and standard error. For the few-shot experiments, we adopted an *N*-way *K*-shot approach by selecting *K* samples from each of the 5 classes (n=5) in the training dataset ("Data Annotation" subsection).

Metrics

We used the following metrics:

1. Macro F_1 measures the overall performance across the 5 categories.
2. *Mean Absolute Error (MAE) of Harmfulness* measures the model's deviation in predicting harmfulness and is categorized into four levels: 3 (most harmful: Illegal Suicide Content), 2 (harmful: Harmful Suicide Content), 1 (potentially harmful: Potentially Harmful Suicide Content), and 0 (not harmful: Harmless Suicide Content and Nonsuicide Content). This metric assesses the extent of the error in terms of harmfulness.
3. *Illegal* identifies illegal suicide content, and it is crucial for prompt regulation.
4. Harmful separates illegal or harmful suicide content from noncritical content, which is essential for moderating the content that poses harm.

In alignment with our objective of identifying and moderating as much harmful content as possible, our model is designed to initially detect harmful content, after which the results are carefully reviewed by a human moderator or expert. Hence, recall is prioritized over precision. This focus is particularly important for the Illegal and Harmful content categories, where missing instances of harmful suicide content pose a far greater risk than misclassifying content that is actually safe. Within our proposed framework, human moderators or clinical experts make the final judgment, ensuring that such misclassified cases can be corrected while minimizing the chance of harmful content going undetected. This design reflects how the system can function in real-world moderation scenarios, where recall is prioritized to maximize safety without disregarding precision.

Leveraging Task Description

We investigated the formulation of a task description document with diverse and extensive information into instructions because instruction construction significantly influences LLM performance [42-44]. The task description document for the harmful suicide content detection task contains crucial details, including the names and descriptions of 5 suicide categories as well as the names and explanations of 25 subcategories constituting up to 60% of the instruction at maximum. Category information includes detailed names and descriptions of the categories and subcategories. Thus, our experiments were designed to determine the details that most significantly impact performance by varying the granularity of the information.

Setup

We evaluate harmful suicide content detection performance by varying the detailed category information levels as follows: (1) category name; (2) category name and description; (3) category name with category description and subcategory name; and (4) category name with category description and subcategory name with subcategory description.

- Category name and description
- Category name with category description, and subcategory name
- Category name with category description, subcategory name with subcategory description

Results

Table 5 shows that the performance improves with more category information, with the most comprehensive level yielding the highest F_1-scores. Specifically, the macro F_1-score increases by 89% (from 18.86 to 35.75), and the illegal F_1 and harmful F_1-scores increase by 200% (from 11.87 to 35.80) and 57% (from 37.63 to 59.10), respectively, as compared with when using only the category name.

The increasing trend in macro F_1 and illegal or harmful F_1-scores suggests that more detailed information enhances the model's detection capabilities. However, adding only category descriptions decreased illegal or harmful recall (from 27.27 and 65.77 to 20.00 and 57.66, respectively).

XSL•FO
RenderX

Table . Results from the category and subcategory information detail experiment[a].

Category information	Subcategory information	Macro F_1	MAE[b]	Illegal F_1	Illegal recall	Harmful F_1	Harmful recall
Name	N/A[c]	18.86 (0.08)	1.4809 (0.0044)	11.87 (0.04)	27.27 (0.00)	37.63 (0.11)	65.77 (0.00)
Name and description	N/A	25.13 (0.16)	1.2173 (0.0042)	13.23 (0.17)	20.00 (0.00)	39.18 (0.04)	57.66 (0.00)
Name and description	Name	32.18 (0.06)	0.9867 (0.0016)	26.36 (0.00)	30.91 (0.00)	45.26 (0.08)	66.67 (0.00)
Name and description	Name and description	35.75 (0.29)[a]	0.8549 (0.0079)[a]	35.80 (0.87)[a]	58.79 (1.21)[a]	59.10 (0.41)[a]	86.79 (0.60)[a]

[a]A consistent increase in macro F_1, illegal F_1, and harmful F_1-scores is observed as the amount of information increases. Values are mean (SE). These values indicate the best performance in each column.

[b]MAE:mean absolute error.

[c]N/A: not applicable.

Formulating LLM Inputs

We assessed performance changes by incorporating images and training examples as inputs. We focused on the impact of images as multimodal data (“Leveraging Multimodality” subsection) and the effect of using training data with the annotation guide as postinstruction when combined with instruction (“Leveraging Few-shot Examples” subsection).

Leveraging Multimodality

Setup

The objective of this experiment was to determine the effect of image information on the classification performance of the model. We used 2 methods of conveying image information and compared their performances: the first method converts images into text descriptions, referred to as image description, whereas the second uses the images directly as inputs, referred to as vision. Three settings were tested for image descriptions: the first did not provide any image information, the second generated image descriptions using a model (gpt-4 - 1106), and the third involved human modifications to the descriptions created by the model. This allowed for a comparison of the performance of the models based on the generation of text-based image descriptions. In addition, we examined the impact of images (vision) when paired with the same image descriptions to observe their influence on performance. This involved adding the original image to each image description experiment for comparison. Overall, this setup evaluates the model’s performance in terms of the modality of suicide content through image descriptions and assesses the model’s multimodal capabilities through vision. Notably, during the annotation process, the annotators labeled the suicide category of the content based on both the text and the original images. We used GPT-4-turbo-2024-04-09, which can use both text and image inputs, for this experiment. We conducted an experiment on 113 test data entries that included images, among which only 3 belonged to the illegal suicide category; thus, illegal metrics were excluded from the results.

Results

Table 6 shows the impact of multimodal information on harmful suicide content detection tasks. In experiments regarding image descriptions without visual information, providing image details leads to superior performance compared with omitting them. Specifically, when using GPT-4–generated image descriptions, macro F_1 increased by 9.16% (from 50.46 to 55.08) and MAE decreased by 15.93% (from 0.3894 to 0.3333), indicating enhanced classification performance across all suicide categories. In addition, harmful F_1 and recall both increased by 8.00% (from 68.50 to 73.98 and from 75.76 to 81.82), suggesting that image information significantly aids in identifying harmfulness within suicide content. Comparing GPT-4 and human-modified image descriptions, using human-modified descriptions results in a reduction of macro F_1 by 3.55% (from 55.08 to 53.19) and increases MAE by 19.4% (from 0.3333 to 0.3982), although harmful F_1 increases by 2.61% (from 73.98 to 75.91) and harmful recall by 16.66% (from 81.82 to 95.45), indicating that human modifications enhance clarity and detection of harmfulness in content while decreasing overall category performance.

[a]We compare 3 types of image descriptions (none, GPT-4-generated, and human-modified) with and without vision input. Without vision, GPT-4 descriptions achieve the best macro F_1 and MAE, while human descriptions perform best on harmful metrics. With vision, we observe an overall decrease in performance. Values are mean (SE). These values indicate the best performance in each column. "O" indicates that the column is used (vision) and "X" indicates that the column is not used.

[b]MAE: mean absolute error.

[c]N/A: not applicable.

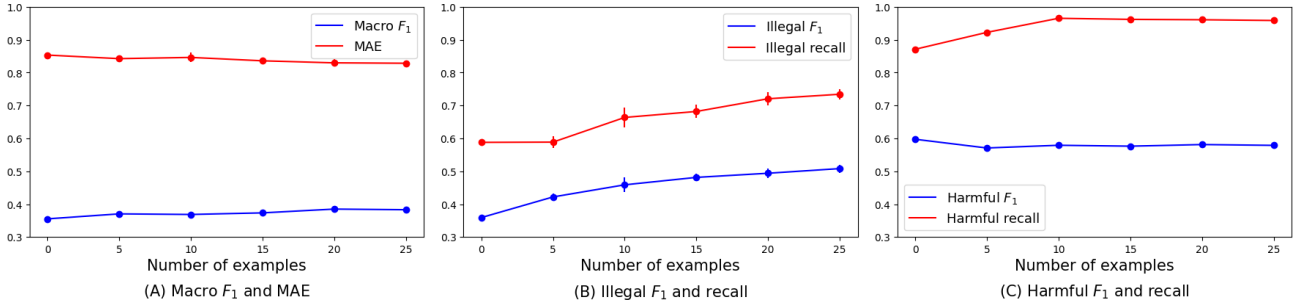
In experiments using image information as visual input, we found a general decrease in overall performance across all settings, with reductions in macro F_1, MAE, and harmful F_1. Even in scenarios without image descriptions, macro F_1 decreased by 5.31% (from 50.46 to 47.78), and MAE increased by 8.41% (from 0.3864 to 0.4189). Particularly, the F_1-scores of potentially harmful content decreased significantly (from 54.46 to 42.77). This is owing to the model's sensitive reaction to certain images of potentially harmful suicide content, overestimating their harmfulness and classifying them as harmful.

However, in settings where we used images only as vision (no image description), the harmful recall score was 90.91, which was higher than when no image information was used (75.76); the score was 83.33 when using images with GPT-4 image description, which was higher than when using GPT-4 image description alone (81.82). This suggests that despite a decrease in the overall model performance owing to multimodality, using image information improves the identification of harmfulness in suicide content. In addition, vision can convey more information about harmfulness than text descriptions when human modification does not explicitly note the harmfulness of an image. Overall, the experiments with image descriptions confirmed that the information contained in an image enhances model performance in the harmful suicide content detection task, whereas adding vision information in a multimodal format decreases performance. However, the increase in harmful recall when using vision supports the potential of using vision as an effective tool for enhancing model capabilities in identifying harmful content, paving the way for future improvements in multimodal model performance.

Leveraging Few-Shot Examples

Few-shot refers to a setting where the model is provided with a small number of labeled examples as demonstrations before classifying new instances [45]. The goal of our few-shot experiments is to assess whether LLMs can effectively learn from only a handful of examples in high-stakes domains, where large-scale annotation is often insufficient to train models.

Setup



We examined 1- to 5-shot configurations, corresponding to 1-5 examples per category, totaling 5-25 examples. To construct the pool of demonstrations, medical experts who participated in the benchmark annotation selected 10 representative samples per category (50 in total). These expert-selected samples were used as the source for training demonstrations, while the remaining annotated data served as the test set. From the pool, 5 examples per category were randomly drawn for each experiment. To ensure robustness, we repeated the same experiment with 3 different random seeds, each sampling distinct few-shot samples, and we report the averaged results across these runs.

Results

Figure 4 shows how the performance metrics changed with the number of demonstration examples, with the standard error represented by vertical bars for each few-shot case. As the number of examples increased, macro F_1, MAE, and illegal metrics improved (Figure 4A), specifically illegal F_1 and recall in the 5-shot (Figure 4B). Although the F_1-score for harmful effects remained relatively stable, recall increased but plateaued after a certain threshold (2-shot) (Figure 4C).

XSL•FO
RenderX

Figure 4. Results from the few-shot example experiment. Increasing examples increases illegal F_1 and recall, with 5-shot setting achieving peak performance in the illegal metric. (A) Macro F_1 and mean absolute error; (B) illegal F_1 and recall; and (C) Harmful F_1 and recall. MAE: mean absolute error.

Comparison Between LLMs

We compared the performance of various LLMs in identifying harmful suicide content. Because open-sourced LLMs have instruction-following capabilities that depend on the language they have seen in the instruction tuning phase, we conducted experiments with different models for Korean and English benchmarks to address language barriers.

Setup

We categorized the selected LLMs into closed and open-sourced models. For the Korean benchmark, we used closed models because of the lack of open-source or multilingual LLMs that can properly follow the task's instructions in Korean. We also included a random baseline that arbitrarily categorized content into one of the 5 categories.

Closed Models

We used OpenAI's GPT-3.5 (gpt-3.5-turbo-16k-0613) and GPT-4 (gpt-4 - 1106-preview), which are accessed through the OpenAI API and capable of handling a context length of 1,28,000 characters. In addition, we experimented with Clova X, an LLM trained on Korean, using the Naver API [46].

Open-Sourced Models

We used the Zephyr-7B-beta model [47], an enhanced version of mistral-7B, which supports a context length of up to 32,000 characters. We also use LongChat-7B-16k [48] and Vicuna-7B-v1.5 - 16k [49], which are both fine-tuned Large Language Model Meta artificial intelligence (AI) models with a maximum context length of 16,000 characters.

To explore the model's adaptability of the model in few-shot learning contexts, we conducted experiments in both the zero-shot and 5-shot scenarios ("Leveraging Few-Shot Examples" subsection). However, for models unable to accept the context length of 12k tokens required for the 5-shot experiments, such as Clova X (4096), we limited our analysis to the zero-shot trials.

Results

Figure 5 shows the performance of the GPT models and Clova X on the Korean benchmark. GPT-4 outperformed all other models in every metric except for harmful recall (Figure 5A-E). GPT-3.5 follows GPT-4 in terms of performance across all metrics, except for harmful recall. Clova X showed lower performance than the GPT models but achieved the highest score in harmful recall (Figure 5F), indicating its high sensitivity to harmful content.

Figure 6 shows the performance of the GPTs and open-sourced LLMs on the translated English benchmark. GPT-4 exhibited the highest performance in differentiating categories in both the zero-shot and 5-shot settings across various metrics (Figure 6A-C and E). It leads the performance charts with macro F_1-scores of 46.37 in zero-shot and 52.59 in 5-shot. Notably, GPT-4 showed a significant MAE difference (0.5655 in zero-shot and 0.5755 in 5-shot), indicating that even when the category predictions were incorrect, they tended to be within similar levels of harmfulness.

GPT-3.5 ranked second to GPT-4 in category distinction performance (Figure 6A, B, and E) in zero-shot settings and showed comparable performance to open-sourced models in 5-shot settings. Its recall was relatively higher than GPT-4 in 5-shot settings (Figure 6C-F), indicating a more sensitive response to harmful information than the GPT-4.

Zephyr outperforms random in zero-shot settings with a macro F_1 of 20.99 and MAE of 1.2711; in addition, it achieves a comparable performance to GPT-3.5 in 5-shot settings with macro F_1 of 37.52 and MAE of 0.8217 (Figure 6A and B). LongChat exhibits the largest standard error in the illegal and harmful metrics (Figure 6C-F), indicating that few-shot examples significantly impact performance compared with other models. It recorded the highest standard errors in illegal F_1 and harmful F_1 at 4.09 and 1.67, respectively (Figure 6C and E). LongChat also showed the lowest recall for illegal and harmful content, particularly in harmful content, suggesting that it is less sensitive to harmful information (Figure 6D and F). Vicuna recorded the lowest performance in category classification (Figure 6A) among all models but achieved high recall for illegal and harmful content (Figure 6D and F). Notably, it scored the highest illegal recall of 76.36 and a harmful recall of 83.78, comparable with GPT-3.5's 85.89.

XSL•FO

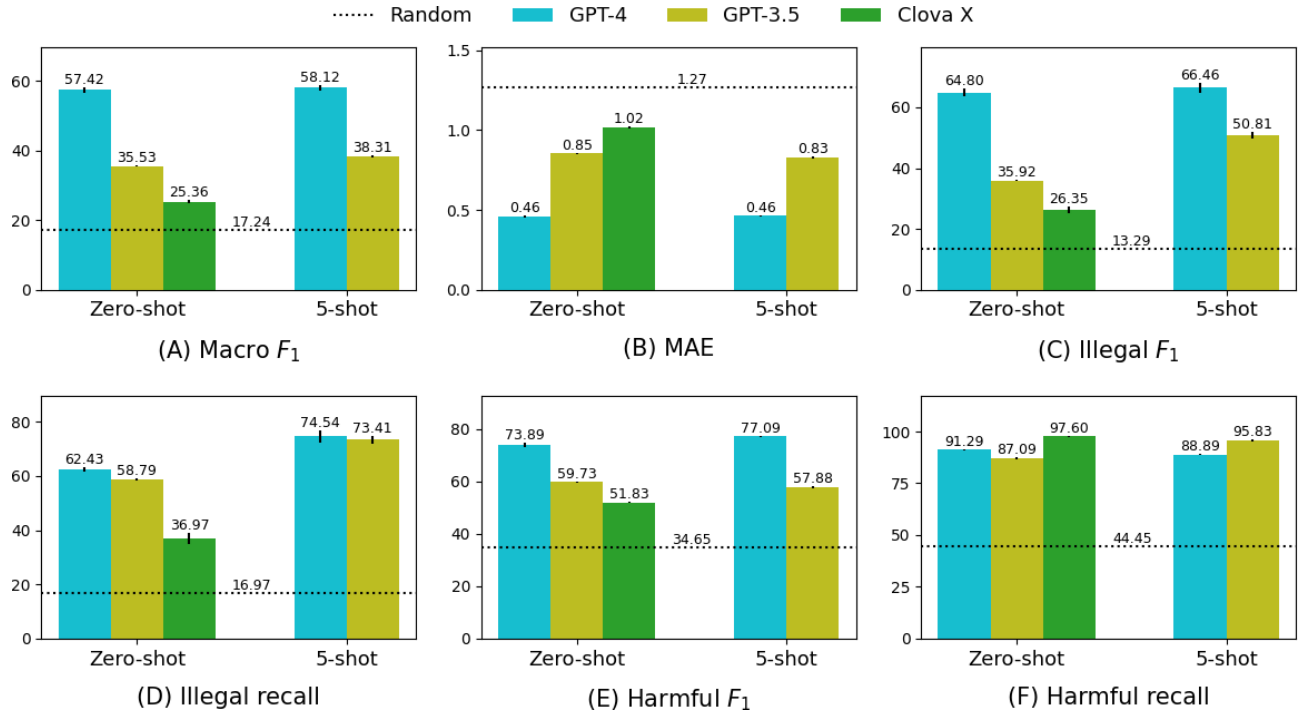
Figure 5. Results from the Korean benchmark experiment. Hatched bars indicate the Korean large language model (Clova X). Although Clova X has lower overall performance than generative pretrained transformers, it excels in harmful recall. (A) Macro F_1; (B) mean absolute error; (C) illegal F_1; (D) illegal recall; (E) harmful F_1; and (F) harmful recall. MAE: mean absolute error.



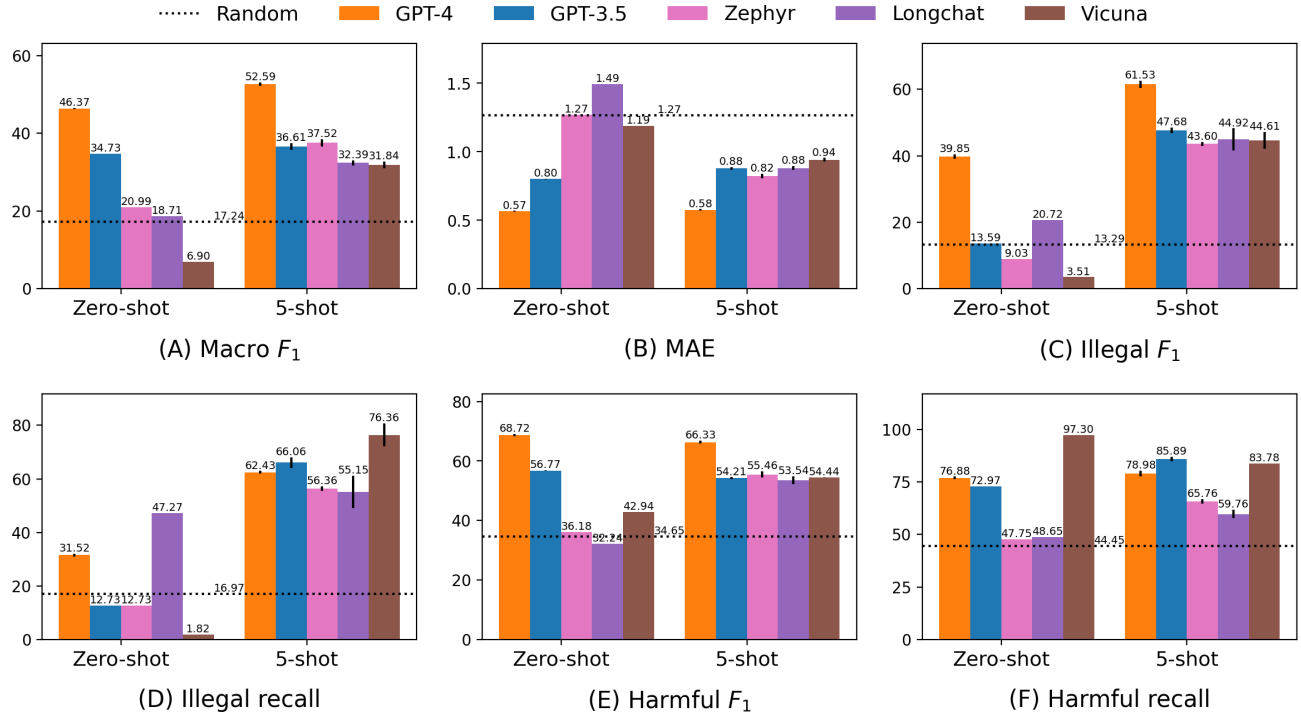


Figure 6. Results from the translated English benchmark experiment. Closed models (GPT-4 and GPT-3.5) show superior performance in the zero-shot setting compared with open-sourced models, whereas open-sourced models reach comparable performance to GPT-3.5 in 5-shot. (A) Macro F_1; (B) mean absolute error; (C) illegal F_1; (D) illegal recall; (E) harmful F_1; and (F) harmful recall. MAE: mean absolute error.

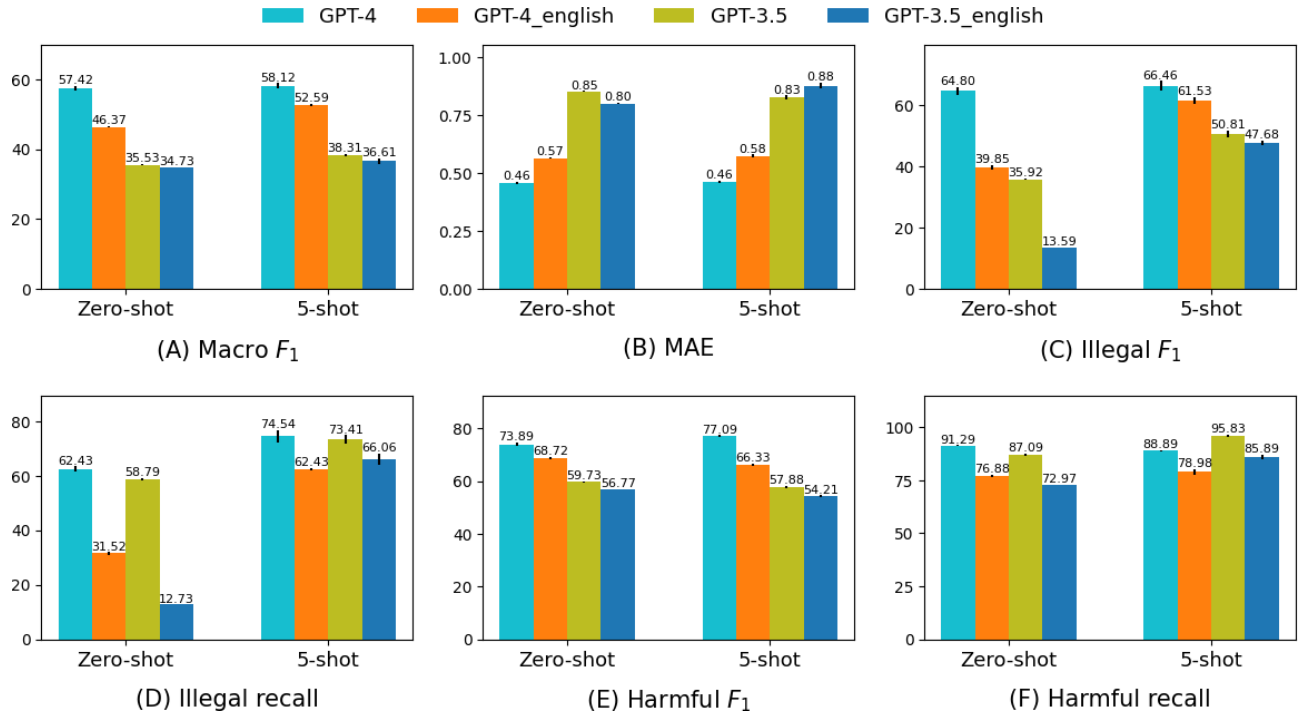
Analysis

Open-Sourced Versus Closed LLMs

GPT-4 recorded the highest performance across all accuracy metrics (macro F_1, MAE, illegal F_1, and harmful F_1) for all few-shot settings. In 5-shot settings, open-sourced models achieve a similar performance to GPT-3.5. However, in zero-shot settings, they struggled to understand lengthy instructions, resulting in random predictions (eg, LongChat) or biased predictions toward specific categories (eg, Vicuna), with Zephyr slightly outperforming random. In 5-shot scenarios, Zephyr matches GPT-3.5 in macro F_1, MAE, and harmful F_1, whereas LongChat and Vicuna show comparable performance in their respective metrics. Except for Vicuna, open-sourced



XSL•FO
RenderX

models generally showed lower recall than closed models in terms of illegal and harmful content.

Original Korean Versus Translated English

Figure 7 shows an analysis of GPT-3.5 and GPT-4's performance on the Korean and translated English benchmarks. Both models performed better on the Korean benchmark across all F_1 metrics (Figure 7A, C, and E). However, GPT-4 shows a decrease in macro F_1 from the English to the Korean benchmark by 19.24% in zero-shot (from 57.42 to 46.37) and 9.51% in 5-shot (from 58.12 to 52.59), with the largest decrease in illegal F_1 by 36.17% in zero-shot (from 64.80 to 39.85). GPT-3.5 also showed a considerable reduction in zero-shot illegal F_1 by 62.17% (from 35.92 to 13.59). Illegal recall decreases considerably, with GPT-4 decreasing by 49.51% (from 62.43 to 31.52) and GPT-3.5 by 78.34% in illegal recall (from 58.79 to 12.73), indicating a larger decrease than in F_1-scores (Figure 7D). The decrease in harmful F_1 is less significant, with GPT-4 decreasing by 7.00% (from 73.89 to 68.72) in zero-shot, and GPT-3.5 decreasing by 4.96% (from 59.73 to 56.77). This indicates that while translating the benchmark using GPT-4 does not significantly affect the overall quality, it may lead to issues in specific categories, notably illegal.

Figure 7. Performance comparison of closed models (GPT-3.5 and GPT-4) on the Korean and translated English benchmarks. Closed models exhibit better classification performance on the Korean benchmark than on the English benchmark, with the most significant difference noted in classifying the illegal category. (A) Macro F_1; (B) mean absolute error; (C) illegal F_1; (D) illegal recall; (E) harmful F_1; and (F) harmful recall. MAE: mean absolute error.

English Benchmark Validation

Considering the use of the English benchmark for experimenting with open-sourced models, it is necessary to evaluate the translation results. In particular, for content containing words related to suicide and harmful information, it is crucial to assess both the overall translation quality and how well the content has been translated. Because OpenAI's use policy potentially refuses to respond to harmful content, there may be instances in which proper translation has not been achieved. Therefore, we analyzed the following 2 aspects: (1) overall translation quality (quantitative analysis), and (2) translation of harmful content (qualitative analysis).

We evaluated the text content (CONTENT_TEXT) of every instance in the benchmark because every instance contains content text and it constitutes the largest proportion of text. We performed a quantitative analysis to assess translation quality using models (GPT-4 - 0613) and a qualitative analysis of the translation of harmful content by the authors.

Translation quality (quantitative analysis): Translation quality assesses how similar the translated content (in English) is to the original content (in Korean). We evaluated translation quality using Scalar Quality Metric (SQM) and Direct Assessment (DA) methods [50] through the GPT-4 - 0613 API, which aligns closely with human evaluations. SQM evaluates the translation quality of the source text (Korean) and target text (English) on a scale of 0-100, with descriptions provided for "no meaning preserved," "some meaning preserved," "most meaning preserved and few grammar mistakes," and "perfect meaning and grammar." DA, such as SQM, rates translation quality on a scale of 0-100 but provides descriptions only for "no meaning preserved" and "perfect meaning and grammar." On average, the translated contents scored 79.55 on SQM and 78.10 on DA, indicating that most instances of the benchmark translation results fall under "most meaning preserved and few grammar mistakes," successfully retaining the original meaning.

Translation of harmful content (qualitative analysis): Illegal and harmful suicide content includes harmful words and

XSL•FO
RenderX

expressions related to suicide and self-harm, encompassing abbreviations, drug names related to suicide, and expressions of methods for suicide and self-harm. Moreover, owing to OpenAI's use policy, there are cases in which harmful content is not translated or translation is refused. Thus, to determine how well such content was translated, we analyzed translation error cases for expressions related to suicide: (1) expressions related to suicide (abbreviations and words), and (2) OpenAI moderation.

Expressions related to suicide: After analyzing 55 instances of illegal suicide content and 56 instances of harmful suicide content, we identified the following types of translation errors: (1) abbreviation translation error, (2) translation of substances used for suicide, and (3) translation of slang related to suicide and self-harm.

Table 7 shows examples of translation errors for each category and error type. *Abbreviation translation error* occurs when abbreviations related to suicide and self-harm are incorrectly interpreted. To evade online platform moderation, abbreviations related to suicide are often used. In these cases, the translation process incorrectly translates these abbreviations into entirely different words. The Korean abbreviation means "commit double suicide and death leap"; however, the English translation misinterprets it entirely. In this study, 12 benchmark instances were identified. *Translation of Substances used for suicide* refers to cases in which drugs related to suicide and self-harm were incorrectly translated. Substances used for suicide are often referred to by abbreviations to avoid online platform moderation, and the actual drug names are often translated into general names for drugs during translation. In this example, the drug "zolpidem" was translated as "SleepingPill," which translates to the purpose of the drug (zolpidem is a type of sleeping pill) rather than the actual name of the drug. However, such translations result in the inability of the model to correctly identify the sale of specific drugs (illegal suicide category) during the category classification process. In this study, 15 instances were identified. *Translation of slang related to suicide and self-harm* refers to errors in the translation of clear expressions of suicide. For example, the Korean expression for "bloodletting self-harm" was incorrectly translated as "blood donation" in English, which changed the meaning of the text. Three instances were identified for this case.

Table . Qualitative analysis of benchmark translation results. The source text is the content text from the Korean benchmark data, and the proper translation is the result translated by a human while preserving the meaning. The translation result is obtained using a model and has been applied to the English benchmark. The underlined words indicate parts where translation errors occurred in the model's output.

Type	Content text
Translation error in the abbreviation (illegal suicide content)	
Source text	ㄷㅂㅈㅅㅌㅅ 하실 분 자차나 면허 있으신 분으로요
Proper translation (human)	Looking for someone who will commit double suicide and death leap, preferably someone with a car or a driver's license.
Translation result (model)	Looking for someone who can do delivery and sales, preferably someone with a car or a driver's license.
Translation error in substances that are used for suicide (illegal suicide content)	
Source text	정품#졸프ㅣ뎀판ㅁㅐ 하는곳 가짜없고 사기없는 솔직한 비밀상담 관심空 #여성최음ㅈㅔ ㄱㅜ입하는 곳. 라인: [ID] 카톡: [ID] 텔레: [ID]
Proper translation (human)	#GenuinezolpidemSellingPlace A place where there are no fakes, no scams, honest confidential consultation. Interested in #FemaleAphrodisiac Purchase place. Line: [ID] Kakaotalk: [ID] Telegram: [ID]
Translation result (model)	#GenuineSpleepingPillSellingPlace A place where there are no fakes, no scams, honest confidential consultation. Interested in #FemaleAphrodisiac Purchase place. Line: [ID] Kakaotalk: [ID] Telegram: [ID]
Translation of slang related to suicide or self-harm (harmful suicide content)	
Source text	사혈자해를 해보고싶다는 생각이 들어
Proper translation (human)	I'm thinking about wanting to try bleeding self-harm.
Translation result (model)	I'm thinking about wanting to try blood donation.

OpenAI Moderation

During the translation process of the benchmark data, we found a few instances where different translation errors occur from those related to expressions of suicide; some content are not translated at all. Unlike parts of the text that are translated incorrectly, the OpenAI API (gpt-4‐1106) refuses to translate and generates content (translated output) that has no relation to the original text (input text). Two instances occurred for this case; one involving content asking for help in committing suicide or self-harm and another involving direct sexual content.

XSL•FO
RenderX

Discussion

English Benchmark Integrity

The English benchmark was generated through machine translation using GPT-4. Quantitative evaluation showed relatively high scores (SQM: 79.55, DA: 78.10), indicating that most meanings were preserved. However, qualitative analysis revealed errors in suicide-related slang, abbreviations, and substance names (eg, bleeding self-harm translated as blood donation, zolpidem simplified to sleeping pill). Such inaccuracies may affect model performance and limit the benchmark's validity for multilingual generalization. Therefore, results on the English benchmark should be interpreted with caution. Future work will involve human validation of high-risk categories and improved translation methods for suicide-specific terminology.

Benchmark Size

Although the harmful suicide content benchmark is an essential step toward understanding and moderating online suicide-related content, it encompasses 452 data entries. This relatively small benchmark size is largely attributable to the fact that posts related to suicide comprise a small fraction of the total online content. In addition, filtering and deleting such content by online sources inherently limit the volume of data available for collection. Nevertheless, a carefully controlled annotation process that incorporates the knowledge of clinical experts supports the credibility of the benchmark and ensures a reliable set of labels. In addition, the task description document details 25 different subcategories of suicide content, and the benchmark comprises a wide array of suicide content, including actual data for each subcategory. Therefore, our detailed task description document and the data within our benchmark lay the groundwork for future efforts to create a large-scale suicide content dataset using the annotations described for the suicide content.

Dataset Usage

The harmful suicide content benchmark includes a task description document containing categories and subcategories of suicide content, along with a dataset of 452 annotated entries. Users can leverage the contents of the task description document as instructions for LLMs. In addition, data labeled for training within the benchmark can be used as few-shot examples, while data labeled for testing can serve as evaluation data.

Future Work

In clinical practice, detecting that a patient who has attempted suicide or self-harm has been exposed to suicide-related content can be highly valuable for preventing further self-harm or suicide attempts. This is because restricting harmful online content represents a relatively modifiable factor among the many risk factors associated with suicide and self-harm [51,52]. Building on this perspective, in future work, we plan to further validate the practical effectiveness of our suicide content detection model. Specifically, we aim to conduct a comparative study between individuals who have attempted suicide or self-harm and a control group of individuals without such experiences. By analyzing their online activity, we will investigate whether those with a history of suicidal or self-harming behaviors are more frequently exposed to harmful suicide-related content. Such a study would not only provide empirical evidence for the real-world use of our detection framework but also offer insights into the role of online harmful content in influencing vulnerable populations.

Funding

This research was partially supported by the Bio & Medical Technology Development Program of the National Research Foundation (NRF) and funded by the Korean government (MSIT) (NRF-2021M3A9E4080780 and 2021M3A9E4080784) and Institute of Information & communications Technology Planning & Evaluation (IITP) grant funded by the Korea government (MSIT) (RS-2019-II190421, AI Graduate School Support Program(Sungkyunkwan University), and Institute of Information & communications Technology Planning & Evaluation (IITP) grant funded by the Korea government (MSIT) (no. RS-2024 - 00509258 and no. RS-2024-00469482, Global AI Frontier Lab).

Data Availability

Our benchmark dataset contains sensitive and, in some cases, illegal information related to suicide. Due to the sensitivity of suicide-related content, the full benchmark dataset cannot be publicly released and is granted only through a controlled approval process [53]. In addition, since the dataset also contains illegal information, it cannot be made publicly available; however, it may be shared under appropriate requests and upon review by the authors [54]. We provide the website [55] to obtain the benchmark dataset and the codes used in the experiments. Applicants must follow the outlined process, after which the authors will review the requests and share the dataset as appropriate. This version includes only references to the original data (eg, tweet IDs, and URLs) and annotations by medical experts, ensuring that no legal or ethical violations occur upon public release.

Abstract

Background: Effective secondary use of healthcare data is hindered by fragmentation and a lack of semantic interoperability due to heterogeneous local terminologies. Standardizing clinical terms using SNOMED CT (Systematized Nomenclature of Medicine Clinical Terms) is essential but remains a manual, labor-intensive, and inconsistent process, especially across multiple institutions. Automated, scalable solutions are needed to support reliable mapping and new concept authoring for large-scale research.

Objective: We aimed to develop a large language model (LLM)-assisted tool that streamlines SNOMED CT terminology mapping and concept authoring, which enables seamless, standardized data integration across multi-institutional clinical datasets.

Methods: The mapping pipeline included preprocessing local terms, syntactic and LLM-based vector similarity mapping, and iterative enrichment based on validated results. Translation and semantic representation used GPT-4o (OpenAI). New concepts were authored through a structured postcoordination process, and both the efficiency and quality of authoring (including duplicate rate and Machine Readable Concept Model validation violations) were quantitatively evaluated. Performance was evaluated using diagnostic and surgical procedural terms from 4 major hospital networks (9 university hospitals) in South Korea, with additional usability feedback gathered from clinical terminologists.

Results: Using reference terms, top-5 accuracy for diagnostic mapping reached 98.7%, 89.7%, 98.5%, and 92.8% across the 4 institutions and 99.2%, 82.6%, 98.7%, and 84.7% for surgical procedural mapping. Implementation of the tool reduced manual mapping rates by 30% and overall manual workload by up to 90%. The proposed tool reduced average mapping and new concept creation time by approximately 75%, while decreasing the final mapping table processing time by 90%. New concept authoring errors also decreased, with duplicate concepts reduced by 83% and modeling rule violations by 72%.

Conclusions: This study developed and validated an automated, LLM-assisted SNOMED CT mapping tool that significantly improved efficiency, mapping accuracy, and new concept quality. Limitations include technical integration challenges and dependency on translation quality. Future directions involve leveraging SNOMED CT's ontology structure and knowledge graphs, enhancing sustainability through ongoing maintenance and quality assurance, and further advancing new concept authoring with automated Machine Readable Concept Model rule enforcement and inactivation processes to achieve robust and scalable terminology standardization.

Introduction

Background

The secondary use of healthcare data holds tremendous promise for advancing medical research and improving patient outcomes [1,2]. However, several critical barriers—such as data fragmentation, the absence of standardized medical terminologies, and semantic interoperability—continue to impede its effective reuse, particularly across multiple institutions [3]. Data generated in different health care settings are often siloed and recorded using heterogeneous systems and local coding practices, resulting in substantial misinterpretation and incomplete integration [4]. Furthermore, these challenges are compounded by the unstructured nature of much clinical data and stringent privacy and security requirements [5,6].

Achieving semantic interoperability—the ability of systems and organizations to exchange data with unambiguous, shared meaning—is essential to overcoming these challenges and unlocking the true value of multi-institutional clinical research [7,8]. At the core of semantic interoperability is terminology standardization, which enables consistent representation and interpretation of clinical concepts across diverse sources [9]. Without such standardization, variations in medical terminology across institutions can lead to inconsistencies, miscommunications, and errors that ultimately undermine the quality and reliability of biomedical research [10]. This challenge has driven international efforts, such as the World Health Organization Digital Health Interoperability Frameworks and Centers for Disease Control and Prevention National Electronic Disease Surveillance System, to prioritize standardized terminologies and interoperable health data infrastructure on a global scale [11,12].

In line with these global initiatives and the growing demands for healthcare data interoperability, Kakao Healthcare has developed the Healthcare Data Research Suite (HRS)—a platform supporting multi-institutional research via standardized data models, advanced artificial intelligence (AI) tools, and robust data privacy features. Notably, HRS places terminology standardization at its core, reflecting both the operational realities and strategic priorities identified by international guidelines [11,12]. By integrating domain-specific standard terminologies, HRS aims to bridge the gaps between fragmented datasets and promote data sharing for research.

To realize this goal, HRS adopts SNOMED CT (Systematized Nomenclature of Medicine Clinical Terms) as its primary terminology. SNOMED CT is recognized worldwide as one of the most comprehensive clinical terminology systems, encompassing a wide range of domains including disorders and procedures [13,14]. Its hierarchical structure, postcoordination capabilities, and rich attribute relationships support the precise representation of clinical concepts and sophisticated querying across large datasets [15]. Despite these advantages, mapping local clinical terms to SNOMED CT remains a significant bottleneck: the process is labor-intensive, demands expertise, and often results in inconsistent mappings both within and across institutions [16].

Recent studies have explored automated SNOMED CT mapping using various AI approaches. Davidson et al [17], 2025, benchmarked SNOMED CT entity linking models by organizing a challenge using annotated clinical notes. Gehrmann et al [18], 2025, evaluated how variable formulation impacts MedCAT's SNOMED CT mapping performance. Kulyabin et al [19], 2024, developed and tested SNOBERT, a BERT-based entity linking model for clinical notes. While these solutions have made meaningful progress in the field, the requirements of multi-institutional research in our context further necessitated several key capabilities: (1) consistent mapping of diverse local terms, both within and across institutions; (2) management of bilingual language inputs, such as the simultaneous use of Korean and English; (3) incorporation of domain-specific curation rules; and (4) the ability to author new SNOMED CT concepts, to achieve accurate mapping that preserves the detailed meaning of source terms.

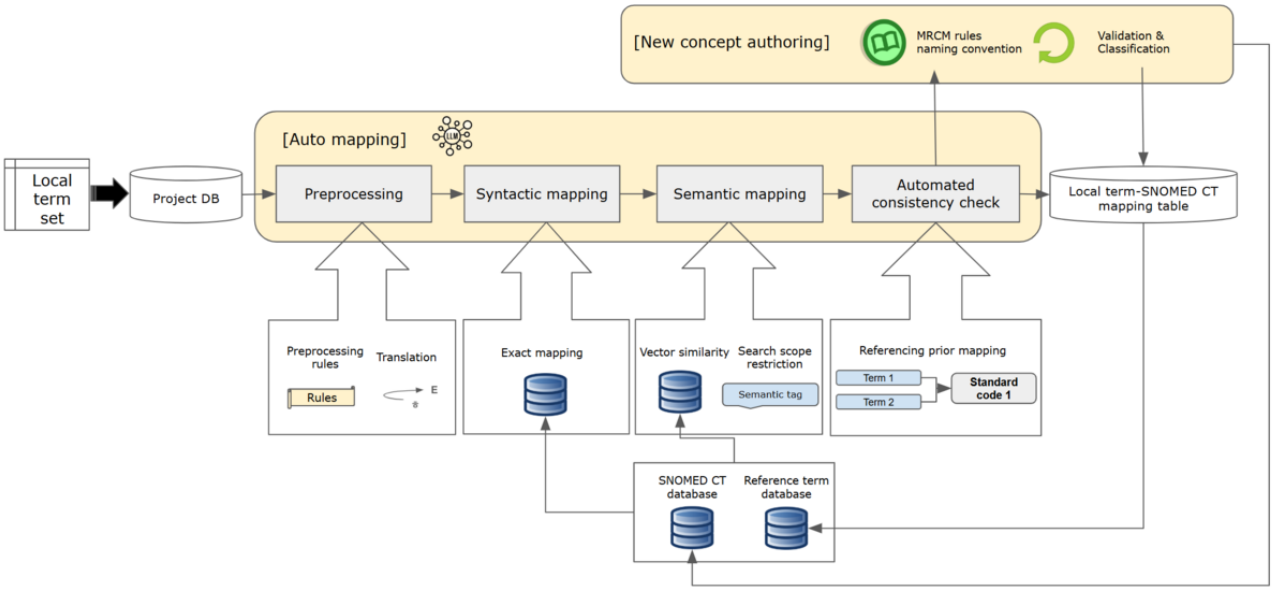
To meet these requirements and enable reliable standardization across multi-institutional studies, we have developed a large language model (LLM)–assisted terminology standardization tool that integrates automated SNOMED CT mapping and postcoordination in a unified workflow. This tool is specifically designed to overcome the challenges of mapping local terms from heterogeneous sources, handle multilingual data, and facilitate the flexible authoring of new concepts as required for large-scale clinical research.

Objectives

The objective of this work was to create an LLM-assisted tool that enhances terminology standardization for multi-institutional research by seamlessly integrating automated SNOMED CT mapping and postcoordination within a single solution.

Methods

Requirement Collection



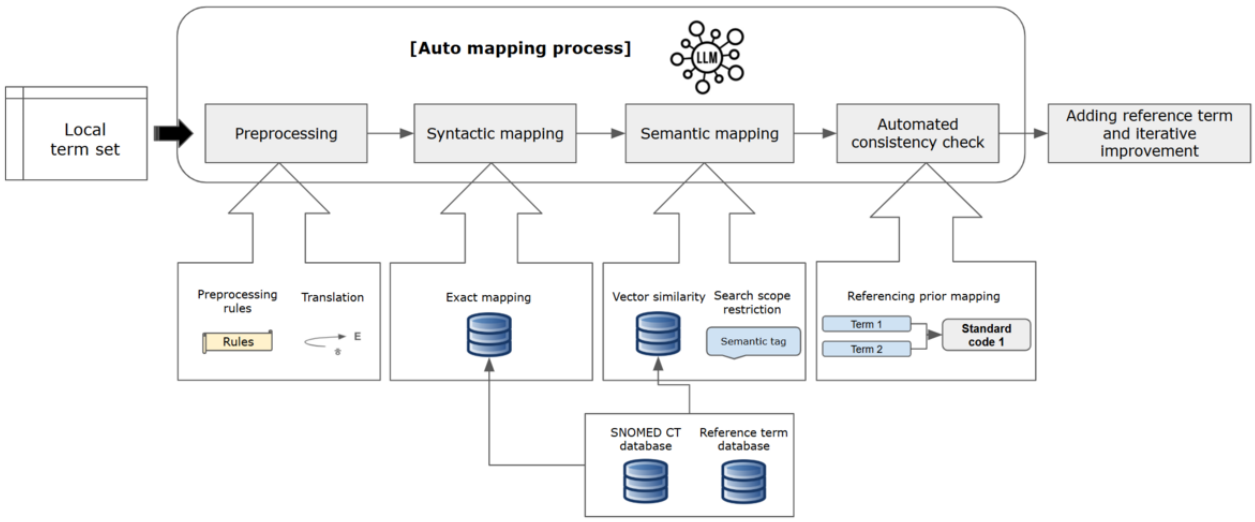
The participants involved in user requirements collection included 10 experienced clinical terminologists and 3 data engineers. Participants were asked to provide feedback on essential features through an open-ended questionnaire.

System Architecture and Implementation

The overall process of automatic mapping is illustrated in Figure 1. The workflow consists of 2 main processes: auto-mapping and new concept authoring. The final mappings are progressively incorporated into the local term-SNOMED CT mapping database and integrated into the custom reference term database, which includes the previous mapping results of local codes.

XSL•FO
RenderX

Figure 1. Overall workflow of the LLM-assisted terminology standardization tool. LLM: large language model; MRCM: Machine Readable Concept Model; SNOMED CT: Systematized Nomenclature of Medicine Clinical Terms.



Auto-Mapping Method

Overview

The automated mapping process, as illustrated in Figure 2, begins with receiving a local term set and sequentially integrates four distinct components: (1) data preprocessing, (2) syntactic mapping, (3) semantic mapping, and (4) automated consistency check.

Figure 2. Overview of the LLM-assisted automated SNOMED CT mapping process for multi-institutional standardization. LLM: large language model; SNOMED CT: Systematized Nomenclature of Medicine Clinical Terms.

Data Preprocessing

Data preprocessing consists of three main steps: (1) removing unnecessary symbols, (2) expanding abbreviations to full terms, and (3) translating non-English terms such as Korean into English with LLM tools (eg, GPT-4o (OpenAI) or Gemini 2.0 Flash (Google)). In the first step, unnecessary symbols are removed based on professional review. Second, abbreviations are converted to their full forms through manual curation, as context-dependent abbreviations such as “MS” can have multiple meanings (“multiple sclerosis” in neurology or “mitral stenosis” in cardiology); automatic expansion is therefore avoided. Third, any local terms in Korean are translated to English using LLMs. Although GPT-4o was used in this study, the system is designed to flexibly substitute other models (eg, Gemini 2.0 Flash) to accommodate institutional IT or cloud service restrictions.

Furthermore, to maximize long-term accuracy, we implemented a postmapping rule-based refinement mechanism. This system analyzes the automated mapping output and removes nonessential terms or extraneous symbols that do not affect similarity scores. This quality assurance step ensures that these refined terms are immediately incorporated into the custom

XSL•FO
RenderX

reference term database for iterative use, thereby boosting subsequent mapping performance.

To enhance the reproducibility and institutional specificity, the system allows each participating institution to define and apply custom rule-based preprocessing before automated mapping. These user-defined rules are automatically applied within the mapping pipeline, allowing each site to enforce its own normalization standards as needed.

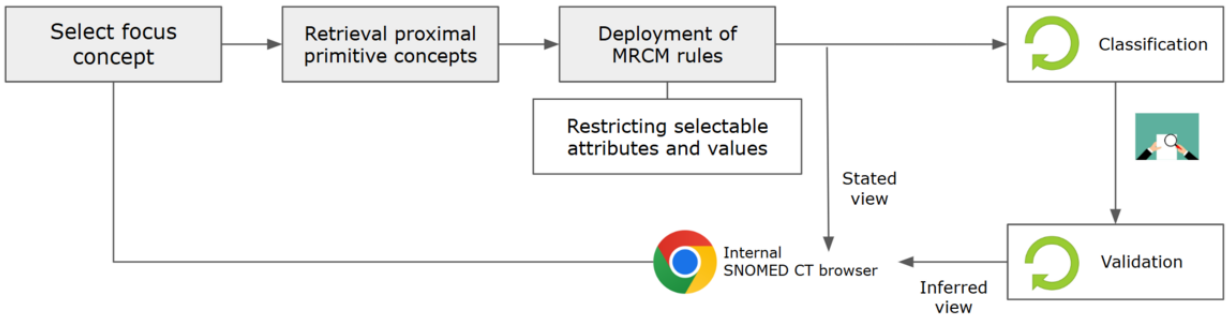
Syntactic Mapping

Following the data preprocessing steps, the syntactic mapping component performs exact mapping by identifying standard codes that are textually identical to the preprocessed local term. To achieve this, the component prioritizes a search that is restricted within the SNOMED CT description table. In addition, the search leverages custom reference terms, which function similarly to the SNOMED CT description and were developed based on previously confirmed mapping results. If a textual identity between the normalized local term and one of the entries in the reference corpus is found, it is recommended to the user as an exact match.

Semantic Mapping

The semantic mapping component is used when the syntactic mapping component fails to find an exact match, using vector similarity search techniques to automatically map local terms to standard codes. This process leverages LLM-based embedding models (such as the text-embedding-3-small model for OpenAI deployments) to encode all reference terms, which include SNOMED CT descriptions and previously mapped local terms. These reference embedding results are stored in the Faiss vector database [20].

To ensure the efficiency and domain relevance of semantic search, the component applies a crucial constraint developed from empirical insights. First, the search is restricted to the SNOMED CT description table and custom reference terms validated through previous mappings. This prioritizes exact and highly relevant matches within established terminology sources. Second, the results are further refined by limiting the search scope to specific semantic tags and datasets relevant to each domain. For instance, the imaging and functional test domain is limited to “Procedure” and “Regime/Therapy” semantic tags; the diagnosis domain exclusively uses “Disorder,” “Finding,” “Situation,” “Event,” and “Person” tags. Additionally, certain cases restricted searches to descendants of specific concepts, allowing for targeted searches within specific datasets. For example, when mapping datasets for culture medium, searches were limited not only to “substance” but specifically to descendants of the concept 421955000 |Culture medium (substance)|, enhancing both speed and accuracy.



Automated Consistency Check

The automated consistency check component serves as the final stage in the automated mapping process. Its primary function is to ensure consistency and adherence to established mapping principles across all mapping candidates generated by the preceding components. This component achieves its goal primarily through referencing a prior mapping rule. This rule is specifically designed to maintain consistency across terms. When duplicate source terms are present, a validated mapping for 1 instance is automatically applied to all others. This rule is applied across different institutions, increasing efficiency and ensuring uniformity, except when the datasets belong to different domains. A successful automated consistency check leads directly to the final system step: adding reference terms and iterative improvement enriching the knowledge base for future mapping runs.

New Concept Authoring Method

Our new concept authoring procedure closely follows the principles and steps outlined in the SNOMED CT Editorial Guide [21]. Subsequently, Figure 3 illustrates the process of the authoring of new concepts through postcoordination. The process consists of four steps: (1) the selection of a focus concept, supported by proximal primitive concept retrieval; (2) concept modeling performed in alignment with Machine Readable Concept Model (MRCM) rules [22], followed by terming; (3) classification and validation; and (4) integration with the mapping table.

Figure 3. New concept authoring process using postcoordination within the LLM-assisted terminology standardization tool. LLM: large language model; MRCM: Machine Readable Concept Model; SNOMED CT: Systematized Nomenclature of Medicine Clinical Terms.

In the current version of our tool, we have operationalized 2 core rules from the editorial guide: the proximal primitive modeling principle and enforcement of MRCM rules. Other elements of the editorial guidance, such as cardinality, concept inactivation workflow, and modeling templates, are not yet implemented and are under consideration for future development.

The first implemented editorial rule is proximal primitive modeling. Adhering to this principle is recommended when

XSL•FO
RenderX

authoring new concepts in SNOMED CT [23]. The principle of proximal primitive modeling is vital for ensuring that classifiers accurately infer the most relevant proximal supertypes, which enhances precise subsumption [24,25]. When a user selects a focus concept required for modeling, not only the concept ID and fully specified name (FSN) of the focus concept, but also the corresponding proximal primitive concept are retrieved via the authoring-form API (Application Programming Interface) provided by Snowstorm [26].

The second implemented rule is the automated enforcement of MRCM rules. The MRCM defines the rules within the SNOMED CT concept model in a computer-readable format, allowing for validation of concept definitions and expressions to ensure compliance [27]. We have integrated these rules into the user interface (UI) by using the Snowstorm API. The tool restricts selectable attributes based on the domain of the focus concept. Using the GET /mrcm/{branch}/domain-attributes API, the focus concept ID is passed as parent IDs to retrieve only attributes relevant to the specific domain.

For naming guidance, our tool supports authors by automatically loading the FSN of the selected focus concept—retrieved via the authoring-form API—as a terming template. This allows users to customize the FSN, ensuring that the created concept precisely reflects the intended meaning, while maintaining overall consistency with SNOMED CT naming conventions.

Classification and validation are crucial steps in authoring new SNOMED CT terms for maintaining the precision and comprehensiveness of SNOMED CT and supporting accurate cohort queries over electronic health records [28]. We used the SNOMED (Systematized Nomenclature of Medicine) Release Validation Framework and the SNOMED OWL (Web Ontology Language) Toolkit in parallel to ensure the quality and consistency of our SNOMED CT editions, generate OWL expressions, and perform classification [29,30].

Once new concepts are authored, they are systematically stored in the mapping table, which is a structured database that includes the source terminology and corresponding target SNOMED CT identifiers [31]. We managed a Kakao Healthcare edition in our database that included all SNOMED International concepts, supplemented with new concepts assigned to a unique namespace identifier of the affiliated institution.

As the SNOMED CT Editorial Guide and modeling rules are subject to periodic updates, we monitor release notes and editorial guide updates on a monthly basis. While we conduct regular follow-up reviews each month, updates are applied to our edition on an annual basis through scheduled manual audits for the new concept authoring to comply with recent editorial changes.

System Implementation

To support the key functionalities of automatic mapping and new concept authoring, the system was implemented as 2 main components: a web application and an automatic mapping server. The web application, developed using Next.js (version 14; Vercel) and TypeScript (version 5; Microsoft), serves as the central platform that integrates various operations such as project management, data submission, mapping review, and concept authoring. React Query (version 5.28.14; TanStack) is used for managing asynchronous data interactions, and Tailwind CSS (version 3.3.0; Tailwind Labs) is used for styling. The application communicates with the backend services and the database to manage workflows and interface with the automatic mapping server. The automatic mapping server, built in Python (version 3.10; Python Software Foundation), performs the core mapping logic, including preprocessing of local terms, translation using LLM, and vector-based similarity search using FAISS (faiss-cpu version 1.9.0.post1; Meta AI Research). The server generates mapping results and stores them in a PostgreSQL (version 14.12; PostgreSQL Global Development Group) database. FastAPI (version 0.110.3; FastAPI framework) is used to serve the backend API.

Performance Evaluation

Method for Evaluating Accuracy

Dataset

The dataset for evaluating performance was collected from 4 hospital networks (a total of 9 university hospitals) in South Korea: Ewha Womans University Medical Center (EUMC) with 2 branches, Korea University Medical Center (KUMC) with 3 branches, DongSan Medical Center (DSMC) with 2 branches, and KyungHee University Medical Center (KHMC) with 2 branches. The selection of diagnostic and surgical procedure terms is strategically made due to their clear and distinct alignment with specific SNOMED CT semantic tags, such as “Disorder” and “Procedure,” which facilitates precise mapping. Furthermore, these codes encompass nearly all medical specialties, ensuring the heterogeneity of local medical practice in South Korea, thereby providing a robust dataset for evaluating the mapping tool’s performance. EUMC contributed 24,554 diagnostic and 8053 surgical procedure codes, KUMC provided 44,646 and 13,734, respectively, DSMC supplied 24,146 and 9432, while KHMC offered 27,842 diagnostic codes and 20,759 surgical procedure codes.

Preprocessing Rules

All performance evaluations were conducted using a common, standardized set of preprocessing rules applied uniformly across all 4 participating hospital networks (EUMC, KUMC, DSMC, and KHMC). The system’s “user-defined rules” functionality, while supported for production deployment, was intentionally not used during the formal testing in this study. This ensured that the comparison of mapping accuracy reflected the system’s performance under standardized, reproducible conditions.

LLM Configuration

All translation and concept generation tasks in this study were performed using GPT-4o (OpenAI, 2024) and its corresponding text-embedding-3-small embedding model for vector-based similarity mapping. The selection of GPT-4o was fixed across all institutions to ensure methodological consistency and reproducibility. All reported accuracy, efficiency, and usability metrics are therefore based exclusively on results generated from the GPT-4o-based pipeline.

XSL•FO
RenderX

Accuracy Assessment Strategy

The performance was measured by comparing its outputs against manually mapped results, which have been established as the gold standard. The manual mapping results were verified for accuracy and reliability through at least 2 rounds of internal review by 5 clinical terminology experts and 1 physician, and were further refined by external review with 2 physicians.

Accuracy was evaluated using both "top-1" and "top-5" approaches. The top-1 accuracy refers to the highest similarity score of a candidate being correct. The top-5 accuracy includes having the correct mapping among the 5 candidates with the highest similarity scores. Furthermore, to better characterize the contribution of the shared knowledge base versus the AI components, we stratified the "accuracy with reference terms" metric. We specifically calculated the "exact match" rate to distinguish successful mappings achieved via syntactic reference identity lookups (memorization from partner hospitals) from those achieved via vector-based semantic similarity search.

Specifically, we used a 2-pronged approach to measure mapping accuracy. First, we assessed the baseline performance at each participating hospital—EUMC, KUMC, DSMC, and KHMC—by using only the descriptions of the SNOMED CT Kakao Healthcare edition. The SNOMED CT Kakao Healthcare edition serves as the core internal database, managing all SNOMED International concepts and supplemented with new concepts assigned a unique namespace identifier of the affiliated institution. Crucially, the baseline analysis intentionally excludes any reference terms (previously confirmed mappings) that were accumulated or validated from the other participating hospital networks.

Second, we enhanced our analysis by adding reference terms from the other participating hospitals into the mapping process. For instance, when assessing EUMC, we introduced reference terms from KUMC, DSMC, and KHMC to gauge any changes in mapping accuracy. This comparative methodology was implemented in stages to allow us to compare the tool's performance before and after the addition of reference terms, as mapping data from other hospitals accumulated. The benefit measured in the subsequent metric, "accuracy with reference terms," therefore represents the isolated effect of integrating this shared, cross-institutional mapping knowledge.

Handling of "Not Mapped" Terms

To ensure comprehensive performance accounting, we clarified the treatment of local terms designated as "not mapped" within the accuracy calculation. These "not mapped" terms were established as part of the gold standard definition by the clinical terminology review committee. Such terms often represent local entries that human experts determined lacked a valid or appropriate SNOMED CT concept (eg, referencing only body structures or materials without a corresponding procedure).

Crucially, the system was not explicitly designed to predict a "not mapped" status. Therefore, when a term is validated by experts as "not mapped" (the gold standard outcome), the system's failure to provide any correct SNOMED CT prediction within the top-1 or top-5 candidates is inherently reflected in the overall accuracy calculation as a system prediction failure or error.

Method for Evaluating Efficiency

As a baseline, all processes were manually executed to assess the time required for each step. Data preprocessing time is the average time required for data cleaning and translation. New concept authoring time refers to the average time it takes for a person to author a new concept in compliance with SNOMED CT's principles. The final processing steps of the mapping table refer to the average time taken per dataset for integrating mapping tables and verifying data integrity. This observation is based on a 6-month operational period of a clinical terminology team consisting of 6 members. During this time, detailed logs and time-tracking data were collected across all stages of the terminology mapping process.

The results from the tool-based workflows were compared with the baseline data to evaluate the improvements: (1) efficiency gains are the reduction in time for each phase of the process, expressed as a percentage improvement over baseline; and (2) resource optimization evaluates the changes in human resource consumption.

Quality Assessment of New Concept Authoring

Quality was evaluated pre- and posttool adoption using 2 metrics derived from the full SNOMED CT authoring dataset as of August 27, 2024. First, the proportion of duplicate concepts was calculated by dividing the number of equivalent errors identified after classification by the total number of authored concepts at each time point. Second, the number of MRCM validation violations was measured by counting rule violations across all authored concepts before and after tool implementation.

System Usability Evaluation by Users

The system usability evaluation was conducted with 5 mappers who had previous experience with mapping methodologies before the tool development. These participants were introduced to the main features of the newly developed tool and were asked to perform approximately 100 sample mappings. After using the tool, they were encouraged to provide feedback in an open-ended format regarding their experience with the tool.

Ethical Considerations

This study was conducted as part of the research project "Development of an LLM-based Named Entity Recognition (NER) tool and a standardization support tool for using multicenter clinical free text." As no human participants or identifiable personal information were involved, institutional review board (IRB) approval was not required for this study itself. However, IRB approval or exemption was obtained from each institution for project administration purposes as follows: Ewha Womans University Medical Center (SEUMC IRB 2025-02-016, approved), DongSan Medical Center (DSMC IRB 2025-01-006, approved), Korea University Medical Center Anam (KUMC IRB 2025AN0239, approved), Guro (KUMC IRB 2025GR0222, approved), Ansan (KUMC IRB 2025AS0122, approved), and KyungHee University Medical Center (KHUH IRB 2025-01-047, exempted). This study was

XSL•FO
RenderX

conducted in compliance with institutional policies, the Korean Bioethics and Safety Act [32], and the Declaration of Helsinki [33]. Informed consent was not required due to the nature of the study.

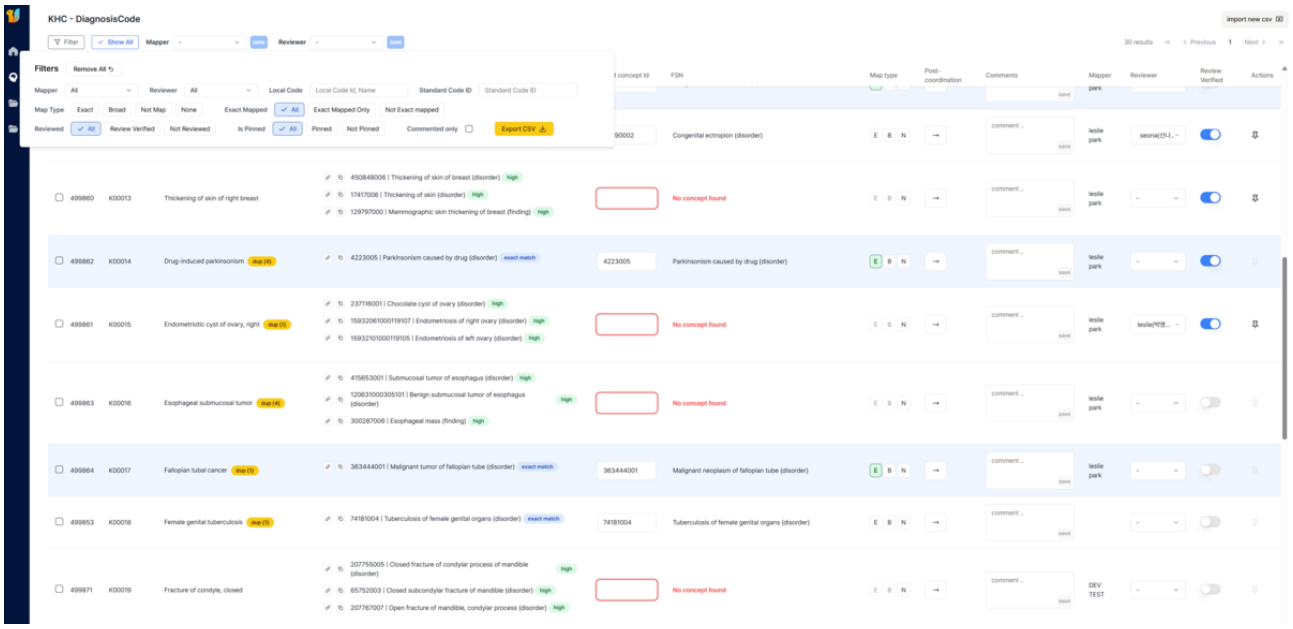
Results

System Development and Deployment

System Development Requirements

Based on the users' survey, we found the following 11 key requirements as shown in Table 1. The UI of the auto-mapping enables users to map terms with a single click in a familiar table-based layout. Figure 4 displays the primary UI for the automated SNOMED CT mapping function. The interface is organized in a familiar table-based layout to facilitate the review and review of local diagnostic and surgical procedure terms. To maximize efficiency and minimize manual errors, the UI provides single-click mapping and automatic retrieval of FSNs immediately upon entering a standard concept ID. Furthermore, the interface supports essential collaborative functions for large-scale projects, including comprehensive filtering options and dedicated fields for review tracking and quality assurance by terminology experts.

Table 1. Key requirements for the LLM[a]-assisted automated SNOMED CT[b] mapping and new concept authoring tool, defined by clinical terminologists and data engineers for multi-institutional research environments.



Category	Key requirements
Project and dataset version management	• The ability to create projects and manage their versions for terminology datasets by institution and domain. • Support for uploading source files and downloading mapping table result files in the computable format (CSV and JSON)
Automated mapping and terminology support	• Automated mapping to eliminate the need for manual browser searches for each local term. • Translation functionalities to support multilingual datasets. • Management tools for mapping tables, including cross-checking mapping results.
New concept authoring and integration	• Functionality to author new concepts during the mapping process. • A user interface applying MRCM[c] rules during authoring. • Application of the classification of newly authored concepts. • Immediate incorporation of newly authored concepts into the browser. • Automatic integration of newly authored concepts into the mapping tables.
Review and quality assurance	• Features for human review of newly authored concepts for naming inconsistencies and semantic modeling errors.

RenderX

The new concept authoring tool, as shown in Figure 5, makes it easier to author new concepts with an intuitive visual editor that supports real-time updates. In illustrating Figure 5, the concept "254644003 |Hamartoma of lung (disorder)|" is used as the focus concept. Its modeling was cloned and then customized for the illustration, as duplicating the modeling of the focus concept is often an efficient and practical method when modeling new concepts. Then, the proximal primitive concept of selected focus concept, "64572001 |Disease (disorder)|," is automatically retrieved. Users can perform authoring within the UI through refinement or qualification methods.

Figure 5. User interface of the new concept authoring page within the LLM-assisted terminology standardization tool. FSN: fully specified name; LLM: large language model; PT: preferred term.

System Deployment

The system is actively deployed for terminology standardization at the Research Alliance participating hospitals, which is organized by Kakao Healthcare. To date, it has processed terminology from a total of 6 hospital networks, encompassing 12 university hospitals and 189,455 terms. The developed tool has been actively used to standardize terms across various domains, including diagnoses, surgical procedures, chief complaints, and laboratory tests.

System Evaluation

Result of Performance Evaluation

Table 2 displays the successful mappings achieved through syntactic matching (exact match lookups) using the custom reference database (baseline) vs those achieved after the iterative enrichment via shared reference terms (accuracy with reference terms) across 4 major hospital networks. The reported percentage represents the proportion of local terms that were successfully mapped by exact identity lookup. The analysis revealed that the inclusion of shared reference terms universally increased the proportion of terms resolved via exact match, reducing the reliance on vector-based search. However, the magnitude of this increase varied significantly across hospital networks.

XSL•FO
RenderX

Table 2. Syntactic mapping performance: exact match accuracy for diagnosis and surgical procedure domains.

Hospital networks, domain	Metric	Baseline accuracy (%)	Accuracy with reference terms (%)	Δ accuracy (%)
EUMC[a]				
Diagnosis	Exact match	36.3	94.5	58.2
Surgical procedure	Exact match	18.5	97.6	79.1
KUMC[b]				
Diagnosis	Exact match	23.4	36.6	13.2
Surgical procedure	Exact match	17.7	29.8	12.1
DSMC[c]				
Diagnosis	Exact match	34.9	94.9	60
Surgical procedure	Exact match	19.8	96.9	77.1
KHMC[d]				
Diagnosis	Exact match	21.9	55.2	33.3
Surgical procedure	Exact match	12.8	28.3	15.5

[a]EUMC: Ewha Womans University Medical Center.

[b]KUMC: Korea University Medical Center.

[c]DSMC: DongSan Medical Center.

[d]KHMC: KyungHee University Medical Center.

Notably, EUMC and DSMC exhibited a dramatic surge in exact match rates. For the diagnosis domain, exact match accuracy increased from 36.3% to 94.5% for EUMC and from 34.9% to 94.9% for DSMC. A similar trend was observed in the surgical procedure domain, where exact match rates reached 97.6% and 96.9%, respectively. In contrast, KUMC and KHMC showed more moderate increases. For the diagnosis domain, KUMC's exact match rate improved from 23.4% to 36.6%, and KHMC's improved from 21.9% to 55.2%. In the surgical domain, the exact match rates remained below 30% for both institutions (29.8% for KUMC and 28.3% for KHMC), though this still represented a gain of over 10% for each.

Table 3 summarizes the comparative performance evaluation of mapping accuracy for diagnostic and surgical procedure domains across 4 hospital networks. For each hospital and domain, mapping performance was measured as top-1 and top-5 accuracy, both at baseline (before incorporating reference terms) and after the inclusion of reference terms. To ensure statistical rigor, 95% CIs were calculated for all accuracy estimates. The absolute improvement in accuracy (Δ accuracy) was also calculated to quantify the benefit of leveraging shared reference mappings.

XSL•FO
RenderX

Table 3. Comparative performance evaluation of automated SNOMED CTa[a] mapping accuracy for diagnostic and surgical procedure domains across 4 South Korean multi-institutional networks. All improvements were statistically significant (McNemar test, $P<.01$ for all cases). 95% CIs were calculated using the Wald method.

Hospital network, domain, not mapped rate (%), metric	Baseline accuracy (%)	Accuracy with reference terms (95% CI)	Δ accuracy[b] (%)

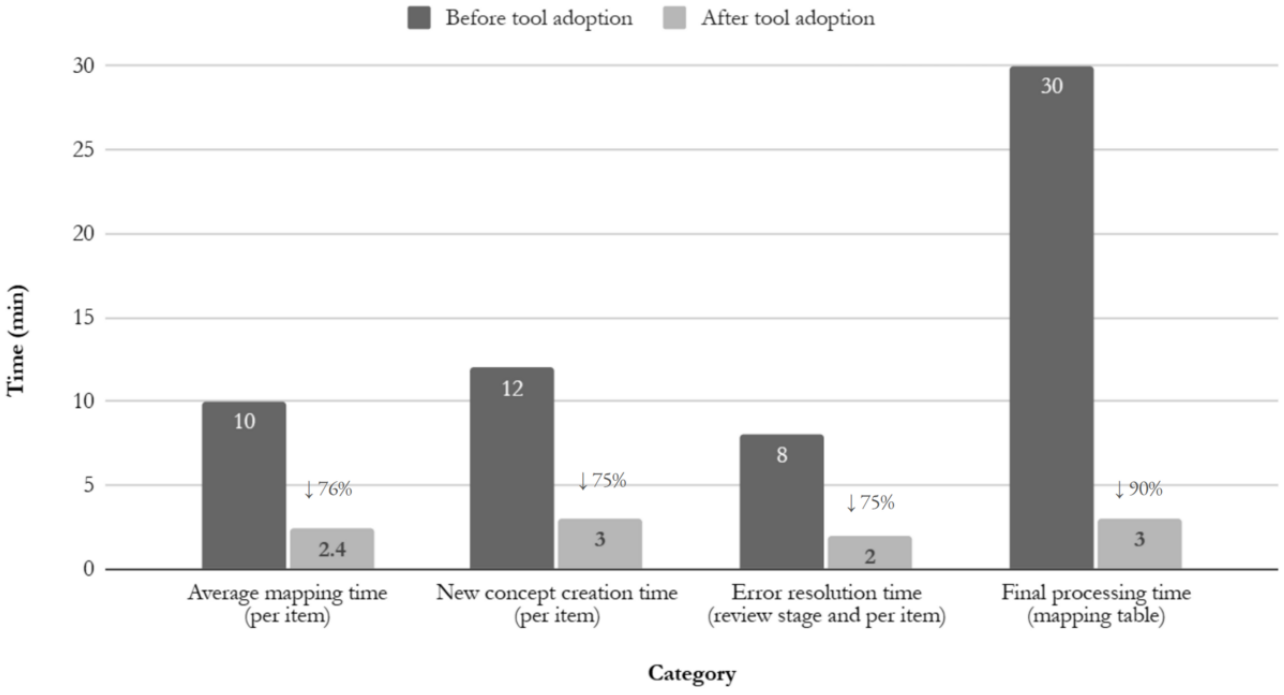
[d]KUMC: Korea University Medical Center.

XSL•FO
RenderX

[e]DSMC: DongSan Medical Center.

[f]KHMC: KyungHee University Medical Center.

At baseline, top-5 accuracy for diagnosis was similar across hospitals, ranging from 85.5% to 88.9%. In contrast, surgical procedures showed greater variation, with baseline top-5 accuracy from 79% to 85.2%. After reference terms were incorporated, top-5 accuracy for diagnosis increased to between 89.7% and 98.7%, and for surgical procedures it rose to between 82.6% and 99.2%. EUMC and DSMC showed the highest postreference top-5 accuracy in both domains and achieved the largest absolute improvement in surgical procedures (up to 14.5% at EUMC and 13.5% at DSMC).



For top-1 accuracy, the improvement after reference terms addition was even more pronounced, especially in surgical procedures, with EUMC reaching a 33.6% increase. Top-5 accuracy remained consistently higher than top-1 in all hospitals and domains, but the relative improvement with reference terms was greater for top-1 than for top-5. All gains in accuracy were statistically significant (McNemar test, $P<.01$). In a supplementary evaluation, the exclusion of the syntactic mapping (exact match) step resulted in negligible variations in top-5 accuracy, suggesting that the vector-based semantic search effectively identifies these identical terms.

To provide context for performance ceilings, we analyzed the prevalence of unmappable terms. The gold standard dataset included terms categorized as “not mapped,” representing local codes for which experts determined no valid SNOMED CT concept existed. These instances were treated as errors in the accuracy calculation. The prevalence of “not mapped” terms varied by institution and domain: EUMC (diagnosis: n=0, 0%; surgical procedure: n=0, 0%), KUMC (diagnosis: n=174, 0.4%; surgical procedure: n=219, 1.7%), DSMC (diagnosis: n=1, 0%; surgical procedure: n=0, 0%), and KHMC (diagnosis: n=0, 0%; surgical procedure: n=0, 0%).

Result of Efficiency Evaluation

Figure 6 clearly demonstrates the efficiency evaluation based on a 6-month operational period, showing significant reductions in manual workload across 4 key stages of the SNOMED CT mapping process. The manual mapping rate decreased from 100% to 70%, indicating a 30% reduction and highlighting the tool’s effectiveness in enabling automated mapping. More broadly, the overall manual workload was significantly reduced, with marked enhancements in efficiency throughout the entire mapping process. Specifically, the average mapping time per item decreased from 10 to 2.4 minutes, representing a 76% reduction. The time required to create a new concept similarly dropped from 12 to 3 minutes (75% reduction), while the time needed to resolve errors during the review stage was reduced from 8 to 2 minutes (75% reduction). Most notably, the final processing time of the mapping table per dataset decreased from 30 to 3 minutes, achieving a 90% reduction.

Figure 6. Efficiency evaluation of the SNOMED CT mapping workflow, comparing manual baseline time to performance after adopting the LLM-assisted automated tool across 4 key stages: mapping, new concept authoring, error resolution, and final processing of the mapping table. LLM: large language model; SNOMED CT: Systematized Nomenclature of Medicine Clinical Terms.

Results of New Concept Authoring Quality Evaluation

After implementation of the tool, both classification and MRCM validation errors decreased substantially, even as the total number of authored concepts increased. The proportion of duplicate concepts dropped from 0.8% (122/15,637) with manual authoring to 0.1% (46/34,401) with the tool, representing an 83% reduction. Likewise, MRCM validation violations

XSL•FO
RenderX

decreased by 72%, from 264 in the manual process to 75 with the tool-assisted workflow.

Result of System Usability Evaluation

Users highlighted several benefits of the system. First, the tool reduced effort during the mapping process by automatically suggesting candidate target concepts, which minimized the number of manual typing and clicking steps required. Second, users noted a significant decrease in errors, as the system eliminated mistakes that previously occurred when characters were deleted or data types were changed during manual copying and pasting of IDs or FSNs. The tool now conveniently enters the FSN when a valid ID is provided, further improving accuracy. Finally, the new system offered enhanced usability compared to the previous spreadsheet-based screens, which users found visually straining and inflexible. With the new interface, users reported a more comfortable and convenient experience.

Discussion

Principal Findings

This study developed an LLM-assisted SNOMED CT automatic mapping tool and evaluated it across multiple real-world hospital settings. Notably, the tool supports postcoordination, which minimizes semantic loss from source terms and leverages the strengths of SNOMED CT. In evaluation, the tool demonstrated high top-5 accuracy rates—92.6% for diagnostic concepts and 93.6% for surgical procedures. Incorporating reference mappings further increased accuracy by over 6% in both areas. Workflow efficiency was markedly enhanced, with mapping and concept authoring times reduced by approximately 75% and the proportion of cases requiring manual mapping dropping from 100% to 70%. Importantly, the tool reduced human modeling errors in new concept authoring, as evidenced by an 83% decrease in duplicate concept rate and a 72% reduction in MRCM validation violations. Error resolution and final processing of the mapping table were also significantly streamlined.

When evaluating site-specific performance, we found substantial variation across different hospital networks, especially after integrating the shared reference knowledge base. Performance in networks such as EUMC and DSMC was exceptionally high, with exact match rates exceeding 94% in diagnosis and 96% in surgical domains—likely reflecting the use of shared electronic medical record systems, which allowed most mappings to be resolved through simple identity lookups.

To analyze the actual contribution of the exact match step, we performed an internal assessment comparing mapping accuracy with and without the preliminary exact match stage. This assessment revealed that the difference in top-5 accuracy between the 2 configurations was negligible. Thus, the primary value of the exact match component lies not in enhancing end-to-end mapping quality but in workflow optimization: by quickly resolving about 30% of cases, it helps bypass computationally and financially intensive processes, contributing to pipeline efficiency and sustainability.

The accumulation and reuse of reference mappings across institutions is also central to our approach and reflects both the realities and strengths of terminology standardization initiatives in Korea; as more hospitals join and contribute to the shared repository, we anticipate continued improvements in mapping consistency and efficiency across various settings.

By contrast, KUMC and KHMC exhibited more modest improvements, as a substantial portion of their mappings could not be resolved through exact identity lookup alone. For these institutions, the shared knowledge base contributed to performance gains but was insufficient on its own; thus, many mappings still required the use of vector-based semantic similarity search. This highlights the ongoing need for advanced AI components when handling diverse or nonstandardized local terminologies that may not be well represented within a shared repository.

Further analysis of auto-mapping errors revealed 3 main sources of reduced accuracy: (1) the presence of local terms that reference only body structures or materials without an associated procedure—instances best categorized as “not mapped”; (2) terms requiring new concept creation via postcoordination—particularly in the surgical procedure domain, where postcoordination was frequently necessary; and (3) unresolved or ambiguous abbreviations. Understanding these error patterns provides important directions for future refinement of the system.

Comparison With Prior Work

A consistent set of challenges emerges across this and prior work, including the persistent difficulty of mapping rare or institution-specific terms, handling ambiguous abbreviations, and resolving semantically unclear expressions [17-19]. Beyond algorithmic advancements, real-world clinical deployment presents unique integration hurdles, such as harmonizing diverse IT infrastructures, maintaining synchronization between terminology servers and electronic medical record systems, and managing evolving local terminologies [18]. Importantly, our study reaffirms that, regardless of automation level, human review remains indispensable—not only for establishing and maintaining gold standard mappings that underpin system performance, but also for defining and updating mapping rules to reflect evolving clinical realities [17,18].

Limitations

First, we encountered various technical difficulties during implementation. The internal PostgreSQL database and the ElasticSearch (Elasticsearch B.V.) engine supporting SNOMED CT search (via SNOMED Snowstorm API and Browser) required frequent manual synchronization due to architectural differences. This was especially challenging since ElasticSearch lacks built-in transactional support. Accordingly, script-based data reconciliation was required to maintain consistency, but it remains to be fully automated.

Second, a significant limitation of our methodology involves the Korean-to-English translation step required for processing bilingual input data. As the accuracy of the subsequent vector similarity mapping is entirely dependent on the quality of the translated term, we acknowledge that the lack of gold-standard

XSL•FO
RenderX

comparisons or error analysis for this step is a methodological limitation.

Third, translation was handled as a fully automated preprocessing step to minimize human intervention and maximize efficiency within the mapping pipeline. To control quality when using models such as GPT-4o or Gemini 2.0 Flash, we used carefully designed, domain-specific prompts (Multimedia Appendix 1). These prompts enforced specific constraints: they defined clinical context (eg, diagnosis type), removed noise, and ensured that terms were translated strictly into the official medical vocabulary. However, the accuracy of subsequent mapping is entirely dependent on translation quality. Despite these controlled prompts, we currently lack external gold-standard metrics or formal error analysis for this critical phase.

We note that the volume of local terms requiring Korean translation was low, at approximately 1.5% of the total mapped terms. While this proportion is small, we acknowledge that translation inaccuracies in even a limited subset of terms could introduce minor bias into the overall mapping accuracy. Accordingly, we recognize the necessity of integrating translation-specific metrics into the overall evaluation framework.

Finally, while the gold standard for mapping underwent extensive review by experienced terminology experts both internally and externally, we did not collect or report an objective measure of interrater agreement, such as Cohen κ. Although this expert involvement likely improved reliability, the absence of a quantitative assessment remains a limitation and should be considered when interpreting our results.

Future Directions

Although retrieval-augmented generation was explored in our preliminary model, we observed limitations where the current general-purpose LLM failed to accurately leverage the inherent ontological structure of SNOMED CT, often yielding results identical to simple vector similarity search [34]. Therefore, further improvement is expected by using LLMs that are specifically designed to leverage both contextual information and the intrinsic structure of SNOMED CT in future research. Further, the use of SNOMED CT's ontology structure and knowledge graphs (eg, GraphRAG) is expected to enhance semantic retrieval and disambiguation capabilities, increasing accuracy and robustness across broader domains [35]. To improve authoring of new concepts, automation features applying detailed MRCM cardinality rules and an advanced inactivation process will be developed, reducing modeling errors and ensuring SNOMED CT compliance.

From a sustainability perspective, widespread adoption will require continued resource investment for tool maintenance and updates, as well as collaboration across clinicians, informaticians, terminology experts, and policymakers. Keeping standard codes current, ensuring ongoing quality assurance, and adapting to multilingual and ICD-11 (International Classification of Diseases, 11th Revision) or International Classification of Health Interventions-integrated environments—particularly for mapping complex surgical procedures—are essential for scalable and future-proof deployment. Despite concerns about the potential for increased operational costs when deploying commercial LLMs, our experimental results indicate that these expenses were negligible relative to the benefits achieved. For example, embedding 1.6 million tokens costs just US $0.03, and translating 1779 cases incurred only minimal costs based on standard token pricing. These findings highlight the economic viability and sustainability of incorporating LLM components into automated pipelines.

Our long-term vision is to deliver this solution as a cloud-based software-as-a-service platform, supporting agile terminology standardization across diverse medical institutions both domestically and worldwide. For effective adoption in new environments, local verification and adaptation may be necessary to address differences in data standards and clinical practices. Notably, the system's methodological approach aligns with the World Health Organization's and Centers for Disease Control and Prevention's international guidelines, supporting its potential generalizability across health systems worldwide [11,12].

Conclusions

We developed and validated the first large-scale, multi-institutional automatic terminology mapping tool supporting both pre- and postcoordinated SNOMED CT concepts. The tool substantially reduces manual workload, improves mapping accuracy, and enhances interoperability for clinical data across the evaluated sites. While our current evaluation was limited to internal implementation, further work will focus on advancing commercialization and expanding deployment. We anticipate that, with continued refinement and local verification, this tool could support terminology standardization and interoperability for broader national and international healthcare data integration in the future.

Acknowledgments

The authors would like to acknowledge the valuable contributions of the Ewha Womans University Medical Center, Kyung Hee University Medical Center, Korea University Medical Center, and Keimyung University DongSan Medical Center, particularly the IT departments at each hospital, for their cooperation. Our deepest gratitude goes to the Clinical Terminology Team and the Standards Technology Team at Kakao Healthcare for their outstanding support and technical expertise throughout the development of this study. We also used the generative artificial intelligence (AI) tool ChatGPT (GPT-4o, OpenAI; used in 2025) solely to assist with English language editing and grammar. The AI was not used to generate scientific content, analyze data, or create figures, tables, or references. All AI-assisted text was reviewed, verified, and edited by the authors, who take full responsibility for the content.

Abstract

Background: Infant incubator adverse events refer to various harmful incidents that occur during the normal use of marketed infant incubators and result in, or may result in, bodily harm. In recent years, however, the number of reported adverse events has continued to rise. This trend has made the monitoring of infant incubator adverse events time-consuming and labor-intensive when relying solely on manual processing by medical device adverse-event monitoring personnel. Meanwhile, general-purpose large language models (LLMs) still face domain knowledge gaps and hallucination issues in specialized fields. Through fine-tuning, LLMs can be adapted to specific application scenarios, while retrieval-augmented generation (RAG) enhances their ability to handle knowledge-intensive tasks. Therefore, LLMs that integrate these 2 technologies hold significant potential for addressing monitoring challenges.

Objective: This study aims to enhance the intelligent monitoring of adverse events related to medical devices by integrating RAG with dual-adapter fine-tuning to construct an adverse-event analysis model for infant incubators. The model enables an integrated workflow centered on extraction and analysis, encompassing structured extraction of adverse events, narrative analysis, and regulatory question answering.

Methods: This study leveraged adverse-event data from Chinese infant incubators to construct a high-quality dataset through prompt engineering. Technologically, it combined 2 parameter-efficient fine-tuning methods—low-rank adaptation and infused adapter by inhibiting and amplifying inner activations—to achieve efficient adaptation on the Qwen2-7B base model. Simultaneously, it introduced the FINBGE embedding model with supervised contrastive semantic optimization to build a knowledge retrieval system that mitigates hallucination.

Results: This study comprises 1565 pediatric disease question-and-answer entries from PediaBench, 2530 specific corpora on adverse events in infant incubators, and 1488 regulatory corpora. Extensive experiments demonstrate the superiority of this analytical model across various metrics. Under the same experimental conditions, the element recall rate reaches 0.815, the accuracy of infant incubator adverse event analysis is 0.898, and the accuracy in regulatory clause question-answering tasks attains 0.938.

Conclusions: The analytical model proposed in this study demonstrates significant advantages in analyzing adverse events related to infant incubators, while also achieving substantial improvements in text generation metrics. When combined with RAG, it not only effectively mitigates hallucination but also enhances knowledge timeliness. This study employs the Qwen model as its foundational framework, leveraging large-model fine-tuning and RAG to achieve intelligent analysis of high-risk medical device adverse-event monitoring data. It demonstrates the feasibility of implementing intelligent medical device regulation within the Qwen ecosystem.

Introduction

Background

Collecting and analyzing adverse event monitoring data for high-risk medical devices is a crucial means of ensuring their safety and effectiveness [1]. Currently, medical device regulatory authorities have widely adopted electronic monitoring systems, which not only enhance data collection efficiency and convenience but also lead to a sustained increase in the volume of adverse event reports submitted [2]. Badnjević et al [3] found that despite clear regulatory mandates for postmarket surveillance obligations across countries, issues persist in adverse event reporting, including inconsistent standards, noncomparable data, and fragmented oversight. In China, infant incubators are classified as class III high-risk medical devices. Adverse event monitoring for these products involves interdisciplinary knowledge integration across multiple fields. Challenges include large volumes of adverse event data, predominantly in unstructured and nonstandardized formats [4], as well as significant variation in data quality reported by health care institutions [5]. These factors substantially increase the workload and complexity of analyzing and processing reports. Recent innovations in natural language processing technology offer new possibilities for balancing efficiency and professionalism. Ruseva et al [6] proposed a deep learning model based on the TensorFlow framework, demonstrating strong performance in assessing adverse drug reaction risks and enhancing postmarketing drug surveillance capabilities. Hauben [7] developed artificial intelligence (AI)–based methods to enhance drug-drug interaction detection and prediction. Borjali et al [8] integrated deep learning to accurately and promptly detect adverse medical events from free-text medical narratives.

While traditional deep learning models can perform text classification, they lack long-range contextual associations [9] and causal reasoning capabilities [10], exhibit weak generalization, and demonstrate poor transferability between events [11]. Lu et al [12] found that Transformer models consistently outperformed traditional convolutional neural network models in nearly all medical text classification scenarios, with convolutional neural networks demonstrating acceptable performance only when categories were balanced. Naik et al [13] highlighted that adapting event extractors to new medical domains suffers from covariate shift issues, rendering direct transfer ineffective and necessitating specialized domain adaptation techniques.

Although large language models (LLMs) can provide solutions to core challenges in medical device adverse event monitoring, pretraining foundational models from scratch for vertical domains incurs prohibitively high costs. For instance, first, training a model with tens of billions of parameters requires multiple graphics processing units and months of computational time [14], demanding substantial computational resources and time investment. Second, pretraining often requires datasets in the gigabyte or even terabyte range [15], while vertical domain data are typically strictly confidential [16]. Publicly available data may constitute less than 0.1% of pretraining requirements, and the processes of data collection, cleaning, annotation, and storage involve substantial human and material resources. Finally, pretraining imposes steep technical barriers, demanding both deep algorithmic engineering expertise and the development of large-scale distributed training frameworks [17]—a burden beyond the reach of most small-to-medium teams.

Therefore, this study constructs an infant incubator adverse event analysis model by fine-tuning LLMs. Methods such as low-rank adaptation (LoRA) and infused adapter by inhibiting and amplifying inner activations, that is, $(IA)^3$, require only minor weight updates, preserving general language prior knowledge while incorporating domain-specific expertise [18]. However, for tasks involving the analysis of adverse events related to infant incubators—which are complex, densely populated with specialized terminology, and characterized by imbalanced samples—a single method has inherent limitations. LoRA excels at capturing long-range contextual dependencies and temporal event correlations through low-rank updates, but its global low-rank matrix may lack sufficient feature resolution when handling rare fault descriptions or subtle terminological variations. Meanwhile, $(IA)^3$ enables fine-grained control over the strength of specific features through dynamic scaling of activation values, but it struggles to model long-range semantic relationships across sentences or paragraphs. Neither approach alone can comprehensively address these challenges.

To this end, this study proposes a “dual-adapter joint fine-tuning” architecture. Its novelty lies not in simple superposition but in a hierarchical division of labor and collaboration: the LoRA component focuses on modeling logical chains and long-range dependencies within adverse events, while the $(IA)^3$ component performs local feature enhancement and normalization on terminology and key entities to suppress noise. Coupled through a dynamic weight transfer mechanism, this approach enables the model to achieve deep adaptation to vertical domain knowledge while preserving general medical semantic understanding. Although vertical domains often lack extensive data, Wang et al [19] demonstrated the feasibility of studying small-sample adverse event data in medical devices when investigating knowledge transfer and calibration for small-sample medical signals (epileptic electroencephalography).

High-quality and task-relevant data form the cornerstone for ensuring that fine-tuned models achieve the expected performance, accuracy, and specific behavioral patterns. Data quality directly determines the nuances learned by the model, the biases it may inherit or mitigate, and its generalization capabilities [20]. The data source used in this study comprises nonpublic adverse event data from infant incubators within

XSL•FO
RenderX

China's Medical Device Adverse Event Monitoring System (the details of adverse events are shown in Multimedia Appendix 1). This dataset authentically captures adverse events generated by infant incubator use in medical institutions in recent years, encompassing complex and diverse semantic expressions within the domain. Real-world noise reflects the challenges of practical application scenarios; mild noise can actually compel the model to learn deeper semantic features rather than relying on spurious patterns in the data, thereby enhancing model robustness [21].

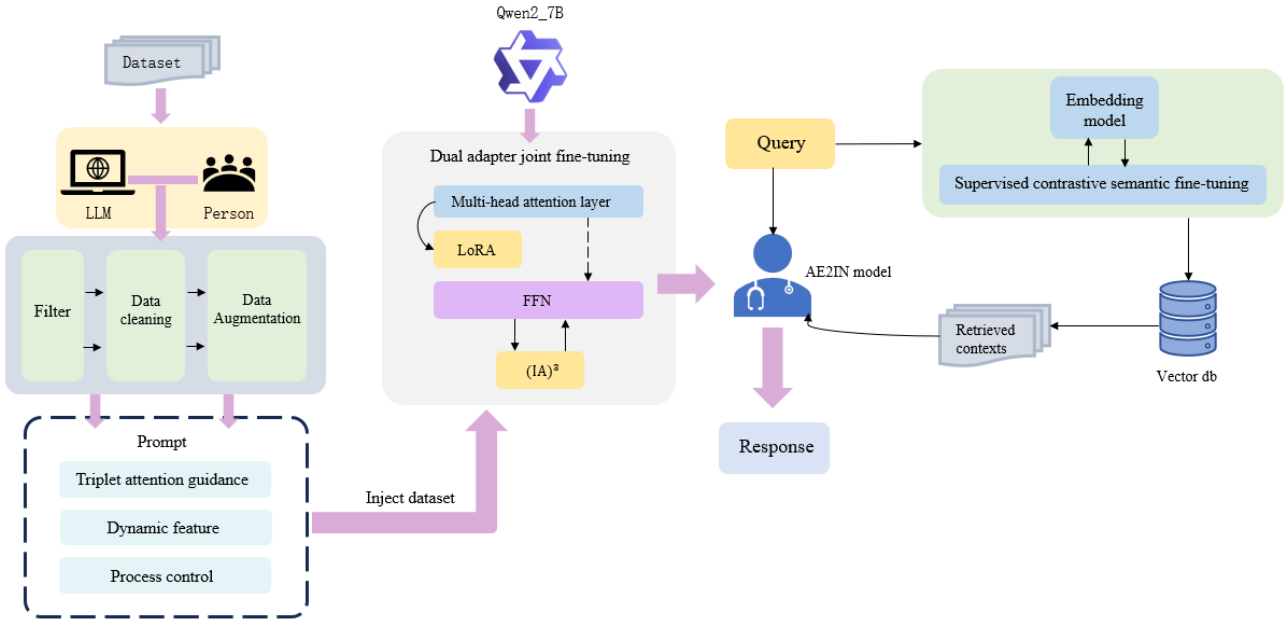
It is important to note that even after model fine-tuning, hallucination persists. From a computational theory perspective, all AI models—including current mainstream LLMs—are fundamentally probabilistic mathematical function approximators [22]. These models map inputs to output spaces through complex parameter matrix operations, generating outputs that are essentially responses sampled from high-dimensional probability distributions. Retrieval-augmented generation (RAG) significantly mitigates this issue. It is an AI technique that combines information retrieval technology with language generation models [23]. This approach enhances the model's capability to handle knowledge-intensive tasks by retrieving relevant information from external knowledge bases and feeding it as prompts to LLMs.

Related Work

In recent years, the rapid advancement of AI technology has increasingly highlighted the application value of large-scale pretrained models across multiple professional domains. Advanced models such as GPT and Bidirectional Encoder Representations from Transformers (BERT), with their exceptional language comprehension and generation capabilities, have demonstrated significant application potential in the health care sector. Research data indicate that models based on the Transformer architecture possess unique advantages in medical text processing: Kim et al [24] confirmed that domain-adapted BERT variants perform well in predicting appropriate medical departments based on patient symptom descriptions and in answering specialized medical questions. Zhang et al [25] utilized LLMs for medical record generation tasks, saving physicians approximately 0.5-1 hour of work time daily.

Notably, the application scope of such models has expanded beyond text processing into medical devices and regulatory domains. Tang et al [26] highlighted that the global AI medical device industry is experiencing robust growth, while the urgent need for regulatory oversight is becoming increasingly apparent—a trend expected to intensify. For instance, Kim et al [27] developed a deep learning predictive model to rapidly and accurately detect mechanical ventilation requirements in neonatal intensive care units using electronic health records; Matheny et al [28] systematically explored how applying LLMs to the US Food and Drug Administration's (FDA) medical product safety surveillance system enhances the identification and assessment of adverse drug events.

Regarding fine-tuning medical LLMs, multiple studies have explored application methods. For instance, Jia et al [29] employed LoRA for instruction fine-tuning of pretrained LLMs, ultimately enhancing the automated generation of children's health science resource labels. Abbasian et al [30] utilized electronic health records from patients with diabetes for P-tuning and LoRA fine-tuning of large models, opening new avenues for diabetes management and improving therapeutic efficacy. Integrating large models with RAG has also become a research hotspot. Hu et al [31] introduced a pioneering personalized dementia care approach by integrating GPT-4, fine-tuned and RAG-enabled, with a vector database. Kulshreshtha et al [32] enhanced a medical chatbot based on the Llama source model using RAG methods to generate reliable, contextually relevant responses, thereby improving clinical judgment and reducing health care workers' workload.



Methods

Overview

The adverse event analysis model AE2IN proposed in this study for infant incubators comprises 2 core modules: a data preprocessing layer and a knowledge-enhanced analysis layer. The specific framework is illustrated in Figure 1.

XSL•FO
RenderX

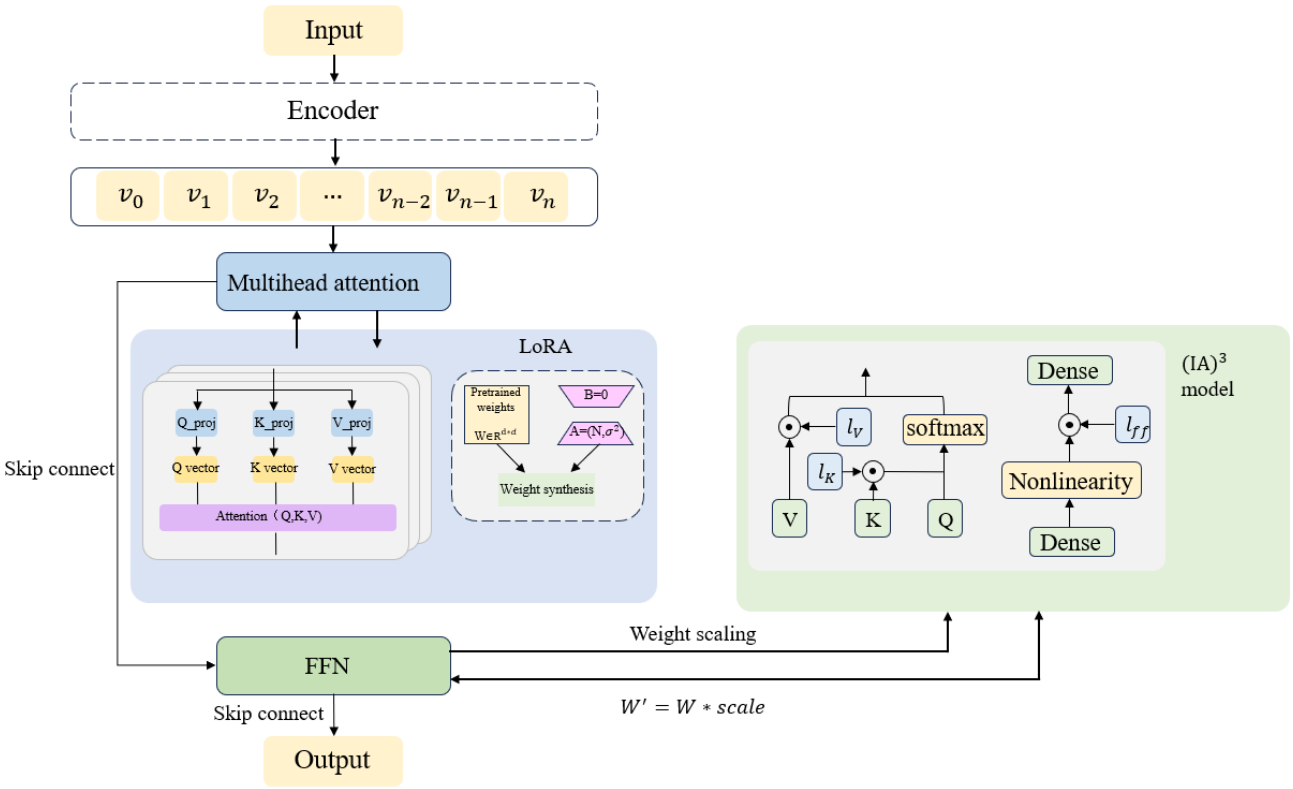
Figure 1. Framework diagram of the AE2IN adverse event analysis model for infant incubators. The preprocessing layer cleans the data, normalizes terminology, and enhances adverse event reports. The knowledge enhancement layer enables collaborative analysis through external knowledge injection and large-model semantic reasoning, using a Qwen model fine-tuned with dual adapters alongside a fine-tuned embedding model. FFN: feedforward network; (IA)3: Infused Adapter by Inhibiting and Amplifying Inner Activations; LLM: large language model; LoRA: low-rank adaptation.

At the data preprocessing layer, the system first standardizes input adverse event reports for infant incubators through data filtering, cleaning, and augmentation. The data standardization, cleaning, and augmentation processes for this study's training dataset leveraged GPT-4 as a teacher model for auxiliary processing. Through knowledge distillation in a teacher-student paradigm, it provided high-quality training samples for subsequent domain-specific fine-tuning of the Qwen2_7B model. Standardization during conventional inference fully utilizes specialized medical dictionaries and regular expression rules to ensure accurate recognition of diverse terminology. The preprocessed structured data are subsequently fed into the knowledge-enhanced analysis layer.

The knowledge-enhanced analysis layer serves as the system's core, employing a dual-path parallel processing mechanism. On the one hand, supervised comparison-based semantic optimization fine-tunes the embedded model FINBGE to vectorize queries and retrieve the most relevant clause content from the medical device regulatory knowledge base. On the other hand, the Qwen2_7B model, jointly fine-tuned via dual adapters, performs deep semantic understanding of the input text. Notably, this model innovatively combines 2 parameter-efficient fine-tuning techniques: LoRA and $(IA)^3$.

Fine-Tuning

Dual-Adapter Fine-Tuning



This study designed a dual-adapter joint fine-tuning method that combines LoRA and $(IA)^3$, 2 parameter-efficient fine-tuning techniques. LoRA focuses on optimizing the Q (query)/V (value) projection matrices within the attention mechanism through low-rank matrix updates (r=32), effectively capturing contextual dependencies in descriptions of adverse events in infant incubators. Meanwhile, $(IA)^3$ refines the feature representations of the feedforward network by learning feature scaling coefficients without introducing additional parameters, thereby enhancing the representation of abnormal features and the generation of handling suggestions. Mathematically, this can be expressed as a composite transformation:

where W represents the original pretrained weights, ΔW is the low-rank update matrix introduced by LoRA, composed of the product of 2 small matrices A and B, and l is the feature scaling vector learned by $(IA)^3$. This architecture retains LoRA's advantage in pattern discovery—learning domain-specific attention patterns through low-rank space—while integrating the precise feature selection control of $(IA)^3$. The overall framework is illustrated in Figure 2.

XSL•FO
RenderX

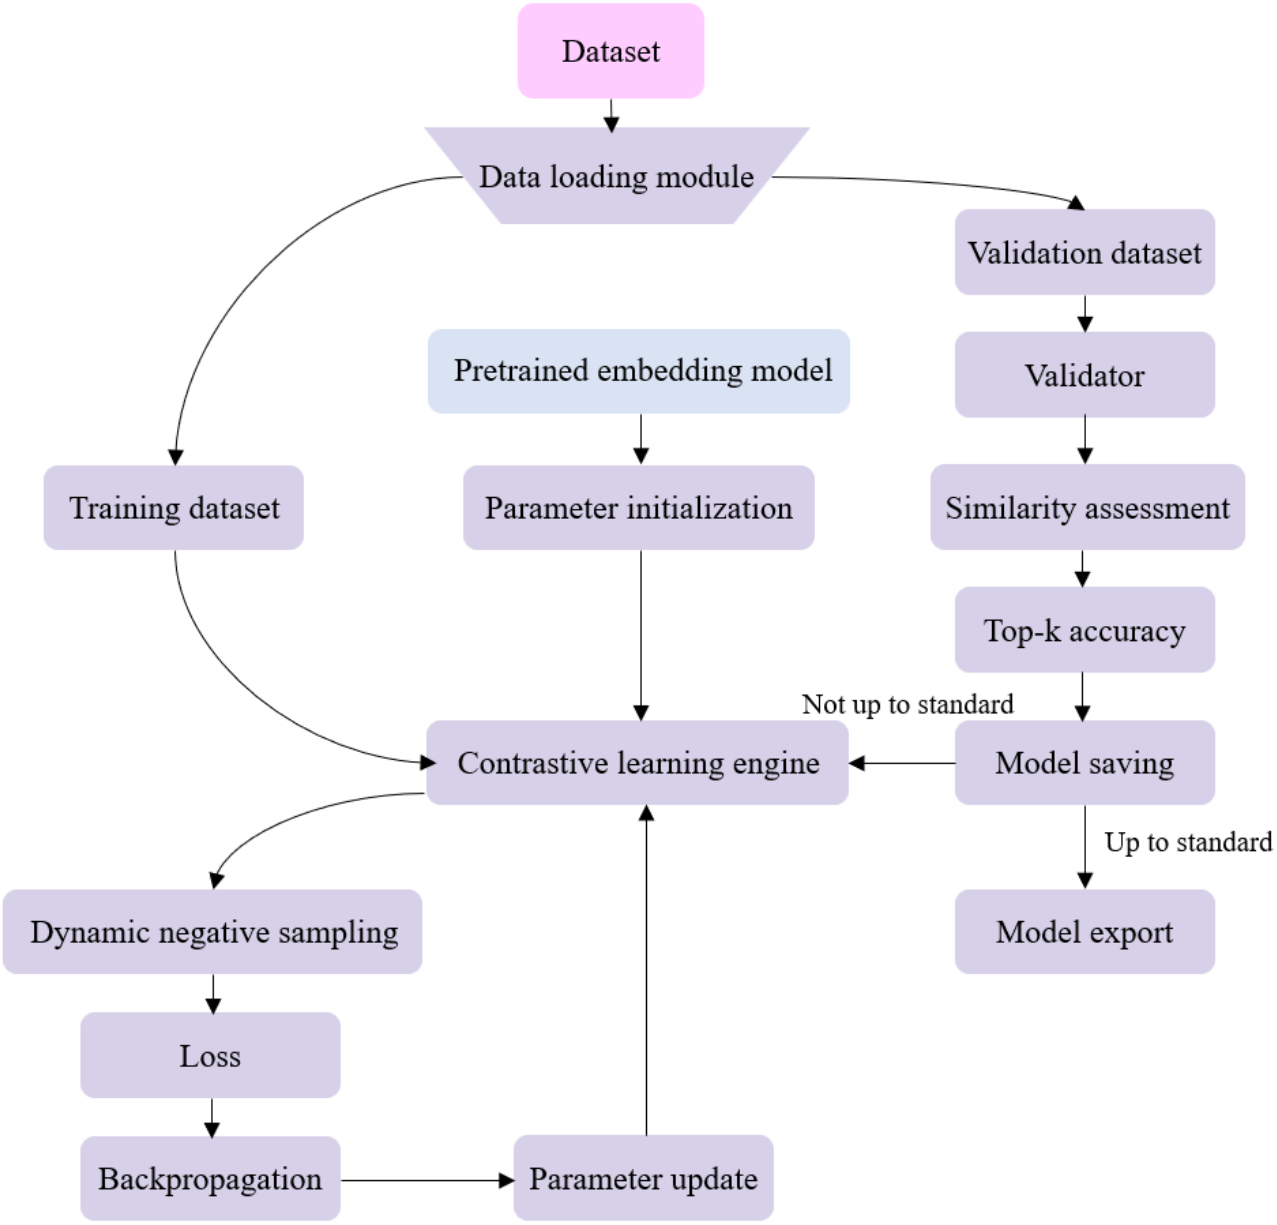
Figure 2. Dual-adapter fine-tuning framework diagram. The architecture is built on the Qwen2_7B foundation model and integrates 2 parameter-efficient methods: low-rank adaptation (LoRA) and Infused Adapter by Inhibiting and Amplifying Inner Activations (IA)3. The diagram illustrates the core design, with LoRA applied to the query/value projection matrices in the Transformer attention mechanism and (IA)3 applied to the feedforward network (FFN). It also depicts the fine-tuning strategy, where pretrained weights are frozen and only adapter parameters are updated, highlighting key processes such as attention computation, weight composition, and feature scaling.

The domain-adaptive training strategy employs a dynamic weighting mechanism to balance domain-specific data with general-purpose corpora. Its objective function is defined as follows:

where λ_d is the domain data weight coefficient; λ_g is the general data weight coefficient, with a ratio of 3:1; D_d and D_g represent the domain dataset and general dataset, respectively; denotes the loss function for a single sample; y_t is the tth token in the target sequence; $y_{<t}$ indicates the historical output sequence; and T is the target sequence length.

By employing a 3:1 weighted sampling mechanism, domain data receive high-frequency exposure to accelerate the model's mastery of infant incubator adverse event norms, while continuous infusion of general data maintains foundational medical semantic understanding.

This method can be divided into 2 stages. The first stage focuses on optimizing the attention mechanism. By utilizing low-rank matrix updates, it establishes cross-layer semantic associations for factors in the Q/V projection matrix that contribute to adverse events in infant incubators. This step notably enhances the model's ability to understand temporal patterns in infant incubator adverse events. It can be conceptualized as the model's capability to accurately capture causal chains such as "temperature alarm → skin temperature probe failure → component inspection." The second stage specifically adjusts the feature representations in the feedforward network. By learning scaling coefficient vectors, it finely controls the generation intensity of infant incubator adverse event terminology and the standardization of subsequent handling recommendations. For example, operations such as "Immediately replace the incubator, monitor the infant's temperature and pulse oxygen saturation, and report to the equipment department for repair" fall under the follow-up actions category, while information such as "Equipment model YP-90B, root cause analysis of the fault" is accurately categorized under the additional information category. This ensures that the model's output maintains both professional precision and compliance with medical documentation standards.



Knowledge inheritance between stages is achieved through dynamic weight transfer—using attention patterns obtained from LoRA training as initialization priors for the $(IA)^3$ stage. This strategy converges faster than parallel training while preserving model generalization capabilities and notably enhancing domain-specific task performance. It effectively overcomes the limitations of either approach: fine-grained feature variations that are difficult for LoRA to capture are compensated by $(IA)^3$, while long-range dependency modeling—a weakness of $(IA)^3$—is supplemented by LoRA.

Supervised Contrastive Semantic Optimization Fine-Tuning

In specialized domains, general-purpose embedding models often struggle to accurately capture subtle distinctions between professional terminology, leading to similar yet unrelated concepts being overly close in vector space [33]. Therefore, this paper proposes a supervised contrastive semantic optimization method to fine-tune embedding models. The fine-tuning workflow framework is illustrated in Figure 3.

Figure 3. Framework diagram of the supervised contrastive semantic optimization fine-tuning process. The model performs comparative learning and parameter updates using both the training and validation datasets.

By constructing an end-to-end fine-tuning pipeline, we achieve efficient domain adaptation for pretrained embedding models. Utilizing the Sentence Transformers Finetune Engine framework, we combine contrastive learning mechanisms with domain knowledge injection. This enables the model to accurately capture domain-specific semantic association patterns while preserving its original semantic understanding capabilities. The core training objective is mathematically expressed as follows:

where q_i is the embedding vector for query i; p_i^+ and p_i^- are the positive and negative samples associated with q_i, respectively; τ is the temperature coefficient controlling the sharpness of the distribution; N denotes the number of queries in the batch; and K represents the number of negative samples corresponding to each query. Cosine similarity establishes the relevance metric between queries and documents. The temperature parameter τ controls the sensitivity of similarity scores. The numerator term $e[\text{sim}(q_i, p_i^+)/\tau]$ generates centripetal force, drawing relevant documents closer to the query point in vector space. The denominator term  generates a repulsive field, pushing

irrelevant documents away from the query point's semantic neighborhood.

Beyond reconstructing the semantic space, feature space calibration requires an embedding projection transformation, formulated as:

$$h = \text{LayerNorm}[W_2 \cdot \text{GELU}(W_1 x + b_1) + b_2]$$

W_1 and W_2 form a parameterized transformation matrix that projects the original embedding onto a subspace more suitable for the current task. The GELU function introduces a smooth threshold, preserving important features while filtering out noise. LayerNorm maintains numerical stability, ensuring comparability between embeddings from different domains.

Infant Incubator Adverse Event Evaluation Indicators

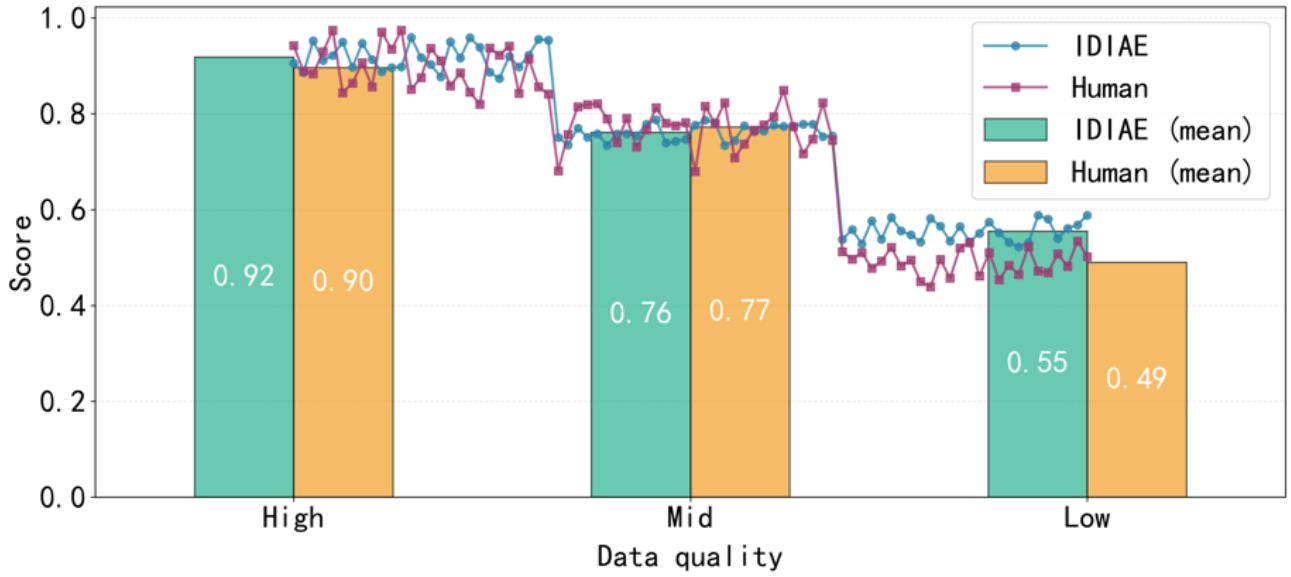
When analyzing adverse events involving infant incubators, core elements are of paramount importance. Yan and Huifang [34] proposed analyzing both the manifestations and root causes within adverse event data for infant incubators. Kaur et al [35] suggested describing the implemented control measures. Additionally, according to the writing requirements of the guidelines issued by the National Medical Products Administration, adverse event reports typically require information such as location, time, source, injury manifestation, device malfunction, cause analysis, and specific control measures. Accordingly, we summarize the core and secondary elements of infant incubator adverse events. The core elements are the "occurrence date" of the adverse event, the "abnormal condition" of the infant incubator, and the "follow-up measures" for risk control. Secondary elements include the "cause of failure" and the "risk triggered" by the infant incubator. Beyond these core and secondary elements, any additional information captured from the original text is categorized as supplementary notes.

Therefore, during testing experiments, in addition to employing general evaluation metrics, we have developed specialized evaluation indicators for adverse events in infant incubators: the element recall rate and the information density index of adverse events with correction factor (IDIAE). The formulas are as follows:

where K denotes the core feature set; E_k^{ref} represents feature k in the reference text; E_k^{pred} denotes feature k in the predicted text; and I is the indicator function. During computation, text segments E_k^{ref} and E_k^{pred} corresponding to the 3 core elements are extracted from the reference text and prediction text, respectively. Subsequently, a hierarchical matching assessment is performed: an exact match is determined by checking whether the normalized reference text is fully contained within the prediction text. If the exact match fails, the similarity ratio based on edit distance between the 2 texts is calculated. If this ratio exceeds the threshold of 0.8, the segment is deemed a match.

$$\beta = 1 + \alpha \cdot (N_{\text{red}}/10) + \gamma \cdot M_{\text{error}}$$

where C_j represents the coverage status of the jth standard report field; m denotes the total number of required fields; w_i is the weight coefficient for the ith category of information (core element weight is 1.0, secondary requirement weight is 0.8); β is the text redundancy coefficient, and the redundancy coefficient incorporates a redundancy word penalty weight α to assess whether the model's response is excessively verbose; N_{red} indicates the number of irrelevant characters; γ is the terminology error penalty weight used to evaluate whether the model captures professional terminology correctly; and M_{error} represents the number of errors.



To determine the globally optimal combination of α and γ and to validate the reliability of the IDIAE metric, this study randomly selected 80 adverse event reports for infant incubators. These were stratified into high-, medium-, and low-quality grades, with 26, 28, and 26 reports, respectively. Experts were invited to rescore the reports under blinded conditions. As shown in Figure 4, varying only the α and γ values revealed that the intraclass correlation coefficient peaked at 0.78 (95% CI 0.72-0.83) when α=.1 and γ=0.2. This indicates a strong positive correlation between IDIAE scores and expert ratings under this weighting configuration (correlation coefficient r=0.82, P<.001), representing the globally optimal combination. To further validate IDIAE reliability, after fixing the weights (α=.1, γ=0.2), analyses across high-, medium-, and low-quality grades showed that the mean IDIAE scores for all 3 groups in Figures 5 and 6 consistently aligned with expert-rated mean trends for both completeness and accuracy. The classification consistency κ coefficient reached 0.71. These results demonstrate that the IDIAE metric effectively reflects expert criteria for assessing report completeness, exhibiting good reliability and clinical applicability.

Prompt Engineering

To efficiently align the model with the desired training outcomes, this study designs 3 prompts for different scenarios, as shown in Figures 7-9. Figure 7 is used to assist in generating a suitable fine-tuning dataset. Figure 8 presents the system prompt embedded in the inference stage, aiming to standardize the model output. The retrieval prompt integration employs a structured constraint template, as shown in Figure 9. System instructions enforce that the model must base its responses solely on retrieved content, annotating each sentence with a source identifier [Ref-N] after interpretation. Each retrieved chunk is organized according to a fixed format. The prompt template constrains model behavior through 3 core rules:

- It explicitly prohibits vague references such as “Article X,” mandating explicit linkage to specific regulatory document names and clause numbers to prevent cross-document clause confusion.
- It requires declarations of “insufficient basis” for uncertain content, thereby eliminating model speculation or the fabrication of nonretrieved clauses.
- Regulatory requirement sections must alternate between verbatim citations and interpretations, with each interpretive sentence immediately followed by a [Ref-N] annotation.

Figure 7. Prompt for generating fine-tuning datasets for embedding models.

Prompt	Original text
<|im_start|>system As a regulatory expert at the National Medical Products Administration, please generate {num_questions} natural questions based on the following text: Important Rules: 1.The format "Article XX of [Regulation Name]" can only be used when the original text explicitly mentions the name of the regulation. 2.When the original text does not mention the regulation name, generating questions that include "Article XX" is strictly prohibited. 3.Questions must not be generated using header or footer content. 4.Ensure that the answers to the questions can be found in the original text. Examples (Correct): -"What are the basic requirements for online sales of medical devices?" -"According to Article 20 of the 'Regulations on the Supervision and Administration of Medical Devices,' what are the requirements for production licenses?" Examples (Incorrect): -"What materials are needed according to Article 5?" (Lacks regulation name) -"What are the requirements referenced in Article 18?" (Lacks regulation name) <|im_end|>	Regulations on the Administrative Law Enforcement Responsibility System of Market Supervision and Administration (Promulgated by Order No. 41 of the State Administration for Market Regulation on May 26, 2021, and effective from July 15, 2021) ..... Article 8: Staff of the market supervision and administration department shall exercise their powers within the scope of their legal authority and in accordance with legal procedures, ensuring strict, standardized, fair, and civilized law enforcement. They must not neglect their duties, exceed their powers, or abuse their authority. Article 9: If staff of the market supervision and administration department, due to intentional actions or serious negligence, unlawfully perform their administrative law enforcement duties, resulting in harmful consequences or negative impacts, this constitutes an administrative law enforcement fault, and they shall bear administrative law enforcement responsibilities in accordance with the law.
Generated question	Correct answer
How should serious negligence by staff of the market supervision and administration department be handled?	Article 9: If staff of the market supervision and administration department, due to intentional actions or serious negligence, unlawfully perform their administrative law enforcement duties, resulting in harmful consequences or negative impacts, this constitutes an administrative law enforcement fault, and they shall bear administrative law enforcement responsibilities in accordance with the law.

Figure 8. System prompt for the inference phase. The template defines the model's role, output specifications, and core constraints for adverse event analysis and regulatory questions and answers in infant incubators. It governs output format, professional compliance, and content boundaries to ensure responses meet specialized regulatory requirements for medical device adverse events.

Prompt

System Role and Task Instructions
You are a professional intelligent assistant for analyzing adverse events in medical devices. Your core task is to perform structured analysis on **raw text reports of infant incubator adverse events** submitted by users, strictly adhering to the following output format.

Core Analysis Element Definitions
You must extract or summarize the following elements from the report:
1. **Occurrence Date**: The specific date or time of the event explicitly stated in the report.
Key Rules
1. **Strictly Evidence-Based**: All output must derive solely from the input text. **Do not fabricate, infer, or add information not present in the original text**.
2. **Original Text Priority**: For precise details like dates or model numbers, reproduce the original text whenever possible. For descriptive text, provide professional, concise summaries.
3. **Handling of Gaps**: If an element is completely absent from the original text, populate the corresponding JSON field with "Not Mentioned" or an empty string.
2. **Anomalies**: Malfunctions, abnormal phenomena, or alarm messages exhibited by the infant incubator. Summarize using standard medical terminology (e.g., "incubator temperature probe failure," "abnormal fan noise").
3. **Follow-up Actions**: Specific risk control measures taken by operators (e.g., "immediately replaced the incubator," "reported for repair").
4. **Root Cause**: (If inferable) The probable underlying cause of the anomaly.
5. **Potential Risk**: (If inferable) The potential safety risk this anomaly may pose to the infant.
6. **Additional Notes**: Other important details, such as equipment model, personnel involved, or associated medical devices.

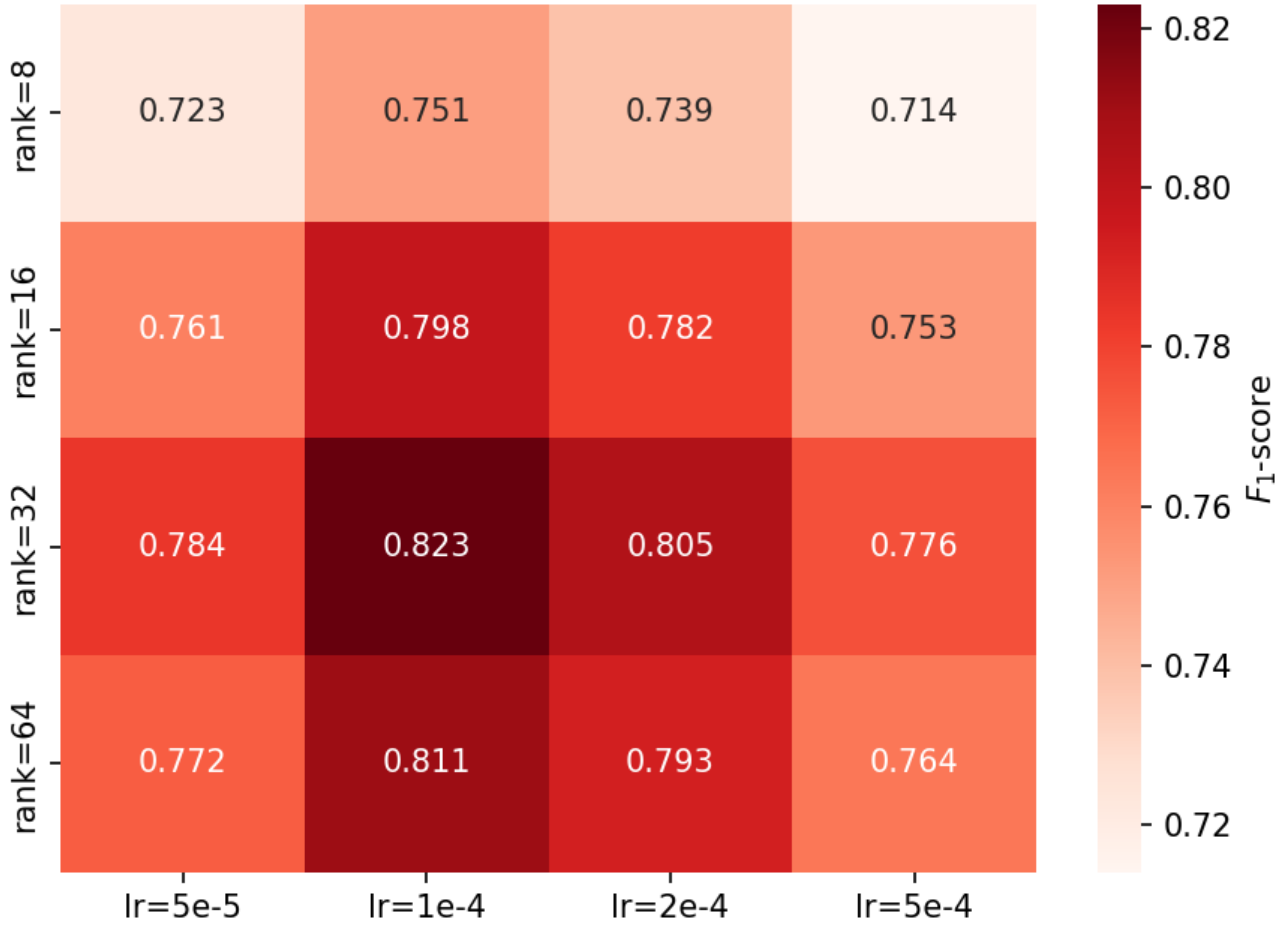
Figure 9. Retrieval-augmented generation retrieval prompt template. Designed for a regulatory expert role aligned with the National Medical Products Administration, it defines 4 mandatory rules and standardized output requirements: conclusions must be based solely on retrieved regulatory provisions; each interpretation must include source citations; fabrication of provisions is prohibited; and any uncertainty must be labeled as "insufficient basis." The template takes user queries and retrieved regulatory texts as input and produces standardized regulatory question-and-answer outputs.

```
Prompt



<|im_start|>system
As a regulatory expert at the National Medical Products Administration, you must answer
user questions **based solely on the retrieved regulatory provisions below**. No
unsupported interpretations are permitted.
Mandatory Rules:
1. Citation Required: Each regulatory reference must be marked with [Ref-N], formatted as:
[Ref-N] "Regulation Title" Article X
2. Prohibition on Inventing Provisions: Use only explicitly stated content from retrieved
regulatory clauses.
3. Prohibition on Ambiguous Language: Avoid non-traceable expressions like "according to
relevant regulations."
4. Uncertainty Disclaimer: When retrieved content cannot fully address the query, clearly
state "insufficient basis."
Output Requirements:
1. Applicable Provisions: [List all referenced Ref numbers]
2. Regulatory Requirements: [Original text + interpretation, each sentence followed by Ref]
3. Operational Recommendations: [Bulleted list, each point supported by a
provision]<|im_end|>
<|im_start|>user
User query: {query}
Retrieved regulatory provisions
{chunks_with_refs}
End of retrieved content <|im_end|>
<|im_start|>assistant

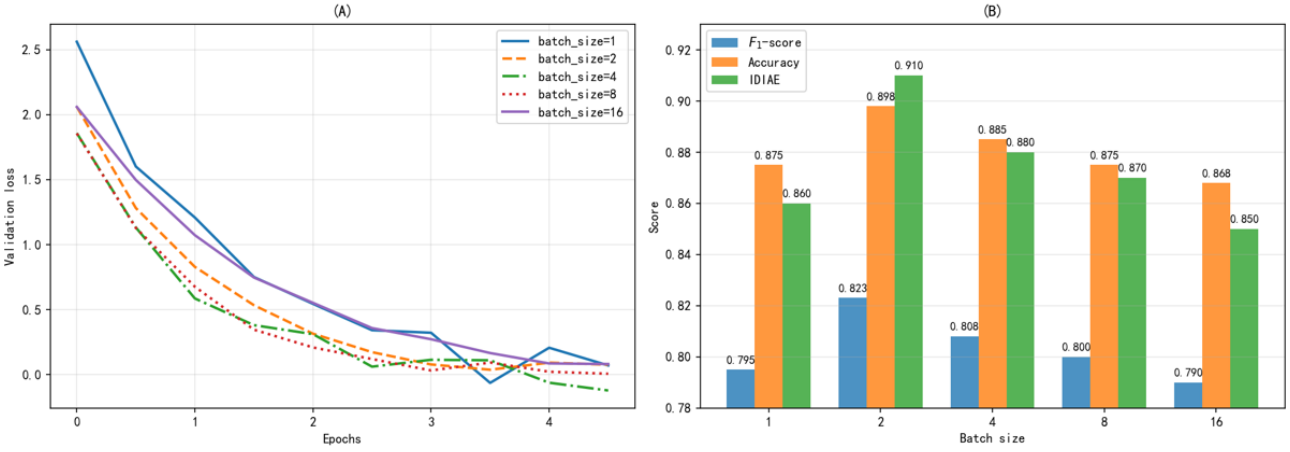
```

Optimal Parameter Configuration

In typical small-sample medical data analysis tasks, r=32 has been validated as an effective LoRA range [36]. Before experimentation, we initially favored selecting r=32. However, to rigorously validate the impact of rank-learning rate combinations on the performance of the infant incubator adverse event question-answering task, we conducted a 4 × 4 grid scan while fixing all other hyperparameters. The resulting F_1-scores are visualized as a heatmap, as shown in Figure 10. The heatmap shows that the F_1-score peaks at 0.823 at rank=32 and lr=1 × 10^{-4}, then decreases toward the surrounding edges, exhibiting an overall bell-shaped "medium-high-medium" distribution. This phenomenon occurs because when the rank is too low, the low-rank matrix lacks expressive power and cannot fully capture the long-range dependencies and medical terminology details in event descriptions; when the rank is too high, the number of parameters increases, which can lead to overfitting on domain data and weaken generalization. Regarding the learning rate, 5 × 10^{-5} converges too slowly, whereas 5 × 10^{-4} has an excessively large step size, making it difficult for the model to stabilize at the optimal weights. By contrast, 1 × 10^{-4} strikes a balance between convergence speed and stability. Therefore, the experiment ultimately adopted the combination of rank=32 and lr=1 × 10^{-4}.



XSL•FO
RenderX

Figure 10. Hyperparameter sensitivity heatmap. The figure shows variation in F1-scores on the test set for the infant incubator adverse event question-answering task as a function of low-rank adaptation rank and learning rate, evaluated via a 4 × 4 grid search.

To investigate the impact of batch size on training stability and performance, we conducted experiments while fixing the other hyperparameters. As shown in Figure 11A, when batch size is 1, the loss curve oscillates notably and converges slowly due to high gradient update noise; a batch size of 2 (the configuration selected for this study) achieves an optimal balance between training stability and convergence speed, with a smoothly declining loss curve and the lowest final convergence value; increasing the batch size to 4 or 8 yields a more stable training process but slightly slower convergence; a batch size of 16 fails to iterate sufficiently due to graphics processing unit memory constraints. Figure 11B further quantifies the final performance metrics across different batch sizes: a batch size of 2 achieves peak values for F_1-score, accuracy, and IDIAE, showing average improvements of 4.0% and 3.4%, compared with batch sizes of 1 and 8, respectively. Therefore, the final experimental configuration adopts a batch size of 2.

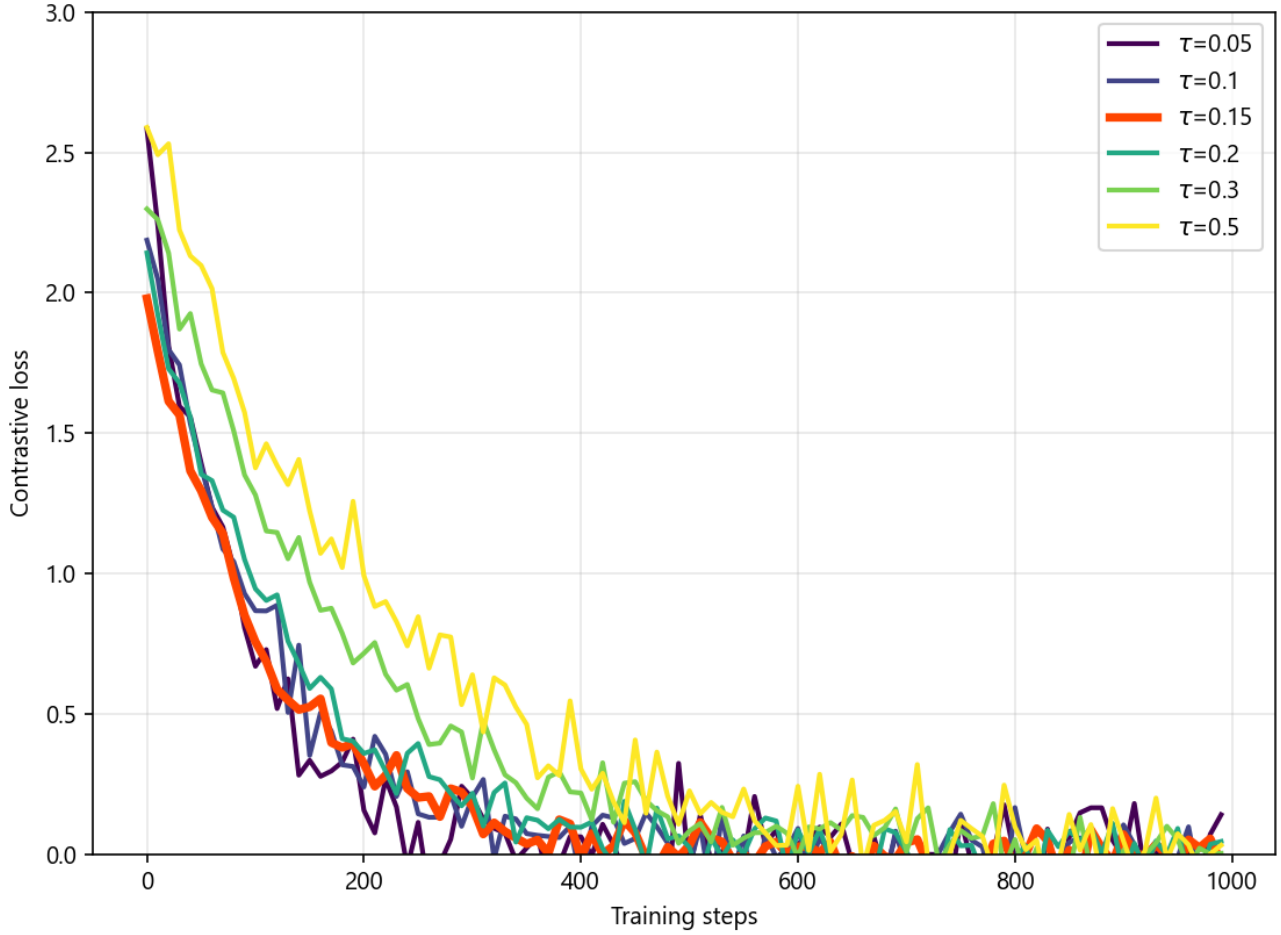


Figure 11. Batch size impact analysis. The figure examines how different training batch sizes affect the AE2IN model's training stability and final performance. (A) Training loss curves across epochs for various batch sizes, with epochs on the x-axis and loss on the y-axis. (B) The final F1-score, accuracy, and Information Density Index of Adverse Events (IDIAE) metric for each batch size, with batch size on the x-axis and metric values on the y-axis.

In supervised contrastive semantic optimization, the temperature coefficient τ controls the sharpness of the similarity distribution. To achieve optimal results, we fixed the other parameters and conducted experiments on the temperature coefficient. As shown in Figure 12, when τ=0.05, the similarity distribution becomes excessively sharp, causing the loss curve to oscillate and converge slowly. At τ=0.15 (the value selected for this study), the loss curve declines smoothly and rapidly to a stable region. When τ increases beyond 0.3, the similarity distribution becomes overly smooth, notably slowing loss convergence. Therefore, τ=0.15 is determined to be the optimal configuration for medical device regulatory retrieval tasks.

Figure 12. Effect of the temperature coefficient (τ) on supervised contrastive learning. The figure shows how different τ values influence convergence of the training loss during supervised contrastive semantic optimization fine-tuning of the embedding model. The x-axis represents training steps, and the y-axis shows the contrastive learning loss.

Ethical Considerations

Our data originate from China's medical device regulatory authorities. The data consist of medical device adverse event reports (similar to the US FDA's Manufacturer and User Facility Device Experience [MAUDE] database). The content primarily includes failure information recorded during device use. These data contain no patient information; therefore, formal ethics approval is not required. This project was jointly completed with regulatory agencies under government-funded research initiatives. All data were authorized, and the research complies with relevant regulations.

Results

Experimental Data

This large-model experimental dataset comprises general-domain data and domain-specific data. The general-domain data originate from the PediaBench dataset publicly released by the State Key Laboratory of Public Big Data at the School of Computer Science and Technology, Guizhou University, China. It contains 1565 question-and-answer entries covering common pediatric diseases such as neonatal disorders, pediatric infectious diseases, pediatric respiratory diseases, and pediatric primary care and developmental behavioral disorders. Domain-specific data originate from private adverse event data on infant incubators within China's Key Monitoring Information System for Medical Device Adverse Events. After manual and GPT-4 screening, data cleaning, and augmentation, combined with prompt engineering, the data were processed into a specialized question-and-answer dataset on infant incubator adverse events, totaling 2530 entries (Table 1).

RenderX

Table 1. Fine-tuning the Qwen model dataset sources and scale.

Dataset	Data source	Data volume
PediaBench	Public dataset from the State Key Laboratory of Public Big Data, School of Computer Science and Technology, Guizhou University, China	1565
Infant Incubator Adverse Event Questions and Answers	Adverse event data on private infant incubators in China's Key Monitoring Information System for Medical Device Adverse Events	2530

We split the data at the adverse-event report level: all question-and-answer pairs derived from the same report were assigned entirely to either the training, validation, or test set, ensuring that no report appears in more than one set. This experimental dataset allocates 60% (2457/4095) to the training set, 30% (1229/4095) to the test set, and 10% (409/4095) to the validation set.

The knowledge base data originate from regulatory documents issued by the China National Medical Products Administration. We selected administrative regulations and departmental rules to form the regulatory provisions knowledge base, comprising a total of 29 documents. The fine-tuning dataset for the embedding model is derived from these regulatory documents. We utilized documents from this knowledge base and, combined with prompt engineering, leveraged GPT-4 to generate fine-tuning datasets. This dataset comprises 1488 entries, with 60% (893/1488) allocated to the training set, 30% (446/1488) to the test set, and 10% (149/1488) to the validation set (Table 2).

Table 2. Knowledge base and fine-tuning the embedding model dataset.

Dataset	Data source	Data volume
Regulatory Knowledge Base	Regulatory documents issued by the China National Medical Products Administration	29 documents
Embedding Model Fine-Tuning Dataset	Generated using regulatory documents issued by the China National Medical Products Administration	1488

To mitigate the "student-teacher" loop bias introduced by large-model rewriting, we collaborated with the Henan Drug Administration to implement a manual quality control process for all data generated by large models. First, we established a 3-tier annotation standard (perfect equivalence/minor drift/significant drift) and trained annotators ($\kappa \geq 0.78$). Next, data were grouped into batches of 100 items for double-blind annotation by pairs of annotators, with a third party serving as the arbitrator. Only when the "significant drift" rate was controlled at ≤5% were the data released. Finally, senior experts centrally reviewed and refined the "significant drift" data.

Experimental Environment

This work selected Qwen2_7B as the source model and employed a dual-adapter joint fine-tuning approach for training, with specific configurations detailed in Tables 3-5.

Base Model Testing

This study selected BGE-Large-ZH-V1.5 as the embedding source model. Here, BGE-Large-ZH-V1.5 was compared with M3E-Large, Text2Vec-Large, and Luotuo on the Massive Text Embedding Benchmark (MTEB) and the Chinese Massive Text Embedding Benchmark (C-MTEB). The embedding dimension was unified to 1024, and the evaluation metrics selected were retrieval, semantic textual similarity, pairwise classification, and classification.

Table 6 compares BGE-Large-ZH-V1.5 with mainstream models, demonstrating that it achieves leading performance on both MTEB and C-MTEB. Its high recall score of 70.46 indicates that it is particularly well-suited as a foundation for RAG systems, demonstrating a superior ability to accurately match specialized terminology within knowledge bases compared with other models.

For large models, this paper compares base-model performance by evaluating Qwen2_7B, Llama3_8B, and GLM4_9B across 8 metrics. The results are shown in Table 7.

Table 6. Embedding base model test results. This table compares the performance of the BGE-Large-ZH-V1.5 embedding model selected for this work against 3 mainstream Chinese embedding models across multiple dimensions on the MTEBa and C-MTEBb standard evaluation datasets.

Model	Embedded dimension	Retrospective retrieval	Semantic textual similarity	Pairwise classification	Classification
BGE-Large-ZH-V1.5	1024	70.46	56.25	81.6	69.13
M3e-Large	1024	54.75	50.42	64.3	68.2

[a]MMLU: Massive Multitask Language Understanding.

Table 7 shows that the Qwen2 model has stronger overall performance than the other 2 models. Qwen2 performs well on the Massive Multitask Language Understanding (MMLU) medical subset and C-Eval medical questions, indicating that the model is stable in diagnostic reasoning and clinical terminology comprehension, but exhibits slight errors in complex calculation questions. Meanwhile, the fine-tuned AE2IN model shows score decreases ranging from 2.1 to 2.7 on the MMLU medical subset and C-Eval medical tasks. Because of the incorporation of PediaBench data during fine-tuning, its scores slightly surpass those of the base model by 0.4 points. By contrast, models fine-tuned solely on domain-specific datasets experienced score declines ranging from 5.4 to 8.0 on the MMLU medical subset and C-Eval medical tasks, along with a 6.2-point drop on PediaBench. These

XSL•FO
RenderX

comparative results validate that AE2IN effectively mitigates catastrophic forgetting.

Comparative Experiment

We selected 5 models for comparative testing with the fine-tuned model. The results are shown in Table 8.

Table 8. Comparative evaluation of the fine-tuned model AE2IN against general models and specialized medical models (HuatuoGPT, DISC-MedLLM) in the infant incubator adverse event domain. This table compares the overall performance of the base large model, the base model combined with the same RAGa framework model, mainstream medical-specific large models, and the AE2IN model proposed in this study on the infant incubator adverse event analysis task. All experiments were replicated 3 times independently. Results are presented as mean (SD), supplemented with 2-tailed (unpaired and independent) samples t test *P* values and statistical significance annotations for each model versus AE2IN.

[a]RAG: retrieval-augmented generation.

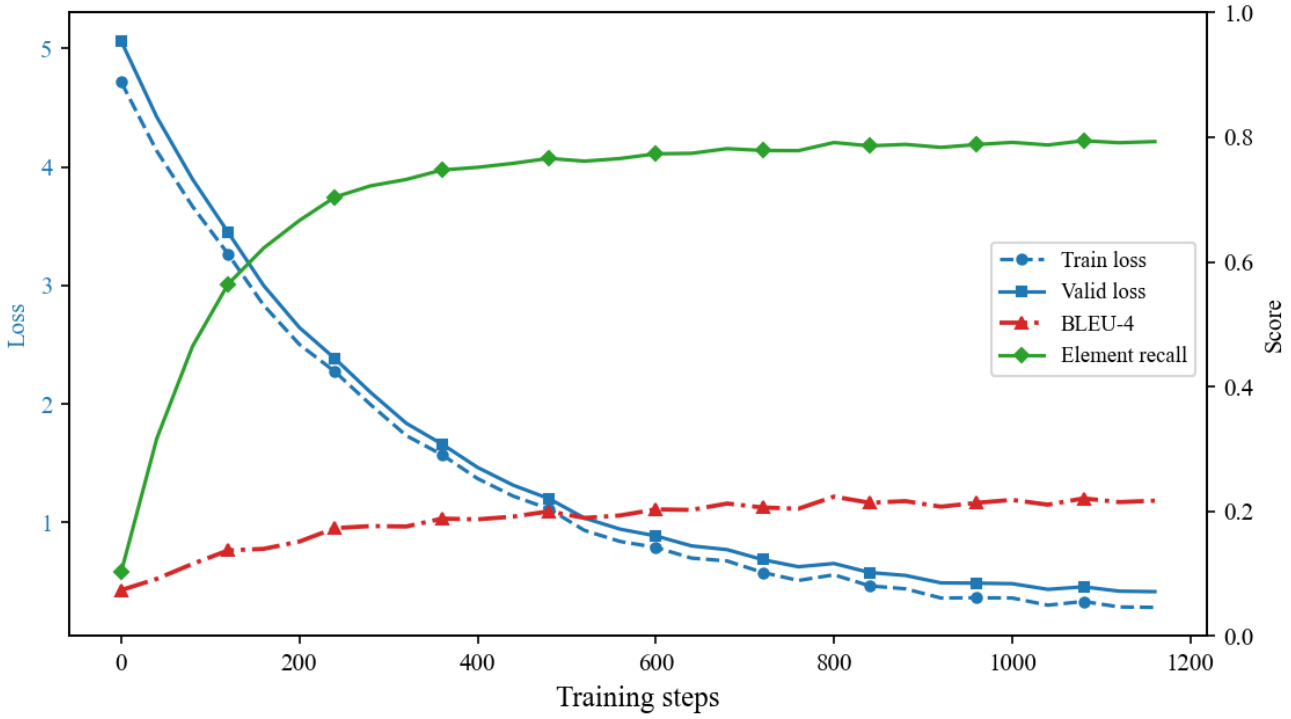
[b]BLEU: Bilingual Evaluation Understudy.

[c]ROUGE-L: Recall-Oriented Understudy for Gisting Evaluation - Longest Common Subsequence.

[d]IDIAE: Information Density Index of Adverse Events.

[e]N/A: not applicable.

Through systematic quantitative evaluation, the AE2IN model demonstrates notable advantages across all key performance indicators in the domain of infant incubator adverse events. In terms of text generation quality, AE2IN attained a BLEU-4 score of 0.215, reflecting a 56.9% improvement relative to the baseline model and a 32.7% improvement over the baseline equipped with the same RAG framework. Its Recall-Oriented Understudy for Gisting Evaluation - Longest Common Subsequence (ROUGE-L) score reached 0.484, corresponding to a 53.7% increase. For core element analysis of infant incubator adverse events, the element recall rate reached 0.815, representing a 17.9% improvement over the baseline model and a 14.0% improvement over the baseline integrated with the same RAG framework. In the experiments, the dual-adapter architecture exhibited strong causal reasoning capacity when processing complex alarm system failure events.



To conduct a more comprehensive analysis of the AE2IN model, we also selected cases in which accuracy, element recall, and IDIAE were all below 0.5. We found that misjudgment of core elements directly affected completeness conclusions and notably impacted both accuracy and IDIAE values. In failed cases, we observed that for rare fault descriptions—such as the onomatopoeic “pushing clack-clack sound”—low frequency and susceptibility to semantic integrity disruption caused the inferred Query-Key similarity to be drowned out by the attention distribution of primary terms after softmax. This prevented the activation of corresponding neurons during value vector weighting. Furthermore, the scaling coefficient update for $(IA)^3$ relies on batch statistics, leading to inconsistent weighting across cases. When encountering such descriptions, the update process may become stuck at a saddle point, failing to amplify this feature.

We continuously record training and validation loss, along with key evaluation metrics, to determine in real time whether the model is in a state of normal convergence, overfitting, or underfitting. As shown in Figure 13, validation loss and training loss decrease smoothly and synchronously over the first 600 steps, maintaining a small difference of less than 0.15, indicating that the learning rate of 1×10^{-4} effectively balances model capacity and regularization. BLEU-4 increases monotonically from 0.07 to 0.22, only 0.005 away from the final test set score of 0.215, confirming that the validation and test sets are identically distributed and that the model has fully converged.

XSL•FO
RenderX

Feature recall also increases from 0.60 to 0.815 over the first 600 steps, rising in parallel with BLEU-4 without intersecting, indicating that the model improves fluency without sacrificing its ability to extract key information. All 3 metrics plateau simultaneously, demonstrating stable convergence without the need for early stopping or secondary parameter tuning. This also indicates that the final test score is not a random peak but the result of stable convergence.

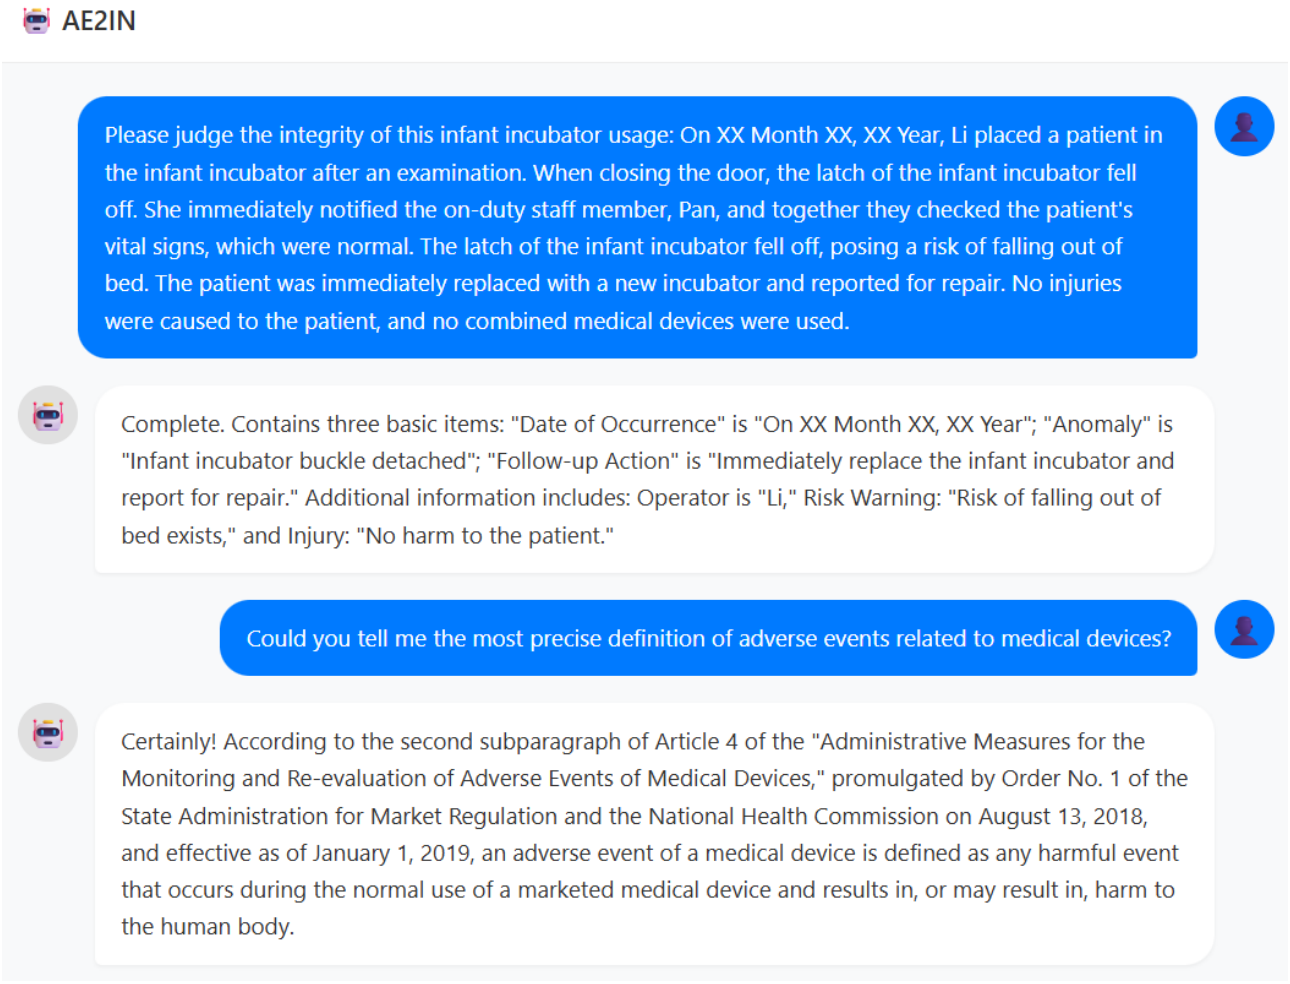


Figure 13. Convergence of dual-adapter fine-tuning (AE2IN). The figure shows the joint evolution of training loss, validation loss, Bilingual Evaluation Understudy-4 score, and ERR metric over training steps. Core hyperparameters were fixed (low-rank adaptation rank=32, learning rate=1 × 10–4, batch size=2). The x-axis represents training steps; the left y-axis shows loss values, and the right y-axis shows text generation and key element extraction scores.

As shown in Figure 14, when determining the completeness of adverse events related to infant incubators, AE2IN directly extracts core elements—incident date, nature of the abnormality, and subsequent corrective actions—while supplementing them with details such as operator information, risk warnings, and injury status. This approach concisely highlights essential information.

XSL•FO
RenderX

Figure 14. AE2IN response examples. The figure presents sample outputs from AE2IN, including assessments of adverse event report completeness for infant incubators and responses to medical device adverse event definitions.

However, compared with other models, AE2IN's responses tend to be more concise. To investigate whether this brevity affects safety, a supplementary risk recall assessment experiment was conducted to quantify the quality of model outputs from a safety perspective. First, a core safety item list was established through expert consultation and alignment with the "Measures for the Administration of Medical Device Adverse Event Monitoring and Re-evaluation" and the national standard "GB 9706.219-2021." This list encompasses adverse event phenomenon identification, safety risk identification, immediate patient safety measures, equipment disposal measures, adverse event reporting measures, and risk cause localization. Next, 100 high-quality data entries, each containing core safety items, were extracted and annotated, and the process was repeated 5 times. The results of the risk recall experiment are shown in Table 9.

Table 9. Risk recall rate comparison. This table displays the risk recall rates and the average number of core safety items identified by AE2IN across various models.

Model	Risk recall, mean (SD)	Average number of core safety items identified
AE2IN	0.92 (0.012)	5.52
Qwen2_7B	0.77 (0.024)	4.62
Llama3_8B	0.75 (0.022)	4.50
GLM4_9B	0.80 (0.019)	4.80
HuatuoGPT-7B	0.82 (0.016)	4.92
DISC-MedLLM	0.84 (0.017)	5.04

AE2IN demonstrates the highest risk recall rate, achieving an improvement of approximately 15% over other models. Although some data may be underreported due to rare fault descriptions, its overall risk recall rate confirms that AE2IN effectively maximizes risk extraction. By outputting structured information that highlights core details, it helps ensure safety.

We used the AE2IN model with the same RAG framework and different embedding models for regulatory question answering.

XSL•FO
RenderX

The experiments used a regulatory clause validation set to compare the performance of the fine-tuned embedding models. The comparative results are shown in Table 10.

Table 10. Comparative evaluation of regulatory question-answering performance between the AE2IN model with different embedding models and general-purpose models.

Configuration/indicators	AE2IN					General model		
	FINBGE[a] (ours)	BGE-Large-ZH-V1.5	M3e-Large	Text2Vec-Large	Luotuo	Qwen2_7B	Llama3_8B	GLM4_9B
Accuracy, mean (SD)	0.938 (0.011)	0.863 (0.015)	0.804 (0.015)	0.780 (0.016)	0.761 (0.017)	0.715 (0.038)	0.652 (0.040)	0.727 0.042)
Recall, mean (SD)	0.894 (0.013)	0.807 (0.016)	0.763 (0.017)	0.759 (0.017)	0.685 (0.019)	0.652 (0.042)	0.594 (0.044)	0.671 (0.050)
F_1-score, mean (SD)	0.915 (0.013)	0.834 (0.016)	0.783 (0.016)	0.769 (0.017)	0.721 (0.018)	0.682 (0.041)	0.622 (0.038)	0.698 (0.04)

[a]FINBGE is a BGE model fine-tuned using supervised contrastive learning.

The experimental results in Table 11 show that the AE2IN model, when equipped with different embedding models, exhibits a clear performance gradient in the regulatory question-answering task. The FINBGE model leads by a notable margin, achieving the highest levels across the 3 core metrics—accuracy, recall, and F_1-score—compared with the source model BGE-Large-ZH-V1.5. This result validates the effectiveness of the supervised contrastive semantic optimization fine-tuning strategy, which successfully narrows the vector distance between the question and the correct answer. Furthermore, comparison with common models reveals that Llama3_8B achieves the lowest scores, likely because the test dataset consists entirely of Chinese regulatory question-answer pairs. The best-performing general model, GLM4_9B, achieves scores of 0.727, 0.671, and 0.698 in accuracy, recall, and F_1-score, respectively, but still lags behind AE2IN. This demonstrates the necessity of domain adaptation and the RAG architecture, which can mitigate model hallucinations, address knowledge timeliness, and improve accuracy.

Table 11. AE2IN model performance ablation study.

Indicators/configuration	BLEU[a]-4, mean (SD)	ROUGE-L[b], mean (SD)	Accuracy, mean (SD)	Element recall rate, mean (SD)	IDIAE[c], mean (SD)
AE2IN	0.215 (0.018)	0.484 (0.021)	0.898 (0.022)	0.815 (0.016)	0.91 (0.01)
Only LoRA[d]	0.187 (0.015)	0.412 (0.019)	0.824 (0.020)	0.763 (0.015)	0.83 (0.01)
Only (IA)[3e]	0.176 (0.015)	0.398 (0.017)	0.795 (0.018)	0.741 (0.014)	0.79 (0.01)
Full fine-tuning	0.168 (0.022)	0.388 (0.024)	0.802 (0.028)	0.735 (0.021)	0.78 (0.02)
None	0.137 (0.031)	0.208 (0.025)	0.785 (0.028)	0.691 (0.023)	0.61 (0.02)

[a]BLEU: Bilingual Evaluation Understudy.

[b]ROUGE-L: Recall-Oriented Understudy for Gisting Evaluation - Longest Common Subsequence.

[c]IDIAE: Information Density Index of Adverse Events.

[d]LoRA: low-rank adaptation.

[e](IA)^3: Infused Adapter by Inhibiting and Amplifying Inner Activations.

Similarly, to conduct a more comprehensive analysis of the system model, we selected cases in which regulatory question-answering accuracy was below 0.5 for further study. We found that hallucinations still occurred—for instance, when the model should have referenced article 23 of the "Administrative Measures for the Monitoring and Re-evaluation of Adverse Events of Medical Devices," it instead cited article 24. This occurs because clauses with high similarity but different article numbers exhibit only minor differences in cosine similarity, leading to the retrieval of incorrect clauses and subsequently triggering hallucinations.

Ablation Experiments

To validate the contributions of each component in the dual-adapter joint fine-tuning architecture, this study designed a systematic ablation experiment, maintaining the same testing environment and hyperparameter settings as previously described. The experiment employed a controlled variable approach, sequentially removing key components and observing changes in model performance.

Table 11 shows that the complete model improves feature recall by an average of 9.25% compared with the single-adapter solution, validating the complementarity of low-rank updates and feature scaling in equation (1).

XSL•FO
RenderX

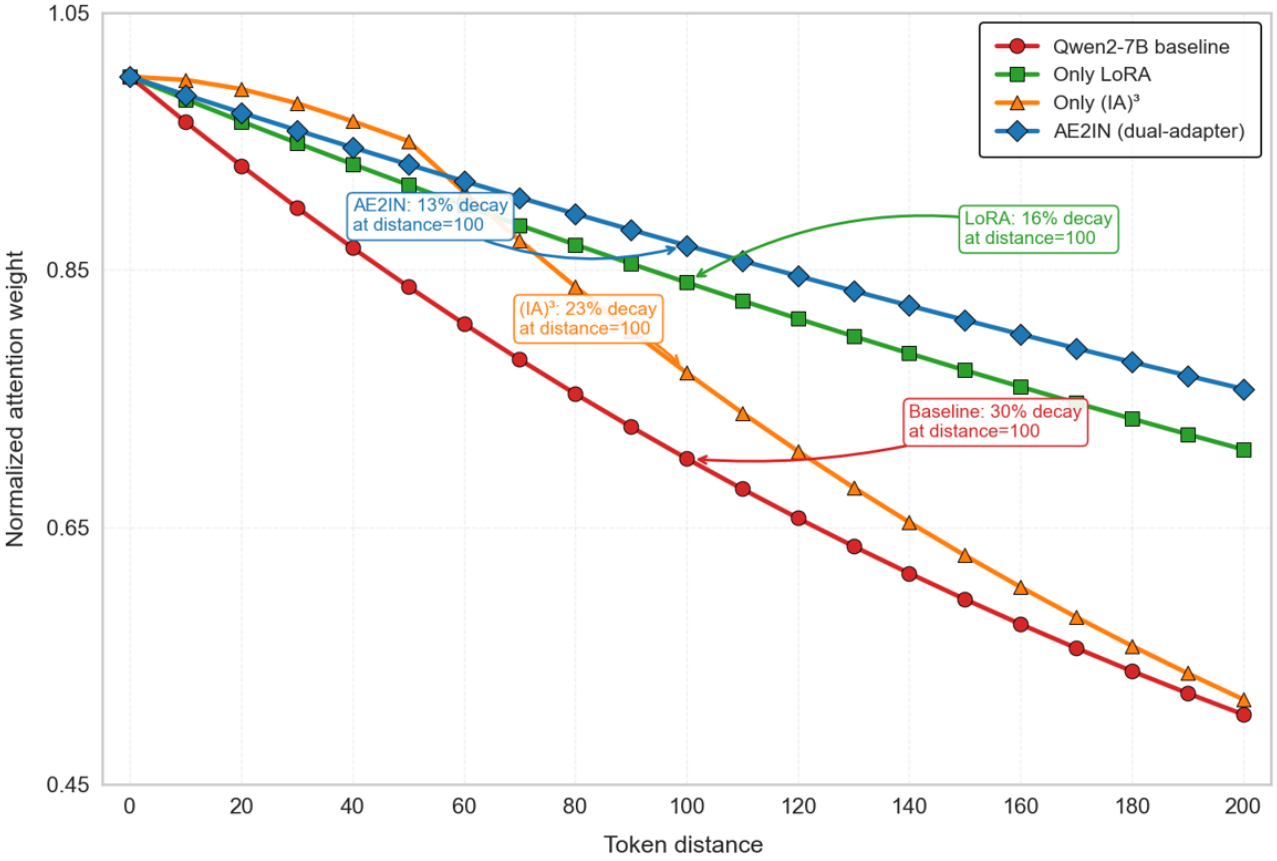
When the LoRA component is removed, BLEU-4 and ROUGE-L decrease notably. This is mainly because LoRA optimizes the long-range dependency modeling capability of the Transformer layer through low-rank decomposition. Its absence makes it difficult for the model to effectively capture the logic in infant incubator failure events. At the same time, the feature recall rate decreases by 10.0%, further validating LoRA's key role in structured information extraction—its trainable parameters are concentrated in the ΔW matrix of the attention layer, enabling more accurate localization of core elements in fault descriptions.

When the $(IA)^3$ component is removed, the IDIAE index decreases notably, due to the weakening of the dynamic feature-scaling function achieved by $(IA)^3$ through the gating mechanism. Specifically, the key-value intervention vector in $(IA)^3$ suppresses the activation of irrelevant features while enhancing the response strength of neurons associated with medical terms.

Following full fine-tuning, metrics exhibited varying degrees of decline compared with AE2IN or single-method fine-tuning. This phenomenon stems from the inevitable overfitting of the 7-billion-parameter model on finite, small samples, validating the necessity of structured parameter fine-tuning for efficiency in small-sample scenarios.

Observation of Table 12 data reveals that, in long-text scenarios, the recall rate of the LoRA configuration alone exhibits a lower decay rate than $(IA)^3$, demonstrating that LoRA's low-rank updates effectively capture long-range semantic associations across clauses. Figure 15 further shows that the attention weights in the LoRA branch decay by 16% for long-distance word pairs, representing a 14-percentage-point reduction compared with the baseline. This indicates that LoRA effectively enhances the interaction strength of distant semantic units. $(IA)^3$ can boost weights over short distances, but long-range dependencies are easily lost, leading to reduced recall rates. This also explains why, under dual-adapter collaboration, the final performance in the infant incubator adverse-event domain improved by approximately 14%, further demonstrating that the 2 adapters can complement each other across different distance scales.

Table 12. AE2IN element recall rate ablation experiment results at different input lengths. This table compares the element recall rate of different model architectures across short and long text adverse event reports for infant incubators.



Configuration	Short text (≤64 tokens), mean (SD)	Long text (>128 tokens), mean (SD)	Attenuation level (%)
AE2IN	0.847 (0.012)	0.810 (0.019)	4.4 (1.1)
Only LoRA[a]	0.834 (0.015)	0.766 (0.024)	8.2 (1.8)
Only $(IA)^3$[b]	0.829 (0.018)	0.739 (0.029)	10.9 (2.2)
Full fine-tuning	0.781 (0.021)	0.704 (0.032)	9.9 (2.6)
None	0.733 (0.028)	0.661 (0.035)	9.7 (3.1)

Figure 15. Dual-adapter semantic modeling capability. The figure demonstrates the model's ability to capture semantics using a long-text test dataset of infant incubator adverse events. It shows the decay of attention weights with increasing token distance: the x-axis represents token distance, and the y-axis shows normalized attention weights, comparing long- and short-range semantic capture across four architectures. (IA)3: Infused Adapter by Inhibiting and Amplifying Inner Activations; LoRA: low-rank adaptation.

Discussion

Principal Findings

This study proposes AE2IN, a large-model framework that integrates RAG with dual-adapter joint fine-tuning for the intelligent analysis of adverse events in infant incubators. Experimental results demonstrate that this framework significantly outperforms baseline models across key metrics, including text generation quality, element recall rate, and regulatory question-and-answer accuracy. Under the same experimental conditions, the element recall rate reaches 0.815, the accuracy of infant incubator adverse event analysis is 0.898, and the accuracy in regulatory clause question-answering tasks attains 0.938. The dual-adapter architecture, that is, LoRA + $(IA)^3$, effectively infuses domain knowledge while preserving model generalization, thereby mitigating catastrophic forgetting. The RAG module, combined with the FINBGE embedding model optimized through supervised contrastive semantic learning, significantly enhances knowledge retrieval accuracy and reduces hallucination.

Comparison With Prior Work

Compared with traditional deep learning models, AE2IN demonstrates superior contextual modeling and causal reasoning capabilities, making it particularly well-suited for complex tasks involving multiple intertwined factors and specialized terminology, such as adverse events in infant incubators. Compared with single fine-tuning approaches, the dual-adapter architecture proposed in this paper achieves a better balance between parameter efficiency and task adaptability. Compared with existing RAG medical applications, AE2IN further introduces a domain-specific embedding model fine-tuning mechanism, enhancing the matching accuracy of Chinese regulatory clauses. When benchmarked against general models such as Qwen and Llama, AE2IN demonstrates higher professional consistency and stronger element-extraction capabilities in specialized tasks, particularly excelling in structured output and terminology standardization.

Limitations

First, the dataset size is limited. The infant incubator adverse-event dataset used in this study comprises 2530 entries. Despite undergoing joint cleaning and enhancement by human experts and GPT-4, the dataset remains insufficient for rare fault types or complex scenarios. To mitigate this issue, we introduced PediaBench general pediatric data for mixed training, employing a 3:1 domain-to-general data sampling ratio to enhance generalization. Future efforts could expand multicenter, multiyear data through collaborations with additional medical institutions to further improve model robustness. Second, the regulatory knowledge base updates lag. The regulatory knowledge base used in this study cannot guarantee real-time coverage of the latest policy revisions. We partially mitigated this knowledge lag by improving the embedding model's semantic understanding of clauses through supervised

XSL•FO
RenderX

contrastive fine-tuning. Future work should consider establishing a dynamic regulatory update mechanism, such as periodically crawling the National Medical Products Administration website or integrating official application programming interfaces to enable automatic knowledge base synchronization. Third, prospective clinical validation was not conducted. This retrospective study did not verify the model's usability and safety within actual clinical workflows. We collaborated with the Henan Drug Administration to implement manual quality control, maintaining a "significant drift" rate ≤5%. However, there remains a lack of assessment regarding clinicians' adoption of model recommendations and the impact of false positives. Future prospective studies should be conducted, inviting hospital equipment departments or adverse-event monitoring personnel to participate in pilot programs and collecting user feedback for iterative optimization.

Future Directions

Current research is limited to adverse events involving infant incubators. Future studies may further explore data-level approaches, such as constructing larger-scale, multicenter, multilingual adverse-event databases covering more high-risk medical device types to enhance model generalizability. Then, at the fine-tuning method level, future work could draw inspiration from distributed entropy regularization [37] to further optimize the learning objective of scaling factors, thereby improving sensitivity to uncommon failure patterns in the training data. At the model level, multimodal fusion could be explored by incorporating visual encoders to process device alarm screenshots or failure photographs, enabling more comprehensive fault identification. Finally, at the system level, an integrated regulatory support system should be developed. This system would integrate the AE2IN model, regulatory retrieval, report generation, and manual review workflows to support multiparty collaboration among hospital equipment departments, regulatory agencies, and manufacturers, thereby advancing the implementation of intelligent regulation.

Conclusions

The safety management of medical devices encompasses all stages of the product life cycle, including research and development, design, manufacturing, clinical application, maintenance, and product recalls, all of which require strict quality control measures. By establishing standardized protocols, refining risk-prevention mechanisms, conducting continuous monitoring, and enhancing professional training, the failure rate of medical devices can be significantly reduced, thereby effectively safeguarding the safety interests of both medical professionals and patients. To advance the management of adverse events related to medical devices and comprehensively support professionals in this field—such as surveillance personnel—this study proposes a large-model solution that integrates RAG technology with dual-adapter fine-tuning. This approach provides an efficient and reliable technical pathway for analyzing adverse events involving infant incubators.

Acknowledgments

We thank the Center for Drug Reevaluation of Henan for providing adverse-event data on infant incubators for this research. Generative artificial intelligence was not used for writing or editing.

Abstract

Background: Adverse drug reactions pose a serious threat to health care, leading to patient harm and substantial economic burden. Dashboards for drug safety surveillance are a valuable tool to tackle it.

Objective: This qualitative study aims to develop a dashboard for drug safety tracking with active and iterative involvement of end users. To support dashboard development, we formulate and iteratively refine design principles (DPs) for drug safety dashboards using the affordance theory.

Methods: Following a design science research approach, we conducted 3 cycles of iterative design and evaluation involving the end users. Four professional end users (with expertise in drug screening, drug discovery, and data science) and 6 nonprofessional end users (drug consumers) were engaged in the requirements gathering sessions through co-design workshops, usability testing through think-aloud sessions, and heuristic evaluation.

Results: The analysis resulted in a set of 8 DPs refined using the prototype's affordances (ie, actionable properties of the dashboard that guide user interaction and interpretation of data). Following themes emerged in the formulation and refinement of DPs: addressing the bootstrap problem through designing for immediate use (DP1a), allowing identification of patterns through visualizing causality while signalizing uncertainty (DP1b), tracking trends for relevant variables (DP1c), implementing user-controlled views (DP2a) and customizable levels of data granularity (DP2b), guiding user's visual attention through spatial layouts (DP2c), designing for higher public value (DP3a) and providing features to support decision-making for varied stakeholders' groups (DP3b). A high-fidelity dashboard prototype for drug safety surveillance was proposed as a result of applying the final set of DPs. Heuristic evaluation of the prototype revealed an overall usability score of 84%.

Conclusions: Applying DPs rooted in affordance theory led to a purposeful and user-relevant artifact that can improve understanding of drug safety data and potentially guide decision-making processes for professional users. Our theoretical contribution lies in providing refined DPs, while also demonstrating how affordances can aid dashboard development in pharmacovigilance. Our findings may be applicable to similar health information systems in related domains.

Introduction

Overview

Adverse drug reactions (ADRs) pose a serious risk, leading to hospitalization of millions of patients every year, and the incidence of ADRs resulting in hospitalization has been consistently increasing in recent years [1-5]. ADRs are not only a major health concern, but also a tremendous economic burden, generating costs of several billion dollars each year [6,7]. Monitoring side effects associated with medicinal products is critical for regulatory bodies, health care providers, pharmacists, and, most importantly, drug consumers.

The rapid spread of health misinformation through online channels poses significant risks to public health [8,9]. Evidence suggests that many individuals, including physicians and medical students, resort to online searches for clinical information (ie, general web and social media queries rather than official pharmacovigilance portals). These channels frequently present user-generated or commercially sponsored content (eg, and influencer posts) that lacks expert review. Only a fraction of users consult credible resources (eg, specialized academic databases) [10,11]. Importantly, more than half of the online searches by health care professionals focus on drug safety and ADRs [12]. Relying on unverified sources for health information can be a major threat to public health, erode public trust, and can lead to severe consequences, including harm or

XSL•FO
RenderX

death [13]. Specialized platforms, such as interactive visualization dashboards for drug safety information at-a-glance, offer drug safety information in a trusted and concise way. Such platforms could be intended for professional users (ie, health care professionals, pharmacists, researchers, pharmaceutical companies, and regulatory agencies concerned with pharmacovigilance), as well as nonprofessional users (ie, patients, medical journalists, or lawyers protecting patient rights).

Dashboards in pharmacovigilance (DiPs), however, are scarce and often have complex interfaces resembling decision support systems rather than accessible designs. Additionally, most of the DiPs are not available online as open-source platforms, but are offered as proprietary software under license [14-17]. As a result, they have a limited audience and lack widespread availability. Moreover, DiP often lacks salient usability features, is poorly designed due to the absence of a structured design approach, or has functional deficiencies [17,18]. Several data mining techniques have been proposed as a valuable tool for early detection of potential safety signals (ie, indications or evidence that suggest a possible new ADR) in pharmacovigilance [19,20]. However, existing DiP rarely integrates data mining methods to enhance raw drug safety information and therefore offers limited insight [21-23]. Given the shortcomings of current platforms for drug safety surveillance and the scarcity of prescriptive knowledge regarding their design, we investigate the idea of finding more fitting designs for handling such data. In search of suitable design principles (DPs) that should lead the development of similar platforms, this study relies on the design science research (DSR) strategy and is guided by the following research question: what are the appropriate DPs for interactive dashboards in drug safety surveillance?

To address this question, we set out to develop and evaluate DPs for a class of dashboards in pharmacovigilance, following the DSR approach. We show that engaging in prototype creation reveals general DPs applicable to similar systems. Consequently, besides the artifact being developed, emergent DPs are proposed as transferable concepts for similar systems within the boundary conditions studied. To this end, we use the notion of affordances—properties of physical things or relationships between actors and these things—to support our research. Affordances help in exploring different designs in this study, since different physical features of the prototype can afford (ie, provide and bring about) the same functionality.

This study consists of the following steps. First, we identify general DPs for visual dashboards of drug safety data. Second, following the DSR methodology, we perform the requirements gathering session with a group of experts in drug screening, bioinformatics, and data science. Third, we create a prototype of an interactive dashboard, where we present drug safety data in a visually friendly manner, with the purpose of improving its general understandability. To this end, we also focus on finding suitable data mining techniques for knowledge extraction from publicly available data in pharmacovigilance. Fourth, we assess the prototype in demonstration and evaluation sessions with users to detect potential usability issues and receive feedback on possible improvements to the design. Altogether, we carry out 3 iterations of the DSR phases.

The aim of this research is thus to enhance the understanding of drug safety data and improve the potential for decision-making among intended users. Specifically, our objectives are to (1) formulate DPs, (2) re-evaluate these in 3 iterations of alternating phases of prototype development, demonstration, and evaluation, and (3) gain insight on how the notion of affordances and DPs can support the development of visualization tools in drug safety surveillance. It is important to mention that, in this study, by “professional users” we refer specifically to researchers in drug screening, bioinformatics, and data science; clinicians and pharmacists were not recruited in our sample. Accordingly, the DPs and evaluation results reported here are grounded in researcher workflows. While some principles are likely cross-cutting across stakeholder groups, we do not evaluate their applicability to clinician- or pharmacist-facing workflows in this study.

Current State of Drug Safety Surveillance Systems and Data Mining Standards

Three major global databases monitor drug safety: Food and Drug Administration (FDA) Adverse Events Reporting System (FAERS) database, VigiBase maintained by the Uppsala Monitoring Center (UMC) and World Health Organization (WHO), and EudraVigilance managed by the European Medicines Agency (EMA). FAERS, the world’s largest repository with more than 24 million reports as of March 2022, serves as a key postmarketing pharmacovigilance tool. EudraVigilance and VigiBase similarly collect ADR reports from the European Economic Area. These reports, submitted by manufacturers (mandatory) and health care professionals or consumers (voluntary), document suspected side effects from one or more drugs per patient case [20,24,25].

Although crucial for surveillance, these reports cannot establish direct causality because of factors such as comorbidities or concurrent medication [25]. To address this, database curators apply data mining to detect safety signals for expert review. The FDA encourages signal detection in drug development, as it positively impacts the process, while the WHO and UMC offer similar services to industry partners [20,26].

Several digital platforms exist for drug safety surveillance, but many, including FAERS, rely solely on reporting frequencies rather than integrated data mining [21]. According to Kumar [17], the FAERS dashboard is affected by limited awareness, unclear purpose, unintuitive navigation, and challenges in interpreting its data. Most reviewed platforms pose accessibility challenges, as they rely on proprietary databases, restricting access, reproducibility, and public transparency [16]. Many are outdated or limited in scope, relying on small datasets or alternative data sources instead of major repositories [14-16,27,28], while others focus only on ADR reporting rather than analysis and visualization [29-31].

Moreover, most platforms were not developed using the DSR process or participatory design methods and lack usability testing. Therefore, their complex interfaces often resemble expert decision support systems rather than accessible designs

XSL•FO
RenderX

[14-16], which can impact usability, hinder tool adoption, and compromise their practical impact [18,32]. These factors emphasize the need for open-source, user-centered drug safety tools that enhance accessibility and stakeholder engagement.

Data mining techniques are routinely used in pharmacovigilance to enhance the understanding of drug and vaccine safety profiles [33-36]. While no universal standard exists, guidelines provide statistical support for interpreting detected signals [37]. Disproportionality analysis (DPA) is currently the most common technique recommended by the FDA, UMC (WHO), and EMA, although the organizations deploy different statistical approaches [38]. Despite its importance, DPA results are seldom integrated into public dashboards, which continue to rely mainly on reporting frequencies [21-23]. This limitation may hinder a thorough understanding of the drug safety profiles and potentially lead to overlooking important trends, which further emphasizes the importance of incorporating safety signal assessments in public dashboards in pharmacovigilance.

New platforms have been developed in recent years primarily leveraging artificial intelligence (AI), machine learning, and real-world data integration for ADR detection in clinical practice. Specific new platforms include the PVClinical system using OMOP-CDM and Observational Health Data Sciences and Informatics (OHDSI) software stack for electronic health record integration [39] and established platforms such as Oracle Argus Safety, repClinical, PvNET, and ArisG for ADR administration and reporting [40]. AI-powered approaches show particular promise, with systematic reviews demonstrating effective natural language processing application across 16 studies for user-generated content analysis [41] and 12 studies showing deep learning models outperforming traditional machine learning for adverse event extraction [42]. However, challenges remain, including data quality, regulatory compliance, and the need for clinical validation of these emerging platforms [43].

Recent research on human-computer interaction (HCI) and user-centered design in pharmacovigilance dashboards is limited but emerging, with only a few directly relevant studies identified in the past few years. The strongest evidence comes from Yu et al [44] who developed a visualization platform for FDA adverse event data with usability demonstration through case studies and validated accuracy against manually processed data. In a study on integrating human-centered design of a public health data dashboard for sexually transmitted infections in the state of New York, Ansari and Martin [45] found that dashboards must reflect actual workflow needs, address data limitations transparently, and use design elements, such as clear notes and estimated data displays, to build user trust and handle common data quality issues. This process resulted in a highly functional design template. Malkani et al [46] identified and ranked key health care dashboard design attributes such as clarity, simplicity, visual hierarchy, responsiveness, and intuitive navigation as most critical for improving usability and user-centered decision-making. Gavriilidis et al [47] applied user-centered DPs to create the PVClinical platform for ADR investigation, identifying “actionability” as a key adoption factor and emphasizing needs for explainable, human-interpretable results. Broader context comes from patient safety dashboard research, where Murphy et al [48] found that among 33 studies, only 4 incorporated informatics or human factors principles in development or evaluation, highlighting a significant gap in rigorous HCI application.

The evidence base remains thin, with most pharmacovigilance visualization research focusing on technical implementation rather than systematic user-centered design evaluation. More rigorous HCI research is needed in this specialized domain [44,47,48]. Table 1 summarizes the limitations of available dashboards and shows the prototype features we explore in response to the identified gaps.

XSL•FO
RenderX

Table . Research gaps were identified through limitations to available dashboards for pharmacovigilance and prototype features were intended to address them.

Platform category (examples)	Key limitations noted in the literature	Intended prototype features
Regulatory public dashboards (FAERS[a]; EudraVigilance; VigiLyze)	Emphasize reporting frequencies; statistical signal detection (eg, DPA)[b] typically not available in the public UI[c]; access and reproducibility constraints (open access but not open source; VigiLyze requires membership). The FAERS public dashboard shows issues with awareness, navigation, and interpretability for nonspecialists [17,21-23]	Integrates DPA outputs in the UI; offers guided interactions; co-designed and usability-tested; open data and code with an open-access dashboard
Enterprise pharmacovigilance dashboards (Oracle Argus Safety; ArisG; repClinical; PvNET)	Proprietary, case-management and regulatory-reporting focus; limited public documentation of integrated analytics, no participatory design or formal usability evaluation; constrained transparency and reproducibility [40]	Offers exploratory analysis; transparent metrics (downloadable DPA files); hybrid-open model enabling inspection, reuse, and migration to a fully open-source stack
Clinical and EHR analytics on OMOP-CDM (PVClinical)	Integrates EHRs[d] via the OHDSI[e] stack and reports user-centered design; scope differs from spontaneous report dashboards; platform availability varies; continued need for clinical validation and regulatory alignment [39,43,47]	Complements PVClinical by focusing on FAERS spontaneous reports; reports outcomes of co-design, think-aloud usability (and its quantitative outcomes), and heuristic evaluation as a result of systematic user involvement in multicycle evaluation process
Academic or research visualization platforms	Often older or limited-scope implementations with small or alternative datasets; few report systematic user-centered design [14-16,28,44]	Built on open FAERS data—the largest, regularly updated public repository with API[f] access; applies recent visualization techniques via implementation of domain-informed design principles
Patient-facing ADR[g] reporting and medication information apps	Designed primarily for ADR submission or mobile information; not intended for exploratory signal analytics or integrated DPA visualization [27,29-31]	Analytic dashboard for exploring suspected drug-event patterns, supporting stakeholder decision contexts

Affordance as a Lens to Study DPs

Affordances are the action possibilities an artifact enables through its material features [49-51]. We use this lens operationally: each DP states (1) the intended user activity (affordance), (2) the dashboard features that enable it (material properties), and (3) the boundary conditions in which the principle applies. In this study, the artifact does not itself cause understanding or decisions; it supports them insofar as its features enable the specified affordances [52].

Formulating the DPs

DPs provide prescriptive guidance for constructing an artifact to meet stated objectives [50,53-55]. Drawing on literature on pharmacovigilance data literacy and dashboard design, we formulated DPs using the structure by Chandra et al [53] that ties (1) intended user activity (affordance), (2) enabling features (material properties), and (3) boundary conditions. We use the following template for DPs formulation:

Provide the system with (material property—in terms of form and function) in order for users to (activity of user or group of users—in terms of action) given that (boundary conditions—user group's characteristics or implementation settings) [53].

We consider drug safety surveillance as the boundary condition and analyze 2 user groups for this DSR prototype: (1) nonprofessionals (drug consumers) and (2) professional users as operationalized in this study (researchers in drug screening, bioinformatics, and data science). While health care professionals and pharmacists are central stakeholders for pharmacovigilance dashboards, they were not recruited in the present sample; consequently, findings and DPs are grounded in these boundary conditions.

We categorize the DPs into three classes: (1) DPs related to functionality that address the question of how well the dashboard serves its purpose, (2) DPs related to the mode of display that refer to the specific visualization techniques, and (3) DPs related to added value, which focus on the benefits the artifact provides to the public or end users.

We selected and refined DPs by applying an affordance alignment test: a principle was retained only when a target user

XSL•FO
RenderX

goal could be mapped to a concrete dashboard feature expected to enable the activity in the drug safety context [52,53]. Subsequent evaluation rounds confirmed and sharpened their scope.

DPs Related to Functionality

The value of new information infrastructures (IIs) lies in the users' community. However, since this community is initially small, the benefits of using the system may not be immediately apparent. Several authors emphasized the bootstrap problem that arises when the benefits of new IIs are perceived as indirect, delayed, or uncertain, which can lead to resistance in the system's adoption [56,57]. To address this issue, Hanseth and Lyytinen [57] recommend designing IIs for direct usefulness, that is, prioritizing immediate practical benefits for the users. This approach may enhance the perceived value of the system and help expand the user community. It may also create a positive feedback loop, where the use of the system leads to its further improvements, which in turn increase its usefulness and value. Consequently, we formulated the following DP: DP1a: it provides features to address the bootstrap problem, so that the system affords immediate use of the dashboard in drug safety surveillance.

Recker [58] investigates public dashboards related to the coronavirus pandemic, concluding that many present data through simple attributes (eg, number of cases, number of deaths, and number of recovered). Integrating state-tracking features that enable monitoring changes in states and events that trigger them (such as fluctuations in infection rates, or timelines of lockdowns and restrictions) could be a significant improvement, and the information presented in dashboards should answer the question how, instead of just how many. We formulated two DPs: (1) DP1b: it provides features to describe possible causality between variables, so that the system affords identification of patterns and trends in drug safety surveillance. (2) DP1c: it provides features to track changes in variables, so that the system affords tracking of the progression of relevant states in drug safety surveillance.

DPs Related to the Mode of Display

Matheus et al [59] suggest incorporating customizable views into decision-making dashboards, as this design strategy may help bypass the interpretation bias—"a single view might result in a limited picture of the situation." Expanding views to more than one view may lead to better understanding of the problem. Customized views help users to focus on relevant information and reduce the cognitive load associated with processing large volumes of data. We formulated the following DP: DP2a: it provides features to support customized views, so that the system affords examining various dimensions of data in drug safety surveillance.

Matheus et al [59] also suggest incorporating customizable features into decision-making dashboards, including the ability to toggle between detailed and high-level data visualizations. As these dashboards often contain a large volume of data, such features can help users understand the problem at hand by providing varying levels of detail. We formulated the following DP: DP2b: it provides overview and details, so that the system affords exploring data of different granularity levels in drug safety surveillance.

Toreini et al [60] follow a set of experiments to find ways to decrease task resumption failures. Tracking the real-time eye movements of the participants, they conclude that users start from and focus their attention on the upper left corner of the dashboard. Several authors suggest incorporating attention-augmenting features into dashboard elements (such as varied color, size, shape, and orientation) and visual cues (buttons and dials) to direct attention toward objects of higher importance [60,61] Consequently, DP2c: it provides features that stimulate attention and place important elements on the top-left area of the dashboard, so that the system affords improved attention management while using the dashboard in drug safety surveillance.

DPs Related to Added Value

Matheus et al [59] claim that creating dashboards should go beyond simply visualizing data. Creating public value should be embedded in the design process, as the data on its own is of little use. This way of thinking of the design process—through the prism of public value—transgresses the initial idea of merely finding the ways to present data in the best visual way. Data visualization should be the means, not the goal, and asking the question "what is the added value?" during the design process is necessary. Designers should prioritize generating public values such as engagement, transparency, and accountability, while also upholding public values such as privacy. Consequently: DP3a: it provides features to create public values, so that the system affords users' engagement in dashboard use in drug safety surveillance.

Embedding features that support decision-making is a crucial aspect of dashboard development [59]. Such features can be valuable for professional users, including health care professionals, pharmacists, researchers, and regulatory bodies in pharmacovigilance. We also expect the users would gain greater understanding and take up higher responsibility toward their own health, which would equip them better for decision-making. We formulated the following DP: DP3b: it provides features to support decision-making, so that the system affords users to evaluate what-if scenarios and consider different alternatives in drug safety surveillance. Initial DPs are shown in Table 2.

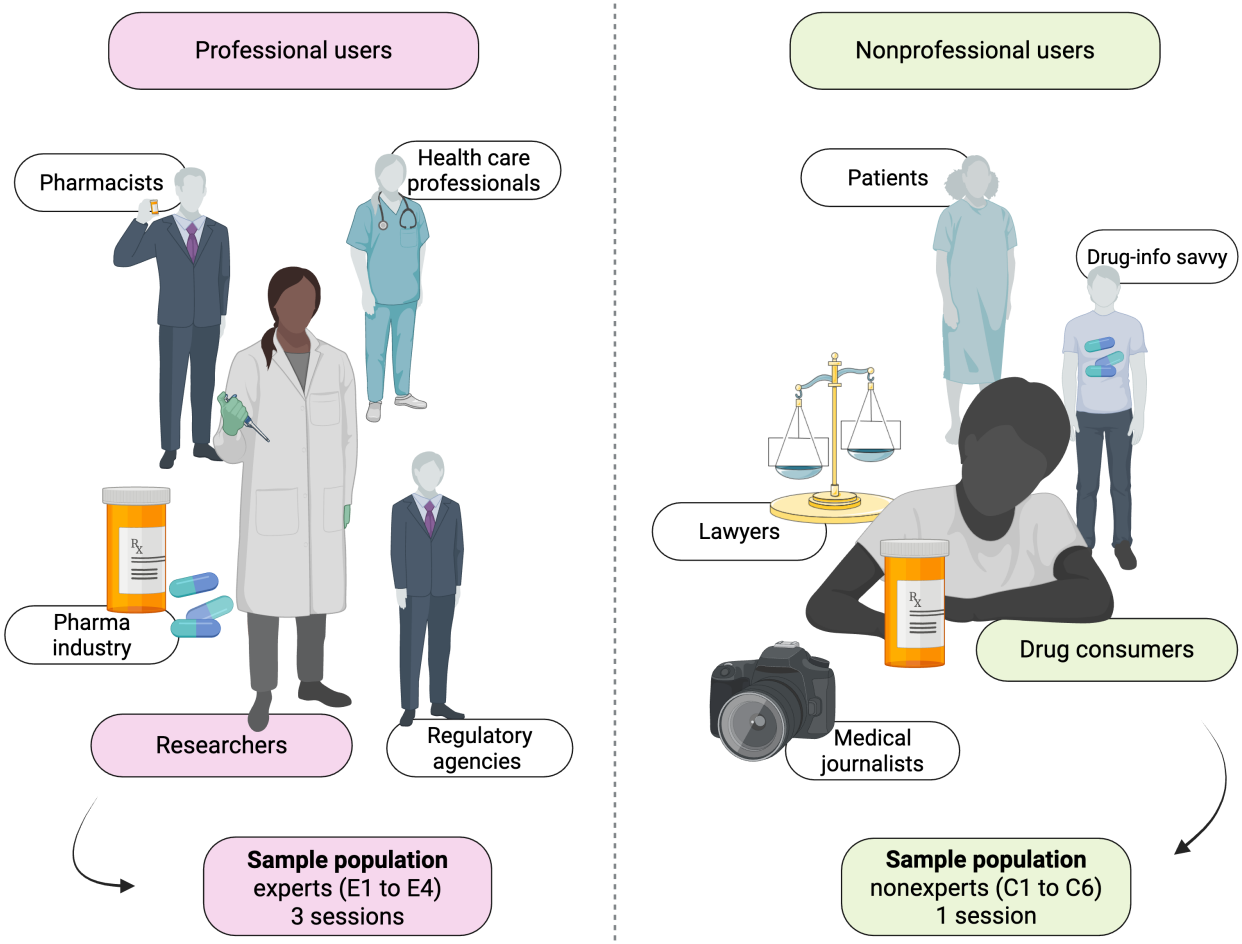
XSL•FO
RenderX

Table . Overview of initial design principles.

Design principle	Affordance	Material properties
DP1a	Obtaining immediate practical benefits while using the dashboard [56]	Features that respond to users' requirements, features that address actual user problems and offer solutions
DP1b	Identification of patterns and trends through exploration of DPA[a] analysis [58]	Features that enable identification and examination of patterns and trends in drug-ADR[b] evaluations
DP1c	Monitoring the progression of relevant states (how variables change over time) [58]	Features that allow tracking changes in relevant variables
DP2a	Exploring, analyzing, and interpreting data from different angles [59]	Features that enable analysis of data from multiple perspectives
DP2b	Exploring data from a broad and narrow perspective by switching between levels of granularity [59]	Features to adjust the level of detail depending on users' needs and the context of analysis
DP2c	Improved attention management while using the dashboard [60,61]	Features that stimulate attention, visual cues that direct attention toward important elements
DP3a	Active involvement in exploring the data, potentially increasing users' satisfaction [59]	Features with a potential to create public value (engagement, transparency, accountability, and adherence to privacy)
DP3b	Evaluating alternatives of actions, exploring what-if scenarios [59]	Features that support decision-making

[a]DPA: disproportionality analysis.

[b]ADR: adverse drug reaction.



Methods

Data Collection and Target Groups

We have considered 2 target groups for this work: professional users and nonprofessional users. We define professional users as those whose professional activities are concerned with drug safety surveillance and thus have extensive knowledge in the domain. For clarity, throughout the paper, "professional users" refers to this researcher group; the implications for clinician- and pharmacist-facing workflows lie outside this study's boundary conditions. In contrast, nonprofessional users are not professionally concerned by drug safety surveillance and in that sense are laymen in the domain of pharmacovigilance. Figure 1 depicts the user groups.

XSL•FO
RenderX

Figure 1. Professional (left) and nonprofessional (right) user groups. The broader professional stakeholder landscape includes health care professionals, pharmacists, researchers, regulatory agencies, and industry. In this study, the professional participants recruited were researchers in drug screening or drug development (E1-E4). Nonprofessional participants were drug consumers (C1-C6).

We have recruited a group of 4 expert users (referred to as experts, with participant IDs of E1 to E4) for this study. All experts were scientists of different academic degrees and expertise levels and were working on drug development and screening projects. Three out of 4 experts had extensive experience in data science and bioinformatics. In addition, all experts had many years of experience in data visualization and communication to the general and scientific community. Experts participated in the co-design workshop, pilot evaluation, and heuristic evaluation sessions.

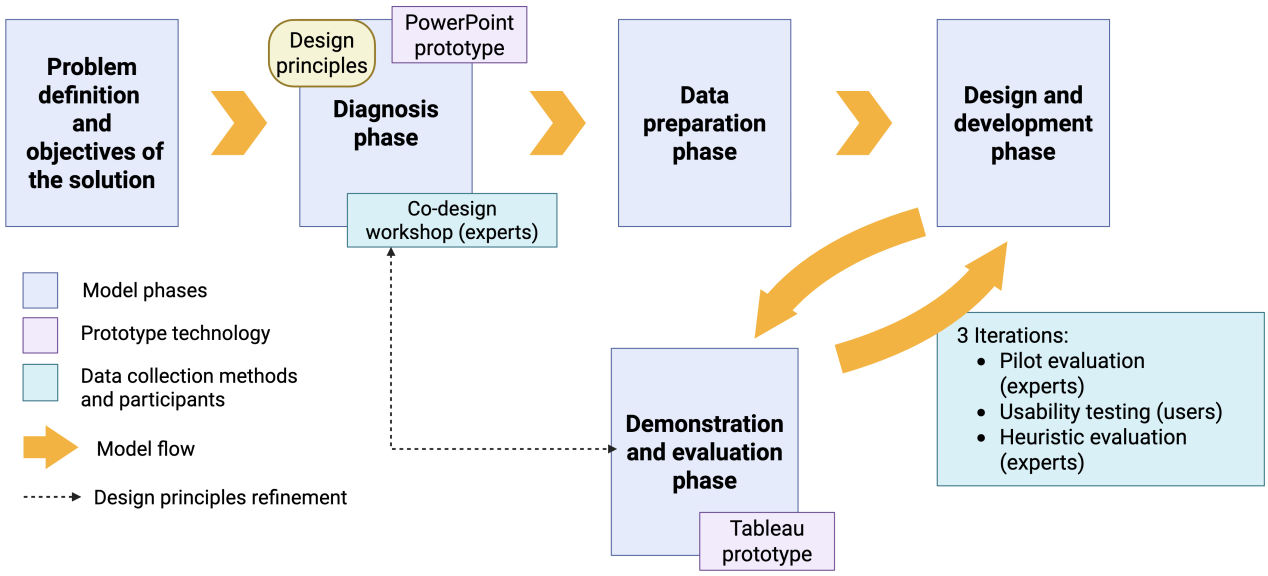
For usability testing (think-aloud session), we have recruited a group of 6 nonexpert users (referred to as nonexperts, with participant ID of C1 to C6). All nonexperts were drug consumers and had a history of continuous medication therapy of at least 7 days at least once in the previous year. We assumed these users were potentially also drug safety information-savvy and might provide meaningful insights into which complex analyses are possible. Importantly, nonexperts were novices in the sense that they had no prior exposure to the tool in question or any other similar dashboards [62]. Although some nonexperts shared parts of professional experience with experts (eg, C4 and C5 had expertise in biomedical engineering and data science), they were not working on drug screening and discovery projects.

By design, think-aloud usability testing was conducted solely with nonprofessional "novice" users to evaluate first-time learnability and immediate practical use (DP1a) without prior-exposure effects from experts who had already interacted with the prototype during co-design and/or the pilot evaluation [62].

Overall, all participants were between 28 and 44 years old and were based in Germany, Sweden, France, Finland, and Portugal. A detailed description of participants recruited for this study is shown in Table S1 in Multimedia Appendix 1. Given the age range and the presence of multiple participants with advanced technical or professional backgrounds, this sample likely exhibits above-average digital and data literacy; while valuable for investigating complex interaction issues in early iterations, this may inflate task performance relative to older adults and users with lower digital health literacy.

DSR Approach

We followed a framework proposed by Sauro and Lewis [63] to quantitatively analyze the user experience. Furthermore, in heuristic evaluation, we quantitatively collected and analyzed data in line with the framework proposed by Dowding and Merrill [64]. Additionally, we qualitatively collected and analyzed data in all experimental sessions in this study.



We modified a staged DSR model, initially proposed by Peffers et al [65]. Thus, the DSR framework applied in this study consisted of the following stages: (1) problem definition and

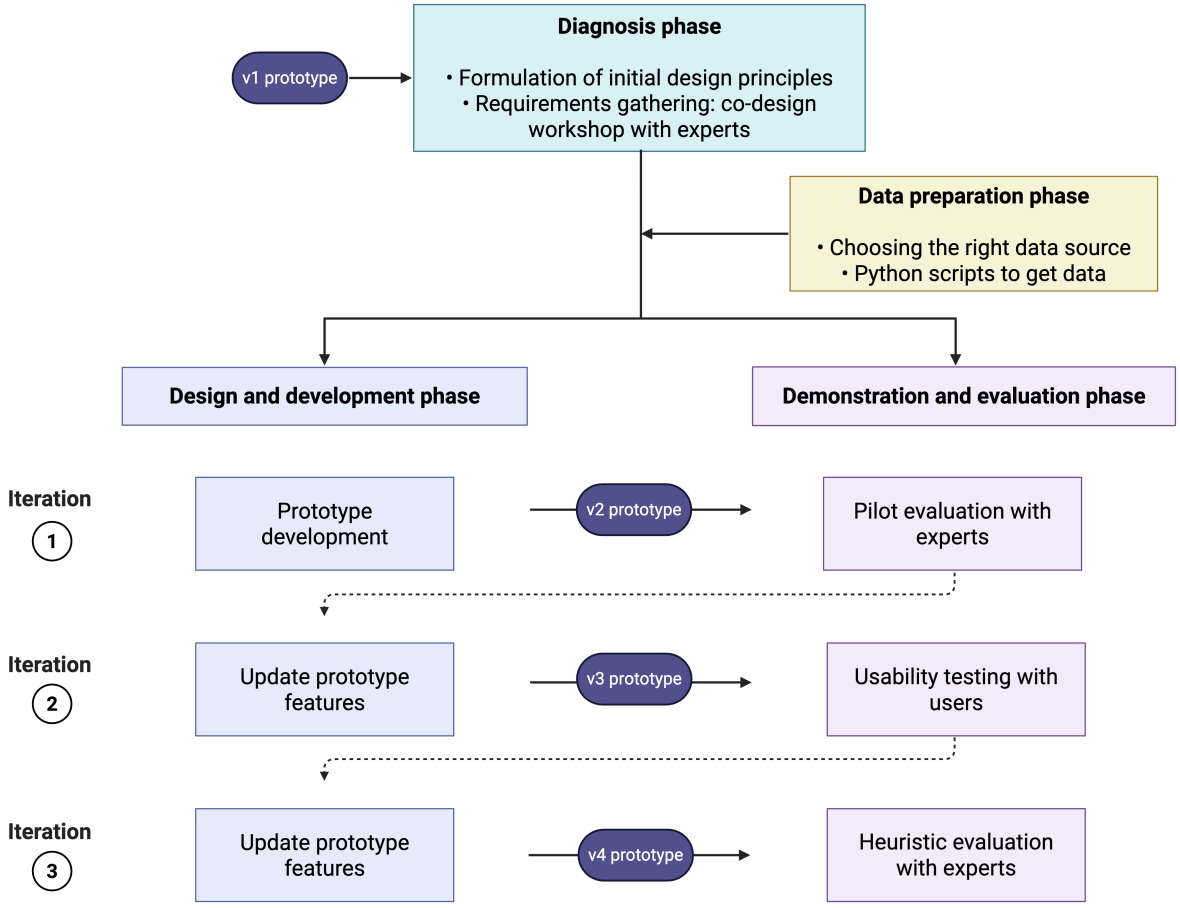
XSL•FO
RenderX

objectives of the solution, (2) diagnosis phase, (3) data preparation phase, (4) design and development phase, and (5) demonstration and evaluation phase. Detailed descriptions of each phase are found in Multimedia Appendix 2.

A depiction of the DSR process is shown in Figure 2. v1-PowerPoint and v2-v4-Tableau prototypes were used in diagnosis and demonstration and evaluation phases, respectively. Blue boxes show individual phases and the order in which they occurred in DSR (yellow arrows). DPs emerged in the diagnosis phase and were then iteratively refined in the demonstration and evaluation phases.

Figure 2. Applied design science research model.

Data Collection in DSR Cycle



We have performed 3 iterations of the DSR cycle. That is, we started with the diagnosis phase, in which we first identified initial DPs by gathering secondary data available in the literature. Then, we proceeded with one requirement gathering session, in the form of a co-design workshop with experts. Next, we have engaged in the data preparation phase, where—after selecting a suitable drug safety data source—we have written Python scripts to get and process the data.

We then performed 3 iterations of alternating design and development and demonstration and evaluation phases. In the first iteration, we developed a prototype in Tableau software (v2; Tableau Software LLC) [66], and tested it in the pilot evaluation session with experts. The results obtained in this way fed the second DSR iteration. We have updated prototype features (v3) and proceeded with usability testing (in a think-aloud session) with nonexperts. Finally, in the last iteration, upon updating prototype features (v4), we performed heuristic evaluation with experts. A flowchart of research activities is shown in Figure 3.

Further details about the design and development phase are provided in Multimedia Appendix 2. In that appendix, we describe the diagnosis phase, including the development of DPs and requirements gathering. We also provide information on how we used Statista [67] and participant requests to inform the selection process of 5 drugs used for prototype development: ibuprofen, acetaminophen (paracetamol), prednisone, quetiapine, and morphine.

XSL•FO
RenderX

Figure 3. Overview of data collection activities.

Demonstration and Evaluation Phase

Iteration 1: Pilot Evaluation

The researcher was moving through the dashboard by performing a set of predefined activities, while the participants controlled the navigation process by suggesting improvements whenever necessary. The session lasted 1 hour and was recorded with Otter.ai (Otter.ai, Inc) [68].

Iteration 2: Usability Testing

We have performed 6 usability tests with nonexpert users in think-aloud sessions. These included live meetings with 4 participants (C1, C2, C3, and C4) and virtual meetings with 2 participants (C5 and C6). Before the session, we have provided the users with a detailed protocol including introduction of the study, explanation on usability testing in the think-aloud session and a list with predefined tasks. These tasks required participants to do activities on the interface without the researchers' guidance. For the most part, researchers remained silent during users' task performance. Users were encouraged to express their thoughts while conducting the tasks. Additionally, 2 participants (C2 and C3) shared their thoughts on the usefulness of the dashboard and their interest in the tool in general. These short and unstructured discussions unfolded at the end of the sessions and were incorporated into findings. Each session lasted between 1.5 hours and 2.5 hours and was recorded with the same software, Otter.ai [68].

Experts were intentionally not included at this think-aloud stage to avoid learning effects from earlier sessions; their structured feedback was captured in the expert-focused co-design phase, pilot evaluation, and in the subsequent heuristic evaluation with 4 and 3 experts, respectively, which is within the 3 - 5 evaluator range known to uncover the majority of usability problems [69,70].

Iteration 3: Heuristic Evaluation

As originally suggested by Nielsen [71] and confirmed by other authors [62,69,72,73], 85% of usability violations can be detected by 3 to 5 evaluators in heuristic evaluation. We have performed heuristic evaluation with 3 experts (E1, E2, and E3).

Data Analysis

Overview

We used the framework method by Gale et al [74] to qualitatively analyze data in search of codes and themes. Importantly, and due to the specificity of DSR as a methodology (ie, when data are collected in iterations to repeatedly improve an artifact), codes and themes in this work refer to identified usability issues, dashboard features or elements undergoing evaluation and refinement, or any concept related to these (ie, the motivation behind the revision of DPs). Additionally, to prioritize the issues detected in usability testing and select appropriate solutions, we applied a method by Sauro and Lewis [63]. Finally, we analyzed the data from the heuristic evaluation through the assessment of 10 usability factors. These concepts

XSL•FO
RenderX

are discussed further below. Overall, we detected 33 themes (entities) in the co-design workshop session and 20 themes in the pilot evaluation session.

Usability Testing

For detecting usability issues, we applied a quantitative method by Sauro and Lewis [63]. We prioritized the usability issues according to their severity, considering the following factors: how much the issue has impacted the user trying to achieve the task, how critical the task was, and what was the frequency of the issue. Thus, the severity of issues was calculated by multiplying task criticality, impact, and frequency of occurrence. Overall, we detected 69 usability issues.

Each issue was then assigned one or more solutions. To choose the optimal solution to each usability issue, we considered 2 factors: complexity and effectiveness. Finally, a cost-benefit ratio (return on investment [ROI]) was calculated by dividing the effectiveness by the complexity. We decided which solutions to implement based on the following criteria: the solution had an ROI of 5 or more, was technically feasible, and was not solving the issue already covered by another solution with higher ROI. Overall, out of 56 conceptualized solutions, we arrived at 22 final solutions to be implemented. For a detailed description of the applied method, refer to Sauro and Lewis [63] and Rosemberg [75].

Heuristic Evaluation

Applying Dowding and Merrill's [64] heuristic evaluation, we assessed 10 usability factors using 49 close-ended questions. Usability factors had varying question counts; the maximum score per factor was calculated by summing questions assigned to it. Scores obtained per expert were calculated by summing the questions answered yes by each expert, per factor. A mean score was calculated by summing individual expert scores and dividing by the number of experts. The final result was the mean score divided by the maximum score (per factor and cumulatively). Next, overall severity rankings per usability factor were assigned, ranging from 0 (no usability problem) to 5 (usability catastrophe). Finally, qualitative analysis of comments per factor informed suggestions on future implementations. For a detailed description of the applied method, refer to Dowding and Merrill [64] and Nielsen [71].

Ethical Considerations

Informed consent was obtained from all participants prior to inclusion. Participation was voluntary, and participants were informed that they could opt out at any time. They were provided with information on how their data would be processed and that study data would be retained for no longer than 2 years from study start. No ethics or institutional review board approval was required for this work.

According to the Swedish Ethical Review Act (2003:460) [76], this study did not require formal ethical approval because it did not involve sensitive personal data, biological material, or any physical or psychological intervention. Only non-sensitive demographic information (country of residence, age, gender, profession) was collected. All participants were adults and data were pseudonymised using participant ID codes prior to analysis. Participants also provided consent for publication of the study results.

Results

Diagnosis Phase: DPs and Low-Fidelity Prototype

We have implemented DPs into a v1-low-fidelity prototype in PowerPoint. One dashboard element could be assigned to multiple DPs, but each assignment involved different functionalities of the element. Some DPs were action-oriented (DP1a and DP3a), and all material properties were assigned to them. We show how DPs shaped the v1-low-fidelity PowerPoint prototype in Table 3.

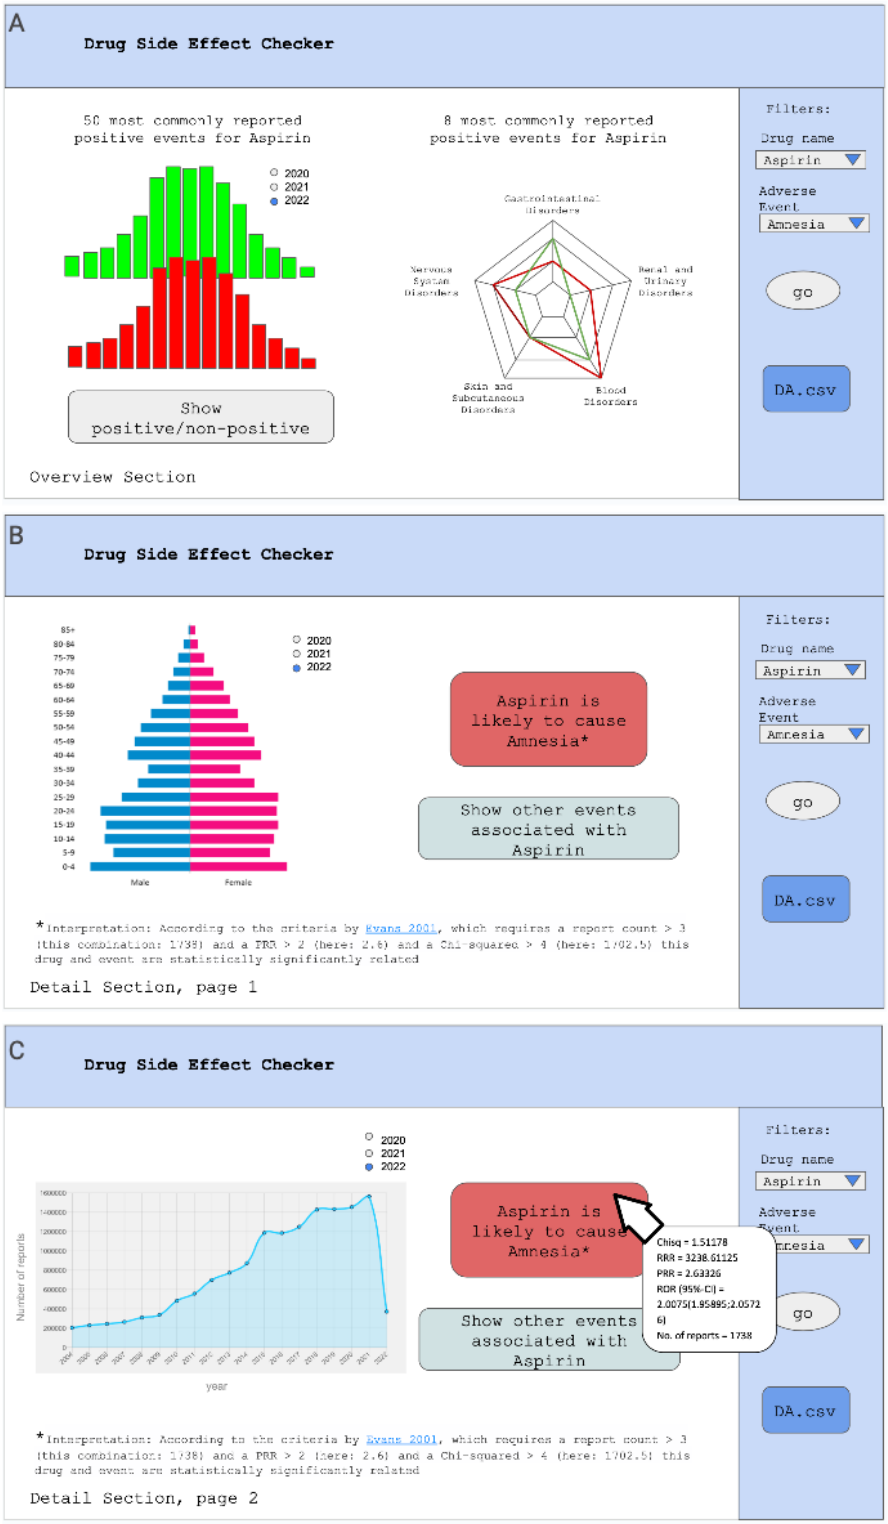
To afford exploration of data of varied granularity (DP2b), we created two dashboard sections: (1) an overview of common side effects for the chosen drug (the overview section) and (2) a detailed analysis of specific drug-side effect pairs (the detail section), split in separate pages where different visualization techniques were used (eg, a graph with age-gender distribution of affected populations). Additionally, we added drug and side effect search fields (Figure 4A–C).

To afford identification of patterns and trends (DP1b), the overview section displays a histogram of commonly reported side effects for a queried drug. Users could toggle between positive and negative side effects using buttons (Figure 4A). To afford monitoring the progression of relevant states (DP1c), a line graph with a year filter tracked reports for drug-side effect pairs over time (Figure 4C). Additionally, to afford improved attention management (DP2c), key graphs were positioned top-left, and warning messages were color-coded.

The system provided downloadable evaluation files containing detailed drug safety metrics (DA.csv, Figure 4A–C) to afford evaluating alternatives of actions (DP3b). Warning messages indicated whether an event was statistically significantly related to queried side effects and provided DPA information on mouse hover (Figure 4C). Two affordances, obtaining immediate practical benefits while using the dashboard (DP1a) and active involvement in exploring the data (DP3a) were expected to be enacted across all prototype features, as they aligned with the prototype's purpose.

XSL•FO
RenderX

Table . Instantiation of material properties.



Design principle	Instantiation of prototype features
DP1a	Initiated by all features and iteratively refined in response to users' input
DP1b	Graphs belonging to the overview section, warning messages with DPA[a] metrics on hover
DP1c	Line graph with the number of reports per drug-ADR[b] pairs, with year filters
DP2a	Interactivity of the graphs (eg, buttons to toggle between positive and negative ADRs), with year filters
DP2b	Splitting the dashboard into the overview and detail sections, with year filters
DP2c	Placing the graphs on the top-left, color-coded warning messages
DP3a	Initiated by all features expected to elicit values related to the transparency of drug safety data or the user engagement in health information tracking
DP3b	DPA metrics as downloadable files (DA.csv), warning messages with DPA information on hover

[a]DPA: disproportionality analysis.

[b]ADR: adverse drug reaction.

RenderX

Figure 4. An excerpt from the v1-low-fidelity PowerPoint prototype. (A) The overview section. (B-C) The detail section.

Diagnosis Phase: Requirements Gathering

Through a collaboration with a group of experts in a co-design workshop, we gathered the requirements for the prototype development. The v1-low-fidelity PowerPoint prototype was used in this session to visualize content of the dashboard, serving as a canvas for design activities. We summarize the principal findings in Table 4.

XSL•FO
RenderX

Table . Principal findings from the co-design workshop.

Feature or element	Related DPs[a]	Feedback
Indication graph	• DP2b (overview and details) • DP3b (decision-making support)	Offers details on common prescriptions for a queried drug, adding an extra variable to the displayed dataset.
Scrolling	• DP2c (attention stimulation)	Use scrolling instead of pagination, it is a preferred way for users to interact with the dashboards.
Drug and event search fields	• DP2b (overview and details)	Users seek information on potential side effects both before and after drug administration. Separate search fields allow users to look up a drug only (before an event occurs) or a drug and ADR[b] (after an event occurs).
DPA[c] metrics files	• DP3b (decision-making support) • DP2b (overview and details)	To influence decision-making of professional users, DPA files should include formulas and information on statistical models used for calculations, as well as the interpretation of calculated indicators.
Removing DPA info from the warning message's hover	• DP2b (overview and details)	While beneficial for researchers, high-level granularity data may confuse nonprofessional users. Access to DPA metrics is provided through downloadable files.
Age-gender distribution graph with modified age ranges, positioned top-left	• DP2b (overview and details) • DP3b (decision-making support) • DP2c (attention stimulation)	The graph provides information on common demographic attributes (age and gender). Using 10-year ranges provides optimal data granularity.
Histogram of most commonly reported side effects, positioned top-left	• DP2b (overview and details) • DP2c (attention stimulation) • DP2a (customized views) • DP1b (causality between variables)	The graph provides an overview of the most commonly reported ADRs, with the option to customize the display using a histogram filter (Related, Unrelated, All events). Limiting the bars to 20 provides optimal data granularity.
Per drug, there is a line graph showing the sum of side effects reported over time (the first line graph) and a second line graph illustrating specific side effects reported over time	• DP1c (state-tracking) • DP2a (customized views)	For researchers, viewing time series of drug-ADR report numbers is crucial. The second line graph helps identify, for example, specific events contributing to sudden increases in ADRs in selected years. The histogram filter is linked with line graphs, enhancing customization options.

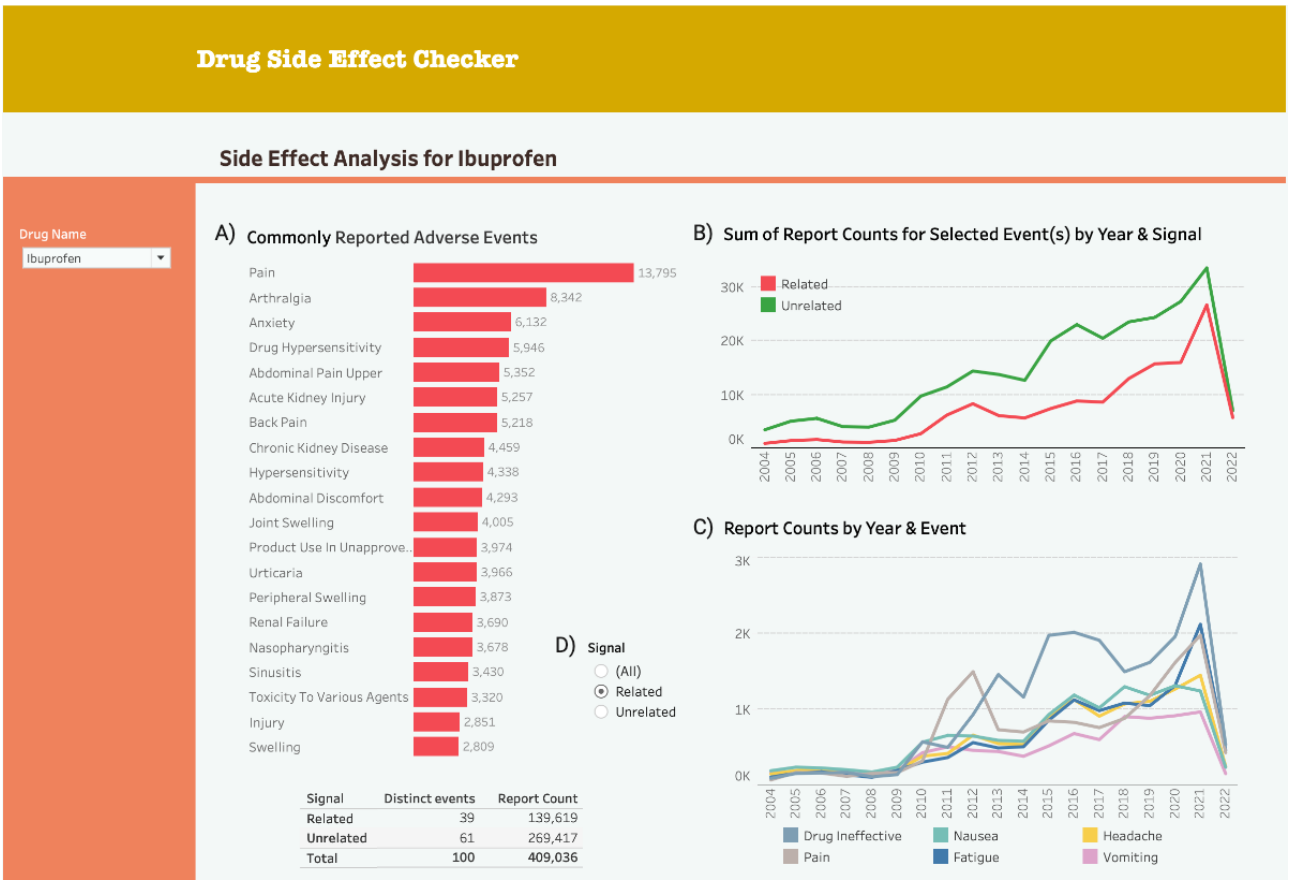
[a]DP: design principle.

[b]ADR: adverse drug reaction.

[c]DPA: disproportionality analysis.

Adjusting Data Granularity

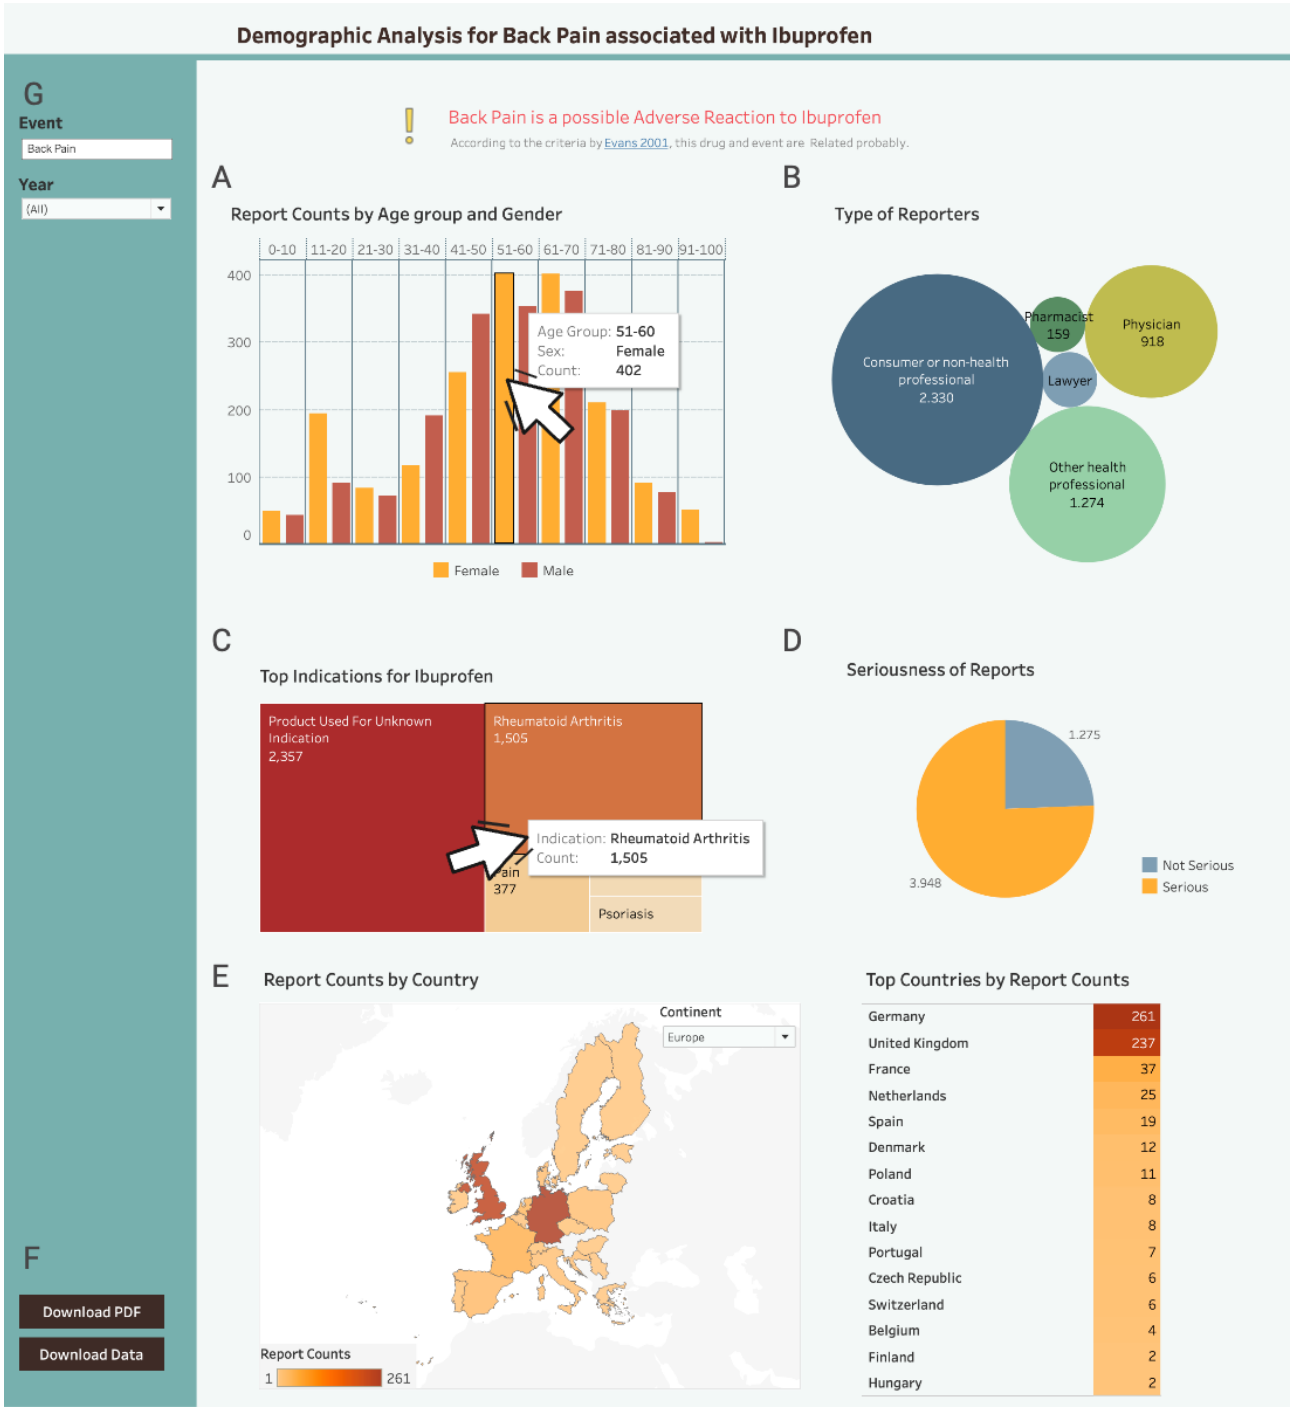
We found evidence that the dashboard supported the exploration of data of varied granularity (DP2b). Feedback from experts suggested adjusting the detail level on display. Some elements were considered too detailed, resulting in information overload, especially on the histogram and the age-gender distribution graph. Recommendations included fixing the histogram's displayed bars at 20 and setting age intervals on the age-gender distribution graph to 10 years (Figures 5A and 6A, respectively). Additionally, it was suggested that displaying detailed DPA metrics while hovering the warning message might confuse users unfamiliar with similar statistical methods, as per E1: this proportional reporting ratio and all that (...) Not super easy to interpret, right? This is greater than 2, but like, what is the upper bound? What is the lower bound? Like, how low can it go? (...) These values are not so easy to understand if you're not the professional who uses them.



Thus, the DPA information was removed from the warning message and added to downloadable DPA files, together with formulas for score calculation and interpretation of indicators. This was also in line with the suggested increase of data granularity on some occasions. Likewise, it has been proposed to implement a functionality to view the data by the condition for which a drug was prescribed. Finally, while initially considered, the BMI variable was ultimately excluded from the age-gender distribution graph. Although useful for analysis, BMI is rarely provided in the reports. Therefore, it was necessary to adjust the intended data granularity to what was available in the datasets. Considering all the above, we revised the following DP: DP2b: It provides an overview and details, while controlling overview-to-detail ratio, so that the system affords exploring data of different granularity levels in drug safety surveillance.

Accounting for different data granularity interest among various user groups, and considering that customizable level of detail

XSL•FO
RenderX



in displayed data can reduce distraction and potentially influence decision-making, we revised another DP: DP3b: It provides features to support decision-making and cluster them by the needs of distinct user groups, so that the system affords users to evaluate what-if scenarios and consider different alternatives in drug safety surveillance.

Figure 5. The first Tableau (v2-high-fidelity) prototype with analysis for ibuprofen (the overview section). (A) Modified histogram. (B) The first line graph. (C) The second line graph. (D) The histogram's filter.

(B) The reporter's type of occupation. (C) The indication graph. (D) The seriousness of the outcome. (E) The map with number of reports per country and the associated table. (F) Download buttons. (G) The event search field.

Scrolling Over Pagination

Feedback suggested changing from pagination to scrolling, as users often prefer to scroll, rather than having to navigate through multiple pages. Pagination is also considered more expensive in terms of browsing and might significantly slow the system down. Thus, we revised the DP: DP2c: it provides features that stimulate attention, place important elements on the top-left area of the dashboard, and promote scrolling over pagination, so that the system affords improved attention management while using the dashboard in drug safety surveillance.

Iteration 1

Design and Development: First Tableau Prototype

We transformed the v1-low-fidelity PowerPoint prototype into a v2-high-fidelity dashboard in Tableau, incorporating refined DPs based on the guidance from the co-design workshop. Figures 5 and 6 show the prototype after the first iteration.

After requirements analysis, to better afford monitoring the progression of relevant states (DP1c), we introduced 2 graphs: a line graph showing all side effect reports per drug per year

XSL•FO
RenderX

(Figure 5B) and a line graph showing specific side effect reports per drug per year (Figure 5C).

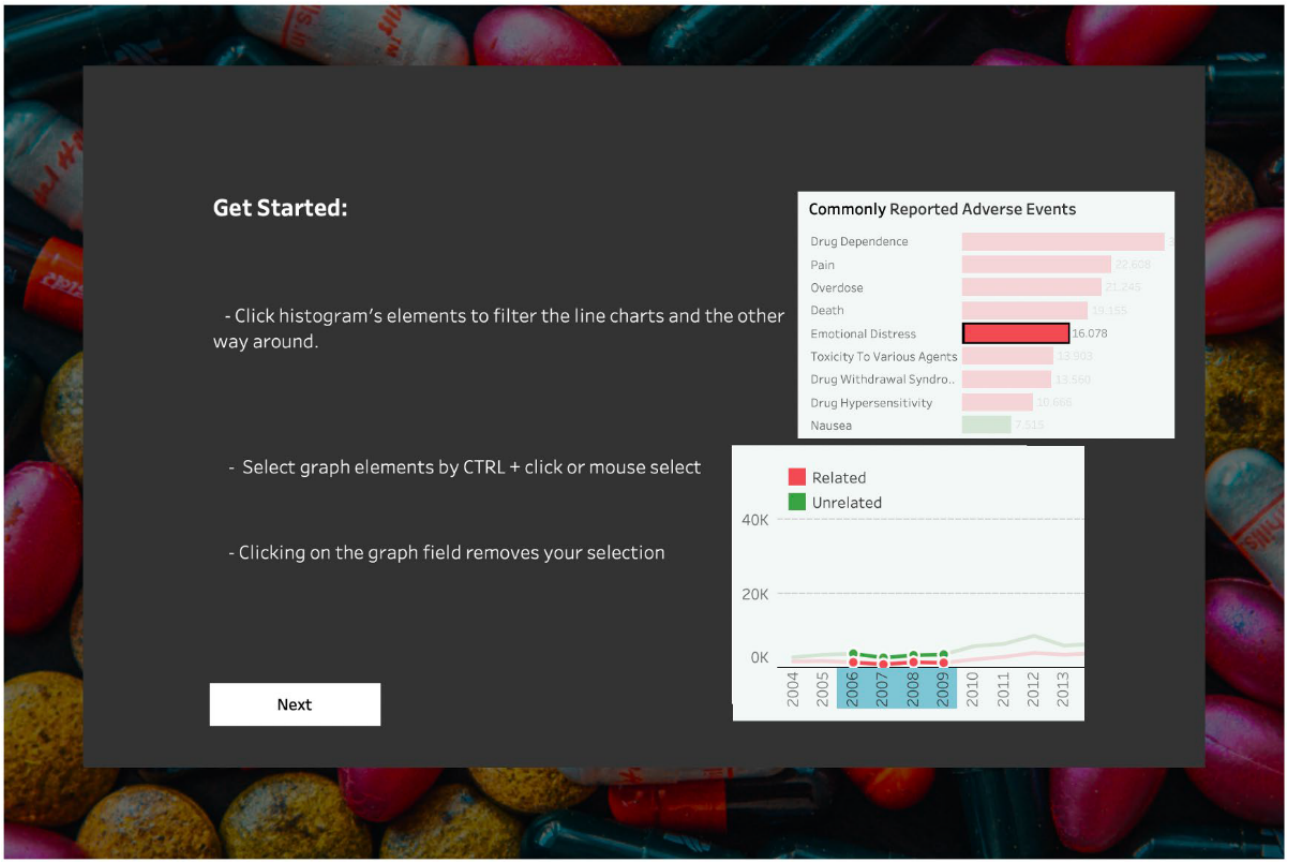
For exploration of data of varied granularity (DP2b), we added an indication graph showing the conditions for which the queried drug was prescribed when a side effect occurred (Figure 6C). In line with revised DP2b, we modified the age-gender distribution graph (Figure 6A). We also modified the histogram by reducing the number of bars to better afford identification of patterns and trends (DP1b). A map displayed side effect distribution per country with interactive continent selection and year filtering (Figure 6E).

With regard to improved attention management (DP2c), we positioned the histogram and the age-gender distribution graph on the top-left overview and detail sections, respectively. We replaced pagination with scrolling, aligning with DP2c. To better afford evaluating alternatives of actions (DP3b), we introduced safety signal reports with DPA information, displayed upon clicking the download data button (Figure S1 in Multimedia Appendix 3). To better afford exploring data from different angles (DP2a), all graphs in the overview section were made interactive: for example, selecting up to 6 histogram bars was reflected in the second line chart, where up to 6 individual events were displayed. It was also possible to limit the dataset by year ranges (Figure S2 in Multimedia Appendix 3).

Demonstration and Evaluation: Pilot Evaluation

While conducting a pilot evaluation, we were looking for suggestions on possible improvements to the prototype before embarking on usability testing. Overall, we received advice to implement a getting started tutorial containing screenshots of the dashboard elements with a short explanation on salient functionalities (eg, how to remove the selection and how to select using keyboard or mouse).

Importantly, expert E3 suggested implementing a feature related to selection-keeping—when the user chooses one or more side effects by clicking on the histogram bars, and then changes their drug selection, the dashboard should keep the selection of side effects. This feature can be useful to quickly compare drugs from the same drug classes (eg, ibuprofen and aspirin). According to E3: if you want to compare that one drug to another drug, to see if it (selected side effect) also occurs really often, then this makes sense (...) And you can see it (selected side effect) directly in the ranking.



This feature was in line with DP3b, potentially enhancing the decision-making of professional users.

Iteration 2

Design and Development: Updating Prototype Features

We updated the system by implementing selected findings from the pilot evaluation session. Thus, we introduced a getting started tutorial with informative screenshots that guided users through the dashboard functionalities (Figure 7).

Figure 7. An exemplary page from the getting started tutorial in the v3-updated prototype.

XSL•FO
RenderX

To better afford evaluating alternatives of actions (DP3b), we introduced the selection-keeping feature. For a detailed explanation, refer to Figure S3 in Multimedia Appendix 3, where we present a real-world scenario demonstrating the comparison of 2 commonly used pain-relieving drugs: ibuprofen and acetaminophen (also known as paracetamol).

Demonstration and Evaluation: Usability Testing

We conducted usability tests with nonprofessional users (refer to Multimedia Appendix 4 for details). We found several usability issues that could hinder obtaining immediate practical benefits while using the dashboard (DP1a). We grouped the issues according to the affected dashboard features or elements, and we discussed them in the corresponding order.

The getting started tutorial was hard to follow and long. Users struggled to grasp how the individual screenshots relate to the dashboard concepts. This confusion arose because the screenshots presented isolated dashboard elements instead of the dashboard as a whole. The inability to skip or revisit the tutorial was also a major issue. Regarding the histogram and associated filter**,** users had trouble understanding how to select bars by clicking or by dragging sections. Finding the histogram's filter (Figure 5D) took more than 15 seconds, which could hinder identification of patterns and trends (DP1b), as failing to use the filter could impede the thorough exploration of data.

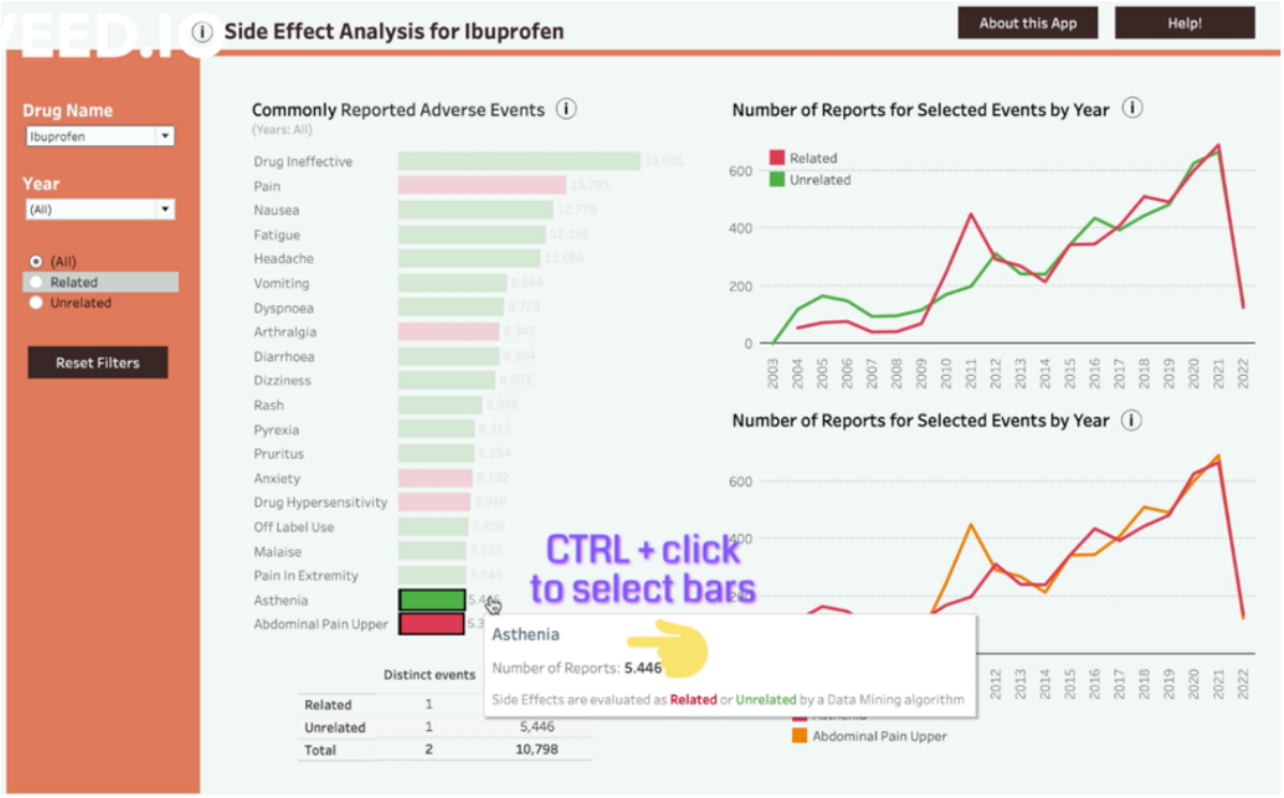
Usability problems also arose for year selection across different dashboard sections. Users didn't fully explore year selection options and found deselecting elements challenging (Multimedia Appendix 4). The absence of a year selection field in the overview section could impede exploration of data of varied granularity (DP2b) and, in consequence, interfere with monitoring the progression of relevant states (DP1c).

Some dashboard elements lacked visibility and clear explanations of their utility. For example, the event search field was not visible enough (Figure 6G) and the utility of the second line graph was not clear to the users. Additionally, the dashboard language was too technical. We also found issues with download buttons, DPA metrics files, and safety signal reports. Multiple download buttons and files made downloads difficult. Moreover, the download dialog box was located beyond eye reach and the system failed to inform about the download status. Finally, safety signal reports were too detailed and specific. According to C2, the report provided "unnecessary information overload" in which the participant was not interested.

End questions revealed users' confusion about the data source and the meaning behind the evaluation of side effects as related or unrelated to a drug by data mining algorithms. This lack of understanding could constrain evaluating alternatives of actions (DP3b). However, users found the system attractive for exploring drug safety information (DP3b). They were often encouraged by its interactivity to explore data from different angles (DP2a) and expressed their interest in using the system as an auxiliary drug information source. C4 suggested that people generally search online for drug safety information, seeking medical advice on websites of compromised quality. The participant considered the dashboard a suitable information source even for users with no pharmacovigilance background, as long as it is supplementary to professional medical advice. Similarly, C3 suggested the system could be useful for direct comparison of drugs with the same active substance produced by different manufacturers. C3 often asks for a cheaper drug alternative at the pharmacy and could use the system to compare the safety information of equivalent drugs.

Iteration 3

Design and Development: Updating Prototype Features



Introducing the Video Tutorial

To better afford obtaining immediate practical benefits while using the dashboard (DP1a), we modified the tutorial. Usability testing revealed that users learn best by doing, but they require basic knowledge to get started. Well-designed tutorials allow users to uncover the true potential of the app and understand the associated benefits [77]. Following the idea that undiscovered features practically do not exist, we replaced the tutorial with the animated walkthrough video.

We recorded key features in a brief video (more than 1 minute) with subtitles explaining dashboard actions. We used icons (eg, pointing finger and large mouse cursor) to guide users and added a skip video button for more experienced users (Figure S5 in Multimedia Appendix 3). Finally, we included a help button allowing users to rewatch the tutorial (Figure 8).

XSL•FO
RenderX

Figure 8. A frame from the getting started video tutorial of the v4-updated prototype.

Emphasizing the Utility of Dashboard Elements

We addressed many usability issues by adding short labels to dashboard elements (Figures 9 and 10).

To better afford monitoring the progression of relevant states (DP1c), we included an info icon next to graphs and section headers. Users could see information about graph functionality and displayed data, as well as the explanation of complex terms. We also included information on the content of the overview and detail sections and explained how graphs interacted with each other.

Similarly, we expected the issue of insufficient visibility and unclear utility of some elements (eg, the event search field and the second line graph) would be addressed by including additional information in the tutorial (Figures S6 and S7 in Multimedia Appendix 3). Finally, we implemented the "About this App" section (Figure 11), where users could find information about the data source, safety signal evaluation, possible limitations to the tool, and external links.

Considering all the above, we refined the DPs: (1) DP1a: it provides features to address the bootstrap problem, add walkthrough videos, and explain dashboard elements**,** so that the system affords immediate use of the dashboard in drug safety surveillance. (2) DP1c: it provides features to track changes in the variables and highlight their utility, so that the system affords tracking of the progression of relevant states in drug safety surveillance.

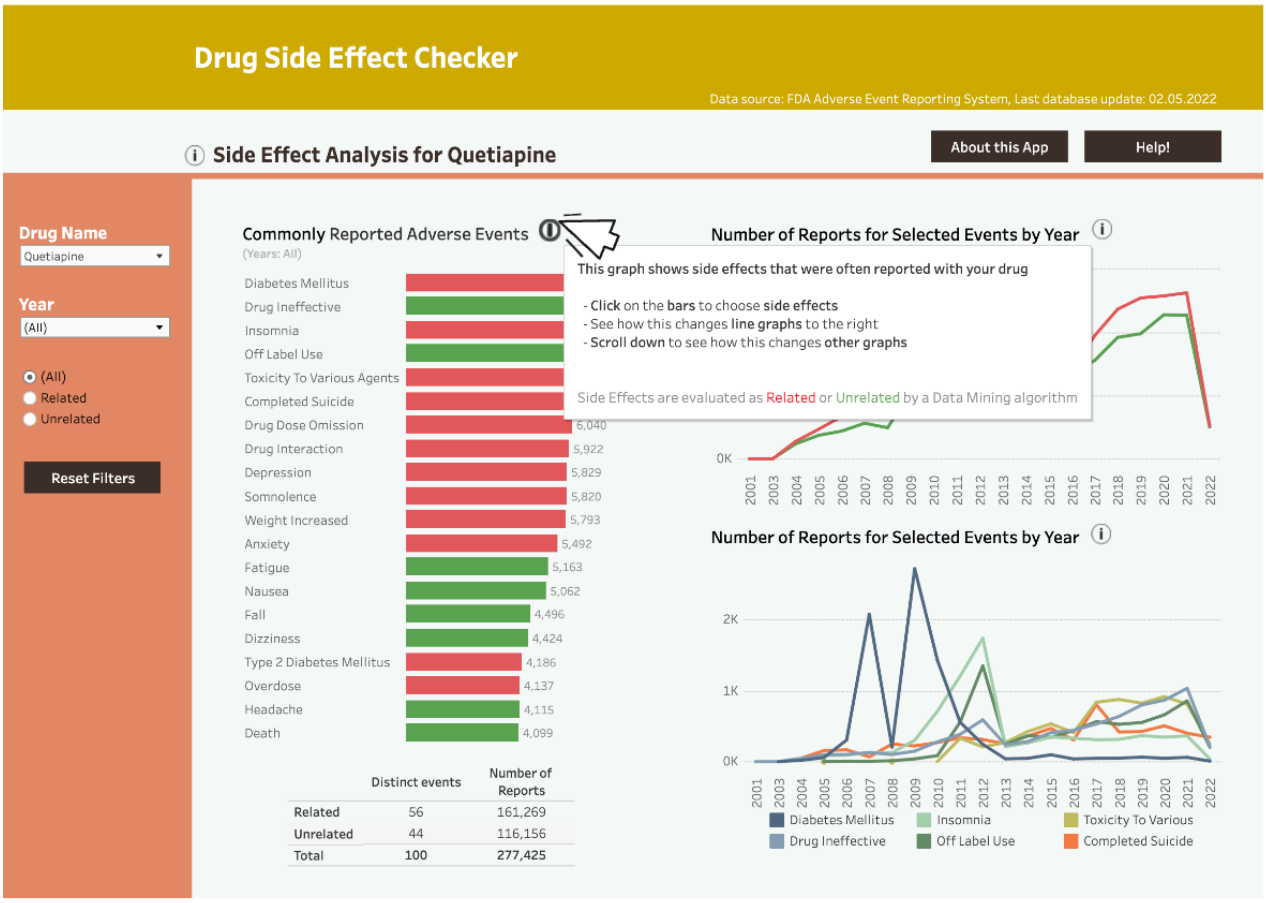
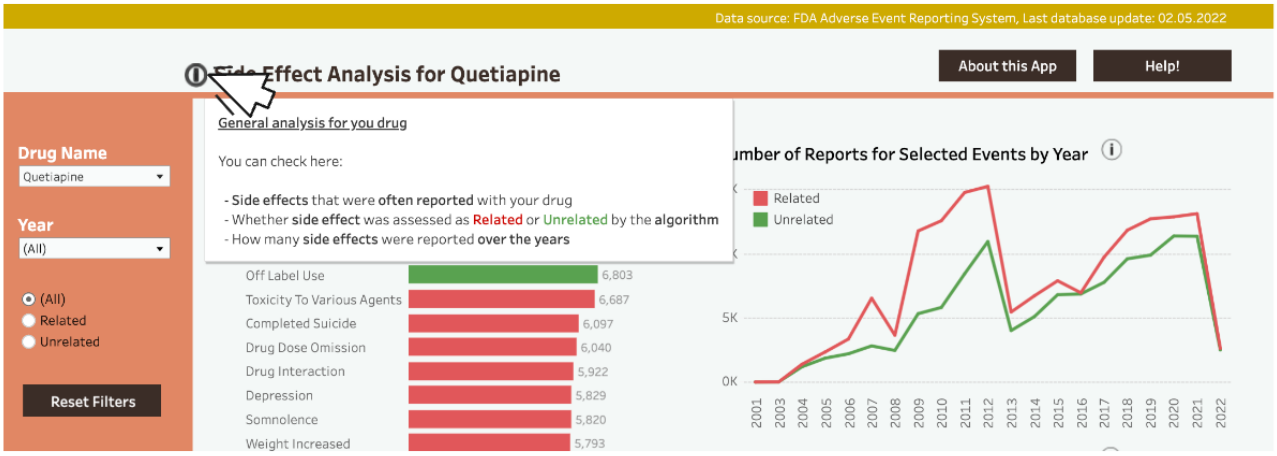
RenderX

Figure 9. Histogram with the info icon. Prototype v4.





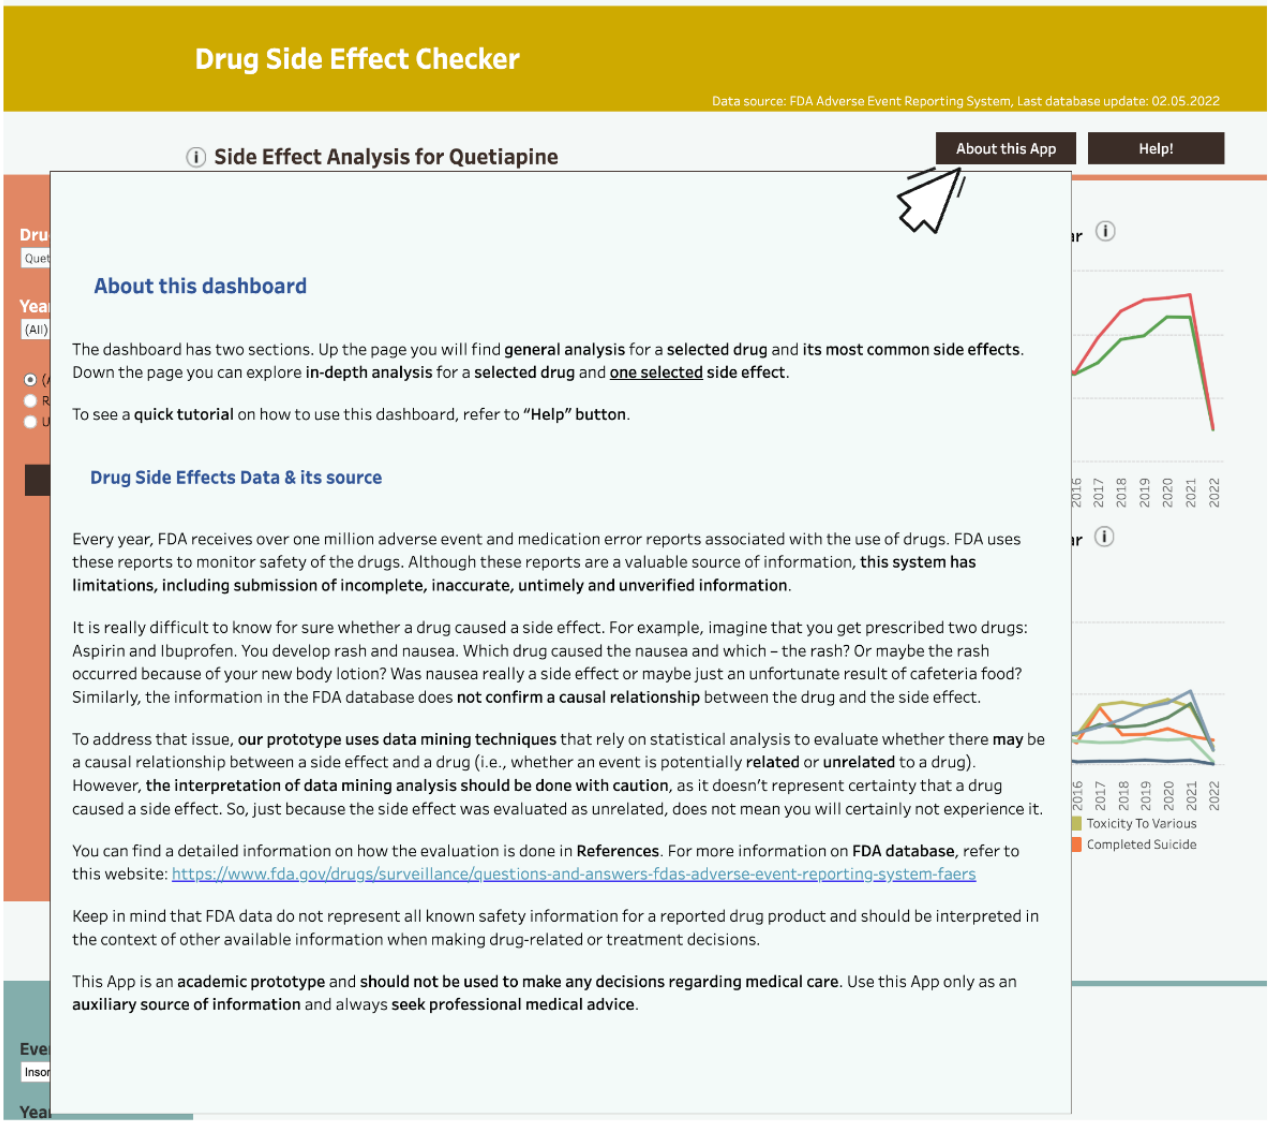


Figure 10. The overview section with the info icon. Prototype v4.

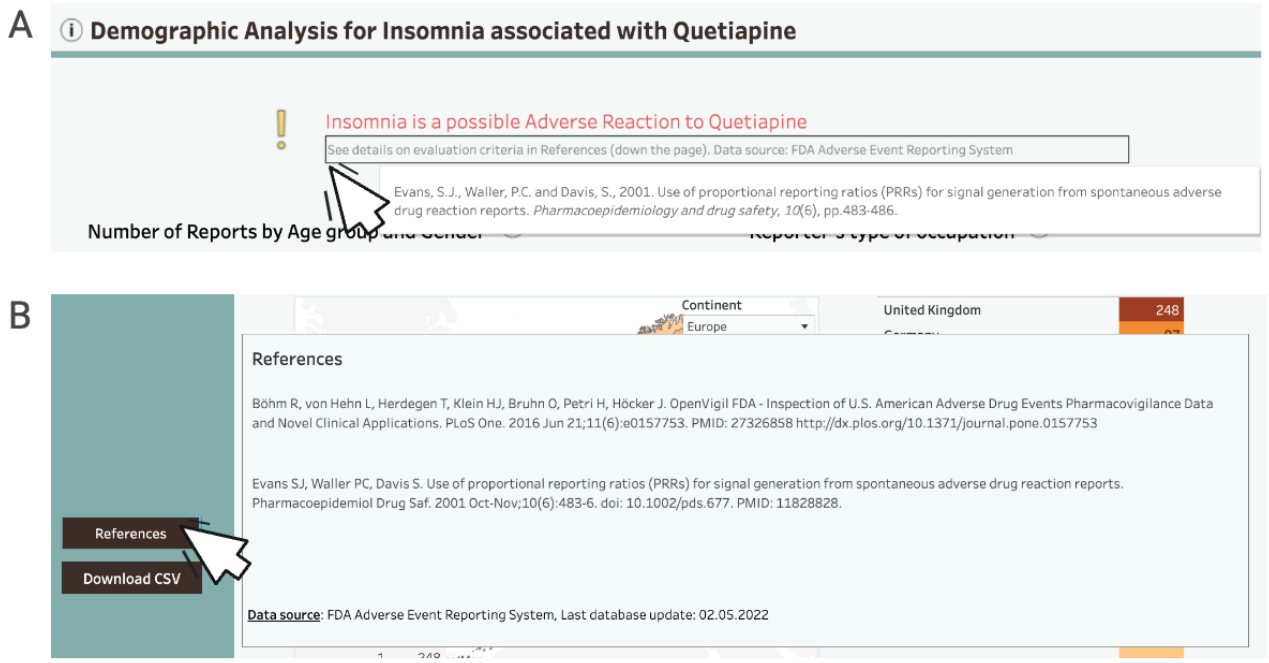
XSL•FO
RenderX

Figure 11. The About this App dashboard section. Prototype v4.

Signalizing the Uncertainty of Data Mining Results



To better afford identification of patterns and trends (DP1b), we added the information on the uncertainty behind DPA evaluation and advised caution when interpreting the results. Since safety signal detection can be used for hypothesis building, but not testing, we found it crucial to highlight these concepts. Safety signal detection is a starting point for further investigations, not a conclusion. Considering ethical and safety concerns, appropriate warnings are necessary.

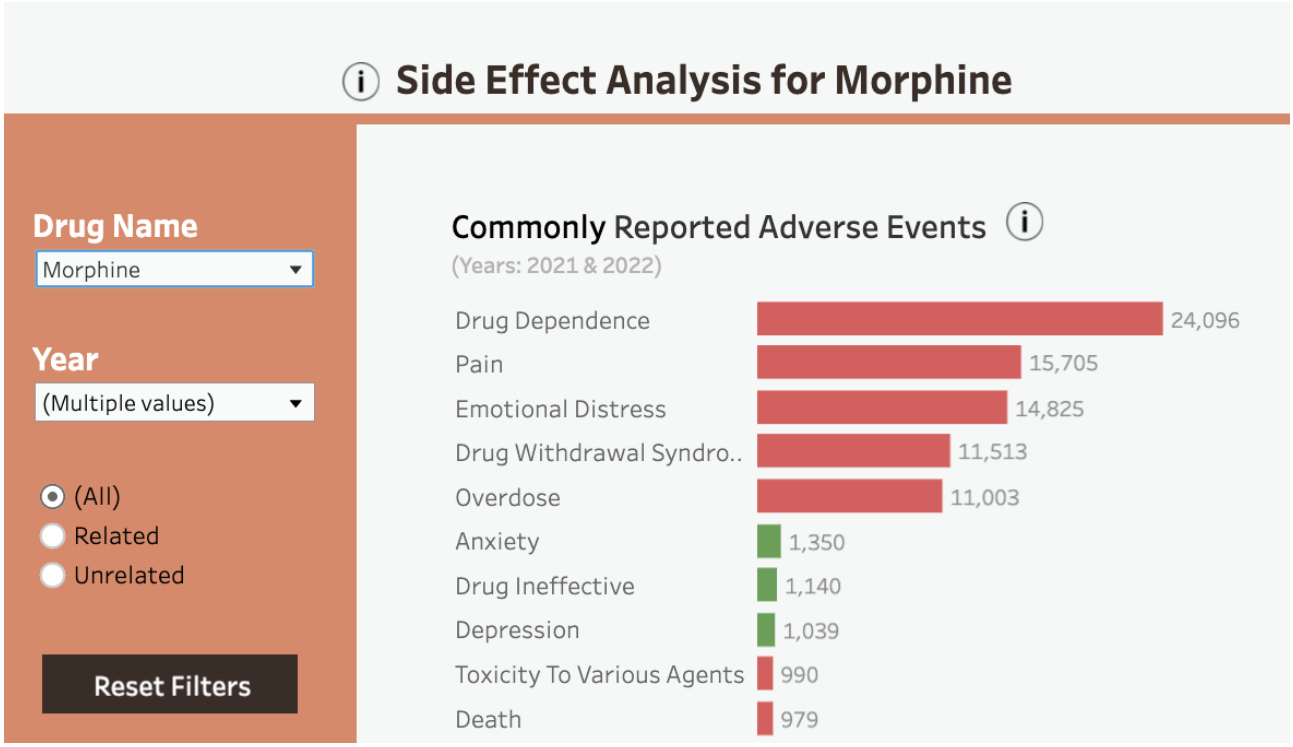
We addressed all the above in several ways. First, we provided the explanation on the interpretation of DPA in a disclaimer (not shown) and in the About this App section. Accounting for users less familiar with the topic, we provided an illustrative real-world case scenario to explain the concepts. We also implemented the References button, providing the links to evaluation criteria and including similar information in the warning message (Figure 12). Finally, we added links to external resources on many occasions and further enriched DPA files in explanation. In line with the above, we refined the following DP: DP1b: it provides features to describe possible causality between variables and signalize uncertainty behind DPA results in different ways, so that the system affords identification of patterns and trends in drug safety surveillance.

Together, these changes replace specialist terminology with plain-language labels and confine full statistical detail to downloadable files, reducing cognitive load for lay users while preserving transparency for professional review.

XSL•FO
RenderX

Figure 12. (A) The warning message with the information on hover. (B) The References button with the information on hover. Prototype v4.

Improving the Usability of Other Elements



To address the usability issues related to the histogram, and to improve attention management while using the dashboard (DP2c), we relocated the histogram's filter to the upper-left corner, removed the confusing filter's name, and added a histogram's year filter with the information about the current year selection. We also implemented a Reset Filters button to unselect elements in the overview section (Figure 13).

To facilitate obtaining immediate practical benefits while using the dashboard (DP1a), we simplified the language and modified download options, removing redundant download buttons and files. With regard to evaluating alternatives of actions (DP3b), and considering different data granularity needs of users (DP2b), we removed safety signal reports from the background of the download page and simplified the view. Finally, we moved the download dialog box to the eye reach (Figure S8 in Multimedia Appendix 3).

The summary of all solutions implemented after usability testing is shown in Table S2 in Multimedia Appendix 4. The final version (v4) of the prototype was made available online [78]. We recommend using Google Chrome as a browser for a better experience.

XSL•FO
RenderX

Demonstration and Evaluation: Heuristic Evaluation

We concluded the DSR cycle by performing heuristic evaluation (Figure 14). We identified 4 out of 10 usability factors with the lowest usability score: flexibility and efficiency of use (52%), user control and freedom (67%), visibility of system status (83%), and consistency and standards (83%). Two usability factors had the usability scores above 90%: recognition rather than recall (92%) and match between system and real world (93%), while 4 usability factors had the usability scores of 100%: aesthetic and minimalist design, orientation, spatial organization, and information coding, where the last 3 factors were related to dashboard visualization. The overall usability score was 84% (Table 5).

XSL•FO
RenderX

Figure 14. Usability scores per usability factor. Total is the overall usability score.

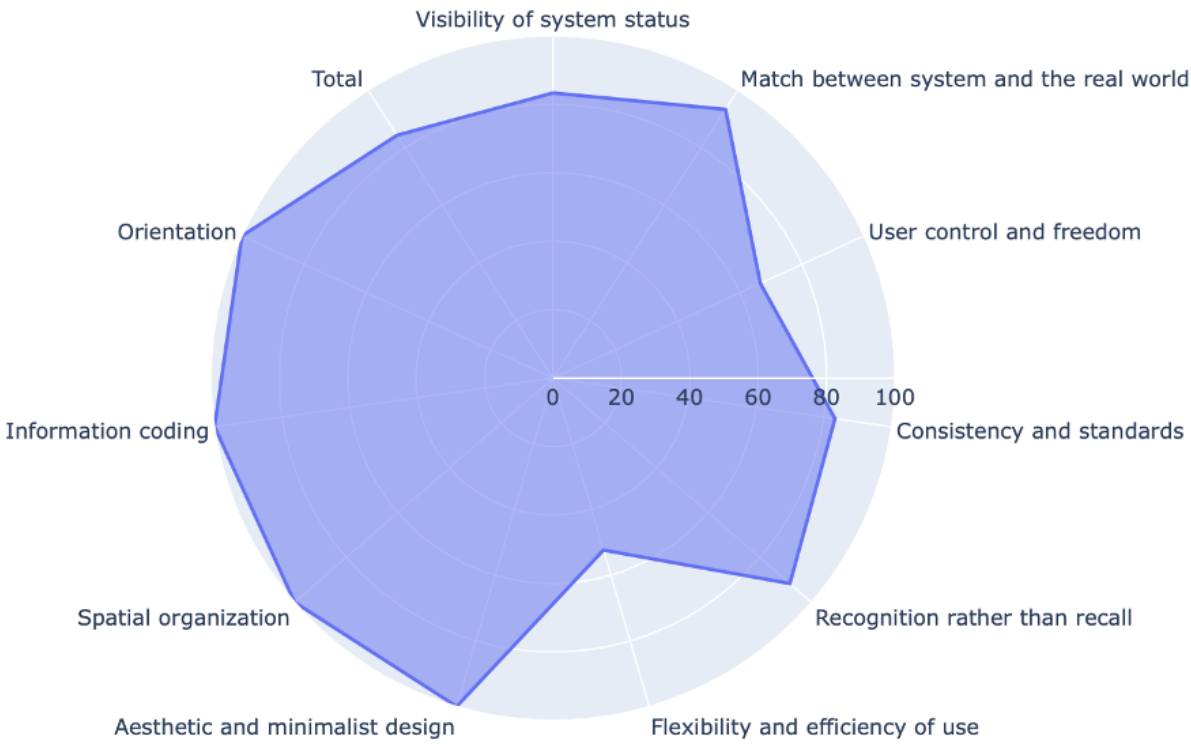

Table . A summary of usability factors with corresponding usability scores. Maximum score is a sum of close-ended questions per usability factor (eg, usability factor #9 had 2 questions, thus its maximum score was 2). E1, E2, and E3 are the scores assigned to each usability factor by each expert (ie, the sum of questions answered as yes by E1, E2, and E3). The result is the mean score divided by the maximum score, displayed as a percentage. Total is the overall usability score.

ID	Usability factor	Maximum score	E1	E2	E3	Mean score	Result (%)
1	Visibility of system status	6	5	5	5	5	83
2	Match between system and the real world	5	5	5	4	4.7	93
3	User control and freedom	5	4	3	3	3.3	67
4	Consistency and standards	6	5	4	6	5	83
5	Recognition rather than recall	4	4	3	4	3.7	92
6	Flexibility and efficiency of use	7	4	4	3	3.7	52
7	Aesthetic and minimalist design	7	7	7	7	7	100
8	Spatial organization	3	3	3	3	3	100
9	Information coding	2	2	2	2	2	100
10	Orientation	4	4	4	4	4	100
	Total	49	43	40	41	41	84

XSL•FO
RenderX

The overall severity ratings (Table 6) were in line with the obtained usability scores in most cases. Usability factor #3—user control and freedom was assigned the severity rating of 2 (minor usability problem), while the usability factor #1—visibility of system status was assigned the severity rating of 1 (cosmetic problem only) by all experts. Surprisingly, the usability factor #6—flexibility and efficiency of use, although it obtained the lowest overall usability score, was assigned the severity rating of 0 (no usability problem) by all experts. Several other usability factors were assigned the severity rating of 1 by some experts: usability factor #2—match between system and the real world (E3), usability factor #4—consistency and standards (E1), and usability factor #5—recognition rather than recall (E2). All remaining usability factors were evaluated as 0 (no usability problem).

The majority of usability issues referred to the flexibility and efficiency of use. We found evidence that the system lacked the ability to control display configurations and to hide unnecessary displays. Interestingly, although all participants noticed the lack of the option to hide unnecessary displays, it was not considered essential. According to E1: no buttons to hide or unhide panels, but not sure if the button is necessary. Information is well spread.

This could explain why this usability factor—although it obtained a relatively low usability score—was assigned an overall severity rating of 0 (no usability problem). Yet, as we saw a clear consensus regarding insufficient control of display configurations, we refined the following DP: DP2a: it provides features to support customized views and to control display configurations, so that the system affords examining different aspects of data in drug safety surveillance.

Table . Overall severity ratings assigned by experts (E1, E2, and E3) in heuristic evaluation.[a]

ID	Usability factor	Overall severity rating		
		E1	E2	E3
1	Visibility of system status	1	1	1
2	Match between system and the real world	0	0	1
3	User control and freedom	2	2	2
4	Consistency and standards	1	0	0
5	Recognition rather than recall	0	1	0
6	Flexibility and efficiency of use	0	0	0
7	Aesthetic and minimalist design	0	0	0
8	Spatial organization	0	0	0
9	Information coding	0	0	0
10	Orientation	0	0	0

[a] A score of 2: minor usability problem, 1: cosmetic problem only, 0: no usability problem.

Feedback also suggested that the system lacked clear exit options and a universal undo function, hindering user control and freedom. We also found support for the utility of the reset button; however, some participants noted that it did not deselect all elements when clicked. Regarding the visibility of system status**,** participants pointed out insufficient system feedback on its status. E3 identified a lack of visual feedback when selecting elements on some graphs. Although this action affected histograms, it was not communicated to the user. Similarly, E2 identified missing information on year selection in the detail section. Finally, concerning the consistency and standards**,** participants noted the absence of visual cues to identify active screens. E2 struggled to identify active screens when navigating between the main and download pages.

As a future agenda, we recommend implementing enhanced user control over display configurations, options to hide unnecessary displays, and adding a back or undo button. The functionality of the reset filters button should be improved to uniformly remove selections. Better feedback on the system status, like displaying selected years in the detail section, is crucial. Prompts and visual cues (eg, the event search box) should be placed where the eye is likely to be looking. Finally, all interactive elements (eg, the histogram and the first line graph) should provide feedback upon selection.

Discussion

DPs and the Value of Affordance Theory in This Study

Following the DSR methodology, we were able to empirically test and refine the initial, theory-driven DPs, by iteratively juxtaposing the results of experimental prototyping with theory-grounded, conceptual design recommendations. Consequently, we prove that the iterative translation of evaluation outcomes into prototype features results in refined design guidelines that could lead other practitioners in similar domains.

XSL•FO
RenderX

Throughout the study, we applied the affordance lens pragmatically: target affordances remained stable while prototype features were iteratively refined to instantiate them, which is in line with the view of Iivari [79] and Chandra et al [53]. Table 7 summarizes each principle in terms of user activity (affordance), enabling features (material properties), and the boundary conditions.

Table . The final list of refined design principles.

Design principle	Revised content
DP1a	Provide features to address the bootstrap problem, add walkthrough videos and explain dashboard elements, so that the system affords immediate use of the dashboard in drug safety surveillance
DP1b	Provide features to describe possible causality between variables and signalize uncertainty behind DPA[a] results in different ways, so that the system affords identification of patterns and trends in drug safety surveillance
DP1c	Provide features to track changes in the variables and highlight their utility, so that the system affords tracking of the progression of relevant states in drug safety surveillance
DP2a	Provide features to support customized views and to control display configurations, so that the system affords examining different aspects of data in drug safety surveillance
DP2b	Provide overview and details, while controlling overview-to-detail ratio, so that the system affords exploring data of different granularity levels in drug safety surveillance
DP2c	Provide features that stimulate attention, place important elements on the top-left area of the dashboard, and promote scrolling over pagination, so that the system affords improved attention management while using the dashboard in drug safety surveillance
DP3a	Provide features to create public values, so that the system affords users' engagement in dashboard use in drug safety surveillance
DP3b	Provide features to support decision-making and cluster them by the needs of distinct user groups, so that the system affords users to evaluate what-if scenarios and consider different alternatives in drug safety surveillance

[a]DPA: disproportionality analysis.

Addressing Existing Research Gaps

Our literature review identified pharmacovigilance systems that did not sufficiently incorporate user requirements, with resulting usability shortcomings [17,18,32]. We respond to this by using the DSR as a methodology. Additionally, this research gap was closely related to the bootstrap problem and DP1a (designing for direct use). We tackled the bootstrap problem in 2 ways: first, by including the requirements gathering phase in the design cycle, we increased the probability of addressing the real needs of users and therefore solving the right problem; second, by giving the users the opportunity to engage with the prototype in the initial stages of development, we initiated its use from the early versions. This positively affects the quality of the prototype and increases the chances of its successful adoption in the future. By iteratively responding to users' needs and targeting usability issues, we built a high-fidelity prototype that is usable for the evaluated tasks and user groups (overall usability score: 84%) and is designed to support sustained use; broader deployment remains future work.

We previously identified the lack of data mining techniques as a limitation of some of the systems for pharmacovigilance [17,21-23]. We suggested this was an important research gap to address, related directly to DP1b (causality between variables). We implemented DPA evaluation in the dashboard by including the information on potential safety signals [80]. We emphasized the uncertainty behind these results in multiple ways to make sure users were aware of their interpretation. Finally, the advantage of our prototype comes with improved visualization techniques. To that end, we followed the guidelines for visual dashboards by Bremser and Wagner [61] when deciding on visualization elements and features.

Consistent with DP3b ("cluster features by the needs of distinct user groups"), we view clinicians and pharmacists, researchers, and public users as distinct personas requiring layered functionality and language; our present DSR cycles cover the latter 2 groups (public users and research professionals), and clinician-facing tailoring should be undertaken in subsequent evaluations by others. In addition, regulatory decision-makers, policy analysts, and global health agencies represent further personas aligned with DP3b; though not evaluated here, they are recognized within our stakeholder scope and remain outside this study's boundary conditions.

Creating Public Value

Here, we articulate how the DPs and their instantiation can create public value when scaled and deployed in appropriate contexts; in this study, we assess feasibility and task-level usability rather than population-level impact.

XSL•FO
RenderX

We previously reviewed systems for pharmacovigilance that use proprietary databases or other data sources limited in diversity of stored information, volume, and availability [14-16,27,28]. To respond to this gap, related directly to DP3a (public value), we based the prototype on rich, open-access datasets with safety reports registered worldwide. In addition, both the code and the prototype are open-source and made available online, potentially contributing to the pharmacovigilance community. Moreover, through improved visualizations, we aim to enhance understanding and encourage users' active participation in interpreting the information.

To counter the misinformation during the COVID-19 pandemic, Murthy [81] recommends addressing information deficits where there is a high public interest but limited quality information available. Additionally, the author advocates for the modernization of public health communications by developing new, credible, and evidence-based online tools to effectively convey information to communities. By providing transparent and accurate drug safety data from reliable sources, our system may contribute to fighting misleading information and negative attitudes toward medication.

Our system is also a step forward in a higher degree of patient empowerment (the restoration of patients' access to public health data) and patient participation (the ability of patients to receive drug safety information and act upon it). In line with our findings, drug consumers could use the prototype for direct comparison of drugs with the same active compound, but produced by different manufacturers. Generic drugs (drug equivalents), although chemically the same as brand-name drugs (drugs produced by the pharmaceutical company that discovered them, protected by the patent), are often negatively perceived by drug consumers [82-84]. This is due to misbeliefs about brand-name drugs being better medicines per se.

There is strong evidence that, through a variety of incentives, medical doctors are influenced by pharmaceutical companies on which drugs to prescribe [85-88]. Physicians often enter contractual relationships with vendors, the latter being mostly representatives of brand-name drug companies, rather than cheaper generic drugs [89]. We suggest that by having a tool to directly compare primary safety profiles of drugs and their alternatives at hand, doctors may be encouraged to make more ethical decisions on their choice of collaboration with pharmaceutical companies.

Enhancing the Decision-Making

We integrated exportable DPA files into the prototype, considering them the main enabler of decision-making. When combined with data visualizations, this feature can significantly benefit pharmacovigilance professionals, including those affiliated with pharmaceutical industry or research institutes. These same affordances are pertinent to policy analysts and global health agencies, who require transparent, auditable summaries and cross-jurisdictional trend overviews. Detecting unusual or previously unknown drug-ADR associations is a first step in drug safety investigations [23,90]. Identified signals prompt further research, influencing actions such as product labelingchanges or potential drug withdrawal [91].

Regulatory bodies such as FDA, WHO, and EMA systematically monitor drug safety signals. Unusual associations undergo thorough scrutiny, involving literature reviews, clinical study revisions, and exploration of biochemical mechanisms. Results are compared with product information, and pharmaceutical companies are asked to provide relevant data, promoting higher industry accountability [91,92].

Contributions

Theoretical Contribution

Our work contributes to the prescriptive knowledge [93] by providing a list of refined, empirically-driven DPs. We suggest that, by delineating DPs, our work puts forward general design recommendations in similar solution domains. These can be extrapolated to a class of similar problems concerned with data visualization in pharmacovigilance. We do not claim the DPs are completely generalizable to other settings. Instead, they are put forward with the ambition to lead research on similar problems in wider contexts.

To our knowledge, there is no previous research that uses DSR methodology in designing dashboards for pharmacovigilance. By engaging in the DSR cycle, we were able to define affordances for similar systems, contributing to better understanding of the problem domain. These were (1) prompting users to engage with the dashboard (enabled by improved usability and attention management), (2) aiding analysis of what-if scenarios to support decision-making processes, (3) presenting data from different angles and at multiple granularity levels to examine its different facets, (4) showing changes in relevant variables over time, and (5) creating public value through generated insights.

Finally, we contribute to DSR by providing insights into how different requirements gathering and evaluation methods can support the development of visualization dashboards. While no claims can be made about the validity of these findings to other systems, we hope the techniques proposed here can be a useful instrument for identifying design issues early in the prototype development.

Practical Contribution

The practical contribution of our study lies in the developed artifact, publicly available online. Our system can be used by researchers and practitioners in pharmacovigilance, upon refinements. The code is open-source [94] and others can repurpose or reuse the scripts as partial solutions or inspiration for their projects. Though we confined our prototype to 5 drugs and 500 secondary events, the code can be adapted to an infinite number of drugs or secondary events to suit others' needs. For larger multisource deployments, the ETL and DPA steps can be executed in batches without altering the front end. Because the user interface consumes flat exports, the prototype can be reproduced in fully open-source dashboards or a custom front end.

The prototype is intended to demonstrate and operationalize the DPs. While usable for the studied tasks, broader public deployment requires the scale-up steps outlined in the next section. Any public-facing release by adopters would also

XSL•FO
RenderX

require clear plain-language disclaimers and risk communication for lay users, basic accessibility compliance, and a documented support pathway; these deployment activities are outside the scope of this study.

Our project however can be considered a hybrid open-source considering our reliance on the Tableau, which is a proprietary software. Table 8 provides an accurate description of the hybrid nature of our project with its respective components.

Finally, we do not claim full generalizability. The DPs are intended as reusable, prescriptive heuristics for similar dashboards within the stated boundary conditions; adaptation to clinician and pharmacist-facing workflows and additional user groups should be iteratively refined in those settings.

Table . Open-source status of project components.

Component	Status	Implication
Data	Open source	Fully accessible and usable by anyone
Code	Open source	All transformation and analysis code (eg, Python or R scripts) is on GitHub under an Open Source Initiative–approved license, allowing others to reuse and modify it
Dashboard prototype	Proprietary/Open access	The dashboard itself is viewable and accessible to anyone via Tableau Public (making it "open access"), but its dependency on proprietary Tableau software means others cannot easily reproduce, fork, or host a modified version without their own Tableau software or an equivalent proprietary viewer

Limitations and Future Research Agenda

This study has some limitations. First, drug safety surveillance can be viewed differently, leading to different affordances than those outlined here. Second, the DSR cycle could be extended to yet another phase. Iivari et al [95] proposes a framework for DPs evaluation in terms of their reusability: through the criteria of accessibility, importance, novelty, actability and effectiveness. Similarly, empirical testing of how revised DPs apply to other settings could be done through their repeated application in different boundary conditions [52]. Future research could address these issues to test the quality of the outcomes of this DSR project. Third, to support broader use, the prototype should be expanded to all FDA drugs and events via direct application programming interface calls [21].

Establishing readiness for broad public deployment of the prototype will require expanded datasets and multisite evaluations beyond the scope of this study. Moreover, including data from other databases (eg, EudraVigilance and VigiBase) would improve DPA evaluation, but requires (1) source-specific mapping into the common schema, (2) robust cross-repository deduplication, and (3) compliance with licensing and governance constraints. If further deployments are undertaken, evaluation can focus on user engagement, operational reliability, and decision support alignment with expert assessments, as these activities are beyond this study.

Relatedly, in the final prototype version, we keep shortcuts and advanced controls to a minimum to maintain clarity for nonprofessional users. This design choice explains the lower expert scores on flexibility, efficiency of use, and user control and freedom, which were nevertheless judged as low-severity issues. For expert-only deployments, future implementers can add more controls and configuration.

Importantly, our participant sample represented young and digitally proficient (late 20s to mid 40s), and several nonexpert participants held technical or professional roles (eg, data science, biomedical engineering, and humanitarian logistics). This sampling may limit generalizability to older adults and individuals with lower digital health literacy [96]. Older adults are more likely to experience polypharmacy [97] and may have distinct interaction needs (eg, larger text, higher contrast, simplified and error-tolerant interactions) [98], which we did not assess in this study. Future independent evaluations should specifically include older adults and lower-literacy users and consider accessibility guidance (eg, larger typographic scales, high-contrast palettes, and keyboard navigability) when adapting the dashboard for these groups.

Relatedly, some nonprofessional users found data mining terms challenging even when aided by tooltips and tutorials. The present prototype mitigates this by using plain-language labels, info icons, an "About this App" section, and by keeping advanced formulas in downloadable files; however, residual risk of misinterpretation remains. We therefore reiterate that DPA supports hypothesis generation rather than confirmation and should be interpreted cautiously by lay audiences. To reduce potential user anxiety, we emphasize this uncertainty in plain language and signpost users to seek professional advice for individual decisions. However, we did not evaluate affective outcomes (eg, worry and decisional conflict) among lay users; given the potential for spontaneous report dashboards to provoke anxiety, such outcomes should be assessed in independent evaluations by others.

Furthermore, it would be beneficial to implement a higher variety of data sources: scientific literature, clinical studies or data from text mining [20]. Also, the prototype would benefit from comprehensive benchmarking, such as head-to-head comparisons with existing pharmacovigilance tools on performance, cost, or user satisfaction. Future work could also

XSL•FO
RenderX

expand DPA methods to improve the validity of detected safety signals. Integrating and systematically evaluating additional machine learning approaches for ADR signal detection could enhance analytical breadth and validate performance across settings.

Finally, integration into health care IIs (eg, electronic health records) was outside the scope of this DSR prototype. The artifact targets public FDA data and does not process identifiable patient records. Any operational deployment by adopters would require institutional governance (eg, data use agreements, access control, auditability, and security increase) and, where applicable, compliance with jurisdictional regulations. The use of standard terminologies, decoupled Python scripts, and portability to open source (Multimedia Appendix 2) is intended to ease such translation, but we do not evaluate these deployment aspects here.

Conclusion

In this study, we applied the DSR cycle to investigate the design of visual dashboards to support activities within pharmacovigilance. To that end, we identified required affordances, developed corresponding DPs that satisfied them, and demonstrated their implementation, showing that they brought about expected outcomes. The developed DPs are anticipated to be applicable in various pharmacovigilance settings. Finally, we hope our research will be a catalyst of further research in similar domains.

Abstract

Background: In recent years, the incidence of cognitive diseases has also risen with the significant increase in population aging. Among these diseases, Alzheimer disease constitutes a substantial proportion, placing a high-cost burden on health care systems. To give early treatment and slow the progression of patient deterioration, it is crucial to diagnose mild cognitive impairment (MCI), a transitional stage.

Objective: In this study, we use autobiographical memory (AM) test speech data to establish a dual-modal longitudinal cognitive detection system for MCI. The AM test is a psychological assessment method that evaluates the cognitive status of subjects as they freely narrate important life experiences.

Methods: Identifying hidden disease-related information in unstructured, spontaneous speech is more difficult than in structured speech. To improve this process, we use both speech and text data, which provide more clues about a person's cognitive state. In addition, to track how cognition changes over time in spontaneous speech, we introduce an aging trajectory module. This module uses local and global alignment loss functions to better learn time-related features by aligning cognitive changes across different time points.

Results: In our experiments on the Chinese dataset, the longitudinal model incorporating the aging trajectory module achieved area under the receiver operating characteristic curve of 0.85 and 0.89 on 2 datasets, respectively, showing significant improvement over cross-sectional, single time point models. We also conducted ablation studies to verify the necessity of the proposed aging trajectory module. To confirm that the model not only applies to AM test data, we used part of the model to evaluate the performance on the ADReSSo dataset, a single time point semistructured data for validation, with results showing an accuracy exceeding 0.88.

Conclusions: This study presents a noninvasive and scalable approach for early MCI detection by leveraging AM speech data across multiple time points. Through dual-modal analysis and the introduction of an aging trajectory module, our system effectively captures cognitive decline trends over time. Experimental results demonstrate the method's robustness and generalizability, highlighting its potential for real-world, long-term cognitive monitoring.

KEYWORDS

mild cognitive impairment; longitudinal speech analysis; multimodal fusion; Alzheimer disease detection; deep learning; autobiographical memory test

Introduction

Alzheimer disease (AD) is a neurodegenerative disorder often associated with memory decline, language impairment, and a diminishing capacity to perform daily activities independently. However, AD remains incurable. Current research indicates that approximately 47 million people were diagnosed with dementia in 2015 [1], and it is expected that the number will triple by 2050 [2]. Such forecasts pose a significant burden on both patients' families and health care systems.

XSL•FO
RenderX

Within the spectrum of cognitive health, an intermediary stage exists between a state of normalcy and the onset of AD, denoted as mild cognitive impairment (MCI). Patients with MCI do not exhibit significant cognitive symptoms compared with those with AD. Those patients are still capable of performing daily activities independently. According to the study by Petersen et al [3], an estimated 16% of individuals with MCI progress to dementia within a year. Therefore, early identification of MCI holds significant value in instigating interventions aimed at impeding the advancement of dementia. However, the detection of MCI presents a notable challenge due to the subtle manifestation of its symptoms.

While biomarkers have demonstrated sensitivity in identifying MCI, such as positron emission tomography and magnetic resonance imaging [4,5], many of them necessitate invasive procedures. The associated costs of data collection for such methods are relatively high. Conversely, leveraging voice data for cognitive assessment offers a simpler and more suitable approach for long-term monitoring of cognitive status. Our approach relies on using autobiographical memory (AM) test data as the primary input [6], wherein interviewers engage participants in a series of questions and answers regarding their life experiences. This method, resembling a casual conversation, is more approachable than other psychological test methods because it reduces the testing stress experienced by participants.

Longitudinal analysis for MCI detection based on speech data remains relatively unexplored compared with other data types, such as magnetic resonance imaging, resulting in a scarcity of research in this area. The research proposed by Al-Hameed et al [7] focuses on extracting solely acoustic features from speech data collected across multiple visits from DementiaBank, which primarily pertains to speech associated with picture description tasks. They aim to predict participants' Mini-Mental State Examination scores and cognitive labels. Following feature selection, they used support vector machine or stochastic gradient descent for prediction. Integrating data from 3 visits achieved a 90% accuracy in distinguishing between healthy control (HC) and MCI in a binary classification task. However, due to label imbalance in the dataset, accuracy as a metric may not be entirely equitable. This study demonstrates that incorporating features from previous visits enhances prediction accuracy for subsequent visits.

Using the same dataset, another survey by Ammar et al [8] concentrates on extracting a wide range of linguistic features related to fluency and richness for Mini-Mental State Examination score prediction. However, unlike the former study, they do not leverage the correlation between previous visits. In the research proposed by Laguarta and Subirana [9], 16 physiological biomarkers were identified from speech data, represented in a personalized subject feature map. This feature map is capable of illustrating and monitoring cognitive changes over time. Achieving 93.6% accuracy in the ADReSS datasets, this study is the only one among them that visually depicts cognitive decline.

Yamada et al [10] used phone calls for long-term participant tracking, manually transcribing the conversations to extract linguistic features. They focused on extracting topic and word repetition features across different calls. Their model achieved an area under the receiver operating characteristic curve (AUROC) of 0.91 in classifying between AD and HC. In our previous work proposed by Chang et al [11], the author first extracted traditional acoustic feature sets, extended Geneva Minimalistic Acoustic Parameter Set [12], from AM audio files collected across multiple visits. The author then used TabNet [13] to learn the cognitive information embedded within these feature sets. To further enhance the model, an aging alignment loss was applied, encouraging cognitive representations in the latent space to be closer to each other. The approach achieved an accuracy of 0.66 and an F_1-score of 0.64.

In this work, we use AM data as the primary input for our model. We analyze the AM data from both linguistic and acoustic perspectives and further establish an aging trajectory module (ATM). By introducing the ATM, which captures cognitive decline across different time points through direction embeddings, our framework provides more representative modeling of longitudinal changes. The key contributions of this work are summarized as follows:

1. Unlike most studies focusing on single time point analysis, this work introduces a longitudinal framework using AM speech data to track cognitive changes over time.
2. The system jointly analyzes linguistic and acoustic features from unstructured AM speech, offering a richer representation of cognitive status than unimodal approaches.
3. Proposed ATM, which models cognitive decline by aligning temporal features across visits through a specially designed alignment loss applied to direction embeddings.

Methods

Problem Setting

There are 2 problem settings in this work: longitudinal type and cross-sectional type. The longitudinal problem setting is our main focus. The cross-sectional problem setting evaluates whether our model is general enough to tackle different tasks of detecting cognitive impairment disease detection tasks.

Longitudinal Problem Setting

In our problem setting, we have the dataset D={D1,D2,…,DV}with the corresponding label set L={L1,L2,…,LV}, where V means the total visit times, and D_k means the dataset at the kth visit. Each D_k is expressed as Dk={x1,k, x2,k, …, xN,k}, where N represents the number of the subjects involved in the test, andxi,k={xi,k1, xi,k2, …,xi,kM} represents the M stories provided by subject i at the kth visit; note that the number of M may vary across different visits. The corresponding labels set Lk={l1,k, l2,k, …, lN,k} shows the cognitive status of each subject, with each $l_{i,k}$ indicating whether the subject is an HC or has MCI.

During the data preprocessing, we extract the feature set {xi,km,a, xi,km,t, xi,km,l} from the raw audio xi,km, where xi,km,a, xi,km,t, xi,km,l represents the acoustic feature set, textual data, and linguistic feature set, respectively. Subsequently, the model input is the sequential visit data defined

XSL•FO
RenderX

in equation 1, where xi,1m1∈ xi,1, xi,2m2∈ xi,2, and xi,VmV∈ xi,V.

(0)m2, . . xmV={xm1m1, xm2m2, . . xmVmV}

It is worth noting that stories from each visit are randomly paired across visits within each subject. This design ensures that the model learns subject-level temporal progression rather than relying on similarities driven by specific story topics or linguistic content. Random pairing is not an arbitrary source of noise but a deliberate mechanism aligned with our longitudinal modeling objective. Because story content varies substantially across visits and participants, enforcing semantic matching or averaging all embeddings within a visit would bias the model toward topic-dependent features, flatten meaningful variability in linguistic complexity, and increase the risk of overfitting to specific story topics. In contrast, random pairing operates strictly within each subject, preserving the temporal order while exposing the model to multiple sampled transitions across training epochs. This provides a richer distribution of temporal transitions, enabling the framework to learn visit-level cognitive progression directions that remain robust to story content and reflect each subject's distribution of linguistic changes over time.

Formally, our model can be viewed as a mapping function fW, where *W* represents the set of learnable parameters. The function fWprojects the input sequence {xi,1m1,xi,2m2,…,xi,vmv} into the label of the last visit l(i,V). In this study, the maximum number of visits per subject, *V*, is 3, following the available structure of the dataset.

Cross-Sectional Problem Setting

In the cross-sectional problem setting, the primary difference from the longitudinal problem setting is that data collected from the same subject at different interview visits are treated as data from independent subjects. Thus, we have the dataset D={x1,x2, …, xCN} with the corresponding label set L={l1,l2, …, lCN}, where CN is the sum of all subjects from all visits, and x_i represents the raw audio for the subject *i* with the cognitive label l_i. The cognitive label l_i indicates that the subject is either an HC or under the targeted condition (MCI or AD). During the data preprocessing, we extract the feature set {xia,xit,xil} from the raw audio x_i. Our cross-sectional model aims to map the model input {xia,xit,xil} into the cognitive label l_i.

Overview

The system overview is shown in Figure 1. The goal of the system is to detect the cognitive condition of subjects, specifically whether they have MCI, using speech data. Before training, the speech data first undergo data preprocessing, which involves converting the audio files to text using automatic speech recognition (ASR), extracting additional linguistic features, and deep learning–based acoustic feature extraction. These steps generate additional text data and acoustic data, which are then intertwined to form dual-modal data pairs serving as the input for the model training. In addition, to effectively capture the features of aging and enhance the detection of potential MCI, the model input should have speech data for this time as well as points of follow-up data. This philosophy leads to our proposed longitudinal analysis for MCI detection.

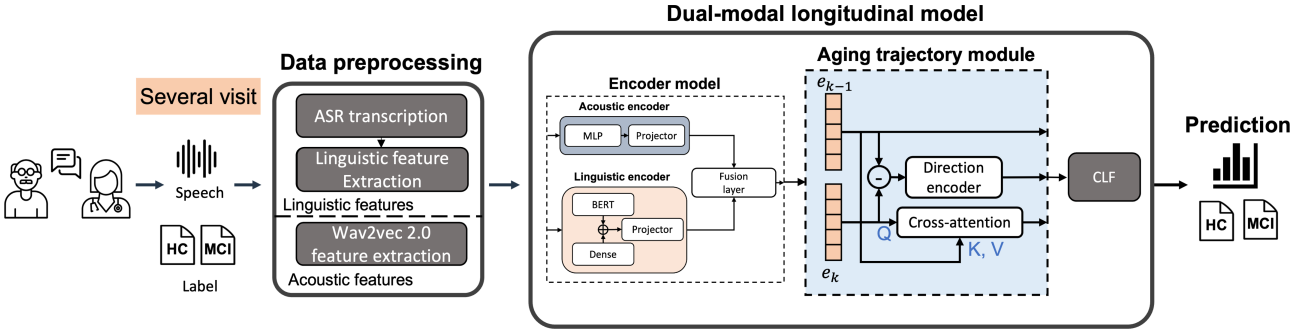

Figure 1. Overall framework of the proposed longitudinal multimodal model. The model consists of two main modules: (1) encoder model, combining a CNN-based acoustic encoder and a BERT-based linguistic encoder to generate fused multimodal embeddings; and (2) aging trajectory module, which models longitudinal changes between consecutive visits using a direction encoder and cross-attention before classification. ASR: automatic speech recognition; BERT: bidirectional encoder representation for transformer; CLF: classifier; CNN: convolutional neural network; HC: healthy control; MCI: mild cognitive impairment.

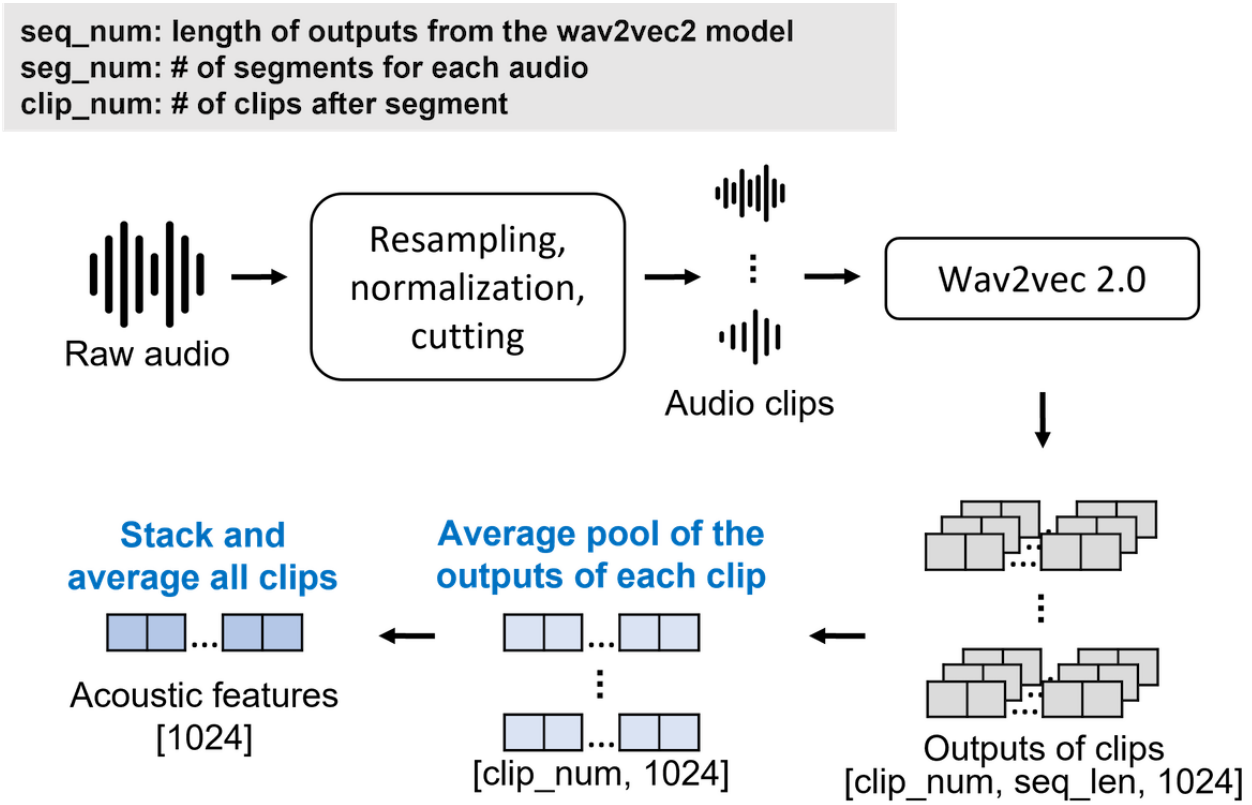
Data Preprocessing



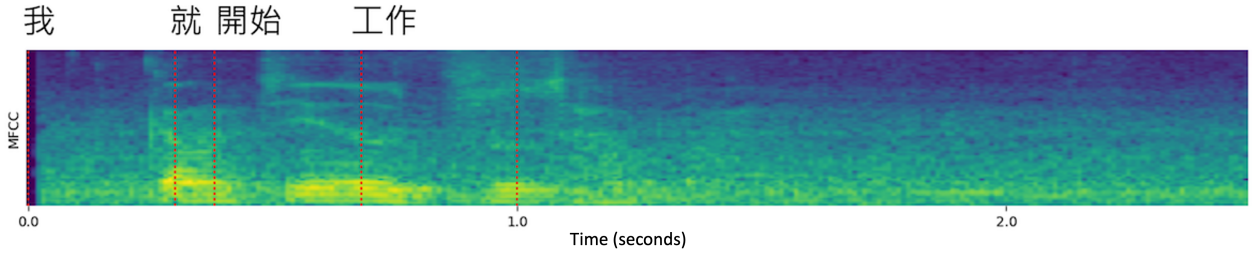
Before the data are input into the model, they need to be preprocessed to ensure data quality and to extract useful features. After data collection is completed, given that the data are based on the entire interview process of each subject during a single visit, we first segment each story recording from the interview. To prepare the audio file of each subject, we segment the audio files based on the story topics provided by the subject, cutting the corresponding recall and probing audio files.

Acoustic Feature Extraction

The preprocessing of audio data is shown in Figure 2. First, the notation xi,km denotes a raw audio waveform, which means the *m*th audio file of the subject *i* collected at the *k*th interview visit undergoes basic processing, including normalization and resampling. Normalization is done using zero-mean unit-variance normalization. Next, the audio is segmented into *t*-second clips with a 5-second overlap. Each audio file can be denoted as xi,km={xi,km,1,xi,km,2,…,xi,km,seg_num}, where seg_num represents the number of clips to which the raw audio file can be divided, and the total number of segments varies for each audio file.

XSL•FO
RenderX

Figure 2. Overview of acoustic preprocessing. Each raw audio recording is divided into multiple fixed-length clips and processed by the wav2vec2.0 feature extractor to obtain frame-level representations. For each segment, the outputs from all clips are stacked and averaged to produce a single clip-level feature. The averaged clip features are then pooled across segments to generate the final visit-level wav2vec2.0 embedding, which is used as input to the acoustic encoder.



In our research, wav2vec 2.0 model [14] is used as an acoustic feature extractor, and we leverage the pretrained model available on Hugging Face. Using the wav2vec 2.0 model in advance to extract deep acoustic representation features offers the advantage of saving memory space and making the subsequent model structure lighter, thereby increasing training efficiency. Each clip is fed into the wav2vec 2.0 model, producing an output with dimensions [seq_len, 1024], where seq_len is determined by the convolution layer in wav2vec 2.0 and the clip length, which is computed by dividing the clip length and the multiplication of the stride length in the convolution layers. After obtaining the output of each clip, the first average pooling is performed, resulting in a 1024-dimensional acoustic feature for each clip. Then, all clip outputs are stacked together, and a final average pooling is conducted to obtain the final acoustic features xi,km,a of the entire raw audio file; hence, the dimension of xi,km,a is 1024.

Linguistic Feature Extraction

The preprocessing of linguistic data can be divided into 2 stages: generating the transcript and extracting features from the generated text. Since not all audio files in the dataset have manual transcripts, we use ASR to generate the transcripts for our research. We use the open-source tool kit "whisper-timestamped," which provides both timestamps and the corresponding text, as illustrated in Figure 3. Previous research [15-17] has confirmed that pauses are an indicator in AD-related diseases, where patients with MCI or AD tend to exhibit more frequent and longer pauses. In our study, we classify pauses based on the interval duration between sentences into 3 types: short pause (duration <0.5 seconds), medium pause (duration between 0.5 and 2 seconds), and long pause (duration >2 seconds) [18]. In addition to pauses, we calculate the mean length of utterance, which is defined as the average number of words spoken in a sentence. In this step, we will generate transcripts with pause information and 4 numerical linguistic features. Besides pause information, we provide additional syntax information to enrich the linguistic features. Previous research [19] has shown that the sentence structures used by individuals with AD and HC are different. Therefore, we use part-of-speech (POS) tagging in this study. After generating the text, we use the open-source tool kit "ckipnlp" for word parsing and POS tagging. The text segments are then categorized into 5 POS types: noun,

verb, adjective, pronoun, and other. In this step, we count the total number of these POS taggers.
